Introduction

Cell-based therapies can be used to treat a variety of human diseases. One important class of cell-based therapies is the system where the cells are vehicles for the delivery of therapeutic proteins [1,2]. They are particularly useful in patients who are unable to produce proteins themselves, where they can be used as an alternative to the frequent administration of exogenous protein. For example, many patients with type I diabetes patients inject daily doses of the protein hormone insulin to attempt to normalize blood sugar levels. Unfortunately, insulin therapy is very labor intensive, requiring multiple measurements and interventions per day [4]. In addition, even the best delivery systems do not provide complete control of blood sugar [5]. In contrast, transplanted islets produce insulin in a dynamic and glucose-dependent manner and can provide long-term control of blood sugar [6–8].

Cell-based therapies have been developed with autologous, allograft, or xenograft donor cell sources. In cases where foreign nonself donor cells are transplanted into hosts, immunosuppression is required to prevent immune rejection of the transplanted cells [9–11]. However, these drugs are associated with health risks such as lymphoma and infection, which limits the patients that are suitable to receive these therapies.

An alternative strategy is to use an immunoisolation device. Immunoisolation devices, originally described by Cheng [12], use a barrier to restrict the entrance of host immune cells that can destroy the foreign, donor cells while allowing for the passive diffusion of the therapeutic protein and nutrients/waste products out of the device (Fig. 22.1). Immunoisolation devices have been investigated as a means to protect cells for treatment of a variety of diseases, especially those characterized by a deficiency in the natural production of a specific protein. These include endocrine disorders such as diabetes [13] and hypothyroidism [14]; genetic diseases such as lysosomal storage disorders [15] and hemophilia/anemia [1]; and neurological disorders such as Parkinson's disease [16], Huntington's disease [17], and retinal degeneration disorders [2,18].

In this chapter, we review (1) nutrition of cells within the device, (2) avoidance of the immune system, and (3) engineering approaches to promote viability and functionality of the encapsulated cells. This includes a brief overview of the mechanisms of immune rejection of foreign tissue and an introduction to how this knowledge can be leveraged in the design of immune isolation barriers. We will also discuss the type of cells that can be included in immunoisolation devices and the challenges associated with providing enough nutrition for those cells. Recent advances in current devices will be examined, and finally, an in-depth look into the strategies to prevent biomaterial-mediated host-rejection of immunoisolation devices through fibrosis will be explored.

Rejection and protection of transplanted cells and materials

The host immune system has a number of strategies to defend itself against "nonself" materials, cells, and

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00023-X

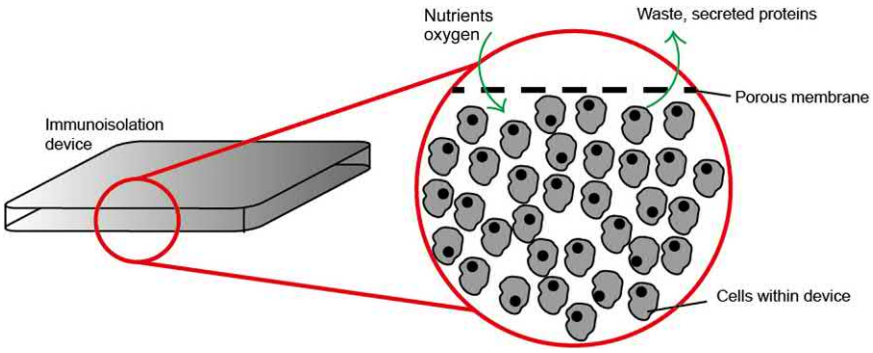

FIGURE 22.1 A schematic overview of an immunoisolation device: cells or clusters of cells are supported in a matrix and entrapped within a device that is isolated from the body by a semipermeable porous membrane. Membrane porosity can be tuned to prevent the entrance of immune cells and control the transport of molecules both into and out of the device.

pathogens found in the body [9,19,20]. Unfortunately, these rejection mechanisms also instruct the host immune system to recognize and respond to cells and materials, which have been implanted therapeutically. Thus there are various immune mechanisms, discussed later, that immunoisolation devices must overcome in order to protect therapeutic donor cells and materials from rejection by the host immune system.

Rejection pathways

Transplanted cell rejection may occur following direct cell contact between host and donor tissues, or through other, noncontact-initiated mechanisms (indirect activation) (Fig. 22.2) [9]. In direct rejection, cell−cell contact occurs between immune cells of the host immune system and the transplanted donor cells, which express as nonself cell surface markers [19,21−27]. This leads to direct activation of $CD4^+$ and $CD8^+$ T cells of the host immune system [26]. Once activated, the cytotoxic $CD8^+$ T cells initiate a cellular response against the donor cells, secreting soluble molecules which lyse the target cells and may initiate inflammation. In addition, $CD4^+$ T helper cells secrete a number of other factors (cytokines and chemokines) that stimulate other cells of the host immune system and help initiate the humoral response [28,29]. Activated macrophages may also recruit additional cell types and can secrete small molecules that can be toxic to donor cells. The activation of B cells leads to the generation of antibodies that can target donor cells. This forms part of the humoral response that also includes the activation of the complement and coagulation cascade [19,30,31].

The use of an appropriately sized immunoisolation barrier can prevent the initial cell−cell contact driving the direct rejection pathway; however, it may not offer protection against immune-activating factors that can diffuse across the barrier, as discussed in detail later. Here, antigens can be released from donor cells due to cell death, cell secretion, or cell shedding and may be small enough to cross the porous membrane protecting the transplanted cells [32−34]. These antigens can be processed by the host antigen presenting cells (APCs) and displayed on the surface of the APCs as part of the major histocompatibility complex [25,35]. Effector cells of the host immune system, such as $CD4^+$ cells, can then recognize the foreign antigen and activate the cellular and humoral immune response as described earlier [25]. In general, immunoisolation devices must provide a barrier to prevent foreign cell contact with the host immune system and prevent activation of the direct pathway. However, even without direct cell−cell contact, immunologic small molecules secreted by encapsulated cells may be able to activate the immune system [32−34]. The porosity of the immunoisolation barrier therefore plays an important role in controlling cell encapsulation and nutrition and may also impact the antigen load escaping from the device, discussed later.

Cellular nutrition

The cells inside immunoisolation devices require nutrients to produce and secrete therapeutic proteins. Nutrients include essential molecular building blocks, such as amino acids, nucleotides, lipid precursors, and molecules important for energy production such as glucose and oxygen. In addition, waste products must be removed, as the buildup of by-products from metabolism (lactic acid, carbon dioxide, and nitrogenous products) can negatively affect the viability of the cells [13].

The exchange of nutrients and waste products in a prototypical encapsulation device occurs by diffusion. Nutrients must diffuse from blood vessels into the interstitial fluid and then diffuse through the semipermeable device barrier to reach the cells in the core of the device. The reverse is true for waste products. The rate of diffusion or mass transport of nutrients can be impacted by a variety of factors. This includes the device architecture/geometrical features, porosity of the semipermeable barrier, nutritional reserves of the transplantation site, the density of cells within the device, and the specific metabolic requirements of the therapeutic cells being utilized.

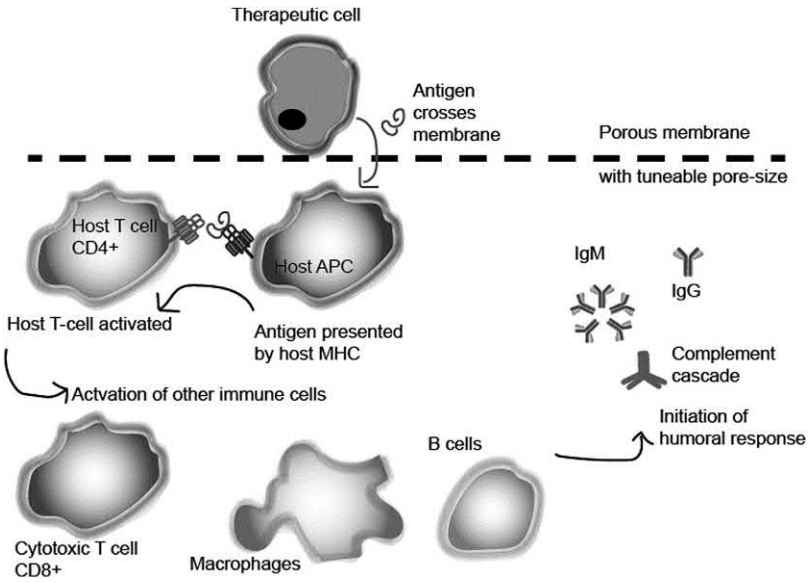

FIGURE 22.2 An overview of the indirect rejection pathway in which the host immune system can recognize foreign encapsulated cells without direct cell−cell contact.

Ideally, the barrier should be as porous as possible to allow for maximal diffusion of nutrition to the cells. However, this can also compromise the protective capacity of the device. Tuning the pore-size of materials utilized for immunoisolation devices can be used to optimize cell nutrition while preventing direct activation and host immune rejection. Mammalian cells are typically in the order of 5−15 μm in diameter. Many immunoisolation devices are therefore composed of cross-linked hydrogels or porous membranes with sizes smaller than this to ensure that host immune cells cannot penetrate into the device and initiate transplanted cell rejection through the direct pathway. However, certain immune cells and cancer cells are able to extravasate from blood vessels through relatively small gaps [36]. In fact, both T cells and macrophages have been shown to crawl or squeeze through small apertures on the order of micrometers and smaller than the typical diameter of a cell [19]. This suggests that pore sizes in immunoisolation barriers need to be in the submicrometer range to prevent host immune cell penetration and possible donor cell escape.

Assuming direct cell contact can be averted, there remain a number of immunological small molecules that may penetrate the immunoisolation barrier [27]. Alginate microcapsules have been used to deliver proteins [37,38], small molecules [39,40], and therapeutic antigens from encapsulated cells used as a vaccination strategy [34].

Donor antigens can be very small and include short peptide sequences [41,42]. These antigens are much smaller than the therapeutic proteins secreted by the cells (such as insulin ~6 kDa) and may be able to leak out of the immunoisolation device to initiate immune cell responses. In order to prevent donor cell destruction, efforts have concentrated on preventing the penetration or leakage of toxic and activating moieties both into and out of the immunoisolation device (Fig. 22.3). Therapeutic proteins such as insulin (6 kDa) [43] can be larger than immunogenic antigens that may be shed by the encapsulated cells [32−34]. The optimal membrane porosity may also be affected by the cell type encapsulated within the device. Allogeneic cells (same species: human into human) are likely to be less immunogenic than xenogeneic cells (cross species: pig into humans) and so may require less restrictive barriers than xenogeneic cells. While the immune system can become activated by these shed antigens [44], it is not clear whether the indirect pathway poses a significant block toward the translation of immunoisolation devices [45].

Therapeutic cells

A wide range of cells has been investigated for use within immunoisolation devices and can be categorized into three main types: primary cells, immortalized cell lines, and stem cells (Fig. 22.4).

Primary cells

Primary cells are isolated from human or animal donor tissues and include cadaveric islets or parathyroid tissue [13,14]. Primary cells are an attractive cell source as the cells are terminally differentiated and already contain the intracellular machinery required to secrete the therapeutic protein. They are typically nonproliferative and genetically stable. However, there are a limited number of human donor organs available, and these are insufficient to treat all patients. To overcome the limited donor supply, especially in the diabetes space, various strategies are

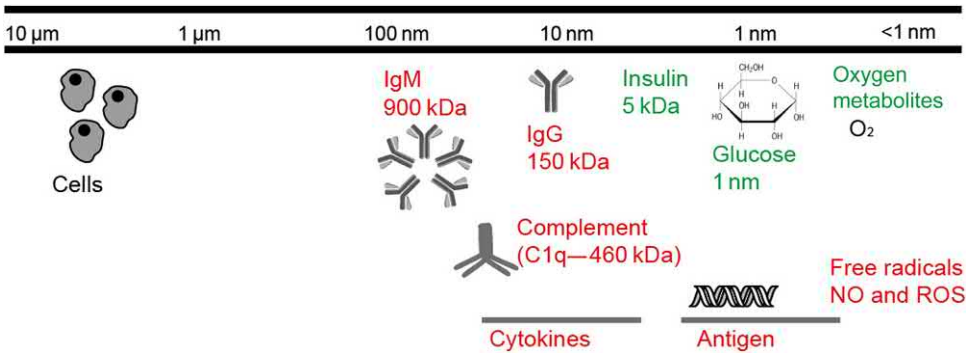

FIGURE 22.3 Immunoisolation barrier porosity as compared to biological length scales. Immunoisolation barriers must be able to transport essential nutrients and oxygen to encapsulated cells and allow for the transport of secreted proteins such as insulin. Some are designed to minimize transport of immunogenic or cytotoxic biomolecules (red).

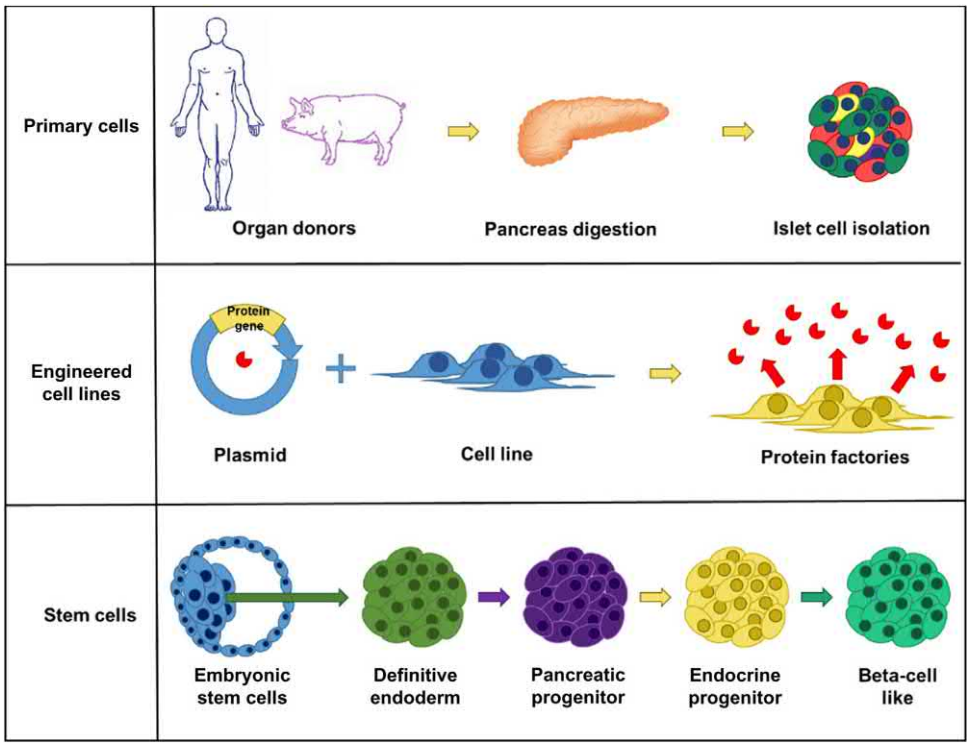

FIGURE 22.4 Cell types used in immunoisolation devices for cell-based therapies.

being developed to provide renewable islet cell sources. This includes porcine islets, proliferated beta cells to expand the number of islet cells isolated per donor, and insulin-producing cells differentiated from stem cells. The use of porcine islets as a renewable supply of differentiated islet cells is attractive but also has potential drawbacks. In particular, there have been concerns regarding cross species pathogen transmission of porcine endogenous retroviruses (PERV) and the production of specific glycans such as galactosyl-α-1 (Galα-1) by pig organs that are hyperimmune stimulatory in humans [46]. However, recent advances in genetic engineering of pig strains in Good Manufacturing Process (GMP) facilities have selectively targeted genes to make Galα-1 and other types of knockout pigs with safe PERV copy numbers to address these issues [47].

Immortalized cell lines

A wide range of immortalized cell lines can be engineered to secrete a therapeutic protein of interest. These can include murine mammalian cell lines that are transfected with agents to introduce genes necessary for producing recombinant proteins by the biopharmaceutical

industry such as Chinese hamster ovary cells, C_2C_{12} myoblasts, baby hamster kidney (BHK) fibroblasts, or mouse 3T3 fibroblasts [1,48]. However, similar to the description of Galα-1 above, there are posttranslational protein modification differences between rodents and humans. This can lead to the secretion of proteins by nonhuman cell sources that are recognized as foreign by the human immune system [26]. Human embryonic kidney cells (HEK293) and HT-1080 cells are two *human*-derived cell lines most often used in the biopharmaceutical industry for the production of protein therapeutics with potential in immunoisolation devices [1,49]. A cell line currently used in clinical trials for immunoisolation devices is human retinal pigment epithelial cells, which have been engineered to secrete ciliary neurotrophic factor to reduce macular degeneration [18].

Next-generation cell lines can be engineered using synthetic biology to secrete therapeutic proteins in a regulated fashion, often in response to known stimuli [50]. This engineered cellular control system allows cells to "turn on and off" protein production, which helps to limit the overproduction/secretion of excess proteins that may damage the body [51]. Synthetic biologists are inserting gene circuits that give cells the ability to sense a specific stimulus and then deliver a desired response [52]. Stimuli can include pH, mechanical forces, chemical signals, or specific energy waveforms, which then actuate a response—causing the cell to produce/secrete the desired protein [51,53–55]. For example, HEK293 cells were synthetically engineered to contain a gene circuit that can respond to applied external radio frequencies. When stimulated, this gene circuit activates the transgene for insulin production/secretion in vivo to help control diabetes [55]. By developing gene circuits with various input/stimuli genes and output/expression genes in a modular fashion, inputs and outputs can be simply interchanged. This facilitates modular genetic engineering of cells for a stimuli responsive protein secretion, depending on the respective disease [51].

Stem cells

Embryonic stem (ES) cells, inducible pluripotent stem (iPS) cells, mesenchymal stem cells (MSC), and other multipotent progenitors all have potential application as therapeutic cells within immunoisolation devices [56–60]. The ability to self-renew and then be differentiated into a specialized, quiescent state makes these cells attractive precursors to therapeutic cells. In addition, some MSCs have been shown to secrete various factors that reduce the immunogenicity of the device [61]. In terms of diabetes the use of stem cells to create an unlimited source of beta cells for widespread application of beta cell-replacement therapies has made significant progress [62]. Historically, stem cell generation of beta cells that contain all the complex intracellular machinery required for glucose-dependent insulin secretion (e.g., K^+ATP channels, voltage-dependent Ca^{2+} channels) has been difficult. But recent developments have elucidated the potential to robustly produce beta cell-like insulin-producing cells from stem cells in vitro. Following the developmental stages shown in Fig. 22.4, these beta cell-like cells have been shown to exhibit glucose-responsive insulin secretion in vitro and induce normoglycemia in diabetic rodent models posttransplantation, and multiple types of stem cells (ES, iPS cells from Type I diabetic patients, and pancreas progenitors) can be used to produce the cells [56–60]. Since undifferentiated ES cells have the potential to form teratomas or cysts, many groups are pursuing immunoisolation devices to protect both the cells and recipient from potential harm [63].

Device architecture and mass transport

The device shape and architecture govern the mass transport and exchange of molecules into and out of devices. The main shapes studied have been spherical, planar, and cylindrical fibers (Fig. 22.5). The shape then dictates the amount of surface area that contacts the interstitial tissue

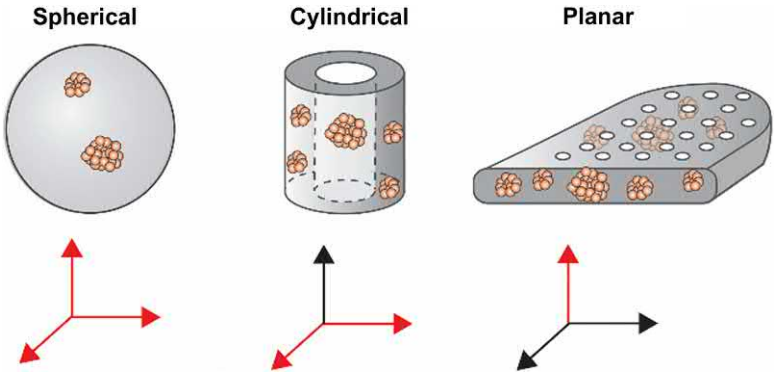

FIGURE 22.5 Main canonical design shapes and metabolite exchange directions (red).

for the exchange of molecules to occur with the body. Spherical designs use cells entrapped within microsphere hydrogels, and the porous hydrogel materials typically act as the immunoisolating barrier. Microspheres are attractive due to their high surface area-to-volume ratio and exchange in all x, y, z, directions. Cylindrical devices can consist of drawn hydrogels or hollow tubes with an outer immunoisolating membrane with exchange in x, y but not z directions. Planar designs contain a central cavity for the cells, which is sandwiched between immunoisolating membranes. Exchange can only occur in a maximum of two z directions.

Spherical devices are generally made from natural or synthetic hydrogels. Alginate is one of the most widely investigated cell microencapsulation materials [64]. This anionic polysaccharide derived from seaweed forms a hydrogel in the presence of divalent cations under cell-friendly conditions [64]. Briefly, islets are mixed with a viscous alginate solution and dripped into a divalent cation solution. This ionically crosslinks the alginate to solidify the gel, thereby entrapping islets within the alginate network [65]. Typically, few islets are encapsulated per sphere, which commonly range in diameters from 0.5 to 1 mm [66–69]. Several sphere formulations, with tunable ionic cross-linking and alginate composition, have demonstrated long-term diabetes correction in rodent models [45,66,70,71]. These promising results prompted the investigation of these alginate-based formulations in three small scale trials involving human patients. Unfortunately, these devices did not provide long-term glycemic control in patients [72–75]. One of the contributing factors to loss of cell function within alginate microspheres is a host fibrotic response to implanted materials. This causes collagen deposition and reduced oxygen and metabolite diffusion into the spheres [76]. Overcoming the host fibrotic immune response is a major challenge for the long-term survival of encapsulated cells that we discuss in a separate section later.

A number of cylindrical macrodevices have been developed to treat retinal degeneration and diabetes [18,77]. The TRAFFIC (thread-reinforced alginate fiber for islets encapsulation) device consists of an alginate fiber with dispersed islets that is mechanically reinforced by a central thread. The central thread uses two twisted nylon sutures that are coated with a poly(methyl methacrylate)/N,*N*-dimethylformamide/calcium chloride (PMMA/DMF/$CaCl_2$) solution to impregnate the central fiber with Ca^{2+} ions. The fiber is then placed into a cylindrical mold with an alginate/islet solution where the calcium ions slowly elute from the fiber to cross-link the alginate network. The TRAFFIC device was tested with rat islets in a diabetic C57bl/6 mouse model of diabetes and was reported to cure 10/14 mice for up to 3 months. The singular device could be retrieved from the mice, and all the cured mice returned to a hyperglycemic state indicating that the glycemic control was due to the TRAFFIC device [77]. This approach of using a reinforced hydrogel matrix could be used with a variety of hydrogel materials or could be impregnated with a range of other bioactive molecules for localized release of vascularizing agents and immunomodulatory drugs.

The shape of the immunoisolation device also controls the number of cells that can be implanted. Microspheres contain few cells per device; therefore multiple devices are required to be transplanted into a patient. Macrodevices, often planar or cylindrical, can contain many cells within one or a few devices. Each of these parameters (shape, size of device, and number of devices needed) presents advantages and disadvantages that must be tuned to the requirements of the specific disease being treated. For instance, microspheres may have beneficial diffusion properties for the nutrition of the therapeutic cells but may be more difficult to retrieve in cases where they need to be replaced or recovered. Macrodevices may be retrieved as a singular device but may have limited exchange kinetics that makes it difficult to support many cells within one device. These factors are interlinked with oxygen demands and the environment of the transplant site.

Transplantation site

Various transplantation sites have been investigated for the implantation of immunoisolation devices, and the appropriateness of the site must take into account specific requirements of the disease, device size and shape, and the cell type utilized. When choosing a transplantation site, careful consideration should be taken to determine the number of cells/protein required, volume of space to hold the device, metabolic requirements of the cells, the nutritional capacity of the site, immune cell activity of the site, transportation of drug from the site to the disease target, and the ease of access for transplantation [78]. These considerations can then guide the design of the device. Many transplantation sites have been investigated for devices, including the liver, kidney, bone marrow, intramuscular, subcutaneous, peritoneal cavity, pleural space, and epididymal fat pad [79–84]. The eye is an interesting space that has shown efficacy in clinical trials for macular degeneration using a very small implanted device [2,18]. This location is proximal to the disease site and is immune privileged: it is not readily infiltrated by immune cells that can cause device failure. A few key transplantation sites are elaborated next.

Subcutaneous (SC): The subcutaneous space offers ease of access through a minimally invasive implantation surgery. Devices implanted in SC spaces can be more easily retrieved in case the cells need to be replaced [85].

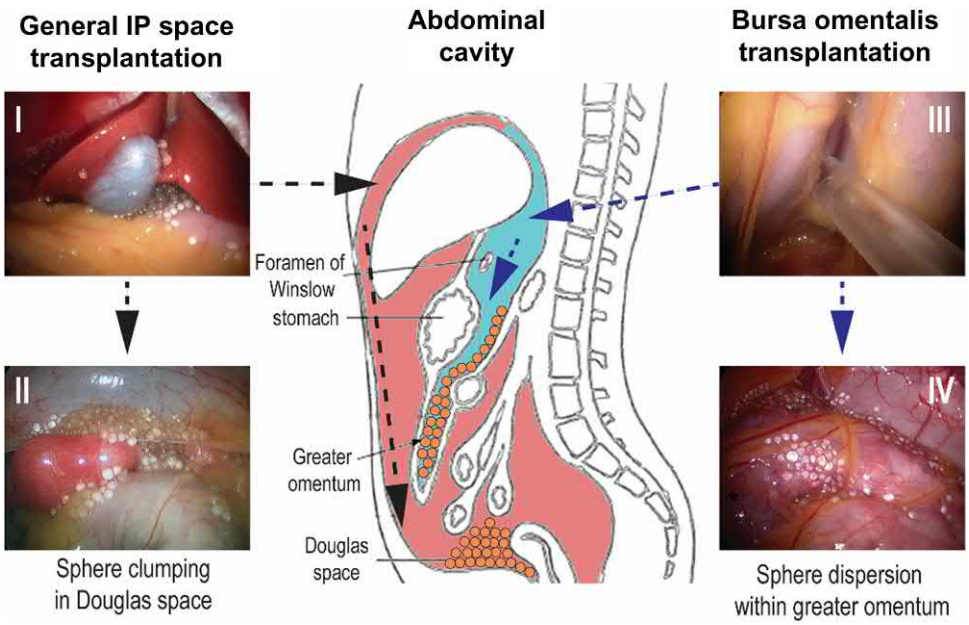

FIGURE 22.6 Schematic depicting the laparoscopic transplantation of immunoisolation devices into the intraperitoneal space and bursa omentalis. The settling of spherical devices due to gravitational sedimentation in bipedal primates was recently shown to be decreased in the bursa omentalis. *Adapted from Bochenek MA, Veiseh O, Vegas AJ, McGarrigle JJ, Qi M, Marchese E, et al. Alginate encapsulation as long-term immune protection of allogeneic pancreatic islet cells transplanted into the omental bursa of macaques. Nat Biomed Eng 2018;2(11):810–21.*

However, this site has also demonstrated suboptimal nutrition and low fluid turnover [86]. To improve the nutritional properties of the SC site for islet transplantation, various engineering strategies have been employed to encourage vasculature in the SC site and within devices, discussed later.

Intraperitoneal space: The intraperitoneal space within the abdominal cavity offers a large volume of space to hold multiple devices (Fig. 22.6). The site can be accessed via a noninvasive laparoscopic procedure, has high fluid turnover from the circulation of peritoneal fluid, and the omental tissue is vascularized but concerns have been raised regarding oxygen availability for implanted cells [3,87,88].

Bursa omentalis: Also located within the abdominal cavity, the bursa omentalis or lesser sac, is formed by a tissue bilayer of the greater omentum (Fig. 22.6). The sac hangs like an apron on top of the intestines and below the intraperitoneal space. The tissue bilayer of the bursa omentalis was recently shown to reduce the settling and clumping of implanted spherical devices that occur in bipedal primates due to gravity sedimentation [3]. Any clumping of immunoisolation devices can lead to enhanced fibrotic responses driven by the host immune system and reduce nutrition for any cells housed in the center of the clumps.

Improving oxygenation of immunoprotected cells

Various strategies have been employed to improve diffusion kinetics and oxygenation of immunoisolation devices (Fig. 22.7). These include maximizing the porosity of the device using superthin porous immunoisolation barriers to reduce diffusion distances [89]. Alternatively, oxygenation can be enhanced by increasing vasculature around the device, including oxygen carriers to enhance oxygen transfer, in situ oxygen generation, an exogenous source of oxygen, or reclustering cells into smaller cell aggregates [79]. Some cell aggregates used for immunoisolation devices are too large for oxygen to adequately reach cells in the center. This can lead to cell death and central necrosis in the core. After dissociation and reaggregation into small aggregates, cells can obtain more oxygen and have been shown to function better under hypoxic conditions and secrete lower levels of proinflammatory biomolecules such as MCP-1 or IL-6 [90].

Many groups have investigated methods to increase vasculature around immunoisolation devices [91–93]. In one approach, researchers induce neovascularization in the transplant site by implantation of a silicone catheter weeks prior to implantation of islet cells. This was reported to improve islet functionality by reducing hypoxia-related islet cell death in the peri–post transplantation period [86]. The delivery and scaffold release of vascularizing ligands and soluble factors such as vascular endothelial growth factor (VEGF)/PEDGF have also been employed to generate neovasculature at the transplant site [1]. One of the first planar devices, TheraCyte, consisted of a hollow chamber surrounded by an immunoisolating membrane. This was then covered with a second membrane that was designed to induce neovascularization for nutrition of the cells at the transplant site [94]. Early studies demonstrated the ability to pretransplant the device to

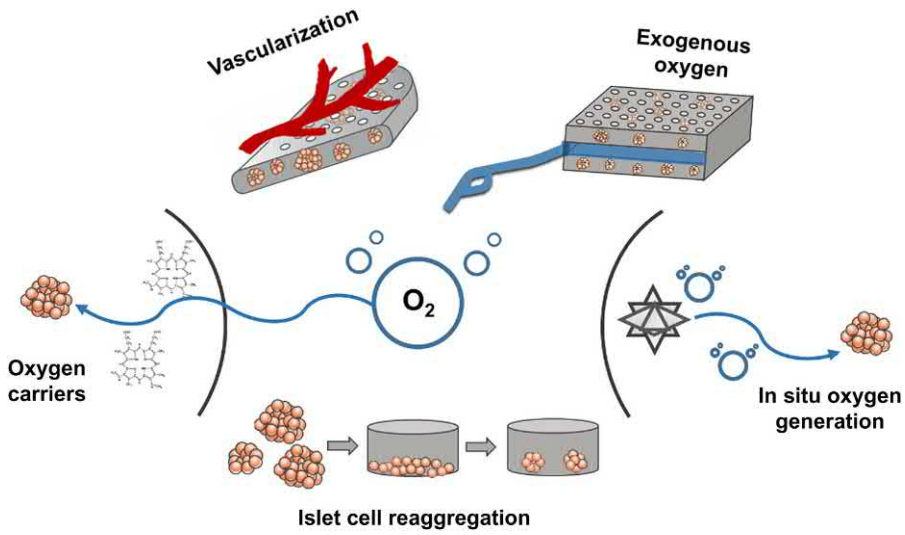

FIGURE 22.7 Strategies to improve oxygenation and enhance cell nutrition.

induce neovascularization in rats prior to loading the allogenic islet cells through a port [95,96]. Currently, studies are being completed with a next-generation device (VC-01) that utilizes a similar macrodevice strategy. VC-01 was reported to support the differentiation of human pancreatic progenitor cells into mature beta-cell like cells posttransplantation using an in vivo mouse model [43]. These results led to a Phase I clinical trial where human stem cells, CyT49, were partially differentiated into pancreatic progenitors (PEC-01) and loaded into the VC-01 devices to investigate the potential for these cells to form into human beta-cell like cells. Unfortunately, of the 19 patients transplanted with devices, only the devices retrieved from two patients were found to contain live cells, while the majority contained few viable cells [63]. The failure of these devices to support cell viability was largely attributed to the foreign body response to the vascularizing membrane [63].

Efforts have also focused on alternative methods of increasing oxygenation synthetically. Perfluorinated compounds or inclusion of hemoglobin substitutes within immunoisolation materials have been investigated as oxygen carriers to enhance the diffusivity of oxygen [97–99]. These have been reported to improve islet cell responses under hypoxic conditions [99]. The OxySite device encapsulates CaO_2 crystals within polydimethylsiloxane (PDMS) disks to provide in situ generation of oxygen for therapeutic cells. PDMS is hydrophobic and slows the hydration of CaO_2 crystals; incorporation of CaO_2 crystals in hydrophilic materials was shown to release oxygen too quickly and induced hyperoxia, which reduced cell viability [100].

The Beta-O_2 device βAir consists of a planar disk with a refillable oxygen chamber surrounded by an immunoisolating membrane. [101] Islets are encapsulated in alginate slabs and placed on each side of the central gas chamber. Ports are connected to the central gas cavity and allow for the daily refueling of oxygen by injection through the subcutaneous port. The whole device is then wrapped in a polytetrafluoroethylene (PTFE) immunoisolating membrane and is transplanted in a subcutaneous pocket [102]. This device has shown efficacy in various diabetic animal models including rats [103], minipigs [104], and nonhuman primates (NHPs) [105], using both allogeneic and xenogeneic islets cell sources. The βAir device is currently in clinical trials, and the first five human patients have been transplanted with a subtherapeutic islet dose [101,106]. The islets have been shown to remain viable and functional in the device for up to 2 years in patients but have only shown moderate improvements in the clinical disease state. The patients were transplanted with a low number of islets (2,100−4,600 islet equivalence (IEQ)/kg patient), which is less than the 10,000 IEQ/kg recommended dose for intraportal islet transplantation [6]. The investigators reported no signs of human leukocyte antigen (HLA) immunization to the foreign islets within the devices. However, a substantial foreign body response and fibrotic capsule around the device was reported in three of four patients in the most recent trial. Increasing the number of islets per device and reducing the thickness of the fibrotic capsule may be ways of improving the kinetics of insulin secretion out of the device in the future.

Controlling immune responses to implanted materials

Immunoisolation devices are designed to protect transplanted cells from the rejection by the host immune

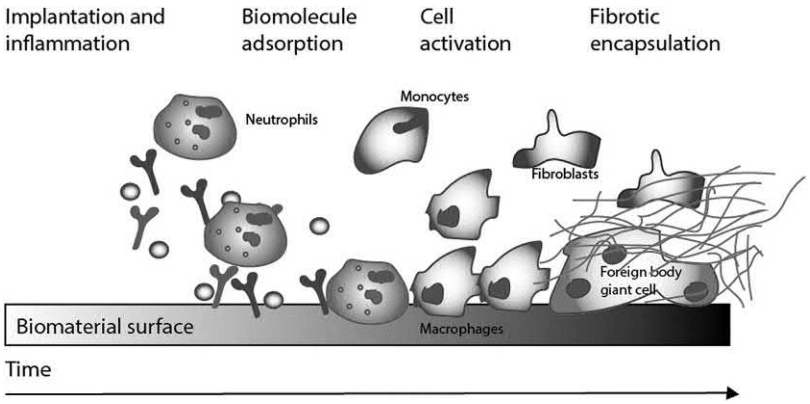

FIGURE 22.8 An overview of the steps in the foreign body reaction. Postimplantation inflammation leads to adsorption of proteins and biomolecules onto the biomaterial surface and the influx of neutrophils. Monocytes and macrophages are activated, causing macrophage fusion into foreign body giant cells. The recruitment of fibroblasts leads to deposition of a collagen matrix and fibrotic encapsulation.

system. However, the immune system may also recognize and react to these implanted materials themselves. Implanted materials can cause the immune system to initiate a foreign body reaction (FBR), which can eventually lead to collagen deposition around the implant [107,108]. This deposition of collagen can form a fibrous capsule around implanted materials, which impairs device function. In the case of transplanted therapeutic cells, it can leave cells deprived of oxygen and at risk of necrosis. Thus a successful immunoisolation device must both protect the transplanted cells from host immune rejection and minimize the FBR to the device. Here, we discuss the FBR and engineering approaches which can help to prevent immunoisolation devices themselves from provoking an undesired immune response.

Steps in the foreign body reaction

In general, the immune system identifies implanted materials as nonself and initiates the FBR (Fig. 22.8). Briefly, implanted biomaterials are exposed to blood and tissue fluids, which causes proteins to adsorb onto the biomaterial surface. These can then be identified by immune cells, which trigger acute (1−2 weeks) and then chronic (2 weeks +) inflammation, culminating in the fibrous capsule surrounding the device [109−111].

Several cell types are known to be involved in the foreign body response, which is mainly orchestrated by innate immune system cells, including leukocytes such as neutrophils, monocytes, and macrophages. Importantly, the recruitment and differentiation of monocytes/macrophages is a key step in the FBR [107,108,112−114]. First, in a process known as "frustrated phagocytosis," the macrophages try to engulf the large device and eventually fuse together to form large polynuclear foreign body giant cells [109,115,116]. These, along with other macrophages that have become activated surrounding the implant, secrete a cascade of inflammatory chemical signals to recruit other cells. These can include fibroblasts that then deposit collagen around the biomaterial, and ultimately, the fibrous capsule containing extracellular matrix proteins and immune cells [113,114,117,118].

The formation of this dense collagen layer and fibrotic capsule isolates the implant material from the rest of the body [113,119−121]. Unfortunately, this also isolates the implant from the local vasculature, often causing cells within the device to experience hypoxia and cell death. In order to combat FBR, material properties must be carefully selected or engineered to limit the key steps in the FBR process, including protein adsorption, inflammation, and immune cell recruitment/activation.

There are additional factors that can influence the foreign body response to implanted materials, including the biological site of implantation, species, and strain of host animal receiving an implant and donor cells, and the surgical technique used to implant the device. Furthermore, intrinsic material properties such as chemical composition, geometry, and morphology have also been shown to affect how the body responds to implants [122]. Engineers can tune immunoisolation devices to resist the FBR by targeting several stages, including protein adsorption, inflammation, and immune cell recruitment [3,123−128].

The role of geometry in the foreign body reaction

The size, shape, mechanical properties, and topography of implanted devices are emerging as factors that can affect the FBR. Many immune cells have been shown to be sensitive to the mechanical properties and underlying topography of their surroundings [129]. Materials with complex topographical features typically present increased surface area for protein adsorption and cellular attachment; however, topographical cues can affect cell behavior [130].

Several cell types, in particular human fibroblasts [131−136], can sense and respond to depressed and elevated nanotopographical features such as wells, pits, and

nanopillars. By altering the nanotopography of materials, cells can be directed to orientate around specific features or to reduce adhesion [131,136–139]. This strategy has been employed in osteo-implants, where changing surface roughness has been shown to impact cell adhesion and clinical outcomes [140]. The role of device geometry in controlling FBR has only recently been explored. For instance, it was found that by increasing the size of spherical devices from 0.5 to 1.5 mm diameter, the foreign body response could be reduced and was similarly observed across many sphere materials [141].

Many of these physical properties (size, shape, geometry, mechanical properties) are intrinsically linked, and the precise role of each of these components in directing cellular behavior in the FBR response has yet to be elucidated. Importantly, macrophages are a key regulator of the FBR, and it has been shown that macrophage phenotype can be modulated toward pro- or anti-inflammatory phenotypes by these properties [142–150].

Tuning chemical composition to prevent attachment

The chemical composition of the material can affect the FBR process. Chemical charge, hydrophobicity, and whether the material is derived from natural or synthetic sources can all impact the response to implanted materials at different stages in the FBR cascade. For example, coagulation Factor II (a component of the coagulation cascade) has been reported to bind to alginate–cellulose materials but not to ionically cross-linked alginate. When these materials were incubated in model systems, materials that could bind Factor II showed increased coagulation, which is an important precursor to downstream fibrosis [151].

Using this principle, immunoisolation devices that resist protein adsorption, or even cellular attachment, have been designed. By coating devices with hydrophilic molecules such as poly(ethylene glycol) or zwitterionic-based materials, both protein adsorption and cellular attachment can be reduced. This strategy of preventing the FBR through the early stages of protein absorption, or the later stage of cellular attachment, has proven useful in minimizing the fibrotic response to implanted devices [152–154]. Recently, a chemically modified microsphere formulation has also demonstrated the potential to reduce fibrosis of alginate-based formulations in mouse and NHP models. Alginate modified with a small-molecule was found to reduce macrophage adhesion and could protect viable and glucose-responsive islets in an NHP model for up to 4 months without fibrosis [3]. These systems were also shown to protect stem cell–derived beta cells and show long-term normoglycemia in immune competent mice with a renewable islet cell source [69,127].

Directing immune cell behavior in the transplant niche

One strategy to minimize the fibrotic response to an immunoisolation device is to deliver signals to the cells in the transplant niche to directly alter their behavior. Such approaches typically focus on suppressing unwanted immune cell responses and recruiting cells that may promote a more receptive transplant environment. For example, macrophages can display pro- or anti-inflammatory phenotypes. Suppressing proinflammatory macrophage activity through the delivery of soluble drugs has been shown to dramatically reduce the foreign body response to implanted materials [107,108,129,135,155–162]. Materials have been engineered to release a soluble form of the CSFR1 inhibitor of macrophage activation or the local delivery of the immunomodulatory protein chemokine CXCL12 and have been reported to decrease fibrosis [69,108,163]. When islets were encapsulated in microspheres, which also eluted these biomolecules, they were reported to induce long-term normoglycemia in diabetic C57bl/6 mice using a variety of islet sources (human, rat, and porcine).

Another microsphere design utilizes a combined approach; a double-coated sphere and the short-term administration of soluble immunosuppressive drugs CTLA4-Ig and/or anti-CD154 mAb for dual costimulatory blockade [164]. The inner core contains encapsulated islets, which is then coated with a poly-L-lysine (PLL) coating to provide a perm-selective immunoisolating membrane. The outer shell is composed of alginate to mask the PLL coating, which has been shown to be immunogenic [165,166]. Recently, various regimens of costimulatory blockade immunosuppression for transplant of encapsulated adult porcine islets were investigated in diabetic NHPs [68]. Results indicate that the immunoisolated islets could remain viable without fibrosis but demonstrated transient improvement in glycemic control of the diabetic NHP. Interestingly, the encapsulated islets could be retrieved from the NHP with transient glycemic control, and following transplantation into diabetic immune compromised mice, the retrieved encapsulated islets were now able to induce normoglycemia in the mice. This study suggests that there may be additional differences between the intraperitoneal transplant sites in mice and NHP, and differences in curative transplant demand due to oxygen or insulin requirements in different host species.

Introduction

Tissue engineering relies on the availability of cells capable of repairing or replacing damaged tissues and organs. Although multiple sources of cells from cadavers to animal tissues have been considered, pluripotent stem cells (PSCs) are of intense interest because they can be expanded indefinitely in culture and can also be directed to differentiate into a particular cell type of interest. Adult tissue-derived stem cells such as those from bone marrow, fat, and skin are among the most studied and while some are currently being used in the clinic, these sources are donor-dependent, have limited expansion potential, and a highly restricted differentiation capacity. Ideally, having a single inexhaustible source of pluripotent cells that can generate large quantities of therapeutic cells would greatly facilitate regenerative medicine endeavors while simplifying quality control and safety testing. Human embryonic stem cells (hESCs) offer the unique possibility of meeting these criteria and thus may be able to circumvent many of the problems associated with variations in donor-dependent cell sources.

Derivatives of hESC have been regarded by many as a panacea for the treatment of various ailments, ranging from osteoarthritis to blindness, heart disease, and spinal cord injuries, among others. The list is long and numerous promising studies in animal models indicate that the question now is not whether hESC-based therapies could be safe and effective but what indications are they best suited for and how soon can they become a standard of care. Before this happens, however, several unique challenges need to be overcome. For example, the generation of hESCs is wrought with controversy as the standard derivation process involves destruction of a developing human embryo. Similar to adult tissue-derived cell sources, another issue that needs to be addressed concerns histoincompatibility between hESC derivatives and the intended recipient. The advent of induced PSCs (iPSCs) could one day alleviate both the ethical and histoincompatibility issues surrounding the use of hESC [1,2]. iPSC can be generated from a person's own mature somatic cells and through the process of reprograming, turned back into a pluripotent state for use as a patient-specific renewable cell source with broad differentiation capabilities. Histoincompatibility may be managed through a variety of different approaches, including the use of immunosuppressive drugs, the generation of hESC banks to help match human leukocyte antigen (HLA) haplotypes between the starting hESCs and the intended recipient, and genetic engineering to make hESCs or allogeneically used iPSCs (and their derivatives) universally immunocompatible. This chapter will focus on hESC derivation and progress toward clinical application of their derivatives yet much of the knowledge that has been gained through this research is applicable or even transferable to the iPSC field.

Approaches to human embryonic stem cell derivation

hESCs were first isolated in 1998 from the inner cell mass (ICM) of a preimplantation human blastocyst in a landmark study by Thomson et al. [3]. As research with hESC gained interest, great promise as well as great controversy was brewing in the press. hESC theoretically have the capability of giving rise to all tissues of the human body and may provide crucial therapeutic treatment for a wide variety of diseases yet the only known hESC derivation process back in the late 1990s/early 2000s involved destruction of a human embryo, and this was seen by some as the equivalent of killing a human being. Acknowledging the enormous potential of hESC research while also trying to quell the ethical firestorm that hESC derivation had garnered, in 2001, the Bush administration made the decision to allow federal funding

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00024-1

for hESC research on the condition that only hESC lines already in existence could be used. The NIH hESC registry list (http://stemcells.nih.gov/research/registry/) was established to keep track of approved lines. The original hESC lines derived by Thomson et al. at the University of Wisconsin [3] were among the first hESC lines registered and have become the most widely used and published hESC lines available. Since then, however, many other hESC lines have been derived using private funds and other stem cell banks and registries have been created. Examples include the University of Massachusetts International Stem Cell Registry [4], European Human Embryonic Stem Cell Registry [5], and UK Stem Cell Bank [6].

hESCs retain a fundamental property of ICM cells—the ability to give rise to all tissues of the human body. The same markers of pluripotency are found in both ICM and hESC—the transcription factors Oct-4, NANOG, Rex-1; cell surface antigens SSEA-3, SSEA-4, TRA-1-60, and TRA-1-81 (Fig. 23.1); and high alkaline phosphatase activity [7,8]. Cells of the ICM only exist for a few days in the natural course of embryo development; they arise during blastocyst formation from a morula on day 4 and persist throughout the first days or hours postimplantation before beginning the highly orchestrated process of differentiation. ESCs may be seen as an immortal extension of the ICM in culture; they retain high telomerase activity and can continue to self-renew indefinitely under appropriate culture conditions. When injected into immunodeficient mice, hESCs form teratomas—tumors that contain derivatives of all three germ layers, the most typical ones being bone, cartilage, neural rosettes, and epithelium of the airways and gut. Like the ICM of a developing blastocyst, pluripotent ESCs in culture are primed to differentiate, and as we will discuss later in the chapter, this makes working with them both easy and difficult at the same time.

Traditionally, ESCs have been derived from day 5−7 blastocysts with or without immunosurgery (removal of the trophoblast) by plating a blastocyst or an isolated ICM (Fig. 23.2) on a feeder layer of mitotically inactivated mouse embryonic fibroblasts [3,9]. Yet, new lines have now been derived using alternative approaches in an attempt to overcome ethical issues surrounding embryo destruction during hESC derivation [10,11]. Moreover, the use of mouse feeder cells and animal products during hESC derivation and maintenance has been eliminated in newer methods because of safety concerns that they could harbor unknown xeno viruses. Producing cells that are compatible with a patient's own immune system is also an important consideration for preventing rejection. Thus at present, hESCs have been derived on human feeders [12−14] and even on feeder-free matrices [15]; they have

been derived from growth-arrested in vitro fertilization (IVF) embryos that cannot be used for implantation [16], from unfertilized oocytes that are incapable of forming a developmentally competent embryo [17–20], and from a single blastomere of a morula stage embryo—a technology that allows the generation of hESC while leaving the embryo unharmed [14,21–23].

Derivation of hESC from chemically activated unfertilized oocytes [parthenote hESC (hPESC)] was reported by several groups [17–20]. These studies showed that hPESCs are very similar to ICM-derived hESCs: they have the same colony morphology and growth behavior, maintain a normal karyotype, express the same markers of pluripotency, and differentiate into derivatives of all three germ layers. These cells could also potentially address the ethical and immune compatibility issues that plague traditional hESC lines, as parthenogenetic hESC lines from carefully selected donors could match a larger proportion of the population because they have a reduced number of HLA. However, some studies showed that a large percentage of parthenogenetic blastomeres were affected by an excessive number of centrioles, a high aneuploidy rate [24], as well as genetic and epigenetic instability [22]. A lot of progress has been made generating hPESC and their derivatives [25–31]. Although the technology is not very widely used, one group has differentiated their clinical-grade hPESC line into midbrain dopaminergic (DA) neurons and begun testing it in Phase 1/2a clinical trials to treat Parkinson's disease (PD) (www.clinicaltrials.gov, clinical trial ID# NCT03119636). Preclinical studies of these hPESC-DA neurons in a non-human primate model suggested that they are safe to use and provided functional improvement in behavioral endpoints for up to 24 months [32]. It remains to be determined if hPESCs can compete with "conventional" hESCs for the generation of cells for regenerative medicine.

A technically challenging yet innovative approach to hESC derivation is based on somatic cell nuclear transfer (SCNT). During a micromanipulation procedure, the nucleus of a donor cell is introduced via a micropipette into the cytoplasm of an enucleated unfertilized egg, which then develops into a blastocyst. ESC isolated from such blastocysts would have the same genotype as the donor of the nucleus, thus their derivatives could be used as autologous transplants. SCNT can also be performed by fusing a donor cell to an enucleated oocyte. Successful generation of SCNT-hESC was reported by several groups who used fetal, neonatal, and adult fibroblasts as donor cells for somatic nuclei [33–35] with a success rate of up to 25% [36]—efficiency comparable to that of hESC derivation from naturally fertilized blastocysts. The efficiency of blastocyst formation and hESC derivation though varied for eggs obtained from different donors and could even correlate with the hormonal stimulation protocol [35]. Another major SCNT reprograming barrier was shown to be associated with severe methylation of lysine 9 in histone H3 in a human somatic cell genome [36], but introduction of KDM4A, a H3K9me3 demethylase during SCNT, significantly improved the development of SCNT embryos. Interestingly, this approach worked even when researchers deliberately used the eggs from the same donors whose eggs previously failed to produce SCNT blastocysts. While the possibility of creating donor-matched hESC lines by SCNT remains attractive, successful implementation of this technique takes years for the operator to develop skills required to perform this procedure with high precision and efficacy and minimal disturbance to the egg or donor nucleus. One of the groups that have been able to successfully derive SCNT-hESCs is now testing the safety and tolerability of their SCNT hESC–derived retinal pigment epithelium (RPE) in patients with advanced dry age-related macular degeneration (AMD) (NCT03305029). Yet, it is unlikely that

SCNT will be commonly used in the future to create new hESCs for clinical use given the many technical challenges that micromanipulation of nuclei presents and the difficulties in procuring suitable oocytes.

Another approach that has proven to be successful for generating hESC without embryo destruction is the use of embryo biopsy. This procedure, once commonly used in preimplantation genetic diagnostics in the course of IVF, involves removal of a single blastomere from a morula stage embryo [37] and has resulted in hundreds of healthy babies being born. Using this procedure, we established several hESC lines from single blastomeres while the donor embryos were allowed to develop to the blastocyst stage and cryopreserved [23]. Single blastomeres were first cocultured with the biopsied embryos and then plated on feeder cells in microdrops [21–23], and outgrowing colonies were treated the same way as ICM outgrowths (Fig. 23.2). In early experiments, blastomere outgrowths were cocultured with green fluorescent protein (GFP)-expressing hESC, which presumably helped condition the microenvironment and boost the outgrowth of hESC from blastomeres. After initial outgrowth was observed and the colony of blastomere-derived cells became large enough for passaging, GFP-negative colonies were marked under the fluorescence microscope and then mechanically dissected and replated; this procedure was repeated for several passages to ensure that the new cell lines were free of any contaminating GFP-expressing hESC. In addition, after the blastomere-derived hESC lines were established, they were extensively tested for the absence of GFP-positive hESC used for coculture and shown to be free of any GFP-expressing hESC [21,22]. Two hESC lines were generated that had similar properties to ICM-derived hESC: they stained positively for Oct-4, SSEA-3, SSEA-4, TRA-1-60, TRA-1-81, alkaline phosphatase and had a normal karyotype and differentiated into derivatives of all three germ layers both in teratoma assays in immunodeficient non-obese diabetic/severe combined immunodeficiency (NOD/SCID) mice and in vitro. In the first proof of principle study, the derivation yield was low, and the embryos were not preserved after the biopsy, but later this study was repeated using an optimized approach, which allowed the derivation of new lines from single blastomeres with higher efficiency and still without embryo destruction. Biopsies that were performed to isolate a single blastomere did not significantly affect the embryos; they developed to the blastocyst stage and were then frozen as expanded and/or hatched blastocysts [23]. Five hESC lines were produced this way from biopsied embryos and all of the embryos developed into healthy-looking blastocysts prior to cryopreservation [23]. This technique was subsequently used by several other groups to derive hESC lines with high efficiency and/or without destroying the embryos under different conditions including human feeder cells, feeder-free, and even from growth-arrested embryos [14,38–43]. Single blastomere–derived hESC showed a similar transcriptional profile to "conventional" hESC [44], and several differentiation derivatives of single blastomere–derived hESC appeared functional in vitro and in vivo in preclinical studies [45–49]. Single blastomere–derived hESC lines have already proven to be a useful starting material for regenerative medicine—one such line, MA09, was among the first of any type of hESC to be used clinically. The safety and tolerability of MA09-derived RPE was demonstrated in Phase 1/2 clinical trials in patients with AMD and Stargardt's disease, the juvenile form of AMD [47,48,50]. By avoiding destruction of human embryos, this technique also addresses the ethical concerns surrounding hESC derivation thereby offering a way to overcome a major hurdle in developing hESC-based therapies.

An interesting new development in hESC generation is the so-called naïve hESC. The term comes from the research on mouse ESCs, which have been shown to exist in two states, "naïve" and "primed" [51–54]. In addition to expressing markers of pluripotency, such as Oct-4, NANOG, and Sox2, pluripotent cells have both X-chromosomes active. Primed ESCs, coming from the epiblast, or EpiSCs, retain the expression of these markers, but only one X-chromosome is active [55,56]. hESC resembles mouse primed ESC rather than truly naïve cells. There are differences in morphology: the forms of hESC colonies are flat, not dome-like as typical for naïve cells, and they are polarized [57]. Metabolism of pluripotent cells relies on glycolysis, while primed cells use oxidative phosphorylation [58,59]. In primed ESC, only one X-chromosome is active, and they are very sensitive to single cell dissociation [51,60]. RNAseq analysis of single cells of human blastocysts showed that at least three types of cells can be identified and that during derivation of hESC, there are changes in gene expression as the cells are adapting to culture conditions [61], but it is still unclear if primed cells already exist in the embryo, or the transition happens during the first steps of hESC derivation.

Mouse ESCs are usually derived and exist in a naïve state, and it takes a special effort and culture conditions to isolate primed mouse ESCs (EpiSCs) from an epiblast. On the opposite, most hESC lines were derived and propagated in a primed state, until naïve, or "ground state" pluripotent hESC were derived [62,63]. Naïve hESC can be established de novo or through conversion of existing hESC lines to the naïve state;[64,65]. In addition, "naïve" iPSC can be established through reprograming under specific culture conditions [66]. In these cases, signaling pathways need to be activated or inhibited using bioactive substances and small molecules, such as the MEK inhibitor PD0325901, GSK inhibitor CHIR99021, STAT3

inhibitor NSC74859, ROCK inhibitor Y27632, LIF, bFGF, and TGF beta 1.

Once established, naïve cells survive single cell dissociation much better, which allows for greater expansion capacity (which could be highly desirable for large-scale manufacturing), their doubling time is much shorter, and they have been shown to differentiate more efficiently both in vivo and in vitro [67,68]—a highly sought after property when differentiation is aimed at making derivatives for regenerative medicine.

Maintenance of human embryonic stem cell

In vivo, the pluripotent cells of the ICM exist only transiently, differentiating into three lineages within a few days after the formation of a blastocyst. Maintaining hESC, the extension of ICM cells, in vitro has been a challenge due to their intrinsic propensity to differentiate as soon as the colonies reach a certain "critical mass." Thus hESC culture conditions have been optimized to prevent such spontaneous differentiation of hESC and maintain them in a pluripotent state over an infinite number of passages. Currently, there are several popular hESC culture systems and with a little optimization, all of them can be used to grow pluripotent cells with relative ease. Mouse embryonic fibroblasts or human fibroblasts derived from fetuses, placenta, or foreskin have been used as feeders for many years, and the corresponding medium for this culture system is based on Knockout-DMEM (KO-DMEM) and Knockout Serum Replacement (KSR, both components from Invitrogen), supplemented with at least 8 ng/mL human bFGF [3,8,12,21–23]. Variations of this system include addition of Plasmanate (plasma protein fraction from pooled donor plasma) [8–10,19] or using a 1:1 mix of KO-DMEM and F12 medium, or feeder-produced extracellular matrix instead of live feeder cells. On feeders, cultured hESCs have a very unique morphology and are best described as well-defined colonies of small tightly packed epithelial-looking cells with a high ratio of nuclei to cytoplasm and visible nucleoli (Fig. 23.1). When grown in KO-DMEM:F12 media mix or in the absence of feeders (i.e., "feeder-free"), hESC can deviate from this phenotype and look more spread-out and even grow as a sheet of cells; however, such cells still retain their pluripotency and are able to both self-renew and differentiate (Fig. 23.1).

A robust and user-friendly feeder-free system that employs a very dilute Matrigel solution (extracellular matrix produced by Engelbreth-Holm-Swarm mouse sarcoma cells), and matching defined medium was introduced by Stem Cell Technologies. Another feeder-free system, made by Invitrogen utilizes CellStart, a human placenta–derived extracellular matrix. Feeder-free protocols are usually provided by individual manufacturers together with a recommended medium and should be optimized by the researcher. In our own studies, we used extracellular matrix produced by mouse embryo fibroblasts, which was deposited and assembled by live cells and provided a three-dimensional growth surface similar to that provided by live feeder cells. This matrix was used in combination with KSR/Plasmanate-based culture medium and was successfully used for derivation of hESC. Derivation of an hESC line when the initial outgrowth consists of only a few cells is more challenging than routine culture of millions of cells, and this culture system proved to be very supportive of such a demanding task [15].

Avoiding animal-derived components and especially, live animal feeder cells, in derivation and maintenance of hESC is desirable for regenerative medicine applications, as this makes the derivatives of hESC more "clinic-friendly." Currently, there are several media–matrix systems on the market that are free of animal-derived materials. Such include Nutristem (Biological Industries, Israel), TeSR2 (Stem Cell Technologies, Canada), and StemFit (Ajinomoto, Japan) media, xeno-free laminin (Biolamina, Sweeden), iMatrix (Nippi, Japan), Vitronectin (Stem Cell Technologies, Canada)—and the number of such materials is growing.

Subculture of human embryonic stem cell

ICM of a developing blastocyst follows the differentiation program after implantation giving rise to derivatives of three germ layers. Pluripotent ESC, and in vitro "extension" of the ICM, can readily and rapidly differentiate when the microenvironment changes. This propensity of hESC makes them a unique source of differentiated cells for regenerative medicine, but at the same time it also creates many maintenance challenges. Spontaneous differentiation can happen regardless of most carefully chosen media–matrix combinations as a result of the colonies reaching a certain size, so the cells inside the colony have special limitations for self-renewal and commit to differentiation. Timely passaging disrupts differentiation-inducing signaling coming from complex cell–cell and cell–matrix interactions established during the first few days at each passage, so newly plated single cells and small cell clumps remain in pluripotent stage and continue to self-renew.

To subculture hESC, several methods can be employed. Mechanical colony dispersion and hand-picking has been the gold standard in the field as it allows one to select colonies of correct morphology with

minimal stress to the cells and is probably the only method to derive new lines when there are only a few pluripotent cells and the colony needs to be dissected to avoid differentiation. However, the operator should have appropriate experience because it is also possible to select for aneuploid cells that have a growth advantage as they are quicker to form good-sized and "good-looking" colonies. On the other hand, a skilled operator may be able to rescue an aneuploid culture by carefully picking colonies of the correct morphology [69]. Of note, extra care must be taken to avoid damaging cells when using mechanical dispersion on hESC grown in a feeder-free system as these colonies are more fragile than those grown in a feeder-based system. Mechanical passaging is very labor-intensive, and for large-scale culture, as required for manufacturing of differentiated cells for therapeutic use, enzymatic dissociation of colonies into single cells and small clumps is much more efficient. Collagenase, accutase, trypsin, TrypLE (Invitrogen), and EDTA are commonly used for enzymatic dissociation of hESC, but all of them can contribute to clonal aneuploidy at later passages, as single cells and small cell clumps (potentially containing aneuploid cells) are distributed throughout the cell population. The tendency of hESC to undergo clonal aneuploidy reinforces the importance of routine karyotyping while subculturing hESC. G-banding with examination of a minimum of 20 cells or fluorescence in situ hybridization with probes to chromosomes 12 and 17 of a minimum of 200 cells are appropriate karyotyping methods as the gain of an extra copy of chromosomes 12 and 17 commonly gives aneuploid ESCs a growth advantage [70–72].

Nuances of human embryonic stem cell culture

Almost every culture of hESC will contain some differentiating cells, and if the colonies are allowed to overgrow, become multilayered, and/or touch each other, they will begin to show massive spontaneous differentiation within hours. Fig. 23.1 shows the morphology of hESC grown on feeder cells and feeder-free on Matrigel in undifferentiated and slightly differentiated states. Once the cells begin to differentiate, it is very difficult to isolate self-renewing cells. Hand-picking may be used in an attempt to isolate nondifferentiated colonies yet even normal looking colonies may harbor cells committed to differentiation; they may have already lost Oct-4 expression and may even express early differentiation markers like nestin (Fig. 23.3).

Other nuances of hESC culture come to light with experience, and it has been observed many times that different culture conditions may predispose hESC to one or another differentiation route or make a routine differentiation method more difficult to perform. For example, embryoid body (EB) formation is a common first step in many differentiation protocols, and it involves plating a suspension of freshly harvested hESC into plates with low adherence properties where they can aggregate into clumps and differentiate into cells of all three germ layers. EB formation occurs quite readily when hESCs have been growing on feeder layers: multitudes of large, round EBs form in suspension with little cell death. Yet, when hESCs have been cultured in a feeder-free system; EB formation is problematic, the EBs that form are much smaller and sparser, with a lot of cell death observed in the culture. In addition, our experience with multiple hESC lines has shown that some slow growing lines are difficult to maintain due to spontaneous differentiation yet they often show very good yields of derivatives when specifically directed to differentiate. On the other hand, other hESC lines are fast-growing and easy to maintain but do not differentiate as robustly. Given these types of peculiarities, differentiation protocols should be tested and modified when different ESC culture conditions or different hESC lines are used.

Directed differentiation

While spontaneous differentiation of hESC in an adherent state or via EB formation may produce certain types of derivatives (e.g., cardiomyocytes, adipocytes, RPE, and neurons), in many circumstances, a higher yield or purity is desirable. Various bioactive factors and/or selective growth conditions can be employed to direct hESC differentiation toward a particular lineage and/or enrich for a desired cell type. While theoretically, hESC can give rise to all cell types of a human body, in reality, some derivatives are easier to produce in culture than other cell types and some have a higher therapeutic potential than others. As we discuss later, several derivatives have already entered human clinical trials. Initial results from such studies have shown that PSC derivatives from both hESC and iPSC are safe and well tolerated, yet it remains to be determined which therapies may show significant efficacy in clinical trials and be allowed to proceed to commercialization.

The majority of hESC-based clinical trials to date have focused on the use of RPE for the treatment of AMD. The eye has many advantages for testing a first-in-man cellular therapy, including an immunoprivileged status, its small, locally contained structure, ability to noninvasively image the transplantation site, and the easy functional readout of visual acuity [73]. RPE provides "life support" to the photoreceptor cells by supplying nutrients, and among other things, removing shed photoreceptor fragments by phagocytosis, and its malfunction

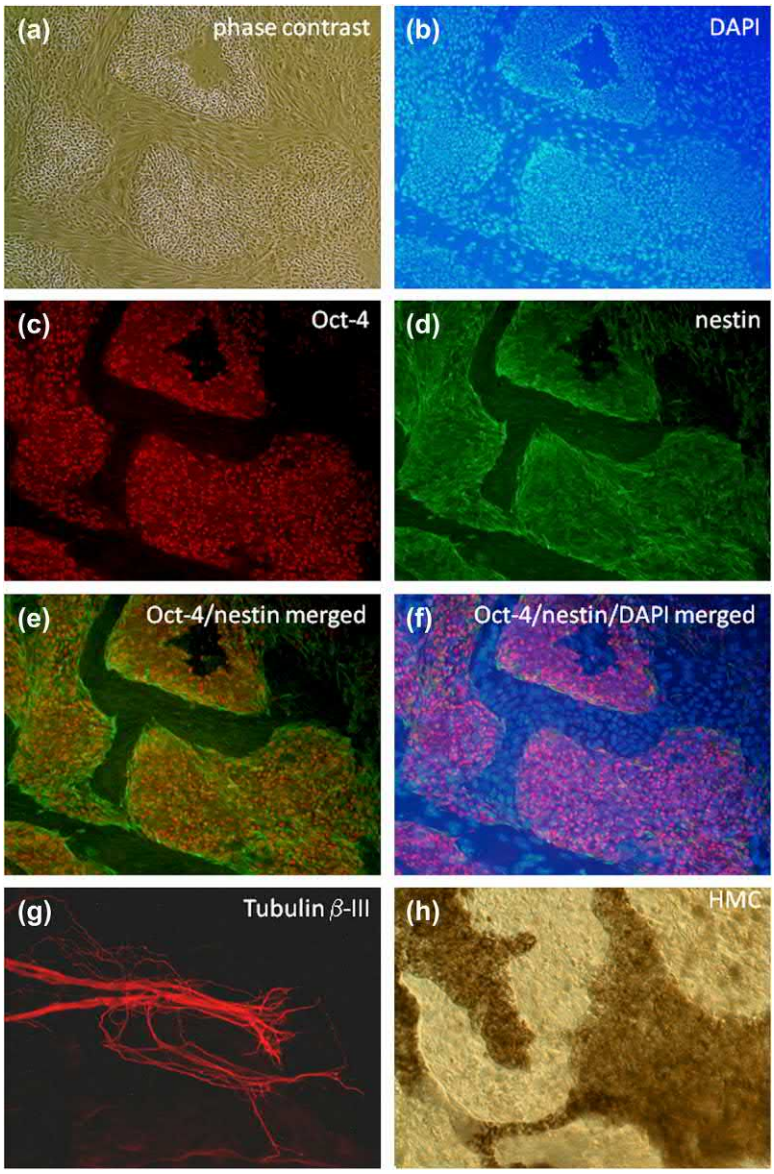

FIGURE 23.3 Spontaneous differentiation of hESC. (A–F)—nestin-expressing cells are seen within Oct-4-positive colonies. (A)—Phase contrast, (B)—DAPI costaining, (C)—Oct-4, (D)—nestin, (E)—Oct-4/nestin merged, (F)—Oct-4/nestin/DAPI merged, (G)—tubulin β-III staining showing a differentiated neuron, (H)—a cluster of RPE. Magnification: (A—F) ×100, (G, H) ×200. *hESC*, Human embryonic stem cell; *RPE*, retinal pigment epithelium. *Images of Oct-4/nestin are courtesy of Jennifer Shepard.*

leads to photoreceptor degeneration and eventually blindness. RPE has several unique features that allow this cell type to be an attractive hESC derivative for regenerative medicine purposes:

1. It is easy to detect in culture and isolate with a high degree of purity. Differentiated RPE cells appear as pigmented clusters visible by the naked eye among spontaneously differentiating hESC after several weeks. Their morphology is very similar to that of cultured human RPE from in vivo sources—polygonal cells with different degrees of pigmentation. When RPE originating from hESC was first discovered in long-term differentiating cultures of hESC, it was due to its unique morphology. Clusters of pigmented epithelial cells were observed and mechanically isolated, expanded, and then confirmed to be of this cell type by the molecular marker analysis [45,74]. This "mechanistic" approach is still being successfully used for isolation of RPE from differentiating cultures of hESC containing multiple layers of multiple cell types, RPE being a minor fraction among other derivatives. When such differentiated cultures are dissociated, it is possible to establish pure cultures of hESC-RPE using cell morphology as the only guidance throughout the mechanical hand-picking of pigmented clusters because, although these cells are mature and differentiated, they are nevertheless fully capable of multiple divisions. One six-well plate of

differentiating hESC can provide enough RPE at passage 2 to treat 10−20 patients (including many more millions of cells for quality testing).

2. The fully differentiated cells retain their proliferative potential for several passages, allowing one to scale up production without any loss of functional properties. This is owed to a distinctive feature of RPE called transdifferentiation. During this process, cells of a differentiated phenotype are capable of partial dedifferentiation and redifferentiation for multiple passages. Under proliferation-promoting conditions, mature RPE cells lose their pigmented epithelial morphology and turn into neural progenitor-like cells (as if going back to their neuroectoderm developmental roots). This is accompanied by the downregulation of mature RPE markers such as bestrophin, CRALBP, RPE65; loss of cell polarity and cuboidal morphology; and upregulation of neural and retinal progenitor markers—for instance, nestin, Pax6, Sox2, and tubulin beta III. When the cells reach confluence and their proliferation slows down, they redifferentiate into pigmented epithelial polarized cuboidal cells and upregulate RPE markers, and if passed again, the cycle would continue for several passages before they senesce and stop dividing or redifferentiating [45,74]. The ability of these fully differentiated cells to proliferate for several passages while maintaining their phenotype and capabilities after they redifferentiate each time is critical for the large-scale production, which is needed for both animal safety studies and human clinical trials.
3. hESC-RPE cells can be frozen and thawed without any loss of functionality and can be maintained in culture in a fashion that ensures optimal conditions for posttransplantation survival and functional engraftment. Thus once mature RPE cells are isolated and plated at passage 0, it becomes possible to monitor and control the degree of their differentiation at each passage. Cells with optimal pigmentation and at the optimal differentiation stage can be identified with differentiation markers and produced for the final harvest. Our studies showed that there was a correlation between the adhesion/survival of RPE in vitro and the degree of maturity/melanin content [48] as well as between their effectiveness in animal models and their degree of pigmentation [45].

The first patient to be given hESC-RPE was in 2011 with a cellular suspension of RPE differentiated from the aforementioned single blastomere−derived, MA09 hESC line. In the United States alone an additional 18 AMD/Stargardt's patients were treated with MA09-RPE, and results from Phase 1/2 trials that have been reported out to 22 months showed the therapy is well tolerated with no evidence of hyperproliferation, tumorigenicity, or rejection—even after transient immunosuppression was discontinued [47]. Additional studies with MA09-RPE [50] and RPE derived from other hESC lines have provided additional evidence supporting the safety and tolerability of cellular suspensions of hESC-RPE [75]. Cellular sheets of hESC/iPSC-derived RPE, either by themselves or on two different synthetic scaffolds, have also been transplanted into AMD patients without any signs of adverse effects [76,77].

In addition to RPE, another PSC-derived ocular cell type, iPSC-corneal epithelium, has recently entered clinical stage testing for corneal disease and injury [78]. Preclinical evidence in a rabbit model of corneal epithelium deficiency shows the transplanted cells restored barrier function. Their generation involves differentiation of a self-formed ectodermal autonomous multizone structure, followed by isolation and expansion of corneal epithelium-like stem/progenitor cells [79]. The group plans to transplant them as a thin sheet into human patients as an alternative to keratoplasty, or the grafting of donor-derived cornea tissue, which is often in short supply. Although iPSCs are being used as a starting material in this study, hESCs could be used in a similar manner.

Ectoderm is often considered to be a default differentiation pathway for hESCs, therefore ectoderm-derived retinal and neuronal cell types have been popular choices for clinical development. As discussed later, several nonretinal, hESC/iPSC-based neuronal cell therapies have begun clinical trials. In fact, the very first hESC-based clinical trial in humans involved testing of oligodendrocyte precursors to treat spinal cord injury. Geron initiated a trial in 2010 for their hESC-oligodendrocyte precursor cell therapy and had treated five patients before funding issues caused them to abandon the trial [80]. Three years later, Asterias Biotherapeutics acquired the asset, rebranded it, and reinitiated Ph1/2a trials. A recent press release from Asterias described safety findings from the trial, which tracked a total of 30 patients for at least 12 months [81]. They reported no adverse effects due to the treatment, and patients either experienced no further decline in motor function or an improvement in motor function recovery following administration of the cells.

Four more PSC-derived neuronal cell types have also reached clinical trials. One of these is another neuronal precursor cell (NPC) type, differentiated from iPSCs, to treat spinal cord injury which has recently received approval to begin clinical testing in Japan [82]. These iPSC-NPC showed therapeutic benefit in a nonhuman primate model of cervical contusion/compression spinal cord injury; they spared motor axons and promoted axonal regrowth, enhanced angiogenesis, prevented demyelination, and improved motor function in behavioral readouts

compared to vehicle controls [83]. A second, neuronal cell type, hESC-derived astrocytes has also been approved to begin clinical trials in Israel in patients with amyotrophic lateral sclerosis (ALS) (NCT03482050). To generate this cellular therapy, hESCs were first differentiated in suspension cultures form to glial-restricted progenitors. Addition of epidermal growth factor (EGF) promoted the formation of neurospheres, followed by adherence and passaging on laminin in the presence of bFGF and EGF to give rise to cryopreservable astrocyte progenitor cells (APCs). These APCs could be further differentiated into committed astrocytes, termed hES-AS, through subsequent 7−28 days of culture without bFGF/EGF. These hES-AS improved survival, slowed disease onset, and improved motor activity in the hSODG93A rat ALS model [84]. In the third recently approved clinical application of neuronal lineage cells, researchers will be transplanting iPSC-derived DA progenitors into patients with PD [85]. In preclinical testing, these cells provided functional improvement in an MPTP-induced nonhuman primate model of PD [86]. In a related study in macaque monkeys, it was found that major histocompatibility complex (MHC) matching of allogeneic DA progenitors (derived from macaque iPSCs) suppressed the recruitment of microglia and other lymphocytes to the graft and thus increased the survival of the cells versus unmatched controls [87]. Such observations suggest that even in an immunoprotected environment such as the CNS, the use of immunocompatible cells may help improve the survival of the graft. The fourth recently approved neuronal lineage trial also involves the use of neural precursor cells, derived from hESC to treat PD (NCT03119636). As mentioned previously, this trial utilizes a parthenogenetic hESC line as the starting material to generate midbrain DA neurons [32]. It will be interesting to follow the clinical testing progress of these various neuronal lineage hESC/iPSC-based therapies to determine which one(s) are most efficacious.

Mesenchymal stromal cells (MSCs), derived from hESCs/iPSCs are a mesoderm-lineage cell type being pursued in clinical trials. MSCs are plastic-adherent, fibroblast-like cells that can be isolated from various tissues including bone, fat, and umbilical cord or derived through directed differentiation of hESC and iPSCs. MSCs secrete a panopoly of growth factors and cytokines, which may impart therapeutic immunomodulatory, antiinflammatory, and trophic support to cells within the body. Several hundred clinical trials are currently underway with adult-derived MSC for treating cardiovascular disease, autoimmune disorders, neurologic disorders, bone and cartilage injuries, asthma, diabetic wounds, and many others [88]. An emerging theory is that younger tissue sources such as cord blood, Wharton's jelly, and hESC may be a better source material for MSC than adult tissues as their youthful nature facilitates greater in vitro expansion and preservation of therapeutic function [49,89,90]. Various preclinical studies have shown MSCs derived from hESCs and/or iPSCs have therapeutic properties in models of, for example, lupus, uveitis, multiple sclerosis, Crohn's disease, hindlimb ischemia, and graft versus host disease [49,91−96]. Three clinical trials are currently testing hESC/iPSC-derived MSCs. This includes Cynata's iPSC-MSCs for the treatment of graft versus host disease (NCT02923375). The company has reported their iPSC-MSCs demonstrated safety and tolerability in a Phase 1 study of 15 treated patients and planning for Phase 2 studies is underway [97]. Two additional studies in China are also underway, where hESC-MSCs are being tested in patients with meniscus injuries (NCT03839238) or primary ovarian insufficiency (NCT03877471). Another mesoderm-lineage PSC derivative that has recently been cleared for clinical trials is Fate Therapeutics' iPSC-derived Natural Killer cell therapy to treat solid tumors (NCT3841110). In November 2018 Fate announced their investigational new drug (IND) application had been approved by FDA [98], and the Phase 1 trial is currently enrolling patients. This represents the first hematopoietic lineage cell type derived from PSCs to reach clinical stage testing. It will be interesting to see which other blood cell type(s) may be next.

Type 1 diabetes and heart disease are two major disease areas for which hESC/iPSC-derived therapies are also being explored. For diabetes the company Viacyte is in Phase 1/2 trials to test their combination product, which consists of glucose-responsive, insulin-producing, hESC-derived pancreatic endoderm cells encapsulated in a delivery device. They reported the first version of their combination product, termed VC-01, was safe and well tolerated out to 2 years, yet the cells did not survive that long in all patients [99]. A newer version of the delivery device has been developed in an attempt to improve long-term viability of the encapsulated cells. This new device, in combination with pancreatic endoderm cells, is termed VC-02, and currently being tested in Phase 1/2 clinical trials (NCT03163511). Viacyte has also entered a collaborative agreement with Crispr Therapeutics to develop a gene-edited version of their allogeneic cell-based therapy in order to bypass the need to encapsulate their cells yet avoid immune rejection [100]. Other groups are also developing PSC-derived pancreatic progenitors or even mature pancreatic beta cells, yet these therapies are still in preclinical development [101−104]. Ischemic heart disease is the other major disease area/large market where hESC/iPSC-based regenerative medicine therapies have reached clinical stage testing. In 2013 Philippe Menasche's group received approval to begin testing his CD15 + Isl-1 + hESC-derived cardiovascular progenitors in a Phase 1 trial (NCT02057900). Six patients were given

a fibrin patch containing 5−10 million progenitors, with epicardial delivery of the patch occurring during coronary bypass procedure. Patients were followed for up to 18 months with no evidence of treatment related adverse events, although one patient died from unrelated comorbidities shortly after the procedure and another patient died of heart failure 22 months posttreatment [105]. Nonetheless, the demonstrated safety and tolerability of this first-in-man study has prompted efforts to test efficacy in Phase 2 studies. A group based in China has also recently launched a clinical study to determine the safety, feasibility, and efficacy of iPSC-derived cardomyocytes (NCT3763136). Several other groups are at the preclinical stage of development for hESC/iPSC cardiac lineage cells to treat heart disease. Recent reports have focused on refining methods for generating more mature cardiac cells from hESCs/iPSCs [106] or trying to understand the basis for and ways to limit arrhythmias associated with grafting of hESC-derived cardiomyocytes in nonhuman primates [107].

Safety concerns

Safety is the number one requirement for the clinical use of cellular products. For hESC derivatives, this means that they have to be nontumorigenic. They must be free of pluripotent cells, which can form teratomas in vivo, and they must show no adverse effects in animal models. They should also be able to survive long enough to be effective after transplantation but not proliferate uncontrollably, although some proliferation followed by a steady quiescent state would be permissible and in certain cases even desirable. This may not be attainable for every derivative of hESC because for clinical use, large numbers of cells need to be generated in culture first. This means that cells of a given type should be able to proliferate in culture but nevertheless maintain a differentiated phenotype after transplantation. This requirement would only allow one to use either fully differentiated cells, which are still capable of multiple population doublings (like RPE), or progenitor/stem cells, which are already committed to a known lineage and do not "misbehave" upon transplantation.

All cell products for clinical use need to be manufactured under good manufacturing practices, pass sterility and mycoplasma tests, and be free of known animal and human pathogens. The presence of animal products during derivation and maintenance of hESC and their progeny could be unavoidable in many cases, but even coculture with live animal cells is not forbidden by FDA regulations. The requirements vary for different countries though. The use of animal cells or products adds more stringency testing of the source cells and their differentiated products. Extensive testing for animal viruses typical for the species whose products were used during manufacturing is required. Special guidelines exist for a xeno product—human cells that have been cocultured with live animal cells—while cells manufactured in the absence of live animal cells and only exposed to animal products are not considered a xeno product. All bovine sera need to come from spongiform-free sources, typically from the United States, New Zealand, and Australia, and gamma-irradiation adds another level of viral clearance.

As previously mentioned, known spontaneous aneuploidy of hESC in culture can occur quite readily and this presents an additional hurdle during manufacturing. Cells need to be frequently monitored for chromosomal aberrations. In addition, any and all hESC derivatives need to undergo extensive testing in animal models to exclude any probability of tumor formation or other serious adverse effects. Such studies should be performed in immune compromised or immune suppressed animals to allow long-term survival of the donor cells. Ideally, the cells should be present in the host for long term, in some cases—throughout the lifetime of the animal; if they proliferate soon after transplantation, they should later become quiescent and stay negative for proliferation antigens, such as Ki67. They should maintain a normal phenotype, which could be assessed by double staining animal tissues with antihuman antigen (nuclei, mitochondria) and antibodies to specific cell markers, and cause no adverse effects including neoplasia. The cells should be able to perform their function in order to justify their transplantation in people. For example, Advanced Cell Technology's MA09hESC-derived RPE met all these safety requirements in long-term studies (9 months) in mouse and rat animal models [45] the cells integrated into the host's own RPE layer, provided photoreceptor support in the models of retinal degeneration (RCS rat) and Stargardt's disease (Elov4 mouse), showed no proliferation beyond the initial 3 months, had normal RPE morphology (cuboidal pigmented polygonal cells), and showed the late RPE marker bestrophin organized in a basolateral, and typical for RPE, in vivo fashion.

Low-level genetic abnormalities or the presence of residual PSCs is a common risk for all PSC-based therapies. To safeguard against the formation of ectopic tissue or tumor formation, hESC/iPSC lines may be engineered with an inducible suicide gene to facilitate elimination of their derivatives after transplantation, if needed. Genetic engineering may be used to provide greater control over the fate of these cells upon transplantation into humans. For example, engineering PSCs with herpes simplex virus type 1-thymidine kinase can induce cytotoxicity of cells exposure to ganciclovir. This may be done by inserting the transgene into a safe harbor locus such as AAVS1 [108] or by tethering its expression to a gene required for cell division, as recently reported [109]. Inducible capsase 9 is another suicide gene that may be used to control

persistence of transplanted cells [110]. In addition to safeguarding PSC derivatives with suicide genes, the issue of potential immunogenicity is a shared risk for application of hESC or iPSCs that are to be used in an allogeneic, off-the-shelf manner. Encapsulation technology, with a variety of different biocompatible materials, has been around for several decades, yet improvements in the technology have garnered renewed hope for its use in protecting transplanted cells against immune responses [111]. As mentioned earlier, Viacyte has been optimizing a semipermeable, biocompatible encapsulation device for their hESC-pancreatic endoderm cells in recent clinical trials. Other recent preclinical studies have focused on the use of alginate derivatives to encapsulate hESC-derived beta cells [104]. An alternative approach that is gaining traction is to genetically engineer cells to make them more immunocompatible. Gene editing technologies such as AAV and Crispr-cas9 are being used to knockout expression of HLA class I and/or class II molecules and overexpress immunosuppressive molecules such as HLA E and CD47 [112–114]. Continued development of such technologies may one day allow hESC/iPSC-based therapies to be used in any organ system with increased safety and reduced risk of immune rejection.

Conclusion

hESCs offer the unique possibility of generating a wide variety of differentiated cells for tissue engineering "from scratch." Their immortal nature allows the production of hESC in virtually unlimited numbers, enabling the creation of a master cell bank and, together with the ability to produce differentiated derivatives, makes it possible to generate the desired cells on a scale large enough for both treating patients and performing all in vitro and in vivo tests necessary to ensure the safety and functionality of these cells. Such derivatives may include progenitor/tissue-specific stem cells capable of differentiating further in vivo (which may offer advantages in tissue repair) and also mature differentiated cells which are still capable of proliferation. The derivatives, when cultured in vitro from an hESC origin, should be maintained in a manner that ensures their optimal in vivo performance. In the coming years, we will hopefully see more hESC-based therapies move from bench to bedside, not only for a range of diseases caused by tissue loss or dysfunction, but as an unlimited source of cells to replace more complex tissues such as skin, bone, and blood vessels, and eventually whole organs such as kidneys and hearts.

Acknowledgment

We thank Jennifer Shepard for the photographic images of immunostained hESC.

Disease modeling

A critical prerequisite for developing therapeutic strategies is to understand the pathological mechanisms of relevant diseases. Animal models have been instrumental in understanding human diseases in an in vivo setting. However, species differences have hindered the full representation of human disease phenotypes in animals. Therefore there is a need for improved models that could better recapitulate the pathophysiology of patients to complement studies in animal models. Primary patient-derived cells are surrogate models that are patient relevant, but primary cells from patients, especially cells from organs such as brain and heart, are not easily accessible. Moreover, mature primary cells such as neurons are not easily expandable. Human-induced pluripotent stem cells (iPSCs) provide an excellent model system for human diseases because of their patient origin, easy accessibility and expandability, and their ability to give rise to nearly any cell types. Moreover, because iPSCs can be derived from individual patients, they can be used to identify patient-specific therapeutic targets for developing personalized medicine [1−4].

For disease modeling using patient iPSC−derived cells, iPSCs derived from healthy individuals were commonly used as a control for patient iPSCs. In addition, the genome-editing technologies have allowed us to generate isogenic iPSC lines that are genetically matched to patient iPSCs but have the disease-causing gene mutations corrected in patient iPSCs, or introduced into control iPSCs. Thus the isogenic control iPSCs will have the introduced mutation as the only variable, allowing the identification of true pathology reliably without the confusion with phenotypes resulted from possible individual-to-individual or line-to-line variations. It is essential to include isogenic iPSC controls when modeling sporadic or polygenic diseases, because phenotypic differences in these situations are expected to be small [5], which can be masked by individual-to-individual or line-to-line variations.

Among the genome-editing technologies, including editing using the zinc-finger nuclease [6,7], the transcription activator−like effector nucleases [8−10], and the CRISPR/Cas9 system [11−14], the CRISPR/Cas9-based editing has been widely used because of its simple design and ease of use. The unmodified Cas9 has been used to achieve gene knock in and knockout [15,16]. The catalytically dead Cas9 (dCas9) fused with a cytidine deaminase enzyme can directly convert cytidine to uridine without double-strand DNA break [17]. dCas9 fused with transcriptional activators or suppressors can activate or suppress gene transcription to induce CRISPR activation or CRISPR interference [18]. Modifications of the CRISPR/Cas9 system also enable mono-allelic or biallelic editing with high precision [19]. The rapidly developing field in CRISPR/Cas9 editing will further facilitate gene editing in human iPSCs and enhance iPSC applications.

iPSC-based modeling is ideal for studying early-onset diseases [20,21], because iPSCs are considered phenotypically young [22]. The relative immaturity of iPSCs and their derivatives may allow them to better recapitulate phenotypes in diseases with an early onset [22]. Modeling late-onset diseases using iPSC-derived cells is more challenging, because aging is an important player in the pathogenesis of late-onset diseases. Different ways are

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00095-2

exploited to induce cellular aging in order to better model late-onset diseases using iPSC-derived cells. One way is to treat iPSC-derived cells with cellular stressors, including small molecules that affect mitochondrial function, such as pyraclostrobin, or compounds that modulate protein degradation pathways, such as MG-132 [23–26]. Another way is transgenic expression of factors that trigger premature aging, such as progerin [27]. Moreover, direct reprogramming one type of somatic cells to another does not go through the iPSC stage, therefore, could maintain cellular aging markers [28]. Indeed, neurons directly reprogrammed from fibroblasts of aged individuals maintained cellular age [29]. Therefore directly reprogrammed cells could provide a complementary platform to model late-onset diseases.

iPSCs are ideally suited for studying genetic diseases because the disease-causing mutations can be genetically corrected by gene editing to generate isogenic iPSC lines for direct comparison with patient iPSC lines. However, majority of the patients have sporadic diseases, for which the genetic causes have not been identified. For example, about 95% of Alzheimer's disease (AD) patients have sporadic AD. iPSCs can also be used to study sporadic diseases, but it is more challenging, because the phenotypes in such diseases are speculated to be caused by multiple genetic risk variants together with environmental factors. The effect of each variant can be small. The phenotypes in iPSC-derived cells from patients with sporadic diseases are expected to be milder than those from patients with monogenic diseases. Despite the envisioned difficulties in modeling sporadic diseases using the iPSC platform, the development of genetically matched isogenic iPSC lines in combination with allele-specific assays has allowed dissection of a genetic risk variant for sporadic Parkinson's disease [30]. Human iPSC–derived cells have also been used to model sporadic AD to better understand the pathogenesis of this disease [31–48]. Such an experimental paradigm is applicable to model other sporadic diseases.

In the past, iPSC-based disease modeling has taken advantage of a single cell type that is disease relevant. For example, iPSC-derived neural progenitor cells or neurons have been used to model schizophrenia [49–56]. Nowadays, more and more studies have included more than one cell types in iPSC-based disease modeling, including cocultures and 3D organoids. For example, cocultures of astrocytes and neurons have been used to study astrocyte functions [57] and to model the pathology of neurological diseases, such as amyotrophic lateral sclerosis [58–61] and AD [43], while cocultures of astrocytes and oligodendrocytes have been used to model leukodystrophy in Alexander's disease [62].

In addition, the network between different cell types can be modeled using 3D organoids. Organoids generated from human iPSCs have been used to mimic various organs for disease modeling [63–79]. More than one cell types can be generated in an organoid in a spatial–temporal order that follows the developmental program in human. The organoid models are powerful in that they can offer the opportunity to study cell–cell interactions in a cellular context that resembles endogenous organs in cellular organization and structure. The 3D organoids allow disease modeling in a physiologically relevant cellular context.

While organoids have been increasingly used for iPSC-based disease modeling, the technology has its own limitations. One hurdle is to create an organoid with high reproducibility [80]. Using miniaturized spinning bioreactors with 3D design has improved reproducibility in generation of forebrain organoids [75]. A recent study showed that prepatterning, especially dorsal patterning, enhances consistency in both shape and cellular composition of brain organoids [81]. While self-patterned whole-brain organoids exhibited big variations, the dorsally patterned brain organoids displayed much improved reproducibility in organoid shape and cell type collection [81]. The development of more standardized culture conditions, including culture medium, extracellular matrix, and patterning condition, may facilitate the generation of organoids with increased consistency for more precise disease modeling [82]. Another challenge is the lack of vascularization in the current organoid system [83]. Accordingly, organoids exhibit limited growth and maturation due to the lack of continuous nutrient supply. Spinning bioreactors and shaking culture platforms have been shown to provide better nutrient supply and improve the growth of organoids [75,84]. Coculture with endothelial cells has allowed the generation of vascular-like network in organoids [64]. Recently, blood vessel organoids were generated from human iPSCs and embryonic stem cells (ESCs). These organoids contain endothelial cells and pericytes and are able to recapitulate the structure and function of human blood vessels [85]. In addition to optimizing the protocol for organoid development in order to generate blood vessels from cells within the organoids, transplanting human organoids generated in vitro into animals could facilitate vascularization of organoids [86]. The in vivo environment could also help organoid maturation [86].

Drug discovery

Screening for efficacy. Targets believed to be related to disease mechanisms form the basis of classical drug screens. However, as compounds resulting from target-based screening have been unsuccessful frequently, phenotypic drug screening is attracting increasingly more interest [87]. The discovery of iPSCs is strongly aligned with this new interest for a number of reasons, which include (1) drug responsiveness in patient iPSC-based

models that are not experienced using cancer cell line models; (2) the fact that iPSC production is scalable and thereby supports assay development; and (3) the pluripotency of iPSCs, by which difficult-to-assess, disease-related cell types can be differentiated [88]. If the gene responsible for the phenotype(s) is known, gene-editing methods can confirm whether the cellular or molecular phenotype chosen as the readout for drug screening from iPSC-derived cells is actually related to the disease. It is worth noting that phenotypic drug screening does not rule out target-based screening, and that iPSCs are also applicable to target-based screens. In addition, patient-derived iPSC models with either screening type may enable the prediction of responder patient groups according to drug response in a culture dish, which is the so-called in vitro trial [89]. Such in vitro trials can be interpreted as clinical trials in a dish, and they might in fact represent a gateway toward the success of future clinical trials. In this regard, in vitro trials are of major importance, as they can be applied to drug responsiveness testing in a wide-range patient population.

Specific cell surface markers [90,91], cell-specific promoters [92], and microRNAs [93] were established by purification and enrichment technologies in order to obtain a large number of high-purity target cells. For example, iPSC-derived cells have been used to screen drugs for familial dysautonomia, a monogenic early-onset disease highlighted by neuron degeneration in the sensory and autonomic nervous systems. iPSCs from patients with familial dysautonomia were differentiated into neural crest precursors for autonomic neurons, which were sorted and purified and used in the first reported study of large-scale drug screening using an iPSC-based disease model [90]. Splicing defect and production of a dysfunctional truncated protein are the results of this disease, which is caused by mutations in the gene coding for the IkB kinase complex-associated protein (*IKBKAP*). Screening was performed with 6912 compounds, and disease-specific aberrant splicing in the iPSC model was observed to have improved with a compound known as SFK-86466. This compound, however, had no effect on nontarget cells, such as iPSCs, fibroblasts, and lymphocytes. It is clear that the use of iPSC-based drug screenings is advantageous for the analysis of cell type−specific pathogenesis.

In order to avoid cell quality variations, a shorter differentiation period is desirable. In this sense, drug screening using cells obtained from direct reprogramming could offer an alternative approach [94,95], because direct reprogramming usually takes shorter time. Target somatic cells (e.g., fibroblasts) are forced to express cell type−specific transcription factors and one somatic cell state is reprogrammed to another one by direct conversion without passing through the iPSC state [28,95]. Myocardial, liver, and neural cells have been reprogrammed from other type of somatic cells, such as fibroblasts, by direct conversion. Authentic human neurons reflecting vital aspects of cellular aging can be generated by direct conversion [29]. However, as the source of cells provided by this approach is not renewable, it may not be practical to use them for large-scale drug screening.

Patient iPSCs might also be differentiated much more rapidly by the forced expression of transcription factors. By screening 1416 compounds using the survival rate of motor neurons derived from these transgenic iPSC as an index, 27 hit compounds were identified. Among these, 14 were found to target molecular pathways related to Src/c-Abl in Amyotrophic Lateral Sclerosis (ALS) motor neurons [96]. In a drug screening for AD a tetracycline-inducible system was used to introduce NGN2 into iPSCs to generate cerebral cortical neurons with an almost 100% purity following 8 days of doxycycline treatment. A compound group consisting of 1258 existing drugs was screened, and a compound with low cytotoxicity that reduces the amount of Aβ42 was selected [89].

In total, more than 1000 compounds for several diseases have been evaluated by iPSC-based drug screening [90,97−99], and a number of clinical candidates have been identified [96,100−105] (Table 24.1).

Screening for toxicity. New drug development comes at an enormous monetary cost, particularly in relation to failures, including unanticipated side effects, and especially in late-stage clinical trials [106,107]. Among the side effects, cardiac and liver toxicities are of major concern. As a result, methods that could effectively predict the likelihood of candidate drugs that could cause such serious side effects have received much attention.

Among cardiac toxicities, lethal arrhythmias with QT prolongation account for 21% of the total cardiac toxicities [108]. QT prolongation is an unfavorable effect related to human ether-a-go-go-related gene (hERG) channels, and hERG assay is mainly used for cardiac safety testing because blockage of hERG current is considered to be associated with a deadly ventricular arrhythmia termed torsades de pointes (or TdP). Studies have shown that 40%−60% of drugs that inhibit the hERG channel current do not precipitate QT prolongation [109,110], and false positive results from the hERG assay have been a major barrier to the development of promising drugs. As a preclinical approach, the use of in vitro human ion channel assays, human-based in silico reconstructions, and human stem cell−derived cardiomyocytes have been proposed for the detection of drug-induced electrophysiological cardiotoxicity [111]. It has also recently been demonstrated that multielectrode array assays using human iPSC−derived cardiomyocytes might provide a dependable, cost-effective substitute for preclinical in vitro testing [112] that could be applied for appraising proarrhythmic risk [113]. Studies of myocardial toxicity, particularly lethal arrhythmia, are

TABLE 24.1 New drugs in the pipeline from induced pluripotent stem cell screens.

Candidate drug	Target disease	Mechanism	Formulation	ClinicalTrials.gov identifier
BIIB092	PSP	Blocking or elimination of N-terminal tau	Antibody	NCT03068468

progressing, and the US FDA consortium Comprehensive in vitro Proarrhythmia Assay has been launched to establish a uniform standard for myocardial assays based on iPSCs.

In regard to hepatotoxicity, hepatocyte cell lines or human primary hepatocytes are generally used. However, these models also have limitations, such as cell resources, function deficits from freezing and thawing, and lot-to-lot variations. Human ESC (hESC)/iPSC-derived hepatic cells have recently been generated, and they express functional molecules such as CYP3A4 and uptake of indocyanine green [114], the latter of which responds to known hepatotoxic drugs [115]. Better drug screening may also be obtained from functional 3D liver organ buds [64].

Finally, in terms of the nervous system, currently under development is a platform based on the use of pluripotent stem cells to evaluate detrimental drug effects. Many negative effects related to the nervous system, such as epileptic seizures and psychiatric symptoms, are often encountered in phase 1−2 clinical trials, and their prediction is almost impossible with animal models. For more timely identification of potential neurotoxicity, assays using human iPSC−derived neuron for functional phenotypes can be conducted, similar to TdP for cardiotoxicity.

Stem cell−based therapeutic development

Since the discovery of hESCs in 1998 [116] and the development of human iPSC technology in 2007 [2,3], continuous efforts have been devoted to apply the technologies into cell therapy development. Of the 21 clinical trials conducted currently with hESC- and iPSC-based cellular products, 12 are for ESC- and 2 for iPSC-derived retinal pigment epithelial (RPE) cells to treat macular degeneration (https://clinicaltrials.gov). A list of clinical trials using human iPSC−derived cellular products is summarized in Table 24.2. The first clinical research using human iPSC products was started in 2014. Autologous RPE sheets derived from patient's own iPSCs were transplanted back to the patient [117]. The therapy has led to a favorable outcome, halting macular degeneration without administration of anti-vascular endothelial growth factor (VEGF) drugs. After a temporary hold of the trial, because mutations were found in the second patient's iPSCs [118], another clinical research using allogenic transplantation was started in 2017.

In order to apply human iPSC−derived cellular product into clinical applications more commonly, several hurdles need to be removed [119]. One concern associated with the development of pluripotent stem cell−based cell therapy is the risk of tumorigenicity from these cells [120]. Therefore before clinical applications, iPSC-derived cellular products need to be carefully tested to ensure their identity, purity, and sterility.

It is critical to safeguard the final iPSC-derived product not to contain undifferentiated pluripotent stem cells that have the potential to generate teratomas. Continuous efforts have been invested to develop protocols for differentiating human iPSCs into specific cell types with increased purity. Another solution is to sort the iPSC-derived cells before

TABLE 24.2 Clinical trials using human induced pluripotent stem cell (iPSC)-based cellular products.

Cell type	Cell source	Disease indication	Trial start time	Sponsor	Investigator
iPSC-derived retinal cells	Autologous	Macular degeneration	2014	Riken Institute	Masayo Takahashi
iPSC-derived retinal cells	Allogeneic	Macular degeneration	2017	Riken Institute	Masayo Takahashi
iPSC-derived dopaminergic precursors	Allogeneic	Parkinson's disease	2018	Kyoto University	Jun Takahashi
iPSC-derived mesenchymal stem cells	Allogeneic	GVHD	2018	Cynata Therapeutics	Kilian Kelly
iPSC-derived corneal cells	Allogeneic	Corneal disease	2019	Osaka University	Koji Nishida
iPSC-derived neural stem cells	Allogeneic	Spinal cord injury	Planned for 2019	Keio University	Hideyuki Okano

GVHD, Graft-versus-host disease.

transplantation. Methods have been established to further purify iPSC-derived cells through positive selection for lineage-specific markers and/or negative selection against hESC surface markers, using fluorescence-activated cell sorting or magnetic-activated cell sorting. Serial spiking human iPSCs into iPSC-derived cellular products and then transplanting the spiked products into animal models to test tumorigenicity could also help to predict the risk of tumorigenicity from any residual iPSC population in the final product.

The iPSC-derived cellular product will be generated under Good Manufacturing Practice (GMP) condition and undergo extensive release tests. Cells that meet the specification of all the release tests can be moved forward to clinical trials. After the cellular product is delivered into patients, the patients who received the treatment will be monitored rigorously for the potential of developing any tumors and activation of the immune system [121].

Human iPSCs can be used to generate both allogeneic and autologous cellular products. A major challenge for allogenic transplantation is immune rejection caused by the human leukocyte antigen (HLA) mismatching, which has been coped through immune suppression. From the immunological point of view, autologous transplantation is ideal for cell therapy because they may avoid the high cost and serious side effects associated with lifelong immunosuppression required for allogeneic cell transplantation [122]. Moreover, using a patient's own iPSCs represents the unique advantage of iPSCs over ESCs and constitutes the cornerstone of precision medicine. Accordingly, the first iPSC clinical research used RPEs from autologous iPSCs [117]. The autologous iPSC products could be ideal for the treatment of orphan diseases, for which a master cell bank is not necessary. For more common diseases, autologous iPSC therapy for a large number of patients may not be practical at the present time because of the high cost associated with manufacturing and long time needed for release testing of each cell line. For these reasons a clinical research using allogeneic iPSC-RPE has been started in 2017 in Japan.

To address the concern of potential immune rejection associated with allogeneic transplantation, iPSC stocks derived from HLA homozygous donors are being established for covering most HLA haplotypes in Japan. It is estimated that more than 150,000 donors need to be screened in order to generate 140 HLA-A, HLA-B, and HLA-DR homozygous iPSC lines to cover 90% of the Japanese population [123,124].

Combining genome editing with the iPSC technology to generate universal donor cells creates another avenue to address immune rejection complications associated with allogeneic transplantation [125]. Knockout the β2-microglobulin (B2M) gene eliminates surface expression of class I HLA molecules, thus could inhibit the immune response from cytotoxic T cells. However, these cells can be lysed by natural killer (NK) cells. Knocking in the HLA-E gene at the B2M locus in human pluripotent stem cells led to cells that could evade immune attack by CD8 + T cells and are resistant to NK-mediated lysis [126]. Knocking in the immunosuppressive receptor cytotoxic T-lymphocyte-associated protein 4-immunoglobulin and programmed death ligand 1, both of which inhibit

T cell−mediated immune responses, has also been shown to protect hESC-derived cells from allogenic immune rejection [127]. More recently, depletion of HLA I and II surface expression by knocking out of the B2M gene (encoding a structural component of the major histocompatibility complex (MHC) class I molecules) and CIITA gene (the master regulator of MHC class II molecules), together with overexpression of CD47 (a membrane protein that interacts with cell surface receptors to prevent phagocytosis) in both mouse and human iPSCs, results in hypoimmunogenic cells that can survive in allogeneic recipients without the need of immunosuppression [128]. In a parallel study, allele-specific genome editing of HLA heterozygous donors was used to generate HLA class I pseudo-homozygous iPSCs [129]. Moreover, deletion of both HLA-A and HLA-B but retention of HLA-C led to the generation of HLA-C-retained iPSCs. Cells generated from both approaches could evade the immune response from T cells and NK cells. It was estimated that 12 lines of HLA-C-retained iPSCs, combined with HLA class II knockout, could cover more than 90% of the population worldwide in an immunologically compatible manner, thus greatly facilitating the dissemination of human iPSC−derived cell therapies.

Concluding remarks

The human iPSC technology has provided a powerful tool for us to understand and treat human diseases. The iPSC platform, along with other technologies, such as gene editing, 3D organoids, and direct reprogramming, has allowed us to directly observe and treat patient cells in a dish. Knowledge gained from iPSC-based disease modeling has enhanced our understanding of both normal development and disease pathogenesis, which will help us to design better therapies for patients with relevant diseases. Much progress and excitements await us to witness in the next decade of iPSCs.

Introduction

The capacity for unlimited self-renewal and the potential to differentiate into any cell in the body made embryonic stem cells (ESCs) a valuable research tool. Mouse ESCs, first derived in 1981 [1], have been used for the last 30 years in conjunction with gene targeting technologies to produce genetically modified mice; large-scale federally funded projects, such as the Knockout Mouse Project, have sought to create a comprehensive collection of mice with specific genetic changes [2].

Human ESCs (hESCs), derived in the late 1990s, proved to be a greater challenge; although they were generated from blastocyst embryos using the methods developed to derive mouse ESCs, they proved to be much more difficult to maintain in cell culture, and when the National Institutes of Health began funding hESC research in 2002, one of their first programs was to sponsor seven hESC laboratory courses across the United States. These courses spawned the publication of comprehensive hESC laboratory methods [3] and trained a cohort of scientists, some of whom went on to use the technology in their own laboratories. In 2006 just as hESC methods were becoming standardized and disseminated, there was a sea change that accelerated the nascent field of regenerative medicine: the discovery that adult somatic cells could be reprogrammed into induced pluripotent stem cells (iPSCs). That discovery fundamentally changed the stem cell field, broadly expanding the possible uses of PSCs.

Reprogramming of somatic cells into induced pluripotent stem cells

The production of iPSCs was first reported by Takahashi and Yamanaka using adult mouse fibroblasts in 2006 and was immediately hailed as a ground-breaking discovery [4]. The introduction of four transcription factors, *Oct3/4* (*Pou5f1*), *Sox2*, *Klf4*, and *c-Myc* (*Myc*), also called the "Yamanaka factors," was sufficient to transform adult fibroblasts into PSCs. In 2007 the group repeated the process using human fibroblasts [5]. The process of reprogramming adult cells into cells functionally equivalent to hESCs has provided an unparalleled tool to study human development and generate cells for regenerative medicine applications. Yamanaka's discovery altered the dogma underlying our knowledge of cell biology and created new fields of study. In 2012 Shinya Yamanaka was awarded the Nobel Prize in Physiology or Medicine, along with John Gurdon, for the discovery that mature cells could be reprogrammed into cells capable of developing into all cells of the body. Gurdon is credited as the first to demonstrate that a cell nucleus could be reprogrammed to a pluripotent state through the process of somatic cell nuclear transfer [6,7].

Since the first iPSC study was published, scientists have gained a much better understanding of what was once mostly a black box process, in which the Yamanaka transcription factors were expressed as transgenes in cells and sometime later pluripotent colonies would emerge. Since the advent of iPSC technology the molecular events underlying reprogramming have intrigued researchers. It is important to note that the minutiae of reprogramming events have been almost entirely studied in mouse cells, which can be made from genetically modified mice and are much more easy to manipulate than human cells. There are important embryological and genetic regulatory differences between mouse and human cells, and we caution that the details of molecular events in human cells remain to be understood.

Early work indicated that the reprogramming process in mouse cells is a positive feedback loop by which core

transcription factors regulate the expression of a network of pluripotency-associated genes [8,9]. Early models postulated that reprogramming is a stochastic process in which most transgenic cells can initiate reprogramming but only a few achieve pluripotency [10,11]. With advancements in single cell gene expression profiling methods, it has become possible to delineate cell types and cell states in order to understand the reprogramming mechanism in molecular detail. Early studies using single-cell approaches at defined timepoints demonstrated that after the initiation of transgene expression, there is a hierarchical phase with *SOX2* as the upstream factor in the gene expression hierarchy, meaning that endogenous *SOX2* expression was required before endogenous expression of other key pluripotency-associated genes [12].

A more recent study examined mouse fibroblast reprogramming by profiling cells at frequent intervals across the first 18 days of reprogramming, using an inducible reprogramming system [13]. Using a mathematical technique called "optimal transport," the researchers were able to temporally couple cells profiled at each timepoint and assign ancestors, descendants, and trajectories. In this study, expression of the Yamanaka factors was withdrawn at 8th day of reprogramming and cell fates immediately bifurcated to two routes: a stromal cell−like state or a mesenchymal−epithelial transition (MET) state. From days 9 to 18, cells that originated from the MET state further branched into three types: trophoblast, neuronal cells, and pluripotent cells. Cells on the trajectory to become iPSCs dropped from ∼40% on day 8.5 to 1% on day 11, suggesting that they go through a tight bottleneck to become iPSCs. Intriguingly, the stromal cells that never became iPSCs could secrete cytokines that promote iPSC formation: for example, GDF9 secreted from the stromal cells appeared to enhance reprogramming efficiency.

Reprogramming itself has been used as a tool to systematically explore the role of various factors in the generation and maintenance of pluripotency. For example, redundancies in the pluripotency network have been identified, such as replacing *SOX2* in the reprogramming process by the closely related *SOX1* and *SOX3* [14]. Kruppel-like factor 2 (*KLF2*) or *KLF5* can be used as substitutes for *KLF4* [15], and MYCL (MYCL proto-oncogene), which has less oncogenic activity, has been used in place of MYC [16]. Multiple research groups have reported that reprogramming is more efficient when the tumor suppressor, p53, is reduced during the reprogramming process (discussed in Ref. [17]).

Epigenetic remodeling

For reprogramming to occur, major epigenetic barriers must be overcome. Epigenetics refers to modifications of the genome that can affect the ability for genes to be expressed. The addition of a methyl (CH_3) group to the five-prime carbon of the cytosine ring is a well-characterized example that typically results in transcriptional inhibition. Throughout the process of differentiation the methylation pattern in the genome changes and stabilizes different cell states, shown most dramatically in vitro by single base-pair DNA methylome sequencing of undifferentiated and differentiated human PSCs [18]. As such, the methylation state of an adult somatic cell must be remodeled during the reprogramming process to unlock access to the pluripotency-associated gene network. Many of these genes are hypermethylated in donor cell types but are hypomethylated in iPSCs [19]. The reprogramming factors do not affect DNA demethylation directly, so modifications of DNA methylation are likely a secondary effect of transcription factor induction. Achieving pluripotency also requires considerable histone remodeling [20].

Some studies have raised concerns that reprogrammed cells retain an "epigenetic memory" of the somatic tissue from which they were originally derived [21,22]. However, studies have indicated that epigenetic differences account for only a small fraction of the variability among iPSCs and ESCs [19,23]. In addition, like the lead character in the movie *Memento* (https://en.wikipedia.org/wiki/Memento_(film)), the epigenetic memories of iPSCs are short-term and easily lost; it has been shown that time in culture reduces the epigenetic differences among iPSCs [22,24]. This suggests that the global epigenetic patterns of iPSCs stabilize over time, although there are enduring hot spots of variation, such as at imprinted regions [19,25]. Detailed analysis of global gene expression and DNA methylation patterns reveals that variability among ESCs and iPSCs occurs largely because of variations among individual cell lines rather than differences among classes of PSCs [19,23,26−28].

Reprogramming techniques

The reprogramming process initially was developed using retroviral transduction. Starting from a candidate pool of 24 transcription factors considered to have important roles in pluripotency, Yamanaka reported that the combination of *Pou5f1*, *Klf4, Sox2*, and *Myc* was sufficient to produce iPSC colonies from adult mouse fibroblasts. Because the first iPSC lines were created with retroviral vectors that integrated within the host genome, there was concern that uncontrolled integration could disrupt tumor suppressor genes or activate oncogenes through the process of insertional mutagenesis. Of additional concern was that one of the Yamanaka factors, Myc, is an oncogene itself and that reactivation of the transgenes could result in tumor formation. Indeed, 20% of the offspring of chimeric mice derived from

retrovirus-reprogrammed iPSCs developed tumors [29]. It has also been reported that human iPSC-derived neural stem cells containing integrated vectors produced tumors in a mouse spinal cord injury model [30].

Because of the potential tumorigenicity of cells reprogrammed with integrating vectors, there is general consensus that the use of reprogramming methods that integrate transcription factors into the host genome is ill-advised if the cells are planned for clinical use. However, tools available to reprogram cells have rapidly evolved, and now a variety of nonintegrating alternatives exist and are widely practiced [31]. Integration-free methods rely on the fact that transcription factors used to reprogram the cells are necessary only during the early stages of reprogramming, after which awakening of the endogenous pluripotent machinery is sufficient to sustain the pluripotent state. The Sendai virus is a commonly used, nonintegrating method of reprogramming (see Fig. 25.1) [32]. This RNA virus does not translocate to the nucleus and is diluted with each cell division. In addition, episomal vectors can be used to deliver the Yamanaka factors; however, it has been demonstrated that episomal vectors can sometimes integrate into the host genome, so iPSC clones must be monitored by genomic analysis [31]. Another popular method for reprogramming is the introduction of synthetic messenger RNAs (mRNAs) [33]. The challenge with mRNA reprogramming is the need to repeat applications [34].

The most widely used somatic cells are skin fibroblasts and blood lymphocytes. Both cell types can be reprogrammed with similar efficiency. The efficiency of the first human reprogramming experiments was less than 1 cell in 100 parental cells, but reprogramming efficiencies of greater than 1% are now common. In general, the methods only need to be efficient enough to produce a few clones of iPSCs; because reprogramming is usually reproducible and much of the effort involved in reprogramming is in confirming pluripotency and characterization of the iPSCs, analysis of more than a small number of clones is not cost-effective.

There are two facts about the production of iPSCs that are initially nonintuitive and therefore important to note. It is important to keep in mind that each iPSC line is derived from a single somatic cell. Both fibroblasts and lymphocytes are mosaic [35], with individual cells differing in genomic sequence, so it is to be expected that multiple iPSC clones from a single individual person would not have identical genome sequence. This may or may not be a problem, depending on whether the genetic variations have developmental or safety consequences.

iPSCs are typically clonally derived, which means that single colonies of reprogrammed cells are picked and subcultured separately from other colonies. Clonal derivation preserves the genetic homogeneity of the iPSC line, a factor that is important in studying genetic disorders, such as trisomy 21, that are variably mosaic, and not present in all of a person's cells. It has been argued that for high-throughput reprogramming, it is necessary to skip the clone-picking step and combine multiple clones [36]. Mixture of clones will lead to fluctuations over time in the subsequent culture population as they are expanded, because some iPSC clones will divide slightly faster or be more resistant to stress than others. Many genetic diseases are also mosaic, so a single blood sample or a culture of fibroblasts will yield both normal and mutant iPSC clones. If clones are combined, they would need to be later subcloned and characterized in order to distinguish the differences.

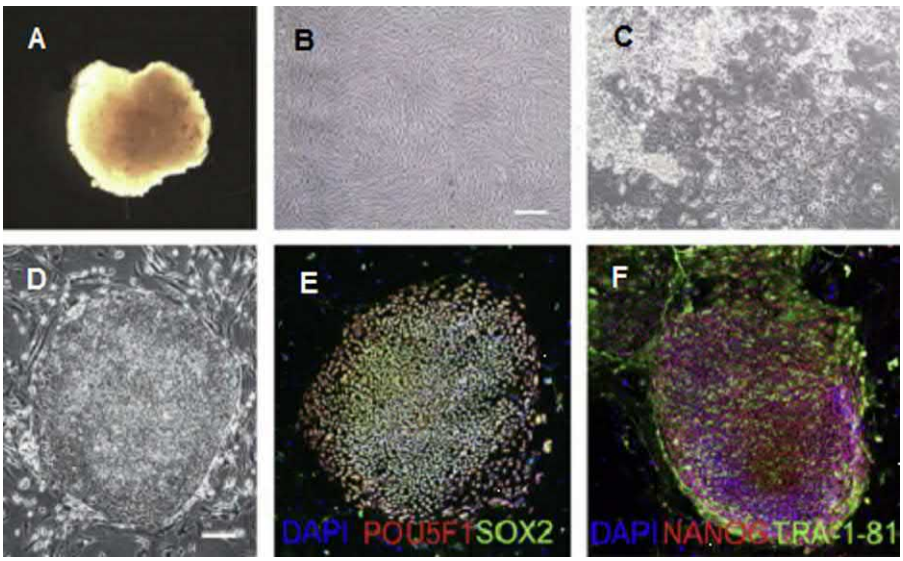

FIGURE 25.1 Reprogramming human dermal fibroblasts using Sendai virus to deliver the four transcription factors. A biopsy of dermal tissue (A) is obtained from the patient. The biopsy is then processed and dermal fibroblasts are isolated and cultured (B). After introduction of the Yamanaka factors, the morphology of the fibroblasts changes (C) as the cells undergo the reprogramming process. Finally, after a period of several weeks, colonies emerge (D) that express pluripotency markers, as shown by immunocytochemistry (E and F). Scale bar 50 μm in (B and C) and 100 μm in (D and F).

Induced transdifferentiation

The same principle of transcription factor–based reprogramming has been applied to direct transformation of one cell type to another. The process of transdifferentiation, also known as lineage reprogramming or direct lineage conversion, can bypass the pluripotent state when converting one cell type to another. Fibroblasts can be transdifferentiated into terminally differentiated cell types, such as neurons [37] or cardiomyocytes [38], without passing through the iPSC stage. Bioinformatic analysis can be used to predict what transcription factors are needed to convert one cell type into another [39], although sometimes the same transcription factor is active in more than one cell type, which leads to cells that are hybrids of two or more cell types [40,41]. Large transcription factor screens have been performed to identify which combination of genes must be induced to be expressed to turn somatic cells into diverse subtypes of neurons [42]. This approach is potentially useful for obtaining mature cell types for which there is currently no robust differentiation scheme, but the cells must still be rigorously characterized. If the products of the transdifferentiation are postmitotic and can be separated from the starting fibroblasts or other cell types, there is less concern about contamination with potentially dangerous proliferating cell types.

There are also drawbacks that should be considered in using direct transdifferentiation of cells such as fibroblasts to mature cell types. Like reprogramming to iPSCs, this process is inefficient, and because mature cell types have a limited capacity to divide (neurons and cardiomyocytes are postmitotic), direct reprogramming requires a large input population and must be repeated each time more cells are required. Transdifferentiated mature populations are not clonally derived, which means that genetic manipulation and characterization of the resulting cell population are difficult or not feasible. These drawbacks may be mitigated by targeting an intermediate progenitor or stem cell that retains a capacity for proliferation but is limited in differentiation capacity; this would allow for purification of the cell type desired and elimination of any abnormally programmed cells [43].

Genomic stability

A study examined the potential for genomic damage during reprogramming using whole-genome sequencing and concluded that the reprogramming process itself is not likely to introduce mutations with adverse side effects [44]. Another exome sequencing analysis of fibroblast and iPSC clones concurred and reported that almost all of the genomic variation in iPSCs originates from the cell population used for reprogramming [45]. However, after reprogramming, populations of iPSCs can drift with time in culture like any other cell type, because genetically aberrant subpopulations can tend to divide more quickly or be more resistant to apoptosis or other forms of cell death. The types of genetic variations observed range from large-scale karyotypic abnormalities to copy number variations and point mutations. Common karyotypic changes in iPSCs and hESCs include trisomies of chromosomes 12, 17, and X, and duplications of subchromosomal regions on these chromosomes [46–48]. In addition, studies of trinucleotide repeat diseases, including Friedreich ataxia and Fragile X syndrome, have reported changes in the repeat length after reprogramming [49,50].

Because iPSCs are self-renewing, they never senesce and will continue to divide as long as they are in culture. Because mutations arise when cells replicate, it is inevitable that genomic abnormalities will accumulate if the iPSCs are cultured for long periods of time. Of particular concern are the appearance of mutations in cancer-related genes such as tumor suppressor *TP53* in hESCs and iPSCs after prolonged time in culture [51,52].

Applications of induced pluripotent stem cells

There has been concern in the field that iPSCs are somehow inferior to hESCs for practical applications. However, a number of reports have demonstrated that hESCs and iPSCs are essentially indistinguishable [19,27,28]. A study on transcriptional and epigenetic comparisons using genetically matched hESC and iPSC lines revealed that hESCs and iPSCs are molecularly and functionally equivalent and cannot be distinguished by their gene expression profiles [53]. This means that all of the applications established for hESCs should be easily transferred to iPSCs (Fig. 25.2).

Disease modeling

Perhaps the most attractive feature of iPSC technology is that it allows scientists to study human diseases using human cells. Much progress in modeling human disorders has been made possible by pioneering work to develop robust protocols to generate specific cell types from human iPSCs, including neurons [54–56] and cardiomyocytes [57]. iPSCs have been used routinely to model genetic diseases, including monogenic disorders and more complex genetic disorders. Animal model systems have been used to study those disorders for decades, but positive results in animals have not always translated to human studies. This should not be surprising because rodents diverged evolutionarily from humans almost 60 million years ago. For example, in the nervous system, understanding the mechanisms underlying neurological

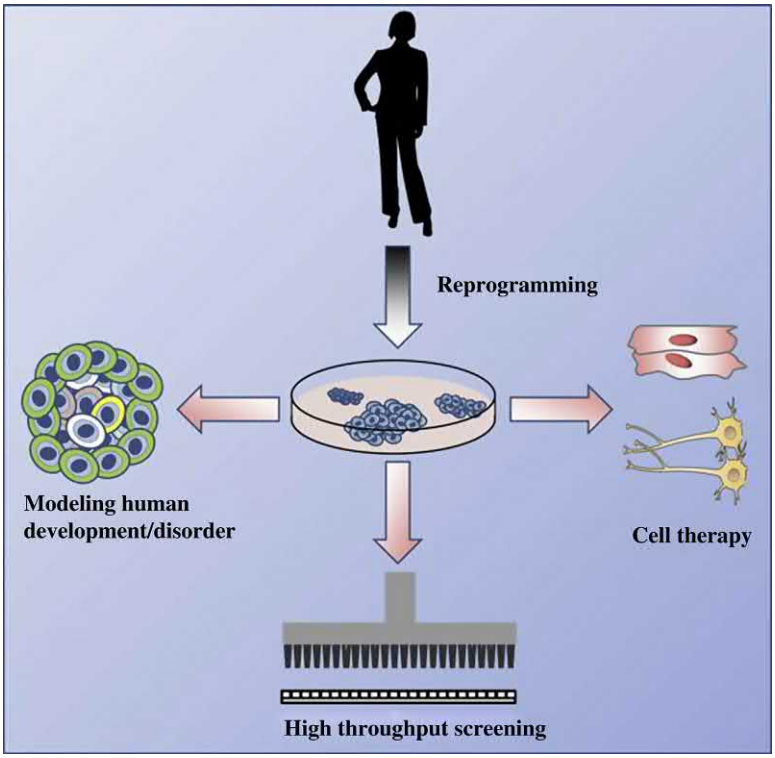

FIGURE 25.2 Applications of iPSCs. Human iPSCs can be used to study and treat human diseases. Aggregates of iPSCs can form organoids that recapitulate aspects of early embryonic development that can be used to model human developmental disorders. Genetically, diverse iPSCs and their derivatives can be used in high-throughput screening to improve the preclinical development of pharmaceuticals. In addition, iPSCs can be used to derive therapeutically relevant cell types for autologous transplantation as a cell therapy to treat human diseases. *iPSCs*, Induced pluripotent stem cells.

disorders and the development of pharmaceutical interventions has lagged far behind disorders affecting other organs. Many highly anticipated drugs, such as those that target Fragile X syndrome [58] and amyotrophic lateral sclerosis (ALS) [59–61], have failed to demonstrate efficacy in human trials after promising preclinical work on animal models. In addition, neurological and psychiatric diseases are complex because they are rarely based on a single gene variant. Notably, many psychiatric diseases arise from mutations in noncoding regions [62,63]. In many cases, these noncoding regions either are not conserved in rodents or they function differently. In contrast, iPSCs derived from patients with genetic disorders contain all of the complex genetic interactions that underlie the disease.

Timothy syndrome (TS) is a neurodevelopmental disorder that has been successfully investigated using patient-derived iPSCs [64]. TS is a rare monogenic form of autism caused by prolonged activation of the L-type $Ca_v1.2$ calcium channel. The prolonged channel activation results from a gain of function mutation leading to dysregulation of $Ca^{2þ}$ signaling in many cell types. One of the striking phenotypes of TS iPSCs is abnormal cortical development; they produce fewer upper layer neurons and a higher proportion of lower layer neurons. Interestingly, elevated $Ca^{2þ}$ signaling leads to the upregulation of tyrosine hydroxylase in cortical neurons. Higher levels of tyrosine hydroxylase, an enzyme that is involved in the biosynthesis of catecholamines, ultimately lead to increased norepinephrine and dopamine production that is associated with aggression in TS patients. Using iPSCs as a model, it was discovered that roscovitine, an L-type channel blocker, can restore normal tyrosine hydroxylase expression and catecholamine production in TS iPSC–derived neurons. Notably, the transcription regulatory element of human tyrosine hydroxylase locus is not conserved in mice, and the catecholamine phenotype is not observed in a transgenic TS mouse model [65]. In this way the TS iPSC model provided preclinical validations for future therapeutic development that would otherwise have been missed using only rodent models. Similarly, studies using iPSCs to model other monogenic forms of autism such as Phelan–McDermid syndrome [66], Rett syndrome [67], and Williams syndrome [68] identified human-specific phenotypes and discovered disease-causing pathways.

iPSCs are also useful for studying diseases for which there is evidence of inheritance but no specific mutations identified. For complex diseases such as idiopathic autism and schizophrenia, most cases lack a clear genetic basis. Deriving iPSCs from the patients preserves their genomes, and when differentiated into the relevant cell types, they can be used to study cellular phenotypes and molecular mechanisms without knowing the genetic cause. However, patients who have complex diseases usually present with a wide range of symptoms. Because

obtaining information about a disease from patient iPSCs requires multiple patients with the same syndrome, careful consideration should be taken in selecting patients and study controls. For example, to study idiopathic autism, a research group selectively focused on patients who presented with the same clinical phenotype: early brain overgrowth. They observed an increased proliferation rate of the disease-associated iPSC-derived neural progenitor cells and determined that it was likely caused by dysregulation of the b-catenin/BRN2 cascade [69]. Selection of appropriate controls is extremely important to minimize nondisease relevant differences; because humans are genetically diverse, variations in individuals' iPSCs could contribute to differences in cellular behaviors that are not necessarily disease relevant. For this reason, iPSCs from unaffected family members are usually used to study idiopathic disease to minimize variability owing to genomic diversity [70].

iPSCs are also valuable for validating human-specific disease-causing variants. Advances in sequencing technology have enabled an increase in genome-wide association studies (GWAS) to identify novel disease-causing candidate mutations. For many complex diseases, candidate mutations are found in noncoding regions and most are not evolutionarily conserved in animal models. iPSCs are an ideal platform for validating such candidate mutations identified through GWAS. An example is a single nucleotide polymorphism risk variant that appeared to contribute to the pathogenesis of Parkinson's disease (PD) [71]. Using genome editing with clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9), risk-associated alleles were introduced into wild-type iPSCs; by comparing the otherwise identical cell lines, researchers showed that the risk allele altered *cis*-regulation of the alpha-synuclein (SNCA) locus and led to an upregulation of SNCA expression. This variant mimicked a duplication of the coding region for SNCA that was known to be a familial cause of PD [72].

Methods have improved for culturing iPSCs in miniature "organoids" that can resemble the structure of human organs. When iPSCs are aggregated during their differentiation in vitro, they can create their own microenvironments and self-organize into three-dimensional structures. Kidney [73], liver [74], stomach [75], and brain organoids [76] can show remarkable similarities to the corresponding tissues. Researchers have just begun to explore possibilities to model disease using organoids. Multisystem organoids have been developed, including intestinal organoids, with components of the enteric nervous system [77]. Organoids may provide a means to produce more fully mature cells in vitro and may be useful for drug screening.

Challenges and future possibilities in disease modeling

It is difficult to mature cells fully in vitro, so it remains challenging to model late-onset diseases. Efforts have been made to age iPSC-derived cells artificially, such as progerin treatment [78] and telomere shortening [79], but it is not clear whether these treatments are realistic mimics of aging. Direct reprogramming from fibroblasts has been reported to preserve age-related characteristics of the donor [80], but direct reprogramming has shortcomings for disease modeling, as discussed earlier. However, in some cases, aspects of late-onset genetic diseases may be detected in iPSC-derived cells. This allows testing of drugs that can correct the cellular phenotype. In one example, ALS patient–derived motor neurons were found to have an abnormal electrophysiological phenotype, which could be corrected with a US Food and Drug Administration approved anticonvulsant drug, Retigabine [81]. A clinical trial was initiated in 2016 (https://clinicaltrials.gov/ct2/show/NCT02450552) to evaluate the effects of Retigabine on motor neuron activity in people with ALS.

For decades, drug discovery has relied heavily on a reductionist approach in which high-throughput screening is used to identify biologically active molecules based on expression of a recombinant target protein of interest in a single transformed cell line. The transformed lines used in these screening processes tend to be of similar ethnic backgrounds. Decades of experience using this model led to the finding that the genetic background of an individual can determine the success or adverse effects of a particular drug. For this reason, regulatory agencies recommend, including a diverse patient population in later-stage clinical trials. A genetically diverse group of iPSC-derived cells would be instrumental in predicting these types of genetically dependent effects in the preclinical stages, making the drug development process more efficient [82].

Proof-of-concept toxicity studies have been performed in stem cell–derived cardiomyocytes [83], hepatocyte-like cells [84], and neurons [85]. However, to draw associations between genotype and drug response, as well as identify associated biomarkers, large collaborative initiatives are needed to generate cell banks that cover diverse ethnic groups, capturing a range of genotypes [82]. Carefully chosen sets of genetically diverse iPSCs could then be used for preclinical development.

In addition to the ethnicity of the patient, multiple disease mechanisms are likely to contribute to one disease phenotype, and one drug is not appropriate or sufficient for all cases. For example, cystic fibrosis is an autosomal recessive disease that is caused by mutations in a gene called cystic fibrosis transmembrane conductance

regulator (CFTR), which encodes for a chloride channel. Mutations in this channel result in abnormal regulation of salt and water, causing severe respiratory and gastrointestinal symptoms. More than 1900 CFTR mutations have been identified (www.genet.sickkids.on.ca). The type of mutation has a direct effect on the efficacy of commonly used medications. For example, for patients who carry a G551D mutation, CFTR channel activity is reduced. Ivacaftor, an oral agent and channel agonist designed to prolong the time in which the chloride channel is open, was effective in treating symptoms in this subgroup of patients [86]. However, this patient subgroup accounts for only 5% of patients with cystic fibrosis. For most patients a truncation in the protein prohibits proper trafficking to the plasma membrane. In such cases a channel agonist is ineffective. Another therapeutic, lumacaftor, which aids in transporting CFTR to the cell surface, is more appropriate for these patients [87]. Identifying the disease mechanism for each CFTR variant could be enhanced by using patient-specific iPSC modeling.

iPSC model systems have been used to predict the clinical outcome of patients with specific mutations. One study examined a selective sodium channel blocker and its effect on inherited erythromelalgia using patient iPSC−derived sensory neurons and could correlate the in vitro results to patient response and specific mutations [88]. As another example, a retrospective study identified patients who clinically experienced drug-induced QT prolongation upon administration of a nonselective beta-blocker, sotalol. Cardiomyocytes derived from these patients' iPSCs recapitulated the patient response in vitro, demonstrating differential arrhythmias after sotalol treatment [89]. These studies demonstrate the exciting potential for using iPSCs to predict patient outcomes and to choose better from clinically available interventions.

Disease-modifying potential of induced pluripotent stem cells

Cell therapy is a fast-developing field in modern medicine. Traditionally, cell therapy was limited to bone marrow cells and blood stem cells, but with the ability to generate clinically relevant cell types from stem cells, PSC-based cell therapies are being developed. A potential advantage of using iPSC-based therapies is that the cell line can be chosen to be patient-specific or a close immunological match. Autologous transplantation of iPSCs and their derivatives is expected to be tolerated by the immune system, and patients could benefit from avoiding immunosuppressant treatment required for allogeneic transplantation. The creation of banks of iPSCs designed specifically to serve as a close immunological match to a large percentage of the population may also be feasible by deriving cells from individuals homozygous for the major human leukocyte antigen (HLA) markers. Such banks would reduce the time and cost needed to produce cells for therapy. The practicality of these banks depends on the number of cell lines needed to match the population served by the bank. In a country such as Japan, it is estimated that a bank of 50−100 carefully chosen iPSC lines could match 90% of the population [90]. In contrast the genetic diversity of the populations of Europe and the United States would necessitate banks with orders of magnitude more cell lines, which makes the design more challenging and less feasible. The HLA-matched iPSC banks have not yet been tested in human trials, and there is concern that minor antigens could cause rejection even when there is a perfect major HLA match.

The expectation of immune tolerance of autologous iPSC-derived transplants, however, has been brought into question by reports showing that transplantation of mouse iPSCs into syngeneic rodents led to immunogenic teratoma formation [91]. Subsequent studies using rodent models, including a humanized mouse model to reconstitute a human immune system, produced conflicting findings. Whereas some reports [92,93] found that autologous transplants were not immunogenic, others [94] found significant immune response upon autologous transplant of some types of iPSC-derived cells. The autologous immune response may be caused by aberrant antigen expression induced by differentiation in vitro and might be cell type−specific. For example, iPSC-derived smooth muscle cells showed aberrant antigen expression but iPSC-derived retinal pigment cells did not [94]. A more recent study demonstrated that rejection of autologous transplants can occur in rare cases, due to increased mutation burden in the mitochondrial DNA and representation of neoantigen from these mutations [95]. Therefore even for autologous transplantation, preclinical studies should include analysis of potential immune response.

Besides the potential immunological advantages of iPSCs, any cell therapy shares the common challenge of properly delivering the cell product [96]. For most cases, delivery of therapeutic cell types must be targeted to a region of interest. Although intravenous injection is simple and easy, it often results in cell capture and the destruction of delivered cells in the lungs or the liver. Consider, for example, the case of myocardial infarction. A myocardial infarct results from the loss of blood flow to a region of the heart, typically resulting from an occluded vessel. The chronic effects of an infarct are physical remodeling of the heart muscle tissue that hypertrophies as the heart struggles to adapt a loss of function. In this case, restoration of muscle function through cell replacement could stop the remodeling process and provide symptomatic relief. Preclinical studies on rodent and

nonhuman primate myocardial infarction models reported that transplantation of ESC-derived cardiomyocytes can be effective to prevent further deterioration of cardiac function by remuscularization of myocardial infarcts [97]. However, the heart is not a mechanically hospitable environment for cell delivery. Cells must be physically and electrically integrated in an appropriate manner to provide meaningful improvements and avoid potentially harmful side effects in humans.

In other areas of the body, such as the central nervous system (CNS), transplanted cells are less likely to escape into the bloodstream. The relative ease of delivery is in part why most PSC-based therapies have focused on the CNS. Several groups have developed cell replacement therapies to treat macular degeneration, which is caused by the loss of the retinal pigment epithelium (RPE). The first trial to use iPSCs for any disease was led by Dr. Masayo Takahashi in Japan; the first patient was transplanted with autologous iPSC-derived RPE cells, but a decision was made to continue the study using allogeneic (unmatched) iPSC-derived RPE; there is discussion about using an HLA-matched Japanese iPSC bank for further trials [98]. Recently, another research group led by Dr. Kapil Bharti has decided to proceed with clinical trials using autologous RPE cells after determining that in nonhuman primates, allogeneic RPE was rejected by the host's immune system [99,100].

PD is another area of intense interest for a PSC-derived cell therapy. PD results from progressive loss of A9 dopaminergic neurons in the substantia nigra, and by the time the symptoms are diagnosed properly, over 50% of the neurons have already been lost. Methods for producing dopamine neurons from human PSCs have improved over the last few years [54]. When neurons whose activity could be optogenetically controlled were transplanted into a rodent PD model, these neurons could integrate into host circuitry, secrete dopamine, and restore movement control [55]. Clinical trials are planned in multiple countries, including Japan, the United States, and Sweden. A report from a meeting of the four major groups planning such therapy indicated that two groups plan to use hESC-derived dopamine neuron precursors, one plans allogeneic therapy with a single iPSC line, and the fourth plans an autologous iPSC approach [101].

There are now robust methods for the generation of specific cell types from hESCs and iPSCs that work for all cell lines regardless of type or genetic background. There is currently considerable discussion about whether the use of autologous or allogeneic iPSCs is a better choice for transplantation [102]. Allogeneic cells, hESCs and unmatched iPSCs, have been reported to be rejected in nonhuman primate studies [99,103], and human trials using allogeneic cells are all planning immunosuppression for at least a year to prevent graft rejection. The debate about which cells are preferable revolves around the main issues of cost of production of autologous cells and risks associated with immunosuppression for allogeneic therapy.

Other applications for induced pluripotent stem cells

The characteristics of iPSCs, their ability to proliferate without limit and differentiate into multiple cell types inspires other potential uses. One of the least straightforward and most challenging applications for iPSCs is their potential for use in wildlife conservation. One such example is the ongoing effort to save an endangered species, the northern white rhinoceros (NWR), which is on the brink of extinction owing to poaching and civil wars. The two remaining NWRs in the world, two females, cannot carry a pregnancy even if artificial insemination with stored NWR sperm is used. In an effort to save the species, iPSCs were first made from cryopreserved NWR fibroblasts in 2011 [104]. This success raised hopes for applying iPSC technology to differentiate NWR iPSCs into gametes to use for assisted reproduction. In 2015 an international group of researchers met in Vienna in 2015 to develop a multifaceted plan to save the NWR using assisted reproduction technology, including iPSCs [105]. This approach is possible only because of the foresight of researchers who, over the past three decades, preserved dermal fibroblasts from 12 genetically diverse NWR individuals in the Frozen Zoo at the San Diego Zoo Institute for Conservation Research (http://institute.sandiegozoo.org/). Since 2011 fibroblasts from several more NWRs have been reprogrammed; the technical hurdles now lie in producing functional gametes and successfully implanting fertilized embryos into surrogate hosts. It was reported that functional oocytes were generated entirely in vitro from mouse iPSCs, which provides further hope that the same can be done with endangered species iPSCs [106].

Conclusion

For decades, human diseases were modeled in the mouse because of the genetic tools available to alter the mouse genome. Then hESCs began to be used to generate multiple human cell types that could be used for clinical cell therapy and disease modeling. However, hESCs lacked ethnic diversity [107], and although there are hESC lines with genetic mutations, they cannot be linked to the phenotype of a living individual. Human somatic cell reprogramming has revolutionized the fields of stem cell biology, regenerative medicine, and the study of human disease. iPSCs share all of the benefits of hESCs and also have the advantages of genomic diversity and linkage to specific individuals whose medical history is known.

The future of reprogramming is difficult to predict because the technology is developing so quickly. For example, one can imagine moving from the culture dish to in vivo reprogramming. Such an approach could be used to augment tissue-specific stem cells to enhance regeneration; however, improvements are necessary in the control over the delivery of the factors in vivo. Interestingly, a study investigated the short-term expression of the Yamanaka factors in genetically engineered rodents and reported a prolonged life span and decreased recovery time after injury [108], balanced by a higher rate of tumor formation. Studies such as this open the door to potential therapies based on iPSC technology.

A complementary technology that is also evolving at a rapid pace is the CRISPR/Cas9 system and other genetic engineering methods that enable targeted genomic editing. Efficient genome editing of iPSCs can be used to correct mutations, allowing autologous cell therapy for genetic disease. Gene editing can also produce better models for disease, allowing the introduction of specific disease-related variants into iPSCs that can be used to better understand phenotypic expression of mutant and wild-type alleles. The applications of iPSCs are a new tool in 21st-century medicine that will improve our understanding of human disease and enable novel approaches to treat currently untreatable diseases.

Chapter 26

Neonatal stem cells in tissue engineering

Joseph Davidson and Paolo De Coppi

Stem Cell and Regenerative Medicine Section, Great Ormond Street Institute of Child Health, University College London, London, United Kingdom

Introduction

In recent decades, fetal diagnosis and therapy have risen to prominence, and with this rise, so too has regenerative medicine started to develop in areas relevant to the fetus and the newborn. Concerning congenital anomalies, a deficiency of tissues in the patient may prevent anatomical reconstruction, and current treatment strategies involve either using an artificial material or a nonanatomical conduit to surgically repair the defect. This has opened new possibilities for tissue engineering solutions for several congenital anomalies.

There are important considerations to be taken when regarding fetal and neonatal tissue engineering: the availability of fetal/neonatal stem cells, the differences between perinatal and postnatal tissue regarding maturation profiles and manipulation capabilities of the tissue ex vivo, and the conditions appropriate for treatment via a tissue engineering approach. Fetal and neonatal cells may also interact differently when seeded upon certain scaffolds to build specialized tissues.

Specific to scaffolding related to the fetus and newborn, the potential for "cellurization in vivo" is an attractive prospect because of the natural ability of cells to grow and to form new tissues during development.

The first part of this chapter will summarize the current landscape of tissue engineering in the fetus and newborn from both stem cell biology and scaffolding perspectives before moving on to describe some of the experimental and clinical applications of tissue engineering in treating a variety of different congenital anomalies.

Stem cells

The use of stem cells in tissue engineering has revolutionized the landscape of the field; these cells can be maintained in culture to varying degrees and can be manipulated through environmental and genetic modification to fulfill a desired role.

Embryonic stem cells

Embryonic stem (ES) cells, found in the inner cell mass of the blastocyst, are extremely widely potent (differentiating into cell lines from each of the three germ layers). Human ES (hES) cells can be isolated and cultured in vitro, and optimal conditions for proliferation have been developed using fibroblast feeder layers and fibroblast growth factors [1]. Further work has also been done to identify the role of transcription factors to suppress differentiation genes within the hES cell (Oct-4, NANOG, and SOX2) [2].

The limitations to clinical applications for hES revolve around their extensive potency and the acquisition of the cells themselves. Prior to implantation in a host, hES cells require very specific direction for appropriate lineage commitment or risk, forming many varied cell types, and bear the potential for teratoma formation. Clearly, these cells must also be allogeneic in origin; since by such a time as a diagnosis of congenital malformation would be made within the fetus, hES will no longer persist within the developing organism. Until recently, the derivation of ES cells has involved the creation of an embryo solely for ES cell harvest, and subsequent destruction of the embryo, but advances have been made whereby ES cells could be isolated from the developing embryo without disrupting its growth [3–5]. This offers a possibility of preserving autologous ES cells for the developing fetus in the case of IVF during preimplantation manipulation. Clearly, the approach of harvesting ES cells from "expendable" embryos bears several ethical dilemmas that are avoided by the use of stem cells derived from the "patient" fetus itself, as discussed in the following sections.

The concept of somatic cell nuclear transfer (SCNT), or the substitution of a cultured oocyte with a nucleus from a donor cell [6], is an alternative means of generating ES cell lines that are functionally autologous in terms of the cell immunogenicity. This technology rose to fame

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00026-5

with the widely publicized cloning of Dolly the sheep [7] but has proven to successfully generate blastocyst-derived ES cells, from which tissues may be engineered in vitro. The translational adoption of SCNT has been limited, however, largely owing to the paucity of human oocytes.

Induced pluripotent stem cells

Inducing pluripotency in somatic cells to create induced pluripotent stem cells (iPSC) is a technique developed in the past decade, first by Yamanaka and colleagues in Kyoto [8]; the process involves the inducing factors associated with pluripotency in ES cells (namely, Oct3/4, Sox2, c-Myc, and Klf4), which reverses the commitment to cell lineage in adult cells in what could be dubbed dedifferentiation. The therapeutic potential of iPS is limited at present, since current methods of induction require use of retroviral vectors that are nondiscriminative in their integration sites within the genome, giving concerns of undesired off-target effects, including tumorigenesis. There have been methods described where induction of pluripotency is achieved with nonintegrating plasmids [9], or nonviral RNA vesicles [10] that are thought to be more acceptable; however, these still do not negate the risk of tumor formation.

The creation of pluripotent stem cells from a donor with an established genetic disorder opens the possibility of gene correction, expansion, and subsequent reimplantation and is an exciting prospect in the treatment of several hemoglobinopathies such as beta-thalassemia and sickle cell anemia [11]. With respect to perinatally acquired stem cells, it has been established that these may be easier to reprogram than adult somatic cells, and this may be advantageous for establishing perinatal therapies. In this regard, it has been shown that first and second trimester CD117 + amniotic fluid (AF) stem cell (AFSC) can be converted into iPSC in a transgene-free fashion by an addition of the FDA-approved chemical valproic acid into the culture media [12].

Perinatal stem cells

Postnatal cells are limited in their potential and, even after reprogramming, maintain epigenetic modifications, which may make their application less safe and effective for patients. Perinatal cells acquired during gestation or soon after delivery may overcome these limitations. While, at birth, cord and placenta are certainly valid alternatives, during gestation AF is certainly a very appealing cellular reservoir.

Cells from the umbilical cord, amniotic membrane, and placenta

Different cell types, such as trophoblastic, hematopoietic, epithelial, and mesenchymal stem cells (MSCs) [13], can be isolated from placenta, either during pregnancy or at the time of delivery [14,15]. While it is still unclear if pluripotent stem cells persist during development beyond the first few weeks [16], the placenta has been demonstrated to contain various stem cell niches, which may reflect the different embryonic origin of its parts. Of relevance, placenta has been reported to contain a population of broadly multipotent stem cells that also show the expression of ES cell markers as c-KIT, OCT4, SOX2, SSEA-3, SSEA-4, TRA-160, and TRA-1-81 [17,18]. These cells have a mesodermal phenotype but show a broader differentiation potential, not limited specifically to mesenchymal lineages, but can differentiate into hepatocytes, vascular endothelium, pancreatic, and neuronal cells [19,20]. Another cell type with relevance is a population of human amnion epithelial cells (hAECs), derived from placenta, which has shown therapeutic promise in preclinical models of a bronchopulmonary dysplasia (BPD), a chronic lung disease that mainly affects premature babies who require ventilator support [21]. The first-in-human clinical trial of hAECs in babies with BPD has recently been started in Australia; allogeneic hAECs (1×10^6/kg bodyweight), by intravenous infusion to six premature babies with BPD, have been safely infused, and future randomized clinical trials to assess efficacy in this patient population are currently underway [22].

Umbilical cord blood–derived cells

The umbilical cord has, along with the placenta, shown to be a valuable source of widely potent stem cells, with limited ethical conflicts in their harvest and culture. In 2005 the group of Denner in the United Kingdom demonstrated embryonic characteristics in cells that were obtained from cord blood at the time of delivery, expressing markers familiar in examples of ES cells (Oct-4, SSEA-3, and SSEA-4, among others) [23]. Cord blood–derived cells have been used in literally thousands of published preclinical models, and several hundred clinical trials are currently underway or have completed with uses spanning from the treatment of hematological disorders to the prevention of tissue ischemia in stroke and myocardial infarction [24].

Amniotic fluid stem cells

AF can be collected safely during second trimester routine amniocentesis (at 14–16 weeks gestation), third trimester amnioreduction (at 28 weeks or later), or cesarean section (end of gestation) and the discovery of fetus-derived stem cells within this fluid has opened up many exciting avenues in tissue engineering [25]. The role of the stem cells within the AF are yet to be clearly defined; it is becoming apparent that extracellular vesicles of AFSCs play a key role in many of the therapeutic effects observed by these cells

[26]; however, work remains to be done to identify from where in the fetus these cells originate, how they find their way into the AF and for what purpose.

AFSCs are broadly multipotent; they may commit to lineages of fat, bone, muscle, endothelium, liver, and neural tissues, thus forming cells of any germ layer. They represent approximately 1% of cells within the AF and can be purified from AF by selection of their expressed CD117. Following selection, AFSC can be cultured and refined in vitro without any need of a feeder layer (which is of importance when considering clinical applications since feeders commonly use xenogeneic cells).

Most importantly when considering broadly potent stem cells, AFSCs do not cause cancers when transplanted, neither when reimplanted back to the donor nor when transplanted to other recipients. Within the AF cell population also exist MSCs (AFMSCs). These cells possess only mesodermal potential (they do not display markers of hematopoietic progenitors), have been shown to grow rapidly in cell culture, and have significant potential at generating extracellular matrix (ECM) components [27].

Given that access to AFSCs often already occurs during the diagnostic workup of many antenatally identified anomalies, there is a preexisting means whereby highly potent stem cells can be obtained and manipulated during the remainder of pregnancy in preparation for either a fetal or neonatal repair.

Scaffolding specifics in fetal and neonatal tissue engineering

Engineered scaffolds that can be seeded with cells to form a structural and functional tissue mark an interface between cell biology and materials science. Several important attributes are desirable to successfully fulfill the requisite role of a scaffold: biocompatibility, biodegradability, and mechanical properties that closely align to those of the target tissue. Optimal scaffolds will also feature promoters for cell survival and proliferation. Materials can be broadly, but comprehensively, divided into those that are either synthetic or naturally derived [28].

Synthetic materials

Synthetic scaffolds represent the most immediate clinical prospect within tissue engineering; by their nature they can be reproduced precisely and relatively cheaply and may be developed to display a range of mechanical properties. Within the wider field of clinical surgery, synthetic patches, grafts, and sutures are already commonly used and have an excellent safety profile displaying minimal immunogenicity and a degradation and permeability profile that can be altered to requirement—the latter being particularly important when considering the necessity for neovascularization in large-scale tissue constructs [29–31].

A key feature of synthetic scaffolds must be the ability for cells to integrate into the structure; nonabsorbable materials, such as polytetrafluoroethane (PTFE, marketed commonly as Teflon or Gore-Tex), will cause a foreign body reaction when implanted, and a fibrous capsule is routinely found around implanted patches, currently used for defect closure in a variety of settings. While the structural properties of PTFE allow it to close defects effectively, the inability for cell ingrowth and, importantly, internal angiogenesis preclude it, and other similar materials, from being used in a tissue engineering capacity. The persistence of the material also gives concern for scaffold erosion through nearby structures—as has been described in the adult case report literature with aortic grafts, tracheal, and esophageal stents invading adjacent structures in the mediastinum. In neonatal surgery, Gore-Tex patches are commonly used to close large defects in congenital diaphragmatic hernia (CDH) [32]; however, issues arise from the inability of the patch to grow with the child, including chest wall and spinal deformities [33,34]. Indeed, as a rule, adapting a synthetic scaffold to feature naturally occurring molecules, such as collagen, markedly improves the capacity of the engineered structure to adhere cells within the prospective recipient, allowing for true tissue integration.

Polyglycolic acid (PGA) and poly-L-lactic acid (PLLA) are two prominent synthetic materials with FDA approval for clinical use. PGA has been demonstrated to provide excellent structures on which to culture smooth muscle cells (SMC), degrading completely after 8 weeks, is replaced by SMC-produced ECM proteins [35]. PLLA behaves similarly in vivo and has proved to be a successful scaffold for isolated endothelial cells [36]. Polycaprolactone (PCL) is a further polymeric material with a longer degradation profile than PGA or PLLA (approximately 2 years). As expected, coating PCL with dopamine, collagen, or fibrin increases its cell-adhesive properties, by removing the hydrophobic domains from the exposed surface of the material, and providing receptors for cell adhesins [37–39].

Natural materials

Naturally formed ECM, such as collagen, has the advantage of a structure that lends itself well to cell adhesion and proliferation. Commercially, collagen can be manufactured using recombinant plasmids in yeast or bacteria and can promote differentiation of a variety of different tissues both in vitro and in vivo; importantly, it stimulates internal angiogenesis when seeded with adipose tissue-derived stem cells [40]. Collagen displays low immunogenicity and can be altered in porosity, resorption, and

mechanical properties per requirements. Innovative means of building collagen scaffolds to template have been developed by causing foreign body reaction within the host—forming a so-called biosheet, with purposing of this for patch repair of diaphragmatic and tracheal defects already demonstrated in animal models with encouraging results [41,42]. Since the protein domains across different species are maintained, the immunogenicity of nonhuman collagen is not an issue for clinical application—indeed we see this in clinical practice where porcine and bovine collagen are currently used in repairing and replacing surfaces in a broad range of surgical procedures [43–45].

Similarly, in manufactured matrices of natural components, naturally occurring tissues can be exposed to a variety of enzyme- and detergent-based treatments to achieve total decellularization [46]. This allows the preservation of ECM proteins, and, significantly, the structure can be preserved (albeit some decellularization techniques have proved to be more effective than others at complete preservation). In maintaining the ECM structure, on the microscopic and macroscopic level, the environment for implanted cells or ingrowing is more dependable, and the mechanical and angiogenic properties simply persist, as opposed to having to be engineered to purpose. Once implanted with stem cells, the structure tends toward taking on a histological architecture resembling that of the original tissue.

Decellularized tissues have been utilized for engineering organs in many promising in vivo experiments to date; however, the arrival of clinically relevant technology for use in humans has so far been limited, although excellent results have been reported in the use of acellular dermal matrix in the treatment of burns for many years [47]. Hollow organ engineering is conceivably simpler than achieving the functional capacity of solid tissues such as liver or heart tissue, and our group report successful outcomes in the use of an autologous stem-cell seeded, decellularized tracheal graft as a treatment for congenital tracheal stenosis—with gradual epithelialization and mechanical strength developing over the 2 years following transplantation [48].

Relevance to prenatal therapy

Tissue engineering–based treatment of congenital anomalies is fast becoming a possibility in the antenatal period. Precision with current diagnostics means that a very accurate estimation of the nature and size of a required tissue graft is possible. Furthermore, the marked increase in growth during the final trimester of pregnancy means that fetal application of a tissue graft allows for a far smaller construct to be used—tackling both engineering and clinical issues related to repairing larger structures. As with any fetal intervention, a thorough evaluation of the risks and benefits needs to be performed; many candidate conditions can be treated in the neonate or older infant without any apparent disadvantage, foregoing the ethical and legal dilemmas of fetal intervention and avoiding the risk of premature delivery. However, there are certainly situations whereby a fetal approach may improve outcomes owing to a progressive condition that can be arrested by intervention in utero [49–51], or those where the transition from fetal to neonatal physiology may impact survival such as in the development of pulmonary hypertension in cases of severe CDH [52]. The accessibility of fetal stem cells in the AF may allow for an ex vivo engineering of a bespoke implant before reimplantation into the patient before or after birth. Furthermore, the fetus has several unique considerations as a recipient to a tissue-engineered implant, which will now be detailed more thoroughly.

Immunology

The maturation of the fetal immune system and the phenomenon of tolerance is an important area to explore regarding the fetus' suitability as a graft recipient. The adaptive immune system begins to develop in the eighth gestational week and is thought to be complete by 20 weeks [53,54]. During this process, positive and negative selection of T-cell precursors results in pro-tolerance regulator T cells (T_{reg}) that suppress immune-reactivity to molecules recognized as "self." This concept can be exploited in the transplantation of allogeneic grafts which may then be tolerated without any need for immune modulation. Liechty et al. have described a persistence of allogeneic stem cells in a sheep model after the supposed tolerance threshold, which has led to the hypothesis of "tolerogenic" cells or molecules that may be exploited for cell therapy in the third trimester fetus [55].

Physiology

The placenta and amnion act as the recovery unit for the fetus after an invasive procedure and appear able to autoregulate blood flow to support fetal homeostasis [56,57]. Further technological advances in the development of an ex uterine support system by Flake, Partridge and colleagues in Philadelphia have demonstrated the possibility of an artificial womb where, hypothetically, fetal subjects may recover after major procedures after a deliberate or unplanned premature delivery [58]. There are clear differences in wound healing between the fetus and neonate, with considerably reduced scarring seen related to wounds made in utero [59,60]. This has important implications where invasive procedures are concerned, and developments have gone still further to develop tissue-engineering solutions for the closure of skin wounds in utero [61].

Conditions of interest

Fetal implantation of an engineered construct really only merits consideration under those conditions where the course of the disease may be markedly altered with successful treatment at the earlier stage of development. A staged approach with fetal cell harvest, leading to a planned early neonatal intervention, benefits from the potency of the aforementioned fetal stem cells, while minimizing risk to mother and fetus of a prolonged fetal procedure. We will now explore preclinical models of congenital anomalies with both fetal and neonatal intervention.

Spina bifida

Fetal treatment of spina bifida or meningomyelocele (MMC) has been shown in randomized control trial to benefit patients beyond neonatal repair and has been adopted widely in many centers across the world, including the authors' own. The antenatal closure of the defect avoids the damage to the exposed neural and reverses the development of the Chiari malformation [50,62]. As of yet, the current approach lacks the potential to regenerate the damaged neuronal tissue. A tissue-engineering approach to spina bifida has been considered in a number of animal models, and in addition to defect coverage, there is also clear potential for neural regeneration. A widely adopted approach is to introduce a regenerative scaffold over the exposed spinal cord and fix this in place by closing the overlying skin [63–65]. The use of a tissue-engineered patch with covering sealant to the defect (as opposed to a sutured repair) allows attempts at closure at an earlier gestation (with an empirically smaller defect and reduced extent of nerve injury). Recent results published by Farmer et al. demonstrate a clear benefit of using patch closure with stem cell seeded scaffold in a rodent model of MMC where decellularized ECM scaffolds were used for MMC and showed a clear benefit of those scaffolds that had been seeded with stem cells derived from human placenta [66].

Gastroschisis

Gastroschisis (GS) is also increasingly considered to be amenable to fetal repair. In this ventral abdominal wall defect, the free bowel being exposed to the pro-inflammatory substance of the AF is thought to lead to prolonged intestinal dysmotility that may be lifelong. Transamniotic stem cell injection with AFMSCs has been shown to mitigate bowel damage in both small and larger animal model of GS [67,68]. Experimental models of GS have also been effectively closed with collagen scaffold approaches, demonstrating effective replacement of the scaffold by multiple cellular and ECM components, as well as limiting the inflammatory peel found on the bowel at autopsy [69,70]. The most complex patients with GS will also benefit in the future of the work done around bowel tissue engineering, and there is an argument for AF cell storage for patients diagnosed with complex GS during gestation.

Congenital diaphragmatic hernia

Patients with CDH may benefit from two distinct regenerative medicine approaches, both regarding the diaphragmatic muscle defect itself and the secondary lung hypoplasia—which accounts for the majority of morbidity and mortality related to this condition. Large hernial defects require a patch in order to achieve closure. Besides reported chest wall and spinal deformity, another long-term complication of patch repair in CDH is rehernia-tion. This is felt to be due to the inability of the patch to grow with the child [71,72], which leads to a weakness along the margin of the repair. There is a hypothesis that a cellular patch would allow growth with the individual and thereby reduce the incidence of herniation. This has been demonstrated to be successful by a number of different groups who presented the superiority of a patch derived from AF-originated fibroblasts [73,74]. It is possible that even a decellularized muscle may be superior to a synthetic scaffold. Indeed, diaphragm-derived ECM was able to promote the generation of new blood vessels, boost long-term muscle regeneration, and recover host diaphragmatic function in a mouse model of diaphragmatic hernia [75].

However, the most important challenge to ameliorate long-term survival for patients with CDH is the lung hypoplasia. Most CDH-associated mortality is indeed secondary to pulmonary hypoplasia and subsequent pulmonary hypertension at the transition to neonatal circulatory physiology, leading to requirements for extracorporeal membrane oxygenation, but often terminal cardiorespiratory failure. We have demonstrated an integrative capacity of AFSCs, resulting in marked histological improvement of lung hypoplasia in the nitrofen-exposure murine model of lung injury [76], demonstrating improved tissue architecture, motility, and innervation, holding valuable potential for lung regeneration in not only CDH-related hypoplasia, but also in lung immaturity in general. Moreover, the use of human AFSCs can promote pulmonary development in a rabbit model for CDH [77]. This may, in the future, translate clinically similar to what has recently been reported for BPD [22].

Esophageal atresia

A tissue-engineered esophagus is increasingly the focus of several groups for the treatment of esophageal atresia

[78,79]. We have published preliminary data on a murine decellularized model seeded with stem cells, demonstrating effective seeding of mesangioblasts and neural crest cells within a natural scaffold [80]. Other groups describe utilizing the aforementioned "biosheet" technique successfully for patch esophagoplasty, demonstrating an effective potential tissue-engineering solution to a condition often managed presently with interposed grafts of nonspecialized intestine [81]. Fetal tissue, such as decellularized human amniotic membrane, has also been adopted for esophageal tissue engineering; myoblasts and oral epithelial cells were seeded, respectively, on acellular porcine ileal submucosa and decellularized human amniotic membrane, and these were used in combination for the circumferential replacement of the cervical esophagus in pigs [82]. The same group describes a similar experiment 2 years later utilizing autologous MSCs seeded on an acellular matrix, demonstrating an essential role for the MSC in promoting ingrowth of the epithelium [83].

Congenital heart disease

Fetal echocardiography now allows for detailed diagnosis of the most clinically significant congenital heart diseases. For many the transition of the circulation at the time of the closure of the ductus arteriosus (DA) leads to a circulatory collapse if untreated. Current management typically involves prostaglandin infusion to maintain patency of the DA in order to plan and deliver a surgical intervention, such as a patched repair or conduit construct using one of the aforementioned materials [84].

Experimental evidence suggests that AFSCs may express cardiac myocyte markers and develop electromechanical connections. Furthermore, they provide a source of functional endothelial cells from which coronary vessels and endocardium may originate [85]. In addition, Chorionic Villus Sampling (CVS)-harvested MSCs have been developed into living heart valve tissues after coculture with cord-blood endothelial progenitors [86]. With the precision of fetal echocardiography in the modern era, we are fast approaching an era where fetal tissues may provide materials for the construct of a patient-derived graft amenable to implantation in postnatal life (Fig. 26.1).

Congenital airway anomalies

Congenital high airway obstruction syndrome, or laryngotracheal agenesis, is known to many fetal medicine specialists who provide the rationale for tracheal occlusion in the treatment of lung hypoplasia in CDH. This condition is almost uniformly fatal around the time of birth, requiring an EXIT (ex utero intrapartum) procedure or emergency neonatal tracheostomy [87]. Airway reconstruction is the only treatment option, and approaching this anomaly with a similar approach to that described previously,

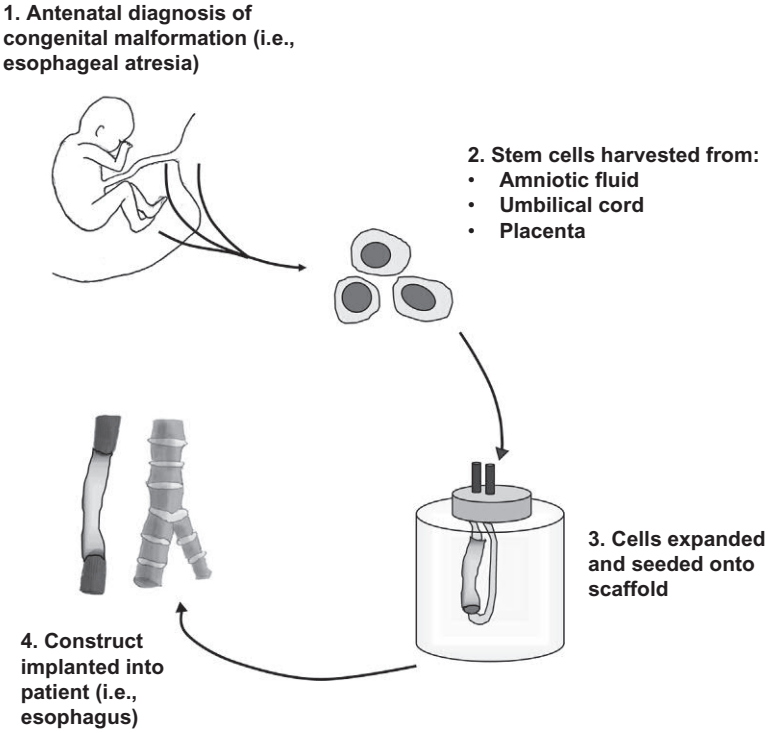

FIGURE 26.1 With accurate antenatal diagnostics, a need for a bespoke organ replacement can be defined. Cells can be harvested from a perinatal source and implanted into the newborn.

with a scaffold seeded with autologous cells obtained during gestation, may prove to be a potential therapy option in this devastating condition [48,88].

Bladder

Bladder exstrophy, with or without an associated cloacal anomaly, is a further area of active research within tissue engineering. Current approaches to reconstruction are limited in terms of achieving the required contractility or elasticity for a satisfactory function of the neo-bladder, and a tissue-engineered solution is a potential means of achieving an improved outcome in this regard. Indeed, Atala et al. reported in 2006 the successful use of collagen or collagen−PGA scaffolds, seeded with autologous urothelial and SMC successfully in human patients with spina bifida who were suffering from poor compliance or high intravesical pressure [89].

Bone and bone marrow

Existing reconstruction of skeletal defects in humans utilizes free bone grafting, various scaffolds with or without seeded bone marrow−derived adult stem cells, and the use of adjuncts such as bone-morphogenic protein [90]. AFMSCs and AFSCs have been demonstrated to produce bone mineral matrix with prolonged mineral production. Both have been utilized to create bone grafts used to surgically correct thoracic and craniofacial defects in animal models [91−93]. Moreover, there is a real possibility of contributing to the treatment of some devastating diseases that can be diagnosed prenatally such as osteogenesis imperfecta (OI). OI results from a defect in the synthesis of type-1 collagen, most commonly (>90% cases) a mutation in the subunit COL1A1 or COL1A2. Severe cases of OI present with prenatal fractures and existing therapy aim to palliate symptoms and decrease acquired deformity. Prenatal transplantation of allogeneic MSCs in OI appears safe, and a clinical trial (phase I/II) is taking place currently in the form of the BOOSTB4 trial [51]. Preclinical benefits have also been shown with AFMSCs. Intraperitoneal injection of human (AFMSCs) into a mouse model of OI reduced fracture susceptibility, increased bone strength, improved bone quality and micro-architecture, normalized bone remodeling, and reduced TNFα and TGFβ signaling [94].

One of the most promising applications of AFSCs is in the ability these cells display to engraft and reconstitute the hematopoietic system [95]. In utero stem cell transplant has long been used in isolated cases of severe immune-deficiencies in humans with encouraging, clinically relevant levels of engraftment [49,96]. It has also been noted that the tolerogenic properties of AFSC seem to allow transplantation at a later gestational age than would be predicted in terms of the onset of fetal tolerance during immune maturation [55].

Conclusion

Progress made in the field of regenerative medicine has direct implication in the development of innovative prenatal and neonatal treatments. Following the last two decades of scientific work, we are now witnessing the initial translation of this into early clinical trials. Both fetal and neonatal interventions with bespoke tissue or whole organ replacement are rapidly becoming a possibility, and the next decade of scientific research promises to deliver many exciting breakthroughs in the care for these patients.

Introduction

It has been estimated that approximately 3000 people die every day in the United States from diseases that could have been treated with stem cell–derived tissues [1]. Given the therapeutic potential and growing public awareness of stem cells to treat disease, it is not surprising that embryonic stem cell (ESC) research has been rapidly expanding since mouse ESCs (mESCs) were first isolated in 1981 [2,3] followed by the isolation of human ESCs (hESCs) in 1998 [4,5] from the inner cell mass (ICM) of human blastocysts (Fig. 27.1). As the development of mouse and human embryos is different, ESCs form these two can also have disparities [7]. Adult stem cells have been used clinically since the 1960s for therapies such as in bone marrow transplantation, and these cells hold great therapeutic promise. ESCs also offer major benefits, including their ease of isolation, ability to propagate rapidly without differentiation, and—most significantly—their potential to form all cell types in the body. In addition, ESCs are an attractive cell source for the study of developmental biology [8] screening of drugs/toxins [9] and the development of therapeutic agents to aid in tissue or organ replacement therapies [10]. Regarding the latter application, which is the focus of this chapter, ESCs have the potential to exhibit a considerable impact on the field of tissue engineering, where current treatments for large tissue defects involve graft procedures that have severe limitations. Specifically, many patients with end-stage organ disease are unable to yield sufficient cells for expansion and transplantation [11]. In addition, there exists an inadequate supply of harvestable tissues for grafting, and that which is available has associated risks, such as donor site morbidity, infection, disease transmission, and immune rejection [12].

Tissue-engineering-based therapies may provide a possible solution to alleviate the current shortage of organs available for transplantation. Expectations for the potential of stem cells have increased even more after the revolutionary generation of induced pluripotent stem cells (iPSCs) that profoundly modified the principles of cell fate and plasticity, and at the same time, may represent a novel remarkably important tool for cell-based therapy [13]. iPSCs were originally generated by the introduction of four transcription factors (Oct3/4, Sox2, Klf4, and cMyc) in a somatic committed cell, the fibroblast, converting it to a pluripotent ESC-like state [14]. FIGURE 27.2 Approaches for using ES cells for scaffold-based tissue engineering.
ES cells can be used in tissue-engineering constructs in a variety of methods. ES cells can be expanded in culture and then seeded directly onto scaffold where they are allowed to differentiate. Alternatively, stem cells can be directed to differentiate into various tissues and enriched for desired cells prior to seeding the cells onto scaffolds. *ES*, Embryonic stem.

gave rise to a completely new field that is not covered in this chapter, and the reader is directed to a number of excellent papers and reviews on this topic.

Tissue engineering has been defined as an interdisciplinary field that applies the principles of engineering, materials science, and life sciences toward the development of biologic substitutes that restore, maintain, or improve tissue function [15]. Thus tissue engineering may provide therapeutic alternatives for the treatment of organ failure or tissue defects that are acquired congenitally or produced by cancer, trauma, infection, inflammation, or surgery. Tissue-engineered products would provide a lifelong therapy and may greatly reduce the hospitalization and health-care costs associated with drug therapy while simultaneously enhancing the patients' quality of life.

A central part of such strategy is the cell source to be used, and the methods whereby sufficient numbers of viable differentiated cells can be obtained. ESCs represent a powerful source of cells capable of multilineage differentiation because they can potentially provide a renewable source of cells for transplantation. ESC-derived cells can be used directly as cellular replacement parts or in combination with other materials (typically in the form of scaffolds, Fig. 27.2). Despite this promise, the application of ESCs in tissue engineering faces numerous challenges, including appropriately differentiating the cells to the desired lineage in a controlled and homogenous fashion and avoiding implantation of undifferentiated ESCs which can potentially form teratomas. With advances made in molecular imaging, this can possibly be tracked and detected [16]. Research has also been looking into blocking teratoma formation through targeting antiapoptotic genes [17]. Currently, ESC-based tissue-engineering research is focused on elucidating soluble and immobilized cues and respective signaling mechanisms that direct cell fate, on characterization and isolation of differentiated progeny, and on establishing protocols to improve the expansion and homogeneity of differentiated cells [18,19].

This chapter discusses key concepts and approaches for

1. the propagation of undifferentiated ESCs,
2. the directed differentiation into tissue-specific cells,
3. the isolation of progenitor and differentiated phenotypes,
4. the transplantation of progenitor and differentiated cells, and
5. the remaining challenges for translating ESC-based tissue-engineering research into the clinical therapies.

Whenever possible, approaches using hESCs are reported.

Maintenance of embryonic stem cells

The self-renewal of ESCs is a prerequisite for generating a therapeutically viable number of cells. Over the past few years, much insight has been gained into the

self-renewal of ESCs. Both mESCs and hESCs were first derived and maintained in culture using mouse embryonic fibroblast (MEF) feeder layers and media containing serum. Considerable behavioral, morphological, and biochemical differences have been observed between mESCs and hESCs, and the research of animal ESCs is not easily translated to hESCs [5,20,21]. For example, mESCs form tight, rounded clumps, whereas hESCs form flatter, looser colonies, grow more slowly and demand more strict culture conditions to maintain their normal morphology and genetic integrity. Unlike mESCs, which can be maintained in an undifferentiated state in the presence of leukemia inhibitory factor (LIF), addition of LIF fails to inhibit spontaneous differentiation of hESC [22]. Although both mESCs and hESCs express common transcription factors of "stemness," such as Nanog, Oct4, and alkaline phosphatase, in the human system, undifferentiated ESCs express stage-specific embryonic antigen-3 (SSEA-3) and SSEA-4, and SSEA-1 is only expressed upon differentiation, whereas the opposite expression is observed in the mouse system. Due to these differences, efforts in hESC research focus on understanding the molecular mechanisms of hESC self-renewal. For example, recently, it has been found that that Bach1 plays a key role in self-renewal, pluripotency, and lineage specification in hESCs by stabilizing pluripotency factors [23].

Mouse and human iPSCs have marker expression profile, and biological properties very similar to the mouse and hESCs, respectively, and this is a general proof of principle of their real pluripotent state. However, after initial studies, data are emerging that iPSCs are actually not identical to ESCs [24], and a growing body of evidence indicates that their pattern of gene expression differ [25] and the epigenetic memory of the original cell type reprogrammed is at least partially maintained (reviewed in Ref. [26]). This may result in a more limited level of pluripotency in terms of spectrum of differentiation if compared to ESCs, but not necessarily a more limited spectrum of possibility of tissue differentiation for transplantation purposes if the original cell type is chosen accordingly [27].

Therapeutic applications of stem cells require the use of moderate to large numbers of cells, hence requiring methods amenable to scale up. Therefore xenogeneic cell sources have also been considered. Using cultures of hESCs on human feeder cells, it was found that human fetal muscle fibroblasts, human fetal skin fibroblasts, and adult fallopian tubal epithelial cells supported the pluripotency of hESC culture in vitro [28]. The same group derived and established a hESC line on human fetal muscle fibroblasts in entirely animal-cell free conditions [28]. Since then different fetal and adult cells have been examined and shown to support the continuous growth of hESCs [29–32]. However, the use of hESCs for therapeutic application requires the use of defined culture media and controlled cell derivation, maintenance, and scale-up procedures. To overcome these obstacles, combinations of factors that influence the self-renewal of hESCs have been investigated, including soluble factors, extracellular matrix (ECM), cell–cell interactions, and mechanical forces.

Significant attempts have been made to identify culture conditions and media components which can regulate hESCs self-renewal. Growth factors in culture media can bind the cell surface receptors to promote self-renewal. These soluble factors include basic fibroblast growth factor (bFGF) [33,34], transforming growth factor β1 (TGFβ1)/activin A/nodal ligands [35,36], insulin-like growth factors (IGFs) [34,37], Wnt ligands [38,39], and glycogen synthase kinase-3 (GSK-3) inhibitors [40]. In one study, it was shown that hESCs can be expanded on human fibronectin using a medium supplemented with bFGF and TGFβ1 [41]. Noggin, an antagonist of bone morphogenetic protein (BMP), was found to be critical in preventing the differentiation of hESCs in culture. The combination of Noggin and bFGF was sufficient to maintain the proliferation of undifferentiated hESCs [42].

It has also been demonstrated that Wnt ligands affect ESC self-renewal and differentiation. For example, spontaneous differentiation of MEFs is inhibited by the addition of Wnt1 to culture media [38]. In addition, hESC differentiation is induced by using Wnt3 [22]; however, hESC self-renewal perturbs by the activation of canonical Wnt/β-catenin pathway through the expression of stabilized β-catenin [43]. Furthermore, hESCs maintained in media containing high concentrations of bFGF (24–36 ng/mL), alone or in combination with other factors, show characteristics similar to those in cultures maintained with feeder cell-conditioned medium [44,45].

The derivation of hESCs has also been achieved with minimal exposure to animal-derived material, using serum replacement and human foreskin fibroblasts as feeder cells [46], instead of the feeder cell layer [47], providing well-defined culture conditions [48]. Research is currently underway to determine how these conditions maintain cell integrity over long-term culture. For example, mTeSR hESC culture medium, which contains TGFβ1, lithium chloride (LiCl), bFGF, pipecolic acid, and gamma-aminobutyric acid, supports long-term self-renewal of feeder-independent hESC cell culture [48]. In addition to growth factors, lipid molecules such as sphingosine-1-phosphate [49–51], albumin [52], and synthetic lipid carriers [53] have been shown to regulate the self-renewal and prevent differentiation of hESCs. Although growth factor and media compositions can control hESC self-renewal, challenges, including maintenance of pluripotency, and production of biologically and functionally identical cells, still remain.

In addition to soluble factors, a defined ECM or biomaterial may be required for maintaining the hESC

self-renewal ability. Various biomaterials, such as Matrigel [54], human fibronectin [41], human vitronectin [55], collagen I [56], complex humanized matrices [48], hyaluronic acid hydrogels [57], or calcium alginate hydrogel [58], have been used as a structural support for hESC self-renewal. For example, Xu et al. showed that hESCs can be maintained on Matrigel or laminin and MEF-conditioned media [59]. These conditions support the growth of pluripotent cells, maintain normal karyotypes, preserve their proliferation and high telomerase activity, and differentiation into derivatives of all three germ layers, both in vitro and in vivo. In an attempt to find ideal ECM components or biomaterials for in vitro feeder-cell-free culture of hESCs, Hakala et al. compared various biomaterials, including ECM proteins (i.e., collagen IV, vitronectin, fibronectin, and laminin), human and animal sera matrices, and Matrigel in combination with a variety of unmodified or modified culture media. Matrigel in combination with defined mTeSR1 culture medium was found to be superior matrix for hESC culture compared to other biomaterials used in this study [54]. Similarly, in a combinatorial study, Brafman et al. developed a high-throughput technology, an arrayed cellular microenvironment, to assess the self-renewal of hESCs cultured on different ECMs in media comprising different growth factors. Long-term self-renewal of hESCs was obtained on a biomaterial consisting of collagen IV, fibronectin, collagen I, and laminin in defined StemPro media and MEF-conditioned media [60].

Self-renewal and differentiation of ESCs can be also regulated through intercellular interactions [60–63] and mechanical forces [64–66]. Cell–cell interactions and the formation of ESC colonies affect the self-renewal and spontaneous differentiation of ESCs. It has been shown that the size and shape of colonies play an important role in controlling ESC expansion [63,67]. Various microfabrication technologies have been employed to control ESC shape and size, such as micropatterning of substrate with ECMs [67] to confine colony formation to patterns, or formation of hESCs colonies in three-dimensional (3D) microwells [61,62]. Another important factor in hESC self-renewal is the application of mechanical forces (e.g., cyclic biaxial strain [64,65] or shear stress [66]) to the cells. Although the physiological effects of mechanical forces on self-renewal and proliferation of ESCs remain unknown, it has been shown that these forces can regulate cellular differentiation. For example, fluid flow–induced shear stress has been demonstrated to enhance the elongation and spreading of undifferentiated hESCs and induce vascular differentiation of hESC at higher shear stress [66].

Large-scale production of hESCs is critical for tissue-engineering applications, which require large numbers of cells. It is generally accepted that "classical" laboratory culturing methods are not suitable for the large-scale production of ESCs for therapeutic applications, and new culture systems are needed. Although two-dimensional (2D) methods such as the high density cultures of ESCs have been developed by combining automated feeding and culture methods, 3D culture may be a more suitable technology for large-scale expansion of ESC production.

At present, the aggregation of multiple ESCs is necessary to initiate embryoid body (EB) formation. The formation of large cellular aggregation may prevent nutrient and growth factor diffusion as well as metabolic waste removal from the aggregates in suspension cultures in large-scale systems. A small number of methods have been developed for the differentiation of mESCs in controlled cultures. Hanging drops and methylcellulose cultures have been shown to be somewhat efficient in preventing the agglomeration of EBs, but their complex nature makes their upscaling a rather difficult task.

A much simpler process in spinner flasks resulted in the formation of large cell clumps within a few days, indicative of significant cell aggregation in the cultures [68]. Compared to static culture system, spinner flasks enhance homogenous expansion of human EBs (hEBs) and can be easily scaled up to 10,000 L bioreactor tanks [69]. In one study, it was demonstrated that the growth rate of hEB is higher when cultured in stirred vessels than in other culture systems (e.g., static culture and rotary cell culture system) [70]. However, an increase of the culture medium stirring rate to avoid agglomeration within the stirred vessels resulted in massive hydrodynamic damage to the cells due to the extensive mixing in the vessels. Therefore in order to establish a scalable process for the development of EBs, there is a need for dynamic cultivation under controlled mixing conditions. One approach used a static system for an initial aggregation period of 4 days, followed by a period in dynamic culture in spinner flasks, to successfully achieve the bulk production of cardiomyocytes from differentiating mESCs [71].

In addition to suspension cultures using hEBs, stirred vessels can be also used for the scale-up expansion of undifferentiated hESCs through the combination of a microcarrier with the stirred culture systems. Various microcarriers such as polystyrene [72], collagen-coated dextran [73], and Matrigel-coated cellulose [74] have been used to promote hESC expansion in spinner flasks. In addition to hESC expansion, this combination of microcarriers and stirred culture systems has been used for directing hESC differentiation to definitive endoderm [75] and cryopreservation and recovery of undifferentiated hESCs adhered to microcarriers [76].

Another dynamic approach that was highly effective for hESCs is to generate and culture EBs within rotating cell culture systems [77]. These bioreactors provide

exceptionally supportive flow environments for the cultivation of hESCs, with minimal hydrodynamic damage to incipient EBs, reduced EB fusion, and agglomeration, and they allow the uniform growth and differentiation of EBs in three dimensions, as they oscillate and rotate evenly. hESCs cultured within these systems formed aggregates after 12 hours that were smaller and more uniform in size and evenly rounded due to minimal agglomeration; the yield of EBs was three times higher than that measured for static cultures. Also, dynamically formed EBs exhibited steady and progressive differentiation, with cyst formation and elaboration of complex structures such as neuroepithelial tubes, blood vessels, and glands [77].

Different rotary cell culture systems, including slow turning lateral vessel (STLV) and high-aspect rotating vessel (HARV), have been used to promote the efficiency of EB formation and differentiation of stem cells [77–80]. Generally, STLV systems are preferable to HARV for the EB aggregate formation and differentiation. It has been shown that the HARV system can lead to significant aggregation with large necrotic areas at the center and differentiations at the peripheries of aggregates. The aggregation rate of hESCs can be controlled by using the STLV system, which results in the formation of small-size hEBs [69,77].

To further enhance the large-scale differentiation of hEBs, a perfused STLV system was combined with a dialysis chamber to allow the diffusion of media as well as removal of waste products from the bioreactor [81]. Compared to static cultures, uniform growth and differentiation of hEBs to neural lineage was promoted when the combined rotary cell culture system/dialysis chamber was used [81]. Although rotary cell culture systems provide low-shear environments for hESCs cultivation and differentiation, they can only be scaled up to volumes of 5–500 mL, which is much lower than the scalability of stirred culture systems. These technologies have demonstrated the potential of engineering for the development of scalable technologies to expand ESC provision for research and therapies.

Directed differentiation

In cell culture, hESCs can spontaneously differentiate into cells of the three germ layers [82]. Perhaps, the biggest challenge in the clinical use of ESCs is the lack of knowledge of how to predictably direct their differentiation. For example, although ESCs can generate cells of hematopoietic, endothelial, cardiac, neural, osteogenic, hepatic, and pancreatic tissues, it has been very difficult to achieve directed differentiation into these tissues. The lack of homogeneous differentiation may be attributed to the intrinsic property of ESCs of differentiating stochastically in the absence of proper temporal and spatial signals from the surrounding microenvironment. Various techniques have been employed to control the differentiation of hESCs and to isolate a specific germ layer for tissue regeneration applications. The limitation of current techniques used for controlled differentiation is the low transformation efficiency, which results in a cell population containing ectoderm and mesoderm germ layers. The segregation of these germ layers can be achieved by using appropriate differentiation protocols. In this section, we describe some of the current approaches used to direct the differentiation of ESCs and give examples of their use.

Genetic reprogramming

To enable the production and propagation of target cell type populations, specific gene(s) are introduced into hESCs. Different techniques for knocking-in and knock-ingout genes into hESCs have already been established. For instance, chemical reagents or electroporation can be used for the transfection of undifferentiated hESCs with specific plasmids. Electroporation has been demonstrated to be useful for the generation of homologous recombination events [83]. Another technique includes the use of self-inactivated lentiviruses for the introduction of transgenes into hESCs, which was shown to be efficient with sustained expression in undifferentiated hESCs as well as in hESCs, which undergoes differentiation [84,85]. However, both the undifferentiated and differentiated hESCs were successfully infected by using adenoviral and adeno-associated viral vectors [86]. Another approach, which uses genetic manipulation, is the introduction of suicidal genes, which permits the ablation of the cells if necessary [87]. Using this approach, hESCs were transfected to express the herpes simplex virus thymidine kinase gene [88].

Genetic techniques involve both positive and negative regulators. The positive regulators include the constitutive or controlled expression of transcription factors that have been shown to derive the differentiation into particular tissues. For example, the overexpression of the Nurr transcription factor has been shown to increase the frequency of ESCs that differentiate into functional neural cells [89] and the use of mir-375 to enhance the differentiation into insulin-producing cells [90]. Alternatively, the negative regulators can be incorporated to induce the apoptosis of cells that differentiate to varying pathways. For example, neomycin selection and suicide genes that are activated by certain transcription factors can be used [91]. Recently, the use of a Forkhead box O1 (FoxO1) inhibitor (Lentiviral silencing) was shown to increase the differentiation of ESC-derived pancreatic progenitors into insulin-producing cells and increased insulin production following stimulation by glucose [92]. FoxO1 has an important

role in metabolic regulation and is profoundly expressed in insulin-responsive tissues [93].

In a study, Zoldan et al. developed a 3D siRNA delivery system using lipid-like materials, lipidoids, for the efficient transfection of hESCs. This system was used to direct the differentiation of hESCs to a specific lineage by knockingdown kinase insert domain receptor to prevent the differentiation of endoderm layer, leading the separation of this germ layer from mesoderm and ectoderm [94]. The developed 3D RNA delivery technique was shown to be preferable over a 2D environment for directing hESC differentiation, in which the transfection reagents are added to the media used for in vitro culture of hESCs-seeded 2D substrates. Clearly, all these techniques would benefit from a deeper understanding of inner workings of transient cells and knowledge of the differentiation pathways and lineages. Recently, the use of a synthetic network to program transcription factors was shown to allow the differentiation of ESCs into insulin-producing beta cells by Ref. [95].

Further analysis of the stem cell and progenitor hierarchy through high-throughput analysis of gene and protein profiles should accelerate this process. Despite the power of these approaches, one potential concern is that the genetic modifications may make the cells unsuitable for transplantation.

Microenvironmental cues

Another approach to directing ESC differentiation is through the use of microenvironmental cues that are important in regulating adult and ESC fate. During development, cells of the ICM are exposed to a series of tightly regulated microenvironmental signals. However, in tissue culture the complex expression patterns and spatial orientation of these signals can be lost. Currently, ESCs are grown in their primitive state as aggregated colonies of cells. To stimulate differentiation, two main methods have been examined. In one method, differentiated cells are derived from EBs. The formation of EBs can be accomplished by using either single ESC cell suspensions or from cell aggregates. EBs have been found to mimic the structure of the developing embryo and recapitulate different stages seen in its differentiation. In addition, clonally derived EBs can be used to locate and isolate tissue-specific progenitors. EBs initiate many developmental processes and help the differentiation of cells into all three germ layers. EBs are generally formed through suspension, encapsulation, and hanging drop methods [96]. More recently, magnetic forces were used to form EBs from iron oxide particle-laden stem cells [97].

In general, the differentiation of ESCs in EBs produces a wider spectrum of cell types, due to the EBs' ability to better mimic the temporal pattern of cell differentiation seen in the embryo. In some applications, combined use of EBs and adherent cultures has resulted in better cell yields. For example, to induce ESC differentiation to cardiomyocytes, EB formation in suspension cultures followed by differentiation in adhesion cultures has been shown to optimize the percentage of cells that give rise to cardiomyocytes [98,99]. Similarly, the production of hepatocytes has been shown to be induced by first culturing the cell in EBs and then in 2D cultures [100].

Neural progenitor cells were isolated from hESCs that showed positive immunoreactivity to neuron-specific antigens, responded to neurotransmitter application, and presented voltage-dependent channels in the cell membrane [101–104]. Various differentiation approaches, including adherent culture or EB suspension culture, have been used to direct the hESC differentiation to the neural lineage [105].

To promote neural differentiation, different soluble factors such as BMP-inhibitors, retinoic acid (RA), and other supplements (e.g., N2, B27, and ITS) are added to the media in adherent culture methods. In EB suspension culture systems, neural induction factors should be added during differentiation to induce neural differentiation of hESCs. The differentiated cells are then cultivated on adherent culture to allow for the neural cell growth. In both approaches the morphological characteristics of the neural progenitors can be maintained, and expression of NP-markers in the medium supplemented with FGF2 and B27 [105]. Highly enriched cultures of neural progenitor cells were isolated from hESCs and grafted into the stratum of rats with the Parkinson's disease [106]. The grafted cells differentiated in vivo into dopaminergic neurons and corrected partially behavioral deficits in the transplanted animals. A subsequent study showed that hESCs implanted in the brain ventricles of embryonic mice can differentiate into functional neural lineages and generate mature, active human neurons that successfully integrate into the adult mouse forebrain [107].

Oligodendrocytes and their progenitors were also isolated in high yield from hESCs [108]. Transplantation of these cells into animal models of dysmyelination resulted in integration, differentiation into oligodendrocytes, and compact myelin formation, demonstrating that these cells displayed a functional phenotype. In addition to in vivo differentiation of hESCs to neural lineages, ESCs can be combined with a biomaterial to induce the in vitro differentiation of ESCs to specific neural lineages in the presence of differentiation-inducing agents. For example, electrospun fibrous scaffolds not only enhanced the differentiation of mouse ESCs into specific neural lineages such as neurons, oligodendrocytes, and astrocytes but also supported the neurite outgrowth [109]. In recent years the use of carbon nanotubes (CNTs) for the neuron

differentiation from hESCs and neural growth has been also explored [110,111]. It has been shown that 2D scaffolds composed of poly(acrylic acid)-grafted CNT thin films promoted hESCs' neuron differentiation efficiency as well as protein adsorption and cell attachment compared to poly(acrylic acid) scaffolds without CNTs [110].

The differentiation of hESCs to neural lineages is induced by supplementation of the culture medium with relevant biochemical agents. Recently, it has been demonstrated that nanopatterning of the substrate can effectively control hESC differentiation to neural lineages in the absence of any biological and biochemical agents. In one study an ultraviolet-assisted capillary force lithography technique was developed to generate 350 nm pattern arrays using polyurethane acrylate [112]. The hESCs seeded on these patterns differentiated to neuronal lineage after 5 days of culture without the addition of differentiation-inducing agents [112]. It was also found that geometry and isotropy influence the efficiency of ESC differentiation and neural differentiation [113]. It was found that with the use of 250 nm topographies is more prone to neural differentiation [113]. Tall nanopillar configuration after chemical stimulation was found to be more efficient for ectodermal differentiation of ESCs [114]. Using gold nanoparticles, it was demonstrated that ESCs can sense topographies having size of less than 5 nm [115].

ESCs have been shown to give rise to functional vascular tissue. Three different strategies have been employed to induce vascular differentiation of ESCs:

1. EB formation
2. Coculture with fibroblast feeder layers or target cells
3. 2D monolayer culture of ESCs in defined chemical conditions combined with differentiation stimuli [116] (Fig. 27.3).

Spontaneous differentiation of ESCs to EB aggregates in a medium supplemented with cytokines has been shown to promote their differentiation to smooth muscle (SM) cells, pericytes, and endothelial cells [117,118]. One limitation of this strategy is that the ESCs differentiate to a heterogeneous cell population composed of vascular cells and other cell types from different embryonic germ layers. Various approaches have been employed to improve the efficiency of EB protocols to promote vascular cell differentiation, such as addition of vascular endothelial growth factor (VEGF)-A [119] or BMP4 [120], to culture media and using magnetic-activated cell sorting or fluorescence-activated cell sorting (FACS) [121].

Another approach to directing the vascular differentiation of hESCs is the use of coculture systems, where undifferentiated ESCs are seeded onto mouse fibroblast feeder layers such as stromal cells [122], MEF [123], or mouse endothelial cells [124] to enhance vascular differentiation. Alternatively, 2D monolayer culture on Matrigel [125], collagen IV [126], and fibronectin [127] combined with differentiation stimuli (e.g., addition of GFs/cytokines [125] or RA [128], mechanical stimulation [129], and hypoxia [130]) has been used for vascular hESC differentiation. Although these strategies increase the differentiation efficiency, isolation of progenitor cells expressing markers, [e.g., CD34, stem cell antigen (Sca)-1, or Flk1] during ESC differentiation is a crucial requirement for deriving homogenous vascular cell populations [125].

Early vascular progenitor cells isolated from differentiating mESCs were shown to give rise to all three blood and vessel cell types: hematopoietic, endothelial, and SM cells [131]. Once injected into chick embryos, these vascular progenitors differentiated into endothelial and mural cells and contributed to the vascular development. hESCs can also be differentiated into endothelial cells by using platelet endothelial cell adhesion molecule-1 antibodies [132]. In vivo, when transplanted into immunodeficient mice, these cells appeared to form microvessels.

Furthermore, it has been shown that monkey ESCs can give rise to endothelial cells when the embryonic cells were exposed to a medium containing combinations of growth factors. The isolated cells were able to form vascular-like networks when implanted in vivo [133]. Endothelial progenitor cells have been isolated from hESCs which presented hematopoietic [134] or SM cells competency. hESCs have been reported to differentiate into hematopoietic precursor cells when cocultured with bone marrow and endothelial cell lines [135]. When these precursor cells are cultured on semisolid media with hematopoietic growth factors, they form characteristic myeloid, erythroid, and megakaryocyte colonies.

Cardiomyocytes have been isolated from hESCs for the treatment of cardiac diseases. The most common approach to induce in vitro differentiation of hESCs to cardiomyocytes is the formation of EB aggregates followed by few days postplating on a 2D substrate to obtain cells with cardiomyocyte characteristics [136]. Cardiomyocyte differentiation of hESCs can be also induced by coculturing undifferentiated hESCs with a mouse visceral endoderm-like cell line (END-2) [137]. Cardiomyocytes isolated from hESCs expressed sarcomeric marker proteins, chronotropic responses, and ion channel expression [137]. One week after culturing in differentiation conditions, beating cells were observed and continued to increase in number while retaining their contractility for 70 days [138]. The beating cells expressed markers characteristic of cardiomyocytes, such as cardiac α-myosin heavy chain, cardiac troponin I and T, atrial natriuretic factor, and cardiac transcription factors GATA-4, Nkx2.5, and MEF-2. Electrophysiology demonstrated that most cells resembled human fetal ventricular

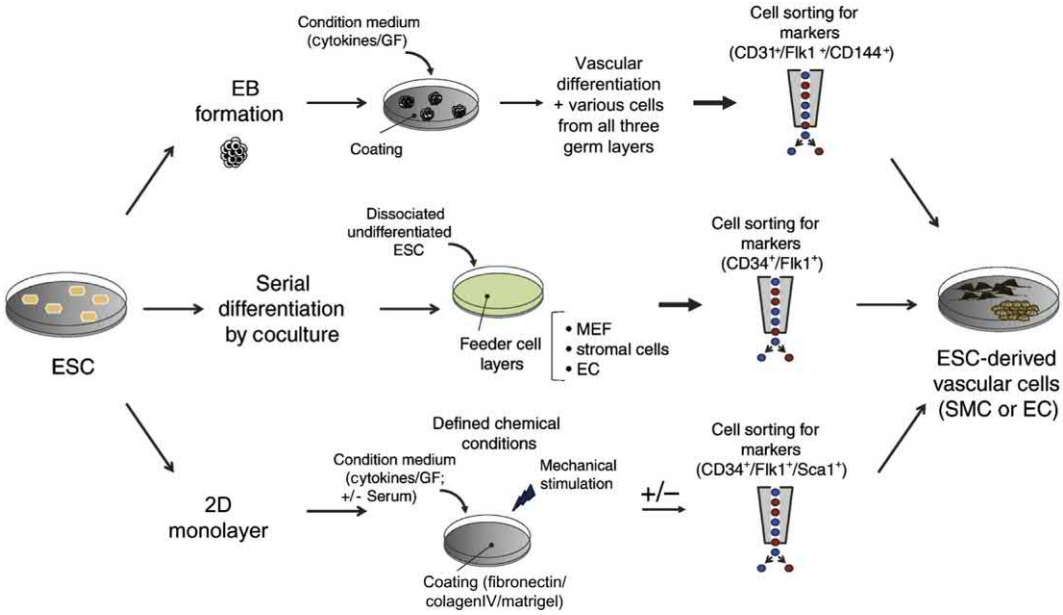

FIGURE 27.3 Approaches used for vascular differentiation of ESCs.
Vascular cell differentiation is mainly induced by three culture methodologies: differentiation through EBs, coculture with fibroblast feeder layers or target cells, and monolayer culture of ESCs in defined chemical conditions. *ESCs*, Embryonic stem cell. *Adapted from Descamps B, Emanueli C. Vascular differentiation from embryonic stem cells: novel technologies and therapeutic promises. Vascul Pharmacol 2012;56(5–6):267–79.*

cells. Despite the progress made over the last decade, knowledge about the mechanism of the formation of functional cardiomyocytes from hESCs remains limited.

Insulin-producing β cells were also generated from hESCs [139], by spontaneous differentiation of hESCs in adherent or suspension culture conditions [140] and using media which contained growth factors [141,142]. Reverse transcription-polymerase chain reaction detected an enhanced expression of pancreatic genes in the different cells [141]. Immunofluorescence and in situ hybridization revealed high percentages of insulin-expressing cells [141].

There has been great interest in examining the osteogenic potential of ESCs derived from both mice and humans. hESCs can differentiate into osteogenic cells (OCs) with the same media supplements that are used to differentiate adult mesenchymal stem cells (MSCs), because of their high self-renewal capability [143]. Current issues associated with the osteogenic differentiation of hESCs include the formation of nonhomogeneous cell populations and limited numbers of differentiated cells. To overcome these limitations, various growth factors and reagents such as β-glycerophosphate, ascorbic acid, dexamethasone, and osteogenic factors have been used to create osteoprogenitor cells from hESCs [144–147]. In addition, the differentiation efficiency of hESCs into a homogeneous OC population was improved through coculturing of hESCs with human primary bone-derived cells in the absence of exogenous factors [148].

The OC-derived from hESCs (OC-hESCs) were seeded on an apatite-coated poly(D,L-lactide-*co*-glycolide)/nano-hydroxyapatite (PLGA/HAp) composite scaffold and subcutaneously implanted in immunodeficient mice to examine in vivo bone formation [149]. The results of in vivo studies demonstrated that the implanted OC-hESCs and apatite-coated PLGA/HAp scaffold induced the formation of large amounts of new bone tissue within the defect site, demonstrating the possibility of using hESCs for bone regeneration [149]. Our group showed that culturing hESCs without EBs leads to an over sevenfold increase in the number of OCs and to spontaneous bone nodule formation after 10–12 days [150]. In contrast, when hESCs were differentiated as EBs for 5 days followed by plating of single cells, bone nodules formed after 4 weeks only in the presence of dexamethasone.

It was shown that the fully decellularized trabecular bones as 3D osteoconductive scaffolds in medium perfused bioreactors cultivated with hESC-derived mesenchymal progenitors led to the formation of large and compact bone constructs. Implantation of engineered bone in immunodeficient mice performed the maintenance and maturation of bone matrix for 8 weeks without any teratomas formation which was largely occurred for groups with undifferentiated hESCs alone or in bone scaffolds. Accordingly, hESC-progenitors can be used in tissue-engineering approaches to grow bone grafts for transitional applications [151].

In another study, native heart ECM was successfully used to direct the cardiac differentiation of hESCs in vitro [152]. Various hydrogels were prepared from decellularized heart ECM blended with collagen type I at varying ratios. Maturation of cardiac function in EBs formed from hESCs was documented in terms of spontaneous contractile behavior and the mRNA and protein expression of cardiac markers. Hydrogel with high ECM content (75% ECM, 25% collagen, no supplemental soluble factors) increased the fraction of cells expressing cardiac marker troponin T (cTnT), when compared to either hydrogel with low ECM content (25% ECM, 75% collagen, no supplemental soluble factors) or collagen hydrogel (100% collagen, with supplemental soluble factors). Native ECM is recognized as a promising biomaterial system since it can induce hESC cardiac differentiation without the need for addition of soluble factors, hence it can be used for basic studies of cardiac development and potentially for the therapeutic delivery of cells to the heart.

Three-dimensional versus two-dimensional cell culture systems

In an appropriate environment, ESCs can differentiate into complex 3D tissue structures. These environments are designed to resemble the key features of the hESC's niche and are favored over the 2D systems, which limit the cellular interactions and signaling and hamper the subsequent differentiation of hESC into functional tissues [6,153]. The use of a biomaterial may act as a temporary ECM, providing physical cues for cell orientation, spreading, differentiation, and the remodeling of tissue structures. Hydrogels represent an attractive option to provide 3D environment. When hESCs were encapsulated in hyaluronic acid, they were shown to retain their pluripotency for 20 days and allow for controlled differentiation [57]. Other types of hydrogels such as chitosan were also shown to preserve pluripotency and self-renewal capacity of the hESCs [154]. The use of alginate hydrogel allowed the preservation of hESC pluripotency for 260 days [58]. It was also demonstrated that the 3D environment created by cell encapsulation in Matrigel failed to support hESC growth and 3D organization, and this was likely due to the fact that Matrigel was unable to resist the force of cell contraction.

It has been demonstrated that the biochemistry, topography, and physical properties of the scaffold can regulate stem cell differentiation and function [6,155]. Culture of hESCs in PLGA scaffolds in specific media containing TGFβ, activin A, or IGF induced the differentiation of the cells into 3D structures with characteristics of developing neural tissues, cartilage, or liver, respectively [156]. Using a chondrogenic medium that contains BMB2 and TGFβ3, it was shown that EBs derived from hESC can lead to the formation of cartilaginous nodules [157]. Cartilage repair was obtained from chondrocytes that were differentiated form ESC-derived MSCs in rats [158]. ESC-derived chondrocytes that were embedded in fibrin gel were also successfully shown to lead to repair of cartilage defects in rats [159].

In the spinal cord the usefulness of ESC-derived neuroprogenitors was demonstrated in one study on experimental dorsal root avulsion injury [160]. Promising results were also obtained from a recent clinical trial employing ESCs for the treatment of spinal cord injury [161]. Oriented Polycaprolactone scaffolds were used to help the differentiation of ESCs to neurogenic lineage [162].

Furthermore, when these cells were cultured in PLGA and poly-L-lactide (PLLA) scaffolds in the presence of media containing nerve growth factor and neurotrophin 3, enhanced numbers of neural structures were observed [163]. In one study, hESC-derived EBs cultured with a 3D collagen scaffold exhibited liver-specific genes expression and albumin production in the presence of exogenous growth factors and hormones [164]. The addition of signaling factors such as activin A and Wnt3a to this system may improve the efficiency of hESCs differentiation and production of functional hepatic endoderm [165].

Similarly, the culture of ESCs in a 3D collagen scaffold, stimulated with exogenous growth factors and hormones, led to the differentiation of the cells into hepatocyte-like cells. These cells were characterized by the expression of liver-specific genes and synthesis of albumin, and the differentiation pattern observed compared favorably to cells differentiated in a 2D system. It was also reported that the differentiation of rhesus monkey ESCs in 3D collagen matrices was different from that which took place in monolayers [166]. Various signaling molecules can be immobilized into matrices and tailor the microenvironment toward desired differentiation [167].

Alginate scaffolds were also used for the differentiation of hESCs [168]. These scaffolds induced vasculogenesis in encapsulated cells to a larger extent than cells grown in bioreactors. Tantalum scaffolds also increased the differentiation of mESCs into hematopoietic cells as compared to traditional 2D cultures [169]. Therefore the 3D culture systems can promote hESC differentiation and assembly into functional tissues, through better mimicking of the 3D structural organization of native tissue compared to 2D systems.

High-throughput assays for directing stem cell differentiation

Today, chemists and engineers are equipped with tools that enable them to synthesize molecules and test their

effects on cells in a high-throughput manner. For example, libraries of small molecules, polymers, and genes have been generated and used to screen candidate molecules to induce osteogenesis [170] and cardiomyogenesis [171] in ESCs as well as the dedifferentiation of committed cells [172]. The use of chemical compound libraries may provide a method of addressing the complexities associated with native microenvironments by directing cell behavior through interacting with transcription factors and cell fate regulators.

Microscale technologies can facilitate high-throughput experimentation and provide a powerful tool for screening whole libraries of molecules and biomaterials. To produce microarrays, where cell–matrix interactions can be tested and optimized in a high-throughput manner, robotic spotters that are capable of dispensing and immobilizing nanoliters of material were used. For example, arrays of synthetic biomaterials have been produced to investigate the interaction of stem cells with various external signals [173]. Using this method, it was possible to synthesize thousands of polymeric materials and investigate their effects on the differentiation of hESCs [174] and human MSCs [175]. Unexpected and novel cell–material interactions were discovered. In future, this technology may prove useful for application in cell-microenvironment studies and in the identification of cues that can be used for the induction of desired cell responses.

In addition to the use of this method for analyzing synthetic material libraries, it is also possible to study the effect of natural ECM molecules on the fate of cells, in a high-throughput manner [173]. In one example, combinatorial matrices comprising different natural ECM proteins were investigated for their ability to maintain differentiated hepatocyte function and to induce murine ESC differentiation into hepatocytes [176]. Recently, Huang et al. used a microscale direct writing technique to print ECM components (e.g., collagen IV, gelatin, and fibronectin) into diverse geometries and compositions on 2D surfaces for assessing the effect of ECM geometry and composition on ectodermal differentiation of murine ESCs [177]. It was shown that ECM compositions, soluble factors, and surface topography could regulate ESC attachment and differentiation [177].

Microfabrication techniques have been also used to control cell–cell interaction and to form hESC-derived EB aggregates with defined sizes and geometries. For example, in one study, soft lithography was used to fabricate cell-repellant poly(ethylene glycol) (PEG) microwells for the formation of EB aggregates with controlled sizes and shapes, determined by the geometry of the microwells (Fig. 27.4A). The EB cell aggregates formed within the microwells remained viable and maintained their geometries over at least 10 days of culture. Using this system, the EB aggregates could pattern into various shapes and sizes (Fig. 27.4B–D) [178]. To control the shape and direct the differentiation of EBs, RA-loaded PLGA microspheres were used to deliver morphogenic factors within EB microenvironments in a spatiotemporally controlled manner [179]. Homogenous differentiation of cystic spheroids with a biepithelial morphology was obtained when EBs were cultured on the fabricated microspheres [179].

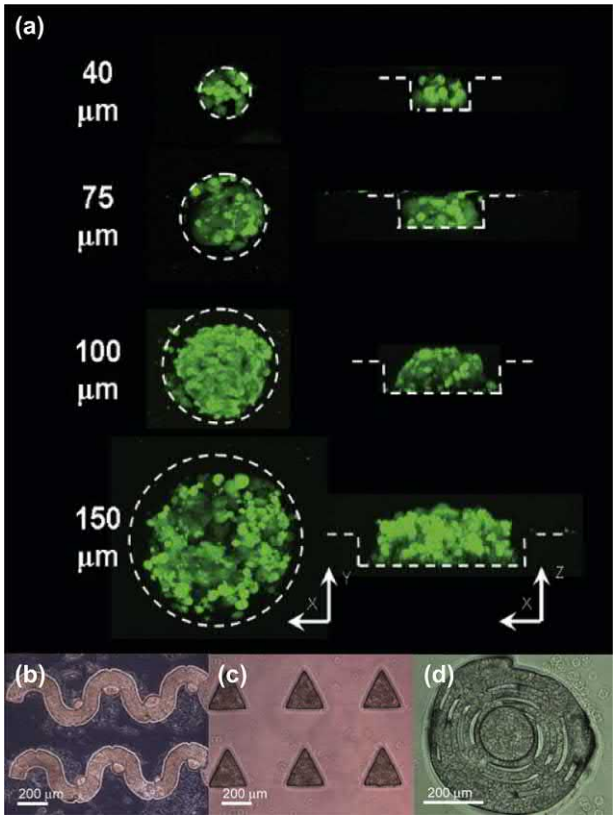

FIGURE 27.4 Microwells for the formation of EBs with controlled size and shape.
(A) Confocal images of fluorescently labeled EB cell aggregates within microwells with different diameter ranging from 40 to 150 μm on day 5 of culture; formation of EBs with different shapes, including (B) curves, (C) triangles, and (D) swirls. *Adapted from Karp JM, Yeh J, Eng G, Fukuda J, Blumling J, Suh KY, et al. Controlling size, shape and homogeneity of embryoid bodies using poly (ethylene glycol) microwells. Lab Chip 2007;7(6):786–94.*

In another study the effect of EB aggregate size on its differentiation was investigated by seeding ESC on PEG microwells of various diameters [180]. It was found that larger microwells (450 μm diameter) induced differentiation of ESC to cardiogenesis through the expression of Wnt11. However, EBs formed in small (150 μm) microwells differentiated to endothelial cell by increased expression of Wnt5a [180].

Cell arrays have been also used to pattern stem cells on substrates. Arrays of cells can be used to localize and track individual cells, which enable clonal analysis of the

fate of stem cells. For example, real-time microscopy was used to track the progeny of neural stem cell clonal populations that were immobilized in microfabricated structures, producing useful information about cellular kinetics and stem cell fate, in a high-throughput manner [181]. It can be, thus, anticipated that such method may be used for investigating the response of individual stem cells to different microenvironmental signals.

Cell patterning on geometrically defined shapes has been used to study the effects of cell shape on cell fate decisions. As cells adhere onto a micropatterned substrate, they align themselves to the shape of the underlying adhesive region. A change in shape induces changes in the cell cytoskeletal features, which in turn influence cell apoptosis, proliferation [182], and differentiation [183]. Coculturing ESCs with secondary cells can promote their differentiation into specific cell lines [184]. For this purpose, Fukuda et al. developed a technique to fabricate micropatterned cocultures of ES with secondary cell lines on surfaces containing three different layers of hyaluronic acid, fibronectin, and collagen [185]. First, the hyaluronic acid was micropatterned on a glass substrate. Then fibronectin was deposited on the areas of exposed glass to create cell adhesive regions. After the cell attachment on fibronectin-coated areas, a layer of collagen was added to hyaluronic acid patterns to switch surface properties and facilitate the adhesion of the second cell type. Using this system, the patterned cocultures of ESCs or AML12 cells with NIH-3T3 could be obtained [185]. Further elucidation of the molecular mechanisms indicated that cell shape regulated the activation of the RhoA pathway demonstrating that stem cell differentiation can be influenced by mechanical stresses. Therefore the use of micropatterning to control cellular microenvironment may be useful for application in directing stem cell fate for tissue engineering.

Physical signals

With advances made in biomaterials, it is becoming possible to influence ESCs by using physical cues such as mechanical forces [186]. Mechanical forces affect the differentiation and functional properties of many cell types and are being increasingly used in tissue engineering. For example, functional autologous arteries have been cultured using pulsatile perfusion bioreactors [187]. Although it is known that mechanical stimuli (such as cyclic stretching and fluid shear stress) may be required to direct the differentiation of ESCs, understanding their effects is still in its infancy [188].

In one study, fluid shear stress was applied to induce Flk-1-positive ES differentiation into vascular endothelial cells through the activation of Flk-1. The expression of vascular endothelial cell-specific markers such as Flk-1, Flt-1, VE cadherin, and PECAM-1 enhanced in the presence of shear stress; however, shear stress had no effect on markers of epithelial or SM (keratin or α-SMA) [188]. In another study, Shimizu et al. demonstrated that cyclic uniaxial stretching on Flk-1-positive ES cells for 24 hours significantly increased the expression of vascular smooth muscle cell (VSMC) markers α-SMA, and SM-myosin heavy chain, decreased the expression of EC marker Flk-1 and had no effect on the other EC markers (Flt-1, VE cadherin, and PECAM-1) [189]. Platelet-derived growth factor (PDGF) receptor beta kinase inhibitor blocked cell proliferation and VSMC marker expression that were induced by applying mechanical stimulation [189]. Mechanical stretching and fluid shear stress have been also used to direct ES cell differentiation into cardiovascular lineages [190,191]. Taken together, these studies demonstrate that mechanical stimulation can enhance the ability of ESCs to respond to exogenous signals and promote their differentiation into a specific lineage. In one study the hESC differentiation on deformable elastic substrates was inhibited by applying a 10% cyclic stretch [65]. The expression of Oct4 and SSEA-4 was promoted in the presence of mechanical stimulation, demonstrating an increase in hESC self-renewal. It was also found that mechanical stretch inhibited hESC differentiation when the cells were cultured in a mouse MEF-conditioned medium. However, differentiation of hESCs was not affected by mechanical stimulation when an unconditioned medium was used [65]. It was also recently found that the mechanical stimulation of ESCs in 3D leads to early expression of cartilage marker gene and to improved differentiation of ESCs to chondrogenic cells [192].

Other environmental factors that may be required include electrical signals. For example, it was found that electrical field stimulation could affect cardiac differentiation and reactive oxygen species generation in hESC-derived EBs [193]. Hopefully, with time, such techniques will allow for the development of ESC-based tissue-engineering applications. The design of bioreactors that control the spatial and temporal signaling that induce ESC differentiation requires further collaborative efforts between engineers and biologists.

Microfluidic systems can be also used to investigate the effect of growth factor and chemical environments on stem cell differentiation in a high-throughput manner. For example, a microfluidic device was developed to generate a concentration gradient of growth factors for optimizing the proliferation and differentiation of stem cells. The developed platform enabled rapid optimization of media compositions by exposing the cells to a continuous gradient of various growth factors within the microfluidic environment to induce proliferation and differentiation in a graded and proportional manner, depending on growth factor concentration [194]. In another study, microbioreactor arrays system comprised a microfluidic

platform, and an array of micro-bioreactors was designed to investigate the effect of culture microenvironments on hESCs differentiation both in 2D and 3D culture conditions [66,195] (Fig. 27.5A–D). Medium perfusion promoted the viability of encapsulated hESCs within hydrogels (67% viability in perfused culture compared to 55% in static culture) (Fig. 27.5E and F). In addition, using this system, it was possible to induce the vascular differentiation of hESCs through the addition of vascular growth factor (hVEGF) to the culture media [195] (Fig. 27.5G and H).

Recently, the role of magnetic particles in guiding stem cell differentiation was reported by Du et al. [97], who used an externally applied magnetic field to pull iron oxide nanoparticle-laden ESCs together and form EBs. These EBs were then exposed to mechanical stretching by using opposing magnetic fields that led the cells to differentiate toward cardiac lineage.

In addition, where both chemical and physical (mechanical) factors are combined to more closely mimic events seen in vivo, new results may be obtained; for example, uniaxial strain was applied to ESC along with chemical stimulus and it was found that myogenic differentiation was significantly higher for group with mechanical loading compared to ESCs alone and ESCs with mechanical and chemical stimuli [196].

Micro-bioreactor arrays for controlling cellular environments: design principles for human embryonic stem cell applications. Methods 2009;47(2):81–9.*

Isolation of specific progenitor cells from embryonic stem cells

Although hESCs can generate specific functional cell types from all three germ layers, it has been exceedingly difficult to directly differentiate the cells in culture and obtain pure cell populations. Isolation of a specific differentiated population of cells for transplantation will eliminate the presence of undifferentiated hESCs, which have tumorigenic potential, and allow for efficient use of the various cell populations for therapeutic purposes. With the exception of few cases, where the enrichment of cells of interest was almost fully achieved [101,106,108], the protocols adopted for the differentiation of hESCs do not yield pure cell populations. Therefore there is a need for suitable techniques to isolate desired cells from heterogeneous cell populations (Table 27.1). One approach for achieving this is to isolate specific cells by using cell surface markers and FACS. In this case, the initial population of cells is immunostained by a single or a combination of different markers, and the desired cell type is isolated by FACS. Part of the initial population of cells is also labeled with isotype controls to gate the populations. The use of FACS yields a pure population of cells and allows one to select cells using different markers [134], but the limitations of this technique may hamper the final cell survival.

Magnetic immunoselection has been used to isolate specific differentiated cells [103,135,204]. Initially, the cells are labeled with relevant cell surface antibodies conjugated with magnetic beads. The magnetically labeled cells are then separated from the other ones by a magnetic

column to purities that are generally higher than 80% [204]. Although these purities are slightly lower than the ones obtained by FACS, the magnetic selection is less harmful to the cells than FACS. Recently, different surface markers specific for cardiomyocytes have been identified: Emilin2 [197] and later SIRPA [198,199] and VCAM [199,200]. These findings allow the prospective isolation of live cardiomyocytes, from ESCs or iPSCs-differentiated mixed cardiac population, with purities above 95%.

Another potential method for cell isolation is through reporter gene knock-in modifications [207]. For example, to trace hepatic-like cells during differentiation of hESCs in culture, a reporter gene expressed under the control of a liver-specific promoter was used [207]. For that purpose, hESCs underwent stable transfection with eGFP fused to the albumin minimal promoter sequence. This methodology allowed one to follow the differentiation pattern of hESCs into hepatic-like cells and to isolate those cells by FACS using the fluorescence of eGFP. Similarly, hESCs are genetically manipulated to carry the Nkx2.5-eGFP reporter construct, allowing the isolation of cardiac cells [199]. Since Nkx2.5 is an early cardiac transcription factor, it allows the identification and isolation of early cardiac progenitors.

Isolation of a specific differentiated population of cells may also be accomplished by mechanical/enzymatic separation of cells exhibiting specific morphology, functional activity, or adhesion to a substrate. For example, cardiomyocytes have been isolated by dissecting contracting areas in EBs and dissociating those areas using collagenase [208]. Oligodendroglial cells were isolated from stem cell aggregates that adhered to a specific substrate [108]. In addition, neuroepithelial cells were isolated from EBs attached to a tissue culture-treated flask by using dispase [103], an enzyme that selectively detached neuroepithelial islands from the EBs, leaving the surrounding cells adhering. It is also possible to take advantage of the cell body content of specific cell types. For example, cardiomyocytes have a higher mitochondrial density than their progenitors and other cardiovascular cells, such as SM and endothelial cells. It is, thus, possible to isolate cardiomyocytes by flow cytometric sorting using the mitochondrial dye tetramethylrhodamine methyl ester percholate without genetic modification or surface antigen staining [201].

Transplantation

The first application of stem cells as a cellular replacement therapy is associated with bone marrow transplantation and blood transfusion in which donor hematopoietic stem cells repopulate the host's blood cells [209]. Today, modalities are being developed for cell-based regenerative therapies of numerous diseases, including diabetes, Alzheimer's disease, Parkinson's disease, multiple sclerosis, spinal cord injury, liver failure, muscular dystrophy, bone, and cardiovascular disease, among others [82]. Despite the advances in the development of disease models [210], only a few studies have reported the in vivo functionality of hESC-derived cells. In most cases the cells are injected into a disease area, and their functionality is evaluated by immunohistochemistry and functional tests. Using such methods, partial functional recovery of a mouse model of Parkinson's disease after hESC-derived neural progenitor cells has been reported [106]. Also, transplantation of hESC-derived oligodendroglial progenitor cells into the *shiverer* model of dysmyelination resulted in myelin formation [211].

Studies of neural regeneration in animal models have given very promising results [212–214]. In particular, hESC-derived oligodendrocytes have been shown to repair injured spinal cord in animal models with rebuilding myelin sheets [215]. Based on this system, in 2010 Geron started the first clinical trial for the treatment of patients with spinal cord injury. A clinical trial also started for the treatment of Stargardt's macular dystrophy, a pathology characterized by the death of photoreceptor cells in the central part of the retina (called the macula). This trial was based on the promising observation that hESCs are able to differentiate into retinal pigmented cells [216–218].

A new important step toward the clinical application of hESCs for infarct therapy is the finding that hESC-derived cardiomyocytes electrically couple and are protective against arrhythmias in the recipient heart when transplanted into guinea pigs [219], an animal model with a much closer heart physiology to humans than that of rodents.

Despite the ability of stem cells to differentiate into cells with desired phenotypic and morphological properties, there have been few scaffold-based tissue-engineering studies that use ESCs, by differentiating these cells in culture, selecting desired cell types, and seeding these into scaffolds. Ideally, scaffolds provide cells with a suitable growth environment, facilitated transport of oxygen and nutrients, mechanical integrity and suitable degradation. The scaffold brings the cells into close proximity and thereby enhances the formation of tissue structures.

Tissue-engineering scaffolds are comprised either synthetic or natural materials or a composite of the two. Scaffolds are commonly made of synthetic materials, such as hydroxyapatite, calcium carbonate, PLLA, polyglycolide, PLGA, poly(propylene fumarate), and natural materials such as collagen, Matrigel, or alginate. Natural materials typically have better biocompatibility, while synthetic materials provide better control of various

properties such as degradation rate, biomechanics, and structure [15]. hESC-derived endothelial progenitors were seeded onto highly porous PLGA biodegradable polymer scaffolds to form blood vessels that appeared to merge with the host vasculature when implanted into immunodeficient mice. These endothelial progenitor cells were also able to support the formation of vascularized skeletal muscle [220]. Osteoblast-like cells derived from hESCs were also transplanted into an animal model by using a poly(D,L-lactide) scaffold. After 35 days, regions of mineralized tissue could be identified within the scaffold by Von Kossa staining and expression of human osteocalcin [144]. For cardiac tissue engineering, synthetic materials were used in the form of injectable hydrogels and surfaces that can be treated to get detached from cardiomyocyte layers [221,222]. Recently, clinical usefulness of ESC-derived cardiac progenitor-laden fibrin was shown [223], including the improvement in their symptoms and systolic motion after ischemic cardiac dysfunction [224]. It was also recently shown that ESC-derived pancreatic progenitors that were encapsulated in alginate were possible to implant and maintain their viability, insulin production, and regulation of glucose levels for over 170 days in mice [225].

Transplantation and immune response

One of the major obstacles for successful transplantation of hESC-derived differentiated cells is their potential immunogeneity. As long-term immunosuppressive therapy would limit clinical applications, the creation of immunologic tolerance would enable stem cell–derived therapy. Methods currently under development include

1. the establishment of hESC line banks large enough to represent the majority of tissue types;
2. nuclear reprogramming of the cells to carry patient-specific nuclear genome (therapeutic cloning);
3. creation of "universal cells" by manipulating the major histocompatibility complex (MHC) [185];
4. deletion of genes for immune response proteins using homologous recombination (as mentioned earlier); and
5. the generation of hematopoietic chimerism, to create the required tolerance for tissues or cells derived from it [226].

The latter method was demonstrated using rat embryonic-like stem cells that permanently engrafted when injected into full MHC mismatched rats [227].

Although the rejection of ESC-derived tissues is triggered by minor histocompatibility antigens, simple host conditioning with monoclonal antibodies against CD4 and CD8 could be sufficient to induce transplantation tolerance of ESC-derived donor tissue, but not of primary animal tissue [228]. It was recently observed that hESCs-derived mesenchymal progenitors have strong immunosuppressive properties [229], similar to bone marrow-derived MSCs [230], resulting in the inhibition of CD4 + or CD8 + lymphocyte proliferation and being more resistant to natural killer cells.

As an alternative to the novel approach of iPSC generation for autologous transplantation or disease-specific drug screening, therapeutic cloning or somatic cell nuclear transfer (SCNT), the process through which Dolly the sheep was cloned in 1997, might be an important tool to create hESCs from patient-specific genome and thus preventing immunorejection [231] (Fig. 27.6).

This is important for the application of hESCs in tissue engineering and regenerative therapeutics [232] where transplantable populations of cells can be generated with genes that are derived only from the patient. Studies to

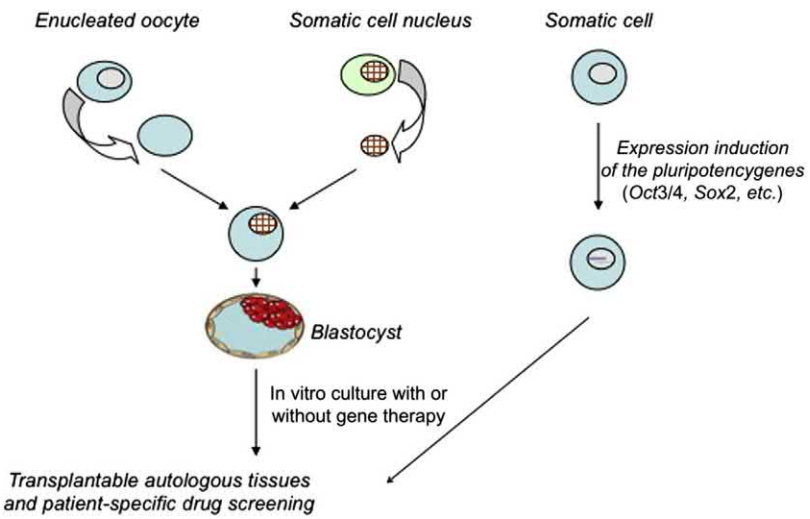

FIGURE 27.6 Schematic diagram of therapeutic cloning.
A somatic cell nucleus is transferred into enucleated oocyte to form a cell capable of giving rise to a blastocyst, which can be used to derive therapeutic cells. Alternatively, somatic cells are reprogrammed into iPS cells that can also be differentiated into therapeutic cells. In both cases, the resulting cells are used to engineer tissues for regenerative medicine and drug screening applications. *iPS*, Induced pluripotent stem.

date have demonstrated that cells derived by SCNT can be expanded in culture and will organize into tissue structures if transplanted with biodegradable scaffolds. However, before SCNT research can be translated into human therapies, the reliability of the overall process needs to be improved, including prevention of the alterations in gene expression.

Immunoisolation systems may help overcome the problems with the immunological incompatibility of the tissue. Thus immunoisolation of cells may prove to be particularly useful in conjunction with ESCs to overcome the immunological barrier associated with the ESC-based therapies. Cells may be immobilized within semipermeable polymeric matrices that provide a barrier to the immunological components of the host. Membranes can be designed to be permeable to nutrients and oxygen while providing a barrier to immune cells, antibodies, and other components of the immune system, by adjusting the cutoff size of membrane pores [233,234]. Within these systems, the engineered tissues can either be implanted or used as extracorporeal devices. Such closed tissue-engineering systems have been used for the treatment of diabetes [235–237], liver failure [238–240], and Parkinson's disease [241–244]. For example, ESC-derived β-cells that can respond to insulin or dopamine-producing neurons can be used in clinics without rejection. In addition, closed systems can protect the host against potentially tumorigenic cells.

Currently, engineering and biological limitations such as material biocompatibility, molecular weight cutoff, and immune reaction to shed antigens by the transplanted cells are some of the challenges that prevent these systems from widespread clinical applications.

Future prospects

Despite significant progress in the field of tissue engineering and ESC biology, there are a number of challenges that provide a barrier to the use of ESCs for tissue engineering. These challenges range from understanding cues that direct stem cell fate to engineering challenges on scale-up, to business questions of feasibility and pricing.

Although the derivation of hESCs from the ICM of preimplantation blastocysts has become a standard procedure and has been performed in a variety of laboratories, live human embryos must be destroyed in the process, which is ethically unacceptable. However, recent reports show that ESCs can be isolated without destroying blastocysts [245]. The generation and use of iPSCs require no embryo at all, overcoming the ethical issues associated with ESCs.

Stem cells and their progeny reside in a dynamic environment during development; thus a scaffold should be designed to mimic the signaling and structural elements in the developing embryo. The use of "smart" scaffolds that release particular factors and/or control the temporal expression of various molecules released from the polymer can help induce differentiation of ESC [246]. For example, by dual delivery of VEGF-165 and PDGF, each with distinct kinetics, and from a single polymer scaffold, resulted in the formation of stable vascular networks [246]. The use of stimuli-responsive materials is another advancing area [247] that can benefit the manipulation and control of stem cell fate and function. An alternative approach to modifying the surface exposed to the cells is to immobilize desired ligands onto the scaffold. For example, arginylglycylaspartic acid peptides, the adherent domain of fibronectin, can be incorporated into polymers to provide anchorage for adherent cells.

Another difficulty with the currently used materials is limited control over the spatial organization of the scaffold. Spatial patterning is necessary to create tissues that resemble the natural structure of biological tissues. In the direct cell patterning system, cells can be seeded into the scaffold at particular regions within the cells. For example, the direct attachment of two different cell types in different regions of the scaffold has been used to generate cells of the bladder. Cell patterning was critical for the effective coculture of hepatocytes and fibroblasts. In addition, the technique of 3D bioprinting has advanced to offer more control over precise localization of cells and active molecules in 3D-printed constructs [248] that can be further used to develop more sophisticated engineered tissue constructs that can be sued for precision medicine. When stimuli-responsive materials are used in 3D printing, a new generation of four-dimensional dynamic engineered constructs can be developed [249]. With the utilization of various molecules, smart materials, and advanced fabrication techniques, it will be possible to leverage the potential stem cells for engineering of tissue constructs.

Stem cells can be used in different 3D bioprinting techniques that include inkjet, extrusion, and laser-assisted printings [250]. Using laser direct writing, EBs with different sizes were formed by using mESCs with controlled initial cell density. The size of the printed colonies was independent of EBs, which represents a viable tool for creating well-defined stem cell microenvironments [251]. Studies have shown that ESCs can maintain their pluripotency following their printing using laser direct writing [252]. 3D bioprinted ESC-laden hydrogel holds promise for use in expansion of ESCs to form pluripotent, high-throughput, and size-controllable EBs [253]. The technique of 3D bioprinting offers new possibilities to expand the potential of stem cells and their use for engineering of tissue constructs that can be used in turn, for the production of tissue models or for regenerative therapeutics.

Conclusion

A number of challenges are still ahead of us before ESC-based therapy can become clinically viable. These include directing the differentiation of ESCs (i.e., using controlled microenvironments or genetic engineering), ensuring their safety (i.e., by eliminating tumorogenicity), functionally integrating differentiated cells into the body, achieving long-term immune compatibility, and improving the cost and feasibility of cell-based therapies. Each of these challenges is currently being addressed. In particular, since ESCs can give rise to many different cell types, solving these challenges for the various possible tissue types will be a major undertaking. Further research is required to control and direct the differentiation of ESCs, in parallel with developing methods to generate tissues of various organs, to realize the ultimate goals of tissue engineering. We might be getting close to a day when ESCs can be manipulated in culture to produce fully differentiated cells that can be used to repair and regenerate specific organs. Clearly, our ability to overcome these difficulties is not confined within any single scientific discipline but rather involves an interdisciplinary approach. Solving these challenges could lead an improved quality of life for a variety of patients that could benefit from tissue-engineering and regenerative therapy approaches.

Gene therapy

Chapter 28

Gene therapy

Stefan Worgall[1,2] **and Ronald G. Crystal**[2]

[1]Department of Pediatrics, Weill Medical College of Cornell University, New York, NY, United States, [2]Department of Genetic Medicine, Weill Medical College of Cornell University, New York, NY, United States

Gene therapy uses the transfer of genetic information to modify a phenotype for therapeutic purposes [1] and has evolved as therapy for diseases that can be cured by the transplantation of genetically modified hematopoietic stem cells [2]. The application of gene transfer to tissue engineering has a myriad of possibilities, including the transient or permanent genetic modification of the engineered tissue to produce proteins for internal, local, or systemic use, helping to protect the engineered tissue, providing stimuli for the engineered tissue to grow and/or differentiate, and to deliver gene editing tools. To provide a background for the application of gene transfer to tissue engineering, this chapter will review the general strategies of the gene therapy, detail the gene transfer vectors used to achieve these goals, and discuss the strategies being used to improve gene transfer by modifying the vectors to provide cell-specific targeting, by regulating the expression of the targeted gene, or by permanently changing gene expression by gene editing. The applications of combining gene therapy with stem-cell therapy will be reviewed. Our overall goal is to provide a state-of-the-art review of the technology of gene therapy, including the challenges to making gene therapy for tissue engineering a reality. For details regarding the applications of gene therapy to specific organs and clinical disorders, several reviews are available [1–11]. An adeno-associated virus (AAV)-based gene therapy treatment for inherited retinal diseases such as retinitis pigmentosa and Leber's congenital amaurosis was approved by the FDA in 2017 [12]. Other cell-based gene therapy approaches that have been included in clinical care are the creation of chimeric antigen receptor (CAR) T cells using lentiviral gene transfer of chimeric anti-CD19 to autologous T cells [13,14].

Strategies of gene therapy

The basic concept of gene therapy is to transfer nucleic acid, usually in the form of DNA (or RNA in retrovirus and lentivirus vectors), to target cells. The vector with its gene cargo can be administered ex vivo, where the gene is transferred to the cells of interest in the laboratory and the genetically modified cells restored to the patient, or in vivo, when the nucleic acid is administered directly to the individual (Fig. 28.1). Independent of the overall strategy, an expression cassette containing the genetic sequences to be delivered, typically a cDNA along with regulatory sequences to control expression, is inserted into a "vector," a nonviral or viral package used to improve efficiency and specificity of the gene transfer. Together, the choice of vector, the design of the expression cassette, and the coding sequences of the gene determine the pharmacokinetics of the resulting gene expression.

Simple in concept, gene transfer is complex in execution. In addition to choosing an ex vivo versus in vivo strategy, the major issues relating to successful gene therapy are the design of vector, how the vector is delivered to the cell population of interest, translocating the vector/expression cassette from outside the cell to the nucleus, and the expression of the gene to obtain the desired therapeutic effect (Fig. 28.2). Independent of the choice and design of the gene transfer vector, successful gene therapy requires decisions regarding the quantity of vector required to modify the numbers of target cells necessary to obtain the desired therapeutic effect and whether or not the vector will evoke a host immune response and/or cause unacceptable toxicity. The gene therapist must also decide how to get the vector to the target cells, including

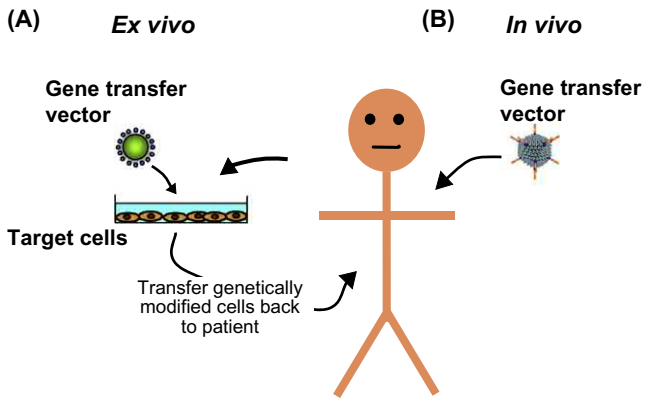

FIGURE 28.1 General strategies for gene therapy for tissue engineering. (A) Ex vivo strategies use a gene transfer vector to genetically modify autologous target cells (e.g., skin fibroblasts) in vitro followed by transfer of the genetically modified cells back to the patient. (B) In vivo strategies transfer the therapeutic gene by direct administration of a gene transfer vector to the patient.

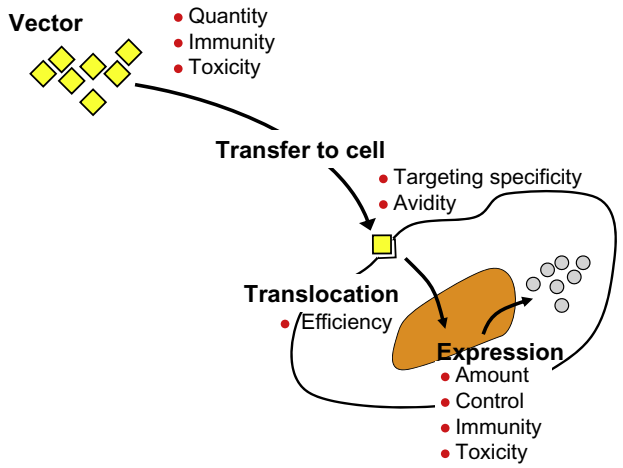

FIGURE 28.2 Issues relating to successful gene transfer. In addition to the choice of vector, successful gene transfer requires decisions regarding the quantity of vector to be used, and that the vector does not induce immunity and/or toxicity that will limit its use. The vector has to be transferred to the cell, a relatively easy task for ex vivo strategies but in vivo may require enhancing targeting specificity and vector avidity to its receptor. Once reaching the target cells, the vector must insure its gene cargo is efficiently translocated to the nucleus. In the nucleus, the gene must be expressed in appropriate amounts, with control if necessary, and without appreciable immunity and/or toxicity induced by the gene product.

targeting specificity and avidity of the vector for its relevant receptor. Once the vector reaches the cells of interest, the gene cargo within the vector must be translocated from outside of the cell to within the nucleus. In designing the gene transfer strategy, it is critical to decide whether or not the gene is to be inserted into the chromosomal DNA of the target cells. Finally, the transferred gene must be expressed, with the concomitant issues of amount and control of expression, and host immunity and toxicity that may be evoked by the expression of the gene. In the sections that follow, we will discuss all of these issues.

Ex vivo versus in vivo gene therapy

There are generally two strategies by which gene therapy technology can be used for genetic engineering, ex vivo transfer of genetic material with subsequent transfer of the modified cells or tissue to the host, and in vivo transfer, with direct administration of the gene therapy vectors to the patient (Fig. 28.1).

Ex vivo

The ex vivo strategy has the advantage that the cell population can be purified and carefully defined, and the transfer of the gene is limited to that cell population and not to other cells or tissues. The challenge for this approach is that, for most applications, once returned to the patient, the genetically modified cells need to have a selective advantage to modulate the therapeutic goal. For applications where long-term expression of the gene is required and the transferred cells subsequently replicate within the patient, the vectors used to transfer the gene must mediate integration of the gene, so that it persists when the cell divides [1,15].

The ex vivo strategy typically is used to genetically modify hematopoietic cells, such as CD34 + cells derived from bone marrow, or skin fibroblasts [5]. Examples of ex vivo gene transfer strategies include the correction of hereditary immunodeficiencies or hemoglobinopathies with retroviral and lentiviral vectors [2], transfer of the factor VIII gene to autologous fibroblasts to treat hemophilia A and transfer of suicide genes to T cells to control graft versus host disease [16–18] or to deliver therapeutic genome editing tools for a variety of therapeutic targets [9]. For tissue engineering applications, the ex vivo strategy is applicable to providing genes to enhance and/or modulate the growth of the engineered tissue, as well as to protect the engineered tissue from host responses or disease processes. The ex vivo strategy is also the most suitable strategy to use gene transfer to genetically modify stem cells.

Although ex vivo gene therapy can be carried out using cells derived from an nonautologous source, potential immune rejection of nonmatched cells generally requires that autologous, or closely matched donor, cells be used for the tissue engineering strategy. However, the immune system can potentially recognize components of the vector and/or transferred gene product. For ex vivo strategies in general, immune recognition of the gene therapy vector is minimal, as the immune system will not be in contact with the total dose of gene therapy vector

used to transfer the gene in vitro, but only the residue of the vector within the cells to be transferred. There is the possibility of immune recognition via MHC presentation of viral antigens inducing antivector immunity, and this may be responsible for shutdown of gene expression over time.

In vivo

In vivo gene transfer strategies administer the gene therapy vector either directly to the target organ or deliver it via the vascular system into vessels feeding that organ. In vivo gene transfer has an advantage over ex vivo strategies in that it avoids the cumbersome (and costly) process of removing cells from the patient, manipulating the cells in vitro, and returning the genetically modified cells to the patient. Challenges that need to be overcome for in vivo gene transfer strategies include the induction of immunity by the gene transfer vector, transport of the gene therapy vector to the targeted cells/organ, efficient binding of the vector to the cell, translocation of the genetic material to the nucleus, and toxicity and immunity induced by expression of virus and/or transgene peptides.

The retina has so far been an ideal target for the in vivo gene therapy approach because (1) it is in a confined, relatively small space; (2) the gene therapy vector can be administered directly; (3) vectors with natural tropism for retinal cells are available; and (4) it is immunoprivileged. The in vivo gene therapy approach has recently achieved a significant success by achieving correction of the genetic disease Leber's congenital amaurosis [19,20].

Chromosomal versus extrachromosomal placement of the transferred gene

One of critical decisions in strategizing gene therapy is whether the transferred gene is to be inserted into the chromosomal DNA of the targeted cells or is designed to function in an extrachromosomal location within the nucleus. There are advantages and disadvantages to both strategies, and the choice of the strategy is determined by the specific application of the gene transfer.

As described next, some gene transfer vectors (e.g., retrovirus, lentivirus) insert their genome, and hence the transferred gene, directly into the chromosomal DNA of the target cells. This has the advantage that it is permanent, and when the genetically modified cells divides, both daughter cells have the newly transferred sequences, as they are now part of the genome of the genetically modified cell population. This is a desirable feature for applications where persistent gene expression is required, such as for the correction of a hereditary disorder. The disadvantage is that, once inserted, the gene cannot be removed, and thus unless controls are designed into the transferred sequences, cannot be shut down. Equally important is the issue of randomness of where the gene is inserted. If the gene is inserted into a relatively "silent" region of the genome, the resulting gene expression will be low, while gene expression from other regions will be high [21]. This genome regional modulation of the level of gene expression will be different for each targeted cell. While there are some more favored regions of gene insertion depending on the vector characteristics, the population of genetically modified cells essentially becomes a mixed population in terms of where the gene has been inserted. Thus expression may be low for some cells, while other cells may be average or high expressors. More troubling, if the gene is inserted into a region influencing cell proliferation, the result may be uncontrolled cell growth, for example, malignancy. This phenomena, referred to as "insertional mutagenesis," has been observed in experimental animal and human applications of gene transfer [21]. Several strategies have evolved out of these observations to improve the safety of integrating gene therapy vectors [22–26].

Some vectors (e.g., nonviral, adenovirus, AAV) transfer the gene into the nucleus, but mostly into an extrachromosomal location, where the gene is transcribed using the same transcriptional machinery as for genomic DNA [1]. The consequences of this strategy is that as long as the cells do not proliferate, and as long as host defenses do not recognize the genetically modified cell as foreign, expression of the transferred gene will persist. However, if the cell divides, the transferred gene will not be replicated, and gene expression in the daughter cells will eventually wane as proliferation continues. The consequences are transient expression of the gene, a "pharmacokinetic" result that is ideal for some applications (e.g., angiogenesis, most cancer therapies) but not desirable for applications requiring persistent expression (e.g., correction of a genetic disease). Independent of the issue of persistence of gene expression, extrachromosomal placement of the gene has the advantage that insertional mutagenesis and variability of gene expression secondary to variability of chromosomal insertion are not of concern.

Gene transfer vectors

There are two general classes of commonly used vectors for gene therapy: nonviral and viral (Fig. 28.3, Table 28.1). Although a variety of vectors have been developed in both classes, the most commonly used nonviral vectors are naked plasmids and plasmids combined with liposomes, and the commonly used viral vectors are adenovirus, AAV, retrovirus, and lentivirus [1,6,7,31–33].

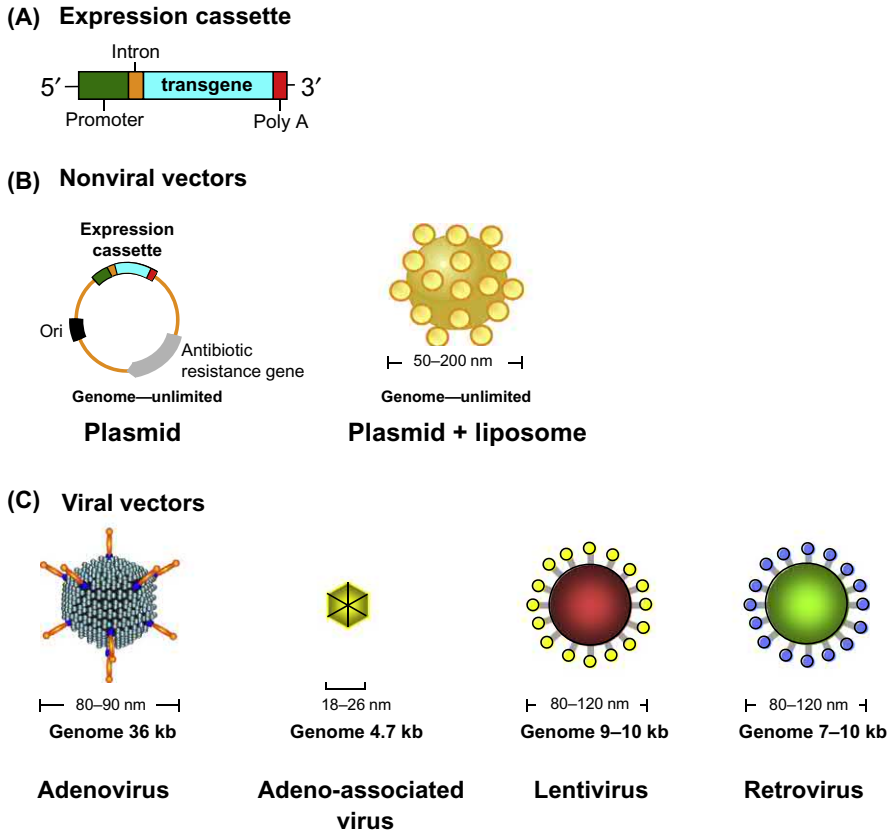

FIGURE 28.3 Commonly used gene therapy vectors. (A) All gene transfer vectors contain an expression cassette with (5′−3′) a promoter, usually an intron, the transgene, and a polyA site/stop signal. (B) Commonly used nonviral vectors, including naked plasmids (typically comprised of an origin of replication, the expression cassette, and antibiotic resistance gene), or plasmid combined with a liposome. The plasmid genome can be unlimited in size, but usually the expression cassette is <10 kb; the liposome/plasmid combination ranges from 50 to 200 nm in diameter. (B) Commonly used viral vectors, including adenovirus, adeno-associate virus, lentivirus, and retrovirus. Shown is the size of the genome of each viral vector, as well as the relative size of each vector. The size of the expression cassette depends on how much of the viral genome is included.

TABLE 28.1 Characteristics of most commonly used gene transfer vectors.

Vector type	Maximum expression cassette capacity (kb)	Transfers genes to nondividing cells	Antivector immunogenicity	Chromosomal integration	Expression	Other characteristics
Plasmids/ liposomes	<10[a]	Yes	None	No	Transient	Poor transduction efficiency
Adenovirus	7−8[b]	Yes	High	No	Transient	Typically, mediates expression for 1−3 weeks
Adeno-associated virus	4.5	Yes	Low	No[c]	Persistent in nondividing cell populations	Expression usually takes 1−3 weeks to be initiated
Retrovirus	8	No	None	Yes	Persistent	Risk for insertional mutagenesis, difficult to produce in high titer
Lentivirus	8	Yes	None	Yes	Persistent	Theoretical safety concerns regarding HIV components; risk for insertional mutagenesis, difficult to produce in high titer

[a]Plasmid size are generally not limited, but plasmids with >10 kb expression cassette capacity are more difficult to produce with consistent fidelity and thus are generally not suitable for gene human transfer.
[b]Typically, Ad vectors have a 7−8 kb capacity for the expression cassette; the capacity can be increased by removing additional viral genes.
[c]Wild-type adeno-associated virus (AAV) integrates in a site-specific fashion into chromosome 19, a process mediated by the rev gene; rev is deleted in the AAV gene transfer vectors; whether or not there is minimal integration of the genome AAV gene transfer vectors is debated [27−30].

Independent of the vector used, all carry an expression cassette, which includes the gene to be transferred together with the relevant regulatory sequences to control the expression of the gene once it has been transferred to the target cells (Fig. 28.3A). The typical expression cassette includes (5′−3′) a promoter, an intron (this is not critical, but it usually enhances gene expression and enables specific polymerase chain reaction (PCR) identification of the cytoplasmic mature mRNA from the pre-mRNA and transferred expression cassette), the transgene itself (usually in the form of a cDNA, but it can contain one or more introns or can be the generic form of the gene), and finally the polyA/stop and other 3′ regulatory sequences, if desired. In special cases, such as *trans*-splicing (discussed in the section on regulation of expression), the expression cassette may contain only a fragment of the gene together with sequences to direct splicing into an endogenous nuclear pre-mRNA.

Nonviral vectors

The most simple gene transfer vectors are plasmids. To achieve relevant transduction of cells in vivo the plasmids are usually combined with liposomes to facilitate attachment and entry into target cells [34,35]. A variety of physical methods have also been developed to promote entry of plasmids into target cells, including microinjection, hydrodynamic administration, electroporation, ultrasound, and ballistic delivery (so-called gene gun) [35]. Most of these physical methods of gene delivery are not applicable for in vivo gene transfer due to the inaccessibility of the target cells to direct manipulation.

Plasmids contain a relatively simple expression cassette with the transgene driven by a promoter and flanked by an intron and the polyadenylation/stop site (Fig. 28.3A). Plasmid DNA has an unlimited size capacity; however, because plasmids >10 kb are potentially unstable, during production most gene transfer strategies being considered for human applications use plasmids <10 kb. Although plasmids can efficiently transduce cells in vitro, their efficiency in vivo is limited. There have been may attempts to correct hereditary disorders with plasmid gene transfer alone but with little evidence of expression of the plasmid-directed mRNA in those trials [36]. Part of the reason of the inefficiency of plasmid-mediated gene transfer is that plasmids have no means to direct their traffic to the nucleus [34]. For gene transfer applications for tissue engineering the most that can be envisioned for the use of plasmid-based systems is to use them in an ex vivo approach with possible need for selection of the transduced cells. There has recently been renewed interest in nonviral gene transfer for the delivery of gene editing systems [37].

Adenovirus

Adenoviruses are nonenveloped viruses containing a linear double-stranded DNA genome of 36 kb [38]. Among the 49 different Ad strains that infect humans, the subgroup C, serotype 5, and serotype 2 are widely used in gene transfer studies and the only serotypes used in humans to date. The Ad5 genome is composed of early and late genes [38]. The E1 region controls the replication of the virus. Conventionally, the Ad gene transfer vectors have a deletion in E1 and E3 (a nonessential region). The expression cassette containing the promoter and the gene to be transferred are usually inserted into the E1 region. The vectors are produced in the 293 embryonic kidney cell line that provides the E1 information in *trans*, enabling replication of the recombinant vector.

Ad vectors can hold 7−7.5 kb of exogenous sequences [38]. If more space is needed, the E2 or E4 region can also be deleted and the vector made in cell lines providing these deleted sequences. The Ad capsid is an icosahedral structure composed of 252 subunits, of which 240 are hexons and 12 are pentons. Hexon is the major structural component of the Ad capsid forming 20 facets of the icosahedron and is composed of three tightly associated molecules of polypeptide II forming a trimer. Polypeptide IX is associated with the hexon protein and serves to stabilize the structure. Each penton contains a base and a noncovalently projecting fiber. Sequences within the fiber are the primary means by which Ad interact with cells, with the penton base providing secondary attachment sequences.

Several cellular receptors have been identified for Ad vectors, and they differ for various serotypes (Table 28.2). The primary Ad receptor for the subgroup C Ad is the coxsackie adenovirus receptor (CAR) [39]. CAR is expressed on most cell types, and thus Ad group C vectors are capable of transferring genes to most organs. Besides the primary CAR receptor, epitopes in the penton base of the group C Ad vectors use $\alpha_v\beta_3$ (or $\alpha_v\beta_5$) surface integrins as coreceptors for virus internalization [40]. Heparan sulfate has also been identified as a receptor for Ad2 and 5, and Ad5 has been shown to bind to vascular cell adhesion molecule 1 (VCAM 1) on endothelial cells and possibly also to MHC class I a2 on the cell surface [44,45].

The group B serotypes Ad11, 14, 16, 21, 35, and 50 utilize CD46 instead of CAR, enabling more efficient gene transfer into hematopoietic cells, cells of the urinary tract epithelium, and salivary glands [47]. For Ad3 of the subgroup B Ad vectors, CD80 and CD86, which are usually expressed on antigen presenting cells, have been identified as a receptor for viral entry [49].

In addition to Ad vectors being effective in delivering genes to a wide variety of cell types for therapeutic

TABLE 28.2 Cell receptors of commonly used viral-based gene therapy vectors.

Vector	Virus group/serotype[a]	Receptor	Reference
Adenovirus	Group C, serotypes 2, 5	CAR; coreceptors—$\alpha_V\beta_3$, $\alpha_V\beta_5$ integrins	[39,40]

[a]*Adenoviruses are categorized in groups and serotypes; AAV is categorized in clades and serotypes, only the serotypes are listed.*

purposes, Ad vectors interact rapidly with antigen presenting cells such as dendritic cells, leading to the induction of immunity against the vector and potentially also against the transgene if it is foreign to the host [7,63]. When Ad are directly administered in large doses to animals and humans, there is an innate and acquired immune response against the vector, resulting in local inflammation and infiltration of CD4, CD8, and dendritic cells [63,64]. The immune response is multifaceted consisting of humoral and cellular immunity against both the capsid proteins and against the transgene expressed by the vector if it is foreign to the host. Intravenously administered Ad also interacts with a variety of host proteins, in particular coagulation factor X [65,66].

Several strategies have been investigated to circumvent the problem of host responses evoked against Ad gene transfer vectors, including the use of immunosuppressants administered together with the vector, or including transgenes expressing immunomodulatory factors to suppress the immune responses against the vector [63]. Considerable effort has also been placed on circumventing the host response by designing vectors with larger genomic deletions (e.g., of E1 plus E2 and/or E4 with complementing cell lines) that evoke milder immune reaction [6,63,67].

One challenge to the use of Ad vectors is preexisting immunity against the vector resulting from previous infection with a wild-type Ad virus from the same serotype [63]. The acquired host responses to Ad vector administration generally results in the inability to readminister a vector of the same serotype. To circumvent this issue, alternative serotypes can be administered, thus circumventing immunity against the first vector [68]. Also, different serotypes to which humans are usually not exposed have been developed as gene transfer vectors. One example is Ad serotype 48, to which humans rarely have preexisting immunity. A chimeric Ad vector containing the hexon loops of Ad5 replaced by those of Ad48 has been shown to be a possible strategy for an Ad-based genetic vaccine approach [69,70] and could also be envisioned to be useful for tissue engineering applications.

Another strategy to circumvent preexisting anti-Ad immunity is the use of nonhuman Ad serotypes [71–73]. Nonhuman primate-derived Ad vectors were developed to

overcome preexisting immunity to common human Ad serotypes and to broaden the repertoire of Ad when used as vaccines [74–76]. For example, Ad vectors based on nonhuman primate serotypes C68, C3, C6, C7 do not circulate in the human population and are therefore not affected by preexisting immunity [71–73]. Nonhuman primate-derived Ad strains have been tested as genetic vaccine platforms. The chimpanzee Ad serotype 3 is considered to be one the most efficient platforms for designing new vaccines against Ebola virus [77,78].

Adeno-associated virus

AAV is a single-stranded DNA virus that belongs to the *Dependovirus* genus of the *Parvoviridae* family. AAV were originally isolated as contaminants in laboratory stocks of adenoviruses [79]. Nine subtypes of AAV were initially described for which humans are the primary host [79]. These isolates were found to be different based on the antibody response generated against them and were thus categorized as he AAV serotypes 1–9. A substantial portion of humans have detectable antibodies against these serotypes. To date, more than 100 human and nonhuman primate AAVs have been identified, including 12 serotypes that have between 51% and 99% identity in capsid amino acid sequence [80], but relatively few have been extensively studied for gene transfer [81]. The exact nature and sequelae of the natural infection with AAV in humans are not known, and there is possibly no human disease associated with AAV.

An AAV consists of a single-stranded 4.7 kb genome with characteristic termini of palindromic repeats that fold into a hairpin shape known as inverted terminal repeats [79]. During replication into a double-stranded form, it expresses genes involved in replication [82] and genes that code for the capsid proteins [83]. In the absence of a helper virus such as adenovirus or herpes simplex, wild-type AAV is capable of infecting nondividing cells and integrating its genome into chromosomal DNA at a specific region on chromosome 19, persisting in a latent form. In the gene vectors, *rep* and *cap* are deleted, and most of the vector genome resides and functions in an extrachromosomal locations [79]. In addition to adenovirus and herpes simplex virus, hepatitis B virus [84] and human bocavirus 1 [85], another parvovirus, have recently been identified as new helper viruses. These two new helper viruses may lead not only to a better understanding of AAV–host interactions in the context of chronic infections [31] but may also have implications for novel antiviral strategies or help the development of better AAV production systems [86].

In the AAV vectors the *rep* and *cap* genes are replaced with an expression cassette. During vector production, the *rep* and *cap* gene products as well as the necessary helper-virus elements (usually Ad-derived) are supplied *in trans*. AAV vectors are commonly produced by transfecting two plasmids into the 293 human embryonic kidney packaging cell line. DNA coding for the therapeutic gene is provided by one plasmid, and the AAV *rep* and *cap* functions plus the Ad helper functions are provided by the second plasmid. Titers are generally significantly lower compared with those obtained for Ad vectors but are sufficient to produce enough vector for clinical trials.

Assembly-activating protein, a small and relatively recently discovered AAV capsid protein, plays an important role in the assembly of AAV [87,88] but not for serotypes 4, 5, and 11 [89]. Several small molecules and also larger proteins such as albumin have been shown to enhance AAV infection [90,91]. This may be relevant for improved vector design and better capsid assembly.

Numerous studies in animals have been performed to assess safety and efficacy of AAV-based vectors, and AAV2 serotype-based vectors have been assessed in humans [92]. AAV-vectors are capable of transducing nondividing cells in vitro and in vivo. The exact molecular intracellular state of the vector genome has not been completely elucidated, but there is little evidence that the vectors integrate when used in gene therapy in vivo. Most transgene expression is thought to be derived from extrachromosomal viral genomes that persist as double-stranded circular or linear episomes [93]. This limits the usefulness of AAV for applications involving dividing cells such as stem cells, since only one daughter cell will receive the vector genome [94].

One disadvantage of AAV vectors is their packaging capacity, limited to expression cassettes of about 4.5 kb. This size limitation is a challenge for the use of AAV vectors for clinically relevant large transgenes, such as dystrophin (11 kb) for muscular dystrophy or factor VIII (7–9 kb) for hemophilia A. Various efforts have been undertaken to deliver larger transgenes using AAV vectors, including coadministration of two vectors each carrying one half of the transgene leading to intermolecular recombination during concatamerization, an intermediate state of the vector genome. One approach to overcome transgene size constraint for AAV have been dual-vector approaches, whereby a transgene is split across two separate AAV vectors [95,96].

The host immune response against AAV vectors is not as strong as that observed with Ad vectors [63,97,98]. AAV vectors generate humoral immunity against the capsid proteins, which impairs readministration of vector of the identical serotype. Cellular immunity against AAV has been detected following administration to experimental animals and humans, but, unless high doses are used, there usually are no destructive cytotoxic T-cell responses generated against the vector or the transgene [97]. Innate immune recognition of AAV2 by mouse or human

plasmacytoid dendritic cells is by TLR9 and is independent of the transgene or capsid serotype [99]. The activation of the innate immune response innate immune is through the AAV genome as well as the capsid proteins [98].

Despite these caveats, AAV vectors have so far been the most promising vector system for in vivo administration to humans for the correction of genetic diseases [12,100–105]. Initial trials used this vector system for liver-directed therapy of hemophilia and retina-directed therapy of macular degeneration and other genetic form of blindness. One of the most promising breakthrough has been in patients with spinal muscular atrophy, where a single intravenous infusion of an AAV9 vector containing DNA coding for survival motor neuron 1 resulted in longer survival, superior achievement of motor milestones, and better motor function compared with historical cohorts [105]. Ongoing trials target other severe genetic lysosomal storage disease targeting the brain for mucopolysaccharidosis [106,107], or the heart for Pompe and Danon disease [108].

There is usually persistent expression of the transgene directed by AAV vectors, particularly in organs with nondividing (or slowly dividing) cells, such as liver, muscle, heart, retina, and brain. The overall expression levels of the transgene appear to be lower with AAV compared with Ad and are dependent on the target organ. AAVs that were identified from tissues of nonhuman primates and humans [109,110] have substantial heterogeneity in the capsid genes and are useful as chimeric capsids combine with the AAV2 genome, leading to improved infection of organs or tissues previously not considered to be valuable targets for AAV gene transfer.

AAV interacts with its target cells by binding to cell surface receptors (Table 28.2). For AAV2, the primary attachment receptor is heparan sulfate proteoglycan [27]. AAV3 may share heparan sulfate proteoglycan as the primary attachment receptor. However, AAV3 may use other receptors, as AAV3 has been shown to infect hematopoietic cells, which were not effectively infected by AAV2 [52]. AAV4 and AAV5 use sialic acid as the primary attachment receptor. AAV4 uses O-linked sialic acid, whereas AAV5 uses N-linked sialic acid [55,56]. AAV1 and AAV6 use N-linked sialic acid as receptor [50,51]. Recently, N-linked galactose was identified as the receptor for AAV9 72. The primary receptors for AAV7 and 8 remain unknown. AAV12, originally isolated from a stock of simian adenovirus 18, does not require cell surface heparan sulfate proteoglycans nor sialic acid for transduction and shows strong tropism for nasal epithelia [50,51]. It is being developed as vaccine vector against respiratory pathogens [111].

AAV2 also uses coreceptors for efficient infection, including $\alpha_V\beta_5$ integrin [28] and fibroblast growth factor-1 [29]. Efficient infection with AAV5 appears to require a coreceptor; platelet-derived growth factor has been identified as a possible coreceptor for AAV5 but may also be able to act as the primary receptor [57]. AAVR (AAV receptor; KIAA0319L), a membrane glycoprotein, serves as cellular receptor for several AAV serotypes [54]. This receptor had originally been described in 1996 for AAV2 [112], and its importance and binding capacity for multiple serotypes was recently rediscovered [53]. Further characterization of the AAV binding sites of AAVR identified several polycystic kidney disease domains that can differ for distinct AAV serotypes [113].

Retrovirus

RNA viruses such as retroviruses, lentiviruses, alphaviruses, flaviviruses, rhabdoviruses, measles viruses, Newcastle disease viruses, and picornaviruses have so far been engineered to be used as gene transfer vector for the treatment of a variety of diseases [32]. Retrovirus and lentivirus vectors belong to the family of retroviridae. Because lentiviruses are capable to infect nondividing cells and have evolved as the more promising gene transfer system of the two with transition to clinical care they are discussed separately next. The original retroviral vectors used for gene therapy were based on endogenous murine viruses. Of these the Moloney murine leukemia retrovirus (MMLV) was the first widely used gene transfer vector and was the first to be used to treat a hereditary disorder using an ex vivo strategy [114].

The genome of the retrovirus vector is a 7–10 kb single-stranded RNA containing long terminal repeats (LTR) on both ends that flank *rev*, *gag*, *pol* and other regulatory genes that are required for viral function. The RNA genome of the replication-deficient retroviral vectors contains an expression cassette to up to 8 kb that replaces all viral protein-coding sequences. The LTR's flank the expression cassette and allow transcription initiation by host cell factors. The vectors are rendered self-inactivating by deletion of the promoter and enhancer in the 3′ LTR to prevent LTR-driven transcription. The packaging of the genomic RNA is controlled in *cis* by the packaging signal Ψ. The production of the retrovirus vectors requires a packaging or producer cell line in which the viral *gag*, *pol* and *env* proteins are expressed in *trans* from separate helper products. Recombination between the helper constructs and the vector can be minimized by using nonretroviral regulatory sequences to control expression [115]. Enhancer and promoter sequences can be deleted from the 3′ LTR to create an transcriptionally silent 5′ LTR during infection of the target cells. This strategy provides the basis for self-inactivating vectors and can also be used for the substitution with tissue-specific promoters [116]. The main reason why MMLV

viruses can only infect nondividing cells is that they are unable to cross the nuclear membrane and can only achieve completion of the infection with provirus integration during cell division.

Retroviruses enter the cells via cell fusion of the envelope protein with the cell membrane. The murine viruses are able to infect only murine cells (ecotropic), whereas derivatives of MMLV or human retroviruses like vesicular stomatitis virus (VSV) can infect both human and murine cells (amphotropic; Table 28.2). Providing the virus with a different coat, a process referred to as "pseudotyping," can change the specificity of binding and entry into target cells. Over the past decade, there has been considerable effort in the development of pseudotyping strategies of retroviral vectors [58,61,115,117].

Most of the gene transfer strategies for retroviral vectors have been ex vivo approaches due to the difficulty in producing high titer concentrated preparations and the rapid inactivation of the retroviral vectors in vivo by complement. Due to their ability to infect rapidly dividing cells, retroviral vectors have been used extensively to develop gene transfer strategies to hematopoietic cells. The first clinical trial to treat an hereditary disorder was to use a retrovirus to transduce T cells of patients with adenosine deaminase—severe combined immunodeficiency (SCID) [114], and since then the technology has evolved to permit successful treatment of children with SCID [118–120].

One advantage of using retroviral vectors is the permanent integration of the vector genome into the host genome, providing long-term and stable expression of the transgene. This however also carries the greatest risk of retroviral vectors, in that they may induce insertional mutagenesis with the subsequent development of malignancies. This has been observed in a clinical trial using a MMLV-based retroviral vector to correct hematopoietic stem cells to treat X-linked SCID [16]. Although long-term correction of the immunodeficiency has been observed in the study subjects, three children developed a clonal lymphoproliferative syndrome similar to acute lymphoblastic leukemia. In two of these cases, there was integration of the retroviral vector near the LIM domain only 2 (LMO2) promoter. Retroviruses are currently mostly used for preclinical anticancer strategies. A replicating retroviral vector expressing cytosine deaminase has been effective in preclinical models of glioma [121]. Retrovirus vectors have been useful for gene modifications of natural killer cells [122]. Efforts are ongoing to use retrovirally modified fibroblasts [123] or keratinocyte stem cells [124] for skin diseases such as epidermolysis bullosa.

Lentivirus

Based on the knowledge that the human retrovirus HIV-1 is able to infect nondividing cells such as macrophages and neurons, replication-defective versions of HIV were developed, capable of infecting nondividing cells, and achieve stable long-term expression through integration of the provirus into chromosomal DNA [125]. The genome of a lentivirus vector is a 9–10 kb single-stranded RNA genome, containing components of HIV-1, but otherwise similar to that of retroviral vectors. All viral protein-coding sequences are deleted and are replaced with an expression cassette that can be up to 8 kb in length.

Unique to lentiviruses are the central polypurine tract and central termination sequences, *cis*-acting sequences that coordinate the formation of a central DNA flap which improves nuclear import [126]. This may explain the increased transduction efficiency of lentiviral compared with retroviral vectors. A *rev*-responsive element can be incorporated into the vector to facilitate the nuclear export of unspliced RNA. The packaging of the genomic RNA is controlled in *cis* by the packaging signal Ψ.

Despite the greater complexity the lentivirus genome, the basic principles of generating vectors free of replication-competent virus are similar to those for retroviral vectors. Packaging systems use the HIV *gag* and *pol* genes, with or without the *rev* gene [127,128]. The HIV virulence genes *tat*, *vif*, *vpr*, *vpu*, and *nef* are completely absent from lentiviral vectors, thus making it theoretically impossible that a virus similar to HIV can be inadvertently produced [129]. The production of lentiviral vectors in high concentrated titers is still a challenge, but the production issues are slowly being solved [125]. Lentivirus expression vectors with associated packaging cell lines have been engineered can be efficiently produced in HEK293 suspension cell cultures in bioreactors [130]. Ecotropic [131] and pantropic [132] lentivirus vectors have been designed. The packaging capacity of inserts is similar to what has been described for conventional retroviruses. The chromosomal integration provides long-term expression. Several inducible lentiviral vectors have been designed by the introducing a multiple cloning site upstream of the Tet promoter for the inducible expression of MYC by doxocycline in lung cancer cell lines [133].

The cellular receptors for the lentivirus vectors are the same as for HIV1-1, including CD4, together with the chemokine coreceptors CCR5 and CXCR4 (Table 28.2). However, the lentiviral gene transfer vectors are usually pseudotyped with envelopes from other viruses, such as VSV-G, mediating the binding and entry into target cells similar to retroviral vectors. Efficient gene transfer of lentiviral vectors has been reported for a variety of dividing and nondividing cell types, including muscle, neurons, glia, and hematopoietic cells. Lentivirus vectors have been successfully used to correct disease phenotypes in experimental animals for CNS disorders such as metachromatic leukodystrophy using in vivo administration of the lentiviral vector to the brain [134] or using an ex vivo

strategy by infecting hematopoietic stem cells with the β-globin gene to correct β-thalassemia [135]. There have only been a few clinical studies using lentiviral vectors, but the results for an ex vivo approach correcting hematopoietic stem cells with lentiviral-mediated gene transfer in patients with adrenoleukodystrophy, a severe demyelinating disease, or thalassemia have been very promising [136–138].

Like retroviral vectors, insertional mutagenesis is a concern for the clinical use of lentiviral vectors, and liver cancers have been observed in mice infected in utero or neonatally with lentiviral vectors [139]. One hypothesis for this phenomenon is based on potentially oncogenic sequences present in the woodchuck hepatitis virus–derived posttranscriptional regulatory element that was included into the vector to increase mRNA stability [139]. Lentivirus-transduced autologous hematopoietic stem cells, transduced ex vivo with lentiviral vectors, have been used successfully for the treatment of cerebral adrenoleukodystrophy, Fanconi anemia, HIV-related lymphoma, and sickle cell disease [140]. A variety of preclinical studies using lentivirus-mediated gene expression in CD34 + cells show promise for a variety of monogenic diseases such a pyruvate kinase deficiency [141], thalassemia [140], and various forms of SCID [142]. As outlined next, RNA silencing tools can be efficiently delivered by lentiviral vectors [143].

Cell-specific targeting strategies

Viral gene transfer vectors use the receptors of their wild-type versions to enter into cells (Table 28.2). Modification of gene transfer vectors to target specific cell types or tissues is an attractive means to increase the specificity of the vectors to the target cell and may also enable the vectors to infect cells which are usually not infected by unmodified vectors. In general, targeting modifications can be accomplished by either genetic modification of the vector genome to change the properties of the outer surface of the vector or by chemical modification of the vectors via the addition of ligands (Table 28.3). Based on the targeting strategy used, the range of tropism can be widened or narrowed (Fig. 28.4).

Targeting of Ad vectors

Strategies have been developed to redirect Ad tropism and to enhance Ad tropism for cells difficult to transfer genes to because of lack of Ad receptors. In general, Ad vectors exhibit a broad tropism due to the widespread expression of the primary Ad receptor CAR and the secondary integrin receptors $\alpha_V\beta_3$ and $\alpha_V\beta_5$. While the widespread expression of the Ad receptors enables the efficient infection of a wide range of target cells, it poses the problem of unwanted uptake and gene expression in nontarget tissue when the vectors are administered in vivo. There are some tissues that have low expression of CAR (e.g., endothelial cells, antigen-presenting cells and some tumor cells), which limits the use of Ad vectors for these targets.

Most genetic targeting strategies for Ad vectors have been focused of ablating CAR binding and have introduced new peptides or other ligands to the fiber knob domain, the primary site for the interaction of group C Ad vectors with CAR [180]. Fiber modifications to modify target-cell binding of Ad vectors include the introduction of poly(L) lysine to allow binding to heparan-containing receptors and the integrin-binding motif RGD, which is essential for penton-mediated internalization to allow integrin-mediated binding and uptake [145]. Peptides can also be incorporated into other sites of the Ad capsid to achieve retargeting, such as incorporation of RGD into the hexon [181] and poly(L) lysine into polypeptide IX [146].

Another approach of genetic retargeting of virus vectors is to create chimeras of different serotypes, which are known to use different cellular receptors. Replacing the fiber or fiber knob domain of the Ad5-based vector with that of Ad3 or Ad7 has been shown to achieve CAR-independent infectivity [149–151]. Replacement of the fiber of Ad2 with that of Ad17 has led to improved infectivity of airway epithelial cells [152]. Replacement with the fiber of Ad35 achieved improved infectivity of hematopoietic cells [163,182] and Ad16 enhanced infectivity of cardiovascular tissue [153]. Ad5 vectors pseudotyped with fibers of the subgroup D Ad19 and 37 increased the infectivity of endothelial and smooth muscle cells [147]. Recognition peptides for fiber modification have been identified by phage display [183–185], and other complex genetic modifications of the fiber to retarget the Ad vector have been reported [154,186]. These cell-targeting modifications can also be combined with the use of tissue-specific promoters to achieve selective infection and transcription in the targeted cell type. For example, inserting the RGD motif into the fiber has been combined with the use of the endothelial cell-specific Flt-1 promoter resulted in more specific infection and gene expression in endothelial cells [187]. Finally, a capsid-modified Ad/AAV hybrid vector was able to achieve long-term expression in human hematopoietic cells [163].

Besides genetic modification of gene therapy vectors to modify tropism and target vector uptake to a particular cell type, chemical modifications of Ad vectors has been utilized for targeting. Ad vectors have been complexed to cationic lipids, polycationic polymers, or cholesterol to increase the efficiency of gene transfer in vitro and

TABLE 28.3 Alteration of viral gene transfer vector cell targeting by modifying capsid/envelope structure.

Modification	Viral vector	Examples	Purpose/target	Reference
Genetic alteration of capsid/ envelope proteins	Adenovirus	Delete CAR[a]	CAR-independent infection	[144]
		Add RGD[b] to fiber	$\alpha_V\beta_3$, $\alpha_V\beta_5$ integrins	[145]
		Add polylysine to fiber or protein IX	Broadening infectivity by targeting heparan-containing molecules	[145,146]
		Replace Ad5 fiber with Ad19or Ad37 fiber	Improved infection of smooth muscle and endothelial cells	[147]
		Replace Ad5 fiber with Ad37 fiber	Infection of hematopoietic cells	[148]
		Replace Ad5 fiber knob with Ad3 fiber knob	CAR-independent infection	[149,150]
		Replace Ad5 fiber with Ad7 fiber	CAR-independent infection	[151]
		Replace Ad2 fiber with Ad17 fiber	Improved infection of airway epithelial cells	[152]
		Replace Ad5 fiber with Ad16 fiber	Improved infection of smooth muscle and endothelial cells	[153]
		Replace Ad5 fiber with trimerization motif of phage T4 fibritin	Chimeric fiber phage fibritin molecules targeted to artificial receptors	[154]
		Replace Ad5 fiber knob with CAV2[c] fiber knob	Target to CAR-deficient cells	[155]
		Replace Ad5 fiber with fiber of ovine AdV7	Targeting to kidney and "detargeting" of CAR	[156]
		Add VSV[d]-G epitope to Ad5 fiber knob	Targeting tropism to CAR-deficient cell expressing phosphatidylserine	[157]
		Replace 7 HVR of Ad5 hexon with HVR of Ad48	Circumvention of anti-Ad5 hexon immunity for Ad-based HIV vaccine	[69]
	Adeno-associated virus	Pseudotyping entire capsid with different serotype	Targeting tropism based on capsid serotype	[158]
		Pseudotyping with capsid of multiple serotypes	Generate mosaic AAV to target different serotype tropisms	[159,160]
		Addition of L14[e] to AAV2 capsid	Targeting to L14-binding integrins	[161]
		Incorporation of tumor-targeting peptide to AAV2 capsid	Targeting to CD13	[82]
		Insertion of serpin receptor ligand to AAV2 capsid	Targeting to serpin receptor	[162]
		Ad5 capsid with Ad37 fiber and partial AAV genome	Vector with increased capacity and tropism for hematopoietic cells	[163]
	Retrovirus	Pseudotyping entire envelope with envelope of vesicular stomatitis virus, Gibbon ape leukemia virus, murine leukemia virus	Targeting tropism of new envelope (from ecotropic to amphotropic)	[58,115,117]
		Addition of peptides:	Erythropoietin receptor	[164–166]

(*Continued*)

TABLE 28.3 (Continued)

Modification	Viral vector	Examples	Purpose/target	Reference
		• Erythropoietin • Heregulin • Epidermal growth factor	Heregulin receptor Epidermal growth factor receptor	
	Lentivirus	Pseudotyping entire envelope with envelope of vesicular stomatitis virus G	Improves infectivity to muscle	[167]
		Rabies 6 envelope	Improves infectivity to motor neurons	[168]
		Ebola	Improves infectivity for airway epithelial cells	[169]
		Hantavirus	Improves infectivity to endothelium	[170]
		Fowl plague hemagglutinin (with expression of influenza M2 protein)	Improves infection in airway epithelial cells	[171]
Chimerical modifications of capsid/envelope	Adenovirus	Cationic lipids, cholesterol, polycationic polymers	Modify tropism	[172,173]
		Polyethylene glycol	Decrease immunity	
		Coupling of U7 peptide to Ad5	Targeting of urokinase plasminogen activator receptor on airway cells	[174]
		Addition of single chain antibodies	Target antibody ligand-expressing cells	[175]
	Adeno-associated virus	Chemical conjugation of avidin-linked ligands to AAV2	Targeting to ligand receptors	[176]
		Incorporation of bispecific antibody to AAV2	Targeting to human megakaryocytes	[177]
	Lentivirus	Polyethylene glycol	Prolonging half-life in serum by preventing inactivation	[178]
	Retrovirus	Addition of single chain antibodies	Target antibody ligands	[179]

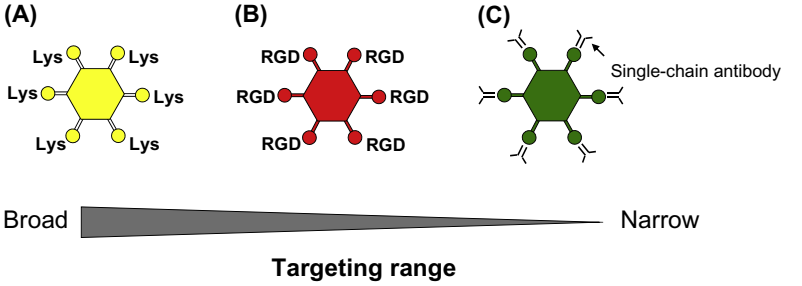

FIGURE 28.4 Examples of modifications of tropism of gene transfer vectors. Shown are three examples of modification of adenovirus vector tropism. (A) The addition of polylysine to the Ad fiber protein provides broad tropism; (B) the addition of the integrin-binding motif RGD enhances targeting of cells expressing $\alpha_v,\beta_{3,5}$ integrins; and (C) the addition of single chain antibodies to the Ad fiber targets cells expressing the antibody ligand. Strategies A→C provide broad to narrow cell-specific targeting.

in vivo [172,173]. Bispecific monoclonal antibodies have been added to the fiber to target specific cell types expressing the ligand for that antibody.

Targeting of adeno-associated virus vectors

The strategy of creating AAV chimeras by pseudotyping with capsids of different AAV serotypes has been used to broaden the tropism of AAV vectors [158–160]. Most of these vectors used the vector genome derived from AAV2 with the capsid from another serotype. For example, this strategy has enabled enhanced transduction in lung-directed gene transfer using an AAV5 pseudotype [188]. The interaction of AAV2 with epidermal growth factor receptor protein tyrosine kinase inhibits transduction and targeted AAV2 for degradation by the proteasome [189]. Mutating tyrosine residues [190] or other kinase targets such as serine, threonine and lysine on the AAV capsid [191] can improve in vitro transduction efficiency and also lead to improved transgene expression [192].

Targeting of retroviral and lentiviral vectors

The classic method to broaden the tropism of retroviral and lentiviral vectors is by pseudotyping, creating chimeras using envelope glycoproteins from other viruses. Most retrovirus vectors are based on MuMoLV, an ecotropic virus, which infects only murine cells. To achieve infection of human cells, the vectors are propagated in packaging cells that express the envelope of the amphotropic or nonmurine viruses such as 4070A murine leukemia virus, gibbon ape leukemia virus, VSV, or the feline endogenous virus RD114 [58,117]. Various envelopes have also been used for lentiviral vectors to increase infectivity of specific cell types, including VSV-G for muscle [167], Ebola for airway epithelial cells [169,193], rabies-G for motor neurons [168] and hantavirus for endothelium [170]. Hybrid proteins of the murine amphotropic envelope have been combined with the extracellular domains of GALV or RD114 envelope to enhance infection of CD34 + cells [194]. As with Ad vectors, strategies have been developed to target retro- and lentiviral vectors by addition of ligands to the envelope glycoprotein. Examples include peptide sequences from erythropoietin [164], heregulin [165], epithelial growth factor and ligands for the Ram-1 phosphate transporter [115] as well as the addition of single chain antibodies [166,179]. The efficiency of these modifications however has not been very high, and the vector production yield is significantly impaired.

Another strategy has been to utilize the membrane proteins that are incorporated during the budding process for targeting. For example, incorporation of the membrane-bound stem-cell factor provided not only a growth signal for the CD34 + cells expressing c-kit, the receptor for stem-cell factor but also lead to increased infection efficiency of the CD34 cells [195]. Monomethoxy poly(ethylene) glycol conjugated to VSV-G protects the vector from inactivation in the serum, leading to a prolonged half-life and increased transduction of bone marrow following intravenous administration in mice [178]. Another strategy for targeting of retro- and lentiviruses in vivo has been to target retrovirus producer cells [196].

Regulated expression of the transferred gene

A variety of strategies have been developed to regulate expression of the genes transferred by gene therapy vectors (Table 28.4). The ability to regulate gene expression is particularly important for application where too much expression of the gene transfer product could lead to unwanted effects, for example, sustained expression of a growth factor that could potentially be tumorigenic. For in vivo strategies of gene transfer tissue-specific regulation of gene expression may be warranted to avoid expression of genes in undesired cells or tissues. In the context of the use of gene transfer vectors to genetically modify stem cells, regulation of gene expression may be critical to avoid differentiation into an unwanted tissue or cell type. The regulation of the gene expression of the transgene could also be combined with inducible systems of suicide genes or factors that could destroy the genetically modified cells, should unwanted differentiation occur.

To turn gene expression on and off at will, a number of inducible promoters and inducible regulated systems have been developed that are applicable to be used in gene transfer vectors (Table 28.4). For example, inducible gene expression in gene transfer vectors can be achieved using inducible promoters such as promoters responsive to glucocorticoids, cGMP, heat shock protein, radiation, and insulin. Inducible regulated systems also include systems based on response to tetracycline, antibiotic resistance, chemical-induced dimerization, steroid receptors, and insect ecdysone receptors. The basic mechanism for these systems is a combination of ligand-binding synthetic inducer or repressor proteins and promoter control system that regulates transgene expression.

The tetracycline-responsive system has been widely used to study gene function and to generate conditional mutants in cell lines and transgenic animals [239]. The transgene is placed behind a promoter that also contains binding sites for the tetracycline response element (TRE), which can act as a repressor or inducer of transgene expression. A fusion protein that binds to the inducer

TABLE 28.4 Regulation of expression of the transferred gene.

Category	Strategy	Note	Reference
Inducible promoter	Glucocorticoid–responsive	Multiple response elements	[197]
	cGMP[a]-responsive	Multiple response elements	[198,199]
	Heat shock protein-inducible	Hyperthermia and cellular stress induce gene expression	[200,201]
	Radiation-inducible		[202]
	Insulin-responsive		[203]
	Tetracycline-responsive	Repressible-TET_{off} or inducible-TET_{on} systems	[204–210]
	Antibiotic resistance	Streptogramin class antibiotic (e.g., pristinamycin) induces pristinamycin-induced protein preventing expression	[211]
		Erythromycin binds to prokaryotic DNA-binding protein MphR(A)[b]	[212]
	Chemical-induced dimerization (FKBP/FRAP[c])	Rapamycin induces heterodimerization of FKBP and FRAP	[213–215]
	Steroid receptor	Transactivator (GLVP[d] or Glp65) targeting genes with GAL-4-binding site in the presence of mifepristone (RU486)	[216,217]
	Insect ecdysone receptor	Ectodysone receptor-ligand induces transactivation of transgene	[218,219]
Tissue-specific promoter	Liver	Albumin, α1-antitrypsin, LAP, transthyretin promoters	[220–222]
	Smooth muscle	Smooth muscle actin, SM-22, smooth muscle myosin heavy chain promoter	[223,224]
	Prostate	Prostate-specific antigen promoter	[225,226]
	Neuron	Synapsin I, neuron-specific enolase	[227]
	Dendritic cells	Dectin 2, vFLIP	[228,229]
	Vasculature	VE-cadherin, smoothelin B	[83]
	Tumor vasculature	Tie2	[230]
Trans-splicing	Therapeutic *trans*-splicing	Target pre-mRNA is *trans*-spliced into independent pre-mRNA	[231,232]
State of differentiation	Differentiation-specific endogenous transcriptional regulatory elements	Beta-globin gene expression by endogenous transcriptional regulatory elements or from other genes with a similar expression pattern	[233,234]
Gene disruption	Nonhomologous end-joining gene disruption by zinc finger nucleases	Disruption of CCR5 gene to create resistance to HIV in T cells and hematopoietic stem cells	[235,236]
MicroRNA	Target cell-specific microRNAs	No transgene expression by incorporating a target sequence for microRNA in the 3′UTR	[237,238]

LAP, Liver-activated protein.
[a]*cGMP—cyclic guanosine monophosphate.*
[b]*MphR/A—a prokaryotic DNA-binding protein that binds to a 35 bp operon sequence.*
[c]*FKBP [30]—FK506-binding protein; FRAP—FK506-binding protein rapamycin-binding.*
[d]*GLVP—a mifepristone-activated chimeric nuclear receptor.*

doxycycline needs to be present on a separate gene construct. The tetracycline transactivator binds to the TRE and activates the transcription in the absence of doxycycline. Upon addition of doxycycline, the expression is turned off (Tet-off). Another fusion protein that can be used is the reverse tetracycline transactivator, which only binds to TRE in the presence of doxycycline, causing induction of expression upon addition of doxycycline (Tet-on). Expression can be controlled in a graded manner; the more doxycycline is added the greater the level of suppression or induction. The disadvantages of this system are the potential side effects of doxycycline. The tetracycline system has been used for regulated gene transfer with gene therapy vectors, including Ad [204,240], AAV [205–207], retroviral [208,241], and lentiviral vectors [209,210].

The steroid receptor systems use a mifepristone-binding progesterone receptor fused to the DNA-binding domain of the yeast GAL4 protein and the transactivation domain from the NfkB p65 subunit [216,217]. The fusion protein binds to a GAL4 activating sequence to regulate gene expression. Upon addition to mifepristone, gene expression is induced and upon removal of the drug gene expression returns to baseline within 5 days.

The insect ecdysone receptor system consists of a fusion protein of the transactivation domain of the glucocorticoid receptor fused the ecdysone-binding nuclear receptor and an ecdysone-response element placed upstream of the promoter driving the transgene expression [218,219]. Upon addition of ecdysone, an insect hormone with no mammalian homologs, the fusion protein dimerizes and induces expression. Because there are no known mammalian factors binding to the insect protein, there is very low background expression in the absence of the drug and expression can be very tightly controlled.

Another strategy to control gene expression at the desired location is the use of tissue-specific promoters (Table 28.4). The majority of tissue-specific promoters have been used to target expression to liver and the cardiovascular system by targeting muscle cells. The challenge in the use of tissue-specific promoters is that the level of expression is usually lower compared with the commonly used strong viral promoters. However, viral promoters such as CMV have been shown to be subject to silencing after several weeks in vivo. This has been seen in airways, cardiomyocytes, and smooth muscle cells in particular with nonviral gene transfer [223].

Another modality to regulate gene expression is by *trans*-splicing at the pre-mRNA level. In therapeutic trans-splicing, the sequence of the target pre-mRNA is modified by being *trans*-spliced to an independent pre-mRNA, the sequences for which are delivered exogenously by a gene transfer vector [242,243]. Therapeutic *trans*-splicing can be used to alter coding domains, to create novel fusion proteins, to direct gene products to various cellular compartments, and to enable gene therapy with large genes or genes coding for toxic products. *Trans*-splicing gene transfer strategies also offer the advantage that the expression of the *trans*-spliced sequence is controlled by endogenous regulation of the target pre-mRNA. *Trans*-splicing strategies have been used to correct animal models of hemophilia, X-linked immunodeficiency with hyper IgM and cystic fibrosis [231,244,245].

Using gene transfer vectors for gene editing

The recent technological advances in gene editing have further broadened the use of gene therapy vectors. Gene editing is applied for the rapid generation of knock-out cell lines or animal models [246], functional genomic screens [247], and other applications of transcriptional modulation/gene silencing [248]. Several viral [249] and nonviral [37] gene delivery systems are currently being explored for in vitro and in vivo delivery of gene editing systems, most commonly clustered regularly interspaced short palindromic repeats (CRISPR), together with CRISPR-associated proteins (Cas). CRISPR/Cas9 are part of the prokaryotic adaptive immune system and have successfully been repurposed for genome editing in mammalian cells [250]. The system generally consists of Cas, a specific endonuclease, and a guide RNA molecule which guides Cas to a specific DNA target [251]. Following translocation across the nuclear membrane, the heterologous complex cleaves a target sequence in the chromosomal DNA. The endonuclease and the guide RNA have to be heterologously expressed, which poses a challenge for their efficient delivery. The class 2 endonuclease Cas9 is the preferred system as it consists of a single protein [252]. Off-target effects of the CRISPR-Cas9 systems in its current form pose a challenge for their safe use in humans. Multiple guide RNAs can be expressed from the same construct to target multiple genes or to enhance the knock-out by targeting multiple sites in the same gene [253].

AAV8 has been used successfully for liver-directed delivery of CRISPR/Cas9 [254]. AAV9 is a suitable vector for delivery of CIRPR/Cas9 to skeletal muscle, heart, and brain [255–257]. However, the low packaging capacity of AAV is not sufficient for the packaging Cas9 and a guide RNA together, which requires around 4.2 kb [258]. This can be solved by using separate vectors for Cas9 gene and the guide RNA with the challenge to deliver both vectors in the same target cell in vivo [259]. A split Cas9 was developed that could be divided over two AAV cassettes and naturally joined after each part of the protein was expressed in the cell with the goal to provide additional space for regulatory elements and/or multiple guide RNAs [260]. A smaller but equally active ortholog of Cas9 from *Staphylococcus aureus* delivered by AAV8 showed efficacy for liver-directed gene silencing in vivo [258].

Lentiviral vectors have also been used to deliver gene editing systems due to their potential to alter cellular tropism by pseudotyping [261] and their ability to integrate into the host genome, which may enhance the risk for off-target effects such as mutagenesis. When nonintegrating, lentiviral vectors are used [10]. Lentiviral vectors are most commonly used to create disease models. Several guide RNA libraries in human and murine cells have been developed by large collaborative genome-wide loss-of-function screening using lentiviral delivery [259,262,263], for mouse embryonic stem cells [264], the identification of targets for West Nile virus [265], gene editing in plants [266], and for the creation of a murine leukemia model [267].

Ad-mediated delivery of CRISPR/Cas9 has been studies to a lesser degree but has nevertheless shown some promise [249]. Ad vectors have been used in animal models to decrease cholesterol levels by creating mutations in mouse liver [268] and in muscle-directed strategies for muscular dystrophy [269,270]. Ad vectors have also been useful in the creation of disease models [271,272]. Ad-mediated delivery of CRISPR/Cas9 to inactivate the SMAD3 gene in human lung fibroblasts and bronchial epithelial cells was studied to create a tool for drug discovery [273].

Nonviral delivery strategies include the use of cell-penetrating peptides [274], a less likely option for in vivo delivery, because the individual components need to be delivered to the same cell simultaneously. DNA nanoclews, nanoparticles based on a cage of DNA that is made by rolling circle amplification, and the complexes Cas9 and the guide RNA [275] are another nonviral vector approach.

To tackle both the caveat for off-targeting and the limited space, strategies have been designed to combine viral and nonviral delivery. A nonviral second vector was used for the delivery of Cas9 mRNA with an AAV8 vector expressing the guide RNA [9].

Combining gene transfer with stem-cell strategies

In general, stem cells are categorized into embryonal stem cells, the bone marrow-derived stem/progenitor cells including mesenchymal stem cells (MSC), endothelial progenitor cells [272], and the tissue-derived stem-cell populations [276]. Stem cells offer the potential for tissue regeneration, and combining gene therapy and stem-cell approaches is a promising strategy to direct the differentiation of stem cells in the desired cell type and to regulate and control growth and differentiation of the stem cell. Stem cells have the potential for both self-renewal and differentiation and are dependent on signals form their microenvironment that direct stem-cell maintenance or differentiation. The precise spatial and temporal presentation of these signals is critically important in development and will most likely be the decisive factor in the success of stem-cell therapies [277]. As the potential of stem cells to be used clinically becomes more realistic, gene transfer strategies may play a pivotal role in controlling stem-cell growth, by either preventing uncontrolled growth and/or directing differentiation into specific cell types and regulating gene expression [278]. In addition, as more of the microenvironmental cues that control stem-cell differentiation into the desired phenotypes become known, the potential to use gene transfer strategies to express or inhibit these signals become a viable strategy to support stem-cell therapy. Three general areas can be currently envisioned for gene transfer to be helpful for stem-cell therapies: (1) to control unwanted stem-cell growth or differentiation; (2) to provide environmental cues for stem-cell differentiation; and (3) to regulate gene expression. In addition gene transfer may also be useful in marking stem cells as a modality to track the cells and their progeny in vivo [279].

Gene transfer to stem cells

The challenges in developing gene transfer strategies for stem cells are (1) how to most efficiently infect the cells, (2) gene silencing during differentiation, (3) if gene expression should be transient or persistent, and (4) if gene expression is persistent should it terminate once the cell has differentiated into the desired phenotype? Gene transfer has been accomplished to a variety of stem-cell types. Human and murine embryonal stem cells have been successfully infected with subsequent gene expression with adenovirus, AAV, and lentiviral vectors [280]. The reported efficiency for each of these vector systems is limited, however, requiring selection to obtain pure populations of genetically modified cells. Gene expression can be affected by subsequent differentiation of the cells, and it is not clear how the stem-cell properties are affected by the various gene therapy modalities themselves without transgene expression. Bone marrow−derived endothelial progenitor and MSC have been successfully transduced with the most commonly used gene therapy vectors [5].

Gene transfer to control uncontrolled stem-cell growth

Gene transfer strategies developed to control the growth of cells for cancer gene therapy applications can be applied to controlling unwanted growth of stem cells, in particular the risk of the development of teratomas with embryonic stem cells. Some of the suicide gene transfer strategies, including the prodrug strategies using herpes-simplex thymidine kinase (ganciclovir) and cytosine-deaminase (5-fluorocytosine) that lead to activation of cell death following administration of the prodrug may prove useful. Other suicide genes may be used with regulatable gene expression systems (as outlined above, Table 28.4) may be useful to control potential malignant stem-cell growth, as long as there is no “leak” of baseline gene expression of the suicide gene.

Gene transfer to instruct stem-cell differentiation

Gene transfer strategies may prove useful in providing the necessary environmental factors necessary to develop

specific phenotypes from stem cells. For example, expression of growth factors or other known differentiation signals secreted by the stem cell should aid in mediating differentiation, that is, the genetically modified stem cell would create its own favorable microenvironment for differentiation. Expression of these factors could be regulated by inducible gene expression systems. For example, for muscle-derived MSC, with their potential for the treatment of skeletal, cardiac and smooth muscle injuries and disease, the cytokines required for the differentiation in the respective lineage have been identified [281].

Gene transfer to regulate gene expression

Regulation of gene expression is critically important in the maintenance and differentiation of stem cells, and the transfer of genes coding for factors that regulate endogenous gene expression in response to specific stimuli could prove very helpful for stem-cell therapies. This concept has been used in gene transfer strategy to regulate angiogenesis in the ischemic myocardium. AAV vector–mediated transfer of a hypoxia a responsive element to ischemic myocardium resulted in endogenous expression of the vascular endothelial growth factor (VEGF) [282]. Similarly engineered transcription factors capable of activating endogenous VEGF expression have been successfully transferred with adenoviral vectors [283]. As more of the gene expression and regulation patterns critical for stem-cell differentiation and maintenance are known, the possibilities to direct or aid in gene expression using gene transfer are significant.

One potential barrier to using embryonic stem cells in humans is rejection of the transplanted cell by the immune system [284]. This could theoretically be circumvented by using gene transfer with the relevant gene to autologous stem cells. For example, transfer of a genetically corrected nucleus to an enucleated egg from an unrelated donor would result in the generation of genetically modified embryonic stem cells that could be then differentiate and correct differentiated cells transplanted to the same patient (Fig. 28.5).

Challenges to gene therapy for tissue engineering

Although proven to be very effective in a variety of model systems, the major challenges for gene therapy to cure human diseases include circumvention of immune responses against viral vectors, transferring the genes to a sufficient number of cells to change the phenotype and controlling the expression of the gene. The main hurdle for successful gene therapy to compensate for a missing or defective protein has been the host response to the gene therapy vector, the lack of long-term gene expression, and problems related to integration into the host genome. However, short-term expression of transgenes has been feasible in humans and shown efficient in a variety of cell types and tissues. Immunogenicity against a nonself transgene, as well as vector-derived proteins, may be an issue if gene transfer is being used for permanent expression of a transgene. Controlling the gene expression is a challenge that needs to be addressed, especially if gene transfer strategies are combined with stem-cell

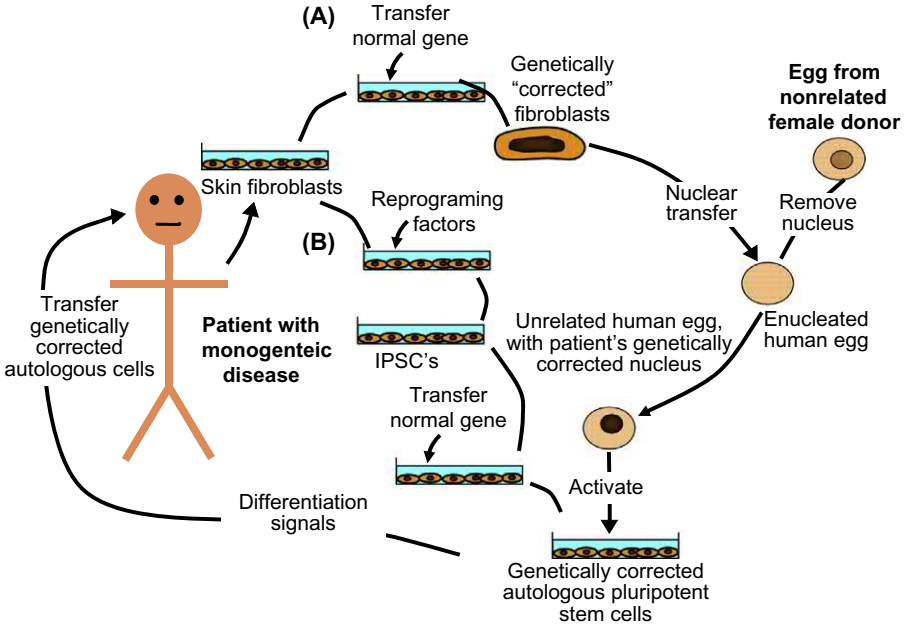

FIGURE 28.5 Strategy to combine gene therapy with nuclear transfer and stem-cell therapy. Shown is an example to genetically modify skin fibroblast of an individual with a monogenetic disease to correct the abnormality. The nucleus of the genetically corrected fibroblast is then transferred to an enucleated egg of an unrelated donor to generate corrected autologous pluripotent stem cells that can be differentiated and then transferred back to patient.

strategies. Most regulatable gene expression systems show some baseline expression, which may be problematic if gene transfer is used to regulate gene expression for stem-cell differentiation.

Over the past decade, progress has been made in addressing many of these challenges that led to clinical approval of several gene therapy vectors for cancer and genetic diseases. Based on the continued focus on solving these issues, together with gene therapy, the knowledge gained from successes and setbacks will also prove beneficial in their use for tissue engineering and stem-cell applications.

Introduction

This chapter provides an overview of intracellular gene and nucleic acid delivery by engineered nanoparticles (NPs) and viral vectors, including particle and vector design, strategies for overcoming cellular barriers, and methods for delivery to cells that are particularly relevant to tissue engineering and regenerative medicine. NPs include a variety of engineered, chemically defined, colloidal objects capable of entering cells and tissues and delivering cargo intracellularly. Viral vectors broadly include a variety of infectious particles with diverse properties that can be adapted to tissue engineering and other applications. This chapter focuses on both nonviral and viral approaches for safe and efficacious intracellular delivery of nucleic acids and delivery routes including systemic delivery and local administration to pathological sites.

Fundamentals of gene delivery

The engineering of nucleic acid delivery systems is a valuable approach for tissue engineering and regenerative medicine. Nucleic acid-based drugs are broadly sought to (1) replace missing, mutated, or deficient genes, (2) for RNA interference (RNAi) to silence aberrant, regulatory, or pathologic genes, (3) to control RNA splicing to remove pathogenic exons, (4) to control microRNA (miRNA) activity, or (5) for genome editing to correct endogenous mutations, or to change cell function or cell fate (Fig. 29.1).

Gene replacement or addition is a more mature but still challenging field that involves transfer of DNA that encodes the desired gene typically through viral delivery [1]. Several gene therapy approaches are now approved clinical products with many more in the pipeline. Gene therapy is based on the premise that loss-of-function genetic disease can be reversed by replacing the defective genes. Through nearly 50 years of development, gene therapy is poised to make a substantial impact in medicine in the coming years.

Because of the potency, specificity, and transient activity of RNAi, engineering vectors for delivery of this class of gene therapy has become a major focus of the tissue engineering and medical communities, and significant progress has been made toward technologies that enable therapeutic gene silencing in vivo, including the first clinically approved RNAi therapeutic [2]. Gene expression knockdown can be achieved through several different strategies, the earliest of which was utilization of antisense oligodeoxynucleotides (ODNs), which are single-stranded DNAs that bind to complementary mRNAs and yield a relatively modest reduction in gene expression [3]. The mechanism for endogenous posttranscriptional regulation through miRNA was subsequently elucidated, and it was discovered that delivery of double-stranded RNA (dsRNA) achieved more potent gene silencing than ODNs [4,5]. Short hairpin RNA (shRNA), which more closely mimics the structure of endogenous miRNA, has also been delivered directly or via encoding plasmids [6]. In both cases, the enzyme Dicer cleaves the larger precursor/transcript to form small interfering RNA (siRNA), which is a 19−21 base pair, dsRNA [7]. siRNA can also be delivered directly to cells as a short dsRNA. The activated RNA-induced silencing complex (RISC) mediates recognition and enzymatic degradation of mRNA that is complementary to the siRNA antisense/guide strand [5].

Targeted exon skipping has been used to restore function of diseased proteins by masking splice motifs and removing out-of-frame exons or mutated pseudoexons

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00030-7

from the mature mRNA. Exon skipping has been applied clinically for Duchenne muscular dystrophy and spinal muscular atrophy with the FDA approval of eteplirsen and nusinersen [8,9].

miRNAs are a class of noncoding RNAs that negatively regulate translation of mRNA. Single-miRNA molecules can regulate hundreds of genes and can act as regulators of entire gene networks. miRNAs are often dysregulated in local pathologies, and as a result, miRNA inhibition has been pursued to improve tissue regeneration [10].

Genome editing has received increasing attention with multiple platforms entering clinical trials for a variety of indications. Notably, zinc-finger nucleases have entered clinical trials for therapeutic cell therapy applications and for the first-in-man genome-editing clinical trial for Hunter's syndrome (MPS II, NCT03041324). CRISPR/Cas9 is used ubiquitously in research and has entered clinical development in cancer immunotherapy (NCT03399448) and was recently granted IND status by the FDA for inherited blindness [11]. CRISPR/Cas9 is extremely versatile as the endonuclease Cas9 is guided to a gene of interest using a guide RNA (gRNA). Genome editing is under extensive preclinical investigation in numerous applications including tissue engineering. Further, nuclease-deactivated Cas9 can be fused with a range of proteins to impart transcriptional control, modify epigenetic states [12], and make targeted single-nucleotide changes with base editors [13].

Gene replacement, RNAi, and genome editing all face common intracellular delivery barriers to reach the cytoplasm or nucleus (Fig. 29.2). Therapies for stable gene expression, including shRNA, must localize to the cell nucleus, while RNAi activity of siRNA depends upon delivery to the cytoplasm, where the RISC machinery is located. Nonviral approaches, which offer a potential safety margin, typically involve formulation with synthetic reagents such as polymers or lipids; however, these synthetic formulations are typically less efficient at triggering cell uptake and navigating subsequent intracellular delivery barriers. Recent advances in viral technologies have made these vectors safer than previous generations, and there are numerous ongoing trials for clinical applications of viral technologies. At the same time, high-throughput screening and other advanced synthetic approaches are yielding more efficient nonviral carriers than ever before, highlighted by the recent successful

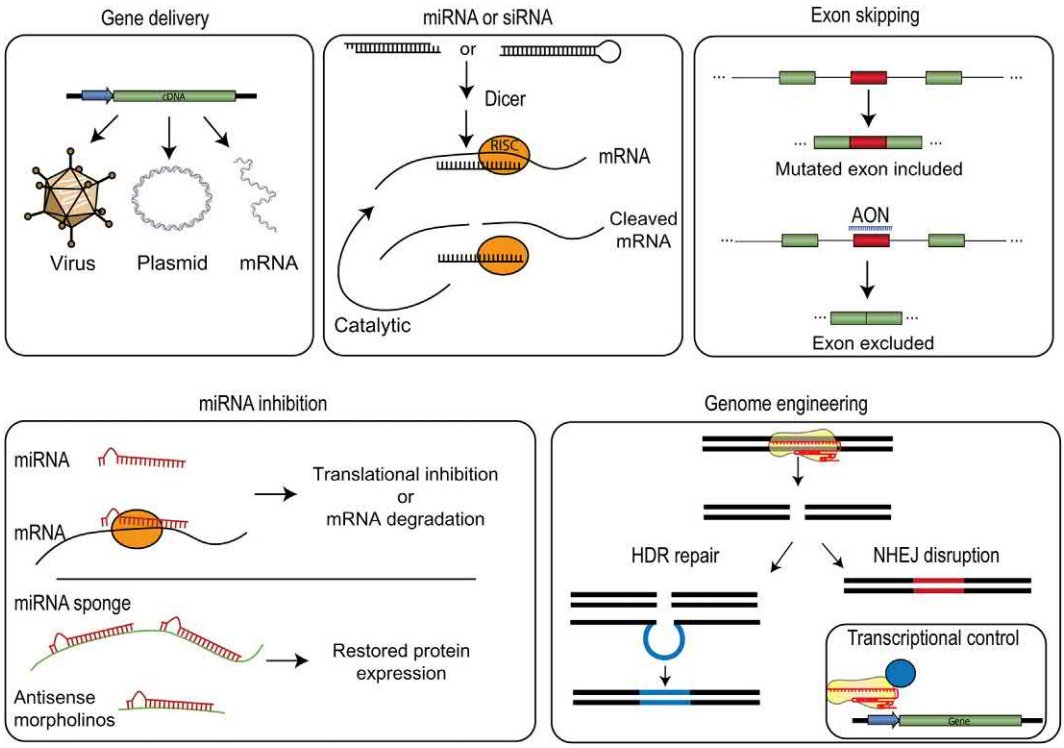

FIGURE 29.1 Gene delivery approaches under investigation. (A) Gene delivery is accomplished by packaging a desired transgene cDNA into a virus, a plasmid or a messenger RNA. (B) RNAi is accomplished by provided a siRNA or a short hairpin RNA to catalyze mRNA degradation. (C) Exon skipping is performed by provided antisense oligonucleotides that mask splice motifs removing target exons from the mature mRNA. (D) miRNA inhibition is performed by providing miRNA decoys or miRNA sponges that prevent translational inhibition. (E) Genome engineering can be accomplished by homology directed repair to precisely repair a gene, NHEJ to disrupt or remove segments of a gene, or to engineer transcriptional activators or repressors. *NHEJ,* non-homologous end joining; *RNAi*, RNA interference; *siRNA*, small interfering RNA.

RNAi product patisiran [2]. Optimized nonviral carriers are being applied broadly including genome engineering displaying high efficiency in CRISPR/Cas9-mediated in vivo hepatocyte editing [14]. Sections "Viral nucleic acid delivery" and "Nonviral nucleic acid delivery" survey the latest technologies for both nonviral and viral approaches to nucleic acid delivery, and subsequent sections address tissue engineering applications and recent clinical trial results.

Biodistribution, targeting, uptake, and trafficking

For successful gene therapy in vivo, viruses or nonviral DNA/RNA carriers have three main delivery barriers that must be overcome (Fig. 29.2):

1. efficient biodistribution to the desired site of action (i.e., tumor or site of tissue damage/dysfunction),
2. internalization of the cargo by the targeted cell type, and
3. trafficking to the subcellular compartment where the cargo will be active (i.e., cytoplasm for siRNA or nucleus for plasmid or genome editing).

Viruses have evolved to efficiently overcome the latter two barriers but achieving efficient access to the desired target cells is still a challenge. The successful design of synthetic delivery systems requires consideration of all three of these barriers and a thorough understanding of the mechanisms that dictate the interactions of delivery systems with target cells.

Tissue biodistribution/targeting

The most straightforward approach to site-specific delivery is local application, such as inhalation of dispersed solutions into the lungs to treat cystic fibrosis, or direct injection into the affected tissue, for example, subretinal injection for inherited blindness. In contrast, systemic delivery systems should be designed with functionalities that enhance the accumulation (biodistribution) of the therapeutic in the target tissue, optimize the kinetics of retention of the cargo within the target site, mediate specific binding to and uptake by a target cell population, and increase trafficking of the cargo to the desired intracellular compartment. These functions are often achieved through optimization of physicochemical properties to preferentially enhance nonspecific accumulation at defined sites and/or inclusion of ligands that target cell receptors uniquely expressed or overexpressed by the target cell type.

Key characteristics for intravenously delivered drug carriers are avoidance of rapid renal clearance or blood clearance by the reticuloendothelial system and preferential accumulation and retention at the site of disease. Long circulation half-lives are vital for optimal performance of delivery systems designed to passively accumulate in target tissues. In some cases, drug carriers with long circulation times can extravasate through abnormally large fenestrations of the cancer vasculature and nonspecifically accumulate in tumor tissues through the enhanced permeation and retention (EPR) effect [15]. The EPR effect occurs in animal models because poorly formed blood vessels in tumors allow leakage of nanomedicines into the tissue, with poorly formed lymphatic drainage contributing to the accumulation. Many cancer-targeted nanomedicines have been designed on this basis. Utilization of EPR effect has also been demonstrated for sites of tissue inflammation, including osteoarthritis [16]. However, It is important to note that the EPR effect has come under scrutiny for cancer therapy owing to variability of efficacy in clinical trials and as a result should be

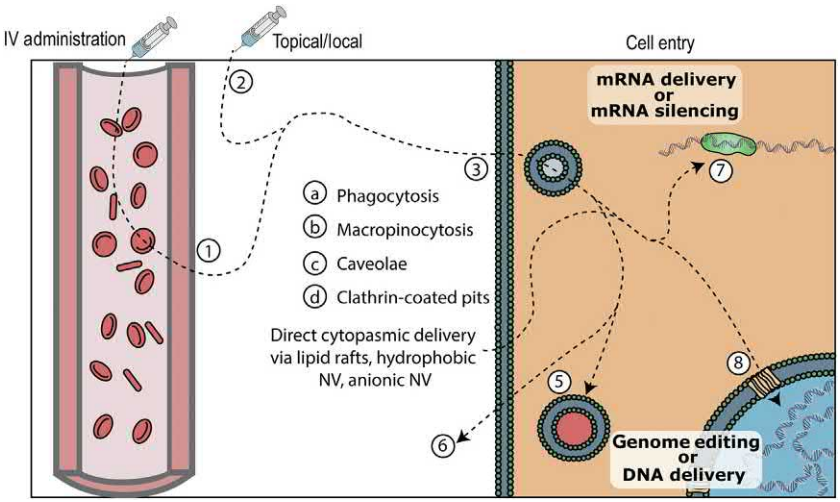

FIGURE 29.2 Gene delivery vehicles must navigate difficult delivery barriers. (1) IV administered vehicles must navigate the circulation and extravasate into the target tissue. (2) Local delivery can bypass the vascular barrier. (3) Particles must be internalized by cells through one of a number of mechanisms. (4) Particles are trafficked through the cytoplasm and must avoid (5) degradation in lysosomes and (6) exocytosis. After endosome escape, (7) mRNA and siRNAs must be delivered to the cytoplasm for activity while (8) DNA and genome editing machinery must be delivered to the nucleus for activity. *siRNA*, small interfering RNA.

evaluated on a case-by-case basis (see Refs. [17,18] for more discussion).

Optimization of physicochemical properties such as surface charge, size, shape, and mechanical properties are major design considerations for achieving the desired biodistribution of nonviral delivery systems [19,20]. Traditionally, nanocarriers have been synthesized using bottom-up synthetic approaches to form NPs such as micelles, dendrimers, and liposomes that have been predominantly limited to formation of spherical structures. For such structures, it has been hypothesized that NPs in the size range from approximately 10−200 nm may be ideal. Structures smaller than 10 nm suffer from rapid renal filtration and systemic clearance and larger structures will have decreased tissue penetration following extravasation [21]. One study administered 80−240 nm spherical NPs and showed the smallest NPs had longer circulation times, decreased hepatic clearance, and increased tumor accumulation [22] and another study showed that the biodistribution of NPs changed in response to systemic inflammation [23]. It may be desirable to design gene delivery vectors to be as small as possible, as long as they are above the size cutoff for renal filtration. However, NP assemblies larger than the renal filtration limit may still be cleared by renal filtration by disassembly at the glomerular basement membrane in the kidneys, especially in the context of the polycationic materials used for gene delivery [24,25]. It may be possible to stabilize the nanomaterial to avoid renal disassembly [26] or adhere to a long-circulating molecule like albumin [27].

In addition to size, the shape of nonviral vectors has a significant effect on behavior for in vivo systemic delivery applications; for example, rod-shaped filomicelles have 10 times longer circulation times relative to spherical micelles [28]. Innovative techniques have been developed in labs such as those of Mitragotri [29,30], DeSimone [30], and Roy et al. [31] that enable nanofabrication of particles with arbitrarily defined size and shape. Decuzzi et al. have contributed computational modeling and in vivo experimental data showing a significant effect of particle shape on biodistribution and ability to achieve vascular targeting [32]. They also demonstrated that shape-defined, discoidal, porous silicon nanovectors accumulate up to five times more in tumor tissues than spherical particles with similar diameters, and these shape-defined particles have also been effectively used for two-stage delivery of siRNA [33]. Decuzzi et al. has further demonstrated polymeric deformable nanoconstructs that can pass through small fenestrations, have high circulation time, and avoid clearance through the mononuclear phagocytic system [34]. In the case of micron-sized particles, stiffness of particles has been shown to have a significant impact, with stiffer particles rapidly distributed to the lungs, and those with a lower elastic modulus preferentially sequestered in the spleen [35].

Surface chemistry, in particular surface charge, can be tuned to act synergistically with physical properties such as size and shape in order to engineer optimal delivery systems. For example, neutrally charged NPs generally have lower rates of opsonization [36], and cationic NPs with superficial amines produce the highest levels of complement activation [37]. Xiao et al. applied a micellar NP (∼20 nM) to study the systemic effect of surface charge on biodistribution of a series of seven NPs with zeta potential ranging from −27 to +37 mV in tumor-bearing mice [38]. The authors determined that a "slight" negative charge (in their case, −8.5 mV zeta potential) was ideal for tumor accumulation and that "highly" positively or negatively charged NPs were preferentially cleared by macrophages (Kupffer cells) in the liver. Arvizo et al. [39] produced similar results using gold NPs, and they found that neutral or zwitterionic surfaces (−1.1 or −2 mV, respectively) produced longer circulation times and better tumor biodistribution than highly negative (−38 mV) or positive (+24 mV) NPs.

Most nonviral nucleic acid delivery systems involve formulation with an excess of cationic biomaterials in order to tightly package the polyanionic nucleic acid cargo into nano-sized particles. Unfortunately, the presence of surface-exposed cationic materials is not amenable to achieving the optimal, "slightly negative" negative surface charge desirable for systemically delivered nonviral vectors. Attachment of poly(ethylene glycol) (PEG), or PEGylation, is a popular approach for giving cationic carriers more stealth by shielding nonspecific cell interactions, reducing reticuloendothelial system clearance, and extending the blood circulation half-lives [40]. There are several fundamental properties of PEG that make it desirable for systemic delivery applications. It is a flexible, hydrophilic, and nontoxic polymer that reduces opsonization and nonspecific interaction with blood cells. It can reduce the access of degradative enzymes to drug cargo and provide increased steric bulk, which minimizes rapid renal clearance. The desirable performance of PEG is well documented in these regards, and PEG polymers are incorporated into therapeutic proteins and liposomal drug nanocarriers currently in the clinic. With the ubiquitous use of PEG, strategies to avoid immune recognition of PEG have emerged, including diversifying the structure of PEG in drug conjugates [41] and alternatives to PEG including zwitterionic phosphorylcholine−based polymers [42]. Zwitterionic poly-carboxybetaine conjugates have also been shown to have reduced immunogenicity compared to PEG even when conjugated to immunostimulatory proteins [43].

For gene therapy, one risk is that the inertness achieved by PEGylation can mask underlying

functionalities necessary to trigger cell uptake and/or endosomolytic activity of nonviral delivery systems. Interestingly, polyzwitterion nanocarriers appear to suffer less from the "PEG dilemma," meaning that large molecular weight zwitterionic polymers can be used that both reduce protein NP surface adsorption and increase circulation time, while maintaining favorable cell interaction/internalization properties [42]. The most common strategy for increasing internalization of PEGylated nanocarriers is incorporation of ligands, antibodies, or peptides that bind to specific cell receptors that internalize drug carriers and ferry them into the cell. Several promising approaches are also under development for attaching PEG by linkages that are reversible when exposed to signals uniquely present in the target tissue. For example, one can use attachment chemistries that are labile when exposed to tumor microenvironmental hallmarks, such as mild acidity and high matrix metalloproteinase (MMP) activity, in order to trigger shedding of PEG from the nanocarrier surface [44–46].

Conjugation of cell receptor ligands to the surface of nonviral carriers is one of the most studied preclinical approaches for enhancing localization, retention, and bioactivity in specific target tissues. Targeted delivery can potentially increase bioavailability of the therapeutic agent at its site of action and concurrently reduce off-site effects. Significant progress has been made in actively targeting unique markers on the vascular endothelium in specific tissues. For example, phage display technology has been instrumental in identifying targeting peptides that bind to specific, vascular "zip codes," and peptides identified using this technique present a potentially promising strategy for enhancing tissue-specific accumulation of nonviral delivery systems [47]. In order to achieve delivery into the tissue, transcytosis must occur across the vascular endothelium or, for the brain, the blood–brain barrier (BBB). Recently, systemic strategies to increase drug penetration into the brain have been developed, including temporary disruption of the BBB, chemical modification of available therapeutic substances, utilization of endogenous transport systems, and employment of lipid-based delivery systems [48].

Many other targeting approaches increase binding to cells at the target site once extravasation from the vasculature has occurred. For these approaches, biodistribution is primarily dictated by the physicochemical properties of the vector, and the targeting moiety affects retention and/or bioactivity at the site. Active binding to extravascular cells in the target site can enhance local retention through decreased diffusion or clearance from the tissue, and this prolonged residence time and/or targeting to actively internalized receptors can improve bioactivity. For example, cell-surface receptors are commonly targeted, because they have increased expression on a variety of cancer types leading to internalization through receptor-mediated endocytosis [49]. While there has been some clinical evaluation of targeted nonviral vectors [50], a variety of techniques are being actively pursued to develop targeting moieties based on natural ligands, antibodies or their fragments, peptides, aptamers, sugars, and small molecules. Furthermore, screening techniques such as peptide phage display are aiding in the discovery of new tissue-specific drug targets. Though they will not be reviewed in detail here, it should also be mentioned that several methods have also been studied for externally stimulated tissue targeting and drug release in response to stimuli such as light, ultrasound, ionizing radiation, or magnetic force [51].

Cellular uptake and intracellular trafficking

Once gene delivery systems have reached the target tissue, their route of internalization and trafficking to the desired subcellular compartment is paramount to achieving optimal bioactivity. To a large degree the mode of internalization dictates the subsequent route of trafficking within the cell. Thus an understanding of intracellular uptake and trafficking facilitates the design of better and more efficient gene delivery systems. Both experimental and simulation-based approaches can aide in the development of strategies for cellular internalization [52]. For additional information, the reader is referred to other reviews on nanovehicular uptake and trafficking [53,54].

Endocytosis is a generalized terminology used to describe cellular internalization. Endocytosis of nonviral vectors is the result of colocalization with the external side of the cell membrane (via receptors or nonspecifically) followed by formation of invaginations in the cell's plasma membrane that buds off inside the cell, to form lipid bilayer-enclosed vesicles that sequester the internalized cargo. Three kinetic modes of endocytosis can be defined: fluid-phase, adsorptive, and receptor-mediated endocytosis [55]. Fluid-phase endocytosis refers to the bulk uptake of solutes in exact proportion to their concentration in the extracellular fluid. This is a low-efficiency, nonspecific process. In contrast, receptor-mediated endocytosis involves internalization of macromolecules that are bound to and concentrated at the cell surface before internalization. In adsorptive endocytosis, molecules preferentially interact with nonspecific binding sites (e.g., electrostatic interaction of cationic vectors with anionic heparin sulfate proteoglycans). Internalized endocytotic vesicles subsequently undergo a complex series of fusion events that direct the internalized cargo to other intracellular compartments.

Endocytosis occurs by multiple mechanisms that fall into two broad categories: phagocytosis, or cell ingestion (of large particles), and pinocytosis, or cell drinking (of fluid and solutes) [56]. Phagocytosis is typically restricted

to specialized mammalian immune cells (dendritic, macrophages, monocytes, and neutrophils). Distinct subcategories of pinocytosis will be discussed further below, including macropinocytosis (MPC), clathrin-mediated endocytosis (CME), caveolae-mediated endocytosis (CavME), and lipid raft-mediated endocytosis (LRME). Transcytosis and exocytosis, though they will not be discussed at length here, are "competing" cellular pathways that involve passage directly through the cell and expulsion of intracellular material into the external environment, respectively. A summary of different mechanisms is presented in Table 29.1.

MPC is generally considered to be a nonspecific process in which cells take up large volumes of extracellular fluids and solutes. MPC is characterized by membrane ruffling and formation of protrusions that ultimately produce large endocytic vesicles called macropinosomes ($>1\,\mu m$ in size, up to $5\,\mu m$), which sample large volumes of the extracellular milieu. The macropinocytotic process is constitutive in specialized cells (macrophages and dendritic cells) and in some tumors, and greater internalization may be achieved by nonspecific binding of solutes to the cell membrane (adsorptive pinocytosis). Although the internal pH of macropinosomes decreases, they do not fuse into lysosomes. This pathway provides some advantageous aspects, such as the increased uptake of particles and macromolecules, the avoidance of lysosomal degradation, and the ease of payload escape from macropinosomes due to their relatively leaky nature.

CME constitutively internalizes cell membrane sites that contain concentrated receptor–ligand complexes to form clathrin-coated vesicles (size $\sim 100-150$ nm), and CME can provide efficient cell uptake of essential nutrients, antigens, growth factors, and pathogens. Since receptors are differentially expressed in various cell types and tissues, receptor-mediated endocytosis via clathrin-coated pits provides a potential strategy for cell- and tissue-specific delivery of nonviral gene vectors. Molecules entering via this pathway experience a drop to approximately pH 6 in the early endosome, with a further reduction to approximately pH 5 during progression to late endosomes and lysosomes [57]. While the initial events in the endocytosis of the receptor–ligand complex are similar for most systems, the processing of the ligand can differ, depending on both receptor and cell type. Following CME, ligands and receptors are sorted to their appropriate cellular destinations, such as lysosomes, the Golgi apparatus, the nucleus, or back to the cell-surface membrane. In the conventional model the internalized ligands are degraded in the acidic endo-lysosomal compartments while the receptor is recycled back to the plasma membrane.

CavME is mediated by flask-shaped invaginations in the cell membrane called caveolae (50–60 nm in size) that are particularly abundant on endothelial cells. Caveolae are cholesterol and sphingolipid-rich microdomains of the plasma membrane, and they are concentrated "hot spots" for a diversity of signaling molecules and

TABLE 29.1 Efficiency of nanoparticle entry via multiple portals as differentiated by cargo chemistry/size[a] and cell type.

Phagocytosis		Pinocytosis				
		Macropinocytosis (fluid phase)	CME	Caveolae-mediated rafts	Lipid rafts	Clathrin- and caveolin-independent
Vehicle size	1–10 μm[b]	1–5 μm[b]	<150 nm	<60 nm	40–60 nm	200–300 nm
Cell types	Dendritic, macrophages, monocytes	Many cells	Many cells	Differentiated endothelial cells, apipocytes, epithelial, and muscle cells	Lymphocytes, cancer cells, rodent macrophages	Specialized cells, endothelial cells, and others

CME, Clathrin-mediated endocytosis.
[a]*Typically, cargo chemistry determines a size range due to technological limitations (e.g., dendrimer-based and micellar-based nano-vehicles are limited to rather small sizes).*
[b]*Phagocytosis and macropinocytosis most likely do not contribute to the nanovehicular uptake.*
[c]*The efficiency of uptake may depend on nanoparticle type and chemistry. The proportion between different uptake mechanisms may vary. Estimated on scale of 1–5, 5 being the highest.*

membrane transporters. A unique aspect of CavME is that it is a nonacidic and nondigestive route of internalization that bypasses lysosomes and thus may be an advantageous route for drug delivery. However, caveolae are internalized slowly and their fluid-phase volume is small; this results in low uptake capacity for external cargo. Although endothelial caveolae constitute 10%−20% of the cell surface [56], it is unlikely that they contribute significantly to constitutive endocytosis.

LRME-independent uptake is an alternative pathway that can be operative for anionic and neutral-lipid liposomes, solid-lipid NPs, and hydrophobic (i.e., polystyrene) NPs. Lipid rafts are cholesterol- and sphingolipid-rich 40−60 nm microdomains that are characteristic of cells that lack caveolin and caveolae. This uptake mechanism is likely mediated through scavenger receptors that are involved in the uptake of both lipophilic and anionic cargo [58]. For example, scavenger receptor class B (SRB1; CD36 superfamily of proteins), which is expressed on mature macrophages, binds to a diversity of polyanionic protein, polyribonucleotide, polysaccharide, and lipid ligands. The involvement of SRB1 in liposome uptake has been further supported by the competitive inhibition of hepatic cell uptake of neutral phospholipid/cholesterol liposomes by the strong polyanion polyinosinic acid [59]. LRME bypasses lysosomes and is facilitated by the cellular transmembrane potential. This is a unique feature of CavME, requires an energy input.

Physicochemical properties of NPs play a significant role on the level of uptake and the mode of transport into cells. Numerous studies have shown that surface charge has a significant impact on cellular internalization of nanocarriers [60]. Size has also long been known to affect uptake, with several studies concluding that NPs in the 100−200 nm range possess the best properties for cellular uptake [61]. Great strides have been made in understanding the interplay between size and shape on cell internalization. Using polystyrene particles of various sizes and shapes, Champion and Mitragotri studied phagocytosis by alveolar macrophages, and they were some of the first to report on the importance of shape rather than just size [62]. In particular, the local particle shape at the cell-particle interface was found to dictate macrophage phagocytosis versus spreading of particles (Fig. 29.3A). DeSimone et al. tested uptake in nonphagocytic HeLa cells for a series of particles with varying sizes and shapes that were fabricated using a lithographic method called PRINT (particle replication in nonwetting templates; Fig. 29.3B) [63]. They found that the internalization kinetics of the NPs by HeLa cells depended on aspect ratio and particle size and/or volume. The most striking finding was that rod-like particles were internalized more rapidly, with cylindrical particles of 150 nm diameter and a 3:1 aspect ratio showing the most rapid uptake in their study. Their data also indicated that the PRINT particles used a combination of the different internalization pathways described above to enter the cells, suggesting that size and shape alone cannot be utilized to fully define the mechanism of uptake and subsequent intracellular trafficking.

In addition to optimizing their physical properties, nanovectors can be endowed with a variety of other specialized constituents that dictate their mode of cellular internalization, either by binding to specific internalizing receptors or by directing traffic to specific intracellular compartments such as the cytoplasm and nucleus. There are several examples of amine-containing polymers that buffer endosome acidification and lead to endosome disruption through the osmotic proton sponge mechanism. Poly(alkylacrylic acids) are another class of polymers that can mediate endosomolysis, but they act through an active membrane disruption mechanism. In this case, protonation of carboxylates within acidic environments transitions the polymers from an anionic, hydrophilic state into an uncharged, hydrophobic, and more compact state that is membrane interactive/disruptive [64]. NPs that show a transition in their surface charge from anionic (at pH 7) to cationic in the acidic endosome (pH 4−5) have can thereby escape from endosomal compartments [65].

For plasmid gene delivery, trafficking to the nucleus is of particular significance. As discussed in section "Nonviral nucleic acid delivery," polymers and lipids are the two main classes of biomaterials used to formulate nonviral vectors, and choice of vector can affect, among other things, the mode of cell internalization. For example, the uptake of cationic lipids proceeds mainly by the clathrin-dependent pathway, but internalization of polymer-based systems is more dependent on the polymer and the cell type. Polymer-based delivery systems can simultaneously proceed by both clathrin-dependent and clathrin-independent pathways in the same cells [66]. Separately blocking either the clathrin- or caveolae-dependent pathway does not dramatically affect quantity of vector uptake, but blockage of caveolae-mediated uptake significantly abrogates gene expression, suggesting this route of uptake plays a significant role in intracellular trafficking to the nucleus [66,67]. In agreement with this result, Sullivan et al. have shown that use of histone H3 tail peptides that predispose trafficking of polyplexes to caveolar pathways can be used to enhance plasmid transfection [68]. Their follow-up work has provided mechanistic evidence that caveolar polyplexes are trafficked to the nucleus through a retrograde Golgi-to-ER (endoplasmic reticulum) pathway [68]. Other mediators of intracellular trafficking have also been successfully codelivered to modulate NP intracellular trafficking. For example, fusogenic, endosomolytic peptides or nuclear localization signals can be attached to NPs to enhance targeting to the

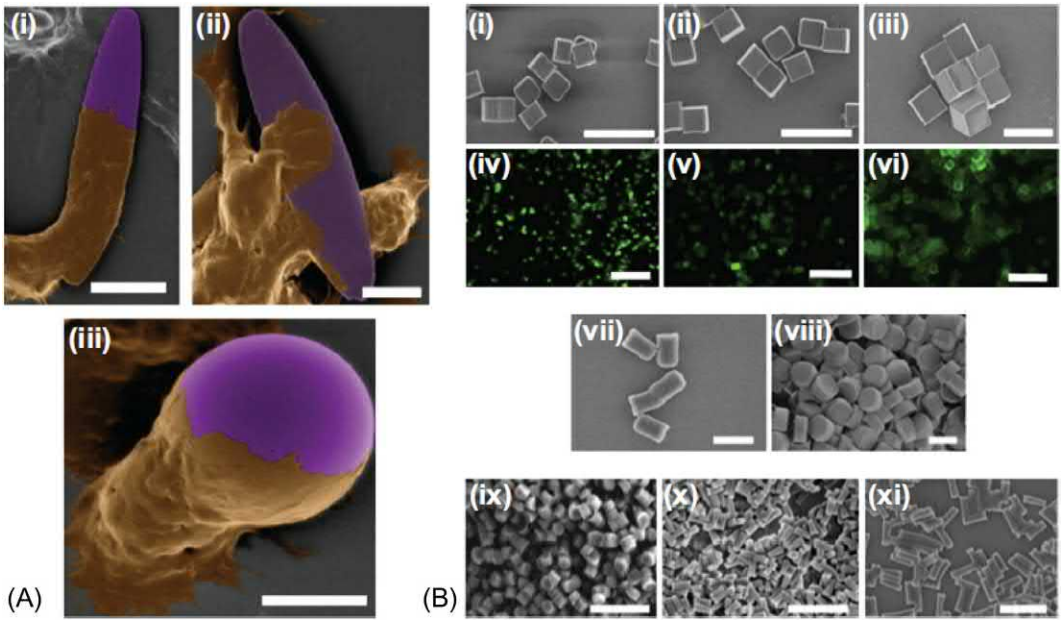

FIGURE 29.3 Nanoparticulate shape variation. (A) Scanning electron microscopy images provided evidence that particle internalization is dependent on local particle shape from the perspective of the phagocyte (cells and particles were colored brown and purple, respectively). Phagocytosis progressed further when the cell approached the end of the opsonized elliptical particle relative to when contact was initiated on the flatter, more elongated side of the particle. Phagocytosis progressed further when a smaller particle dimension was approached by the cells, that is, as shown for the smaller spherical particle in panel (iii). Scale bar = 10 μm is subpanel (i) and 5 μm in subpanels (ii)−(iii) [43]. (B) Panel of micrographs demonstrating PRINT particles varying in both size and shape. Subpanels (i)−(iii) show scanning electron micrographs of cubic particles of size 2, 3, and 5 μm, respectively, and subpanels (iv)−(vi) show fluorescence micrographs of the same cubic particles. Subpanels (vii) and (viii) show scanning electron micrographs of cylindrical microparticles of 1 μm in height with diameters of 0.5 and 1 μm, respectively. Subpanels (ix)−(xi) show scanning electron micrographs of (ix) 200 nm diameter and 200 nm height (x) 100 nm diameter and 300 nm height and (xi) 150 nm diameter and 450 nm height. Scale bars = 20 μm for (i)−(vi) and 1 μm for (vii)−(xi) [44].

nucleus. Recently, it has also been shown that treatment with histone deacetylase inhibitors can be used to liberate polyplexes from sequestration at the perinuclear recycling compartment/microtubule organizing center and to thereby increase transgene expression by up to 40-fold [69].

Viral nucleic acid delivery

Introduction to viral gene therapy

A virus is a biological NP consisting exclusively of components including proteins, lipids, carbohydrates, and nucleic acids. Each virus carries a viral genome that encodes the structural and functional elements of the infectious particle, but it does not encode the necessary machinery for transcription, translation, and genome replication. Therefore viruses infect living cells and can only replicate inside these hosts by hijacking native cellular transcription and translation processes.

Viruses have evolved to be extremely effective at infecting and replicating within host cells. Therefore many of the challenges of nonviral gene delivery, such as cellular uptake, trafficking, and nuclear import, are readily addressed by the innate biological properties of viral vectors. To take advantage of these properties, researchers have reengineered natural viral vectors by removing all pathogenic components and signals necessary for virus replication within infected cells and replacing them with therapeutic genetic sequences. This approach has been widely successful in engineering vectors for efficient gene delivery in research but has encountered severe hurdles en route to clinical efficacy.

The first gene therapy clinical trial in 1990 used a retroviral vector for gene delivery to T cells of patients with severe combined immunodeficiency [70]. After 30 years, there have been over 2000 new clinical gene therapy clinical trials worldwide with over 200 initiated in both 2017 and 2018. Over 66% of these trials have used viral vectors for gene delivery [71]. The first gene therapy approved for clinical use was an adenoviral p53 vector for cancer treatment in China in 2003 [72]. In 2012 a landmark gene therapy was approved in Europe consisting of an adeno-associated virus (AAV) encoding a gene to treat a rare genetic disorder known as lipoprotein lipase deficiency (LPLD) [73], although it has since been withdrawn from the market. In 2018 several new approvals and promising

clinical trial results indicate the potential for viral gene therapy, but the delay in clinical success also underscores the challenges in viral vector engineering.

The viral gene therapy field encountered severe complications before reaching this more recent emergence of positive results. In 1999 a patient named Jesse Gelsinger was treated in a clinical trial with an adenoviral vector as a therapy for a genetic metabolic disease. He died 4 days after vector administration due to a severe inflammatory episode and multiorgan failure, which was later linked to an immune response against protein components of the virus [74]. One year later, another landmark event occurred when the first reports of successful gene therapy for curing a genetic disease, in this case a fatal immunodeficiency disorder, were reported [75]. In all, 20 children were treated with autologous hematopoietic stem cells transduced with retroviral vectors carrying a therapeutic transgene, and ultimately 17 of these patients were cured of the disease [76]. However, five of these cured patients later developed leukemia as a result of integration of the viral vector into the genome near to an oncogene, leading to oncogene activation [77]. One of these five patients died as a result of the leukemia. Due to these adverse events, viral gene therapy was the subject of social and scientific stigma in the early part of the 21st century. However, investigators have been able to identify and address the mechanistic basis of these adverse events, leading to improved viral vectors in numerous ongoing and successful clinical trials. Nonetheless, the fundamental source of these challenges is the complexity of viral vectors, each of which contains hundreds to thousands of copies of dozens of distinct biological macromolecules that perform complex functions. The complexity of viral biology is a primary motivating factor for engineering nonviral delivery vehicles comprising defined chemical components to achieve precise control over all elements of gene transfer and expression.

Although the clinical trial results discussed above are largely focused on rare hereditary disorders, the history and critical concerns of viral vector development are essential to understanding the potential of viral nucleic acid delivery for tissue engineering and regenerative medicine. Furthermore, new medical technologies such as gene delivery are often first developed for fatal diseases for which there is no other option, such as genetic disorders and cancer. The technology development and demonstration of safety and efficacy of gene transfer in these areas is directly translatable to applications in other fields, including tissue engineering.

Types of viral vectors

A variety of viral vectors have been employed to deliver genes to cells. Each approach has its own advantages and disadvantages, including packaging capacity, persistence of expression, immunogenicity, and nonspecific effects on the cellular genome [78,79].

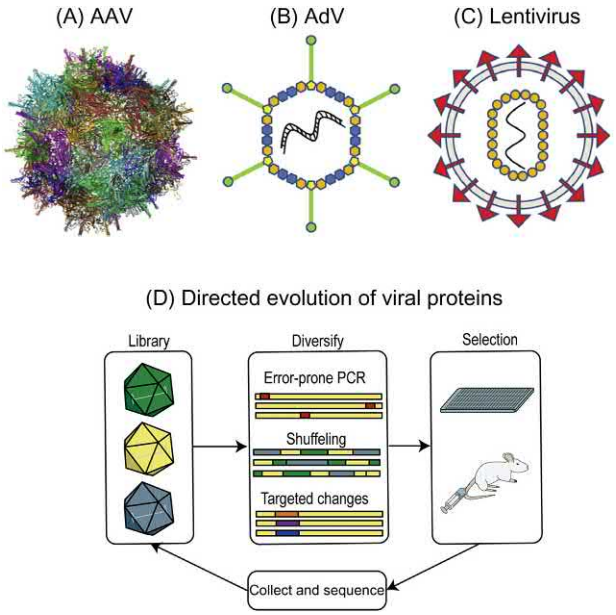

FIGURE 29.4 Representative schematics of viral structures and directed evolution of viral proteins. (A) Adeno-associated virus. The crystal structure of the AAV capsid proteins that encompass the vector and interact with cellular receptors is shown (MMDB ID 20256). Capsid monomers are represented by different colors. (B) Adenovirus. Adenoviral vectors consist of a capsid shell made up of proteins known as hexon (blue), penton (orange), and the penton base (yellow), to which the fiber protein (green) is attached. The double-stranded DNA viral genome is packaged inside the capsid. Other accessory proteins are not shown. (C) Retrovirus/Lentivirus. Retroviral and lentiviral vectors are encompassed with a lipid bilayer envelope (gray), which contains proteins that interact with cell surface receptors (red). Within the envelope, a capsid shell (orange) surrounds the single-stranded RNA genome. (D) Viral vectors can be improved by directed evolution to avoid neutralizing antibodies or find new tissue tropism. Several methods are available to diversify viral libraries including error-prone PCR, capsid shuffling, or targeted changes to the capsid structure. *AAV*, Adeno-associated virus.

Adenoviruses remain a commonly used therapeutic viral vector, largely due to applications in cancer therapy. An adenovirus consists of a double-stranded DNA genome and a protein shell, known as a capsid (Fig. 29.4A). The adenoviral particle binds to cells through fiber proteins in the capsid that recognize specific receptors on the cell surface, followed by endocytosis of the virus. Adenoviral vectors are engineered as replication deficient, exist extrachromosomally, and therefore are not copied with the cellular genome during cell division. As a result, gene expression is transient as the vector is degraded or diluted out during cell replication. The adenovirus has an outstanding ability to escape endosomes, enter the cytoplasm, and pass through the nuclear membrane pore. Despite extensive investigation of dozens of

viral vectors for cancer treatment and promising results in clinical trials, the FDA (Food and Drug Administration) has not approved any adenovirus-based therapeutics to date. Because they cause significant immunogenicity, adenoviral vectors can only be delivered once to a patient. Therefore adenoviruses are not an optimal choice for chronic conditions but can be very useful for modifying cells ex vivo. The primary advantage of the adenovirus is its ability to achieve very high viral titers ($>10^{12}$/mL). Unlike unstable RNA viruses with lipid bilayers, including retroviruses and lentiviruses, adenoviruses can easily be concentrated and these vectors can infect dividing as well as nondividing cells with high efficiency. This is a major advantage for some applications, including in vivo gene transfer to tissues such as the lung, where cell division is infrequent.

AAV are small viruses with single-stranded DNA genomes and a protein capsid (Fig. 29.4B). Unlike other viral vectors developed for gene therapy, wild-type AAV is not known to cause any human disease. The main disadvantages of AAV are that the vector can efficiently package only small transgene cassettes (up to 4.7 kb), the capsid proteins can be immunogenic, and the preparation of the recombinant vector is complex. Nonetheless, AAV is becoming the preferred vector in the gene therapy field [80,81]. This is because like adenovirus, AAV can be prepared to high concentrations and is relatively stable in storage. In addition, recombinant AAV does not efficiently integrate into the genome, and, therefore, there is little risk of disruption of native genes. In contrast to adenoviruses, the AAV vector is particularly stable within the nucleus and can exist with high levels of gene expression for months or years [82–85]. As discussed in more detail next, many serotypes of AAV exist, and the capsid proteins are exceptionally flexible for being reengineered to target new cell types. AAV can also be engineered for tissue-specific targeting following systemic delivery [86].

Retroviral and lentiviral vectors contain a single-stranded RNA genome, a protein capsid, and a lipid bilayer, known as the envelope, that also contains transmembrane proteins (Fig. 29.4C). The vectors are able to efficiently carry about 8–10 kb of transgenic material. A disadvantage of these vectors relative to adenoviruses and AAVs is that the RNA genome and lipid bilayer make them comparably unstable, with a half-life of less than 12 hours at 37°C. This also creates challenges for storage, and the titers of these viruses are relatively low (10^6–10^7 particles per mL), although they can be concentrated to $>10^9$/mL. The major advantages of retroviral and lentiviral gene transfer are that, in contrast to nonviral systems, recombinant viruses are capable of transferring genes to a wide range of different primary cell types, and the genes are stably integrated into the chromosomal DNA. Therefore these vectors are ideal for applications requiring long-term gene expression. However, the integration of these viral vectors into the genome also has the potential to disrupt endogenous genes, such as critical oncogenes and tumor suppressors, as discussed earlier [87]. There are two ways in which this has been addressed. First, self-inactivating (SIN) vectors have been developed in which the strong viral promoters and viral splice sites have been disabled, and therefore the virus is less likely to alter the expression of nearby genes [88]. Second, integrase-deficient lentiviral vectors have been engineered that have the advantages of high-efficiency lentiviral transduction. However, these virions do not integrate into the genome, and they result in only transient gene expression [89]. It is becoming more common that lentivirus is preferred over retrovirus, as retroviral transduction is dependent on cell division, whereas lentiviral transduction is not [90].

Herpes simplex virus type-1 (HSV-1) is a human neurotropic virus used primarily as a vector for gene transfer to the nervous system, although the wild-type HSV-1 can infect and lyse other nonneuronal epithelial cells [91]. Because of its large genome size, up to 30–50 kbp of transgenic material can be packaged into recombinant HSV-1 vectors. At present, two major classes of HSV-1 vectors have been developed: replication-defective viruses and replication-conditional mutants. However, the ability of HSV and these mutant recombinants to establish lifelong latent infections raises concerns about the use of these vectors in humans. Efforts have been made to create HSV-1 amplicon vectors essentially free of HSV-1 helper virus, which might be a promising genetic vehicle for in vivo gene delivery.

Most commonly, viral vectors are used to deliver cDNAs of transgenes encoding proteins that will confer some therapeutic effect. In the context of tissue engineering, these transgenes may facilitate progenitor cell expansion, cell differentiation, tissue formation, and/or wound healing. However, viruses can also be used to deliver siRNAs to silence target gene expression [92]. In order to take advantage of the RNAi mechanisms of processing short dsRNAs by the RISC complex, viral vectors are designed to express shRNAs that mimic the structure of the naturally occurring miRNAs. Both AAV and lentiviral vectors are routinely used for shRNA-mediated gene knockdown. Other possible cargo for viral vectors includes aptamers, ribozymes [93], and genome-editing technologies [94]. Viral particles have also been engineered for the transfer of proteins across the cell membrane [95].

Engineering viral vectors

The natural evolution of viruses has produced a wide variety of gene transfer vectors with innate capabilities

for overcoming many of the challenges of gene delivery to living cells, including recognition of cell-surface proteins, internalization, endosomal escape, trafficking to the nucleus and transfer across the nuclear membrane, and ultimately transcription of viral genes. However, these natural properties do not necessarily address all of the challenges for many applications of gene delivery for gene therapy, regenerative medicine, and tissue engineering. Additional challenges include virus purification, immunogenicity of viral proteins, proper virus localization following systemic delivery, targeting the virus to specific cell types, tissue-specific gene expression, and controlled release of viral vectors from biomaterials. To address these challenges, the biological properties of these vectors can often be reengineered via rational design. Alternatively, the complex properties of these systems may be more easily altered by high-throughput selection of large libraries of variants of viral particles (Fig. 29.4D) [96].

Viral particles predominantly interact with cells via the proteins on the surface of the virus. In the case of retroviruses and lentiviruses, these interactions occur through the proteins in the lipid envelope that comprise the outer surface of the particle, whereas for adenoviruses and AAVs, the capsid proteins encompass the particle [96]. Therefore exchanging these proteins with those of other serotypes, in a process known as pseudotyping, provides a means of changing the tropism of the virus, which is defined by the types of cells the virus will transduce. Modifying the capsid and envelope proteins can also be used to alter the recognition of the viral particles by the immune system. For example, pseudotyping adenoviral vectors with alternative capsid proteins led to increased transduction of human cell lines and primary cells, including transduction of intact human saphenous veins and human bone marrow stromal cells for seeding onto scaffolds for bone tissue engineering [97]. Adenoviral pseudotyping has also been used to evade antivector immunity [98]. The pseudotyping of retroviruses and lentiviruses is particularly straightforward, since the envelope proteins exist in the lipid bilayer and do not serve important structural roles, as the capsid proteins do [99]. This approach has been used to broaden virus tropism to facilitate transduction of many cell types [100] or to narrow tropism to limit transduction to a specific cell type, such as neural stem cells in the brain [101]. Pseudotyping these vectors can also enable the transduction of tissues that are otherwise resistant to gene transfer, such as the airway epithelium [102] and spinal cord [103]. AAV has been pseudotyped both by using capsid proteins from alternative serotypes, mixing capsids from two serotypes, and generating single chimeric capsid proteins with elements from multiple serotypes [96].

As an alternative to pseudotyping, which uses surface proteins from other virus serotypes, grafting targeting peptides into the viral genome can also functionalize the capsid and envelope proteins. For example, insertion of the Arg-Gly-Asp integrin-targeting peptide sequence into adenoviral vectors has directed viral transduction to cells expressing high levels of integrin receptors [104,105]. This approach has also been used to preferentially direct viral transduction to endothelial cells [106]. Alternatively, biotin-binding peptides [107], single-chain antibodies [108], and genetically encoded imaging agents [109,110] have been incorporated into adenoviral capsid proteins as general approaches for redirecting cell targeting or tracking viral localization. Similar strategies have been explored for AAV including targeting ligands [111], biomolecular conjugates [112], and protease-activatable targeting [113]. Single-chain antibodies have also been grafted into retroviral and lentiviral vectors to control targeting [114], though typically with a decrease in overall transduction efficiency [115]. Alternatively, growth factors and cytokines have been inserted into the envelope to target transduction to cells bearing the complementary receptor [116,117].

In many cases, our understanding of the structure−function relationships of the viral proteins is insufficient to allow rational design of highly active engineered proteins with new functions. In these circumstances a directed molecular evolution strategy may be useful. In this approach, large viral variants libraries allow for selection of variants with desirable properties [118]. For example, display of random peptide libraries on AAV and adenovirus have led to vectors with increased selectivity and/or transduction efficiency of endothelial cells [119] and myoblasts [120]. Random mutagenesis or DNA shuffling and selection of novel AAV capsids has led to new variants with beneficial immune evasion and purification properties [121,122], and this approach has enhanced the transduction of human airway models [123,124], specific neural cell types [125,126], and induced pluripotent stem cells [127]. Collectively, these technologies provide a means to design improved viral vectors for a variety of applications.

In contrast to genetic modification of the viral proteins, adaptors or chemical modifications can be used to redirect viral transduction. PEGylation can be used to mask viral vectors from the immune system, but in many cases, this approach will decrease overall transduction efficiencies [128]. In contrast, conjugation of the PEG group to a functional targeting moiety, such as an antibody, can lead to simultaneous protection of the vector and delivery to specific cell types in vivo, such as endothelial cells [129]. Other work has used bispecific adaptors that bind both the viral surface proteins and a particular cell-surface receptor [130,131]. The incorporation of antibody-binding domains or biotin molecules into viral capsids has led to a general approach in which

the virus can be retargeted to any cell type via an antibody linker targeted to a cell-surface epitope [132] or a fusion protein of streptavidin and a targeting ligand [133].

The methods described above are predominantly designed to control which cells a virus will transduce. Another approach to controlling gene expression is to use an engineered promoter that can be regulated in magnitude, time, space, and/or tissue type [134]. These approaches are applicable to both viral and nonviral systems. The most commonly used inducible gene expression system is based on the antibiotic tetracycline [135]. Examples of this system that are relevant to tissue engineering include its use to control gene expression for bone tissue engineering [136,137], treatment of arthritis [138], and control of drug or hormone production by engineered tissues or implanted cells in vivo [139], among others. Systems have also been developed to control gene expression in response to a variety of other chemical inducers, including ecdysone [140], rapamycin [141], and other antibiotics. Other systems to control gene expression of implanted cells with an exogenous operon have been based on skin lotions containing phloretin [142] and inhaled gases containing acetaldehyde [143].

In addition to chemical inducers, gene expression can also be controlled from promoters that are sensitive to hypoxia and temperature that have been used to trigger gene-mediated cardioprotection and angiogenesis [144,145]. More recently, optogenetic approaches have emerged in which genes are placed under the control of light-inducible proteins from plants or the eye [146–148]. Consequently, the magnitude, dynamics, and spatial patterning of gene expression can be controlled with illumination in vitro and in vivo. Engineered transcription factors can be designed for light-inducible transcriptional activation in vivo with a far-red illumination source. A recent report showed light-induced neuronal differentiation with a CRISPR-based, light-inducible transcription factor [149]. In the future, this approach may be used to control tissue formation as part of a regenerative medicine strategy. Finally, gene expression can be restricted to certain cell types by regulating transgenes with promoters that correspond to genes only expressed in particular tissues. This approach has been widely employed to create promoters that are specific to bone, cartilage, skeletal muscle, cardiac muscle, retina, and liver.

Nonviral nucleic acid delivery

Introduction to nonviral nucleic acid delivery

While viral delivery systems are equipped with inherent, evolved mechanisms for efficient intracellular delivery, nonviral nucleic acid delivery systems can offer a well-defined and potentially safer alternative that can be cheaply made on large scales. However, optimizing these systems to approach the efficiency of intracellular delivery achievable with viral vectors has remained elusive. A variety of synthetic systems have been sought for nonviral nucleic acid delivery, primarily based on polymers (synthetic and natural), lipids/liposomes, and inorganic NPs (Fig. 29.5). Significant progress has been made in the development of nonviral carriers that can overcome the

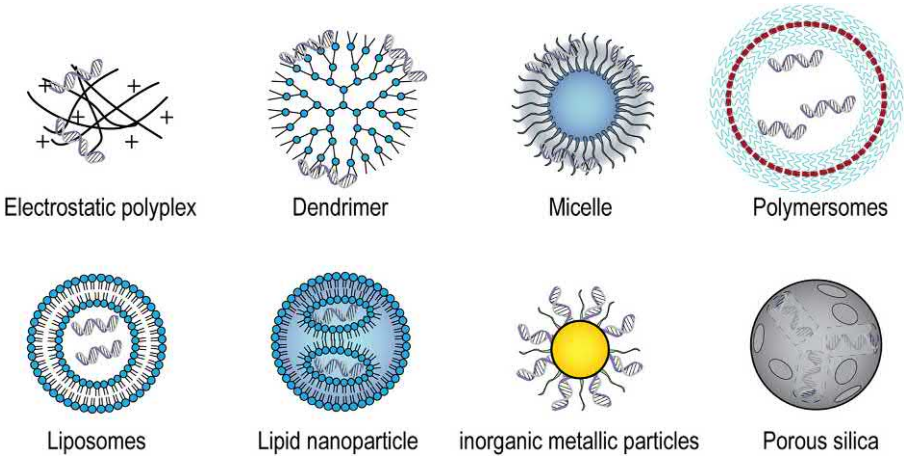

FIGURE 29.5 Nonviral gene delivery formulations. (A) Polymers are assembled into a range of nanosized structures. Electrostatic polyplexes formed by the condensation of positively charged polymers and negatively charged nucleic acid. Positively charged dendrimers electrostatically condense siRNA into polyplexes. Micelle structures have hydrophobicity in the core and typically have a positively charged corona to form complexes with nucleic acid. Polymersomes are formed from amphiphilic block copolymers forming an aqueous center. (B) Lipid materials are used to formulate siRNA and are the first approved delivery vehicle for an RNAi drug. Liposomes are formed from lipoid materials into a lipid bilayer with an aqueous center. Lipid nanoparticles are composed of a nanostructured core. (C) Inorganic particles are used as a scaffold for the construction of nanosized vehicles that often have additional imaging and therapeutic capabilities. Gold nanoparticles are often used in the delivery of siRNA. Porous silica nanoparticles have a large internal surface area, are biodegradable, and can be charge agnostic making them better suited for delivery peptide nucleic acids. *RNAi*, RNA interference; *siRNA*, small interfering RNA.

primary intracellular delivery barriers such as cellular internalization, escape from endo-lysosomal pathways, and trafficking to the desired intracellular space (i.e., cytoplasm for siRNA and nucleus for plasmid). Although the available design space for engineering of nonviral vectors is vast, and numerous preclinical studies have emerged in the last few years with exciting results, to date, there are two clinically approved, nonviral gene delivery product indicating the significant engineering challenge for nonviral gene delivery. The remainder of this section will provide a more thorough overview of nucleic acid modifications and polymer, lipid, and inorganic NP technologies that have been recently developed for nucleic acid therapeutics.

Oligonucleotide modifications

Nonviral delivery vehicles provide the opportunity to engineer the oligonucleotide chemistry to improve stability, nuclease resistance, activity, and immunogenic properties of delivered oligonucleotide cargo (Fig. 29.6A). For siRNAs, 2′-*O*-methyl modifications, 2′-Fluoro modifications, and a phosphorothioate backbone have shown improved properties in large animal studies and clinical trials [2]. Messenger RNA has been modified to avoid innate immune responses caused by ssRNA delivery [150,151]. One study found that 25% substitution of 2-thiouridine for uridine and 5-methylcytidine for cytidine avoided toll-like receptor recognition and led to protein production in mice [151]. Intravenous delivery of lipid NPs (LNPs) containing modified mRNA encoding vascular endothelial growth factor (VEGF)-A improved cardiac function in a mouse model of myocardial infarction [152]. Another study used modified mRNA encoding VEGF-A in patients with type 2 diabetes led to increased VEGF-A expression and improved blood flow [153]. For genome editing, modifications to the gRNA have been used to improve nuclease resistance and reduce innate immune response in vivo. In a recent report from Intellia Therapeutics, an LNP system delivering Cas9 mRNA and modified gRNA edited the mouse transthyretin gene in hepatocytes reducing serum protein levels by 97% [14]. Peptide nucleic acids (PNAs) are an engineered variant of nucleotides with a peptide backbone [154]. PNAs have been used to interfere with miRNAs [155] which have substantial roles in tissue engineering (reviewed here [10]). PNAs have been delivered to mouse hepatocytes with porous silicon NPs to interfere with miR-122 in mice leading to improved HDL cholesterol values [156]. PNAs can also be designed to form triplexes with genomic DNA to force strand invasion and induce DNA repair and precise genome editing (reviewed [157]). A recent study by the Glazer and Saltzman groups used PNAs in a mouse model of beta-thalassemia delivered by intravenous administration of PLGA NPs achieved 7% gene correction [158]. Follow-up work from the same groups showed an increase in gene correction up to 10% when administered in utero, which led to improved survival in mice up to 500 days post injection [159].

Conjugates

Direct conjugation of macromolecules can enhance the bioavailability of oligonucleotides (Fig. 29.6B). Molecular conjugates will likely comprise the next wave of approved siRNA products with several candidates in late clinical trials with one approved product (Givlaari). Most notably, *N*-acetylgalactosamine (GalNAc) conjugates have been used for efficient liver delivery of siRNAs by binding the asialoglycoprotein receptor on hepatocytes resulting in internalization and target gene silencing [160]. Other promising conjugates include the hydrophobic modifications palmitic acid [161,162], cholesterol [163,164], and diacyl lipid [165]. Lipid-modified siRNAs designed to bind to the serum protein albumin greatly improve in vivo circulation half-life and bioavailability and may have advantages over application of larger, conventional NPs for tumor targeting (see review Ref. [27]). For example, a diacyl lipid−modified siRNA shows improved circulation time and tumor accumulation in a patient xenograft model of triple-negative breast cancer overcoming limitations of the absence of the EPR effect in many tumor models [165].

Synthetic polymers

A variety of natural and synthetic polymers have been developed for nucleic acid delivery systems. This includes standard synthetic polycations, such as polyethylenimene (PEI), poly(2-(dimethylamino)ethyl methacrylate) (PDMAEMA), and cationic dendrimers, biodegradable synthetic polycations such as poly(beta-amino esters) (PBAE), glycopolymers, and peptide/protein-based polymers.

The earliest polymeric approaches to nonviral gene therapy employed cationic, amine-rich polymers such as PEI, PDMAEMA, and the cationic poly(amido amine) (PAMAM) dendrimers (Fig. 29.7A). PEI is commonly used in both in its linear and branched forms for DNA plasmid delivery, whereas PDMAEMA is typically utilized as a linear homopolymer or as a diblock polymer with PEG or other compositions. Dendrimers such as PAMAM have more complex “tree-like” architectures that form spherical, monodisperse macromolecules. These branched structures are synthesized either from the central core toward the periphery (divergent synthesis) or starting

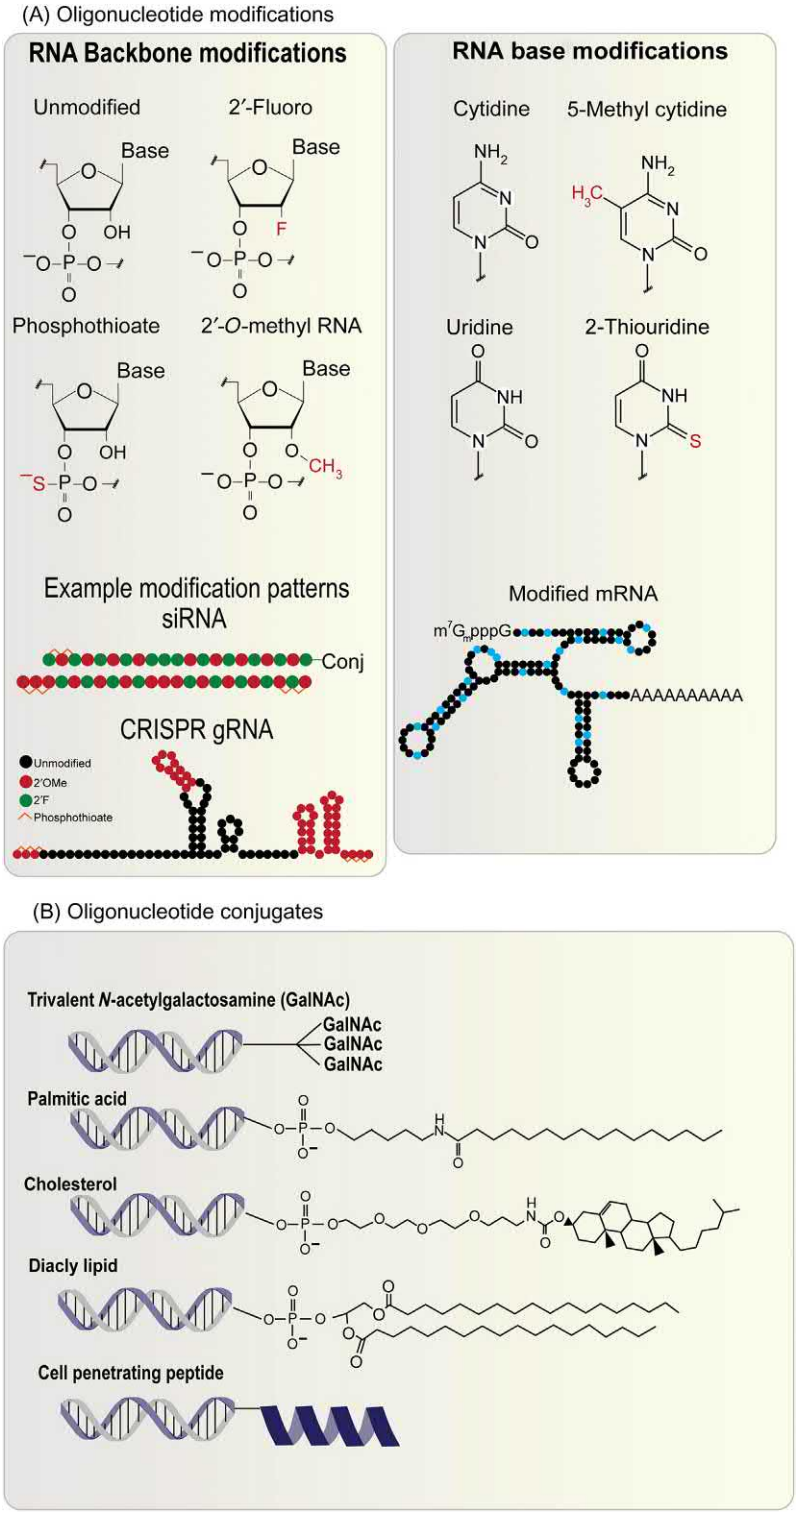

FIGURE 29.6 Modifications used to improve activity and reduce immunogenicity of delivered RNA. (A) Backbone modifications can be used to improve activity, increase nuclease resistance, and reduce innate immunity include 2′-Fluoro, phosphothioate, and 2′-*O*-methyl among others. An example siRNA modification pattern is shown with orange phosphothioate backbone, green 2′F modifications, and red 2′OMe modifications. A highly active modification pattern for CRISPR gRNAs is also shown. Individual bases can be modified to improve mRNA translation and reduce immunity which include 5-methyl cytidine and 2-thiouridine. A schematic of a modified mRNA is shown with ~25% substation. (B) Reported conjugates to siRNA that improve transfection efficiency or pharmacologic properties of IV-administered siRNA include trivalent GalNAc, palmitic acid, cholesterol, diacyl lipid, or cell-penetrating peptides among others. *gRNA*, guide RNA; *siRNA*, small interfering RNA.

from the outermost residues (convergent synthesis). Commonly used, commercial PAMAM forms spherical polymers with good aqueous solubility because of its highly charged, exposed surface groups, which include abundant primary amines for convenient functionalization [166].

The amines can serve three primary functions in these systems: nucleic acid packaging, enhanced cell uptake, and endosome escape. By mixing with polycations in aqueous solutions, DNA and siRNA, with their negatively charged, phosphate-containing backbone, can be

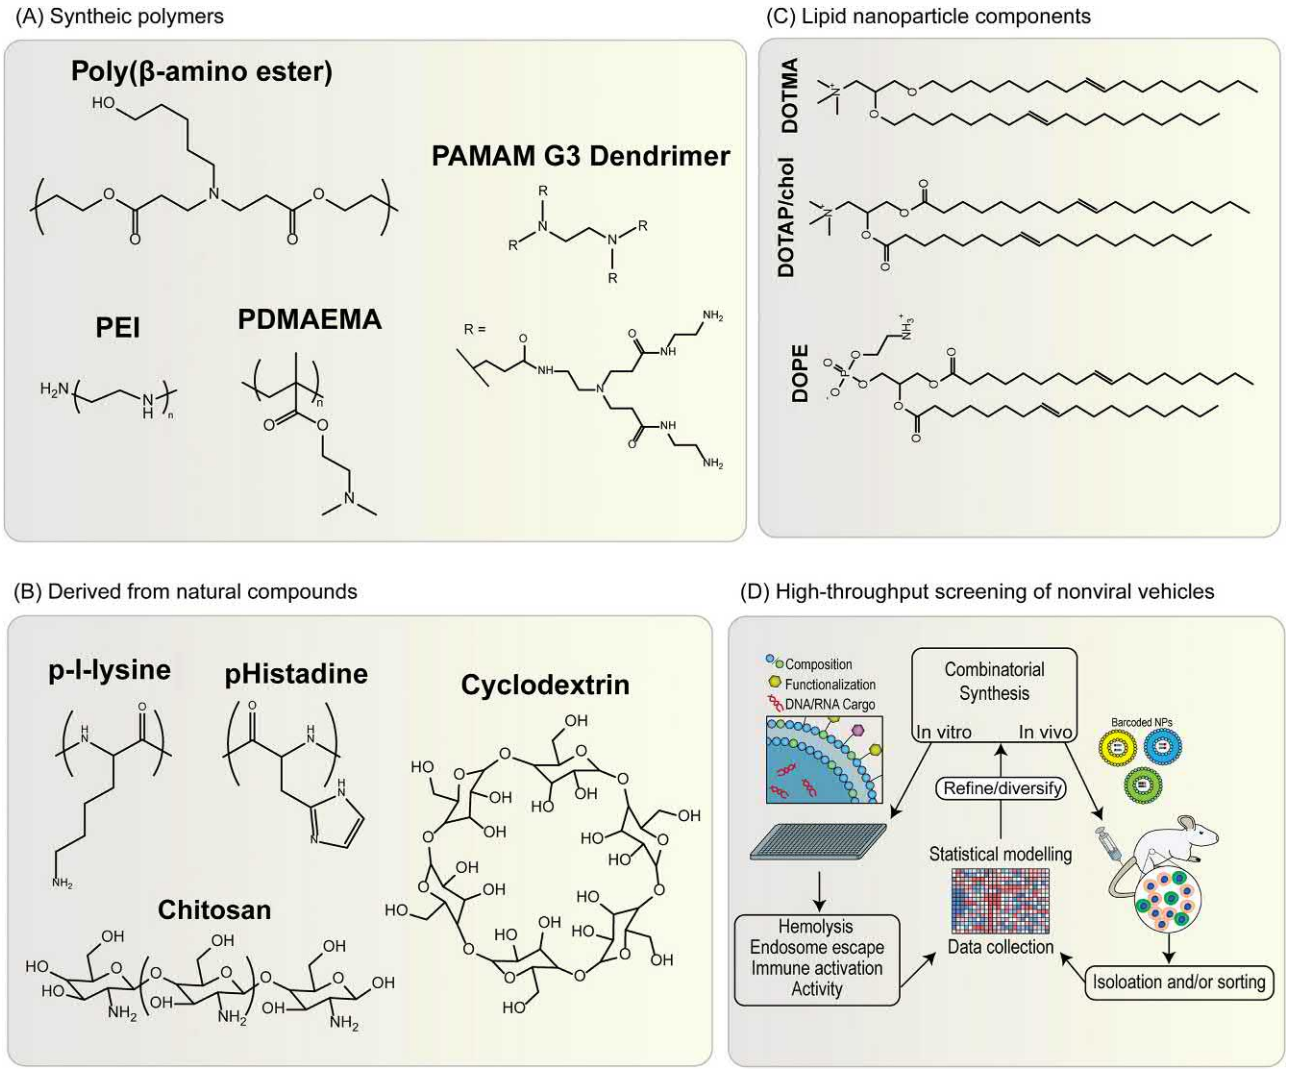

FIGURE 29.7 **Design and optimization of nonviral vehicles for gene delivery.** (A) Several polycationic polymers for nanoparticle production are shown including poly(B-amino esters), PEI, PAMAM dendrimers, and PDMAEMA. (B) Examples of polymers derived from natural components that are used for nucleic acid delivery are shown. These include amino acid-based polymers such as poly(Lys), poly(His), and CPP-containing peptides have been actively tested for delivery applications. Likewise, chitosan and polymers containing β-cylcodextrins and other carbohydrate-containing polymers such as PGAAs have also shown tremendous potential. (C) Lipids traditionally studied for nucleic acid delivery include DOTMA and DOTAP. (D) Recent progress has been made using high-throughput combinatorial approaches for identifying optimal siRNA delivery systems including in vitro assay development or in vivo screening of carriers. Further rounds of optimization can be accomplished by statistical modeling to refine the library or add further library diversification. *CPPs*, Cell-penetrating peptides; *DOTAP*, 1,2-dioleoyl-3-trimethylammonium-propane; *DOTMA*, *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride; *PAMAM*, poly(amido amine); *PDMAEMA*, poly(2-(dimethylamino)ethyl methacrylate); *PEI*, polyethylenimene; *PGAAs*, poly(glycoamidoamine)s; *siRNA*, small interfering RNA.

electrostatically condensed into particles, termed polyplexes. Typically, an excess of the polycation is used during polyplex formation, yielding particles with an overall net positive charge. The positive surface charge of the polyplexes increases interaction with negatively charged cell membranes, a process that is likely mediated through anionic, heparan sulfate proteoglycans anchored on the cell surface [167]. This binding enhances their endocytotic cell uptake. Following endocytosis, these polyplexes are capable of mediating endosomal escape through the osmotic disruption (e.g., the proposed "proton sponge" effect) [168].

Cationic polymers composed of secondary and tertiary amines, which enable endolysosomal escape through the proton sponge mechanism, can efficiently transfect nucleic acids into cells [169]. Although these net cationic polyplexes can effectively delivery nucleic acids in vitro, they can cause cytotoxicity, and they have a limited biodistribution profile if delivered intravenously. This is because the cationic surface charge of these polyplexes

causes aggregation with serum proteins and red blood cells. These nonspecific interactions can cause disproportionate biodistribution to the capillary beds of the lungs, very short circulation times, and acute toxicity [170]. Thus many strategies have focused on decreasing the cytotoxicity and improving steric stabilization of cationic polyplexes. As discussed above, the incorporation of PEG onto the polyplex surface is an important design aspect for reducing the positive surface charge, improving biodistribution, and decreasing acute toxicity [40,171]. Bioreducible polycation variants that are degraded by the reducing environment in the cell have yielded polyplexes with lower cytotoxicity and higher transfection efficiency [172,173].

Micelles formed from synthetic polymers represent another promising category of nucleic acid carriers [174]. For nucleic acid delivery, the Kataoka group has focused on micelles driven by electrostatic interactions or polyion complex micelles [175]. These nanovehicles typically self-assemble after mixing of nucleic acids with diblock polymers consisting of PEG and a polycationic segment such as poly(L-lysine) [poly(Lys)]. This class of carriers has been shown to achieve gene silencing in vitro, and a variant composed of a diblock polymer of PEG, poly(Lys) and cyclic Arg-Gly-Asp (RGD) targeting peptides efficiently achieved gene silencing and reduced tumor mass following delivery of antiangiogenic siRNA in vivo [176].

Micelles are traditionally defined as core-shell self-assemblies of amphiphilic diblock polymers into morphologies where a more hydrophobic block forms the micelle core, and a more hydrophilic block forms the corona. This class of micelles, which self-assemble into NPs in aqueous solutions even in the absence of added nucleic acid, has shown great promise [177–179]. One example of a micelle-forming polymer is composed of a block of PDMAEMA and a second block that consists of a random terpolymer of 50% butyl methacrylate (BMA), 25% DMAEMA, and 25% propylacrylic acid (PAA). This polymer self-assembles into micellar NPs of approximately 50 nm in diameter, with the poly(BMA-*co*-DMAEMA-*co*-PAA) terpolymer block in the particle core. The 50 mol.% of the hydrophobic BMA drives self-assembly, and electrostatic interactions between PAA and DMAEMA also help to stabilize the micelles near physiologic pH. The homopolymer block of DMAEMA forms the micelle corona and provides a cationic surface that can be used to electrostatically condense siRNA into serum stable siRNA-NPs, sometimes referred to as micelleplexes. DMAEMA and PAA monomers both contain protonatable groups (tertiary amine and carboxylic acid, respectively) with pK values approximately equal to physiologic pH. The net charge of the anionic PAA and cationic DMAEMA is relatively balanced at physiologic pH, stabilizing the micelle core. However, due to concurrent protonation of DMAEMA and PAA, the core-forming terpolymer block acquires a net positive charge when it enters the acidic endolysosomal pathway. This causes a shift to a net cationic state that electrostatically destabilizes the micelle core, exposing the terpolymer block, and activating its membrane disruptive activity. This terpolymer composition has been fine-tuned for intracellular delivery based on the BMA content [178] so that this pH-driven transition occurs in environments representative of the early and late endosomal compartments.

The micelles described above have a cationic surface charge that is not amenable to effective intravenous delivery because, as described for PEI and PDMAEMA homopolymers, particles with cationic surfaces have short circulation times. As discussed above, reversible PEGylation can be utilized to create more stealthy cationic carriers in the circulation while maintaining key, underlying functionalities. For example, a variant of this micelle has been created with a PEG corona that can be removed by naturally occurring proteases for "proximity-activated targeting" [45,180–183]. The intact PEG corona reduces nonspecific binding and uptake in the circulation, while high MMP activity at the pathological site releases the corona and triggers activation of the underlying siRNA-NP.

Evidence suggesting that toxicity profiles are improved with biodegradable versions of traditional polycations has spurred the development of new and better optimized biodegradable polymer chemistries. PBAEs are one very promising class of biodegradable polycationic nucleic acid carriers that have been shown to be superior to in vitro transfection reagents such as Lipofectamine 2000 [184]. A key characteristic of PBAEs is that they are amenable to parallel, high-throughput synthesis for simultaneous screening of large numbers of polymer variants. Using this approach, PBAE compositions have been identified with transfection activity superior to other nonviral agents and that rival the performance of viral vectors in some applications [185,186]. Conveniently, PBAE-based carriers rapidly hydrolyze and degrade into low molecular weight diols and bis(β-amino acids) in response to the pH drop that occurs during endosomal/lysosomal trafficking, which both facilitates nucleic acid release and makes them less cytotoxic than polymers like PEI [187].

Polymers derived from natural sources or monomers

Amino acids and saccharide-based materials have been extensively explored for nucleic acid delivery, as more thoroughly reviewed elsewhere [188,189]. These natural

building blocks have the potential to have reduced cytotoxicity and, if optimized, superior overall function relative to fully synthetic biomaterials. Here, peptide-based and carbohydrate-based nucleic acid delivery polymers will be surveyed (Fig. 29.7B).

The first amino acid–based polymer to be pursued was poly(Lys) [190], and many iterations of this cationic polymer have been extensively studied in a fashion similar to PEI and the other synthetic polycations described above. Poly(Lys) can efficiently complex nucleic acids, but its transfection efficiency is low, and it requires cell treatment with endosomolytic agents such as chloroquine to enhance gene expression. Nonetheless, the early studies on poly(Lys) yielded important mechanistic insights related to polyplex formulation, intracellular trafficking, and endosome escape [190]. While the clinical promise of poly(Lys) is limited, these early studies have had a significant impact on the field.

Poly(histidine) (poly(His)) is another amino acid–based polymer that has shown some usefulness for gene therapy. The amino acid His has an imidazole R-group containing a secondary amine that endows poly(His) with proton sponge activity for endosomal escape [191]. Polymers containing both Lys and His have also been utilized successfully in combinations. In these hybrid polymers, the primary amines on Lys are fully protonated and cationic at physiologic pH, enabling efficient electrostatic complexation with DNA. The lower pKb of the secondary amines from His provide complementary proton sponge activity for endosome escape [192]. The transfection efficiency of polymers with poly(His) grafted to poly(Lys) is significantly improved by the addition of the endosomal disruption agent chloroquine, indicating that the polymers alone are still partially prone to endosomal entrapment [193]. Highly branched architectures of His/Lys polymers and His-containing reducible polycations have also been found to efficiently deliver siRNA [194,195]. There is also a precedent for incorporation of amino acid–based subunits into other gene therapy systems in order to produce "hybrids" with enhanced delivery functionality. For example, His has also been used to modify chitosan (discussed more next) to enhance its endosomal escape and transfection efficiency [196].

Cell-penetrating peptides (CPPs) and pH-responsive, fusogenic peptides are two other classes of peptides that have been rigorously explored to trigger cell uptake and endosomal escape, respectively. These peptide classes have been used both in combination and as components of multifunctional polymer and liposomal delivery systems. Most CPP and fusogenic peptides are derived from bacterial toxins and viral vectors, or they are synthetic analogs of the naturally occurring peptides. The *trans*-activating transcriptional factor of HIV-1 [197], and the antennapedia peptide derived from *Drosophila* [198] are two examples of well-studied CPPs. These peptides are typically rich in cationic amino acids, and as a result, synthetic, arginine-rich CPPs of various types have also been found to mediate biomacromolecular cargo cell uptake. Fusion of a CPP with a dsRNA-binding domain has been used to deliver siRNA into primary cells considered difficult to transfect [199]. Other CPPs derived from Transportan 10 (designated PepFect) [200] and CADY [201] have been designed for efficient intracellular delivery. Fusions of tumor-penetrating and CPPs have been generated that have shown silencing of an oncogene improved survival in mice [202,203] The ability of CPPs to trigger cell internalization has been leveraged for delivery of several classes of therapeutic cargo including plasmid DNA and siRNA (see CPP reviews for additional information).

Fusogenic peptides are pH-responsive peptides that can fuse with or form pores through the endosomal membrane. An example is the diphtheria toxin, which has a subunit that forms transmembrane pores in endosomes that enable entry of a disulfide-linked toxin fragment into the cytosol [204]. Another example is hemagglutinin, an influenza protein that creates pH-dependent endosomal membrane fusion to deliver the viral genetic material into the cytoplasm [205]. The peptide GALA is a synthetic, pH-dependent, fusogenic peptide that has been extensively characterized [206]. GALA self-assembles and inserts into lipid bilayers at acidic pH, forming a pore that allows of the membrane transit [207]. For example, GALA has been successfully applied to enhance efficiency of cytosolic delivery of nucleic acid cargo packaged in PAMAM and liposomes [208–210].

The polysaccharide chitosan, oligosaccharides-like cyclodextrins, and a variety of other saccharide-containing glycopolymers represent another polymer class for nucleic acid delivery. For example, natural anionic saccharide–based polymers can be fabricated into thermodynamically stable, polyelectrolyte complex (PEC) NPs through spontaneous association triggered via mixing of polyelectrolytes of opposite charge, as reported by Prokop et al. [211,212]. Typically, PEC NPs are made by mixing polyanionic core polymers, such as alginate or chondroitin sulfate with corona polycations such as spermine hydrochloride or poly(methylene-*co*-guanidine) hydrochloride. This multipolymeric nanoparticulate approach has been shown to be effective for gene transfer in vitro [213], particularly in cell systems that are normally refractory to gene transfer, such as pancreatic islets and antigen-presenting cells. In addition, PEC coronal surfaces can be decorated with PEG-ligand complexes to increase cell targeting and reduce nonspecific uptake.

Chitosan, a polysaccharide composed of glucosamine and N-acetyl glucosamine units bonded via $\beta(1\rightarrow4)$ glycosidic bonds, is one of the most thoroughly studied saccharide polymers. Chitosan benefits from being a "green"

approach, because it is a renewable resource derived from chitin. This natural polymer is also biodegradable and nontoxic. The Alonso laboratory introduced chitosan-based NPs [214] made via ionotropic gelation, based on the interaction between the negative groups of pentasodium tripolyphosphate and the positively charged amino groups on chitosan. The chemistry of chitosan is also adaptable to nonviral gene therapy, since it contains several primary and secondary amines capable of endosomolysis via the proton sponge effect. Therefore chitosan has been examined as a pH-responsive polymer for nucleic acid delivery. Howard et al. employed chitosan NPs containing siRNA to knock down enhanced green fluorescent protein (eGFP) in both H1299 human lung carcinoma cells and murine peritoneal macrophages (77.9% and 89.3% reduction in eGFP fluorescence, respectively) [215]. The chitosan NP has a high potential for transmucosal delivery. Effective in vivo RNAi was achieved in bronchiolar epithelial cells of transgenic eGFP mice after nasal administration of chitosan/siRNA formulations (37% and 43% reduction as compared to mismatch and untreated control, respectively). The principal drawbacks of chitosan are poor solubility in physiological buffers and lower endosomolytic activity compared to some stronger proton sponge polymers. As a result, several variants of chitosan have been made with modifications to increase endosomal escape and solubility. For example, PEI and imidazoles have both been conjugated to chitosan to enhance its performance in gene therapies [216].

Cationic polymers containing beta-cyclodextrins (β-CD) showed early promise for clinical RNAi. Cationic β-CD-based polymers (βCDPs) synthesized by the condensation of a diamino-cyclodextrin monomer with a diimidate comonomer are capable of forming polyplexes with nucleic acids, and their transfection performance depends on βCDP structure [217]. The β-CD-containing polycations are especially unique because cyclodextrins contain an interior cavity that can be used to form inclusion complexes with hydrophobic moieties. For example, β-CD binds tightly to the hydrophobic molecule adamantine, and this provides a convenient "handle" from which to functionalize the surface polyplexes made from βCDPs with PEG or targeting ligands [218,219]. The Davis laboratory translated this concept from benchtop to clinical trials [220]. This carrier was the basis for a report demonstrating the first example of human RNAi using targeted polymeric NPs. This carrier was composed of βCDPs functionalized with both PEG and the cancer-targeting ligand transferrin [221]. After this landmark finding the clinical trial was ended primarily owing to dose-limiting toxic events [222] with no follow-on trials. Arrowhead Pharmaceuticals subsequently focused on conjugates and no follow-on phase III clinical trials were initiated.

A variety of other novel, synthetic cationic glycopolymers are also in the developmental pipeline for clinical applications of nucleic acid delivery [189,223]. The Reineke lab has made key contributions in this area (see recent review Ref. [224]), and an example class of glycopolycations developed by this group are the poly(glycoamidoamine)s (PGAAs) [223]. A library of PGAAs was made through the condensation reaction between carbohydrate and oligoamine comonomers. These PGAAs were varied based on a variety of parameters, including the carbohydrate size, the hydroxyl number and stereochemistry, the amine number, and whether or not heterocyclic groups were present. These polymers have been screened for gene delivery, and optimized formulations have been identified that facilitate efficient DNA packaging and intracellular delivery properties. The Reineke group has also sought a variety of trehalose-based polymers, and promising results continue to suggest the potential for clinical translatability of this safe and efficient class of polymers [225]. This glycopolymer has also been adapted to deliver CRISPR-based transcriptional activator [226].

Exosomes are cell-derived extracellular vesicles contain a variety of nucleic acid types. These natural vehicles participate in cell communication and are increasingly being used in drug and gene delivery [227]. A major challenge in utilizing exosomes for gene delivery is loading of the vehicles with nucleic acids. While electroporation is the more common method of loading DNA, sonication, extrusion, and freeze-thaw cycles are other methods for loading exosomes [228]. Loading of exogenous siRNA or DNA remains a challenge owing to low efficiency and aggregation during electroporation. For regenerative medicine, exosomes derived from stem or progenitor cells may encourage tissue regeneration on their own without exogenously delivered DNA including muscle regeneration [229], wound healing [230], angiogenesis, and cartilage repair [231].

Lipid-based delivery systems

Lipids are one of the most commonly used approaches for nucleic acid transfection. Lipid agents can form small, artificial, spherical liposomal vesicles with a lipid bilayer membrane surrounding an aqueous interior. Liposomes can be produced from natural nontoxic phospholipids and cholesterol. Liposome properties vary substantially with lipid composition, size, surface charge, and the method of preparation. Because of their size, hydrophobic and hydrophilic compartments, as well as biocompatibility, liposomes are promising systems for drug delivery. Hydrophilic drugs can be encapsulated, or cationic lipids can be used to form lipoplexes with anionic nucleic acids. Like other nucleic delivery systems discussed,

PEGylation can be used to shield liposomal surfaces to reduce nonspecific protein and cell interactions and to improve circulation time [232]. Targeting of liposomes has also been accomplished by anchoring a variety of targeting ligands, such as antibodies, to the liposomal surface [233]. The earliest approaches to lipid-based nucleic acid delivery focused on cationic lipids such as *N*-[1-(2,3-dioleyloxy)propyl]-*N*,*N*,*N*-trimethylammonium chloride (Fig. 29.7C) [234].

A large number of IV-delivered siRNA drugs that have advanced into clinical testing to date employ lipid-based delivery systems, with the LNP delivery technology providing the first clinically approved product, patisiran for siRNA delivery. Langer and Anderson have been significant contributors to the literature on optimization of lipid-like materials for delivery of siRNA through a series of high-throughput combinatorial approaches seeking to identify optimized lipid-like materials, or lipidoids, for siRNA delivery. In some of the first published work using this approach, they synthesized nearly 700 lipidoids based on the conjugate addition of alkyl-acrylates or alkyl-acrylamides to primary or secondary amines [235]. This library featured compounds with varied alkyl chain length, linker degradability, amine R-groups, and postsynthesis quaternization of the amine to induce stable cationic charge. The resulting lipidoids were used to package siRNA and screened for optimal transfection efficiency in vitro and in vivo. In these studies, efficient gene silencing activity was shown in both rodents and nonhuman primates at doses of 2.5 mg/kg and greater. In a follow-up paper, they synthesized a library of 126 lipid-like compounds using a unique synthetic strategy based on epoxide chemistry [236]. Their screen in this study identified some of the most potent RNAi delivery compounds produced to date, and their best lipidoids produced liver-specific silencing at 0.01 mg/kg in mice and at 0.03 mg/kg in nonhuman primates. Similar work has also been utilized recently to identify lipidoids for transfection of pDNA, and compounds were identified that were superior to Lipofectamine 2000, which is a gold standard of commercially available in vitro transfection reagents [237]. Delivery of CRISPR/Cas9 mRNA has been accomplished with LNPs in vivo with the observation that the short duration of exposure of CRISPR/Cas9 components maximizes the ratio of on to off target ratio editing relative to sustained expression [238]. One of the limitations to much of the lipidoid work is that it has been primarily limited to liver targets; however, high-throughput screens are beginning to reveal other tissue targets [239]. The promising current data suggest that clinical success will be established first in the liver and that subsequent work will optimize this class of carriers for additional clinical applications.

Inorganic nanoparticles

In some applications, inorganic NPs, "theranostic" technological advances have been pursued that combine both image contrast and therapeutic functionalities. For example, quantum dot NPs, recognized for their optical properties, have been functionalized to successfully deliver siRNA [240,241]. NPs that provide MRI contrast have also been successfully utilized to simultaneously provide image contrast and siRNA delivery [242]. Recently, gold NPs have come to the forefront of inorganic NP approaches for siRNA delivery. Mirkin has been a leader in this field through development of polyvalent siRNA conjugates on the surface of gold NPs [243]. These particles are efficiently internalized by pattern-recognition scavenger receptors and can mediate gene silencing without addition of any additional transfection reagents [244]. Interestingly, these gold NPs surrounded by a dense shell of covalently bound siRNA have been recently found to efficiently penetrate the epidermal layer of the skin, indicating that they may be especially useful for clinical applications where topical delivery is a logical approach [243].

These skin-penetrating NPs may obviate the need for the previously popular biolistic particle delivery systems. This older method used a handheld gene gun with a pulse of helium to fire gold particles coated with DNA into target cells. This method of transfection is an effective physical means of rapid plasmid delivery into mammalian tissue. It is generally restricted to local expression in the dermis, muscle, or mucosal tissue since the gold particles are shot into confined tissue sites. Transfection depth is limited to about 1 mm, and about 10% of the cells in the tissue (skin) can be transfected. From a translational perspective, the DNA-loaded particles have a relatively long shelf life, and they have been successfully used for cutaneous administration of growth factor/receptor constructs [245–247].

Inorganic NPs may be better suited for delivery of uncharged cargo including CRISPR ribonucleoproteins (RNPs) or PNAs. As described above, porous silicon NPs have been adapted to deliver PNAs to hepatocytes in vivo based on the large capacity and ability to load the uncharged PNAs [156]. In addition, two papers described the utility of gold NPs for delivery of CRISPR RGNs and DNA repair template in a mouse model of DMD and fragile-X syndrome [248,249].

High-throughput screening

High-throughput screening has been applied to find more active nonviral gene carriers with improved pharmacological properties (Fig. 29.7D). High-throughput in vitro screening takes advantage of advances of combinatorial

parallel synthesis of carrier precursors and high-throughput screening readouts to examine the efficiency of thousands of carriers [235,250,251]. Other assays can be used to screen large libraries in vitro for safety and efficiency before animal experiments including hemolysis [252], stability in serum [253], and galectin 8 intracellular tracking [254]. High-throughput screening can be combined with machine learning to optimize multiple design parameters at once as recently demonstrated by the Mirkin group with the spherical nucleic acid delivery platform [255].

Another approach uses barcoded DNA encapsulated within libraries of nonviral carriers that can be screened directly in vivo for efficient delivery or activity in the tissue of interest [239]. This approach has the potential to find nonviral carriers with unique target tissues and can dramatically expand the number of particles with in vivo efficiency data. A combination of approaches can be used to find carriers that are safe for systemic administration and efficient for gene delivery.

High-throughput genetic screens have been enabled by CRISPR-Cas technologies. Genome-wide libraries are available to screen cells based on a custom reporter output, proliferation, cell death, or other readout [256–258]. CRISPR gRNAs can be paneled on genes of interest to examine functional genetic elements or nuclease deactivated CRISPR can be fused with transcriptional activators or repressors to screen for effects of gene silencing or gene activation [259–261]. Paired with advances in single-cell sequencing [262], these technologies can reveal mechanistic insights in tissue regeneration. The resulting information from these screens can reveal new targets for gene therapy or targets for small molecule drug development [12].

Engineering tissues with gene delivery

Introduction to engineering tissue with gene delivery

Multiple gene delivery approaches have been used to engineer tissues, including ex vivo and in vivo genetic manipulation of cells. The most developed applications include oligonucleotides for muscle gene therapy, gene therapy to improve cardiac regeneration, regenerating skin, bone, and others. In contrast to systemic applications where circulation time and target cell uptake is maximized, tissue engineering approaches typically bypass systemic barriers and depend on rapid cell recognition and intracellular delivery.

Viral delivery to engineer tissues

The most common approach to viral gene delivery for tissue engineering is to genetically modify the cells in standard cell culture, and then subsequently seed them onto a three-dimensional scaffold [263,264]. However, this approach involves extra procedures and in vitro manipulation of the cells that adds significant complexity to an expensive and work-intensive process. Therefore there has been considerable effort in functionalizing biomaterial scaffolds with viral vectors, such that cell seeding onto the scaffold and cell transduction by gene delivery vehicles becomes a single procedure [265]. This approach may also enhance transduction efficiency by colocalizing the cells and virus and also protect them from the immune system. Patterns or gradients of viral vectors can be generated to spatially control gene transfer and tissue development. Material-mediated gene delivery also preserves and potentially isolates the vector from the immune system and controls the localization of the virus. These approaches typically involve either encapsulation of the virus within a hydrogel, immobilization of the virus to a surface, or a combination of these strategies. The unique biological properties of each virus require distinct techniques for each vector.

The incorporation of adenovirus into hydrogels or protein matrices has led to control over the spatial and temporal delivery to surrounding tissue while also protecting the virus from loss of activity [266,267]. Delivery of therapeutic genes from hydrogels can also enhance the wound healing properties of materials such as fibrin [268] and collagen [269]. This approach has been particularly successful in promoting the healing and integration of dental implants in animal models, suggesting a promising application in oral defects and disease [270]. Adenovirus may also be bound to exposed surfaces of polymer scaffolds via conjugation of antiadenovirus antibodies to chemically reactive surfaces [271] or the use of biotinylated adenovirus [272]. This strategy can be used to spatially organize gene transfer by controlling chemical functionalization [273]. Adenovirus has also been widely used in gene-eluting stents and heart valves to prevent restenosis and valve disease [274–276].

Schwarz et al. have shown that the enhanced stability of AAV vectors can be exploited to create biomaterials, allografts, and other tissue substitutes with freeze-dried AAV coatings that are taken up by cells after implantation. The coating of bone allografts with osteogenic and angiogenic factors encoded by freeze-dried AAV vectors led to increased bone healing [277]. The same approach has also been used to engineer bone tissues in vitro by coating allografts [278] or polymer scaffolds [279].

The electrostatic properties of the retroviral and lentiviral lipid bilayer can modulate virus interactions with biomaterials, leading to enhanced and controlled transduction of cells [280]. This approach has been used to create gradients of retroviral particles on three-dimensional scaffolds that encode genes that direct tissue formation,

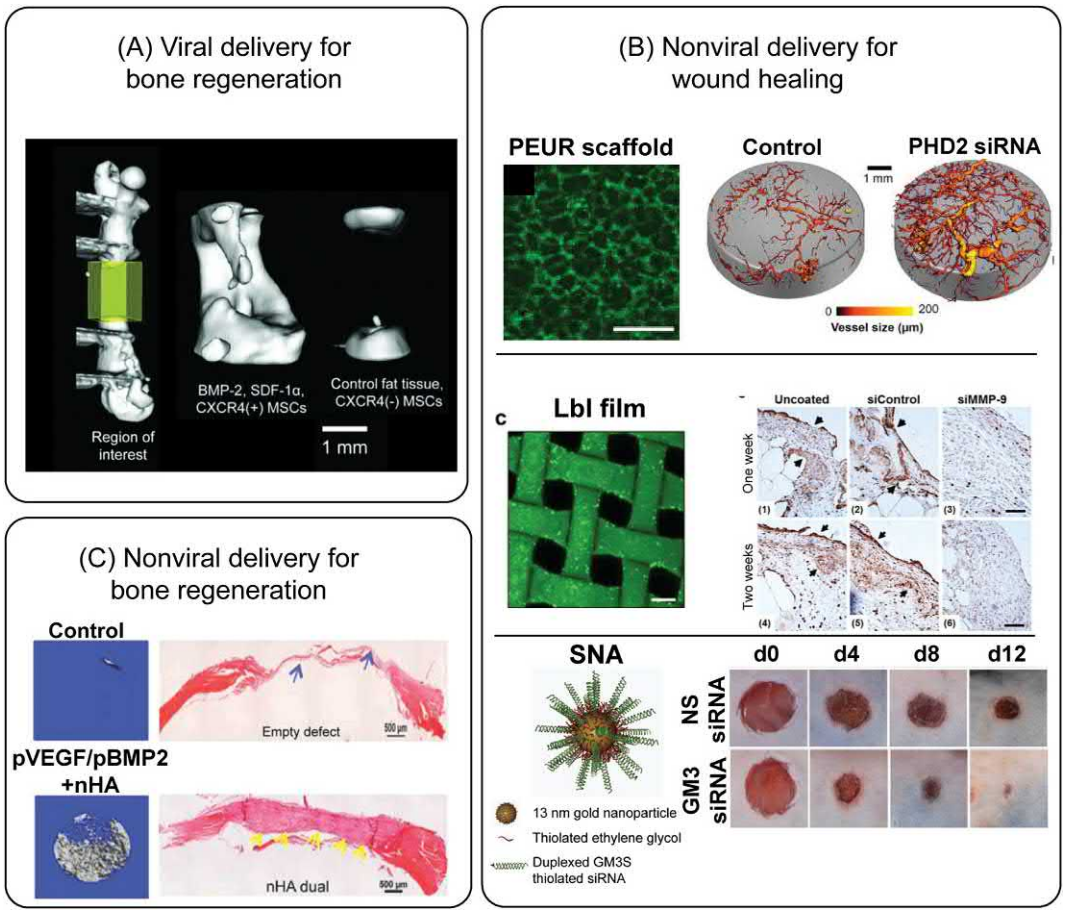

FIGURE 29.8 **Promising preclinical data for tissue engineering includes viral and nonviral delivery.** (A) MSCs transduced to overexpress CXCR4 were implanted and Adenovirus delivering BMP-2 and SDF-1α was delivered showing improvements in bone formation in a critical defect model. (B) Several approaches to heal skin wounds with nonviral delivery of siRNA have been developed. The first example used polymeric nanoparticles loaded into a PEUR scaffold with siRNA targeting PHD2 to increase angiogenesis. MicroCT shows increase angiogenesis relative to the control group. The second example used layer-by-layer deposition of siRNA to decrease MMP-9 expression and improve wound healing in a diabetic mouse model. The last example shows the use of spherical nucleic acids to silence GM3 to improve wound healing in a diabetic mouse model showing more rapid wound closure by 12 days. (C) Nonviral plasmid DNA delivery was used to regenerate bone in a mouse defect model. MicroCT images show restored bone growth when both VEGF and BMP2 plasmids are delivered with nHA particles from a collagen scaffold. *siRNA*, Small interfering RNA. *Reprinted with permission from Curtin CM, et al. Combinatorial gene therapy accelerates bone regeneration: non-viral dual delivery of VEGF and BMP2 in a collagen-nanohydroxyapatite scaffold. providing a means for more complex tissue formation that better mimics natural development [281]. Ionic interactions can also be used to load lentivirus onto hydroxyapatite NPs that protect the virus to enable incorporation into hydrogels [282,283]. Lentivirus has also been immobilized onto a variety of other materials with various properties that can be tailored for controlled gene transfer in vitro and in vivo [284,285]. Viral vectors can also be used to directly transduce cells in local pathologies including articular cartilage, muscle, bone, and regenerating skin [286–288]. For example, a combinatorial therapy of mesenchymal stem cells (MSCs) expressing CXCR4 and adenoviral delivery of BMP-2 and SDF-1α was able to significantly improve bone regeneration in a mouse critical defect model (Fig. 29.8A) [289]. A recent study from the Belmonte lab used AAV as a gene delivery vector to reprogram cells in vivo to improve wound healing. In this study, the authors delivered four transcription factors to reprogram mesenchymal cells into a more pluripotent state which assisted epithelializing the wounds in animal models. Four transcription factors (DNP63A, GRHL2, TFAP2A, and MYC) delivered by AAV serotype DJ were used to reprogram cells to improve wound closure [290].

Nonviral delivery from scaffolds

Local, nonviral delivery of nucleic acids from biomaterial scaffolds presents a promising approach for tissue regeneration. Scaffold-based delivery can provide an efficient means to stimulate local, site-specific effects without the need for targeting and other challenges presented by systemic, intravenous delivery. These approaches can be designed for both delivery of gene-encoding plasmids and RNAi gene silencing through delivery of siRNA or plasmids that encode shRNA. These local, nonviral gene therapies have applicability for improving repair of a variety of tissues such as skin wounds, bone defects, and myocardial infarcts.

There is a relatively established precedent for scaffold-mediated plasmid delivery for increasing expression of growth factors such as platelet-derived growth factor (PDGF) to induce blood vessel and tissue formation within the scaffold [291]. It has been shown that embedding plasmid DNA within a biodegradable tissue scaffold or immobilizing it on a biomaterial surface can provide a 10−100-fold increase in transfection efficiency because of increased local concentration and extended retention of plasmid at the cell-biomaterial interface relative to a local injection of plasmid-containing solution [291−293]. Mechanistically, "substrate-mediated delivery" of nucleic acids is believed to operate through multiple modes of endocytosis, though caveolae-mediated uptake may play the largest role [294]. This bioinspired approach to tissue regeneration is also analogous to the pathways that viruses "hijack" when they attach to extracellular matrix as a strategy to increase their cell internalization and infection [295]. The seminal work on scaffold-based plasmid delivery by Mooney and Shea has been subsequently applied in a diversity of applications, including delivery from both natural [296] and synthetic biomaterials [297,298]. Through more complex approaches to surface immobilization, plasmid delivery systems can also be engineered to control spatial patterning, concentration gradients, and temporal profiles in 2D and 3D [299]. Work is also underway to optimize the therapeutic benefits of substrate-mediated delivery by using enzymatically labile tethers [300], cell-specific targeting proteins [301], and other means of cell-specific targeting and intracellular release.

Scaffold-based local RNAi through delivery of siRNA is a more recent development and was initially approached primarily using natural biomaterials such as alginate, collagen, and agarose [302−304]. The first in vivo studies demonstrated gene silencing in skin wounds using Lipofectamine 2000 siRNA lipoplexes embedded in agarose gels. These commercially available cationic lipoplexes were released in a rapid burst and were effective for short-lived, topical siRNA application [304,305]. Prefabricated, electrospun scaffolds made from ε-caprolactone and ethyl ethylene phosphate copolymer nanofibers have also been pursued for the release of siRNA/transfection reagent complexes and have been shown to achieve more sustained delivery of bioactive siRNA [306].

The Duvall lab adapted a polyester urethane PE-UR scaffold-based platform for local delivery of siRNA-NPs in regenerative applications [307,308]. The PE-URs can be fabricated using a two-component foaming process that allows injection into a defect, followed by rapid curing in situ to provide mechanical support for tissue in-growth [309] and biodegrade hydrolytically and oxidatively into biocompatible side products at tunable rates [310]. By delivering siRNA targeting PHD2, angiogenesis was significantly increased in a mouse model with release rates tunable by the scaffold formulation (Fig. 29.8B) [308]. The scaffold can be formulated with a reactive oxygen species−degradable linker that provides on-demand degradation and improved tissue granulation leading to improved wound healing in a rat model of wound healing [311].

Another example from the Hammond lab used layer-by-layer scaffolds to locally silence either MMP-9 to improve wound healing [312] or connective tissue growth factor (CTGF) to reduce scarring [313]. The layer-by-layer platform allows the functionalization of commercially available wound dressings with chitosan-siRNA NPs with release profiles that are tunable based on the number of layers leading to improve wound closure (Fig. 29.8C) [312]. To improve scarring in a burn wound model, commercially available silk sutures can be subjected to the same layer-by-layer process loading CTGF siRNA with chitosan-reducing fibrosis and scarring [313]. miRNA inhibition can be used to improve wound healing. One study delivered a LNA targeting miRNA210 with lipid NPs injected intradermally to improve ischemic wound closure [314]. Another example for wound healing used siRNA targeting ganglioside-monosialic acid 3 synthase delivered by gold NPs suspended in in the commercial ointment Aquaphor, which improved wound healing in a diabetic mouse model (Fig. 29.6B) [315].

For bone regeneration, gene delivery can be used to improve osteogenesis either by overexpression of target genes or siRNA to silence target genes in stem cells encapsulated in a biomaterial. For overexpression, BMP-2 and VEGF plasmid DNA were encapsulated within collagen-nanohydroxyapatite scaffolds and implanted in vivo showing complete bridging of a bone defect model in rats 4 weeks after administration (Fig. 29.8D) [316]. Another approach used siRNA targeting Noggin or miRNA-20a embedded within PEG hydrogels which improved osteogenic potential of MSCs encapsulated in the hydrogel [317].

Nucleic acid delivery for tissue engineering advances into the clinic

Clinical development of genetic medicine for tissue engineering is ongoing in numerous preclinical studies. Significant progress in the last decade, specifically in cancer therapy and inherited disorders, indicates a groundswell of gene therapy products in the pipeline. Currently approved products include viral vectors, antisense oligonucleotides, cell therapy products, and a LNP-delivered RNAi product. Alipogene tiparvovec (Glybera), the first approved gene therapy product approved in Europe, used an AAV for LPLD, however was withdrawn in October 2017 owing to the high cost and low usage rate. Strimvelis is a gamma-retroviral vehicle for ex vivo stem-cell therapy to replace the defective gene for ADA-SCID. Luxturna is an AAV gene therapy to replace RPE65 to treat Leber Congenital Amaurosis-type 2 and Onasemnogene abeparvovec is an AAV gene therapy that was recently approved for spinal muscular atrophy. In 2016 two splice-modulating oligonucleotides delivered without a carrier were approved. Exondys 51 (eteplirsen) is a carrier-free oligonucleotide injection that restores marginal dystrophin protein expression in Duchenne muscular dystrophy in patients amendable to exon 51 removal (~13% of DMD patients) [8]. Shortly after, nusinersen was approved for spinal muscular atrophy, which is delivered by intrathecal injection which increases the local concentration and extends the half-life from days to months [9]. In 2018 OnPattro (patisiran) was the first RNAi drug approved. Onpattro is an siRNA delivered by lipid complex to treat hereditary ATTR amyloidosis by silencing abnormal transthyretin [2] with other RNAi approaches advancing through clinical trials targeting PCSK9, antithrombin, and delta aminolevulinic acid synthase 1 [318–320]. The accelerating pace of gene therapy clinical work and approved products signals that the gene therapy field is coming to maturity and on the cusp of providing significant clinical impact.

Despite the promises of gene therapy, there currently is no approved gene delivery product for improving tissue regeneration. Although a promising approach, there have been numerous approaches for gene therapy in wound regeneration by delivering gene-encoded growth factors via multiple vectors but have not yet translated to an approved product [321]. Early results showed that adenovirus that expresses rhPDGF-BB to improve bone and skin regeneration [269] was shown to be equally effective as the scaffold alone when compared to standard of care [322]. Similarly, cardiac regeneration has been pursued through intramyocardial delivery of plasmid or viral vectors expressing growth factors but previous clinical trials have suffered from inefficient delivery despite a good safety profile [323].

Gene therapy for rheumatoid arthritis and osteoarthrosis has advanced into clinical trials with one approved product in Korea (Invossa) which is under close scrutiny as of this writing owing to irregularities in the cell preparation. Other approaches in the clinical pipeline include AAV delivery of Etanercept and IFN-β for rheumatoid arthritis and IL-1Ra for osteoarthristis [324]. An IND-enabling study indicated that a self-complementary AAV2.5 expressing IL-1Ra was safe and effective in a rat model of osteoarthritis [325]; this technology is expected to begin phase I clinical trials in 2019 (NCT02790723).

Moderna recently published the results of a phase 1/2 trial using modified VEGF mRNA to treat vascular deficiencies in men with type 2 diabetes mellitius. Intradermal injections of modified mRNA carrier-free led to nearly double VEGF-A protein levels at the higher dose of 360 μg and a statistically significant blood flow increases at day 7 and 14 measured by laser doppler fluximetry (Fig. 29.9A) [153]. A previous preclinical study showed the eventual application of VEGF-A mRNA delivery may be broad including cardiovascular regeneration, diabetic wound healing, and others [152].

One of the most remarkable clinical results was the gene therapy treatment of junctional epidermolysis bullosa with autologous keratinocytes transduced by a retrovirus encoding laminin-332. The study enrolled a single 7-year-old patient with complete epidermal loss on 80% of his body. After three autologous transplantations delivered by plastic- of fibrin-cultured grafts resulted in near complete epidermal regeneration that remained intact through the 21-month follow-up. Biopsies taken at follow-up visits indicated restoration of laminin-332 expression in the patient epidermis-dermis junction (Fig. 29.9B) [326]. This study also demonstrated the feasibility of repopulating the entire epidermis with genetically modified stem cells. Various forms of epidermolysis bullosa affects nearly 500,000 people worldwide, and this approach could be applied to many of them with several clinical trials underway (NCT03490331, NCT02984085).

Future challenges

To avoid repeating clinical trial failures of the past, a large body of work has been dedicated to characterizing the safety of gene therapy approaches before and during clinical trials. Specifically, immunogenicity, transduction toxicity, and genotoxicity are being studied. Immune response against viral vectors, specifically AAV, have been extensively studied and clinical studies are provided valuable insights but many questions remain [327]. The Wilson group recently identified severe toxicity in pigs and nonhuman primates injected with AAV serotype hu6 (a variant of AAV9) at a high dose similar to the dose used in clinical studies for spinal muscular atrophy [328].

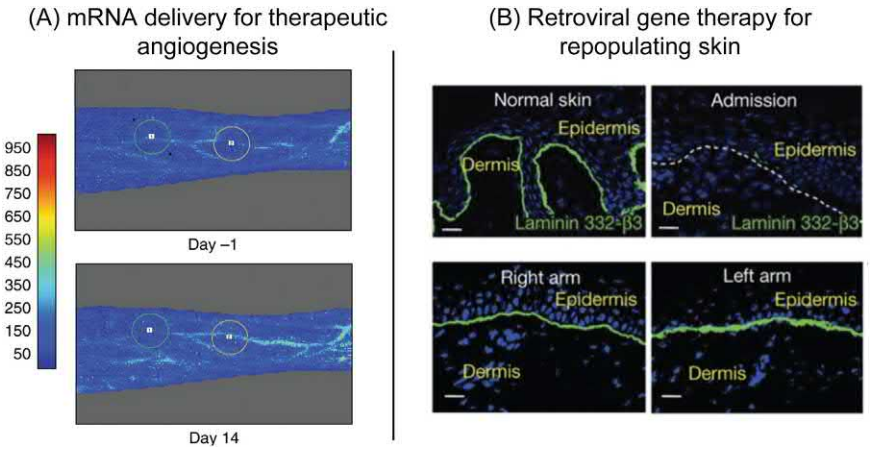

FIGURE 29.9 Clinical trial results for gene delivery and tissue engineering. (A) VEGF-modified mRNA was used to increase angiogenesis and perfusion in patients with type 2 diabetes shown here by laser doppler fluximetry. (B) A single-patient trial restored Laminin 332 expression by retroviral transduction of autologous keratinocytes with near complete restoration of the epidermis. In this image, green indicates Laminin 332 staining, which is absent after admission of the patient (upper right image) but complete restored at follow up (lower images). *Reprinted with permission from Hirsch T, et al. Regeneration of the entire human epidermis using transgenic stem cells. Nature 2017;551:327–32, doi:10.1038/nature24487; Gan LM et al. Intradermal delivery of modified mRNA encoding VEGF-A in patients with type 2 diabetes. Nat Commun 2019;10:871, doi:10.1038/s41467-019-08852-4.*

The authors noted dorsal root ganglia sensory neuron lesions necessitating euthanasia of the piglets and transaminase elevation in primates with one of three primates euthanized for liver failure. The authors suggest that the toxicity is caused by the transduction and not an immune response to transgene or capsid [328]. Genotoxicity can develop from unwanted genetic changes induced by viral vectors or genome editing. Unintended integration upstream of oncogenes resulted in cancerous transformation as seen in a previous clinical trial for X-SCID [77]. New generations of SIN retrovirus have avoided cancerous transformation in more recent clinical work [329] while other modifications can change the integration profile to reduce integration into actively transcribed genes. AAV has a low rate of integration which has raised some genotoxicity concerns in the past that have been controversial [330–333]. In the context of genome editing, undesired genome modification on- and off-target may potentially lead to genotoxic outcomes. Previous work has shown undesired genome modifications at off-target locations in the genome or at the target site inducing unwanted changes including vector integrations [334], large deletions [335], or large duplications [336]. In one case, the large duplication created a negative immune phenotype in mice [336]. Efforts should be made during clinical development to characterize genotoxicity including monitoring activation of oncogenes and clonal expansion of transduced or gene-edited cells.

Outlook

Three decades of laboratory-based gene and nucleic acid delivery have provided compelling arguments for continuing the refinement of vehicles and mechanisms for improving the safety and efficacy of gene manipulation. Recent advances in vector design have yielded vectors with improved systemic distribution and spatiotemporal control for gene expression which has propelled gene therapy into clinical evaluation for numerous conditions. Carrier-free technologies are also rapidly emerging based on innovative, highly stable nucleic acid chemistries, especially for applications where siRNAs are deployed in conjugate formats where targeting or hydrophobic modifications contribute to cell penetration. Relevant to tissue engineering, there are sharp contrasts among the design features for systemic versus local delivery, acute versus sustained activity, regulated versus constitutive expression, and extrachromosomal versus chromosomal localization. Thus the delivery criteria vary by application and the etiology of the disease.

Numerous challenges remain to optimize therapeutic potential for delivery of nucleic acids including increasing efficiency and ensuring safety of delivery strategies. Preclinical and clinical work will seek to characterize and avoid immune response to carriers, genetic cargo, and expressed genes. More work to detect cellular toxicity and genotoxicity will be needed. Ongoing clinical work will seek to address these concerns and characterize long-term safety and efficiency in patients.

In the coming years, we expect vigorous progress in increasing efficiency of delivery to new cell types and tissues. Tissue engineers will continue to develop new strategies for controlled gene delivery. Combined with advances in virology, new chemistry approaches, increased capacity for high-throughput screening, and

new technologies for specific DNA editing, the future is bright for gene delivery to improve tissue regeneration. Ongoing clinical trials in gene therapy will pioneer the frontier of genetic medicine brining us closer to revolutionary improvements in tissue engineering.

Breast

Chapter 30

Breast tissue engineering: implantation and three-dimensional tissue test system applications

Karen J.L. Burg[1] and Timothy C. Burg[2]

[1]Department of Small Animal Medicine and Surgery, University of Georgia, Athens, GA, United States, [2]Department of Veterinary Biosciences and Diagnostic Imaging, University of Georgia, Athens, GA, United States

Introduction

The chance of a woman developing breast cancer in her lifetime is approximately 13% [1]. It was estimated that in 2020 there would be approximately 276,000 new breast cancer cases and 42,000 breast cancer–related deaths in the United States [1]. The chance of breast cancer–related death in women is approximately 2.6%. Fear of disfigurement due to mastectomy or lumpectomy and limitations of breast-conserving options precipitated interest in tissue-engineering breast reconstruction options. Similarly, the impact of the disease, both psychological and physical [2,3], and the limitations of traditional two-dimensional (2D) bioassays used to understand, combat, or prevent the disease have driven the interest in engineering three-dimensional (3D) tissue test systems.

This chapter summarizes the various cell types that may be useful for breast reconstruction, the polymers that are being used or explored for use in breast reconstruction, and the limitations/advantages of specific animal models that allow one to test new tissue-engineering approaches. Avenues to potentially promote the vascularization of engineered tissues are discussed, as the major limitation in engineering large tissue volumes is the inability to deliver nutrients and remove waste products once the tissue is implanted. Finally, the chapter overviews the concept of tissue engineering to create benchtop breast tissue test systems that may be able to aid in developing breast cancer therapies and preventatives.

Breast anatomy and development

The breast is a dynamic organ that evolves constantly throughout a woman's lifetime. This tissue comprises multiple cell types that actively interact with each other [4]. Microenvironmental signals are key to the developmental processes of the breast throughout maturation [1]. The complexity of the breast must be considered when investigating strategies for engineering breast tissue; however, understanding of the many interactions that occur between the stromal cells and epithelial cells in the breast tissue remains limited. Evidence indicates that paracrine molecules produced by stromal cells likely determine the success or failure of tissue-engineered solutions for breast tissue repair [5]. To better understand the development of breast cancer, it is important to first review the anatomy of the breast and the structures and functions of the tissues (Fig. 30.1). The breast structure is located on top of the pectoralis muscle, which is located on top of the rib cage. Each breast contains 15–20 lobes that comprise 20–40 lobules [6]. It is inside these lobules that the mammary glands responsible for milk production are found [7]. The lobules are connected together through ducts; the milk is collected in the ducts and then flows out through the nipple. The space between these structures is filled with fat and fibrous tissue, the ratio of which determines breast density. A high concentration of lymphatic vessels and lymph nodes is found throughout breast tissue; these structures facilitate the flow of lymph, which comprises white blood vessels called lymphocytes and a fluid from the intestines called chyle, which contains proteins and fats [8]. The lymph flows to the nearby lymph nodes located in the underarm, above the collar bone, and behind the breast bone [7]. Blood vessels are also present to carry blood around the tissues to provide nutrients to the cells. The size and shape of the breast is determined

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00031-9

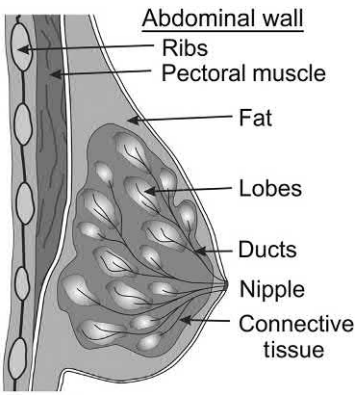

FIGURE 30.1 Breast physiology.

by the skin envelope and the adipose tissue surrounding the connective and glandular tissues. The firmness of the breast mound is dependent on the number of adipose clusters located within the breast, with higher adipose content resulting in a softer breast mound. The deep fascia and a thin layer of loose connective tissue are located between the breast and the pectoralis muscle; the connective tissue allows the breast to move freely over the deep fascia. The breast is attached to the skin through suspensory ligaments, also termed Cooper's ligaments, which provide additional support and contribute to the shape of the breast mound [9].

Several changes occur in the breast as a woman goes through puberty and menopause. During puberty, hormones released by the ovaries and pituitary gland cause the tissue to grow and the ducts to expand, forming mature ductal structures. While the structures are completely formed, they do not become fully active until pregnancy, when the lobules grow and begin producing milk. During menopause, when hormones are no longer produced by the ovaries, the lobule count in the breast decreases, and those lobules that remain shrink in size. This change leads to a lower breast density, since the ratio of dense, fibrous tissue to adipose tissue decreases. For this reason a woman's breast is typically denser before menopause than after [9].

Breast cancer diagnosis and treatments

Historically, breast cancer was not detected at a very early stage and therefore was treated with radical mastectomy, or removal of the entire breast, underlying pectoral muscles, and axillary lymph nodes. As breast cancer detection methods improved, however, breast cancer was discovered at earlier stages, allowing modified radical mastectomies or removal of small tumors. Randomized prospective clinical trials, conducted over 18 years comparing less deformative techniques, demonstrated equivalent survival rates to modified radical mastectomy [10]. These studies demonstrated that, for most women with small breast tumors, simple excision (lumpectomy) of the breast cancer, sampling of the axillary lymph nodes, followed by radiation provides a similar outcome to a radical mastectomy. A more recent study [11] of >5000 women with early stage breast cancer showed, over an 18-year period, no difference in survival rate for women undergoing breast-conserving surgery (e.g., lumpectomy) versus those undergoing mastectomy. However, breast-conserving surgery coupled with radiation treatment resulted in significantly enhanced survival rates in 10 years. Because the time span of the data studied is so great, the information should be further examined to determine correlation, if any, between age and treatment and if treatment options change over time with advances in knowledge and technologies.

Different treatment options can be used in combination to maximize the desired outcome. Breast cancer patients have therapeutic options, such as chemotherapy, radiation, and hormone therapy, and/or surgical options. Most often the treatment will be a combination of surgical and therapeutic options; treatment is determined on a patient-by-patient basis since individual cases of breast cancer have distinct characteristics. The treatment option is chosen based on the stage of the cancer (e.g., in situ or invasive), size of the tumor, health condition of the patient, and several other factors.

There are two main surgical procedures, mastectomy and lumpectomy. The progression of the breast cancer is the main determinant of the procedure. If the cancer has spread beyond the tumor mass formation, then a mastectomy, or removal of the entire breast, is recommended. If the cancer has not progressed outside the initial tumor mass, then a lumpectomy, or removal of the cancerous mass, can be performed followed by the use of an adjuvant therapy, most often radiation [12].

A mastectomy involves the removal of the interior of the breast mound, the nipple, the areola, as well as a wide margin of tissue around the incision. Prior to surgery, the extent of the axilla tissue that must be removed in order to remove the cancerous tissue is determined. Cancer cells most easily spread through the lymphatic system, so the progression of the cancer can be determined by examining the lymph nodes around the cancerous breast [12]. Because of the ease of travel through the lymphatic system, it has become common practice to remove some of the surrounding lymphatic vessels and nodes.

Breast reconstruction

There are extremely limited cosmetic surgical procedures available for lumpectomy patients. In select instances, tissue flaps or fat grafts may be implanted; however, the surgical processing and implantation technique is paramount

to the viability of the transplant, where deviation from established procedures can result in calcification of the breast tissue [13]. Following a mastectomy, patients are given the option of undergoing breast reconstruction surgery. The type and timing of reconstruction is determined first by the physical limitations of the patient and then by preference. An option that has grown in popularity is breast reconstruction immediately following mastectomy [14]. Previously, it was thought that reconstruction should be delayed to prevent any possible interference with an adjuvant therapy. However, benefits to immediate reconstruction include one surgery and hospital stay, better psychological outcomes, and improved aesthetic results. Risks involved with this combination surgery include extended surgical time and an increase in complexity of the procedure [14]. The risk and rewards of undergoing such a procedure are evaluated on a patient-by-patient basis. There are two primary types of tissue implants for breast reconstruction: synthetic and autologous.

Synthetic implants

Generally, synthetic implants are simpler and require less surgical time, but the results are not as aesthetically satisfactory. The simplest reconstruction is a silicone breast implant, which is a silicone gel−filled or saline-filled silicone bag that is implanted in the submuscular position beneath the removed breast mound. In some instances the void volume may be increased by the progressive inflation of a tissue expander [14] prior to the placement of a silicone breast implant. Because an implant is a foreign body, it may trigger a substantial inflammatory response, resulting in fibrosis, thickening, capsular contraction, and an unnatural shape and tactile quality. Also, implants may leak and require replacement. Silicone-filled implants are now rarely used due to fears of possible complications caused by the leakage of silicone.

Tissue flaps

Autologous breast reconstruction relies on the use of the patient's own tissue, is more complex, requiring more extensive surgery and a longer recovery time, but the results are much more natural and aesthetically pleasing than those of prosthetic implants. There are several primary tissue retrieval sites, including the abdomen, the back, and the buttocks or thigh. The transverse rectus abdominis myocutaneous (TRAM) flap, located in the abdomen, is surgically excised, including fatty tissue, abdominal wall skin, often with the blood supply network intact, and is molded into the breast mound. A TRAM flap procedure requires that an additional surgery be performed to reconstruct the nipple−areola and to improve the shape of the reconstructed breast mound; a weakening of the abdomen as well as contour abnormalities of the abdomen can occur after this procedure [9]. The latissimus dorsi flap is removed from the back in a similar but less involved manner than removal of the TRAM flap. Disadvantages of this flap procedure include susceptibility to atrophy and lack of patient-to-patient tissue volume consistency. Muscle-free flaps from the buttock (gluteal) or thigh (tensor fascia lata) may also be used; in some instances a muscle sparing procedure may be used, wherein only fat/skin is transplanted. Adipose tissue matrices, devoid of lipids and cells, have been investigated for use in soft tissue defect repair [15].

Cell transplants

Some of the very first studies performed regarding adipose tissue replacement used a method called autologous fat transplantation. This methodology simply involved harvesting adipose tissue from a location into the patient and transplanting that tissue to the breast tissue void. This procedure was completed without a scaffold in place to guide the shape of the tissue replacement. The results of this type of procedure were very poor, with 50%−70% reduction in volume due to the resorption of the grafted tissue. Resorption occurred because adipocytes are anchorage dependent and require a scaffold to survive. In addition, the adipocytes found in the tissue graft were terminally differentiated and therefore could not proliferate [9]. After many failed cell transplantation attempts, it was suggested that a scaffold was required for proper breast tissue replacement. However, while scaffolds became a subject of significant research activity, interest in lipofilling continued, and studies raised awareness of both the inhibitory and stimulatory potential of lipofilling and underscoring the criticality of the extraction and implantation processes/techniques in free fat transfer [16]. A review of clinical cases suggests that injection of a fat bolus can lead to fat necrosis, oil cysts, and long-term inflammation and calcification. The review further suggested that the better results are achieved by injecting fat diffusely as tiny aliquots throughout the target site [13]. Improved methods in cell harvesting are needed to increase the yield of viable fat cells. Cryopreservation technologies must also advance to allow later serial injections, obviating the need for repeated fat removal procedures.

The cellular material used for transplantation is obtained from lipoaspiration, a process that can damage and lyse the cells. Researchers are developing means with which to treat lipoaspirate, for example, it may be washed in a polyoxamer, which is thought to stabilize the cellular membranes of damaged adipocytes and lend greater stability for implantation and graft survival. Preliminary studies suggest that the treatment can increase implant viability post implantation [17].

Cellular scaffolds

Breast tissue engineering is another reconstructive option, beyond that of synthetic or autologous implants. Breast tissue engineering may involve cellular or acellular scaffolds. Much of the current research is still focused on traditional approaches of ex vivo cell expansion; however, due to financial, regulatory, and logistical obstacles, more focus must be placed on "just-in-time" delivery options that do not incorporate cell expansion ex vivo. Currently, viable breast tissue-engineering technologies have not been translated from the laboratory to the clinic due to several existing challenges related to cell culture, scaffold type, and animal model selection that affect our ability to build a vascularized tissue that maintains volume in the long term.

Cell types and related challenges

Many issues must be considered when choosing which cell type(s) should be used in human breast tissue engineering. The first consideration is that there is substantial variability in the size, shape, and consistency of the breast. The breast changes over time, with a tendency for breast parenchyma (glands and ducts) to involute or regress as a woman ages, particularly after menopause, and be replaced by fat [18]. Also, comparing breast tissue among women of any given age, there is considerable variability in the size, shape, tactile, elastic, and tensile characteristics of the tissue. The tensile and elastic characteristics of the breast are influenced by three major factors:

1. the amount and quality of fat within the breast
2. the amount and quality of glandular and ductal tissue in the breast
3. the mechanical characteristics of the fibrous support structures of the breast (Cooper's ligaments)

The creation of a functional breast with lactational ability is not needed and, in fact, may add to a woman's breast cancer risk by introducing mammary epithelial cells that may be predisposed to cancer development. The major, immediate goal of breast reconstruction is to produce a breast mound with all of the aesthetic properties of a normal breast.

Normal breast tissue comprises adipocytes; however, these lipid-laden fat cells (adipocytes) are terminally differentiated and will not divide further in vivo or in vitro. Indeed, studies have shown that if not maintained in a 3D culture environment, these differentiated cells will likely dedifferentiate and become fibroblastic [5]. Hence, the use of adipocytes requires harvesting fat in the exact volume required for the construct [19–21]. In addition, the majority of mature fat cells in a lipoaspirate sample rupture [8,9,21]; accordingly, measures must be taken to compensate for or prevent this loss.

Preadipocytes may be used for engineering soft tissue [22,23] as these cells are not susceptible to retrieval damage and can potentially be expanded in culture. Preadipocytes are similar to fibroblasts in structure and possess the ability to expand in culture [24]. Several studies have shown ways of inducing differentiation into adipocytes. These cells can be successfully harvested and isolated from sites such as the subcutaneous tissues or the omentum. Investigations of autologous preadipocyte implantation with a sheep model have been promising [25]. Technologies are being developed to allow simple harvesting and fast isolation of preadipocyte cells for immediate reimplantation into the patient [26]. Studies in mice have shown that the incorporation of "adipose-derived regenerative cells" in fat grafts decreases cell apoptosis and increases expression of growth factors [27]. Induced pluripotent stem cells (iPSs), that is, cells derived from skin or blood cells and genetically reprogramed to an embryonic stem cell–like state, have been tested for adipogenic potential; in one specific instance assessing reprogramed human dermal fibroblasts, the iPSs were found to have similar lipid accumulation and transcription of adipogenesis-relevant markers as those found in two human embryonic stem cell (hESC) lines [28].

Possible other cell types include smooth muscle cells, fibroblasts, skeletal muscle, and elastic cartilage. Fibroblasts contribute greatly to the support structure of the breast by laying down bands of collagen that connect the breast tissue to the skin and to the pectoral muscle, as well as helping maintain the overall shape. The density and firmness of the breast is determined primarily by the glandular epithelium and ductal structures, where tissues that have similar tactile and elastic properties are almost exclusively muscle. Smooth muscle cells can be readily isolated from a number of organs and expanded in culture; implantation of smooth muscle-containing polymers can lead to the reformation of significant tissue masses, with reorganization of the smooth muscle tissue into appropriate 3D structures [29]. Muscle myocytes can also be greatly expanded in vitro, and have been demonstrated to reform functional tissue masses under appropriate conditions [30,31]. However, it remains to be demonstrated that smooth or skeletal muscle myocytes will maintain a tissue mass over long periods of time without neural stimulation. An alternate approach might even be to incorporate chondrocytes in an engineered breast tissue. Elastic cartilage has many of the mechanical properties of glandular breast tissue that are potentially important for tissue engineering of breast (e.g., elasticity). Chondrocytes can be expanded in culture and are able to survive in low oxygen tensions. Chondrocytes have been used extensively in tissue engineering to engineer a variety of tissue constructs both in vitro and in vivo [32–34].

However, the more commonly studied cell types for breast tissue engineering include human bone marrow–derived mesenchymal stem cells (hBMSCs) and human adipose-derived mesenchymal stem cells (hAMSCs) [35]. Both cell types have the ability to differentiate into adipocytes when introduced into an adipogenic differentiation medium. The hBMSCs are harvested from the bone marrow, through a relatively painful procedure, which lessens their clinical relevance, while hASCs can be harvested in large volume from adipose tissue obtained via biopsy or liposuction [35]. Recognizing that regeneration may most effectively occur in situ with cues from the native tissue, cell types such as mesenchymal stem cells and embryonic stem cells have rapidly become the most popular cells for breast tissue-engineering research. hESCs are readily able to differentiate into adipocytes [35]; however, a great deal of work will need to be done to ensure terminally differentiated cells, which once transplanted, do not have the potential to form a tumor mass. The implantation of embryonic stem cells has the potential to result in teratoma formation in vivo [36,37]. Studies in mice have shown that the formation may be site dependent and exacerbated in the presence of specific biomaterials [38].

Standard cell isolation and expansion protocols must also be developed; critical steps influencing successful outcomes will include aseptic technique in the harvest, routine quality control testing of all cultures, long-term cell storage, and on-site operating room handling. It may also be possible to isolate all the cell types required for breast tissue engineering from a single tissue source; furthermore, it may be advantageous to retrieve tissue isolates rather than cellular isolates [39]. For example, fat, in addition to adipocytes, contains a large vascular network, composed primarily of capillary endothelial cells and some vascular smooth muscle cells as well as a collagen stromal structure produced by fibroblasts [40]. Hence, multiple cell types or cellular aggregates (tissue isolates) can potentially be obtained from this tissue. In attempting to produce fat tissue in vivo, it may be beneficial to expand the cellular components of fat without isolating each component, as the complexity of the mechanisms may be crucial and impossible to rebuild from cellular blocks. Given the complexity of tissue, it is most likely that a mix of cells, with respect to maturity and type, will result in the most promising tissue-engineering solution.

Scaffolds

An important consideration in engineering breast tissue is the scaffold selection. Selection of a material chemistry and form to use as a scaffold depends on the purpose and characteristics of the tissue that is being replaced as well as the physical characteristics and health of the patient. Scaffolds may be fabricated to induce tissue integration or they may be developed to house or attract cells which, in turn, assist in inducing tissue integration. Several key characteristics make a biomaterial suitable for tissue-engineering application. First, with in vivo endpoint, favorable biomaterials must be absorbable or degradable and therefore facilitate new tissue integration with native tissue over time. The shape and texture of the material does not have to resemble that of natural tissue, but it should induce growth of new breast tissue resembling native tissue, that is, be soft and pliable. Cellular affinity is another important aspect of a biomaterial, whether considering in vivo or in vitro endpoint. The biomaterial must interact favorably with cellular components without negative impact (e.g., the material cannot be tumorigenic or toxic). Some element of porosity or surface texture is helpful and potentially allows cellular ingrowth into the material and/or transfer of nutrients and waste products, the establishment of a vascular network into the biomaterial scaffold [41], and/or differentiation of multipotent cells [42].

Synthetic materials

Aliphatic polyesters of polyglycolide (PG) and polylactide (PL) are well-characterized synthetic biodegradable polymers that are clinically familiar to biomedicine and are familiar also to tissue-engineering researchers [43]. PG is highly crystalline and has a high melting temperature and low solubility in organic solvents. PL is more hydrophobic than PG due to the presence of a methyl group. PL has a low water uptake and its ester bond is less susceptible to hydrolysis, due to steric hindrance by the methyl group. Therefore PL degrades more slowly and has higher solubility in organic solvents than PG. Copolymers of PL and PG can be readily synthesized; their physical properties are modulated by the ratio of glycolic acid to lactic acid. Often incorrectly named in the literature, PL and PG are synthesized by ring-opening polymerization, while the lower molecular weight polylactic acid and polyglycolic acid are synthesized by step growth. The latter are in the order of thousands of Daltons and are limited to use in structures with low mechanical demands, such as films and spheres [44]. Aliphatic polyesters can be readily processed into various physical forms appropriate for tissue-engineering applications. A number of techniques have been proposed to generate highly porous scaffolds, including solvent casting/particulate leaching [45], phase separation [46], emulsion freeze-drying [47], fiber extrusion and fabric formation [48], and gas foaming [49,50].

Polyethylene glycol (PEG) scaffolds [51] are readily modified by degradation and adhesion peptides and thus have been the subject of preadipocyte studies. The combination of adhesion and degradation features appears to allow

the highest adhesion and proliferation of preadipocytes. Nondegradable polymers have also been examined for tissue reconstruction applications. For example, in vitro studies have been conducted with fibronectin-coated polytetrafluoroethylene (PTFE) scaffolds. Human preadipocytes have been shown to successfully attach, proliferate, and differentiate into adipocytes on the PTFE scaffolds [52]; however, these nondegradable scaffolds are likely better suited for 3D in vitro tissue test systems.

A number of other synthetic polymers could be used to fabricate scaffolds for breast tissue reconstruction, including polycaprolactones (PCLs), polyanhydrides, poly(amino acid)s, and poly(ortho ester)s [53]. PCL is an aliphatic polyester, a semicrystalline polymer with high solubility in organic solvents, a low melting temperature, and a low glass transition temperature (T_g). The degradation rate of PCL is much slower than PG or PL; because of the low T_g, PCL has a flexible, sticky quality that can be advantageous in a scaffold. PCL has been tested in scaffold form in animals [54,55] and is used clinically in orthopedic applications. Polyanhydrides are usually copolymers of aromatic diacids and aliphatic diacids. These materials degrade by surface erosion, the rate of which can be controlled depending on the choice of diacids [56]. Poly(amino acid)s have been studied due to their similarity to proteins and widely investigated for use in biomedical applications such as sutures and artificial skin [57]. Poly(amino acid)s are usually polymerized by ring opening of *N*-carboxyanhydrides; versatile copolymers can be prepared from various combinations of amino acids. However, due to the low solubility and limited processability of poly(amino acid)s, "pseudo"-poly(amino acid)s were developed [58]. It has also been reported that poly(amino acid)s containing L-arginine, L-lysine, or L-ornithine cause endothelium-dependent relaxation of bovine intrapulmonary artery and vein, and they stimulate the formation and/or release of an endothelium-derived relaxing factor identified as nitric oxide [59]. Poly(ortho ester)s are biodegradable polymers, which degrade by gradual surface erosion and have been investigated for controlled drug delivery.

Naturally derived materials

Naturally derived polymers have been used for adipose tissue engineering; scaffolds produced from these materials typically are hydrogels or structural forms such as mesh, sponges [9], or beads. Investigations have been conducted, for example, using Matrigel (reconstituted basement membrane of mouse tumor) and fibroblast growth factor 2 (FGF-2) to induce in situ adipogenesis. Matrigel consists largely of type IV collagen, laminin, and perclan and, although a highly variable material with many ill-defined components, it is considered the gold standard in cancer cell biology benchtop studies. Preliminary small animal studies have demonstrated the migration of native preadipocytes as well as endothelial cells into Matrigel when this material is injected into subcutaneous tissue [9,41,60].

Hyaluronic acid (HA) is a natural component of the extracellular matrix of many tissues. HA comprises repeated sequences of glucuronic acid and acetylglucosamine; this material is susceptible to enzymatic degradation via hyaluronidase. Simple modifications have been made, such as cross-linking the chains to form insoluble hydrogels [61]. In its natural form, HA plays a role in enriching wound healing by promoting early inflammation and stimulating angiogenesis [62]. Hyaluronan benzyl ester (HYAFF 11) scaffolds are derived from HA that is esterified with benzyl groups at the glucuronic acid monomer. Researchers experimented with these sponges, seeding them with human preadipocytes and surgically implanting them into subcutaneous tissue of athymic nude mice. The sponges allowed good cellular penetration as well as the development of new vascular networks within the sponges. However, adipose tissue development remained sparse [63]. The researchers also compared collagen scaffolds to HYAFF 11 scaffolds in vivo and concluded that there was increased implant weight, adipose tissue formation, and distribution of cells in the HYAFF 11 scaffolds [64]. Hydrogels of HA have been prepared by covalent cross-linking with various kinds of hydrazides [65] and have been used in drug delivery [66].

Collagen is the best-known tissue-derived natural polymer and is the main component of all mammalian tissues, including skin, bone, cartilage, tendon, and ligament. Collagen has been used as a tissue culture or artificial skin scaffold due to its high cell affinity. However, collagen offers a limited range of physical properties, can be expensive [67], is highly variable, and can elicit a strong immunologic response. Chemical modification and incorporation of fibronectin, chondroitin sulfate, or low levels of HA into the collagen matrix can change cell adhesion [68]. In vivo comparisons of freeze-dried collagen scaffolds with HA sponges and nonwoven mesh, implanted in mice for 8 months, revealed a greater number of adipocytes in the hyaluronic sponges than in the nonwoven mesh. This difference was mainly attributed to the porous nature of the sponge, which allowed greater surface area for adipocyte cell distribution and growth [64,69]. Recent studies also have assessed the idea of creating a fibrovascular tissue bed or natural scaffold, using a preexpansion vacuum into which fat cells are transplanted [70].

Alginate is a naturally occurring hydrogel that can be easily formed into an injectable gel or beads but must be modified with a peptide sequence to allow cell attachment [25,71,72]. Interestingly, the human body does not contain

alginase, the enzyme that breaks down the alginate chain; hence, molecular weight is a crucial consideration for implantation as large molecular weight alginate chains will not be eliminated from the body. That is, the molecular weight of many alginates is typically above the renal clearance threshold of the kidney [73]. Alginate chains are bound together with divalent ions that migrate in areas of divalent ion deficiency, causing uncontrolled dissolution. To address this point, hydrolytically degradable, covalently cross-linked hydrogels derived from alginate were developed [74]. Specifically, polyguluronate blocks with molecular weight of 6000 Da were isolated from alginate, oxidized, and covalently cross-linked with adipic dihydrazide. The gelling of these polymers could be readily controlled, and their mechanical properties depended on the cross-linking density. It was also demonstrated that alginate gel degradation can be readily regulated by controlling the molecular weight distribution of the polymer chains in the gels, and their susceptibility to hydrolytic scission by partial oxidation [75].

Other materials have found limited, preliminary use in breast tissue engineering. Chitosan is relatively biocompatible and biodegradable [76,77], making it useful for breast tissue engineering [78] and wound healing [79]. Chitosan is abundant and easily derivatized by coupling molecules to the amino groups [79,80] and has shown early success in murine studies focused on injectable breast tissue-engineering systems [39]. Fibrin glue has been used as an adipocyte scaffold and, in small animal studies, has facilitated maintenance of adipose tissue up to 1 year after implantation [81]. Fibrin is a blood-based product, a characteristic which has slowed its translational appeal in the United States.

Therapeutic scaffolds

Some scaffolds provide more than a simple matrix on which cells will grow. Some scaffolds have an incorporated therapeutic agent such as a drug or growth factor and are termed therapeutic scaffolds. The concept behind these scaffolds is that the therapeutic agent incorporated in the scaffold is released as the cells remodel the scaffold during cell growth and proliferation. The therapeutic agent therefore has a direct effect on the surrounding tissue where the scaffold is placed; accordingly, the use of growth factors and the stimulation of cell growth must be carefully evaluated in breast cancer–related reconstruction, to avoid facilitating the cancer process.

Indeed, therapeutic agents can affect the tissue surrounding the implanted scaffold. An example can be seen in a study where the therapeutic agent, angiogenin, was incorporated into a scaffold [82]. Angiogenin is a drug that has been shown to promote neovascularization, so the intent of its incorporation was to help promote the growth of new vasculature throughout the scaffold, increase the chances for the success of an implanted tissue replacement, and improve the overall outcome of the procedure. The investigators subcutaneously implanted these scaffolds into rabbits and, after 28 days, the scaffolds were excised. The study showed that scaffolds with incorporated angiogenin had increased neovascularization. Other therapeutic scaffolds have been designed; for example, a collagen/chitosan/glycosaminoglycan scaffold was assessed [83]. The agent for this therapeutic scaffold, transforming growth factor-beta 1 (TGF-β1) targeted cells grown on the scaffolds rather than the surrounding tissue. Accordingly, TGF-β1 was incorporated into chitosan microspheres that were embedded into the scaffold.

A final example of a therapeutic scaffold is one in which the agent targets and neutralizes a specific type of cell found in the surrounding tissue, such as a cancer cell. Researchers developed, for example, scaffolds with nanoparticles containing emodin, an anticancer drug [84]. These scaffolds were intended to fill a site where a cancerous tumor was removed from the breast. The concept of this scaffold is that as cells proliferate on the scaffold and remodel it, the emodin contained within the nanoparticles is released and neutralizes cancerous cells in the surrounding tissue. These scaffolds were implanted next to the mammary fat pads of nude mice in which cancerous cells had been injected. The results of this study indicated that the size and number of the tumors next to emodin-loaded scaffolds were reduced compared to those next to scaffolds without emodin.

Injectable scaffolds

Early scaffolds took forms such as foams or mesh; they required implantation via an open surgical procedure. However, the reality of the transport and surgical limitations of large volume implants led to the development of injectable composite scaffolds, comprising a “solid,” absorbable fraction of injectable size in a degradable carrier gel [85]. Injectable scaffolds can be combined with cells and surgically implanted in a minimally invasive manner, including by syringe, catheter, or endoscopic needles [86,87]. These injectable materials take forms such as gels, beads, or composite gels. Examples of injectable scaffold chemistries that have been assessed for breast tissue engineering include alginate, chitosan, HA, collagen, polyanhydride, degradable PEGs, decellularized adipose tissue, small intestinal submucosa, and blends thereof [15,39,85,88,89]. While gels support cell growth and readily conform to a defect, they typically do not support the necessary functions of anchorage-dependent cells and are therefore useful as carriers but not as scaffolds in breast tissue engineering. Beads and composites (which contain beads or other filler), in contrast, are amenable to breast tissue engineering.

Combination scaffolds

It is likely that a combination of biomaterials, with respect to chemistry and form, will result in the most promising tissue-engineering solution. Scaffold combinations that use two or more types of materials can be used to help combat and overcome the weaknesses and shortcomings of one material. For instance, a material that has excellent cell attachment characteristics but is not very durable can be combined with a more durable material, hopefully resulting in a scaffold that is both durable and able to support cell growth.

One of the first combination breast tissue-engineering scaffolds was an injectable composite comprising beads in a delivery gel [85]. Indeed, cellular constructs that are approximately 500 μm in thickness or less, once implanted, may optimize diffusional transport of nutrients to the cells while each small cell-polymer unit becomes vascularized. Accordingly, these injectable composites were developed specifically to allow trafficking and infiltration of blood vessels, nutrients, waste products, other factors, and cell types, within the discrete portions of the scaffold (i.e., between beads) [39,85,90]. The beads, or a fraction of the beads, may be selectively loaded with appropriate factors to induce tissue growth or prevent abnormal tissue growth. The gel is degradable and facilitates delivery of the composite through a needle and also allows the composite to conform to and fill an irregular defect site. The gel may be loaded with factors for release on degradation. A variety of studies have been conducted to demonstrate the modularity of an injectable composite approach [39,72,85,91,92].

It is unlikely that there is a one-size-fits-all biomaterial chemistry or form; accordingly, there is interest in a wide range of combination scaffolds. In one study, gelatin sponges, PG mesh, and monofilament polypropylene mesh were used to construct 3D scaffolds of predefined shapes on which hAMSCs were grown [93]. The scaffolds were made of an outer polypropylene mesh pocket that contained gelatin sponge cubes and PG mesh. Gelatin is an attractive scaffold for cell growth and attachment and can be molded into a desired shape but rapidly loses its dimensional stability over time. The PG mesh was used to increase the surface area available for cell attachment. Polypropylene mesh was used because of its ability to maintain dimensional stability after being implanted into the body. These scaffolds were seeded with a high-density hAMSC suspension and cultured for 2 weeks. Subsequently, the scaffolds were implanted into the backs of nude mice for 2 months and then excised for analysis. Analysis showed that the scaffolds contained new adipose tissue as well as neovascular structures. The gelatin cubes, as well as the PG mesh, were completely absorbed by the body, but the outer polypropylene mesh retained the predefined dimensions; the neovascular structures may have simply been the transient part of the normal foreign body response.

Strategies to enhance the vascularization of engineered tissue

A critical challenge to engineer breast tissue, or any tissue of significant thickness, remains the development of a vascular network to support the metabolic needs of the engineered tissue and integrate it with the rest of the body. Adipose tissue is highly vascularized, with a resting blood flow two to three times higher than that of skeletal muscle. The presence of vascularized networks in natural metabolic organs results in short diffusion distances between the nutrient source and the cells [94], and these vascular networks must be created in engineered tissues as well. Nutrient diffusion in vivo is constrained to a distance of approximately 150 μm. Most metabolically active cells that are located further than this distance from a nearby capillary are subject to hypoxia. Thus the success of any large engineered tissue hinges on its blood supply. The important interrelationship between preadipocytes and endothelial cells was demonstrated in hypoxic culture experiments. Frye and coworkers [95] exposed cell cultures of pure preadipocytes, as well as mixed cultures of preadipocytes and microvascular endothelial cells, to hypoxic conditions (5%−2% O_2) and found that preadipocytes cocultured with microvascular endothelial cells had higher viability than cultures consisting of preadipocytes alone.

Several general approaches have been taken to date to promote angiogenesis in engineered tissues; however, none provide a robust, consistent solution to this complex problem. Bland and coworkers [96] provided a detailed review of approaches to combat hypoxia in tissue-engineered systems. In short, this problem has been unsuccessfully addressed in the long term by incorporating endothelial cells or angiogenic factors in tissue-engineered implants. Concerns about blood vessel promoting factors are high when targeting solutions for breast cancer patients. The composite injectable systems do provide the option of gradually building smaller volumes of tissue over time to collectively build a large volume [97]. Many studies highlight angiogenic response at short time points, suggesting that the foreign body response provides the necessary vascularity [98,99]. Indeed, while this is the case in the short term (and at later defined intervals, as the material is further degraded or absorbed and elicits further response), the vascularity is temporary only. Blood vessel ingrowth occurs slowly with this approach, will likely not be sufficient to engineer large tissue volumes, and will likely subside with termination of the foreign body response. Other approaches attempt to actively

modulate the vascularization process by either delivering angiogenic molecules or blood vessel forming cells (e.g., endothelial cells) to the site at which the tissue is being engineered. Prevascularization, either in vitro or in vivo, has also been proposed and investigated by numerous groups, but the problem of integrating newly developed vasculature with host tissue remains unsolved. In addition, for reconstruction following lumpectomy or mastectomy, there is concern of igniting rapid vascular growth and supporting cancerous cell growth [100].

Microstamping using nano-fluid chambers is one research approach of interest in liver tissue engineering [101], where the long-term goal is to develop a 3D vascular bed ex vivo that could be anastomosed to the host vasculature to support cellular engraftment. This approach could also be developed for breast tissue engineering. Another approach involves the direct association of an implant with a preexisting blood supply. Experiments with nude mice were performed, in which silicone molds packed with PG fibers were sewn to the inferior epigastric blood vessels. These silicone molds were injected with a combination of Matrigel and FGF-2. In situ adipogenesis was demonstrated over a 4−20-week time course. Direct application of a vascular pedicle to a construct is another promising approach. Prefabricated flaps have been created with vascular pedicles since the 1960s; vascular pedicles can be supplied in many different configurations. In general, however, conduits comprising an intact artery and vein fare better than those comprising a single vein alone [102,103].

Special considerations

The need for nipple reconstruction occurs after mastectomy. Traditional implants include free composite grafts, local tissue transfer, and prosthetic devices. Free composite grafts were initially used and created from autologous tissues such as the labia, inner thigh, cartilage (auricular or costal), the contralateral nipple, or the toe. Complications at the graft site made this technique less desirable. Local tissue flaps are the most popular option for nipple reconstruction. Commonly used techniques include the bell flap, the modified star flap, and skate flap [104−107]. Unfortunately these techniques can be hindered by flap necrosis and poor aesthetic results, including loss of nipple projection. In addition, the presence of underlying subcutaneous fat is important for bulking; this layer is not always sufficient. Tissue-engineering approaches include the use of tissue flaps coupled with acellular, naturally derived (collagen, extracellular matrix, etc.) matrices [108] and/or fat grafts.

Breast cancer modeling

As Savage stated, “Cancer is not a simple disease” [109]. A significant challenge to both the development of breast cancer treatments and fundamental understanding of breast cancer processes is the development of a tool, a model, which allows isolation and control of specific parameters of interest. The study of basic disease processes and treatments in a patient is generally very inefficient because of the number of confounding biological (and ethical) issues. In response to this challenge, researchers have proposed animal models, mathematical models, and benchtop test systems as the means to more effectively study breast cancer.

Animal models

It is important to first consider the application for which an animal study is planned before the selection of the animal model itself. Either the nude (nu/nu) or severe combined immunodeficiency (SCID) mouse model is used for the transplantation of human-derived cells [110]. These animals have compromised immune systems to the extent that they will often accept xenogeneic transplanted tissues, and these mice have been particularly useful for transplantation and immunologic studies of human tumors, bone marrow, skin, and other tissues [97,111,112]. SCID and nude mice are used to evaluate various polymer constructs with and without human cells in vivo, without the adverse effects of a major immunologic reaction. Furthermore, basic questions about human cells and polymers in vivo may be answered without launching human trials prematurely. Development of these models may not be straightforward since there are subtle differences between strains with respect to the acceptance of various tissues and growth of the implanted tissues in different sites (e.g., a tissue may grow in one mouse strain but not in another, or may grow in a subcutaneous site but not in an internal location). Even though mice are genetically altered for immunodeficiency, the particular genetic modifications can vary. These varying genetic modifications can cause varying levels of different hormones throughout the host body. Hormonal differences will result in adipose tissue development differences that will likely result in different biological reactions to the same implant. Several different genetic varieties of laboratory rats exist, which poses complications when attempting to compare studies [110]. Biologically, males and females of the same species have different hormone levels due to differences in development and maturation. In addition, gender-induced differences in hormones cause a difference in adipose tissue development which may result in different biological reactions to similar scaffold constructs [110].

Nude mice lack a T-lymphocyte response, while SCID mice lack both a T- and B-lymphocyte response. However, both types have natural killer cells that may interact with some transplanted materials. These mouse colonies must be monitored closely for changes in the immune status of

the mice that, at times, occur spontaneously. In addition, the human cells must be routinely screened for the human immunodeficiency virus, hepatitis, and mycoplasma before being transplanted into immunosuppressed mice to assure the safety of the animals and workers, and the validity of the experiments.

Another complicating factor is the size of the actual animal in question. Small size animals include animals such as mice and rats, while larger sized animals include sheep, domestic pigs, and cows [110]. When considering mammary tissue, the larger sized animals are more physiologically relevant to humans. This issue raises the question of applicability of relating animal model results to an expected human clinical trial outcome. Large animals can accommodate the same size implant as one that would be used in a human. Also, the internal anatomy of larger animals, such as the domestic pig, is much more similar to the human anatomy in regard to organ size and heart rate. It has also been shown that the histoarchitecture and hormonal control of the mammary glands of larger animal models is much more applicable to humans than those of rodents [113]. Studies have shown that bovine cells as well as human cells do not grow in the mammary fat pads of immune suppressed mice. This observation suggests that the fat pads of rodents do not provide an environment suitable for the proper growth of human or bovine mammary epithelium. It has also been shown that progesterone has a very different effect on the mammary tissue of mice when compared to that in larger animals, including humans. In mice, progesterone stimulates epithelial proliferation and ductal side branching, whereas progesterone has a limited effect on the mammary epithelium of larger animals and humans.

There has been excellent success using inbred female Lewis rats as a small animal model for the development of transplantable tissues with absorbable polymers such as PG, PL, poly(lactide-*co*-glycolide), and hydrogels such as alginate [114]. This model allows transplantation of cells between individuals without concern for immunologic rejection, which parallels the likely autologous nature of cell transplantation for breast engineering. In addition, the Lewis rat is larger than many other strains, allowing the testing of larger (1−2 cm) or multiple constructs in the same animal.

In evaluating larger animals as models for breast tissue engineering, animals with skin and subcutaneous tissues that are similar to humans are required in order to evaluate larger constructs subcutaneously. For this reason the same animal must be used as a tissue donor and recipient. Porcine skin and subcutaneous tissues are very similar to that in humans, but most pigs continue to rapidly gain weight throughout their lives, which makes monitoring implants very difficult. Sheep have very little subcutaneous fat and, depending on the location, have well-defined subcutaneous space for cellular engraftment. Hence, if new adipose tissue is formed there is a high probability that this is developed from the implanted cells. One of the few locations in the sheep where there are significant fat deposits is the omentum. Researchers have shown that preadipocytes isolated from the omentum can be expanded in culture, seeded onto porous alginate−RGD fragments [25], where they attach, proliferate, and spread onto the biomaterial surface. Cellular alginate−RGD fragments were subsequently injected into the nape of the neck of sheep to determine if new adipose tissue would form. Although the cells were autologous and not labeled with a tracking marker, there appeared to be de novo adipose tissue formation in the cell implant sites compared to the acellular biomaterial control sites.

Indeed, further investigation of breast tissue-engineering options within a large animal that has biological characteristics comparable to that of humans is required. The bovine mammary gland consists of the same anatomical structures and tissue types as that of the normal human breast [115]. Histological evaluation reveals that bovine mammary tissue is more similar to that of humans than is mammary tissue of traditional animal models such as mice and rats [90]. The ductal structures in the human and cow are surrounded by relatively dense stromal tissue [116,117] unlike the ducts in the mouse which are almost completely enclosed by adipocytes [118].

Table 30.1 summarizes the similarities and differences seen in mammary gland development in mice, humans, pigs, and ruminant animals such as sheep, goats, and cows. However, larger sized animals present logistical and financial issues. Large animals are much more expensive than smaller animals and fewer researchers are trained in, or have the facilities for, the proper care of these larger animals [113].

Breast tissue test systems

To gain better insight into the in vivo setting, 3D tissue test systems were first proposed as a new application of tissue-engineering methodology to create benchtop organs or tissues [119]. Subsequently, it became rapidly apparent that these benchtop systems could be used to model experimental clinical conditions or biological situations. Events that are notable in a 3D setting, that is, in vivo, may not be present in a 2D model, or vice versa [5]. Hence, 3D models are sought to probe 3D phenomena. Breast tissue test systems can be used to inform tissue-engineering reconstructive techniques, or to better understand and prevent the disease process through identification of biomarkers or decoding of complex pathways [120,121]. Many studies have been conducted to assess breast cell cocultures in 3D. The 3D material, that is, the scaffold, has enormous influence on cellular behavior and

TABLE 30.1 Comparative aspects of mammary gland development [113].

Attribute	Mice	Humans	Pigs	Ruminants
Morphology	Sparse ducts: alveolar	TDLU	TDLU	TDLU
Stromal histology	Adipose»connective	Intralobular, interlobular connective»adipose	Intralobular, interlobular connective»adipose	Intralobular, interlobular connective»adipose
No. of ductules/TDLU (Types 1, 2, and 3, respectively)	N/A	11, 47, 81	9, 24, 64	Not defined
No. of galactophores	1	~8–15	2	1
Epithelial proliferation	Concentrated in end buds and alveoli	Concentrated in end buds or TDLU	Concentrated in end buds or TDLU	Peripheral zones of TDLU
Response to estrogen	End buds	Epithelial	End buds, TDLU	Epithelial
Response to progesterone	Alveoli	Negative, or no effect	No effect	No effect
Mammary tumors	Spontaneous, viral origin	Spontaneous	Rare, few cases	Rare, few cases

can be selected according to the biological aspect of interest.

In order to distinguish tissue test systems from in vivo human or animal models and refine the expectations of an in vitro model, a tissue test system can be defined as a modular unit of "useful" biology. A tissue test system is depicted in Fig. 30.2 as a tissue model built using a Lego-like approach with biological and nonbiological components that can then be used to answer biological questions. This Lego-like approach may be extended to interconnect complementary tissue-engineered organ modules to model more complex phenomena [122,123]; Clemson University Research Foundation (disclosure 2005-32) such as drug pathways and pharmaceutical tissue interactions. The three primary questions that must be considered in designing a test system are as follows:

1. What is the biological question of interest and how can this question be answered with an approximate biological model?
2. What are the elemental components (i.e., the Lego blocks) and how are the elemental components arranged to make the biological model?
3. How will the elemental components be assembled and the final tissue cultured?

One cannot survive in the world without mentally forming cause and effect relationship models that provide useful advice about behaviors of the systems around us. Many natural systems are understood through models, which provide useful information, such as predicting the future state of a system for a change in inputs to the system. As an example from physics, the behavior of a resistance may be described by the simple Ohm's law mathematical model of the voltage across the resistance equals the resistance multiplied by the current, $v = Ri$. This model is "useful" to make calculations such as how many light bulbs could be connected to an electric circuit. The Ohm's law model is easy to use, scales to more complex problems, is consistent and reliable since it works for anything that behaves like a pure resistance over a specific operating range, has been verified by experimentation, is cost effective to use, can be extended to account for additional physical phenomena, and increases understanding of the system. Thus even though the Ohm's law model is not a copy of the resistance, it provides useful information. A tissue test system holds the same promise to provide a model that facilitates the creation and sharing of new knowledge of breast tissue processes.

The Ohm's law resistance model has obvious limitations. When the model is tested under unmodeled conditions such as very high temperatures, the information from the resistor model becomes less accurate and hence less "useful." In this case the resistance model can be updated by changing the constant resistance to a function

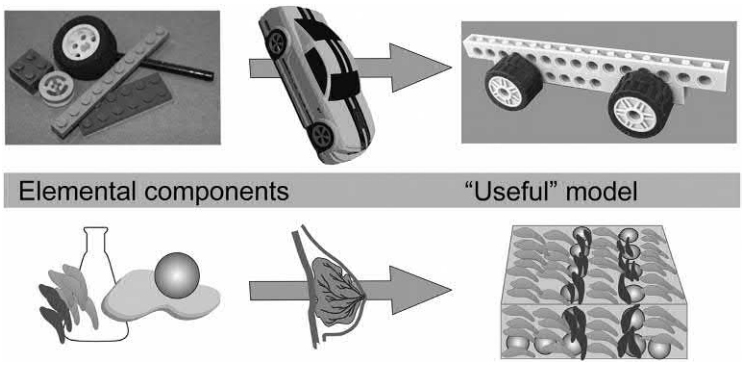

FIGURE 30.2 Top row shows the Lego approach where plastic blocks are used to build a model of a car. This model is simple, representing one specific aspect of the car; however, the complexity of the model can be increased to match the end goal, that is, to isolate the element(s) of interest. Clearly models cannot, and are not intended to, replicate all aspects of a functional system and are only valid within their stated, limited bounds. The analogy to biofabrication of a tissue test system is shown in the bottom row where the elemental components, for example, cellular units, biomaterials such as beads, fibers, or gels, and biochemical agents are assembled to produce relevant aspects of a tissue, that is, a tissue model.

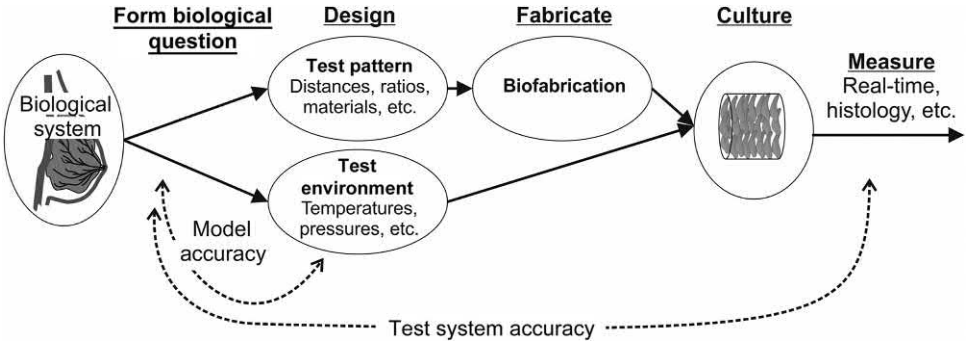

FIGURE 30.3 Process of developing biologically relevant tissue test systems. A final relevancy/benchmarking check is conducted to determine if the test environment is providing meaningful information, relevant to the biological system (again realizing that a model approximates and simplifies, it does not replicate).

of temperature, that is, $R(T)$. Specifically, the resistor model must be designed to include the phenomena that affect the accuracy and resolution needed to provide useful information for a specific question of interest. Thus a breast tissue test system must be defined to match the expectations of the user to provide useful information. Practically, a tissue test system must be defined to meet the user's needs and should not be a quest to reproduce the full in vivo biology; rather, it should be a design approach to capture only the salient physiological, mechanical, biochemical, morphological, and biological elements needed to study a specific phenomenon.

A general schematic of the process of designing, fabricating, and using a tissue test system is shown in Fig. 30.3. Tissue test system development begins with assessing the physical system to identify the scope and features needed in the test system model. The first challenge in using a tissue test system is defining what behaviors in the native system must be included to address a specific question of interest; that is, what does one intend to learn from the tissue test system and what are the first-order factors that affect the behavior under study. Model accuracy is used here to describe the translation of a biological question into a test pattern or structure for the tissue test system. Note that high model accuracy does not mean that the test pattern must be an exact reproduction of the biological structure, in this case the breast; rather, it must be a representation of the underlying chemical, physical, electrical, etc. phenomena that are useful for answering a specific biological question regarding breast tissue. In fact, a well-designed test system will exclude factors that confound answering the biological question of interest. Hence, different biological questions will require different test system models. As an example, there are currently test systems, such as those addressing adhesion assays, that comprise cells seeded onto a plate. These are relatively straightforward test systems to implement and hence are often the first assays performed. Such a flat, 2D system can answer important questions; for example, adhesion assays were used to study the expression and function of Laminin-511 during metastatic breast cancer progression [124]. These results can inform decisions regarding incorporation of Laminin-511 in a breast tissue implant, or regarding selection of reconstructive biomaterials that may promote or inhibit production of this extracellular protein. Note, however, that 2D cultures are not amenable to the study of breast ductal structures or questions regarding spatial colocation [125]. Following Fig. 30.3, the test pattern must be fabricated, for example by biofabrication, and then cultured. The biofabrication system to produce a desired test system and then the culture system, for example, a bioreactor, to produce the environmental conditions, such as temperature or pH, present significant instrumentation challenges. Test system accuracy describes the overall degree to which the biological question of interest can be studied in the in vitro culture.

An established tool in breast cancer studies that is also applicable to breast reconstruction research is the breast

tissue organoid, which is formed by digesting harvested tissues into duct-like structures that resemble the original organ in appearance or function. While it is obvious that an organoid model formed by removing tissue and allowing the remaining tissue to grow in a new manner is not a physical copy of the breast tissue, it has been shown that this simplified model can produce useful results. For example, in the work by Cellurale and coworkers [126] the authors were able to isolate the role of cJun NH2-terminal kinase signaling in mammary gland development and tumorigenesis using mammary organoid cultures. In other studies [127], organoids were used as the basic building block of human mammary epithelial cell cultures. The organoid model uses an elemental component that already has significant structure and is directly derived from the biological source. Researchers developed a protocol and created over a hundred breast cancer organoid lines for research and drug development [128].

There are more general approaches to building test systems that use biofabrication techniques to assemble smaller elemental pieces. Biofabrication is the process in which cells, biomaterials, and biochemical agents are arranged into a biological structure. The components of materials must be chosen and assembled such that they promote cellular growth and behaviors. The specific fabrication technologies dictate the degree to which the materials and cells can be arranged in heterogenous patterns. Current discrete deposition techniques can be labeled as "quantum-on-demand" bioprinting as small units of cells or biomaterials are used to build the biological structure. Fig. 30.4 illustrates three general modes for depositing a quantum of cells and biomaterials at a specific time or location [123]. The "cells-on-demand" mode describes the direct placement of cells in the structure. The "liquid/gel-on-demand" mode describes placing an extrudate, a cellular or acellular "bioink," at precise locations. The "particle/bead-on-demand" mode involves the deposition of a hard biomaterial particle or bead. Fig. 30.5 shows considerations in biofabricating a test system model. The first source of potential error is the discretization of a proposed test pattern based on the resolution of the fabrication system. The 2D pixel error is illustrated in the second column of Fig. 30.5 where it can be seen that the biofabrication system with the coarser resolution produces a lower fidelity replica of the test pattern. The 3D equivalent of pixel error is the voxel error, which includes the pixel error as well as a depth component. For example, if a test pattern is defined at the cellular level using micron resolution, such as a scan of a histology slide, then a biofabrication technique that has the smallest

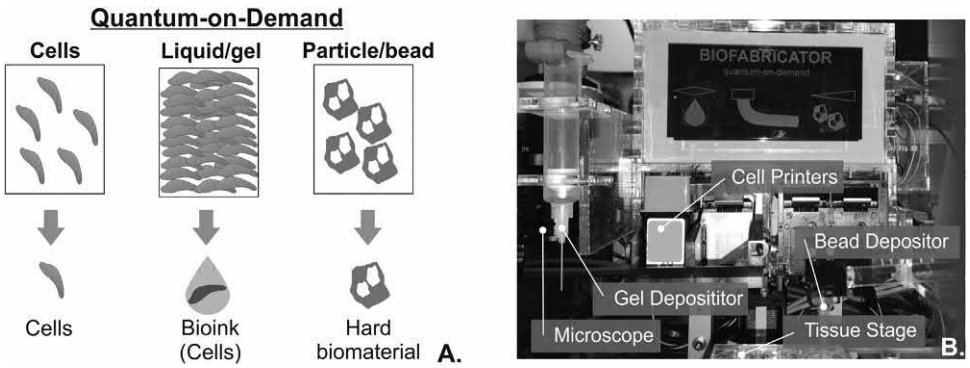

FIGURE 30.4 (A) The three general modes to apply a quantum of cells and/or biomaterials during biofabrication of tissues and (B) photo of a biofabrication system with multiple deposition stations for cells and biomaterials.

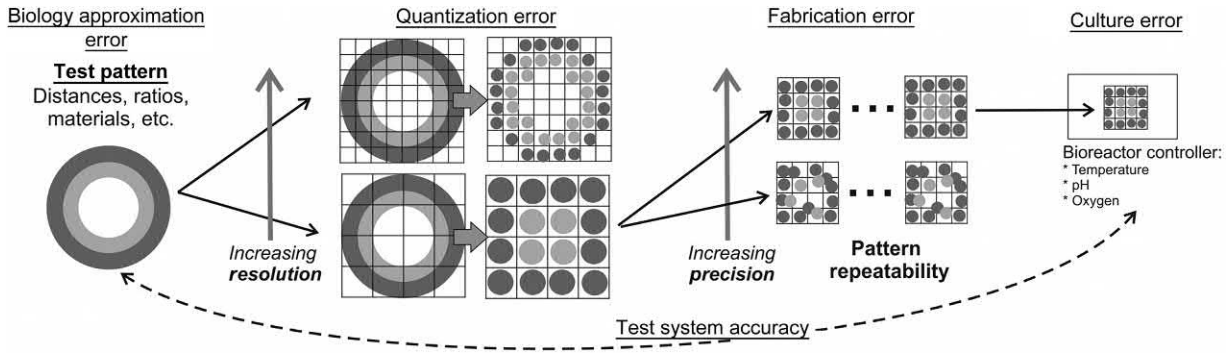

FIGURE 30.5 Sources of error in biofabrication of tissue test systems include the quantization error that arises from resolution of the fabrication instrumentation, the fabrication error that arises from the precision and repeatability of the fabrication instrumentation, and the culture error that arises from the ability of the culture controller to reproduce environmental conditions.

fabrication component in the order of a millimeter can only produce an approximate copy of the desired pattern. Thus the approximation of continuous biology with discrete fabrication components leads to quantization error.

The second fabrication error type is in the ability of the biofabrication technique to result in the placement of elemental components at a desired location. As illustrated in the third column of Fig. 30.5, high precision means that the system can closely replicate the discretized test pattern. The ability of a process to produce identical replicates of a test pattern is then defined as the pattern repeatability. This is defined as different from the machine precision because occurrences such as cell settling in storage reservoirs can cause evolution of the biofabrication instrumentation precision over time. Note that there is much debate about how much quantization error and fabrication error can be tolerated in building a useful tissue structure. One consideration is that tissue structures will self-assemble from an appropriate starting condition [129]. Specifically, placing cells "close enough" will allow them to move and assemble based on their natural behaviors. Any approach to tissue fabrication will require that nature take over for the final stage of tissue assembly, the idea of "close enough" is actively debated.

The ability of the tissue culture system to reproduce environmental conditions can greatly affect overall results, the culture error is shown in the last stage of Fig. 30.5. An important part of specifying the tissue test system is to define the environmental conditions, for example, dissolved oxygen level, that will be used to incubate the tissue. The capability of the culture system to produce these conditions must be considered; limitations occur in the ability of the instrumentation to measure a quantity of interest and the ability of the control system to maintain or modulate that quantity. As with all aspects of the tissue test system, the environment is a simplified model of the actual environment and as such must be designed at the start of a project to address a specific question of interest.

As a final consideration, the state or feature of interest must be measured in the tissue or medium during and/or after culture. A tissue test system can present the same imaging and measurement challenges as in vivo experiments—real-time measurements such as oxygen levels, discrete measurements such as magnetic resonance imaging, and endpoint analysis such as classical histology may all be used but have the same fundamental instrumentation limitations. However, there are several important advantages of a tissue test system over an in vivo model. First, there is the possibility that sensors can be embedded directly into the tissue design. For example, it is possible to embed a temperature sensor in the center of a tumor mass as it is fabricated. Second, the tissue is potentially more amenable to direct observation than in vivo, for example, a tumor model could be grown on a microscope stage and images automatically taken at regular intervals to observe spreading or growth. There is generally improved access to both inputs and outputs of the culture in a test system, agents can be applied without metabolism or complex pharmokinetics distorting the input. As an example, it is possible to apply an anti-angiogenic agent to a cell culture and know the local concentration without measurement because the pharmokinetics can be easily modeled as a mixing problem in a fixed volume. Similar arguments suggest that observation of outputs, such as metabolic byproducts, are more accessible in a test system. Perhaps the most important advantage that the tissue test system can have over an in vivo test is that, given low fabrication errors and culture errors, each copy of the test tissue should be nearly identical. This means that replicates can increase the power of observations and increase the ability of outside groups to repeat experiments and results. In general, a tissue test system should make the biology of interest more accessible for observation and manipulation.

In summary, tissue test systems are an evolving approach to modeling complex biological systems in vitro. Ethical, economic, and scientific drivers will ensure that this technology continues to evolve. However, the use and expectations of the test system must recognize that the tissue and culture environment is an approximate model that must be designed to address a specific question of interest. As researchers and clinicians begin to appreciate all of the subtleties of designing, fabricating, culturing, and assessing tissue test systems, these approximate models will help reveal the complexities of breast biology and disease processes. As tissue test systems, the basic units of useful biology, become standardized, they can be integrated to produce systems capable of answering ever more complex questions.

In silico breast cancer models

Mathematical modeling of breast cancer continues to advance rapidly, so much so that any summary is nearly obsolete at the time of writing. However, a brief overview of some approaches helps demonstrate the potential and challenges of mathematical and computer models. Generally speaking, there are two starting points for deriving a mathematical model, the first is the application of basic chemical and physical equations (first principles) to create a model and the second is the observation of physical behavior and use of mathematical tools to capture this behavior. A model may be proposed to work at a specific scale, such as at the molecular level, the cellular level, the organ level, the organism-wide level, or the population level. Initially, models were developed to

capture the behavior of an isolated system at a fixed scale. As modeling sophistication has increased, multiscale models [130] of connected subsystems have evolved. Often the models are referred to as "in silico" to indicate that the simulation is performed on a computer and to highlight their similarity in role to in vivo or in vitro models. As with other modeling approaches, the best model is the one that allows the user to address the question at hand.

As an example of a simple model, tumor angiogenesis is modeled as a set of two interconnected differential equations, one subsystem models tumor growth and the other subsystem models the carrying capacity of the vascular network [131]. This model appears to be a gross summary (as an ordinary differential equation) of the physical diffusion processes and the effects of the biological signals that stimulate or inhibit angiogenesis. However, analysis of the model has provided new insight into the scheduling of antiangiogenic treatments. The traditional dosing of such a therapy centers on applying a constant dose at regular time intervals; however, the model provides the structure to apply optimization and control techniques that suggest a more efficient use of the treatment agent [131,132]. There will always be questions about the resolution and accuracy of any mathematical model. For example, the angiogenesis model may not be sufficient to model clinical cancer treatment. By connecting a second subsystem model, the movement of bone marrow–derived endothelial progenitor cells to the tumor site and their effect on tumor growth can be used as a starting point to model vasculogenesis [133]. Such a model can clarify further the possible treatment strategies, including chemotherapy and anti-angiogenic therapies, aimed at suppressing vascularization, which may be incorporated in a tissue-engineered implant.

Concluding remarks

Tissue engineering may provide a means of both assessing and building reconstructive tissue implants for a woman undergoing lumpectomy or mastectomy. The development of vascularization and the long-term retention of tissue volume are keys to viable breast reconstruction options. Benchtop tissue test systems will be critically important in addressing these two major issues, by facilitating markedly improved understanding of the normal and diseased states and, accordingly, assessing and developing advanced reconstructive options.

Acknowledgement

We are grateful to Beau Inskeep, whose previous insights and coauthorship (Chapter 36, Principles of tissue engineering, 4th ed.) provided a foundation for this updated chapter.

Origin of cardiac stem/progenitor cells

Adult cardiac stem/progenitor cells are thought to be derived from the cells that form the heart and related structures during development. The heart is derived from four distinct cardiac precursor cell lineages, the first and second heart fields (FHF and SHF, respectively), the proepicardial organ (PEO), and the cardiac neural crest (CNC). Each of these cardiac precursor cell lineages forms at different stages during embryogenesis. Initially, a continuum of epithelial-to-mesenchymal transitions (EMTs) in the epiblast lead to the gastrulation of the FHF, SHF, and PEO cardiac precursors as parts of the mesodermal germ layer [1,2]. The CNC will arise later, at the stage of neurulation, in response to transient EMT at the junction of the neural plate and nonneural ectoderm.

Upon gastrulation the FHF precursors migrate cranially and coalesce into a crescent-like shape—the cardiac crescent—which will morph into the linear heart tube. These cells will proliferate and differentiate into the majority of the left ventricular free wall, as well as regions of the interventricular septum (IVS) and atrial myocytes and vessels. The SHF, added medially to the cardiac crescent, is patterned into an anterior and posterior segment. The anterior SHF gives rise to the right ventricle, portions of the IVS, and part of the outflow tract (OFT); while the posterior SHF produces the remaining parts of the atria, parts of the OFT and is also thought to contain precursors of cardiac conduction system myocytes [3−6]. The PEO, a cauliflower-like structure that develops at the inflow region of the looping heart tube [7−9], produces the epicardium, myofibroblasts and contributes to the development of the coronary vasculature [10−13]. The CNC contributes to cardiac and aorticopulmonary septation, valvulogenesis, and the autonomic nerves [14].

Each of these four lineages is specified through the induction of specific genes and signaling pathways during the development, a process that is influenced by the local concentration of growth factors and other morphogens (see Refs. [15,16]). Whether any of these embryonic cardiac precursor cell programs is transmitted into the postnatal life and persist as resident adult cardiac stem/progenitor cells, remains unclear.

The FHF and SHF lineages are specified before gastrulation, with the FHF and SHF derived from an early and late wave of cells, respectively, expressing the mesoderm posterior 1 (*Mesp1*) gene. A crucial event in cardiogenesis is the response of these cells to the morphogen wingless-type MMTV integration site (Wnt) family member proteins. Canonical Wnt (e.g., Wnt3a) signaling activates ß-catenin, a protein that has myriad effects, both as a transcription factor and extranuclear. While Wnt signaling early in development induces the mesoderm, later exposure to Wnt inhibits cardiogenesis posterior to the cardiac crescent while promoting cardiomyocyte differentiation of FHF and SHF cells. These effects are mediated, in part via simultaneous exposure of these cells to other factors/morphogens such as bone morphogenetic protein (BMP)-2 and -4, fibroblast growth factors (FGFs) and others (see Ref. [15] for review).

Following differentiation, cardiomyocytes proliferate extensively, a process controlled, at least in large part, by the Hippo/Yes-associated protein (Yap) pathway. Hippo/Yap helps regulate the growth of many organs during the development. Overexpressing a constitutively active YAP in cardiomyocytes stimulated proliferation [17,18]. Yap

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00032-0

appears to interact directly with ß-catenin to control cardiomyocyte proliferation and heart size [19].

The FHF and SHF have common and distinct gene expression profiles. Both progenitor populations express transcription factors crucial for cardiomyocyte differentiation: the homeodomain transcription factor NK2 transcription related, locus 5 (Nkx2-5), and GATA binding protein 4 (Gata4). However, FHF cells express T-box transcription factor 5 (*Tbx5*) and the basic helix-loop-helix transcription factor *Hand1*, whereas SHF progenitors express *Hand2*, Islet1 (*Isl1*; which may also be expressed in the FHF), forkhead box h1 (*Foxh1*), FGF 10 (*Fgf10*), and *Mef2c* [3,20,21].

The PEO is derived from an early wave of $Mesp1^+$ progenitors, which are thought to be distinct from the FHF/SHF-forming $Mesp1^+$ cardioblasts [22]. These progenitors ultimately give rise to the epicardium, a layer of cells that delineates the outer layer of the primordial heart and contributes to the development of the coronary vasculature and myofibroblasts, although not cardiomyocytes. However, the epicardium does promote cardiomyocyte proliferation during development via its secretion of growth factors such as insulin-like growth factor 2 [23], FGF, and (perhaps) Follistatin-like 1 [24] (Fig. 31.1).

Early during heart development, proepicardial cells undergo EMT and attach to the myocardial surface, where they proliferate and migrate to form a continuous cell layer. In humans the atrial epicardium is a monolayer as is the entire epicardium in other organisms [26]. The migrating epicardial derived progenitor cells (EDPC) differentiate into perivascular and interstitial fibroblasts. Murine EDPCs can also differentiate into vascular smooth muscle cells, pericytes, and, as mentioned previously, mesenchymal stem cell (MSC)-like cells (CMSCLCs). However, their ability to differentiate into cardiomyocytes appears to be very limited; and despite initial reports, EDPCs are likely not a source of endothelial cells (ECs). Zebrafish and mouse models illustrate that perturbing the differentiation of EDPCs produces abnormalities in cardiac structure [27].

EDPCs are clearly not a homogenous population. The cells express one or more of a number of transcription factors, including Sema3d, Scx, Tbx18, Tcf21, Raldh2, and Wt1, which can affect the differentiation potential of EDPCs (see Ref. [28] for review). While characteristic, these markers are not exclusively seen in EDPCs. The epicardium of the healthy adult heart is normally quiescent but can be quickly activated following injury.

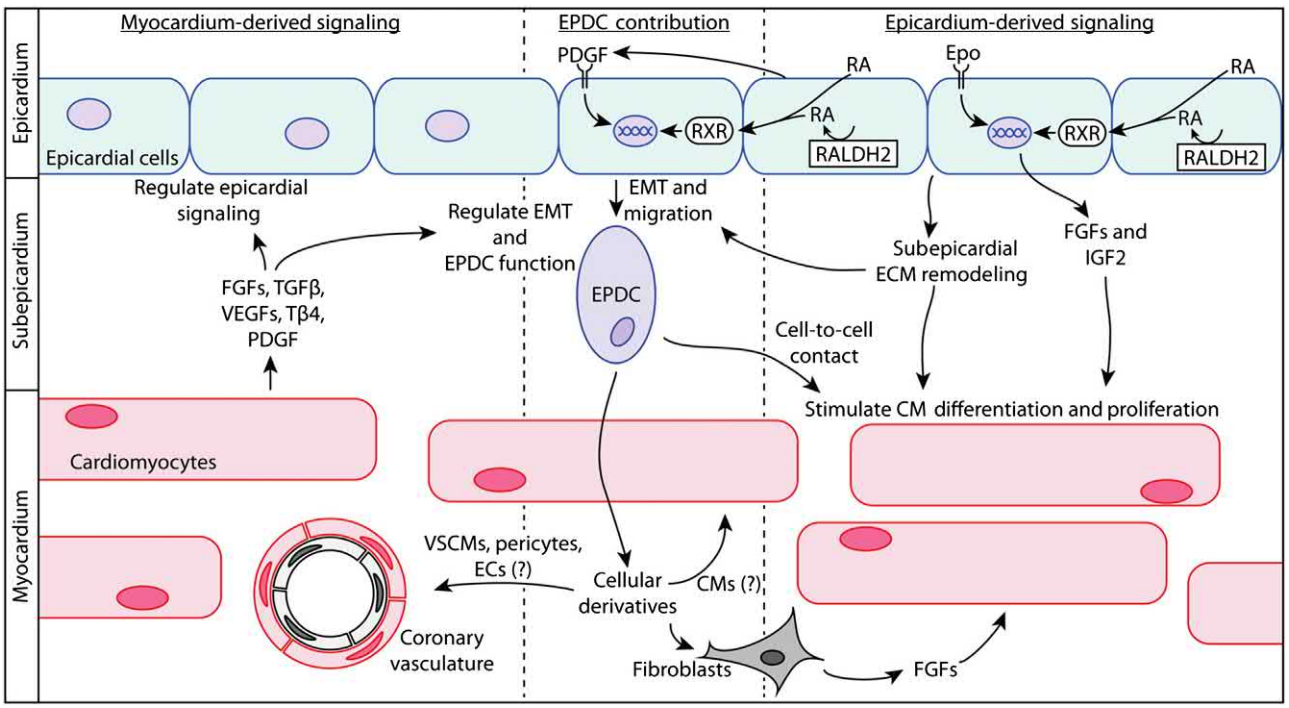

FIGURE 31.1 Epicardial cell contribution and reciprocal epicardial–myocardial signaling are critical for cardiac development and may similarly determine epicardial potential for cardiac regeneration. *CM*, Cardiomyocyte; *EC*, endothelial cell; *EMT*, epithelial-to-mesenchymal transition; *EPDC*, epicardium-derived cell; *Epo*, erythropoietin; *FGF*, fibroblast growth factor; *IGF2*, insulin-like growth factor 2; *PDGF*, platelet-derived growth factor; *RA*, retinoic acid; *RALDH2*, retinaldehyde dehydrogenase 2; *RXR*, retinoid X receptor; *T4*, thymosin 4; *TGF*, transforming growth factor; *VEGF*, vascular endothelial growth factor; *VSMCs*, vascular smooth muscle cells. *From Duffey OJ, Smart N. Approaches to augment vascularisation and regeneration of the adult heart via the reactivated epicardium. Glob Cardiol Sci Pract 2016;2016(4):e201628.*

EDPCs revert to a gene expression pattern reminiscent of fetal cardiac development. Following myocardial infarction (MI), *Wt1*, *Raldh2*, and *Tbx18* are upregulated in what appears to be a process controlled by the C/EBP family of transcription factors [29] and BRG1, an ATPase subunit of the SWI/SNF chromatin-remodeling complex [30]. This reactivation of developmental gene expression patterns is also induced by thymosin ß4, an actin sequestering protein that interacts with BRG1. However, the thymosin ß4 effects are seen only when it is administered prior to MI [30]. The upregulation of Wt1 likely promotes migration of the newly (re-)activated epicardium resulting in the rapid replacement and thickening of the epicardium lost at the injury site. During this repair process the activated epicardium also appears to stimulate cardiomyocyte proliferation (Fig. 31.1), reminiscent of its function during development (see Refs. [25,28,31] for review).

CNCs are $Mesp1^{-}$ cells and are derived from the neuroectoderm [32]. Neural crest cells are a crucial component of mammalian development and differentiate into a wide variety of structures ranging from the bones, cartilage, and muscles of the head and neck, to melanocytes and parasympathetic ganglia. In the heart the CNC contributes to cardiac and aorticopulmonary septation, valves, and the autonomic nervous system [14]. Approximately 10% of cardiac myocytes in mice and fish appear to be derived from the CNC [16,33–35]. Hatzistergos et al. demonstrated that CNCs expressing c-kit [CD117, the receptor for stem cell factor (SCF) [36]], become cardiomyocytes in the atria, ventricles, and IVS as well as pericardial, endocardial, and epicardial cells [16]. Adult cardiac progenitors may be the descendants of these CNC. The number of different stem/progenitor cell populations that reside in the adult heart, their role in maintaining homeostasis in the healthy heart, the extent of their participation in repairing the damaged heart, their ability to differentiate into cardiomyocytes, EC, and/or vascular smooth muscle is controversial and is being actively studied.

Modeling cardiac development with pluripotent stem cells

The ability to model cardiogenesis using pluripotent stem cells (PSCs), that is, embryonic stem cells (ESCs) and induced PSCs (iPSCs), has greatly expanded our understanding of the origin and differentiation capabilities of cardiac progenitors. ESCs are pluripotent cells derived from the inner cell mass of mammalian late blastocyst embryos. iPSCs are adult somatic cells that have been reprogrammed into pluripotent cells through the introduction of a combination of specific factors [37,38]. PSCs can be differentiated into cardiomyocytes by following well-established protocols involving the transient inhibition and subsequent stimulation of Wnt/ß-catenin signaling [39,40].

Human (h) ESCs (hESC) and iPSCs that express the signal-regulatory protein α produced a population of cardiac precursors and cardiomyocytes that were virtually all cardiac troponin T + and could contract. Other cell surface proteins, such as PECAM, THY1, PDGFRß, and ITGA1, identified nonmyocyte cells [41]. Wu et al. [42], Christoforou et al. [43], and Hatzistergos et al. [16] showed that a fraction of mouse PSC-derived $Nkx2\text{-}5^{+}$ cardiomyogenic cells express c-kit on the cell surface.

Another advantage of using PSCs is their ability to differentiate into cardiomyocytes with atrial or ventricular characteristics. For example, Lee et al. showed that ventricular and atrial cardiomyocytes are derived from different mesoderm populations. Ventricular cardiomyocyte progenitors express Glycophorin A (CD235a), whereas atrial cardiomyocyte progenitors express retinaldehyde dehydrogenase 2 (RALDH2) [44]. This study as well as a more recent study by Lemme et al. [45] demonstrated that retinoic acid is a critical factor for specifying human atrial cardiomyocytes.

Hatzistergos et al. used a murine PSCs model of CNC development to demonstrate that the differentiation of $c\text{-}kit^{+}$ cardiac progenitors into cardiomyocytes is regulated by BMP. They observed that in the presence of BMP, few cardiomyocytes were produced, but exposing the cells to a BMP antagonist (e.g., dorsomorphin) promoted the differentiation of these neural crest cells into beating cardiomyocytes [16].

Exposure of hPSCs to BMP4 from early stages of cell culture results in cells that express *WT1* with or without expression of *Tbx18*, both epicardial markers [10]. Treatment with the BMP antagonist, Noggin, abrogated the differentiation into epicardial cells. In addition to BMP4, epicardial cell differentiation also requires Wnt signaling. Therefore formation of epicardial cells requires signals opposite to those required for cardiomyocyte formation [10]. Furthermore, these epicardial cells undergo EMT following exposure to transforming growth factor (TGF)-ß and basic FGF (bFGF) [10] (Fig. 31.2). These results suggest that the local environment into which progenitor cells migrate or reside during development is a key factor regulating their differentiation capacity. Studies in hPSCs also demonstrate that stage-specific activation of tumor suppressors (negative cell cycle regulators) promotes the cardiomyocyte development [46].

Zhang et al. recently used a dual reporter system to isolate and examine hiPSCs that differentiated into four lineages; FHF, SHF, epicardium, and endothelium based on positive or negative expression of *Tbx5* and *Nkx2-5*. Using this approach, they identified cells with characteristics of ventricular or atrial myocytes, the sinoatrial node

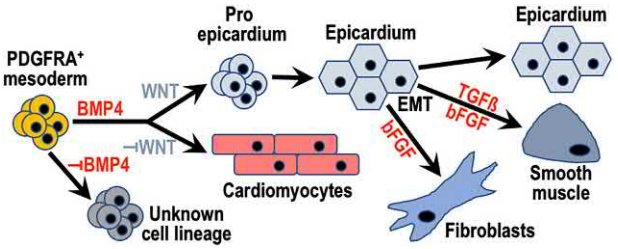

FIGURE 31.2 Model highlighting the specification of PDGFRA + mesoderm to the cardiomyocyte and proepicardial lineages by BMP4 and canonical Wnt signaling. When passaged in the absence of factors, the proepicardial cells form epithelial sheets resembling the epicardium that can be identified through the aldefluor assay. In the presence of TGF-ß + bFGF or bFGF, the passaged cells undergo EMT and give rise to smooth muscle-like and fibroblast-like cells, respectively. *bFGF*, Basic fibroblast growth factors; *BMP*, bone morphogenetic protein; *EMT*, epithelial-to-mesenchymal transition; *TGF*, transforming growth factor. *Modified from Witty AD, et al. Generation of the epicardial lineage from human pluripotent stem cells. Nat Biotechnol 2014;32 (10):1026–35.*

(SAN), or endothelium. They then assessed each lineage for drug responsiveness and concluded that this methodology has potential clinical value [47]. Other studies using hPSCs have modeled the formation of the SAN [48] and cardiac valves [49].

Analyzing the transcriptome [50] and chromatin structure/accessibility of human PSC subpopulations [51] has identified important regulatory pathways associated with cardiac progenitor differentiation. Techniques, such as CRISPR/Cas9 and novel inhibitors/stimulators of signaling pathways, have increased our ability to manipulate pluripotent cells and will expand our understanding of the development, differentiation, and therapeutic potential of cardiac progenitors in a manner not previously possible.

In vivo fate mapping of cardiac progenitors

Identifying the existence, progeny, and differentiation ability of cardiac progenitors is possible in vivo using genetic fate-mapping techniques. In this approach, cells are conditionally labeled, often beginning at specific stages of gestation, and the pre- and/or postnatal expression of the marker is then assessed. Most of these studies use mice with two genetic manipulations, a label that is normally inactive in all cells and a transgene comprised of a recombinase (e.g., Cre) controlled by a specific (truncated) promoter. When the promoter is activated, expression of the recombinase occurs in a cell- or tissue-specific manner. The recombinase acts on the DNA to activate expression of the label only in those cells. All cells derived from the labeled cells are similarly labeled. Expression of the recombinase can be further controlled temporally (e.g., by tamoxifen administration) so that the label can be activated in the tissue beginning at a specific stage of gestation or postnatal life. Genetic fate mapping can also be done in zebrafish (e.g., Ref. [52]). These fate-mapping approaches can produce ectopic expression of the label resulting in conflicting/confusing results; but improvements to the system are ongoing (e.g., Ref. [53]).

In vivo fate mapping has been used to assess the source(s) and differentiation ability of c-kit$^+$ cardiac cells. The role of c-kit$^+$ cells in cardiomyocyte development and regeneration is controversial [54]. These cells were originally thought to comprise multipotent cardiogenic mesoderm-derived postnatal myocardial progenitors that persist in the postnatal heart [42,43,55]. However, lineage-tracing studies of cardiac c-kit$^+$ cells using an intersectional genetic fate-mapping approach showed that expression of c-kit is rarely activated in the myocardial lineage and marks CNC rather than mesoderm-derived myocardial cells [56]. Furthermore, genetic fate-mapping studies in mice indicate that expression of c-kit in the cardiac mesoderm is largely associated with coronary endothelium rather than myocardium-producing cells [56] (Fig. 31.3).

A similar intersectional genetic fate-mapping approach was recently devised by Li et al. to address the role of resident cardiac progenitor/stem cells in postnatal cardiomyogenesis [59]. This study examined the ability of nonmyocytes (including putative cardiac progenitors) to convert into cardiomyocytes in embryonic and in healthy and injured adult mouse hearts. Using a newer gene-mapping technique [53], they found evidence for nonmyocyte to myocyte conversion in embryonic hearts but not in adult hearts. Their results did not provide evidence for the existence of cardiac stem cells (CSCs) in the adult during homeostasis or after injury [59]. However, these mapping studies provide only indirect measures of activity/lineage tracing and likely do not measure cells that are inactive or silenced.

An alternative approach to understanding the ontogeny and progression of cardiac progenitors is through single cell RNA sequencing. Cells are isolated at specific stages of cardiac development and a cell-specific transcriptome established that enables the identification of distinct populations of cardiac progenitors. For example, Lescroart et al. identified subsets of Mesp1$^+$ cardiac progenitors that become committed to different cell lineages during the heart development. This approach represents a first step toward characterizing the molecular signature associated with this stage of lineage restriction [60].

Neonatal cardiac repair

Unlike the adult heart, the neonatal mammalian heart is capable of completing regeneration if the injury occurs in the first few postnatal days (P). Partial apical resection or

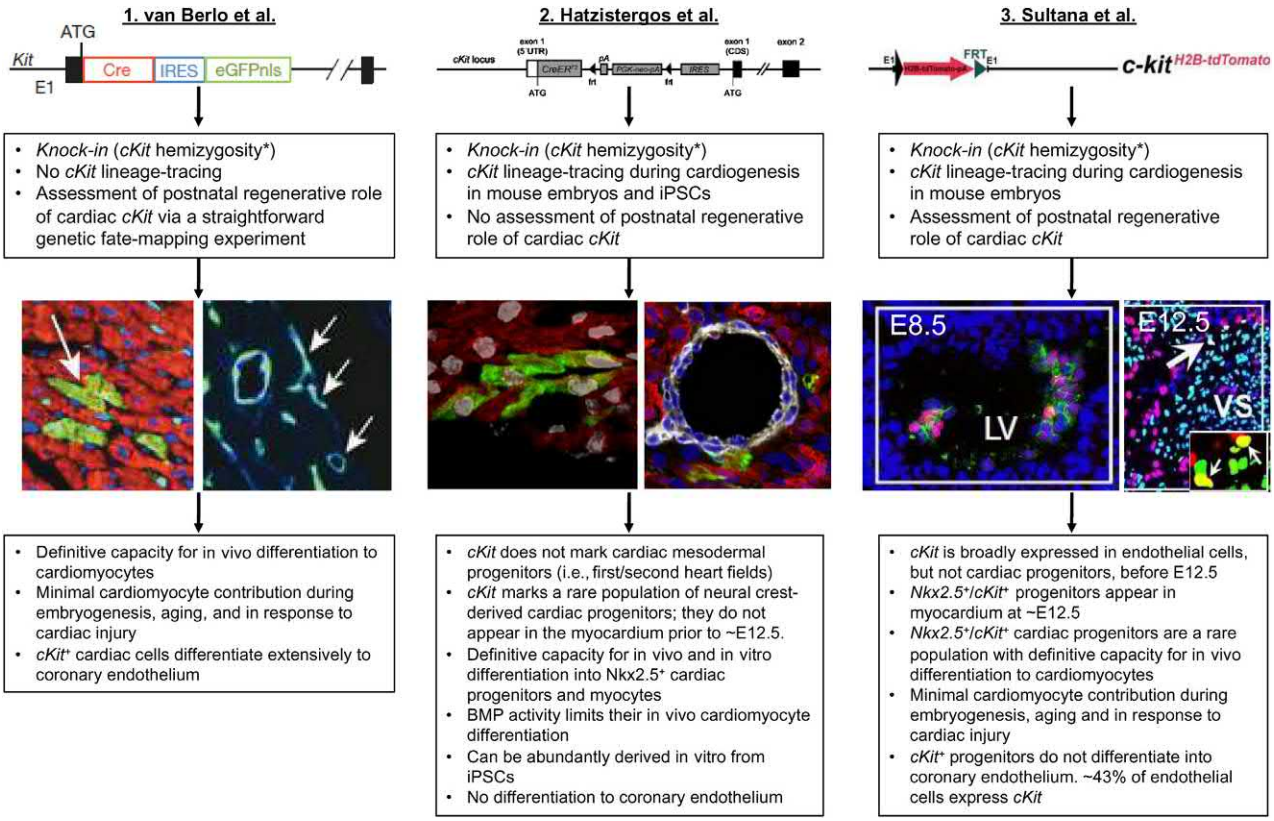

FIGURE 31.3 Differing opinions on the extent of myocardial contribution of c-kit$^+$ cells. c-kit$^+$/Nkx2.5$^-$ vasculogenic cells and c-kit$^+$/Nkx2.5$^+$ cardiomyogenic lineage are derived from cardiac neural crest cells. These three genetic lineage fate-mapping studies demonstrate that cardiac c-kit$^+$ cells form cardiomyocytes in the murine heart at a low level but differ on endothelial differentiation. van Berlo et al. [57] showed that c-kit$^+$ cardiac cells exhibit extensive endothelial cell differentiation. Hatzistergos et al. [36] and Sultana et al [58] disagree, although the latter shows that ≈43% of coronary endothelial cells are c-kit$^+$ (possibly at low levels). Hatzistergos et al. [36] and Sultana et al. [58] both establish that c-kit$^+$/Nkx2.5$^+$ cardiomyogenic progenitors are only present after embryonic day (E)12.5. *Note*: All three studies used knockin mouse models in which the gene-targeted c-kit allele was nonfunctional, an approach that may produce abnormalities in c-kit$^+$ cardiac cells in these mice (e.g., proliferation, migration, and differentiation). *BMP*, Bone morphogenetic protein; *LV*, left ventricle; *VS*, ventricular septum. *Reproduced with permission from Hatzistergos KE, Hare JM. Murine models demonstrate distinct vasculogenic and cardiomyogenic cKit + lineages in the Heart. Circ Res 2016;118(3):382–7.*

ischemic MI performed on neonatal mice at P1–2 was completely healed within 21 days; however, incomplete regeneration occurs following cryoinjury or if the resection is too large (see Ref. [61] for review). The capacity for complete cardiac repair rapidly declines after the first two days of life and by P7, regenerative capabilities are similar to the adult, leading to incomplete recovery and scar formation [61,62]. Proliferation of resident cardiomyocytes is the underlying mechanism of repair [62] and is promoted by activation of the Hippo/YAP pathway [18,63] but inhibited by the microRNA (miR)-15 family [64]. Other factors appear crucial for neonatal regeneration, including an intact cardiac parasympathetic [65] and sympathetic [66] nervous system (Fig. 31.4).

A recent study demonstrated that MI during P1–2 induces the formation of collateral arteries, allowing for complete cardiac repair [68]. This novel mechanism, termed "artery reassembly," involves arterial ECs migrating to the injury site along capillaries and reassembling into collateral arteries. The arterial ECs express CXCR4, and following injury, appear to migrate in response to capillary-produced CXCL12 (SCF-1), the ligand of CXCR4. Deletion of CXCL12 or CXCR4 in mice significantly reduced collateral artery formation and regeneration of the neonatal heart [68].

Similar to neonatal mice, P1–2 neonatal pigs can also recover from MI via proliferation of existing cardiomyocytes. The neonatal pigs exhibit minimal fibrosis and normal cardiomyocyte function and number. However, this ability is lost by 3 days after birth [69,70]. Pig and human hearts are very similar in structure and function, suggesting that human neonatal hearts can similarly recover. Neonatal pig hearts highly expressed genes involved in cytokinesis and, like neonatal mice, it appears that this cardiomyocyte proliferation/regenerative program involves an ongoing process at this early stage and is not induced in response to the injury [69,70].

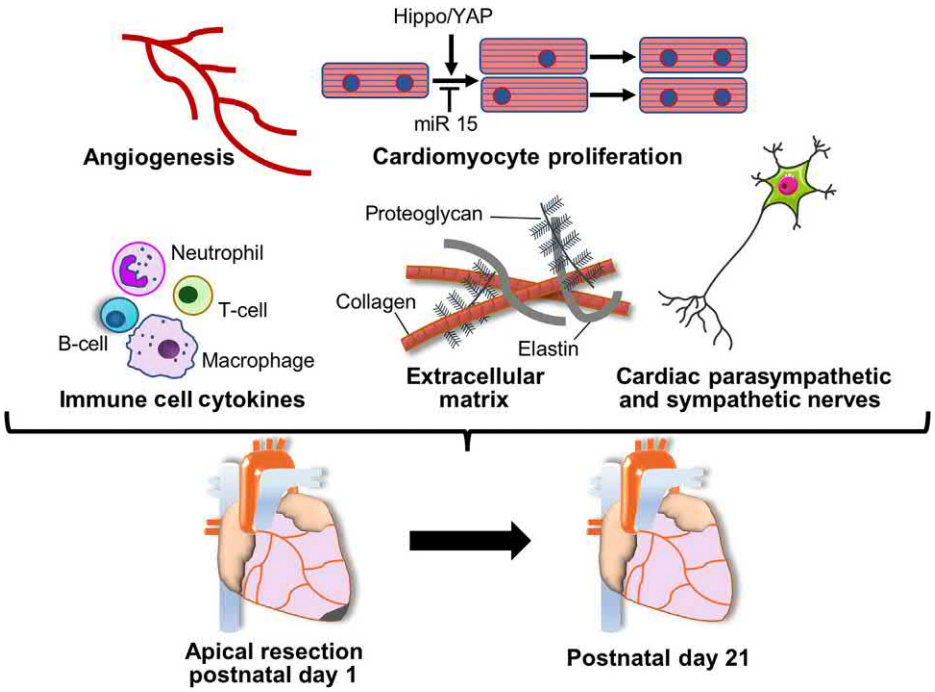

FIGURE 31.4 Factors that promote cardiac regeneration in the neonatal heart. *Adapted from Mahmoud AI, Porrello ER. Upsizing neonatal heart regeneration. Circulation 2018;138 (24):2817–9 [67].*

Reprogramming cardiac fibroblasts

Cardiac fibroblasts are the most abundant cell type in the heart and the possibility of converting them into cardiomyocytes to replace those lost following injury is a very appealing idea. While they are not progenitor cells, per se, cardiac fibroblasts do differentiate into myofibroblasts in response to a variety of stressors (Fig. 31.5) a process that is associated with cardiac injury and progression toward heart failure (reviewed in Ref. [71]). Cardiac fibroblasts can also adopt an osteoblast cell–like phenotype following injury and directly contribute to myocardial calcification. When these fibroblasts are transplanted from an injured to a healthy heart, they promote calcification in the healthy heart. (Fig. 31.5) [72].

Ieda et al. first demonstrated direct reprogramming of cardiac and tail-tip fibroblasts into cardiomyocyte-like cells (induced cardiomyocytes; iCMs) in vitro using viral-mediated overexpression of the cardiomyocyte transcription factors: *Gata4, Mef2c*, and *Tbx5* (a combination they called GMT) [73]. The GMT-transduced cells were injected into NOD/SCID mouse hearts 24 hours later and within 2 weeks, some of these cells expressed α-actinin and exhibited sarcomeric structures [73]. GMT reprograming could occur in vivo and reduced scar size post-MI, an effect that was improved when combined with thymosin ß4 administration [74]. The addition of *Hand2* to GMT (GHMT) or GMT plus *Mesp1* and *Myocd* (GMTMM) more efficiently reprogramed cells (see Refs. [75,76] for review). While there are reports of differentiating human fibroblasts into iCMs in vivo (see Refs. [75,77] for review), this approach is still far from being used clinically.

Cardiac resident mesenchymal stem cells

MSCs are found in all tissues and are identified by their expression of CD105/CD90 and lack of CD45, among other characteristic surface markers, and by their ability to differentiate into osteogenic, chondrogenic, and adipogenic lineages ex vivo [78]. Cardiac resident MSCs (CMSCs)/CMSCLCs are found in adult human [79], mouse [80,81], and swine [81] hearts in proximity to other cardiac progenitors. Monsanto et al. isolated a biopsy from a human heart failure patient, digested it into a single cell suspension and grew the cells overnight [79]. Three cell populations were isolated based on the presence or absence of c-kit. The c-kit$^+$ population was expanded in either cardiac progenitor or endothelial progenitor media resulting in c-kit$^+$ cells that were either CD133 negative or positive, respectively. From the c-kit$^-$ population, CMSCs were isolated based on expression of CD90 and CD105. CMSCs, unlike bone marrow–derived MSCs (BMMSCs), also express cardiac lineage markers such as smooth muscle actin and perhaps GATA-4.

While CMSCLCs may have therapeutic potential, their isolation requires a cardiac biopsy, thereby limiting their potential use. In an attempt to avoid this complication, human CMSCLCs were recently isolated from discarded surgical tissues obtained following coronary artery bypass surgery, primarily from the right atrial appendage [82].

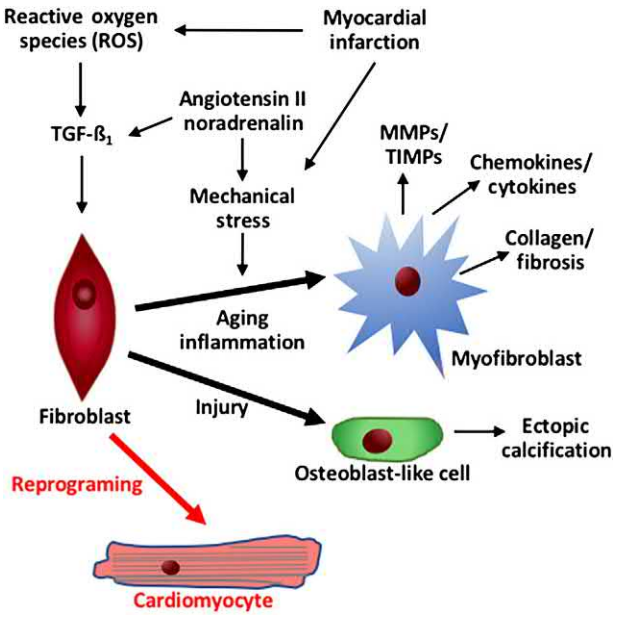

FIGURE 31.5 Fibroblasts can transform into myofibroblasts [71] or osteoblast-like cells in response to a variety of stressors. Myofibroblasts participate in scar formation and osteoblast-like cells produce ectopic calcification of the myocardium [72]. Cardiac fibroblasts can be reprogrammed into cardiomyocytes. *Adapted from Tarbit E, et al. Biomarkers for the identification of cardiac fibroblast and myofibroblast cells. Heart Fail Rev 2019;24(1):1–15.*

These cells possessed some consensus MSC characteristics $CD105^+/CD166^+/CD44^+/MHC\ I^+/MHC\ II^-$ [78]. However, they only rarely differentiated into osteogenic, chondrogenic, or adipogenic lineages in vitro, a characteristic of MSCs [78]. Rather, most of the CMSCLCs exhibited cardiomyocyte characteristics following ex vivo culture [82]. The therapeutic efficacy of CMSCLCs was not assessed.

Cardiomyocytes and cardiac repair/ regeneration

Bergmann et al. demonstrated that the number of left ventricular cardiomyocyte nuclei remains constant throughout life, even though the size of the heart increases significantly [83]. What is different is the density of these nuclei, which is ~15-fold greater in neonates than later in life. The increased size of the heart and the decrease in cardiomyocyte nuclear density are due to the proliferation of noncardiomyocytes: endothelial and mesenchymal (fibroblasts, pericytes, and smooth muscle) cells [83] and hypertrophy of cardiomyocytes (see Ref. [84], for example). Cardiomyocyte renewal slows down with age and only ~<50% of cardiomyocytes are renewed during a person's lifetime [83]. A consensus was established stating that cardiomyocytes normally undergo mitosis, albeit at a very slow rate, but this rate may increase following injury [85]. The key to cardiac repair is the replacement of lost cardiomyocytes following injury, regardless from where they originate. As previously discussed, the differentiation of cardiac resident progenitors into cardiomyocytes is an infrequent event. Therefore strategies designed to promote endogenous cardiomyocyte renewal appear to be the best approach to promoting cardiac repair. One such approach is cell-based therapy.

Cell-based therapy

Initial studies hypothesized that following injection of stem/progenitor cells post-MI either intramyocardially, or into the coronary or system circulation, the cells would engraft and become cardiac progenitor–like cells and/or differentiate to replace cells (cardiomyocytes, vascular structures) lost to injury. Large animal studies demonstrate that cells that engrafted did exhibit differentiation into cardiomyocytes, endothelium, and vascular smooth muscle cells; however, improvements in cardiac structure and function were incomplete and the amount of engraftment was very low and insufficient to account for the improvements [86,87]. The limited engraftment of transplanted cells led to the hypothesis that the injected cells, whether or not they engraft, secrete factors (secretome) that activate resident cardiac progenitors and cardiomyocytes [88].

The paracrine hypothesis was first proposed by Gnecchi et al. in 2004. They showed that serum-free conditioned media from Akt-overexpressing MSCs had antiapoptotic effects on rat neonatal cardiomyocytes in vitro and reduced scar size within 72 hours of being injected into the myocardium post-MI in vivo [89,90]. This local release of trophic factors includes a wide variety of bioactive compounds such as growth factors and chemo-attractant molecules, as well as exosomes and extracellular vesicles (EVs). Exosomes and EVs are membrane bound micro- or macrovesicles, respectively, which contain mRNA, noncoding RNA (microRNA, etc.), peptides, and other molecules. These secreted molecules are thought to stimulate resident cardiac progenitor cell (CPC) activation, cardiomyocyte proliferation (see Ref. [91] for review), and angiogenesis [92–96], thereby reducing cardiac injury (see Ref. [97]). Exosomes derived from human fetal cardiomyocyte progenitors or adult hBMMSCs were equally effective at stimulating angiogenesis in vivo [98]. CPCs, cardiac fibroblasts, and perhaps even cardiomyocytes release exosomes and EVs that can have beneficial effects on the heart (see Ref. [91] for review).

Recent animal studies have suggested that intact cells or their isolated exosomes produce similar beneficial cardiovascular effects [99] but only when exosomes were injected directly into the myocardium. No improvement

was seen when exosomes were administered via the coronary arteries [100]. Therefore although exosomes represent a cell-free treatment that appears to be therapeutic for MI, additional studies are needed to establish their extent, duration, and the most effective route of administration.

Interaction between cardiac resident and injected cells can also occur through gap junctions [101,102] and "tunneling nanotubes" (TNTs), a process known as heterocellular coupling. Gap junctions are gated channels that allow for the transfer of small molecules (<1000 Da) between cells. This communication is important for coordinating activities between neighboring cells during development and in adult tissues [103,104]. Cells of the myocardium normally communicate with each other through gap junctions as do MSCs that engraft within the myocardium [86]. TNTs are 50–200 nm tubes through which adjacent cells can exchange cell components, including mitochondria and other organelles. The transfer of mitochondria appears to be important for rescuing/repairing injured cells by restoring cellular bioenergetics and oxidative phosphorylation [105,106].

Cardiac progenitor/stem cell therapy

Oskouei et al. directly compared the therapeutic efficacy of human embryonic c-kit$^+$ CSCs and hBMMSCs for cardiac repair in an AMI model in immunodeficient mice. The hCSCs produced greater improvement in hemodynamic parameters and were able to reduce scar size similarly to 30-fold more adult hBMMSCs [107]. Genetically, modifying c-kit$^+$ CSCs to overexpress Pim1 kinase increased their retention within the myocardium and improved their therapeutic efficacy in both a mouse [108] and swine [109] model of acute MI. CSC-derived exosomes recapitulate the major therapeutic effects of CSC administration in both acute and chronic mouse MI models [110]. In a pig chronic MI model, intracoronary delivery of c-kit$^+$ CSCs promoted mitosis in cardiomyocytes. Some of the injected (GFP$^+$) CSCs engrafted and differentiated into cardiomyocytes, vascular smooth muscle, and ECs [111].

While administration of CSCs does promote cardiac repair post-MI, pretreating CSCs with BMMSC-derived exosomes produced greater cardiomyocyte proliferation, migration, and angiogenic potency in vitro [112]. When introduced into the myocardium in a rat model of acute MI, these pretreated CSCs exhibited greater engraftment and promoted greater capillary density, reduced cardiac fibrosis, and improved cardiac outcome than unpretreated cells [112].

ALCADIA (NCT00981006), was an open label, nonrandomized, phase I clinical trial in patients with ischemic cardiomyopathy who underwent coronary artery bypass surgery. This trial addressed the safety and feasibility of intramyocardial injection of autologous c-kit + CSCs in combination with bFGF. Preliminary results showed improvement in left ventricular ejection fraction (LVEF), scar size, and maximal aerobic exercise capacity [113]; however, final results have not been reported.

Combination stem cell therapy

To improve therapeutic efficacy, a novel approach is to combine cells. Small and large animal studies have combined cardiac and extracardiac cells. Quijada et al. created cardiac-chimeras (CCs), a fusion between murine BMMSCs and c-kit$^+$ CPCs, and tested the efficacy of CCs, compared to the combination of BMMSC/CPC or each cell type alone, in a mouse model of AMI. CC-treated animals showed enhanced wall thickness 4 weeks postinjection. At 6 weeks, cardiac function was improved in the CC group, whereas it required 18 weeks for the BMMSC/CPC group. Infarct size reduction and greater persistent engraftment were noted in the CC group compared to BMMSC/CPC [114].

Intramyocardial injection of a combination of BMMSCs and CSCs [cell combination therapy (CCT)] improved cardiac structure and function in swine models of MI. Administration of hBMMSCs and hCPCs (200:1) to immunosuppressed swine 14-days post-MI produced a twofold reduction in scar size, sevenfold enhanced engraftment, and improved LV compliance and contractility 4 weeks later compared to each individual cell type, even though the individual cell types produced significant improvements compared to placebo-treated animals [115]. In a swine chronic MI model, autologous CCT administered 3 months post-MI improved LVEF, stroke volume, cardiac output, and diastolic strain compared to BMMSCs alone. Both cell-treated groups significantly improved scar size, wall motion, and viable tissue compared to placebo [116]. CCT treatment also increased myocardial proliferation compared to placebo (Fig. 31.6). A similar study using allogeneic BMMSCs and/or CSCs again showed that CCT produced greater improvements in cardiac structure and function [117] at least in part by increasing endogenous myocardial cell proliferation [116,117]. Building upon these preclinical large animal studies the ongoing CONCERT-HF (Combination of Mesenchymal and C-kit$^+$ Cardiac Stem Cells as Regenerative Therapy for Heart Failure, NCT02501811) trial, a phase II, placebo-controlled study, is designed to assess if transendocardial administration of autologous CCT with BMMSCs and c-kit$^+$ CPCs provides greater therapeutic efficacy than either cell type alone.

Pluripotent stem cells

Several mouse studies have demonstrated that ESCs can differentiate into functional cardiomyocytes within the host myocardium, improve cardiac function, and prevent

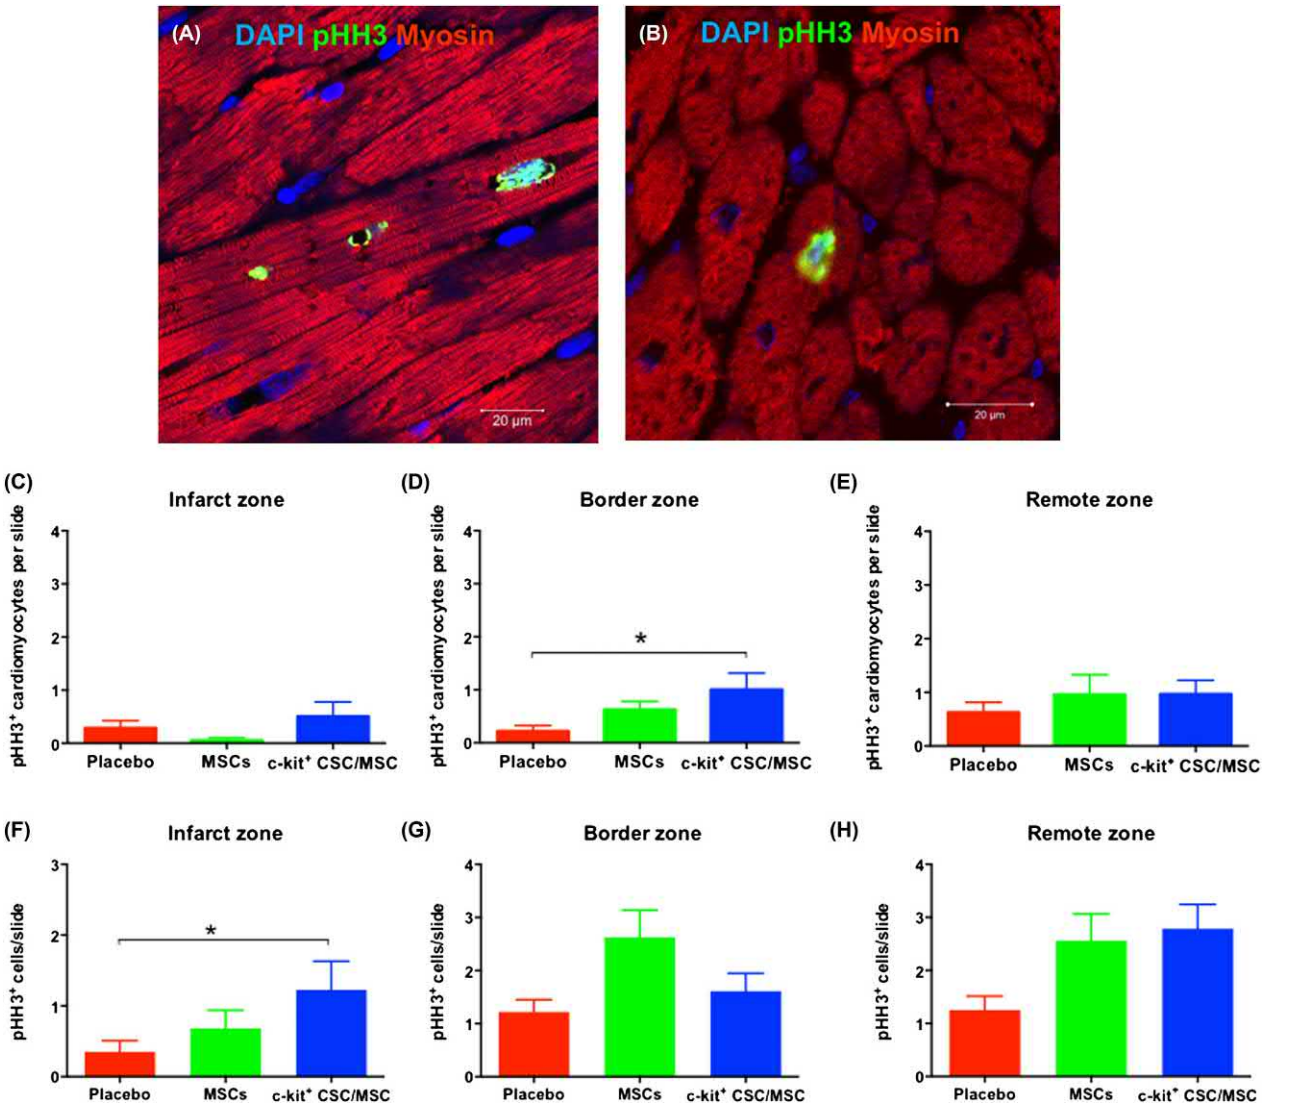

FIGURE 31.6 **Cell treatment–enhanced myocardial mitotic activity.** Pigs received either placebo, autolous MSCs, or autologous CCT. Confocal microscopy depicts increased mitotic activity of endogenous cardiomyocytes [phospho-histone H3–positive (pHH3) nuclei] in (A) border and (B) remote zones in cell-treated hearts 3 months poststem cell administration. Based on the average number of pHH3 mitotic cardiomyocytes per slide per group in the (C) infarct, (D) border, and (E) remote zones, combination cell therapy significantly increased mitotic activity in the border zone compared with placebo ($*P < 0.05$). As depicted, the average number of pHH3 mitotic cells within the myocardium per slide per group in the (F) infarct, (G) border, and (H) remote zones, was increased by CCT which produced significant increases in mitotic cells in the infarct zone compared with placebo. $*P < 0.05$. Red, placebo; green, MSCs; blue, CCT. *CCT*, Cell combination therapy; *DAPI*, 4′,6-diamidino-2-phenylindole; *MSC*, mesenchymal stem cell. *From Karantalis V, et al. Synergistic effects of combined cell therapy for chronic ischemic cardiomyopathy. J Am Coll Cardiol 2015;66 (18):1990–9.*

negative ventricular remodeling after transplantation into the infarcted myocardium [118–121]. However, the pluripotent nature of ESCs risks their developing into teratomas. To circumvent this possibility, more recent studies have focused on pluripotent-derived cells that are more committed toward cardiac lineages. ESC-derived cardiomyocytes (ESC-CMs) express specific cardiomyocyte transcription factors, including Nkx2-5, GATA4, and others [122] and exhibit spontaneous beating activity [123], but these cells remain immature. Similarly, iPSC-derived CMs (iPSC-CMs) are immature [124]. As discussed previously, PSC-derived CMs (PSC-CMs) differentiate into ventricular-, atrial-, and nodal-like cardiomyocytes, and each subtype can be characterized by unique electrophysiological properties [125]. These different types of cardiomyocytes can potentially be used as a therapeutic agent for specific types of cardiomyopathies. Another goal is to direct this differentiation into a more adult cardiac myocyte phenotype with respect to contractility, electrophysiologic performance, and appropriate response to pharmacologic stimulation.

ESC-CMs have demonstrated therapeutic efficacy. Administration of ESC-CMs into post-MI rats improved cardiac function [126] and attenuated the progression of heart failure [127], without the development of teratomas. Furthermore, a comparison of the ability of ESC-CMs, ESC-derived cardiovascular progenitors (ESC-CVPs), and bone marrow–derived mononuclear cells (BMMNCs) to improve cardiac function demonstrated many similarities but also indications that the ESC-derived cell types were similarly efficacious and were generally more therapeutic than the BMMNCs [128].

In nonhuman primate models of MI, hESC-CMs improved cardiac structure and function but produced arrhythmias [129,130]. Another nonhuman primate study demonstrated that ESC-CVP administration improves cardiac function despite an absence of long-term engraftment; a result that supports a paracrine mechanism [131]. Similarly, iPSC-CMs in a nonhuman primate study produced some positive- but also some adverse-effects, including arrhythmogenesis [132]. A direct comparison of hESC-CMs and iPSC-CMs in a nude rat MI model demonstrated that both cell types produced comparable cardioprotection. Furthermore, exosomes derived from these cells contained identical populations of microRNAs and long noncoding RNAs [133]. These studies illustrate the potential of PSC-CMs as a therapeutic agent for cardiomyopathies.

There are few human studies using PSCs. A case study demonstrates that ESC-derived CPCs embedded within a fibrin scaffold and implanted into a patient with severe heart failure improves cardiac function without arrhythmias, tumor formation, or immunosuppression-related adverse events [134]. The ESCORT (transplantation of hESC-derived progenitors in severe heart failure) in which ESC-derived cardiac progenitors were injected into HF patients ($n = 6$) showed safety and efficacy [135].

To date, hiPSC cells have not been tested clinically for heart-related diseases, although based on preclinical studies such studies have been proposed [136]. Transplantation of iPSC-CMs have demonstrated functional benefits in mouse, rat, and pig models of heart disease [137–139]. Furthermore, intramyocardial administration of allogeneic iPSC-CMs post-MI into immune-suppressed, nonhuman primates, resulted in engraftment of the iPSC-CMs and improved cardiac function [132]. However, there was evidence of posttransplant arrhythmias [132]. These results, while promising, require further study to replicate findings and develop countermeasures against malignant ventricular arrhythmias.

Future directions

There is considerable disagreement regarding the role of cardiac progenitor/stem cells in the adult heart. Do they differentiate into cardiomyocytes or support cardiomyocyte proliferation in the healthy and/or injured heart? Can they be manipulated to improve recovery from cardiac injury? PSC models of cardiac development have clarified the role of growth factors in progenitor cell differentiation during cardiac development as have fate-mapping studies in vivo. These approaches, along with newer techniques, including gene editing using CRISPR/Cas9 and in vivo reprogramming of resident cardiac progenitors, cardiomyocytes, and fibroblasts will not only provide answers to these questions but also have the potential for generating an effective therapeutic to reduce the effects of cardiac injury.

Introduction

In the developed world, cardiovascular disease is responsible for the loss of more human lives than all cancer combined. Due to the minimal intrinsic ability of adult heart to regenerate itself following injury [1], the myocardial infarction (MI) results in rapid death of hundreds of millions of cardiomyocytes (CMs), and vigorous inflammatory response. Over subsequent weeks to months, fibroblasts (FBs) and endothelial cells (ECs) form granulation tissue and a dense collagenous scar that reduces the contractile function of the heart and eventually leads to a pathological remodeling and, in many cases, heart failure. Adult CMs are terminally differentiated, thus it is not possible to expand them in vitro to sufficient numbers starting from small cardiac biopsies. Current clinical trials focus on cell replacement through application of bone marrow mesenchymal stem cells (MSCs), peripheral blood mononuclear cells, or resident cardiac cells. Most of these cell types have no intrinsic ability to give rise to a large number of CMs; instead they improve function through paracrine effects. In addition, cells can be applied alone or in combination with different types and forms of biomaterials (e.g., hydrogels and scaffolds). An appropriate combination of a biomaterial, cell type, delivery method, and requirements for tissue culture prior to implantation will depend on the specific type of heart disease and patient population. Here we provide design criteria for the generation of functional cardiac patches and discuss different biomaterials and cell types used during the tissue engineering process.

Clinical problem

Cardiovascular disease is the leading cause of death worldwide. In the United States, cardiovascular diseases account for approximately 30% of all deaths, with cardiovascular disease population constantly increasing [2,3]. In 2008 alone 86.2 million Americans were living with some form of cardiac disease, and this number is projected to grow to 40.5% of the American population by the year 2030 [4]. *Concomitantly*, the financial burden of disease is also projected to rise, from present estimates of $300 billion to $800 billion [4]. On a global scale, cardiovascular disease is responsible for 60% of deaths and will become increasingly important as global obesity and malnutrition continue to rise. Importantly, cardiovascular disease is responsible for 80% of noncommunicable diseases in low- and middle-income countries [5,6], with grave social and economic consequences.

One of the key limitations for the treatment of cardiovascular disease is the lack of regeneration after myocardial injury. The majority of existing therapies aim to mitigate the progression of heart failure, intervening on the cyclic progression of the neurohormonal cascade, but the options for improvement or regeneration of diseased tissue are limited. The most common pathogenesis is the ischemic heart disease, which occurs when a portion of the heart does not receive blood supply of oxygen. Coronary artery disease, or a narrowing of the lumen in the coronary arteries, most often by atherosclerotic change, limits the perfusion of certain sections of the heart. Limiting oxygen delivery past a certain threshold leads to angina, characterized by reversible discomfort or heaviness to the chest. Complete occlusion of an artery, or MI, is associated with a typical pathological progression. Depletion of Adenosine triphosphate (ATP) occurs within seconds, leading to irreversible cell damage by 20−40 minutes [6]. Coagulative necrosis begins ∼30 minutes after coronary occlusion, followed by robust inflammatory response that begins with the release of reactive oxygen species and neutrophil invasion ∼24 hours postinfarction and continues for the next 2−3 days, in parallel to the continued necrosis.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00033-2

Macrophages ultimately dominate the infarcted zone by 5−7 days postinfarction and are responsible for removing dead cells and creating granulation tissue. Weeks to months after infarction, collagen deposition dominates, and a fibrous scar is formed [6].

Heart failure, which results in the inability of the heart to adequately pump blood, ensues most commonly after ischemic injury but may also have other etiologies, including valvular disease, hypertension, or genetic cardiomyopathies [7]. An increase in cardiac work requirements leads to one of two patterns of dysfunction in the heart, one where pressure overload dominates, leading to concentric hypertrophy of CMs and a thickening of the myocardial wall, or a second one where volume overload dominates, leading to eccentric hypertrophy of CMs and a thinning of the myocardial wall [6]. In either case, increased fibrosis, abnormal gene expression, and insufficient vascular function lead to pump dysfunction and activation of the neurohormonal system, where the sympathetic nervous tone, renin secretion, and arginine vasopressin secretion all increase. Together, these cues lead to myocardial remodeling at the cellular level that contributes to the progression of heart failure, by mechanisms that are not well understood.

Presently, heart transplant and ventricular assist devices (VADs) can improve cardiac function, but the numbers of available donor hearts are limited, and the VAD is only a temporary solution. Therefore biological treatment strategies that can enhance cardiac function are especially attractive for countering the pathophysiological progression of heart failure. With the advent of induced pluripotent stem cells (iPSCs), there is the newfound promise for cardiac regeneration using patient-specific cells, since CMs were previously unattainable by any other means. Present approaches involve direct cell injection or the creation of a cardiac patch. Cell injections are attractive due to relative simplicity, though poor cell retention is a recurring obstacle [8,9]. A cardiac patch approach would be aimed at replacing or repairing the specific lesion created by MI, using a lab-grown piece of contractile cardiac tissue. Continuing challenges are vascularization and electromechanical integration of such a construct, and these are among the key areas of active research.

Engineering cardiac tissue: design principles and key components

The heart functions as a highly organized physiological pump. The CMs, comprising 80%−90% of the heart volume, are not only elongated and hypertrophied but also aligned and electrically coupled to surrounding CMs. CMs are constantly active, stimulated to beat, and therefore have a high metabolic demand for oxygen. Supporting cell types—ECs and smooth muscle cells—organize themselves into a dense vascular network supplying nutrients to the CMs. FBs support the CMs and generate a collagen-dense matrix. On an organ level, pacemaker cells spontaneously generate action potentials that propagate the volume of the heart, generating a synchronous contraction. The flow of blood through the heart necessitates mechanical stress on the heart, as a preload that stretches the myocardium and afterload to push against.

Fabrication of a functional cardiac patch depends on a multitude of parameters that collectively recapitulate some aspects of the complexity and function of the heart. Since CMs are terminally differentiated, current studies are focusing on deriving a renewable source of CMs from human embryonic and iPSCs. Other studies have aimed at recapitulating one or more physiologic aspects of cardiac tissue (e.g., the incorporation of multiple cell types, aligning CMs, or electrical stimulation of cardiac tissue). Table 32.1 contains a collection of studies that aim to mimic aspects of the native myocardium. The three classical tenets of the tissue engineering paradigm have been used for cardiac constructs: cell source, scaffold materials, and biophysical stimulation (Fig. 32.1).

Cell source

The limited ability of human CMs to divide and expand has restricted the scope and therapeutic potential of cardiac tissue engineering. The first evidence that the application of cells may be a viable therapeutic approach for MI came from animal studies with the injection of fetal or neonatal CMs, wherein CM injection improved left ventricular function and thickness, thus attenuating pathological remodeling upon MI [10−13]. Injected CMs integrated through gap junctions and intercalated disks with the host CMs [14]. However, these findings have limited clinical relevance, and human fetal and neonatal CMs cannot be readily obtained for transplantation due to obvious ethical issues.

The search for a clinically relevant cell source has led to the transplantation of skeletal myoblasts [15], human PSC (hPSC)-CMs [16−18], bone marrow−derived MSCs [19,20], and hematopoietic stem cells [21−23] into animal models of MI (reviewed in Refs. [24,25]). Among these cell sources, skeletal myoblasts and MSCs were pursued into the clinical trials. A metaanalysis of recent clinical trials with injection of bone marrow and peripheral blood mononuclear cells demonstrated a significant, albeit low (3%), increase in left ventricular ejection fraction (LVEF) as well as a significant reduction in infarct size (−5.6%) and end-systolic volume (−7.4 mL) in patients treated by intracoronary cell injection after acute MI [26].

TABLE 32.1 Design parameters for cardiac tissue engineering.

Native cardiac attribute	Engineering method	Results	References
Cell source	Sequence of activin and BMP4 cytokines induces cardiac cell differentiation in human embryonic and iPSCs	Flow cytometry at multiple timepoints revealed high sensitivity of multiple Embryonic Stem Cell (ESC) and iPSC lines to concentrations of induction factors. However, optimization of the times and concentrations lead to improved differentiation yields	Kattman et al. [77]
	Lentiviral iPSC technology using epigenetically specific cell sources, ventricular cells versus fibroblasts	Ventricular cells as material for iPSCs improved cardiac differentiation potential when compared to using fibroblast cells, suggesting epigenetic memory for iPSC lines	Xu et al. [78]
Patient cell source	iPSCs were derived from fibroblasts of patients with long QT syndrome type I using infection with retrovirus encoded with Oct3/4, Sox2, KLF4, and c-MYC. They were subsequently differentiated into CMs	Generation of iPSCs was confirmed with Nanog staining, and generated CMs showed striations when stained with cardiac troponin T. LQT1 disease phenotype of lengthened ADP 50 and ADP 90 was confirmed by single-cell patch clamp. Myocytes generated from LQT1 patients showed KCNQ1 channel localization to the endoplasmic reticulum, suggesting a possible mechanism for the disease	Moretti et al. [79]
	IPS cells derived from patients with familial DCM were generated using Oct4, Sox2, Klf4, and c-MYC. They were subsequently differentiated into CMs using the protocol developed by Yang et al. [32]	Immunofluorescence images of Oct4, Nanog, TRA-1−81, and SSEA-4, as well as hypomethylation as seen by quantitative bisulfite sequencing confirmed the generation of iPSCs. Multielectrode array analysis of DCM-derived CMs displayed similar beat frequency, interspike intervals, and field potential durations as the control group. Immunohistochemistry and TEM displayed similar cell size, but DCM-derived cells had a higher relative percent of disorganized cells based on α-actinin staining. Overexpression of Serca2a resulted in restoration of contraction force as measured by Atomic Force Microscope (AFM). Treatment of cells with β-blockers decreased the percentage of disorganized cells	Sun et al. [80]
Multiple cell types	Porous PGS scaffolds were preseeded with cardiac fibroblasts encapsulated in Matrigel for 5 days and were subsequently seeded with CMs for another 5 days. This was compared to constructs of cardiac fibroblasts coseeded with CMs	Immunofluorescent analysis of constructs preseeded with fibroblasts showed a greater percentage of actin-positive cells compared with vimentin-positive cells, and compared with actin-positive cells in the coseeded group. The preseeded group further showed lower excitation threshold, higher fractional area change, and increased fluorometrically measured DNA and protein content	Radisic et al. [46]
	Endothelial cells were cocultured in cell sheets with CMs at different ratios	Higher seeding ratios of endothelial cells resulted in higher density of vascular networks as appreciated by fluorescent images. ELISA for secreted factors showed higher levels of VEGF, basic fibroblast growth factor (bFGF), and Hepatocyte growth factor (HGF) in endothelial coculture groups compared to CMs alone. Fluorescent views of implanted cocultured cell sheets showed neovascularization into the myocardium	Sekine et al. [47]
	External endothelial cell addition to cardiac tissue constructs	Increased CM DNA content demonstrated a 35% increase in CM proliferation due to addition of endothelial cells, validating coculture effects of endothelial cells. In addition, vascular engraftment was shown when implanted with blood vessels of patient	Tulloch et al. [43]

(*Continued*)

TABLE 32.1 (Continued)

Native cardiac attribute	Engineering method	Results	References
High cell density	Cell sheet method, where confluent layers of cells are detached from a temperature-dependent poly(*N*-isoproplyacrylamide) substrate and stacked on top of other cell sheets using a cell sheet manipulator. Cell sheets were compared to cell injection in an infarct model	There was a greater in vivo bioluminescence of implanted green fluorescent protein (GFP)-expressing cell sheets compared to injected GFP cells. Macroscopic fluorescent views of cell sheets versus injected cells showed dense localization 4 weeks posttransplantation. Immunohistochemistry showed a greater density of cells. TUNEL staining showed a significantly lower level of TUNEL-positive nuclei compared to cell injection	Sekine et al. [9] Haraguchi et al. [68]
Ultrastructure	Microcontact printing of fibronectin into rectangles of various aspect ratios and seeded with CM pairs	Connexin-43 immunosignal and conductance as measured with dual-voltage clamp was greater in the 5.2 length:width ratio as compared to 3.5	McCain et al. [81]
Alignment/ anisotropy	Soft lithography of PGS into accordion-like honeycombs of overlapping diamonds	Differential long and short-axis elastic moduli and excitation threshold that mimic the anisotropy of the heart. Immunofluorescent actin images demonstrating elongation in the preferred direction	Engelmayr et al. [56]
	Polydimethylsiloxane (PDMS) microcontact printing of fibronectin into shapes of various aspect ratios	Image analysis of immunofluorescence actin images demonstrated greater anisotropy in shapes with >2:1 aspect ratio as compared to the 1:1 group	Bray et al. [61]
Extracellular Matrix (ECM)	Neonatal hearts were decellularized with antegrade coronary perfusion of SDS and were recellularized with neonatal CMs, fibrocytes, endothelial cells, and smooth muscle cells	Decellularization and recellularization were confirmed by histological analysis and staining. The perfused recellularized heart showed synchronous contraction as measured by ECG and left ventricle pressure (LVP) after electrically stimulated depolarization. Ejection fraction totaled 25% of an equivalently aged healthy fetal heart	Ott et al. [49]
	Decellularized sheets of human myocardium were used as a scaffold for human mesenchymal progenitor cells suspended in fibrin and implanted into infarcted rat hearts	Histological staining of ECM proteins and tensile testing showed that decellularized tissues were similar to native tissue. Echocardiographs performed on constructs transplanted on rat hearts preserved left ventricular systolic area and fractional area change	Godier-Furnemont et al. [50]
	PGS scaffolds were prepared at different stiffnesses by altering the curing time and were subsequently seeded with neonatal rat CMs	Low stiffness groups were found to have the greatest functional change (contraction amplitude) and also the greatest compressive stiffness	Marsano et al. [82]
	Comparison between collagen/Matrigel mixture with and without fibrin	Fibrin enhances the CMs alignment	Zhao et al. [83]
Cardiomyocyte hypertrophy	Molded rings of neonatal rat CMs, Matrigel, and collagen I and cultured in different hypertrophic stimuli (angiotensin II and phenylephrine versus hypertrophic inducing serum) on a cyclic stretch device for 12 days	Immunofluorescent analysis of single cells in the angiotensin II and phenylephrine group showed no change in length but displayed increased width and total volume suggesting concentric hypertrophy. Similar analysis on the "hypertrophic inducing serum" group displayed significant elongation without a widened morphology suggesting eccentric hypertrophy. Further evidence for hypertrophy in both groups is supported by high levels of gene expression of atrial natriuretic peptide (ANP) and low levels of gene expression of α/β-MHC	Tiburcy et al. [54]

Electrical stimulation	Carbon electrodes field stimulation	Ultrastructurally improved contractile apparatus and gap junctions. Histology and immunostaining showed increased linear organization. Contracting force increased and improved electrical maturity	Radisic et al. [74]
	Gold nanowire impregnated alginate scaffolds	Electrical conductance through gold impregnated scaffolds was increased. Connexin-43 expression was doubled compared to nonimpregnated controls	Dvir et al. [84]
	hESC CMs transplanted in ablated large animal heart model	ECG mapping colocalized injected CMs to ectopic ventricular pacing, demonstrating pacing potential of injected hESC pacemakers	Kehat et al. [85]
	Advanced functional maturation through progressive electrical stimulation	Extensive functional maturation with adult-like gene expression profiles, remarkably organized ultrastructure, physiological sarcomere length (2.2 μm) and density of mitochondria (30%), the presence of transverse tubules, oxidative metabolism, a positive force–frequency relationship, and functional calcium handling	Ronaldson-Bouchard et al. [86]
	Chamber-specific cardiac tissue maturation via chronic electrical stimulation	Chamber-specific tissue maturation in terms of electrophysiology, genetic profile, structural and functional protein expression, and chamber-specific drug responses	Zhao et al. [87]
		Specifically designed 8-month electrical conditioning simulates the chronic cardiac workload, and allows manifestation of disease phenotypes (left ventricular hypertrophy) in vitro	
Vascular perfusion	Perfusion bioreactor through channeled scaffolds	Perfused channeled scaffolds showed nearly 50% increase in viable cells compared to nonperfused controls. Finite element modeling provides a rational approach for vascular perfusion design through engineered cardiac tissue	Radisic et al. [63]
	Omental prevascularization of cardiac patch	Prevascularization improved engraftment on the infarcted heart and mitigated decline in cardiac function based on echocardiography	Dvir et al. [84]
	Multilayer prevascularized cardiac patch	Built-in hierarchical vasculature made of biodegradable scaffold allowing extensive perfusion and direct surgical anastomosis	Zhang et al. [67]
Force generation	Engineered heart tissues, ring-shaped CM aggregates in a mixture of Matrigel and collagen, were placed onto load-adjusted coils to apply a passive, auxotonic load on the tissues	Engineered heart tissues on auxotonic load displayed a greater twitch tension by isometric force contraction analysis. Four weeks after implantation onto an infarcted rat heart, echocardiographs, MRI, and catheterization together demonstrated decreased left ventricular volumes, lower left ventricular end-diastolic pressures, and shorter relaxation times when compared to sham-operated rats	Zimmerman et al. [55]
	CMs in porous chitosan–collagen scaffolds were stretched by moving four pins on the scaffold. Nominal strain of approximately 20% were applied at a frequency of 1 Hz for 6 days	Regions of high local stress were determined using a mathematical model. Immunohistochemical analysis showed high levels of connexin-43 staining at the regions of high stress. Histological analysis and scanning electron microscopy (SEM) also demonstrated elongated morphologies in areas of high stress in comparison to areas of lower stress	Zhang et al. [58]
Patch assembly, delivery, and integration	An elastic and microfabricated scaffold based on a biodegradable polymer [poly (octamethylene maleate (anhydride) citrate)] for functional tissue delivery via injection	The patches significantly improved cardiac function following myocardial infarction in a rat, compared with the untreated controls. Successful minimally invasive delivery of human cell–derived patches to the epicardium, aorta and liver in a large animal (porcine) model was achieved	Montgomery et al. [88]
	A bio-scaffold with a microfabricated hook and loop system allowing rapid integration of a large functional cardiac patch	The technology enables on-demand tissue disassembly while preserving the structure, physical integrity, and beating function of individual layers. The technology also allows instant establishment of coculture conditions by spatially defined stacking of cardiac cell layers or through endothelial cell coating	Zhang et al. [65]

BMP4, Bone morphogenetic protein 4; *CMs*, cardiomyocytes; *DCM*, dilated cardiomyopathy; *ECM*, extracellular matrix; *iPSCs*, induced pluripotent stem cells; *SDS*, sodium dodecyl sulfate; *TEM*, transmission electron microscopy; *VEGF*, vascular endothelial growth factor.

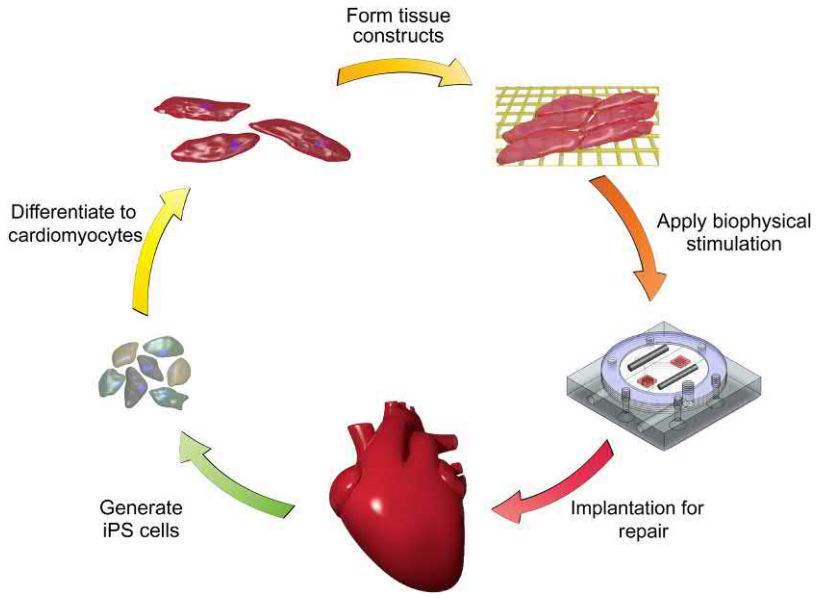

FIGURE 32.1 Cardiac tissue engineering approach.

A dose–response effect of the injected cell volume on LVEF change was also reported [26]. During the last year, resident cardiac stem cells, either c-kit + (SCIPIO) or those derived from cardiospheres (CADUCEUS) demonstrated promising functional improvements in Phase I clinical studies and restoration of viable tissue per MRI imaging, presumably due to the new CMs in addition to vascular cells [27,28].

Although these studies are encouraging, modest long-term improvements in function upon cell injection have motivated the investigation of new cell sources and methods that increase survival and retention of injected cells. Pluripotent stem cells such as *human embryonic stem cells* (hESCs) or *iPSCs* can both give rise to bona fide CMs and be expanded to sufficient numbers (millions/patient) using existing technologies. The discovery of human iPSCs (hiPSC) [29] and the ability to generate CMs from them [30] could provide effectively unlimited numbers of autologous CM for cell therapy without the ethical concerns raised by the use of hESC. Studies from a number of groups have shown that it is possible to generate CMs from mouse [31] and hESCs [32] and iPSCs [30]. With years of optimization the cardiac differentiation protocols can provide billions of CMs [33] in an efficient manner by regulating lineage commitment in the early embryo [32]. The protocols are now being adapted to defined culture conditions, with the use of small molecules such as glycogen synthase kinase 3 inhibitors and chemical inhibitors of wingless-type MMTV integration site family (WNT) signaling [34].

While in many ways iPSC-derived CMs are ideal, the exact approach for their utilization is not entirely clear. Though the differentiation process has become more specific than previous work relying on stochastic cell differentiation, further refinements are possible and necessary. In particular, there are multiple phenotypes of CMs, each with a different set of functions [35]. To be more specific, atrial, ventricular, and pacemaker cells are three major subtypes of CMs. With differentiation protocol refinement, chamber-specific atrial and ventricular CMs [36] as well as pacemaker cells [37] can be obtained in high purity. These cells can then be used for the construction of chamber-specific cardiac tissues. Shiba et al. recently demonstrated conclusively that hESC-CMs can electrically couple and suppress arrhythmias in hearts upon MI induced by cryoinjury [38]. As cell death is a major problem for cell injection studies—with up to 90% injected cells dying or being washed away from the injection site—the authors used a prosurvival cocktail consisting of Matrigel and various growth factors to enhance cell persistence upon injection [39].

Another issue is the cell maturity [40–42]. Being recently differentiated, iPSC-derived CMs are relatively young, and further phenotypic maturation may be needed to grow them into adult-like myocytes with their inherent contractile properties. Furthermore, even after differentiation and maturation, a pure population of CMs would not be most apt for building cardiac tissue. Coculturing with nonmyocyte populations, such as cardiac FBs, ECs, and smooth muscle cells, has been shown to effectively enhance tissue function, mimicking the heterogeneity of cells found natively [43–48]. The cell-related parameters of interest for building a cardiac patch include cell identity that accounts for specific CM type, relative ratios of different cells, cell density, and cell maturity.

Scaffold

Scaffolds provide a three-dimensional (3D) environment in which the cells are cultured. The constituents and

organization of the scaffold dictate the organization, maturation, and function of the forming tissue constructs. The scaffold material itself ranges from the native heart matrix itself [49–51] to natural hydrogels such as collagen, fibrin, and Matrigel [8,52–55] to synthetic polymers, such as poly(glycerol sebacate) (PGS) or polyacrylamide [56–58]. The scaffolds differ in the way they are processed (e.g., decellularization for native heart matrix versus temperature-related gelation for Matrigel), their mechanical properties, their ultrastructure, and their biodegradability. With the wide library of materials to choose from, scaffolds can be made into virtually any size or shape, depending on the application. Micropatterning has been employed as a way to control CM alignment and cell–cell interactions on a single-cell level [48,59–61], while macrosized constructs offer amenability to force generation and animal implantation studies [39,48,62].

Due to the large metabolic demand of CMs, scaffold design must take oxygen and nutrient delivery into account. The cardiac tissue engineering scaffolds are in general porous and perfusable to enable oxygen supply in vitro [41,63–65] and designed to promote angiogenesis to enable oxygen supply in vivo [62,64,66,67]. Some methods of cardiac tissue engineering do not utilize scaffolding material. For example, the cell sheet method [9,68–70] relies on stacking confluent sheets of CMs and the extracellular matrix (ECM) these cells alone produce.

Biophysical stimulation

Further phenotypic maturation of cardiac constructs can be achieved using biophysical stimulation. Perfusion of engineered constructs helps alleviate the diffusional limitations [62–64,67], which is of particular importance for the highly metabolically active cardiac tissue. The flow of medium across or through the engineered construct mimicking the vasculature found in native tissue to provide fresh media and nutrients while removing toxic metabolic products from the cells. These approaches are critically important for the generation of large and thick, clinically relevant sized cardiac constructs with homogenous distributions of cells.

Other stimulation modalities rely on the excitation–contraction coupling property that is inherent to heart tissue [71]. Stimulation systems can excite cells using either electrical depolarization, mechanical strain, or the combination of both. Mechanical stimulation systems use active or passive tension enhancing cellular organization, morphology, and contractile force generation. Auxotonic systems maintain passive tension on engineered cardiac constructs, providing a tonic resisting force for the cells to pull against [55,72]. Phasic systems provide active, cyclic strain to improve cardiac function, though some studies have shown improved twitch forces created using the auxotonic method [43,55,58]. Electrical field stimulation uses electrodes to provide a depolarizing stimulus [42,64,73–76]. The electrical field that excites the cells of the construct is created by a voltage difference across the two electrodes. This cyclic depolarization improves electrical synchronization of cardiac constructs, while also improving contractile function and cellular organization. Both of these modalities of biophysical stimulation lead to functional enhancements such as improved CM ultrastructure, improved sarcomeric linearization and organization, and increased functional gap junctions.

Directed cardiac differentiation of human stem cells

Cardiac tissue engineering requires a reliable source of CMs. Human adult CMs are unsuitable as they do not have the ability to proliferate. Recent advances in hESC and iPSC technologies have allowed for the generation of human CMs from healthy progenitors as well as from diseased individuals. We describe here the differentiation of CMs from an ESC-derived progenitor. We further discuss the purification and characterization of CMs, as well as current efforts to generate patient-specific CMs.

Derivation of cardiomyocytes from human pluripotent stem cells

One of the first accounts of generating human CMs from an ESC source comes from Yang et al. [32]. This study focuses on the discovery of a common cardiovascular progenitor capable of generating the different cell types dominant in the adult heart, that is, CMs, ECs, and smooth muscle cells. This method uses a combination of several factors to recapitulate cardiac development (Fig. 32.2A and B), resulting in a large percentage of troponin-positive cells (Fig. 32.2C). The ESC cultures were first induced with activin A and bone morphogenetic protein 4 (BMP4), generating a $T+$ population, or one which overexpressed brachyury, an important transcription factor defining the primitive streak and mesoderm. The cultures were next induced with Dickkopf-related protein 1 (DKK1), a canonical WNT inhibitor, and vascular endothelial growth factor. DKK1 was necessary for generating CMs, as demonstrated by a subsequent increase in ISL1, a marker for the secondary heart field, and NKX2.5, a marker for cardiac differentiation, and increases in cardiac-specific proteins MLC2A and cardiac troponin T.

Interestingly, flow cytometric data of embryoid bodies at various stages of cultivation demonstrated three distinct populations at day 6 of induction (Fig. 32.2D). Stage I corresponds to a stem cell growth factor receptor

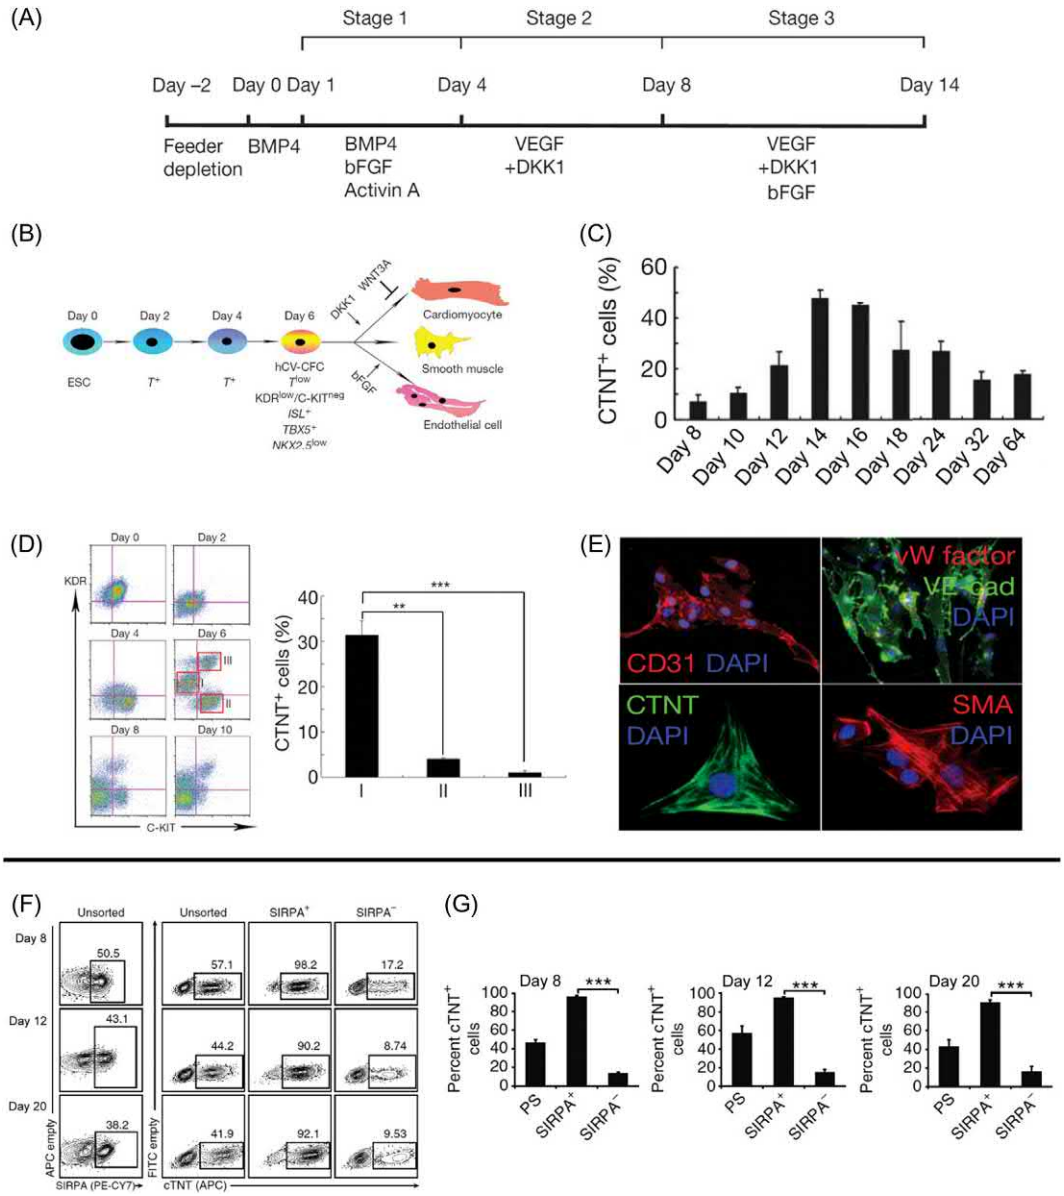

FIGURE 32.2 Generation of cardiomyocytes from embryonic stem cells [32]. (A) Cardiomyocyte derivation protocol and (B) corresponding schematic of development of cardiovascular lineages. (C) Percentage of troponin-positive cells over time using the protocol in (A). (D) Flow cytometry reveals three populations on day 6 of differentiation KDR^{low}/C-KIT^{neg} (I), KDR^{neg}/C-KIT^{pos} (II), and KDR^{high}/C-KIT^{pos} (III), where differentiation of the KDR^{low}/C-KIT^{neg} population yielded the highest percentage of troponin-positive cells. (E) Immunostaining for endothelial cell markers CD31 and vWF, cardiomyocyte marker cTNT, and smooth muscle marker SMA on cells differentiated from the KDR^{low}/C-KIT^{neg} lineage. (F) Flow cytometric analysis of hESC-derived cardiomyocytes sorted for SIRPA on various days (8, 12, and 20) of differentiation. (G) SIRPA positivity selects for a cardiomyocyte progenitor, resulting in up to 98% troponin-positive cells. *hESC*, Human embryonic stem cells; *SIRPA*, signal regulatory protein alpha.

(KDR)^{low}/stem cell growth factor receptor (C-KIT)^{neg} population, stage II corresponds to a KDR^{neg}/C-KIT^{pos} population, and stage III corresponds to a KDR^{high}/C-KIT^{pos} population. KDR and C-KIT were chosen for further investigation based on their significance in mouse stem cell studies. In particular, KDR was shown in mice to give rise to cardiac progenitor, and C-KIT was shown to derive hematopoietic and vascular lineages [31]. Low KDR expression and C-KIT positivity defined a cardiac progenitor, developing into cells with a greater number of cardiac troponin-positive cells (>50%) compared with the other subpopulations (Fig. 32.2D). As lineages of cardiovascular cells are induced, significant populations of CMs, ECs, and smooth muscle cells form in culture (Fig. 32.2E). Transplantation of these progenitors into murine hearts has led to differentiation into the same three cell types—CMs, ECs, and smooth muscle cells—and resulted in an increase in ejection fraction (56% vs 39%).

Whole-cell patch clamp and microelectrode arrays of the CMs demonstrated results consistent with cardiac phenotype. Together, these results suggest the identification of a cardiovascular progenitor that gives rise to CMs, ECs, and smooth muscle cells.

Furthermore, Lian et al. have demonstrated that cardiac differentiation can routinely achieve high (up to 98%) purity and high yield (15 CMs from 1 PSC) through precisely regulating Wnt signaling pathways with small molecules (CHIR99021 and IWP4) or a genetic approach [34,89]. This robust, inexpensive, completely defined, growth factor−free scalable method of producing CMs can be achieved for multiple hPSC cell lines and has been widely adapted by several cardiac-related research fields [83,86,87,89,90].

CMs have many subtypes. CMs from atrial, ventricular chambers, and Sinoatrial (SA) nodal area have distinct action potential profiles, different protein expression, and differential drug responses [87]. Therefore it is important to obtain the CM subtypes at a high purity for better chamber-specific functional tissue constructs. The studies of mouse and chick embryos have revealed that retinoic acid (RA) is a key regulator of cardiovascular fate [91,92]. Addition of RA in a specific time window is a key to differentiate chamber-specific CMs subtypes, such as atrial and ventricular CMs. Lee et al. extensively evaluated the experimental outcomes and precisely defined the atrial-specific differentiation protocol, which includes the addition of 500 nM RA at the beginning of the mesoderm induction (day 3−12 after start of the CM differentiation) [36]. Without further purification, the percentage of atrial CMs, defined as $MLC2v^{neg}/cTNT^{posi}$, was above 80% [36]. Portze et al. developed the first SA nodal−specific differentiation protocol. hPSCs were first induced to mesoderm with a combination of bFGG, low amount of activin A and BMP4. The cells then went through inhibition of bFGF, TGF-β, and Wnt signaling in the presence of BMP4 and RA [37].

Purification and scalable production of stem cell−derived cardiomyocytes

While this original study and subsequent studies have identified reproducible ways of generating cardiovascular lineages with high purity and high yield [93], one major challenge was to completely separate the CMs from the nonmyocyte cell types, necessary to provide more defined cellular compositions for cardiac tissue constructs. In a screen for a marker of hESC-derived CMs, signal regulatory protein alpha (SIRPA) appeared to specifically select for CMs above the other cell types (including ECs and smooth muscle cells) [94]. Indeed, cell sorting with this marker and depletion of ECs and smooth generation of a pure cell source is of particular importance since the implantation of undifferentiated cells may lead to teratoma formation. Another purification method is through the unique metabolic activity of CMs [95]. Burridge et al. replaced glucose in the media with lactate to realize metabolic purification. By eliminating the glucose in the media, only CMs in the culture are able to use the tricarboxylic acid cycle (TCA) cycle to produce ATP and other cell types are starved to death. In this case the CM purity after metabolic selection is >90% based on TNNT2 flow cytometry [95].

Given the precision required to generate specific cell types from stem cells, protocols must be optimized. For example, the procedure originally proposed by Yang et al. has been further modified and applied to multiple cell lines, including iPSCs [77]. Use of micro-bioreactor arrays allows controlling over the 3D cellular microenvironment in a multiplexed fashion, toward experimental optimization of cell derivation procedures on a small scale [96]. In addition, these devices allow controlling more than simply the concentration or type of cytokines.

The small molecule differentiation protocol enables scalable CMs differentiation process. Tohyama et al. recently demonstrated the ability to differentiate hPSC-derived CMs in monolayer culture in 10-layer, 1.2-L culture flasks with active gas ventilation, creating near a therapeutically relevant number of $1.5-2.8 \times 10^9$ cells with >66% purity [97]. Chen et al. seeded undifferentiated hPSC aggregates in reactors to scale up the production of hPSC-derived CMs in 3D suspension culture. The reactor can yield 1.5−2 billion CMs in a 1 L spinner flask with >90% purity [98].

Scaffolds

Cells alone do not compose functional tissues; other critical components include substrate and ECM that surrounds and instructs the cardiac cells. Natively, the ECM provides microenvironmental cues, mechanical support, and architectural guidance, acting as the scaffold upon which cardiac cells grow and function. Previous tissue engineering scaffolds have used polymeric materials, lyophilized collagen sponges, and micropatterned anisotropic materials. These artificial materials have design advantages in that they can be microfabricated, functionalized and are highly reproducible, but other approaches have used decellularization of native matrix as a different starting point, providing scaffold with improved biological activity at the cost of some of the versatility of synthetic approaches.

Decellularization approach

Decellularization of native heart material is a powerful approach to easily recapitulate the in vivo architecture

and extracellular composition of the heart. In 2008, Ott et al. decellularized whole rat hearts using a perfusion system of 1% sodium dodecyl sulfate in deionized water as shown in Fig. 32.3A [49]. The subsequent washes of detergent removed all of the cellular components from the native heart leaving behind a "ghost" heart, translucent in appearance, composed on thin walls of native heart matrix, which retained macro- and microscopic architecture.

When reperfused with a native blood supply, the decellularized hearts clearly showed maintenance of vascular channels, demonstrating the preservation of overall native morphology (Fig. 32.3B). When reseeded with neonatal rat cells, the heart regained a cellularized appearance, and sections cut from the reseeded heart were capable of beating and matched the pacing rate applied through the external electrical field, either at 1 or 2 Hz (Fig. 32.3C). Over the 8 days of culture, there was an increasing trend of contractile function and pressure generation. The whole heart preparations were also exposed to phenylephrine, which increased contractile pressures, suggesting pharmacological responsiveness (Fig. 32.3D). Overall this study provided a basis for whole heart decellularization with subsequent repopulation, providing a cardiac pump function 2% of the adult rat heart output.

Since cardiac MIs are localized as compared to the whole heart, sometimes only a specific section, importantly the left ventricle may need to be the target of therapy [50]. Decellularized scaffold patches can be made from native human heart sections using sequential detergent washes. However, the direction of sectioning is important, as different planes of section result in different scaffold architectures and different pore sizes (Fig. 32.3E).

Alternatively, decellularized cardiac tissues and other tissue types can be digested into gels and used as injectable scaffolds loaded with CMs or other cells [99]. Despite losing intrinsic architecture of decellularized ECM, injectable hydrogels are touted for their minimally invasive delivery, ability to self-assemble in situ, and capacity to encourage host tissue regeneration. The material has since shown efficacy to increase cardiac muscle, reduce fibrosis, and improve cardiac function post-MI in small and large preclinical animal models [100,101].

When vascular progenitor human MSCs are seeded onto these native scaffolds, they act as depots of vasculogenic factors improving recovery of left ventricular function damaged by infarction. As shown in Fig. 32.3F, the presence of infarct improved migration of the vasculogenic MSCs into the damaged tissue, in both acute and chronic models, and suggested that the stimulus of injury improved the responsiveness of cardiac tissue to the therapeutic cells. Notably, cells did not stay at the surface epicardium of the heart, and instead, they penetrated into the myocardium even when only microinfarcts were created using sutures alone to damage the myocardium. These native cardiac patches acted as a vehicle for a vasculogenic cell–based therapy and showed improved heart function, using echocardiographic metrics such as fractional shortening and fractional area change of the regions infarcted (Fig. 32.3G). The use of the native matrix scaffold improved recovery above cell injection alone proving additional benefit as a delivery vehicle for the vasculogenic cells.

Artificial scaffolds

Despite advances in using native matrices as scaffolding agents for the delivery of cells to injured heart, rational design of artificial scaffolds is still an active area of research. One primary limitation of fabricated scaffolds was the lack of electrical conductivity, a property that might enhance cell–cell communication and synchronization of the heart. Dvir et al. used gold nanowires impregnated in a conventional scaffold material, alginate, to bestow conductive properties to the material [84]. Fig. 32.3G outlines how conductive scaffold allows electrical signal propagation. Since alginate was chosen as the base scaffolding material, it maintained many of its familiar features. Even with the addition of gold nanowires (Fig. 32.3H), the viscosity and material properties of alginate were not altered enough to change the porosity of the final scaffolds. The presence of the nanowires improved expression and organization of connexin-43, the primary gap protein associated with electrical–mechanical coupling and communication between cells, assessed using immunofluorescent staining and western blot quantification (Fig. 32.3I). When calcium transients were investigated, the nanowire impregnated scaffolds showed fluorescent signal consistent with electrical propagation through the scaffold material, providing electrical stimulation to the cells. Similarly, carbon nanotubes can also be incorporated into the scaffold material (1,2,4 polymer elastomer) at 0.5 wt.% to improve the electrical conductivity, which eventually enhanced the functional maturity of the cardiac tissue [102]. Thus engineered materials can incorporate unique properties to cardiac scaffolds, such as mechanical properties [65,67], conductivity [102], topographical niche [65,67,88,103], and tailor their functionality to that found in the native heart muscle.

Engelmayr et al. created an accordion-like scaffold using laser boring of 250 μm thick PGS layer [56]. The accordion-like honeycomb was made by overlapping two 200 by 200 μm^2 at the angle of 45 degrees. The pore walls and struts were ~50 μm thick. The scaffolds were pretreated with cardiac FBs followed by seeding of enriched CMs. At the end of cultivation the authors obtained contractile cardiac grafts with mechanical properties closely resembling those of the native rat right

(B) Perfusion of the decellularized heart with the host vasculature through the aorta demonstrates maintenance of the decellularized blood vessels [49]. (C) Hearts recellularized with cardiomyocytes beat spontaneously after 4 days in culture and can generate force when paced at 1 or 2 Hz [49]. (D) Maximum pressure and d*P*/d*t* after 8 days in culture and after stimulation with PE [49]. (E) Scanning electron microscope images of various slices of heart yield different pore sizes [50]. (F) Migration of human mesenchymal progenitor cells (MPCs) from MPC/scaffold/TGFβ constructs to acute infarcts, chronic infarcts, or normal myocardium 4 weeks after implantation [50]. (G) Fractional shortening and fractional area change for 3 days postinfarction rats (baseline), which were subsequently stratified into three groups: a control that received no additional intervention, an MPC group that received an injection of MPCs, and a patch group, which received composite scaffolds containing MPCs in the decellularized scaffold [50]. (H) Schematic of cardiomyocytes (red) in an alginate matrix or in the nanowired composite [84]. (I) Transmission electron microscope images of alginate-nanowire composite scaffolds, where nanowires of approximately 5 μm in length were incorporated into the scaffold material [84]. (J) Connexin-43 (green), troponin (red), and 4′,6-diamidino-2-phenylindole (DAPI) (blue) immunostained cardiomyocytes organized in the nanowired scaffold [84]. (K) Connexin-43 and actinin expression by western blot relative to Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) in nanowired group versus the alginate only group 3 or 8 days after seeding with cardiomyocytes. *PE*, Phenylephrine; *SDS*, sodium dodecyl sulfate [84].

ventricle. In addition the cells in the pores were aligned along the preferred direction.

In another study, Feinberg et al. seeded a layer of neonatal rat ventricular CMs on a polydimethylsiloxane membrane that could be detached from a thermosensitive poly(isopropylacrylamide) layer at room temperature, which is called muscular thin films. These cell-covered sheets could be designed to perform tasks such as gripping, pumping, walking, and swimming by careful tailoring of the tissue architecture, thin-film shape, and electrical-pacing protocol [104].

Biophysical cues

Biophysical stimulation has been used to improve the phenotypic maturity of cardiac tissue–engineered constructs. These stimuli are designed to be biomimetic and simulate the native heart environment to facilitate proper cardiac growth and maturation.

Electrical stimulation

One of the primary features of the heart is its electrical connectivity and synchronization. Previous studies have shown improved conductive and functional characteristics of heart tissue grown in the presence of a stimulating electrical field. These results validate the use of electrical stimulation as a functional cue to improve phenotypic maturation of cardiac tissue; however, the precise techniques to apply electrical stimulation to engineered tissues are a topic of further exploration. Various electromechanical cues can be added in order to further recapitulate the cardiogenic niche, allowing true optimization of stem cell derivation procedures [105].

To establish baseline parameters, Tandon et al. compared multiple electrode materials and stimulation regimes to optimize electrical field conditioning of engineered heart tissue [76]. Petri dishes were outfitted with 1/8 in. rod-shaped electrodes, spaced 1 cm apart, and 4 cm in length made from the following materials: carbon, steel, titanium nitride, and titanium. When comparing injected charge and recovery, the electrodes made of carbon recovered the most charge (95%), meaning that they had the least amount of lost charge due reaction products in the solution. The carbon electrodes were also best able to maintain a current through the bioreactor over the 2 ms time range for the depolarizing stimulus. With respect to effect on cell function, the results comparing various electrode materials was more modest, but carbon electrodes still had a favorable trend in their ability to properly capture the pacing of cardiac constructs as well as a lowered excitation threshold. This suggests that the carbon best communicates with the tissue-engineered constructs with minimal side reactions. Based on these studies, the effect of field stimulation improves cardiac tissue function, shown by increased troponin and connexin-43 markers, key proteins in both cell–cell connectivity and contractile apparatus.

Using carbon electrodes in the culture, electrical stimulation has been extensively studied by several research groups to promote functional maturity. Nunes et al. were the first to use a daily step-up protocol to increase stimulation frequency from 1 to 6 Hz within a week. The resulted cardiac tissues showed significant functional improvement in terms of electrophysiology, calcium handling, and cellular morphology compared to nonstimulated controls and 1–3 Hz step-up controls [106]. Ronaldson-Bouchard et al. then changed the step-up stimulation frequency to 0.33 Hz daily from 1 to 6 Hz (Fig. 32.4A) and used cells early after differentiation at day 12. These interventions resulted in a remarkable tissue maturation, including multiple hallmarks of adult myocardium, such as positive force–frequency relationship, adult-like gene expression profiles, remarkably organized ultrastructure (first M line present in engineered cardiac tissues), physiological sarcomere length (2.2 μm) and density of mitochondria (30%), the presence of transverse tubules, oxidative metabolism, and functional calcium handling [86] (Fig. 32.4B–E). Another study done by Zhao et al. had further facilitated chamber-specific stimulation protocols, where ventricular stimulation protocol takes 6 weeks to increase the stimulation frequency from 1 to 6 Hz, whereas atrial protocol involves a 0.4 Hz daily step-up stimulation. The stimulation protocols both resulted in a significant improvement of chamber-specific functions in terms of protein and gene expression, as well as electrophysiology [87].

Mechanical stimulation

Mechanical stimulation approaches the electrical–mechanical coupling of heart tissue from the stretching and mechanical contraction perspective. It has been shown that passive or active tension can increase the cardiac functionality and orientation of cardiac cells. In one study, chitosan, a polysaccharide based scaffolding material, was processed to have defined channel pores for perfusion and high porosity for cell seeding (Fig. 32.4F–H). Due to its attractive mechanical properties (Fig. 32.4I), it was used with a radial stretch device to characterize contraction using active tension. Strain maps of the scaffolds could be generated modeling the surface mechanics of the chitosan, showing stereotyped stress fields around the large pore areas (Fig. 32.4J). Interestingly, increased cell density and organization followed the predicted stress map suggesting that the mechanical stress provides a biophysical cue for cellular organization and communication (Fig. 32.4K) [58].

Static or cyclic stretching of cardiac tissues often uses specialized mechanical stretcher that applies uniaxial tension to the 3D microtissue constructs. The process mimics the preload of cardiac chamber and aims to improve the electromechanical coupling of the 3D tissue constructs. One study showed evidence that static stretching facilitates better cellular alignment with larger cell area and upregulation of maturation markers in gene expression, including MYH7, TNNT2, NPPA, NPPB, CACNA1C, RYR2, and ATP2A2 [107]. Cyclic stretch was also shown to promote more Cx43 and TNT protein expressions [108].

Moreover, dynamic culture in the combination of increased nutrient availability and constant shear stress stimulation significantly improved the contractile force and conduction velocity of the 3D cardiac patch, both of which have approached the level of adult myocardium [109]. CMs after dynamic culture also have better cellular hypertrophic appearance [109].

Perfusion

Another critical biophysical stimulus—perfusion—is required for proper metabolic function. The transport of fresh oxygen and nutrients along with removal of metabolic products is particularly essential for cardiac tissue. Native tissue combines active perfusion and electrical−mechanical coupling, and in Maidhof et al., these two critical stimuli were combined in a novel bioreactor to enhance cell density and contractile protein expression of troponin [64]. A perfusion system, forcing fluid through a channeled scaffold, was built around the standard paradigm of carbon electrodes (Fig. 32.4L). This resulted in a more uniform cell distribution due to removal of diffusion limitations encountered when growing thicker pieces of cardiac tissue. When electrical stimulation was also applied, the cells were both more numerous while maintain an even density distribution throughout the tissue (Fig. 32.4M). The two stimuli, perfusion and electrical stimulation, had a synergetic effect on troponin expression (Fig. 32.4N). The three biophysical stimuli—electrical stimulation, mechanical stretch, and perfusion—all can contribute to the functional maturity of engineered cardiac tissues.

In vivo applications of cardiac tissue engineering

The ultimate goal of cardiac tissue engineering is the implementation of cells or tissue constructs in an injured heart and subsequently improving cardiac function. An "ideal" cardiac patch would mechanically connect with the host myocardium, integrate with host vasculature, couple electrically with the surrounding myocardium, and generate force in synchrony with the host myocardium to improve the contractile function of a failing heart. We describe in this section two general methods of fabricating a cardiac patch, the first of which focuses on using mechanical load to create force-generating constructs, and the other focuses on introducing multiple cell types to enhance vascularization of the cardiac patch. Open questions for in vivo systems include the functional differences between cell injection and scaffold implantation, and the type of arrhythmogenic or immunogenic response the foreign cells will have when near the host tissue.

Engineered heart issue

Zimmermann et al. outlined an approach to generate contracting rings of cardiac tissue, which can be implanted into infarcted rat hearts, resulting in an improvement in cardiac function [55]. Engineered heart tissues were created by casting neonatal rat CMs, collagen I, and Matrigel in a circular mold, followed by 7 days of culture in 40% oxygen, under static, "auxotonic" load, and in media containing insulin. Five of these loops were then stacked to create a large (15 mm diameter × 1−4 mm thick), fused, synchronously beating tissue assembly amenable to implantation (Fig. 32.5A), similar constructs have been made with hPSC-CMs as well [89,90,110].

Structural and electrical integration with the host myocardium as well as whole heart function were examined in rats with infarcted hearts implanted with engineered heart tissues. Immunostaining of the engineered heart tissue 4 weeks after implantation showed an elongated, sarcomeric pattern suggestive of highly differentiated CMs (Fig. 32.5B). In addition, there was neovascularization within the tissues from the donor cells that connected to the host vasculature (Fig. 32.5C). Electrical coupling was improved in the engineered heart tissues, as demonstrated by lower total activation times and higher QRS amplitudes. In vivo studies allow for the functional examination of whole hearts. Rats with engineered heart tissues demonstrated shorter left ventricular end-diastolic diameter and a lower maximum left ventricular volume when compared to sham-operated rats, suggesting no additional dilation of the infarcted rat hearts as might be expected (Fig. 32.5D). Further, there was no decrease in fractional area shortening of the heart after the operation (Fig. 32.5E).

In another study, Montgomery et al. developed an elastic shape-memory scaffold with a defined microfabricated lattice structure. Because of the unique structure, scaffold seeded with cardiac tissue can be delivered into the heart and other organs through minimally invasive surgery (Fig. 32.5F). Upon delivery the tissue can self-unfold to its original shape without functional losses, and it can be fixed in place with surgical glue or suture. After the delivery the tissue can remain in position for up to 6 weeks. The scaffold also incorporates the center grooves

(I) Circumferentially oriented nanofibers in scale-model ellipsoidal ventricle scaffolds seeded with human cardiomyocytes to produce tissue-engineered ventricles [111]. (J) Calcium transient of the whole tissue–engineered ventricles on day 14. Left: spontaneous activity, middle: field stimulation from far end, and right: apical point stimulation (indicated by *yellow arrows*) with conduction velocities of 9.33 cm/s for Neonatal rat ventricular myocytes (NRVM) ventricles and 5.2 cm/s for hiPSC-CM ventricles [111]. (K) Representative cross section of grafted heart at 14 days posttransplantation showing substantial remuscularization of the infarct scar (blue) by human myocardium (*dotted lines*) [112]. (L) Representative ECG traces acquired on days 1, 3, 4, and 24 posttransplantation suggesting diminished arrhythmias over time [112]. *CM*, Cardiomyocyte; *hiPSC*, human induced pluripotent stem cell; *MI*, myocardial infarction; *PV*, pressure–volume.

for vasculature integration with the host. To evaluate the cardiac patch in vivo, a rat MI model was used to assess the functional effects of cardiac patch implantation. Subcutaneously injected rat cardiac tissues exhibit signs of vascularization and CM persistence. The patch group resulted in smaller scar area and their functional improvement was also evident. The representative pressure–volume (PV) loops measured 5 weeks after patch implantation demonstrated a higher end-systolic pressure and smaller left ventricular volume in the patch group compared with MI-only controls and improved ventricular wall thickness (Fig. 32.5G and H). The delivery method was also validated with porcine model to further conclude the feasibility of the shape-memory tissue patch [88].

MacQueen et al. have recently developed a tissue-engineered model of the whole ventricle [111]. The scaffold was made of nanosized fiber electrospun into a ventricle-like chamber. Because of the architecture of the scaffold, seeded rat CMs or hiPSC-CMs naturally aligned with the fiber orientation, which precisely recapitulated the orientation of native myocardium (Fig. 32.5I). The established tissue-engineered ventricle has a diastolic chamber volume of 500 μL and was capable of ejecting liquid with synchronized contraction. Although the ejection fractions and contractile functions are much smaller than the native rat and human ventricular chamber due to the limited chamber wall thickness (100 μm) and limited cell number, the chamber was well sealed with cells and provided intra ventricular PV measurements and whole ventricle calcium mapping (Fig. 32.5J). By damaging the chamber wall, the engineered chamber can be considered as structural arrhythmia disease model to study the arrhythmia induced by structural damage such as MI through calcium transient mapping [111]. This is the first study that reported the full-scale tissue-engineered heart chamber with human and rat cells, which is the key for drug screening and personalized medicine.

Vascularized cardiac patches

Vascular integration of the cardiac patch with the host myocardium is important for the prolonged survival of thick tissue patches, especially given the high oxygen demand of cardiac tissue. Stevens et al. demonstrated the utility of prevascularizing cardiac tissue prior to transplantation into the infarcted area [48]. Cardiac patches were created from hESC-derived CMs and human umbilical vein ECs, on mouse embryonic feeders. Several experimental groups were investigated: a CM only group, a group consisting of CMs and ECs, and a group consisting of all three cell types. Histology showed that the group consisting of all three cell types resulted in the largest number of vessel-like structures, and the stiffest construct with higher collagen contents, that were most similar to native myocardium. Upon implantation into a skeletal muscle environment, the tri-culture group demonstrated great area staining for β-myosin heavy chain, the greatest number of vessel lumens, and neovascularization and anastomosis with the host vasculature.

Preestablished vasculature in the cardiac patch can significantly promote the integration to the host tissues. A more recent study conducted by Zhang et al. [67] describes a new the organ-on-a-chip model named Angiochip. The Angiochip has multilayered, interconnected, branching lumen that can be coated with ECs and perfused with culture media. The network can significantly improve oxygen and nutrient delivery within the parenchymal tissues by gravity-driven media flow. The smallest microchannel in the network was 100 μm by 50–100 μm, with a wall thickness of 25–50 μm, which is approximately the same size as venules. The Angiochip also has microsized holes on the side of the lumens, which allow on-demand EC sprouting and transmigration into the parenchymal space. The Angiochip is scalable to a thickness comparable to the rat ventricle wall. Because Angiochip is mechanically stable and is capable of withholding blood pressure in rat, the inlet and outlet of the Angiochip can be surgically attached to the femoral vessels on the hindlimbs of adult Lewis rats, in both artery-to-artery and artery-to-vein mode. The two different configurations of direct surgical anastomosis were demonstrated with success, which further demonstrates that the prevascularized cardiac patch can be integrated quickly into the host tissues [67].

Electrical coupling of cardiomyocytes on the heart

One question remains whether or not CMs, when applied to the heart, will form adequate connections with the host tissue, or if the engineered tissue constructs are proarrhythmic, thus potentially negating any therapeutic effect. In one study, Shiba et al. showed that these grafts may electrically couple with the host and suppress arrhythmias [38]. hESC-derived CMs were transplanted onto a guinea pig cryoinjured heart and were subsequently analyzed for electrical coupling with the host tissue. They showed not only 1:1 coupling with the host myocardium, but also the reduced susceptibility of the heart to premature ventricular contractions, and sustained ventricular tachycardia. As a result, this study represents one of the first accounts that CMs are nonarrhythmogenic when implanted. This supports the continued study of the interactions between the native host myocardium and the tissue-engineered construct.

Encouraged by the previous study, Chong et al. had moved to a primate model hoping to better understand

whether clinical-scale hESC-CM transplantation is feasible, safe or can provide sufficient myocardial regeneration in a nonhuman primate model [33]. Due to the large size of injury, one billion hESC-CMs were manufactured and delivered to the injury site. The CM injection generated extensive remuscularization of the infarcted heart with incomplete maturation over a 3-month period. The injected grafts were penetrated with a significant amount of host vasculature. There were also adequate electromechanical junctions between the graft and the host myocytes, which were proved by synchronized calcium transients from the graft and the host electrocardiogram. Despite the success in a small animal, nonfatal ventricular arrhythmias were observed in all hESC-CM-engrafted primates [33].

The injected ESC-CMs typically have a fetal phenotype and were experiencing spontaneous beating. Since guinea pigs and other small animals have a much faster heart rate than humans, it is possible that the spontaneous beating from the human CMs was proarrhythmic but was covered by the fast heart rate in small animals. When the host heart rate is low, the higher spontaneous beating rate would manifest. In a recent publication using a porcine model [112], similar remuscularization and functional improvements were reported to occur after hESC-CMs transplantation into hearts (Fig. 32.5K). Although monomorphic ventricular tachycardia was routinely found in grafted animals, the arrhythmia eventually disappeared potentially due to the maturation of grafts over time (Fig. 32.5L).

In comparison with single cells, engineered cardiac tissues have been shown to exhibit much lower spontaneous beating rate after maturation regimes [86,87], which may minimize or eliminate the risk of arrhythmias upon implantation.

Weinberger et al. implanted engineered cardiac tissue made of hiPSC-derived CMs and hiPSC-derived ECs [113]. The grafts were transplanted onto large defects (22% of the left ventricular wall, 35% decline in left ventricular function) of guinea pig hearts 7 days after cryoinjury. Twenty-eight days after transplantation, the hearts repaired with tissue that had remuscularized 12% of the infarct area. These grafts showed CM proliferation and vascularization; however, the evidence for electrical coupling to the intact heart tissue was limited. Another similar study demonstrated that implantation of engineered cardiac tissues did not provoke or attenuate ventricular arrhythmias [114]. It is possible that due to the extensive level of cellular reorganization during tissue compaction phase of engineered cardiac tissues, less cell−cell interaction would occur during the implantation to facilitate electromechanical integration. Therefore limited success was achieved for engineered cardiac tissue implantation.

Modeling of disease

In vitro models of disease represent an important avenue in studying disease and identifying potential therapeutic options. Here we describe the use of patient-specific cells to generate diseased CMs. We further describe the utility of tissue engineering in providing a faithful representation of diseased myocardium, and how this may be used in high-throughput screens and drug studies.

Generation of patient-specific cardiomyocytes

iPSCs have allowed for the generation of patient-specific CMs. One of the first accounts came from Moretti et al., who generated iPSCs from patients with a particular genetic mutation leading to long QT syndrome and subsequently differentiated them into CMs (Fig. 32.6A and B) [79]. Localization of the mutated channel (KCNQ1) in the endoplasmic reticulum confirms this channel as the likely cause of disease (Fig. 32.6C and D). These CMs displayed the electrophysiological phenotype of long QT syndrome, including the classic lengthened action potential duration (Fig. 32.6E and F). The use of induced pluripotent cells to recapitulate disease phenotype is particularly amenable to patients with genetic mutations. Since the studies on long QT syndrome, CMs from patients with other diseases, including arrhythmogenic right ventricular cardiomyopathy and familial dilated cardiomyopathy (DCM), have been generated [80,115]. The iPSCs from patients harboring genetic cardiac mutations have been differentiated into CMs. These include cells from Timothy [116], long QT [79], and LEOPARD [117] syndromes and DCM patients [80].

Engineered heart tissue models

While induced pluripotent cells are useful in generating cells from patients with specific genetic mutations, many cardiac diseases are multifactorial and require a biomimetic environment to faithfully reproduce the disease phenotype.

Cardiac fibrosis

Engineered cardiac tissue can be used to model myocardial fibrosis, which is a severe global health problem due to its prevalence in all forms of cardiac diseases. Wang et al. [118] have demonstrated an in vitro disease model of human myocardial fibrosis. The disease model is constructed with an excessive initial cardiac FBs population. The resultant tissue has massive collagen production and sparse distribution of CMs, which precisely recapitulate contractile, biomechanical, and electrophysiological complexities of fibrotic myocardium (Fig. 32.6G and H). By

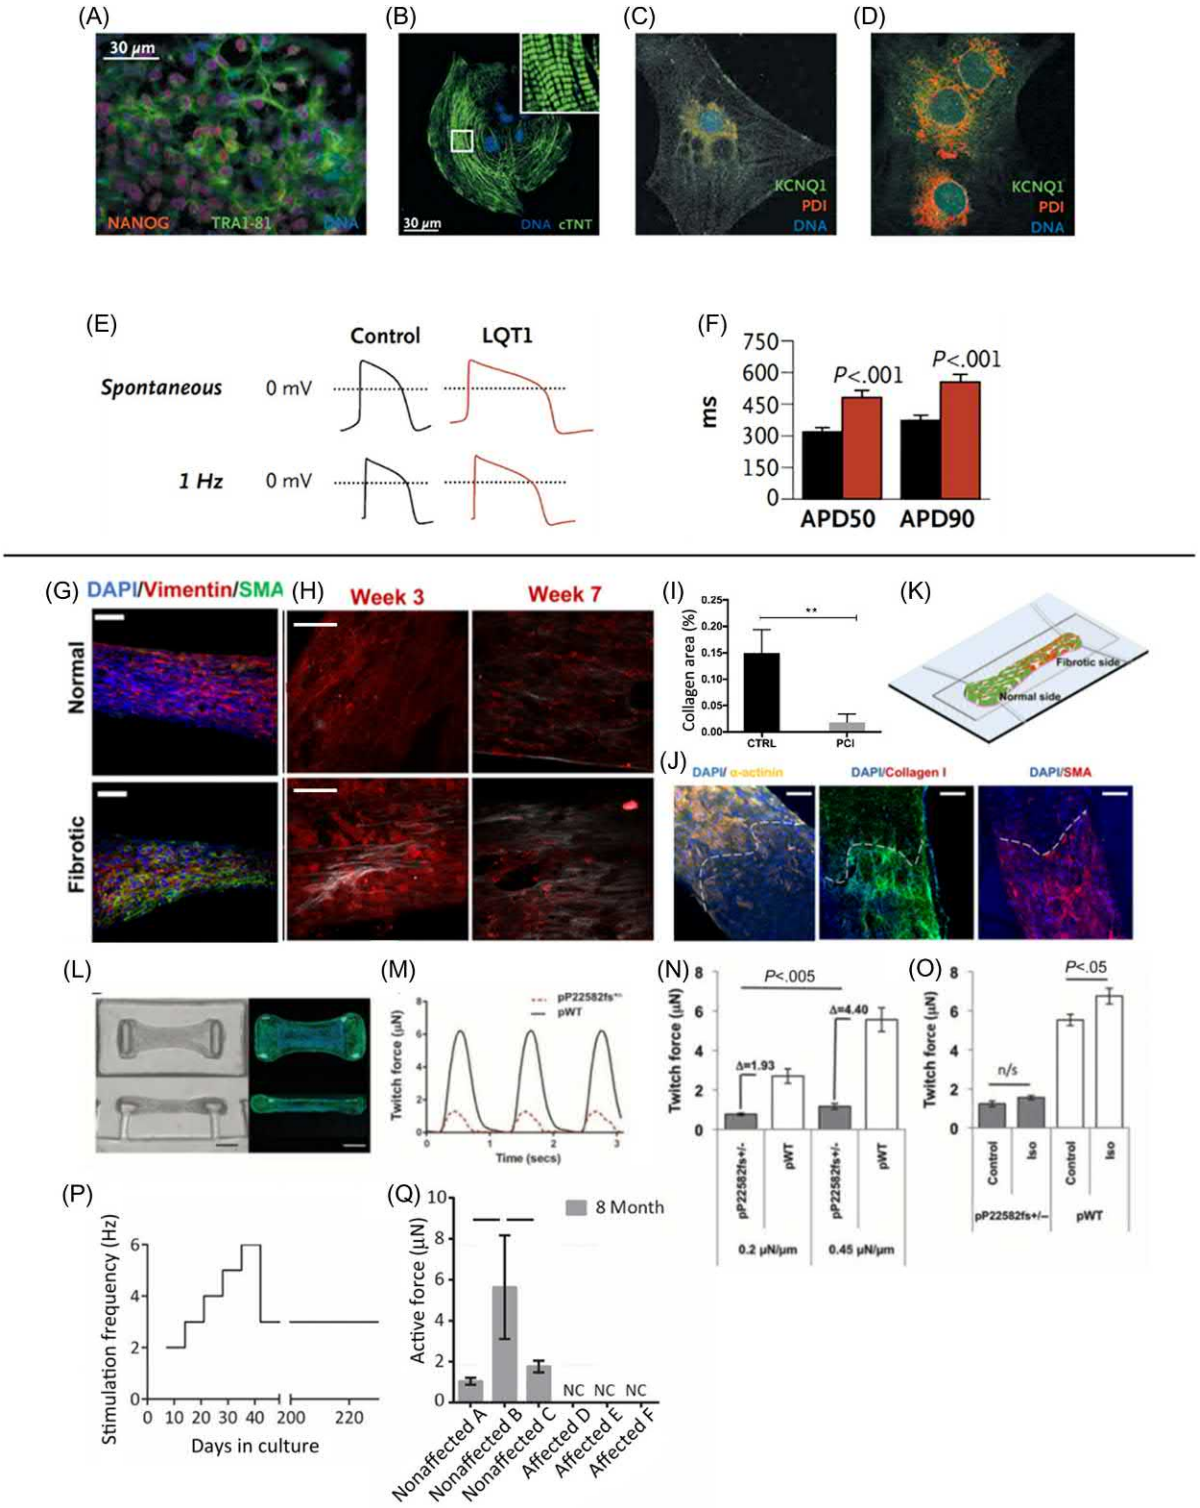

FIGURE 32.6 **In vitro models of disease.** (A) immunostain of induced pluripotent cells from LQT1 patients for Nanog and Tra1-81 [79]. (B) Troponin staining showing sarcomeric organization in iPS-derived cardiomyocytes. KCNQ1 (green) and Protein Disulfide Isomerase (PDI) (red) staining for control cardiomyocytes (C) and patient cardiomyocytes (D) [79]. (E) Single-cell action potentials of control and patient-derived stem cells spontaneously beating or stimulated at 1 Hz [79]. (F) APD50 and APD90 for control (black) or patient-derived (red) cardiomyocytes [79]. (G) Immunostaining images of normal and fibrotic tissues double-stained for vimentin and α-SMA (scale bar = 100 μm) [118]. (H) SHG images to reveal collagen content in normal and fibrotic tissues at week 3 and 7 of cultivation, (scale bar = 100 μm) [118]. (I) Schematics of the integrated scar-myocardium model [118]. (J) Representative immunostaining images of the integrated tissue stained for sarcomeric α-actinin, collagen type I, and α-SMA. (scale bar = 100 μm) [118]. (K) Quantification of fibrotic tissues treated with antifibrotic compound for 7 days (mean ± SD, $n \geq 3$, Student's *t*-test) [118]. Comparison between engineered cardiac tissue−derived from wild type (pWT) and titin truncated diseased cell line in terms of (L) bright field and fluorescent image (scale bar = 50 mm), (M) force traces, (N) active force responses to different pillar stiffness, and responses to isoproterenol [119]. (P) Electrical stimulation regime simulating chronic cardiac overload to induce disease phenotype [87]. (Q) Absence of contractile forces in the affected groups in comparison to the nonaffected groups [87]. *iPS*, Induced pluripotent stem; *SHG*, secondary harmonic generation.

using this disease model, evaluation of antifibrotic compounds can be carried out with human models with clinical relevance (Fig. 32.6I). Taking a step further, a heteropolar integrated model was constructed with a fibrotic end and a healthy end, which may capture the regional heterogeneity of scar lesion, border zone, and adjacent healthy myocardium [118] (Fig. 32.6K and J).

Titin mutation–related dilated cardiomyopathy

Engineered cardiac tissue can also be used to model DCM, which is mostly caused by a genetic mutation of sarcomere protein titin (TTN-truncating variants). By using patient-specific cell lines, engineered cardiac tissue can be a powerful tool to evaluate the pathogenicity of titin gene variants. To be more specific, the model recapitulated the A-band domain of TTN mutation caused DCM in terms of sarcomere insufficiency, impaired responses to mechanical and β-adrenergic stimulation, and attenuated growth factor and cell signaling activation. The titin truncation caused the missing link between sarcomerogenesis and adaptive remodeling [119] (Fig. 32.6L–O).

Diabetes-related cardiomyopathy

Engineered heart tissue has been used by Song et al. to study diabetes-related cardiomyopathy and the effect of drug therapy on diabetic engineered heart tissues [120]. Briefly, the diabetic rat heart treated with high concentration of glucose exhibited diminishing electrophysiological properties and increased ratio of myosin heavy chain isoform β to α, both of which were indications of diseased states of the heart.

Chronic hypertension induced left ventricle hypertrophy

Chronic hypertension is a well-known risk factor for left ventricular hypertrophy. To model this polygenic disease, cardiac tissues were made with six patient–specific cell lines from hypertensive patients, only three of which experienced left ventricle hypertrophy. Zhao et al. designed an 8-month long electrical stimulation protocol to first serve as a maturation protocol and then chronic cardiac overload to simulate hypertension (Fig. 32.6P). After the protocol, only the tissues from patients with left ventricle hypertrophy had completely seized contraction, while others retained some level of contraction with electrical pacing (Fig. 32.6Q). The tissue model with specialized electrical conditioning successfully manifests the disease phenotypes, in terms of function and genetic profiles. Many polygenic diseases only display disease phenotypes after reaching adulthood, which requires significant CM maturation in vitro [87].

Barth syndrome

Barth syndrome is a mitochondrial disorder caused by a genetic mutation of the Tafazzin, which can lead to mitochondrial cardiomyopathy. Using patient-specific CMs, disease phenotypes manifested through metabolic, structural, and functional abnormalities. To be more specific, the diseased tissue models have smaller mitochondria, much lower metabolic activity, and abnormal sarcomerogenesis, which has been fully resolved in isogenic cell line–derived tissues. Therefore the study successfully recapitulates Barth syndrome with an in vitro tissue model to study the disease mechanisms [121].

Tissue engineering as a platform for pharmacologic studies

Given the active nature of cardiac tissue, new methods have been developed to study the function of engineered cardiac tissues in multiplexed in vitro systems [122]. Particularly, Schaaf et al. cast hESC-derived CMs in fibrin across a 24-well format that allowed the real-time measurement of force generation [123]. This system was then used to examine the effect of various proarrhythmic drugs (e.g., E-4031, quinidine, procainamide) on the beating dynamics of the heart tissue. As expected from the known electrophysiological effects of the drugs, the engineered tissues displayed irregular beating at low relaxation velocities.

In a similar fashion the Biowire platform also enables cultivation of miniaturized, high fidelity cardiac tissues and high-content online functional readouts to facilitate drug screening and toxicity evaluation [87]. In addition to commonly tested proarrhythmic drugs (e.g., E-4031) and currently used therapeutic drugs (isoproterenol, lidocaine, milrinone, diltiazem, nifedipine, and thapsigargin), Wang et al. used their preestablished fibrotic tissue model to screen a group of small molecule candidates for their antifibrotic potential. The results had preliminary success in that one small molecule candidate exhibited a significant antifibrotic tendency and significantly reduced the collagen content in the fibrotic cardiac tissue [119]. In another study, cardiac tissue model of Barth syndrome was also used to find a therapeutic target. By assessing ATP levels and mitochondrial function, linoleic acid would be the ideal candidate to correct the metabolic phenotype of Barth syndrome iPSC-CMs [121].

In a separate study, sheets of engineered cardiac tissues were fabricated in a similarly multiplexed format, which allowed the measurement of stress exerted by the cells [124]. Myocytes were seeded on a micropatterned surface to facilitate alignment of CMs. The system was imaging compatible, allowing for the quantification of

images or videos to determine contractility, action potential propagation, and cytoskeletal architecture.

Summary and challenges

When considering all the challenges facing the field and the methods which individual groups use to find answers, it becomes obvious that the biggest obstacle that must be overcome is better standardization of experimental and measurement techniques as well as properly defining the level of cardiac regeneration after insult (functional, morphological, etc.) deemed to be successful. The reasons for this are clear when one considers the results reported by different groups. While it seems that all of the in vivo models discussed are similar, rarely can a direct comparison between results be done. All discussed studies report significant improvement in function; however, looking at ejection fraction alone groups reported anything from ~12% to 77% difference between the treatment group and MI-only as being significant and clinically relevant [33,113,114,125–129]. One could argue that the greatest improvement corresponds to the best system. However, when one examines different models discrepancies regarding timing of application of cells and tissues, different animal models and evaluation become obvious.

Introduction

In the early 1900s, Alexis Carrel first described the utility and limitations of autogenous and synthetic grafts, including the unique challenges of small-diameter synthetic grafts. Fifty years later, Voorhees et al. first utilized a vascular graft for larger artery replacement [1]. In 2019 small-diameter synthetic grafts continue to have worsened long-term patency rates compared to autogenous vessels.

Since patients with cardiovascular disease are living longer, there is a growing need for more vascular interventions. Annually, there are between 600,000 and 1.4 million bypass operations in the United States, and this number has remained stable in recent years. There has also been a significant growth in endovascular procedures (e.g., angioplasty and stenting) for the lower extremity, together these efforts have correlated with a decrease in major amputations [2]. Despite periprocedural benefits of endovascular approaches (decreased early mortality and morbidity), endovascular procedures have inferior durability. Thus there remains a critical need to create small vessel vascular conduits and to apply bioengineering approaches to endovascular therapies to improve the effectiveness of all vascular interventions for the treatment of cardiovascular disease and injury in patients.

This chapter discusses the native vasculature, clinically available and experimental bypass grafts, including tissue-engineered vascular grafts (TEVG), and modifications of these grafts to facilitate healing, function, and efficacy.

Normal and pathologic composition of the vessel wall

For arteries, the intima (tunica intima) is composed of a relatively quiescent endothelial cell (EC) monolayer and its surrounding basement membrane proteins (e.g., type IV collagen, perlecan). Together with the underlying internal elastic lamina, the intima maintains vascular smooth muscle cells (VSMCs) in their contractile state and inhibits pathologic VSMC activity. Deep to the intima and separated by the internal elastic lamina is the medial layer (tunica media). It is the thickest arterial layer, and in nonpathologic states it is composed of VSMCs and many extracellular matrix (ECM) proteins (e.g., elastin and the fibrillar collagens such as type I collagen). Medial VSMCs here respond to intimal cues to dilate or contract the vessel. The medial layer in veins is difficult to define because it lacks an internal elastic lamina and has limited VSMCs, but after exposure to arterial flow via vein graft bypass, there is robust proliferation of VSMCs in the media of veins that approximates that of native arteries [3]. The external elastic lamina defines the abluminal edge of the media, and the vaso vasorum is prominent in the outer adventitial vessel layer (tunica adventitia). This vaso vasorum provides for the metabolic needs of approximately the outer two-thirds of the vessel wall. The adventitia is composed of loosely arranged connective tissue and fibroblasts, along with some progenitor cells [4], and it may play an important role in the progression of restenosis and late interventional failure after angioplasty. This is inferred from more favorable vessel remodeling after adventitial delivery of therapeutics [5].

In the absence of disease or injury, native blood vessels possess an endothelial lining that constantly secretes bioactive substances promoting fibrinolysis and inhibiting thrombosis and VSMCs switching from a contractile to synthetic phenotype [6]. In addition, the artery is more than a pipe. It is a complex tissue that responds (radially and longitudinally) to the three components of the cardiac cycle to accommodate the systolic flow bolus of blood,

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00034-4

provide resistance to maintain blood pressure during early diastole, and then propulse blood distally during late diastole. This latter phase is the only part of arterial flow dependent on the artery rather than the heart and is critical to maintaining communication between the heart and the tissue beds.

Developmental biology cues important in vascular tissue engineering

During development artery and venous identity is quickly decided by a complex and highly orders series of signaling and mechanical stress-mediated molecular pathways [7]. Once determined, there are obvious and lasting matricellular differences between arteries and veins that are important to this chapter's focus on blood vessels and blood vessel replacement strategies.

Key among these differences is the completeness of the medial layer and the mechanical differences due to the amount and orientation of elastin [8]. The undisturbed vein has vastly different solid mechanics than the artery, and the adventitial collagen is the key component of vein mechanics. This collagen enables veins to withstand great pressures (such as those generated by standing) [9]. However, the pulsatility or hysteresis of veins is lost at ~25 mmHg, and veins require skeletal muscles to extrinsically push the blood from the lower extremities toward the heart. In contrast, healthy arteries keep pulsatility at arterial pressures. This is due in large part to Windkessel effect, which is functionally derived by the elastin content and orientation [10].

Unfortunately as we age, both arteries and veins do not deposit more elastin. In fact, elastin degradation is the rule with aging [11,12]. With aging, vessels do develop more collagen, creating a stiffened phenotype that impacts cell biology and perfusion of target tissues [13,14].

Vessels, particularly arteries, are known to contain and attract progenitor and immune cells in their walls. These cells interact with the more prominent endothelial (intima), VSMCs (media), and fibroblasts (adventitia) to mediate homeostatic changes in the vessel wall thickness and remodeling cues, including axial and radial growth or shortening [15,16].

Conduits

Arteries

Few autogenous arteries are available for use as conduits due to the lack of redundant arteries in the body, and the lengths of available arteries limit their use to the short bypasses in the coronary circulation. In cardiac surgery, the use of the internal mammary artery has outstanding long-term patency rates that far exceed that of vein grafts [17]. The benefit is less clear when different arteries (e.g., radial artery) are used for coronary bypass grafting harvesting [18]. The theoretic advantage of using arteries over veins is that arteries have already been functioning under arterial flow conditions, whereas veins need to "arterialize" after exposure to arterial flow. However, all bypass targets are not identical, and graft remodeling is also determined in part by the hemodynamics of the perfusion bed as demonstrated with vein grafts to the myocardium of the heart compared to the skeletal muscle of the lower extremity in nonhuman primates [19].

Veins

Superficial and deep veins can be utilized as conduits for arterial bypass, but superficial veins are better tolerated and more commonly used. The benefit of veins over synthetic grafts for small-diameter graft bypasses is well known for most bypasses [20]. The greater saphenous vein is the most commonly used conduit for coronary and infrainguinal bypass grafting, and it is duplicated in ~8% of persons [21]. The lesser saphenous vein is shorter in length and not easily accessible in the supine position, but it can be useful as a conduit when working posteriorly or through a separate harvest incision [22–24]. Cephalic veins can also be used but due to their decreased length, they are often spliced together for long bypasses after a bilateral arm vein harvest [25,26].

Once implanted, veins arterialize, and the ECs in the vein appear to lose their venous identity but they do not gain arterial identity [27], which may contribute to vein graft failure rates. Since vein graft arterialization stimulates desirable and undesirable biologic responses, it is not surprising that a number of vein grafts fail or require adjunctive procedures to maintain patency (Fig. 33.1). The mode of failure is more prominent at certain times after implantation. Initially, vein graft failure is usually technical, that is, related to the technical aspects of the implant procedure. Between 2 months and 2 years, failure usually is from myointimal hyperplasia (frequently at anastomotic or valve sites), and after 2 years, it is most commonly due to progression of atherosclerosis in the inflow and/or outflow arteries, or in the vein graft proper.

Current status of grafts in patients

Conduit patency and failure

The results of the PREVENT III and IV trials, which tried to arrest vein graft proliferation, have demonstrated that vein graft failure is relatively common and similar after both infrainguinal and coronary revascularizations [28,29]. And the primary patency rates for infrainguinal bypass are strikingly similar to those reported more than

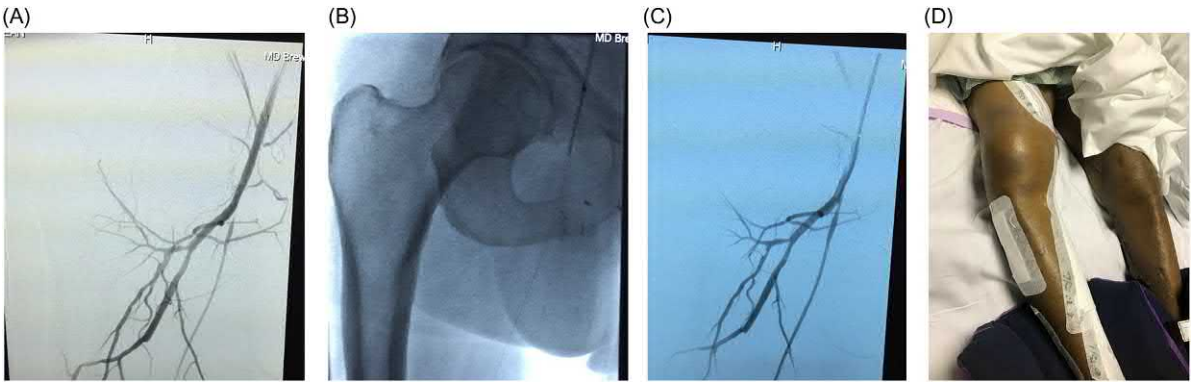

FIGURE 33.1 Vascular interventions. (A) Vein graft stenosis (*denoted by arrow*) just distal to the proximal anastomosis. (B) Angioplasty balloon delivery to area of stenosis. (C) Satisfactory resolution of vein graft stenosis post angioplasty. (D) Bandages mark incisions for saphenous vein harvest and use in a femoral to anterior tibial artery bypass in a patient with severe PAD. *PAD*, Peripheral arterial disease.

30 years ago [20]. However secondary patency rates are better, emphasizing the importance of vein graft surveillance.

A variety of mechanisms can also lead to synthetic vascular graft occlusion. Immediate graft failure is usually the result of technical error from the operation or the patient having a hypercoagulable status; failure in the first month following graft placement is most likely the result of thrombosis secondary to poor distal blood flow. Smaller-diameter grafts have lower flow velocities that are thought to promote thrombosis and make them particularly susceptible to anastomotic myointimal hyperplasia (IH). Thus graft thrombogenicity is an enduring concern for vascular grafts. Anastomotic pseudointimal hyperplasia is the most common reason for graft failure from 6 months to 3 years after graft insertion, and later graft failure is frequent due to the progression of distal atherosclerotic disease. Pathophysiologically, injured intima or exposed luminal area of a graft may lead to thrombosis via platelet deposition and activation of the coagulation cascade, and over time it promotes pathologic smooth muscle cell (SMC) migration, proliferation, and ECM deposition, leading to IH. IH in turn narrows the vessel lumen (restenosis) disturbing blood flow to the point that it may occlude, thrombose, or cause symptomatic ischemia in the relevant distal end organs such as the brain (stroke), heart (myocardial infarctions), and extremities (acute or critical limb ischemia).

Venous reconstruction

Ring-reinforced expanded polytetrafluoroethylene (ePTFE) grafts are commonly used for large-caliber venous replacements in unusual circumstances, such as the replacement or bypass of the inferior or superior vena cava [30–33], iliofemoral, jugular [34], and portal vein [35] or the construction of portosystemic shunts for portal hypertension [36,37]. The ring-reinforcement in theory resists respiratory compression better and thus prevents graft collapse that may be a factor in promotion of thrombosis. However, no comparative study with nonringed grafts has been done and is not feasible given the small numbers of patients in even the largest reports with these procedures. A temporary arterial graft to these venous reconstructions may improve their patency [38].

Breuer and Shinoka have now implanted their bioengineered vena cava replacement into 25 patients. With an average follow-up of 11 years, they have had no graft-related mortality, and the seven stenotic grafts identified were all successfully treated with balloon angioplasty [39]. This exciting success in children may have broadening impact on developing bioengineered grafts for clinical use in other anatomic locations.

Hemodialysis vascular access

Typically, long-term access to the vascular system for hemodialysis is provided by an arteriovenous (AV) fistula or an AV graft. Synthetic AV grafts account for approximately half of all permanent grafts placed in patients with incident end-stage renal disease in the United States. However, only 26% of them remain patent without complication 2 years after placement [40]. The secondary 3-year patency is better at 42%–60% [41–43]. The failure of synthetic AV grafts is often associated with stenosis at the venous outflow anastomosis, which leads to subsequent thrombosis. Again, infection is the most dreaded risk of synthetic graft use for hemodialysis. This population is particularly susceptible to infection because renal failure suppresses the immune system, and there is a potential for graft contamination at each dialysis session.

ePTFE grafts are usually the synthetic choice for dialysis access when a primary AV fistula for hemodialysis cannot be performed or has failed. Dacron grafts often

have patency, bleeding, and wall integrity difficulties. Various modified grafts have been studied for many years in an attempt to improve the performance of the synthetic grafts for the angioaccess application. The modifications to synthetic materials have included changing the wall structure, adding luminal or extramural coatings, and incorporating additional layers to limit postdialysis bleeding. ePTFE can be modified into a stretch, thin, or thickened wall configuration that certainly affects handling but may also impact graft function over time [44].

Dialysis access grafts procedures require a period of time after implantation prior to use. Autogenous AV fistulas typically require a maturation period of 6 weeks to 2 months before first cannulation, whereas synthetic grafts are typically delayed 2–4 weeks prior to access to permit incorporation of the graft into the surrounding tissue. There are a couple of grafts on the market that are designed for earlier access. The Flixene, Avflo, Acuseal, and Vectra are examples. Primary patency rates for these grafts are generally poor but secondary patency rates are acceptable [45]. The handling of these grafts is also technically more challenging as they are more rigid than standard hemodialysis grafts [46].

Inflammation and the host response to interventions and grafts

The inflammatory response to vascular interventions is complex because these patients have systemic inflammation, which may influence the degree and direction of local inflammation. Potent chemoattractants such as complement 5a (C5a) and leukotriene B_4 recruit neutrophils to the graft surface where they localize in the fibrin coagulum of the graft's inner and outer capsule via β2 integrins. Also, IgG binds to the neutrophils' Fcγ receptors activating neutrophils' proinflammatory response while inhibiting normal clearance of bacteria. Control of neutrophil response (and Netosis) may have great benefits in vascular tissue engineering applications [47]. Neutrophils also interact with various other deposited proteins, including C3bi and factor X, and they adhere to the ECs in the perianastomotic region through selectin- and integrin-mediated mechanisms. L-selectin is thought to modulate neutrophil/EC interactions by presenting neutrophil ligands to both E- and P-selectin on the vascular endothelium. In addition, selectin–carbohydrate bonds are important for the initial cellular contact while the integrin–peptide bonds are responsible for strengthening this adhesion, as well as the transmigration of neutrophils. Both intercellular adhesion molecular-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on the EC surface bind these integrins as well, and ECs upregulate ICAM-1 and express VCAM-1 when stimulated by inflammatory agonists such as interleukin (IL)-1, tumor necrosis factor (TNF), lipopolysaccharide, and thrombin. Further, activated neutrophils release oxygen-free radicals and various proteases, which result in matrix degradation and may inhibit both endothelialization and tissue incorporation of the vascular tissue and grafts [48].

Circulating monocytes/macrophages are also attracted to areas of injured or regenerating endothelium, especially in response to IL-1 and TNF-α. There are many plasma monocyte recruitment and activating factors, including LTB_4, platelet factor 4, and platelet-derived growth factor (PDGF). This process is propagated in the presence of these plasma activating factors, driving monocytes to differentiate into macrophages that direct the host's chronic inflammatory response via the release of proteases and oxygen-free radicals. They also are thought to be critical to promoting arteriogenesis via monocyte chemotractant protein-1.

A variety of cytokines are released from the inflammatory cells activated by vascular grafts. Lactide/glycolide grafts are composed of bioresorbable materials that are phagocytosed by macrophages; in culture these materials stimulate macrophages to release mitogens that stimulate vascular cells. This mitogenic activity appears to be related to the secretion of fibroblast growth factor (FGF)-2 since pretreatment of the culture media with a neutralizing anti-FGF-2 antibody significantly diminishes the stimulatory effect on SMC growth in culture [49]. Cultured monocytes and macrophages incubated with Dacron and ePTFE have been demonstrated to produce different amounts of IL-1β, IL-6, and TNF-α that are biomaterial specific [50]. TNF-α is one of the factors that may contribute to the enhanced proliferation of SMCs caused by leukocyte-biomaterial interactions, while IL-1 may be partly responsible for the increased SMC proliferation caused by leukocyte-EC reaction. IL-1 also induces upregulation of insulin-like growth factor-1 expression in ECs, and coculture of neutrophils with IL-1β-treated ECs dramatically increases PDGF release.

It is attractive to think that the host inflammatory response can be manipulated to promote favorable cellular and protein responses with the goal of promoting autogenous ingrowth of TEVGs. Recently, Shinoka and Breuer have demonstrated that the populating cells can be manipulated by modifying the homing cells with angiogotensin inhibitors [51]. Since the inflammatory reaction elicits a cascade of growth processes, it has also been proposed that approaches attenuating the initial inflammatory reaction may improve long-term graft patency. Over time certain inflammatory and profibrotic responses limit the long-term patency of vein grafts [52–54] and can promote a more aggressive atherosclerosis via endothelial to mesenchymal transition [55]. Excitingly focused antiinflammatory interventions may be able to counter this

inflammatory process [56]. Similar inflammatory processes are likely involved in arterial disease. We have recently demonstrated that flow-mediated arterial stiffening occurs through specific and reversible profibrotic pathways in both mice and patients with peripheral arterial disease (PAD) [57], and now for the first time, investigators have demonstrated that antiinflammatory medication can decrease cardiovascular events such as strokes and heart attacks [58]. These pathways are likely also important to AV fistula and biologic graft function [51,59], and clinically available blockade of angiotensin signaling pathways may limit this process [51].

Host environment and the critical role of the endothelium

It is well known that smoking, diabetes, renal disease, and atherosclerosis all have a significant effect on blood vessels (Fig. 33.2), so it is not surprising that these conditions also affect bioengineered vessel remodeling [60,61] through aneurysm [62,63] and calcification [64,65]. Unfortunately, the lack of clinically relevant and aged animal models has limited solution-based testing of TEVG in these specific diseases.

Arteriogenesis or the growth of existing collateral arteries is one promising way of improving perfusion in persons with obstructive vascular disease. Newer models of arteriogenesis may be useful in translating effective strategies of this approach [66]. However, the more clinically relevant the animal models are, the less arteriogenic capacity exists [67].

Since thrombogenicity and intimal hyperplasia represent the most common causes of graft failure and are both mediated at the luminal interface of the vessel or graft, the inner lining of grafts has been the subject of much investigation. Unfortunately, and unlike most animal models in use that spontaneously endothelialize synthetic grafts, humans manifest only limited EC ingrowth not extending beyond 1−2 cm of both anastomoses. However, endothelial islands have been described in the midportions of grafts at significant distances from the anastomosis, suggesting that other EC sources for graft endothelialization may exist. Interstitial tissue ingrowth accompanied by microvessels from the perigraft tissue is one potential source. There is also evidence that circulating ECs, endothelial progenitor cells (EPCs), or stem cells can be directed to these areas. Such homing can be promoted through affixation of EC attractant antibodies to the grafts in a similar fashion to that utilized in coronary artery stents [68].

However, ECs growing on synthetic graft surfaces are not necessarily the same as their normal quiescent counterparts in uninjured vessels. These ECs are often "activated," secreting bioactive substances (e.g., PDGF) that actually promote thrombogenesis and changes in SMC phenotype. This has been seen in the perianastomotic region, which is the most frequent site of interventional failure after implantation. SMCs found within the myointima of synthetic grafts are also functionally altered. They produce significantly higher amounts of PDGF, as well as various ECM proteins, compared to those of the adjacent vessel, which along with the body's inflammatory reaction to synthetic material, contribute to the development of intimal hyperplasia [69]. Incomplete luminal surface cellular coverage can be found at the mid-region of synthetic grafts, even years after implantation [70,71].

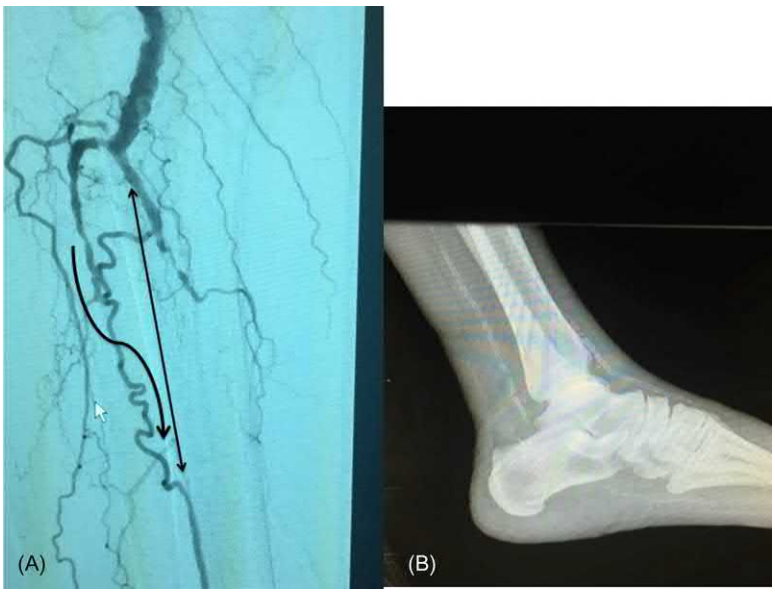

FIGURE 33.2 Vascular pathology in PAD. (A) Severe obstructive PAD in a diabetic patient. Tibial arteries are all occluded proximally. Arteriogenic (*curved arrow*) collaterals have developed to link proximal blood flow to distal peroneal artery (*straight arrow*). (B) Calcified arteries are evident in plain X-ray of the foot in an end stage renal disease patient. *PAD*, Peripheral arterial disease.

Prevalent grafts in clinical use

Cryovessels

Cryopreserved allografts provide an alternative to femoral vein harvest or antibiotic soaked Dacron with omental flap coverage for infected aortoiliac reconstruction [72]. They have also been reported to provide acceptable limb salvage rates. However, their exceptionally poor primary patency rates for infrainguinal bypass [73–75], even with immunosuppressive therapy [76], and tendency toward aneurysmal dilation and blowout limit the use of these conduits to patients without leg or arm vein and the presence of infection.

Synthetic grafts

Readily available large diameter synthetic grafts exposed to high flow conditions, such as those used for aortic reconstruction, have a superb 5-year patency rates (~80%) [77]. Conversely, when small-diameter synthetic grafts are used in lower flow environments such as the infrapopliteal region, the results are poor with 1- and 3-year patency rates for of 43% and 30%, respectively [20]. Since we cannot change to flow environments of different arterial beds, work has been done to better match the graft to the vessel size and flow environment.

Polyethylene terephthalate (PET or Dacron) and ePTFE are the predominant materials currently used in synthetic vascular grafts. Both Dacron and ePTFE react with blood components and perigraft tissues in clinically desirable and undesirable manners. In fact, all grafts, regardless of their composition and structure, evoke complex but predictable host responses that begin immediately upon restoration of perfusion.

Dacron

Dacron was first introduced in 1939, and it was patented by DuPont as Dacron fiber in 1950. Vascular grafts made from Dacron were adopted early by Julian and DeBakey [78,79]. Clinically available Dacron grafts are fabricated in either woven or knitted forms. In woven grafts, the multifilament Dacron threads are fabricated in an over-and-under pattern in both lengthwise (warp) and circumferential (weft) directions. This structure results in limited porosity but the best dimensional stability of the finished grafts. Accordingly, woven grafts have less bleeding through interstices and less likelihood of structural deformation after implantation. Knitted grafts employ a textile technique in which the Dacron threads are looped to form a continuous interlocking chain. Crimping technique is utilized to increase flexibility, distension, and kink resistance of textile grafts. Crimping can decrease thrombogenecity of vascular grafts [80]. Crimping may also reduce the effective internal diameter of the graft and creates an uneven luminal surface. The latter can potentially interfere with laminar blood flow that leads to increased thrombogenicity of the graft. While such considerations may not be critical in large-diameter grafts, it is very important in small-diameter situations. As a result, synthetic rings or coils are applied to the external surface of grafts to provide external support to resist kinking and mechanical compression.

Dacron grafts, especially knitted grafts, are prone to dilate when implanted into the arterial environment. A 10%–20% increase in graft size upon restoration of blood flow is considered to be in expected range. Direct relationship between uncomplicated graft dilatation and structural failure has not been established. Consequently, there is no recommendation on a specific degree of dilation that constitutes a significant hazard and warrants graft replacement.

After implantation, a coagulum containing fibrin, platelets, and blood cells builds up during first few hours to days and stabilizes over a period of 6–18 months forming a compacted layer. The histological characteristics observed within Dacron grafts are a compact fibrin layer on the blood contacting surface and densely packed foreign body giant cells between the outer layer of graft wall and surrounding connective tissue capsule. The fibrin layer within the midgraft portion remains acellular regardless of whether the grafts are woven or knitted. Protein impregnation changes the surface properties of Dacron grafts and may induce more inflammatory reaction but does not change the clinical patency rates of these grafts.

Expanded polytetrafluoroethylene

PTFE was patented by DuPont in 1937 as Teflon, but its use as a vascular graft occurred in the 1960s as ePTFE. Bard and WL Gore have recently settled this patent case with each owning part of the ePTFE patent. Interestingly, this patent lawsuit has lasted from the 1970s into 2010s and may not be over yet [81].

The PTFE molecule is biostable and the graft made from it does not undergo biological deterioration within the body. The surface of the graft is electro-negative, which minimizes its reaction with blood components. ePTFE grafts are manufactured by stretching a melt-extruded solid polymer tube that then cracks into a non-textile porous tube. The characteristic structure of ePTFE is a node-fibril structure in which solid nodes connect through fine fibrils with average internodal distance (IND) of 30 μm for standard graft.

The initial host response to ePTFE grafts is similar to that of Dacron grafts [82]. A fibrin coagulum or amorphous platelet-rich material develops over a time sequence similar in both materials (Fig. 33.3). Interestingly, ePTFE may have some comparative resistance to certain infections in vascular procedures [83].

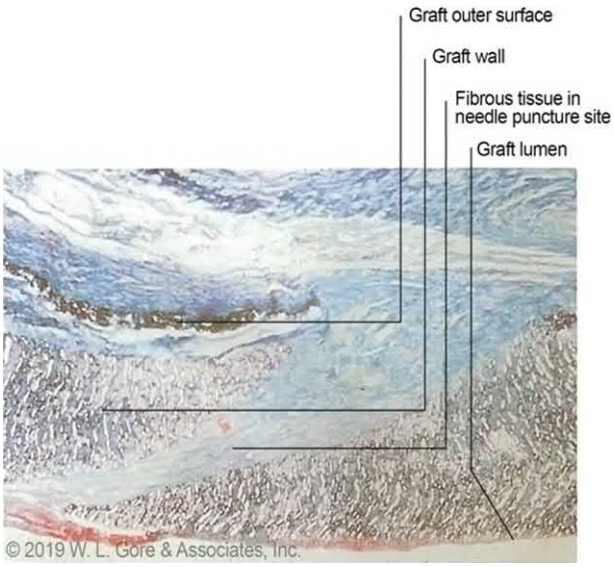

FIGURE 33.3 GORE-TEX integration. Representative image of host response to a needle entry site. Over time fibrous tissue incorporates into prosthetic grafts. *Image has not been previously published and is provided for use in this Chapter by W.L. Gore and Associates.*

Our improved understanding of these cellular and molecular components of biomaterial/tissue interactions has led many to pursue more intelligent designs of grafts that maximize beneficial ingrowth while minimizing the chronic inflammatory changes that lead to graft dilation or occlusion. These approaches include protein adsorptive grafts (growth factors, anticoagulants, antibiotics, etc.) as well as improved graft skeletal construction via synthetic polymers or biologically derived structural proteins that can be bonded to various bioactive cytokines and growth factors to induce a more favorable host response.

Vascular tissue engineering

Early efforts—in vitro tissue-engineered vascular grafts

Weinberg and Bell were the first to develop a TEVG in vitro [84]. Using collagen and cultured bovine vascular cells, they demonstrated the feasibility of creating a TEVG, but their graft had prohibitively low burst pressures, requiring external Dacron support. In the following decade, L'Heureux et al. constructed a human blood vessel with an acceptable burst strength and a thromboresistant endothelium in vitro using cultured umbilical cord-derived human cells [85], but because of the immunogenic effects of the heterogeneic ECs in vivo, this graft devoid of ECs had only a 50% patency rate at 8 weeks in a canine model. Since neonatal cells have a greater regenerative capacity, the above TEVG was not considered applicable to the aged population, who will derive the greatest benefit from a TEVG. In recent years, considerable progress has been made in the development and testing of TEVG.

Endothelial cell seeding

The prototype TEVG was created by seeding ECs onto ePTFE grafts in vitro, and then implanting them clinically. A confluent EC monolayer can prevent the development of myointimal hyperplasia by

1. preventing the deposition of platelets that release bioactive factors responsible for SMC migration, proliferation, and production of ECM;
2. maintaining a mechanical barrier to VSMC invasion via intimal basement membrane and the internal elastic lamina; and
3. assuming a quiescent EC phenotype that does not stimulate SMC activity.

In 1978 Herring et al. [86] first reported that EC seeding onto a graft surface enhanced graft survival in animal models. It was quickly discovered that the kinetics of EC loss following seeding showed that between 20% and 70% of initially adherent cells are lost during the first hour and as few as 5% were retained after 24 hours [87]. Retained cells at least partially compensate for the cell loss by migration and proliferation. Preconditioning the seeded EC monolayer with graded shear stress promotes reorganization of the EC cytoskeleton and production of ECM, which in turn enhances the EC retention at flow exposure [88]. In addition, Dacron and polyurethane have better cell attachment rates than ePTFE.

To maximize immediate cell inoculation density, a two-stage seeding procedure can be performed in which ECs are harvested, allowed one to proliferate in vitro to sufficient numbers, and then seeded and grown to confluence on the vascular graft prior to implantation. The disadvantages of this technique include the increased potential for contamination, the alterating of EC phenotype and function, the requirement of a 3–4 weeks waiting period for expansion of the cell population, and the necessity for two distinct procedures (first vein harvest for ECs; second the bypass). Zilla et al. demonstrated increased patency and decreased platelet deposition in clinically implanted EC-seeded (two-stage approach) ePTFE femoropopliteal bypass grafts over 3 years as compared to unseeded grafts, and this group more recently reported an overall 7-year primary patency rate of 62.8% for 153 endothelialized femoropopliteal ePTFE grafts [89]; this is comparable to the patency rate of saphenous vein grafts in this region. However, the seeded grafts have not been reproducibly shown to significantly reduce anastomotic pseudointimal hyperplasia. Despite the safety and efficacy demonstrated with this approach,

current use of this technology has been limited by stricter regulatory requirements.

There are also concerns about the ultimate function of those ECs on the graft surface, the cells having been injured by the process of manipulation and/or exposure to a nonphysiologic environment. Unlike their uninjured counterparts, injured ECs produce a variety of procoagulants such as von Willebrand Factor (vWF), plasminogen activator inhibitor, thrombospondin, and collagen. Higher levels of PDGF and bFGF have also been measured in EC-seeded grafts; this is particularly concerning, given their potential role in stimulating the migration and proliferation of SMCs, which can lead to IH.

In vitro approaches to tissue-engineered vascular grafts

The two main components of engineered arteries de novo are the cells and their scaffolds. There is much discussion about the proper cells to use for cell seeding ex vivo or cell homing in vivo. The EC is the most fastidious vascular cell to grow, and heterogenous ECs are highly immunogenic. Therefore in the absence of immunosuppression or genetic modification, autogenous ECs are thought to be a requirement for TEVG. TEVG media and adventitia can also be created by using vascular SMCs or fibroblasts with or without exogenous matrix scaffolding. These cells can be harvested from the patient in need, but since these patients are typically older with significant comorbidities, their cells (particularly VSMC and ECs) may not retain sufficient doubling capacity required to generate these TEVGs.

Niklason's approach of using healthy donor fibroblasts as the cell source obviates the challenges with autogenous but aged tissue that she has reported prior [90–92]. While quite a U-turn from prior work in cardiovascular tissue engineering, decellularized tissue scaffolds are appealing because they are already composed of native vascular ECM proteins that exhibit reasonable structural characteristics as well as providing instructive cues for cellular ingrowth. This is the current approach of Niklason's company, Humacyte, which is currently finishing phase 3 data collection with their TEVG as a hemodialysis conduit. It is an ECM derived from fibroblasts that are removed prior to processing the tissue (an acellular graft). These authors have recently published a certain degree of autogenous cell integration over time with progenitor cells in this construct when used for hemodialysis access [93] (Fig. 33.4).

L'Heureux et al. also created a suitable TEVG [94] that was shown to be a reasonable alternative for

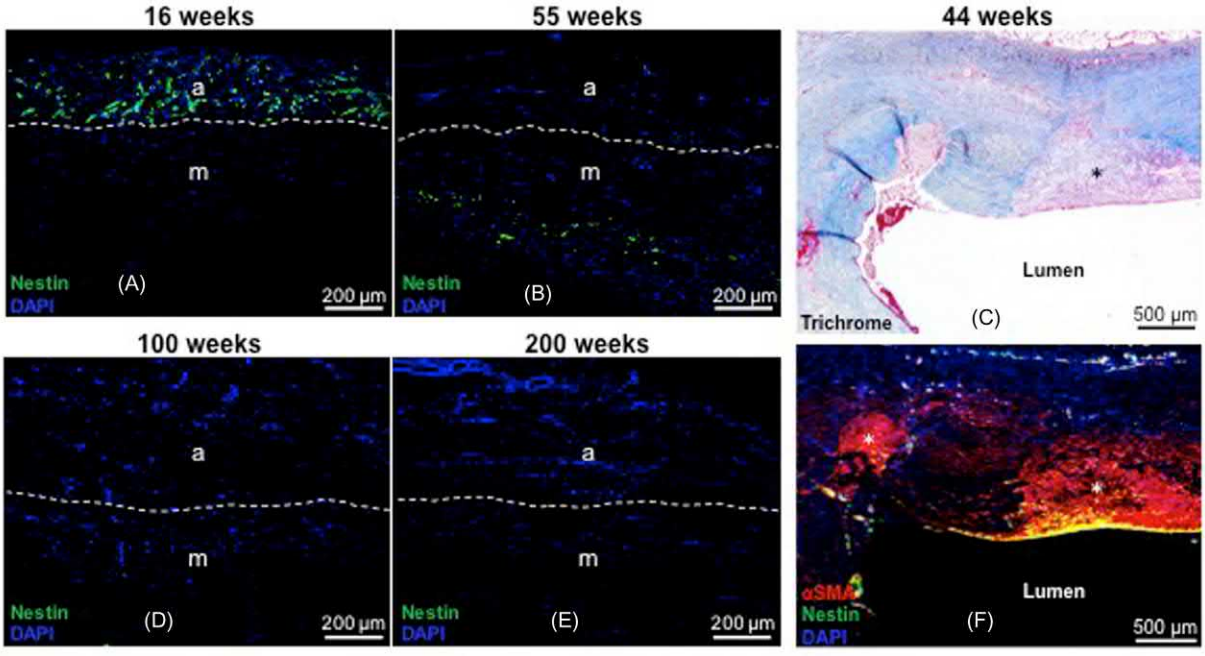

FIGURE 33.4 Autogenous cellular population of TEBV in dialysis patients. Representative immunohistochemistry and histologic stains of a TEBV from different patients harvest during reoperation at different time points. Nestin is represented in fluorescent green and DAPI in blue. (A and B) Nestin + progenitor cells are seen in two different TEBVs at 16 and 55 weeks after implantation. (C and F) Trichrome staining demonstrating "healing" of a needle puncture site. IHC staining demonstrating smooth muscle actin and Nestin + staining in the "healing" needle track. (D and E) Lack of Nestin + staining at 100 and 200 weeks after implantation. *TEBV*, Tissue engineered blood vessel; *IHC*, immunohistochemistry. *Image has not been previously published and was provided for this chapter by Laura Niklason's research group.*

hemodialysis use [95,96]. The L'Heureux laboratory has now demonstrated that critical components of the ECM are maintained during the devitalization process [97], which will likely be useful in developing and delivering novel devitalized cardiovascular tissue.

Using biologic gels, such as those composed of type I collagen or fibrin, one can promote tissue ingrowth and direct remodeling in a bioreactor, thereby promoting favorable characteristics such as improved mechanical strength or vessel reactivity over time [98]; these approaches are easily modified by the addition of growth factors with refined delivery systems in order to enhance and sustain cellular ingrowth [99]. Further refinement of these scaffolds can mimic the differential mechanical properties of the intimal and medial arterial layers. Syedian et al. reported development of TEVG from neonatal fibroblasts in a fibrin gel [100]. This promising approach has been updated recently with preclinical patency rates similar to that of some synthetic grafts [101], and the clinical testing of this approach is likely.

In vivo tissue-engineered vascular grafts

Current clinically available synthetic vascular grafts, composed of ePTFE, Dacron, or polyurethane are permanent prostheses within the host after implantation. Theoretically, it is possible with bioresorbable materials to stimulate a rapid and controlled ingrowth of tissue to assume the load bearing, sufficient for resistance to dilation, and to incorporate cellular and extracellular components with desirable physiologic characteristics to form a new artery in vivo, whereby the synthetic material itself would cease to be necessary following tissue ingrowth. Still, the limited regenerative capacity of aged or diseased cells discussed above may also compromise cellular ingrowth in vivo.

Bioresorbable grafts

Aneurysmal dilatation of bioresorbable grafts is the major limitation of this promising approach. This is due to the degradation of the graft material outpacing autogenous cellularization of the construct. The first published report of a fully bioresorbable graft was by Bowald et al. [102] and described the use of a rolled sheet of Vicryl (a copolymer of polyglycolide and polylactide). We have reported that 10% of woven polyglycolic acid (PGA) grafts have aneurysmal dilation within the first 3 months after implantation, but that this does not increase over the next 9 months, suggesting that the critical time for the development of aneurysms is during material resorption prior to the ingrowth of tissue. These studies also demonstrated the ability of bioresorbable grafts to support sufficient cellular ingrowth. Here, 4 weeks after implantation, these 24 mm by 4 mm grafts contained an inner capsule with a confluent layer of ECs and myofibroblasts amidst dense collagen fibers [103]. Similarly, constructed and implanted Dacron grafts demonstrated an inner capsule composed solely of fibrin coagulum with minimal cellularity. Macrophage infiltration and phagocytosis paralleled the resorption of PGA, which was totally resorbed at 3 months postimplantation.

In order to limit aneurysmal dilation, several approaches have been developed. One is to combine the bioresorbable material with a nonresorbable material in order to retain a mechanical strut. Another solution involves the combination of two or more bioresorbable materials with different resorption rates so that the more rapidly degraded material evokes a rapid tissue ingrowth while the second material provides temporary structural integrity to the graft. Third, growth factors, chemoattractants, and/or cells can be applied to the graft to enhance tissue ingrowth, structure, and organization.

Using a more slowly resorbed compound, polydioxanone (PDS), Greisler et al. demonstrated decreased incidence (1/28) grafts exhibited aneurysmal dilation with explant times as late as 1 year. The explanted specimens of these PDS grafts also demonstrated biomechanical characteristics similar to native arteries, being able to withstand static bursting pressures of 6000 and 2000 mmHg mean pulsatile pressure without fatigue [104].

Using the differentially resorbed approach with composite grafts woven from yarns of 74% PG910 and 26% PDS, we reported a 1-year patency rate of 100% with no aneurysms in a healthy rabbit aorta model. The PG910 was totally resorbed by 2 months and the PDS by 6 months. The regenerated arteries withstood 800 mmHg of pulsatile systolic pressure ex vivo without bursting, and a confluent, functional, vWF-positive EC layer over circumferentially oriented smooth muscle-like myofibroblasts formed in the inner capsule of both these grafts. Tissue ingrowth into all tested lactide/glycolide copolymeric grafts was observed to parallel the kinetics of macrophage phagocytosis and synthetic resorption. In vivo, the rate of cell proliferation and collagen deposition in inner capsule also paralleled the kinetics of macrophage-mediated synthetic resorption [105].

Composite grafts constructed from yarns containing 69% PG 910 and 31% polypropylene implanted into rabbit and dog arteries demonstrated superb results without aneurysmal dilation. Galletti used Vicryl (polyglactin 910) prostheses coated with retardant polyesters to temporarily protect the Vicryl from hydrolytic and cellular degradation [106]. When implanted into the canine aorta, material resorption was seen at 4 weeks and was complete by 24 weeks. In separate experiments, another group evaluated grafts prepared from a mixture of 95% polyurethane

and 5% polylactide [107]. They found that only relatively compliant grafts that induced circumferential smooth muscle development contained elastin and remained mechanically stable without dilating. They concluded that modifications of the graft preparation, including SMC seeding, help one to enhance the optimal orientation of the SMCs and prevent aneurysm formation.

There are a number of investigators currently pursuing this approach, but this approach seems further from clinical testing than decellularized constructs [108,109].

The living bioreactor

Campbell et al. have developed a modification of the Sparks' mandrel to create a TEVG. Here they utilize the abdominal peritoneum's reaction to foreign bodies as a living bioreactor [110]. After the graft has matured, it is removed from the mandrel and inverted; this creates a TEVG with a mesothelial inner lining. This graft's resistance to aneurysmal dilatation and rupture has not yet been proven, but Rotmans' laboratory is now using this in vivo approach to create tissue-engineered conduit for hemodialysis [111]. Clinical implantations have occurred and data should be forthcoming soon.

Cellular and molecular mediators of graft outcome

Cellular recruitment

Regardless of the approach, cellular recruitment occurs in all grafts (vein, synthetic, biologic), but perhaps it is most critical in decellularized constructs. Autogenous cells cannot populate an entire scaffold by migration or proliferation alone, they must be recruited internally via circulating ECs or EPCs or externally from the surrounding tissue or exogenous source through transmural angiogenic ingrowth (outside in radially) during tissue incorporation of the graft. In addition to the benefit provided by the localization of cells to the vessel lumen, transmural ingrowth also provides for a kind of "vasa vasorum" that can provide oxygen to cells beyond the distance supplied by simple diffusion (100 μm); such a *vaso vasorum* is desirable and could be incorporated into preexisting capillary networks (inosculation). Proof of concept of this approach has been demonstrated in cardiac sheet grafts [112]. The induction of a vaso vasorum can obviously be supplemented by the delivery of angiogenic proteins or genes to these constructs. With further research, a small diameter, totally resorbable vascular graft may be useful in creating a human artery replacement.

Physical or chemical modification of current grafts to improve durability

Since thrombogenicity and IH are the most common causes of graft failure and are both mediated at the luminal interface of the vessel or graft, the inner lining of grafts has been the subject of much investigation.

Surface characteristics

The thrombotic interaction at the grafts' luminal interface is dependent on both the chemical and physical properties of the graft (e.g., surface charge, surface energy, and roughness). A negative surface charge attenuates platelet adhesion and a positive charge promotes it, while a heterogeneous charge density distribution is also thought to be thrombogenic. A myriad of approaches have been designed to limit the thrombotic reaction, including modification of surface properties, incorporation of antiplatelet or anticoagulant substances onto the graft surface, and endothelialization of the luminal surface. In addition to thrombogenic reactions to the luminal surfaces, the rate and extent of endothelialization will vary depending on the characteristics of the surface [113]. Therefore properties must be optimized for both reduced thrombogenic reaction and maximized endothelialization.

Surface modifications

The simplest modification of a graft surface is to coat it with a relatively inert polymer. Since the 1960s, it has been known that carbon coating decreases surface thrombogenicity through its negative charge and hydrophobic nature. Experimentally, the carbon-impregnated synthetic graft was found experimentally to reduce platelet deposition, but the advantage of these grafts was not confirmed in a prospective multicenter clinical study of 81 carbon-impregnated ePTFE and 79 standard ePTFE grafts for below-knee popliteal and tibial/peroneal artery bypasses. Here the investigators failed to show a significant difference in patency rate between the two groups at up to 12 months after implantation [114].

Silicone polymer coating is another approach to alter the luminal surfaces of grafts; this process produces a smooth surface that is devoid of the usual ePTFE graft permeability and texture, and when followed by plasma glow discharge polymerization, it effectively abolishes pannus tissue ingrowth as well as graft surface neointimal hyperplasia in a baboon arterial interposition graft model. Further, Nojiri et al. [115] have developed a three-layered graft consisting of PET for the outer layer (to promote perigraft tissue incorporation), nonporous polyurethane in the middle layer (to obtain a smooth surface), and a 2-hydroxyethyl methacrylate and styrene copolymer coating for the inner layer (to establish a nonthrombogenic blood interface). These grafts with an ID of 3 mm were

implanted in canine carotid arteries and remained patent for over 1 year. Only a monolayer of adsorbed proteins was described on the luminal surface of the grafts with no pannus ingrowth from the adjacent artery, no thrombus, and no endothelial lining, or neointimal formation.

Thromboresistance

Early platelet deposition on vascular grafts is mediated by vWF and platelet membrane glycoproteins. After adherence to a graft, platelets degranulate, releasing many bioactive substances, including serotonin, epinephrine, ADP, and thromboxane A2. These substances in turn activate additional platelets and promote a prothrombogenic reaction. Activated platelets also release growth factors, such as PDGF, epidermal growth factor, transforming growth factor, which promote SMC migration and proliferation as well as ECM degradation and ECM protein synthesis. In addition, platelets release monocyte chemoattractants such as platelet factor 4 and β-thromboglobulin, which mediate the recruitment of macrophages to the graft. Platelet deposition and activation continues chronically after graft implantation as evidenced by increased thromboxane levels and decreased systemic platelet counts 1 year after Dacron graft implantation in a canine model [116], and human studies have confirmed platelet adhesion to grafts up to 1 year after implantation.

Since the deposition and activation of platelets elicits various pathologic cascades, the thrombogenic nature of the synthetic graft surface can lead to both early and late graft failure. A myriad of approaches have been studied to attenuate platelet deposition, aggregation, and degranulation. Antiplatelet agents directly targeting platelet/graft-binding molecules such as platelet surface GPIIb/IIIa and different functional domains of thrombin have been shown to at least transiently decrease the accumulation of platelets on Dacron grafts [117]. Also the surface thrombogenicity of grafts can be altered experimentally as described earlier.

Similar approaches can be utilized to decrease thrombogenicity by disrupting the activation of the blood system's coagulation cascade on thrombogenic surfaces, such as cardiovascular stents and synthetic grafts. These are now commercially available in various formulations. Genetic approaches to increase thromboresistance have been employed by multiple groups through the overexpression of thrombotic inhibitors, but since ECs themselves are antithrombotic, there may be limited benefit of this approach when compared to a functioning endothelium.

Heparin bonding to Dacron and ePTFE has shown promise in lower extremity bypass but has not been useful (over standard grafts) in hemodialysis [118]. Theoretical risks of heparin bonding, including the induction of heparin-induced thrombosis, have not been seen to date [119].

Protein adsorption

Another approach is to cover vascular grafts' lumens with proteins. Protein coating has been used as an alternative to preclotting with blood to decrease the initial porosity of Dacron grafts in order to limit transmural blood loss. Knitted Dacron prostheses coated with albumin, gelatin, and collagen have all been available for clinical use. As the impregnated proteins are degraded, the graft undergoes tissue ingrowth.

The most abundant serum proteins are albumin, fibrinogen, and IgG. They adsorb to grafts almost instantaneously following exposure to the systemic circulation. Subsequently there is a redistribution of proteins, known as the Vroman effect, according to each protein's relative biochemical and electrical affinity for the graft surface and their relative abundance [120]. Since platelets and blood cells interact predominantly with the bound proteins and not with the synthetic material itself, the constitution and concentration of bound protein has profound influence over the type and degree of cellular interaction with the graft. Fibrinogen, laminin, fibronectin, and vitronectin all have an arginine−glycine−aspartate (RGD) sequence that is recognized by platelets' glycoprotein (GPIIb/IIIa) receptor and initiate platelet activation. RGD sequences are also recognized by β_2 integrin, which directs leukocyte adhesion to the graft. Additional plasma proteins, including complement components, can also be differentially activated directly by different synthetic surfaces. For example, the generation of the monocyte chemoattractant, C5a, is greater following implantation of Dacron compared to ePTFE grafts in an animal model [121]. In addition, the rapid accumulation of coagulant proteins such as thrombin and factor Xa on the luminal surface after implantation contributes to the thrombogenicity of vascular grafts.

Porosity

The prevalence of open spaces or pores determines the porosity of a scaffold or synthetic graft, while the permeability of a graft is defined by its ability to permit passage of a substance through itself. Since ePTFE is composed of a number of solid nodes interconnected by a matrix of thin fibrils with no uninterrupted transmural spaces, it is best categorized by the average distance between these nodes, which is defined as the IND. This spacing, when above approximately 5−6 μm, as is commonly used in clinically available prostheses, allows for cellular ingrowth, but transinterstitial ingrowth is not strictly a function of porosity. We have shown that the extent of ingrowth varies greatly among different biomaterials

(e.g., PGA and Dacron) despite these biomaterials having similar porosity [122].

Still, the rate of tissue ingrowth can be improved by optimizing graft porosity or permeability. Clowes et al. have demonstrated enhanced tissue ingrowth and complete reendothelialization of 60 or 90 μm IND ePTFE grafts in a baboon model [123]. However, transinterstitial capillary ingrowth was not seen with the more commonly used 30 μm IND ePTFE. Human trials using ePTFE with these expanded INDs failed to show any advantage in platelet deposition compared to the standard 30 μm IND ePTFE grafts [124].

Compliance

The compliance mismatch between arteries and grafts causes flow disruption in vivo which may contribute to anastomotic pseudointimal hyperplasia [125]. It is for this reason that various surgeons have suggested interposing a segment of vein between the synthetic graft and artery, creating a composite graft at the distal anastomosis. This has led some investigators to design more compliant grafts using more flexible materials and/or changing the parameters of graft construction to improve graft compliance. Although animal experiments have suggested concept validity, the clinical benefit of this approach remains controversial. Many factors may contribute to this confusion, including longitudinal variability in the diameter and compliance of the arterial tree and the effect of activated endothelium on intimal hyperplasia. Further, there is a robust fibrotic response after implantation that leads compliant grafts to become incompliant after implantation; thus even if a compliance match were attained initially, it would not likely persist. In the *para*-anastomotic region there are dynamic changes in compliance that vary over time. First a *para*-anastomotic hypercompliant zone exhibits a 50% gain in compliance, then later its compliance is lessened 60% from baseline [126]. It is likely that this bimodal effect limits the practical value of this approach.

Resistance to infection

Vascular graft infection is rare, but it is catastrophic when it occurs; as demonstrated by an amputation rate of approximately 50% and a reported mortality rate that ranges from 25% to 75%. In an attempt to limit this dreaded complication, penicillin and cephalosporins have been successfully bound to Dacron and ePTFE grafts and found to limit *Staphylococcus aureus* infection in animal models. Rifampin-bonded gelatin-sealed Dacron grafts have also been shown in vitro to lessen bacterial colonization [127]. Intuitively, tissue ingrowth itself may also provide resistance to infection.

Graft infection is not only limb but also life threatening (Fig. 33.5). Interestingly, one of the benefits of the decellularized grafts being tested is resistance to infection. If this is demonstrated, it may drastically change clinical use of synthetics, even if patency rates are unchanged from synthetic [128].

Biological modification through exogenous sources

The delivery of potent angiogens or genes that promote EC-specific mitogenesis or chemotaxis upon synthetic surfaces may be used to regenerate a rapid and complete endothelium after vascular intervention. Such synthetics could store these genes or proteins and provide a controlled expression or release of these genes or proteins locally to circulating or surrounding ECs in a cell-demanded fashion. Ideally, this kind of synthetic would be available as an off-the-shelf alternative to autogenous vein.

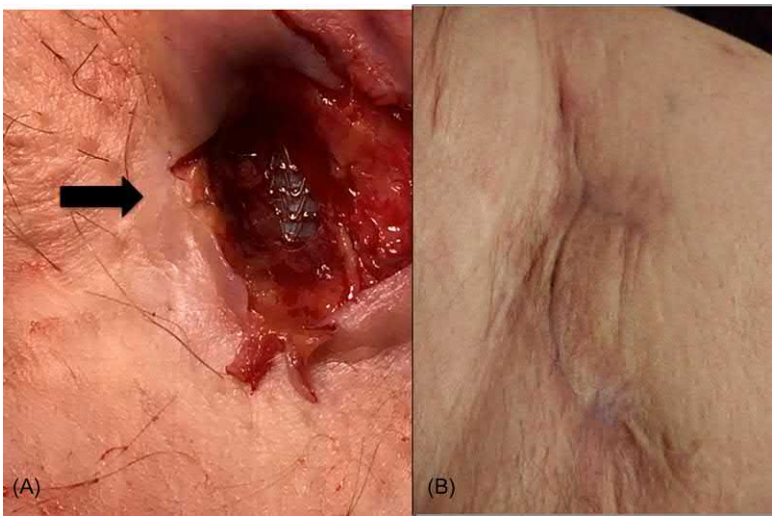

FIGURE 33.5 Exposed ePTFE stent graft. (A) Representative picture of a contaminated vascular graft after debridement in the operating room. (B) Here graft salvage was obtainable with a multidisciplinary medical and surgical team through aggressive debridement, focused antibiotic therapy, and a tissue flap. *ePTFE*, Expanded polytetrafluoroethylene.

Protein therapy

Although tissue incorporation is a desirable process for implanted prostheses, excessive vascular cell proliferation as well as ECM deposition can lead to intimal hyperplasia and ultimately graft failure. The ideal healing process in vascular grafts would be rapid endothelialization of blood contacting surfaces concomitant with a spatially and temporally limited subendothelial SMC growth, and followed by phenotypic and functional differentiation of cellular components and the subsequent remodeling of a mature ECM. The recent expansion of knowledge concerning the mechanisms responsible for the migration and proliferation of ECs and SMCs, angiogenesis, ECM deposition and remodeling, and physiologic parameters provides optimism for the possibility of manipulating the healing process through the directed manipulation of the microenvironment within the graft and perigraft tissue.

Since ECs have only limited capacity for regeneration, reendothelialization of the relatively large surface areas encountered clinically exceeds the normal mitogenic and chemotactic capacity of surrounding ECs. Thus endothelialization of large surfaces requires the recruitment of ECs from sites beyond the anastomotic border via the circulation or through transinterstitial migration from the surrounding tissue and/or the vasa vasorum. This is possible under the direction of localized angiogenic stimuli, and to a limited degree this is what occurs in vivo as protease-driven ECM changes and local availability of growth factors stimulate ECs, SMCs, and fibroblasts to enter the cell cycle.

The local delivery of growth factors or selected ECM may be utilized to promote desirable cellular events, such as endothelial ingrowth of synthetic grafts. For example, local delivery of exogenous angiogenic factors through a biologic delivery system (e.g., fibrin) may induce transmural capillary ingrowth in vivo, which can be the source of cells for an endothelial lining within synthetic grafts. The Greisler lab has evaluated the affixation of FGF-1 to synthetic surfaces. In early attempts, FGF-1 was applied to various synthetic grafts via a fibrin glue delivery system that, due to its structural orientation and state of polymerization, had been found not to be thrombogenic [129]. After delivering FGF-1 from fibrin glue to 60 μm IND ePTFE in both canine aortoiliac and thoracoabdominal aortic models, there was a significant increase in luminal EC proliferation as assayed by en face autoradiography, and a more rapid development of a confluent factor VIII positive endothelial blood contacting surface [130,131]. There was also extensive transinterstitial capillary ingrowth observed throughout the graft wall. Cross-sectional autoradiography did find a significant increase in subendothelial myofibroblast proliferation in these treatment grafts at 1 month, but this returned to baseline at later time points. Still, treated grafts developed a significantly thicker pseudointima (139 ± 178 vs 93 ± 89 and 67 ± 151 μm) at 140 days. In order to limit this IH response, we have developed site-directed mutants based on the FGF-1 angiogen and bioactive chimeric proteins that promote favorable characteristics, including prolonged bioactivity, EC specificity, or increased potency, while removing unfavorable characteristics such as heparin-dependent activity and susceptibility to thrombin-induced proteolysis [132,133].

Coimmobilization of FGF-2 and heparin in a microporous polyurethane graft by cross-linked gelatin has also been demonstrated to accelerate tissue regeneration on synthetic grafts, associated with a greater extent of endothelialization via perianastomotic and transmural capillaries ingrowth, in a rat aortic grafting model [134]. A consistent "neointima," approximately 40 m thick with intermittent endothelialization as well as SMCs and fibroblasts underneath the luminal surface were observed in the middle portion of treatment grafts, whereas the control grafts were only covered with a fibrin layer. However, because of the cross-talk that exists in the vessel wall between EC, SMC, and fibroblasts, multimodal therapies that promote EC coverage while limiting activation of VSMCs or the delayed delivery of cell cycle inhibitors may be required to optimize graft healing.

Gene therapy

Gene therapy shares the same promise as proteins, but it may also allow sustained or controlled protein expression in a desired location that is not possible with protein formulations. These qualities could obviate some of the current limitations encountered with the direct application of growth factor proteins to tissue beds for the regeneration of the endothelium.

This approach shows much promise as a delivery system, but single gene therapy trials have not yielded straightforward results. For example, although VEGF does improve endothelialization consistently, it does not reliably limit IH (and sometimes even promotes IH) in the literature. Gene therapy still requires cellular transduction or infection, and this has a variable effect on the cellular behavior. Also controversial results have been reported in the literature related to the proliferation, adhesion, and retention of genetically modified ECs on the surface of synthetic grafts. Another concern is that genetically modified ECs display poor retention on graft surfaces in vivo. This was demonstrated at 6 weeks in canine thoracoabdominal aortic ePTFE grafts seeded with lacZ-infected ECs compared to noninfected control ECs [135]. Further, Dunn reported only 6% retention of ECs that had been retrovirally infected with thromboplastin on Dacron grafts after 2 hours of exposure to flow in vivo [136].

For these reasons, little success has been documented to date concerning the long-term benefit of genetically modified EC-seeded grafts in vivo.

Cell therapy

Recruitment of EPCs into scaffolds provides a robust replication potential ideal for TEVG, and these cells acquire mature EC markers and function upon seeding into TEVGs [137]; these attributes may be further augmented by gene therapy.

In addition to the emphasis on the endothelialization of the flow surface, the function of other cell types, particularly the SMCs, in the vascular wall have become better appreciated. It has been suggested that ECs by themselves cannot produce a stable intima without SMCs or fibroblasts underneath. In support of this contention, tissue fragments containing multiple cell types, including venous tissue, adipose tissue, and bone marrow, have been seeded onto grafts and found to accelerate graft-healing processes.

Bone marrow–derived cells incubated on decellularized canine carotid arteries by Kim et al. demonstrated cellular incorporation into the scaffold and subsequent differentiation of these cells into endothelial and vascular SMCs and subsequently into three distinct vessel layers [138]. Similarly adipose-derived stem cells have been used successfully as a cell source for TEVG by a number of investigators [139,140]. However, at least in adipose-derived stem cells, it appears that diabetic donors severely compromise TEVG patency [141]. More recently, Brewster et al. have demonstrated robust secretome profiles from both bone marrow and adipose tissue of diabetic patients with PAD and PAD alone [142,143], suggesting that MSCs (at least after culture) retain many of their desirable paracrine properties.

Interestingly, bone marrow cell seeding was also reported to induce an abundant capillary ingrowth in the graft wall and a rapid, complete endothelialization of the inner surface without intimal hyperplasia. Since the bone marrow stem cells have the ability to differentiate in response to their microenvironment and to proliferate as well as secrete cytokines critical to their survival, they may provide a useful cell source for blood vessel tissue engineering.

Conclusion and predictions for the future

Much progress has been seen in recent years, and yet old things also become new again. Since the publishing of the last chapter, the decellularized "nude" implantation of a decellularized TEVG appears to be what will be clinically available first. Phase III publications will be coming forth soon to confirm this. However, promising tissue engineering approaches using bioresorbable grafts and/or the intelligent induction of a vaso vasorum into TEVG or existing synthetic grafts will likely be version 2.0 for TEVG work. Likely, these next generation TEVGs will be tested in clinically relevant animal models, as their path to clinic will likely require this.

Finally, as more patients live with cardiovascular disease than die from it, there is little doubt that promotion of durable graft healing will be more effective than blockade strategies of pathologic processes such as IH. However, both strategies, as well as combinatorial strategies, will likely yield new insights and problems for future investigators. Such a rich clinical need worldwide creates a sustained need for research investment. Those who persist and involve clinical trialists in the development of their TEVG will have the greatest chance of bringing reality to the dream of blood vessel replacement [144].

Introduction

Heart valve function and structure

The physiological function of a heart valve is to maintain unidirectional nonobstructed blood flow without damaging blood elements, causing thromboembolism, or placing excessive mechanical stress on the leaflets and cusps. The native heart valve is remarkably well adapted to performing these functions. This capability arises from a near perfect correlation of structure to function, enabling the valve to avoid excess stress on the cusps while simultaneously withstanding the wear and tear of 40 million repetitive deformations per year, equivalent to some 3 billion over a 75 year lifetime [1]. There are four valves in the human heart: two semilunar and two atrioventricular (AV). The semilunar heart valves represent the outflow tracts of the heart and include the structurally similar aortic and pulmonary valves. The AV heart valves include the tricuspid and mitral valves, which separate the atrium from the ventricle on the right and left side of the heart respectively. The following text describes the relation of structure to function in the semilunar valves from a macroscopic (tissue) to microscopic (cellular) level.

Grossly, the semilunar heart valves are composed of three thin cusps that open easily when exposed to the forward blood flow of ventricular systole, and then rapidly close under the minimal reverse flow of diastole [1]. The three cusps of the aortic valve are the left, right and noncoronary cusps. Each cusp is attached to the aortic wall by a thick base known as a commissure. Despite the force applied to the leaflets during diastole, prolapse is prevented by substantial coaptation of the cusps in a crescent shaped region of the cusp termed the lunula. In addition, the structural elements within the aortic valve cusps are anisotropically oriented in the tissue plane, resulting in disproportionate mechanical properties of the valve cusps with greater compliance in the radial rather than the circumferential direction. This compliance allows the cusp thickness of the aortic valve to vary from 300 to 700 μm throughout the course of the cardiac cycle [2]. Further structural specializations that occur are lengthwise folding of collagen fibers, and orientation of collagen bundles in the fibrous layer toward the commissures. This orientation conserves maximal coaptation, and thereby prevents regurgitation. Thus, both the macroscopic valve geometry and the fibrous network within the cusps work to transfer stresses caused by the diastolic force to the aortic wall and annulus.

Microscopically, the semilunar heart valve is composed of three layers: the ventricularis, spongiosa, and fibrosa (Fig. 34.1). It is the unique extracellular structural characteristics within these layers that create a specialized biomechanical profile necessary for proper function. The fibrosa, which is exposed to the aortic lumen, is composed of primarily collagen fibers, which are densely packed and arranged parallel to the cuspal free edge. It is these collagen fibers, mostly types I and III, which provide most of the mechanical strength of the valve [3]. The ventricularis layer faces the ventricle and is composed of collagen and radially aligned elastin fibers. Elastin forms an encompassing matrix that binds the collagen fibrous bundles throughout the heart valve, thereby creating an elastin-collagen hybrid network of interconnected fibers that provides greater mechanical strength [4]. The centrally located spongiosa layer is composed of glycosaminoglycans (GAG) and loose collagen fibers. The GAG side-chains of proteoglycans make a gelatinous substance in which other matrix molecules are able to form covalent crosslinks that support other components of the extracellular matrix (ECM) [5]. Human heart valve GAGs are

composed predominantly of hyaluronic acid, with smaller amounts of dermatan sulfate, chondroitin-4-sulfate and chondroitin-6-sulfate [6].

Cellular biology of the heart valve

Valvular endothelial cells

The two most prevalent cell types in heart valves are valvular endothelial cells (VECs) and valvular interstitial cells (VICs). VECs line the surface of valve cusps on both the aortic and ventricular surfaces. They provide a nonthrombogenic blood-tissue interface and maintain a semipermeable membrane that regulates the transfer of large and small molecules through the vascular wall [2]. Endothelial cells are also critical in the control of inflammatory and immune reactions, in regulating the proliferation of other cell types, and play a role in metabolism and protein synthesis [7].

The role of VECs in the heart valve is not passive. VECs can respond to external stimuli by phenotypically changing and acquiring new, inducible properties through a process known as endothelial activation. Both cytokines and hemodynamic forces have been shown to induce this process [2]. Once activated, VECs produce cytokines, chemokines, adhesion molecules, growth factors, and vasoactive molecules, all of which contribute to valve adaptation in response to the initial stimuli. Most often, this process is beneficial and allows for maintenance of valve homeostasis. However, a form of endothelial activation can occur that is known as endothelial dysfunction, which results in a surface that is adhesive to inflammatory cells or thrombogenic and can be a source of valve pathology [2].

Although VECs are often grouped together, there is in fact heterogeneity among these cells, as there is among endothelial cells in general. Their source, be it arterial or venous tissue, can affect cell phenotype, as can their location (aortic or pulmonary) [8]. Moreover, there is an increasing appreciation for the substantial data suggesting that VECs differ in many ways from other types of endothelial cells. For example, in response to mechanical stress, VECs align perpendicularly to blood flow, whereas vascular endothelial cells in the aorta align in parallel with flow [9]. In a separate study, investigators demonstrated significantly different transcriptional gene profiles of VECs on aortic and ventricular sides of porcine aortic valves [10].

Valvular interstitial cells

VICs are the most abundant cell type in heart valves and are primarily responsible for heart valve stability by the synthesis and remodeling of valve ECM. This process maintains the appropriate structural and functional relationship that allow for long-term heart valve competence. VICs contain varying characteristics of myofibroblasts, fibroblasts, and smooth muscle cells. There are five subtypes of VICs: embryonic, progenitor, quiescent, activated, and osteoblastic. Each subtype is unique and VICs can change phenotypically from one to another depending on the mechanical environment, chemical cellular or hormonal signals, or in response to injury. Embryonic VICs undergo endothelial-to-mesenchymal transformation (EMT), initiating the formation of the valve in the embryo [11]. Progenitor VICs represent a heterogeneous cell population that is thought to be important to valve repair [11]. Osteoblastic VICs regulate the process of calcification within the valve [11].

The two most important VIC populations to valve function are those that are quiescent and those that are activated [5]. In the quiescent state, VICs most closely resemble fibroblasts in that they have low levels of α-smooth muscle actin [12]. VICs can be activated by a variety of different stimuli and conditions, including during embryonic valve development and with exposure to TGF-β or cyclic stretch. In addition, various valvular pathologies can induce VIC activation. Importantly, studies have shown a distinct transition from quiescent to active VICs after implantation of a tissue engineered heart valve (TEHV). Similar results were seen after implantation of a pulmonary autograft as an aortic valve replacement [13].

VICs are of central importance to heart valve repair and maintenance operations. The constant and rigorous mechanical movement of valves results in persistent low level valvular damage and an ongoing ECM synthesis, remodeling, and degradation process. VICs regulate and perform this process by expressing ECM components and the proteins involved in matrix remodeling like matrix metalloproteinases (MMPs) and tissue inhibitors of

metalloproteinases (TIMPs). Importantly, over-expression of MMPs has been observed in several heart valve pathologies, indicating a possible target for clinical diagnostic and predictive markers as well as for therapeutic intervention [14,15]. More investigation is needed to better understand the mechanism of action of MMPs and TIMPs and their importance in valve tissue morphogenesis, repair and remodeling.

Even though ample data exists regarding the reparative properties of VICs, their function is still not fully understood [5]. Important to understanding and potentially manipulating VIC phenotype and cellular activity is knowing how these cells send and receive signals, how mechanical information is transmitted from the ECM, and what specific factors can induce a variety of cellular responses like cell migration, adhesion, growth, and differentiation [16].

Innervation and vasculature

While the VICs and VECs make up the majority of the cellularity of the valves, nerves and vascular networks are also present and worthy of attention. A large number of nerve cells have been demonstrated in valve leaflets, particularly in the aortic valve, and they have been shown to impart some control over the mechanical properties of the valve [17]. The nerves are present primarily on the ventricularis side of the valve, and are present throughout nearly the entire valve surface, except for being noticeably absent on the coapting edges of the leaflets [18]. The pulmonary valve is innervated similarly to the aortic valve, while the AV valves are more heavily innervated, being primarily innervated on the atrial side with innervation including the entire surface up to the coapting edges as well as through the chordae tendineae [19,20]. This nervous system control may allow for the mechanical properties of the valve leaflet to change throughout the cardiac cycle to better adapt to the differing conditions present throughout the cardiac cycle.

The vasculature also differs between the AV and semilunar valves. Aortic and pulmonary valve leaflets are thin enough to be perfused from the surrounding blood and as such contain few blood vessels. Mitral and tricuspid leaflets, on the other hand, contain capillaries in their most basal portion to aid in perfusion, with some small vessels also present in portions of the chordae tendineae [21].

Heart valve dysfunction and valvular repair and remodeling

Heart valve dysfunction

The American Heart Association has estimated that over 300,000 heart valve replacement procedures were performed in the United States between 1998 and 2005 [22]. Population growth, population aging, and improvements in longevity will fuel demand for heart valve replacements in the future, with a projected need of 850,000 in year 2050 [23]. The pathology of heart valve disease manifests itself in two ways, the first being a reduction in forward flow caused by failure of a valve to completely open, known as stenosis. The second is back flow during diastole caused by failure of a valve to completely close, known as insufficiency or regurgitation.

Aortic stenosis is a common valvular pathology. When severe, this disease can cause dyspnea on exertion, chest pain, and syncope. The most frequent cause of aortic stenosis is dystrophic calcification of the aortic valve cusps and ring (annulus). Overall prevalence of aortic stenosis in the United States is 2% and is increasing with time as the American population ages. Bicuspid aortic valves are the leading cause of aortic stenosis in younger patients, and represent one of the most frequent congenital cardiovascular malformations in humans, affecting approximately 0.5% of the young-adult population [24]. Bicuspid aortic valves are also sometimes associated with aortic insufficiency and increase the risk of infective endocarditis. Through retrospective community studies of patients with an identified bicuspid aortic valve, the total combined risk related to the bicuspid aortic valve, including aortic regurgitation, surgery, and infective endocarditis, was 52% for men and 35% for women [24]. The main source of chronic aortic insufficiency is aortic root dilation. This results in distended and outwardly bowed commissures as well as impaired cuspal coaptation.

Mitral valve prolapse is defined as the displacement of valve leaflets into the left atrium during systole and is the most common indication for surgical repair or replacement of this valve. Mitral valve prolapse is most commonly caused by myxomatous degeneration, identified by a diffuse build-up of GAGs within the valve, and is also seen in patients with Marfan syndrome. Patients with mitral valve prolapse are exposed to increased risk of a variety of different complications including heart failure, bacterial endocarditis, mitral regurgitation, atrial fibrillation, and thromboembolic events [7]. The most common cause of mitral stenosis worldwide is rheumatic fever, which can cause lasting damage to the mitral valve leaflets, leading to leaflets thickening and fusing later in life [2].

The leading cause of dysfunction of the tricuspid and pulmonary valves is congenital heart disease. Approximately 20,000 infants are born in the United States each year with a congenital heart defect, of which many involve absence or malformation of the pulmonary valve and pulmonary artery [25]. Major congenital heart disease diagnoses of the right ventricular outflow tract (which includes the pulmonary valve and pulmonary artery) include truncus arteriosus, pulmonary atresia with

ventricular septal defect, severe Tetralogy of Fallot, transposition with ventricular septal defect and pulmonary atresia, and double-outlet right ventricle. It is these children who would benefit most from TEHVs, which offer the potential to grow with the child thereby preventing need for re-operation.

Valvular repair and remodeling

When valvular injury occurs, it stimulates VIC proliferation, migration, and apoptosis. The initial events in valve repair of a linear superficial denuding wound have been modeled in vitro and are characterized by prominent migration and proliferation of VICs [26]. The migration of VICs is governed by a sequence of processes including activation of integrins, which are cell surface heterodimeric receptors that control cell−ECM and cell−cell adhesion [27]. Changes in macroscopic mechanical stimuli like shear and solid stresses are also propagated via signal transduction through a complex cell−ECM network, which allows small external changes in valvular mechanics to ultimately affect cellular activity and function [7].

Activation of VICs results in a change of phenotypic subtype to activated myofibroblasts, as demonstrated in leaflets from patients with myxomatous mitral valve degeneration [14]. These phenotypic changes resemble the evolution of physiological wound healing in mitral valves associated with the phenotypic modulation of interstitial valvular cells from fibroblasts to myofibroblasts [2]. That said, when equilibrium is reached after injury, cells revert back to a quiescent phenotype like that of a fibroblast. However, in cases in which there is persistent injury or where a steady state equilibrium cannot be achieved, VICs will remain persistently activated, contributing to ECM remodeling and initiation of valvular pathologies [28].

Important to understanding VIC function and activation in response to injury is the interaction between VICs and the ECM. VICs takes cues from and act upon ECM by secreting ECM components and their proteolytic enzymes, and by promoting avenues of cellular migration. Interstitial collagenases, gelatinases and other MMPs are involved in the degradation and remodeling of connective tissue and are primarily secreted by activated VICs [29]. As in tissue throughout the body, MMPs in heart valves are critical in tissue morphogenesis, wound healing, and other tissue remodeling processes. The interaction between MMPs, their inhibitors (TIMPs), and their regulators are particularly important in cardiac and vascular remodeling [2]. In the degradation of ECM, interstitial collagenases MMP-1 and MMP-13 mediate the preliminary phase of collagen breakdown by disassembling the native helix of the fibrillar collagen. The resulting collagen fragments are then accessible to further proteases, like gelatinases [30]. These interstitial collagenases are secreted by activated VICs in a similar manner as they are secreted by inflammatory cells in a multitude of systemic diseases [2]. That is, VICs are being stimulated by signal transduction, be it mechanical, chemical, hormonal, or otherwise, to produce and secrete soluble ECM proteases that allows for remodeling of ECM in response to changes in external environment. One means of signal transduction is cardiac catabolic factor, which is derived from porcine heart valves and found to stimulate collagen and proteoglycan breakdown in vitro [31]. While MMPs are a necessary component to normal remodeling of heart valves, excessive levels of MMP activity can lead to excess collagen and elastin breakdown, thereby weakening heart valve leaflets and predisposing to disease [14].

Heart valve replacement

Standard treatment for end-stage valvular dysfunction is heart valve replacement. The first successful implantation of a human valve was performed in 1952 [32]. Since then, more than 80 different designs of prosthetic heart valves have been developed [33]. Heart valve substitutes have undergone a progressive evolution as newer models are developed to remedy the deficiencies of older devices. Prosthetic heart valves are either mechanical and composed entirely of synthetic material, or bioprosthetic and therefore fashioned from biological components. Slightly more than half of the world's implanted valves are mechanical, while the remainder are bioprosthetic [34]. While each type of heart valve is used successfully to improve the quality and length of life, each valve type also has its own unique set of problems [35]. The overall rate of complications is similar for mechanical prostheses and bioprostheses [36]. Four categories of valve-related complications predominate [1]:

1. Thromboembolism, thrombosis, and secondary anticoagulation-related hemorrhage;
2. Prosthetic valve endocarditis;
3. Structural dysfunction including failure or degeneration of the prosthetic biomaterials; and
4. Nonstructural dysfunction including complications arising from technical problems during surgical implantation such as perivalvular leak and biological integration (tissue overgrowth).

Each valve type is associated with its own unique set of advantages and disadvantages. The mechanical heart valve is characterized as having excellent durability due to the mechanical properties of the synthetic materials from which it is constructed. The material properties of mechanical heart valves allow them to last longer than 15 years following implantation [37]. Unfortunately, these synthetic materials also give rise to poor biocompatibility.

Specifically, mechanical prosthetic valves are associated with a substantial risk of thromboembolism and thrombotic occlusion caused by the lack of an endothelial lining and the flow abnormalities that result from a rigid outflow structure [38]. To minimize this risk, chronic anticoagulation therapy is required for all mechanical valve recipients. However, systemic anticoagulation renders patients vulnerable to potentially serious hemorrhagic complications. Thus, the combined risk of thromboembolic complications and hemorrhage secondary to anticoagulation constitute the principal disadvantage of mechanical prosthetic valves. A metaanalysis found an incidence of major embolism in the absence of antithrombotic therapy of 4 per 100 patient years, which was decreased to 2.2 per 100 patient years with antiplatelet therapy and to 1 per 100 patient years with anticoagulant therapy (e.g., warfarin) [39]. However, long-term anticoagulation is not without its own risks. Disadvantages of long-term warfarin use include increased risk of bleeding complications, lifetime need for blood tests and therapy to maintain a therapeutic international normalized ratio, and high rates of noncompliance [40]. In a review of randomized trials of anticoagulation therapy in patients 65 years and older, incidence of major bleeding ranged from 0% to 4.6% per year, with incidence of minor bleeding as high as 10.5% per year [41]. Indeed, patients over the age of 75 on anticoagulation for mechanical heart valves compared to patients who received a bioprosthetic valve assessed for bleeding rates had an odds ratio of 18.9 [42]. Mechanical heart valves are also prone to fibrotic ingrowth and regurgitation [43]. As mechanical heart valves do not undergo biodegradation or remodeling, any tissue growth onto the valve components over the life of the implant can contribute to compromising the valve performance [44]. Other disadvantages of mechanical heart valves include their ability to cause hemolysis and an increased susceptibility to endocarditis [45].

Bioprosthetic valve replacements such as glutaraldehyde-fixed xenografts and allografts are associated with a lower risk of thrombosis and hemolysis than mechanical heart valves [35]. Patients with glutaraldehyde-fixed xenograft valves do not require anticoagulation and therefore do not incur the risks of anticoagulation-associated bleeding. However, because of their mechanical properties and their composition of biologic material, the durability of a glutaraldehyde-fixed valve is more limited than that of the mechanical valve. The major disadvantage of tissue valves is progressive structural deterioration that eventually results in stenosis and/or regurgitation. The degradation mechanisms of bioprosthetic valves are progressive and the rate of failure is highly time dependent.

Alterations of their molecular composition and/or tissue structure of bioprosthetic valves during manufacturing can lead to valve failure [1]. One such example is the permanent fixture of one or more valve cusps in a specific configuration during manufacture which is associated with only one specific phase of the cardiac cycle [2]. In this case, normal cyclic rearrangements in the valve subarchitecture cannot appropriately occur and irregular tissue stress is created. Other examples include process-induced destruction to the endothelial coating which then allows penetration of inflammatory cells and plasma into the cusp after implantation, leading to valve inflammation-induced thickening and possible valve deterioration [2].

The principal problems for bioprosthetic valve durability after implantation are cuspal mineralization and noncalcific mechanical fatigue. Calcification occurs when calcium from plasma binds with residual organic phosphates of the crosslinked, nonviable cells of the preserved valve [7]. Further weakening can occur from proteolytic degradation of the collagenous ECM [46]. MMP activity has been demonstrated in explanted valve tissue that has undergone structural degradation, which signifies a degree of inflammation and ECM remodeling within damaged valves [47]. Similar findings have been found in in vitro models of valve function, suggesting that the mechanical stress that bioprosthetic valves are subject to may alone contribute to ECM degradation and prolonged remodeling [48].

Despite improvements over the last several years in bioprosthetic valve durability, structural valve deterioration is a significant problem particularly in patients less than 65 years old. In one study looking at patients having had a bioprosthetic aortic valve replacement, 60% of patients younger than 65 years required re-operation by 18 years postimplantation [49]. Indeed, the risk of structural failure is strongly age dependent, with individuals less than 35 years of age, and especially children and adolescents, having the highest rate. Nearly uniform failure occurs by 5 years in those less than 35 years old but 8%–27% fail in 20 years in those older than 65 [50]. The major cause of bioprosthetic valve dysfunction is structural deterioration of the cuspal tissue [51]. Two distinct yet potentially synergistic processes are causal: calcific degradation [1] and noncalcific degradation [2]. Both eventually lead to failure of the connective tissue matrix of the tissue valve [1].

Another type of bioprosthetic valve is the cryopreserved homograft, which is particularly advantageous in those patients requiring aortic valve replacement or those needing congenital heart reconstruction with right-sided conduits [52]. However, the use of the cryopreserved homograft is a form of transplantation and thus subject to many transplant-associated problems, including the implanted tissue invoking a host immune response, thereby potentially increasing the risk and rapidity of

structural valve deterioration. Cryopreserved homografts are currently the most biocompatible replacement heart valve and the treatment of choice in most pediatric cardiothoracic applications [53]. However, used in this application, they are severely limited by their inability to grow and by a significant incidence of structural deterioration resulting in limited durability and frequent need for reoperation. Overall, the poor long-term durability of currently available heart valves in young patients (children and adults <35 years) makes clear the clinical need for an improved replacement heart valve, a need which tissue engineering can help fulfill.

A recent advancement in the field of heart valve replacement is the transcatheter approach to heart valve deployment, first performed in a human patient in 2002, with over 250,000 procedures being done to date [54,55]. This technique consists of a valve within a stent that is delivered through a catheter, and may be performed as an initial valve replacement therapy or as a follow-up therapy to replace a failing bioprosthetic valve, referred to as a valve-in-valve procedure. Transcatheter deployment carries the benefit of being minimally invasive, particularly compared to a traditional open surgical approach, allowing for the option of valve replacement in high risk patients who may not be eligible for open surgery. Transcatheter valve replacement is not without its own risks, however. Transcatheter valve deployments have shown higher rates of perivalvular leak, cerebral embolism, and conduction anomalies requiring pacemaker implantation than surgical valve implantation [56].

The application of tissue engineering toward the construction of a replacement heart valve

Tissue engineering theory

The ideal heart valve replacement would be perfectly biocompatible, readily available, durable, and have the potential for growth. The construction of an autologous, TEHV could potentially fulfill all of these requirements by utilizing natural mechanisms for repair, remodeling, and regeneration. The central paradigm underlying tissue engineering involves combining cells with a platform matrix to create neotissue [57]. The matrix acts as a three dimensional scaffold until proliferating cells produce sufficient ECM in vitro to permit in vivo implantation [2]. This process is followed by scaffold degradation, neotissue formation, and growth.

Tissue engineering is currently limited by the inability to construct microvasculature de novo, the inability to control innervation of neotissue, and the difficulties surrounding culturing certain cell types [58]. Although the semilunar heart valve is not totally avascular, oxygen and nutrients needed to sustain its function are supplied via two complementary pathways: diffusion from the blood stream and via a capillary network. In addition, semilunar heart valves are composed of cells that are readily grown in culture. This allows for the isolation and expansion of autologous cells for construction of TEHVs. The blueprint for constructing an ideal TEHV has evolved from a large body of research in bioprosthetic valves, diseased heart valves, and other tissue valve substitutes. Although these investigations have largely been clinical in nature, they have identified useful markers of cell function, matrix physiology, and matrix structure. These results led to several key interrelated concepts of functionally adaptive valvular remodeling and regeneration [2]:

1. Valves are composed of a highly specialized arrangement of collagen and other ECM components;
2. Native and substitute valves are subject to structural deterioration over time;
3. The generation of new valvular ECM is dependent on VIC viability and function.

Therefore, the long-term success of a tissue engineered valve replacement is theorized to depend on the ability of its living cellular components, whether seeded cells or infiltrating host cells, to assume normal function with the capacity to repair structural injury, remodel the ECM, and potentially grow.

Tissue engineering offers the potential to create a nonthrombogenic, biomimetic, immunologically compatible tissue valve substitute that is capable of providing ongoing remodeling and repair which would allow growth in maturing recipients (Fig. 34.2) [2]. Such a technology would have dramatic implications in a clinical setting and greatly contribute to improving patient outcomes.

Biomaterials and scaffolds

Over the last several decades, an exhaustive variety of biomaterials have been explored to serve as scaffolds for TEHVs. These biologic scaffolds have the primary responsibility of promoting tissue regeneration and must be biocompatible, biodegradable into safe byproducts, easily manufactured and handled, highly porous to facilitate cell attachment and infiltration, and yet mechanically stable enough to appropriate function [2].

Scaffolds can be manufactured from either synthetic or natural materials. Natural biomaterials include ECM components such as collagen, fibrin, elastin, GAG, or decellularized tissues, such as heart valve, pericardium, arterial wall or small intestinal submucosa [60]. Synthetic polymers have an advantage in that they have predictable chemistry and their properties can be well-controlled [2]. In addition, these materials are FDA (Food and Drug Administration) regulated and many have been

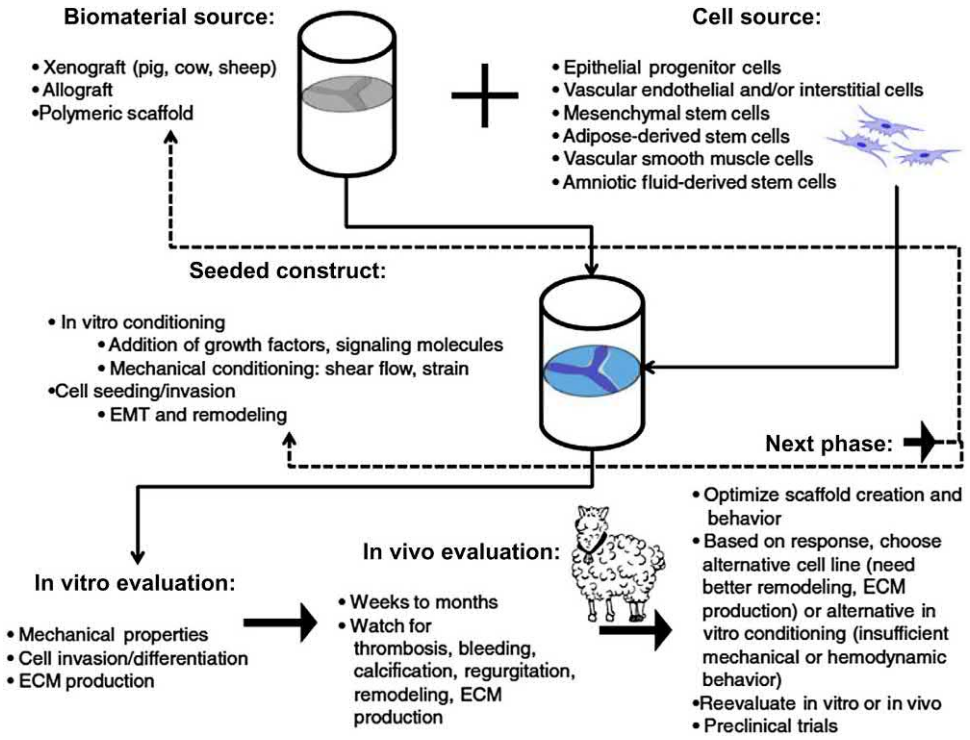

FIGURE 34.2 Overview of tissue engineering heart valves [59].

approved in clinical applications [59]. The most commonly utilized synthetic polymers in tissue engineering include poly(glycolic acid) (PGA), poly(L-lactic acid), copolymer poly(lactic-*co*-glycolic acid) (PLGA), poly (ethylene glycol), and polyhydroxyalkanoate.

A number of natural biodegradable polymers have been explored for use as scaffolds. They have the advantage of offering a more biocompatible template on which cells grow [5]. Decellularized small intestinal submucosal (SIS) matrix has been isolated to use in tissue engineering [61]. Other investigators have used porcine SIS scaffold as a resorbable matrix to make pulmonary valve leaflet replacement in porcine models [62]. When the explanted constructs were evaluated they revealed resorption of the submucosal matrix, fibrous connective tissue growth and formation of neo-vasculature.

Much of a heart valve's mechanical and tensile strength originates from its collagen composition and alignment [63]. Due to their highly conserved genetic code across species, collagens are weakly immunogenic and have been used widely for TEHV constructs seeded with both human and porcine-derived cells [64,65]. Another natural scaffold that has been explored is fibrin gel. It has been used as an autogeneic scaffold in heart valve tissue engineering [66]. Some advantages of using fibrin gel as a material for scaffold construction include that it is made from the patient's own blood, and also that it is readily biodegradable. However, early attempts at utilizing fibrin gel were limited by its tendency to shrink and its inability to withstand surgical implantation [5].

The process of removing cells from a biological matrix can reduce the immune response to the bioprosthetic while maintaining the potential for endothelialization by host VECs and VICs, either through cell ingrowth or via cell seeding [67]. Methods of tissue decellularization range from enzymatic digestion, detergent treatment, sonication and hypo-/hypertonic immersion [68]. These treatments effectively remove antigenic components such as nucleic acids, cell membranes, cytoplasmic structures, lipids, and soluble matrix molecules but retain elastin, collagen and GAG components of the scaffold ECM [69]. Decellularization has been utilized in porcine matrices that were subsequently seeded with human endothelial cells. The resulting construct had a confluent and viable monolayer cell surface, an important feature in reducing thrombogenic risk [70]. Further experimentation in vivo utilized a decellularized pulmonary valve seeded with endothelial cells and carotid artery myofibroblasts followed by implantation in an ovine model [71]. After 1 month, the valve leaflets were completely endothelialized with dense infiltration by myofibroblasts by 3 months. However, enthusiasm was tempered by the finding of subvalvular calcification and inflammation resulting in increased thickening of the valve leaflets [5].

The commercially available SynerGraft valve (CryoLife Inc., United States) is based on the decellularization model of tissue engineering [72]. The SynerGraft decellularization process involves cell lysis in sterile water, enzymatic digestion of nucleic acids and a multiday isotonic washout period. The method was developed as an alternative to glutaraldehyde crosslinking to decrease xenograft antigenicity. Histological evaluation 150 days postimplantation in porcine models showed intact leaflets with local myofibroblasts ingrowth and no calcification [5]. Early failure of the valve, however, was reported in human trials [73]. The SynerGraft matrix initiated an early strong inflammatory response followed by a lymphocyte response. Rapid structural degeneration of the valves occurred within 12 months. Furthermore, the valve scaffold was not repopulated with host cells, and calcific deposits were detected.

A comparison of decellularized cryopreserved allografts to traditional cryopreserved allografts by Burch et al. showed while there were no differences in degree of insufficiency, the decellularized allografts had a minor improvement in pressure gradient over their traditional counterpart [74]. However, Burch et al. also noted that the decellularized allografts had one-tenth of the shelf life and cost substantially more than traditional cryopreserved allografts [74].

Proponents of synthetic matrices argue that customized polymers can be designed to exact specifications in a reproducible fashion. Also, by utilizing biodegradable polymers, complications associated with biocompatibility can be minimized. Initial work focused on polymers composed of PGA and PLA [75]. These "off the shelf" polymers were selected because they are biocompatible, biodegradable, well characterized, and already FDA approved for human implantation. Cells readily attach to and grow on these synthetic polymers. The resulting neotissue construct possesses adequate biomechanical properties to be used for surgical application. However, the biomechanical profile of the construct is substantially different from that of a native heart valve. TEHVs using polyglycolic acid and PLA copolymer-based matrices are thicker, stiffer, and less pliable than native valves.

Early experiments used matrices made of a PLGA woven mesh sandwiched between nonwoven PGA mesh sheets. The scaffolds were seeded with arterial myofibroblasts, followed by arterial endothelial cells and were then transplanted into the pulmonary position as a single leaflet in sheep. The seeded cells were seen in the structure after 6 weeks, and a postmortem evaluation revealed a native tissue-like architecture [76]. Furthermore, there was confirmation of elastin and collagen production in the leaflets, which had mechanical properties similar to native leaflets [76]. This approach, however, resulted in only limited success, as the PGA and PLA polymers were too stiff for use as flexible trileaflet valves.

Polyhydroxyoctanoate (PHO), a more flexible synthetic polymer has been used to create a composite heart valve scaffold in a low-pressure pulmonary system [77]. The valve consisted of a layer of PHO film sandwiched between two layers of nonwoven PGA felt. The leaflets were composed of a monolayer of porous PHO that was sutured to the conduit wall with polydioxanone. Postimplantation examination revealed a uniformly organized tissue with large amounts of collagen and proteoglycans, but with no elastin. The PHO scaffold, however, had not completely degraded after 24 weeks, suggesting a longer degradation profile than glycolic or lactic acid polymers. Additional studies revealed smooth flow surfaces but could not demonstrate a confluent endothelium which could affect the long-term durability of the structures [78]. In addition, although collagen and GAG deposition was seen, the constructs were devoid of elastin and demonstrated mild stenosis and regurgitation.

Hoerstrup et al. developed a novel composite scaffold material consisting of PGA coated with a thin layer of poly-4-hydroxybutyrate (P4HB)—a flexible, thermoplastic polymer with a more rapid degradation time than PHO [79,80]. Trileaflet heart valve scaffolds were fabricated from the composite material using a heat-application welding technique. Autologous myofibroblasts and endothelial cells from ovine carotid artery were seeded onto the scaffolds, cultured in a bioreactor for 14 days and then implanted in an ovine model [80]. When explanted, they showed increased ECM synthesis, more organized internal structure and improved mechanical properties over static controls.

It is not clear whether natural or synthetic scaffolds will ultimately prove to be more appropriate for TEHV development, as there are still certain limitations associated with both. The design of a replacement aortic valved-conduit, for example, will require the inclusion of three dilated pouches alongside the "cusp-like" leaflets to approximate the sinuses of Valsalva; AV valve designs may require the addition of other components of the AV valve apparatus, including chordae tendineae and papillary muscles [81]. Using stereolithography, Sodian et al. fabricated plastic models with an exact spatial representation of human aortic and pulmonary valves [82]. These models were then used to fabricate heart valve cell scaffolds using poly-3-hydroxyoctanoate-*co*-3-hydroxyhexanoate and P4HB, which were shown to function well in a pulsatile flow bioreactor under both normal and supranormal flow and pressure conditions. The choice and design of scaffolds will be integral to the successful clinical outcome of TEHVs. As well as conforming to a

suitable anatomical shape, heart valve scaffolds will be required to possess adequate tensile and elastic properties, being strong enough to withstand the pressure of blood flow without breaking while also not being so stiff as to impede flow. The scaffolds must be biocompatible, bioabsorbable or remodelable, and should provide a suitable template for facilitating development of new tissue. Scaffold permeability is also vital for the control of cell nutrition and removal of waste products [5].

The search for appropriate cell sources

An ideal cell source for TEHVs would demonstrate phenotypic plasticity and be able to change biomechanical properties in response to dynamic alterations in flow. It is an area of continued investigation. The use of autologous cells as opposed to xenograft or allograft tissue has the advantage of avoiding an immunological response that could result in rejection [83]. In an early attempt at tissue engineering a heart valve in 1995, valve leaflets were constructed by seeding cells from both autogeneic and allogeneic sources onto biodegradable polymeric scaffolds which were then implanted in an ovine model [76]. As anticipated, the autologous scaffold provoked less of an inflammatory response in the host, resulting in better performance and a higher success rate compared to allogeneic comparators.

A logical cell source for a TEHV would be autologous VICs and VECs harvested from a patient's own heart valve leaflet. The use of these cells would eliminate the risk of rejection while imparting the requisite phenotypic profile [5]. Preliminary studies using an ovine model utilized valve biopsy samples as a VIC source [84]. In this study, the biopsy procedure generally did not appear to compromise leaflet function, with 9 of 13 animals showing intact valves and normal leaflet anatomy postmortem. However, for human patients, it would be challenging to isolate and culture enough cells from a small biopsy to be of clinical use. It is also known that the ability to culture cells decreases with age, making this technique less feasible in older patients. In addition, patients requiring valve replacement have diseased VECs and VICs which may not be ideal for tissue engineering a replacement heart valve. Thus, the risks involved in valve biopsy are seemingly too high to make this a feasible technique in human trials. Recent studies have shown that decellularized human pulmonary valves seeded with autologous VICs and cultured in vitro demonstrated significant cell proliferation by 4 days, which suggests that such a construct can be manufactured in a shorter timeframe than initially thought [85].

Subsequent studies have utilized ovine femoral artery-derived cells as an autologous source [75]. This has failed to gain much favor given its potential for limb ischemia from disruption of the lower limb arterial blood supply. Myofibroblasts harvested from the carotid artery have also been investigated, but it was concluded by the investigators that the sacrifice of an intact tissue structure and the potential for injury introduced prohibitive risks [77]. In search of a more practical source, Shinoka et al. performed a study comparing dermal fibroblasts to arterial myofibroblasts as cells of origin for a TEHV [86]. Unfortunately, leaflets derived from dermal fibroblasts were much thicker, more contracted and less organized than those derived from arterial myofibroblasts. It was therefore surmised that cells of mesodermal origin, such as arterial myofibroblasts, provide more specialized phenotypic properties than ectodermally derived skin fibroblasts.

Myofibroblasts derived from human saphenous vein have similar phenotypic properties to VICs and represent a more realistic source for clinical applications of TEHVs [87]. Unlike arterial cells, these cells can be harvested without the risk of limb ischemia [5]. These myofibroblasts were cultured on polyurethane scaffolds and were shown to be viable and confluent at 6 weeks. Moreover, compared to neotissue derived from aortic myofibroblasts, collagen production and mechanical stability were found to be higher in saphenous vein-derived structures. Follow-up studies have compared myofibroblasts isolated from ovine tricuspid heart valve leaflets to cells from jugular vein and carotid artery [88]. Interestingly, cells from jugular veins also demonstrated higher initial collagen production, but the study showed that all cell lines had a marked drop-off in collagen, elastin and GAG synthesis with time. This finding suggests that there is a critical timeframe for seeded cells to be placed on scaffolds while they are still able to perform necessary protein synthesis and organization [59]. In the first long-term follow-up of a clinical application of a TEHV, Dohmen et al. seeded a decellularized pulmonary allograft with cells isolated from saphenous vein and cultured in a bioreactor for 2 weeks. They cite 100% survival with adequate pressure gradients and no incidence of calcification at 10 year follow-up [89].

In the search for an alternative cell source, different stem cell sources have been investigated. In particular, umbilical cord-derived cells, amniotic fluid-derived cells, and chorionic villi-derived cells appear to carry great promise [16]. One group demonstrated the possibility of using autologous umbilical cord cells [90]. The isolated cells represented a mixed population of cells derived from umbilical cord artery, vein, and the surrounding Wharton's jelly. It was found that the cells demonstrated features of myofibroblast-like differentiation, such as expression of α-smooth muscle actin, vimentin, and

deposition of collagen types I and III. More importantly, the cells successfully attached to scaffolds and formed a layered tissue-like structure comparable to scaffolds seeded with vascular cells [80]. Initial enthusiasm was tempered when it was observed that elastin was not being produced and GAGs were present only in low levels. Much more work is needed in characterization of the mixed cell population before the suitability of this source can be properly evaluated. Likewise, mesenchymal stem cells show promise, though many of the details remain to be elucidated. Their ability to develop into a variety of connective tissues, including bone, cartilage, muscle and fat, as well as easy collection via bone marrow puncture make these cells an attractive possibility [91]. In one experiment, human bone marrow stromal cells were collected and partially characterized using a number of myofibroblast markers [92]. Like umbilical cord cells, they were shown to express α-smooth muscle actin and vimentin, and produce collagen types I and III. Biodegradable polymeric scaffolds cultured with mesenchymal stem cells in vitro demonstrated an organized internal structure and mature tissue development. Despite the encouraging results, it is not clear whether bone marrow stromal cells reliably differentiate into appropriate cell types in the scaffold or if they continue to remain differentiated in vitro, ensuring long-term function and durability of the replacement heart valve [93]. Investigations utilizing circulating endothelial and smooth muscle progenitor cells are at a similar stage [94]. However, given their remarkable differentiation potential, embryonic and adult stem cells may become valuable resources for heart valve tissue engineering.

The search for an ideal replacement for both VICs and VECs is ongoing, but the underlying goal across all these techniques is the same: transplanted cell populations in a scaffold can achieve the same distribution and differentiation pattern of cells in the native valve [95]. It is hard to prove this assertion, however, as there is limited data regarding the phenotypic profile of these cells once they are implanted into the scaffolds, especially when it comes to long-term follow-up data [5].

Cell seeding techniques

Growing valvular neotissue under in vitro and in vivo conditions remains a challenge in the development of reliable and reproducible TEHVs, and much of the difficulty is rooted in challenges of cell seeding and attachment to scaffolds. Indeed, cell attachment is a critical step in initiating cell growth and neotissue development [96].

Whereas relying on adjacent autologous myocardial cell migration into unseeded valve scaffolds has proven to be an unreliable and inconsistent technique to date, directed cell seeding either in vitro or in vivo has been successful. In seeding scaffolds under in vitro conditions, early strategies for improving cellular attachment included increasing seeded cell number or density, increasing scaffold porosity, or increasing scaffold surface area. More sophisticated techniques sought to enhance cell attachment by coating the matrix prior to seeding with various cell adhesion molecules like laminin [97]. Similarly, prior to seeding a pulmonary allograft for a Ross operation, Dohmen et al. covered the decellularized valve with a commercially available synthetic ECM protein to enhance cell attachment [89]. Cell seeding was then performed using a sedimentation technique, with excellent cellular attachment and eventual neotissue ingrowth [98].

Indeed, covering valvular scaffold with molecules that can target or attract specific circulating cells offers an avenue for in vivo autologous cell seeding which precludes the need for in vitro cell culture and all the microbial risks therein. Jordan et al. utilized this principle in conjugating a decellularized porcine pulmonary valve with CD133 antibodies as a means of promoting scaffold seeding by circulating endothelial progenitor cells [99]. This strategy led to increased endothelial cell attachment, increased interstitial cell number, increased structural proteins, and improved biomechanical properties when compared with unconjugated or traditional cell-seeded valves [99].

The method of cell seeding used also influences efficiency of cellular attachment to scaffold. Traditional methods of seeding polymer scaffolds employed static cell culture techniques, in which a concentrated cell suspension is pipetted onto polymer scaffolds and left to incubate for a variable period of time, during which cells adhere to the scaffold. Dynamic cell seeding methods employ a seeding method in which either the medium or both the medium and scaffold are in constant motion during the incubation period. Dynamic cell seeding is often used in combination with a bioreactor and offers improved cellular attachment compared to static cell seeding [100]. Nasseri et al. concluded that dynamic cell seeding onto tissue engineered scaffolds increased cell adhesion, alignment in the direction of flow, cell infiltration, and seeding density [101]. There are various factors that can be further modulated in cell seeding, including use of mixed versus pure cell populations, interval cell seeding, and single-step versus sequential seeding of different cells.

Adequate, uniform and reproducible cell seeding of both natural and synthetic polymeric scaffolds remains a challenge in the field. Optimization of rapid seeding techniques will be important in the development of a TEHV, as it maximizes the use of donor cells, hastens the

proliferation and subsequent differentiation of cells, decreases the time in culture, and provides a uniform distribution of cells [102]. Advances in the modification of scaffold surfaces to enhance cell adhesion and subsequent function offers a strategy to augment ex vivo valve seeding in a timely fashion [5]. This strategy also offers the potential to direct autologous circulating cell seeding of heart valves, which if successful precludes the need for ex vivo cell culturing and allows for an "off the shelf" TEHV.

Bioreactors

The use of bioreactors for tissue engineering heart valves has increased over the last several years due to both improvement and complexity of available systems and the encouraging results that have been published with their use. Simplistically, a bioreactor is a biomimetic system used to optimize in vitro neotissue development. Ideally, the bioreactor system is designed to mimic the physiologic or pathophysiologic condition that is to be corrected with the engineered tissue. Factors such as shear stress, flow rate, flow profile, pressure, and media should be easily manipulated to change experimental conditions as researchers see fit [23]. In addition, bioreactors should be easy to access, easy to exchange media, remain sterile under long culture times, accommodate multiple samples to facilitate adequate sample sizes for statistically significant comparisons, and should be arranged to allow for direct visualization of the samples [46]. In mirroring physiologic conditions in the heart, an ideal bioreactor for tissue engineered cardiac valves consists of pulsatile flow and cyclic flex in order to generate the complex biomechanical environment that implanted valves must withstand [103]. Exposure to pulsatile flow modulates the biomechanical properties of the neotissue, which is especially important in the development of a TEHV in order to prevent premature valve deterioration [104].

One specific type of bioreactor used in the construction of a TEHV is the pulse duplicator. This pulsatile bioreactor provides physiological pressure and flow to the developing TEHV and promotes both the development of mechanical strength and the modulation of cellular function [105]. In using human umbilical cord blood-derived progenitor cells to seed heart valves made from biodegradable polymer, Sodian et al. used a pulse duplicator bioreactor wherein pulsatile flow (300−500 mL/min) and pressure (5−15 mmHg) were gradually increased over the course of 7 days [106]. This technique led to TEHVs with similar connective tissue and ECM composition as that seen in native heart valves.

Other approaches to bioreactors for TEHVs include bioreactors that can provide cyclic strain or dynamic flexural strain. Exposure of seeded valve tissue in vitro to mechanical strain results in more pronounced and organized tissue formation with superior mechanical properties over unstrained controls and results in TEHV cusps that are significantly less stiff than static controls [107]. This technique also yields substantial increases in DNA and net collagen content [108]. Cyclic flexure, which is a significant source of heart valve deformation, was used as the mechanical stimuli in a bioreactor into which cell-seeded and unseeded valves were incubated for 3 weeks. Cell-seeded valves undergoing cyclic flexure had >400% increase in effective stiffness compared to the unseeded controls and also had increased amounts of ECM [109].

Importantly, there is no uniform standard bioreactor that is used in tissue engineering heart valves, in part because of the complexities of the mechanical environment in vivo. Further understanding of the relationship between embryonic valve development and biomechanical signals may offer insight into designing an ideal bioreactor for in vitro development of heart valves. Current ongoing studies aim to take advantage of the high regenerative potential of the fetal environment as a natural bioreactor to treat congenital valve defects.

Neotissue development in tissue engineered heart valves

The process of neotissue development is poorly understood and appears to be controlled by a multitude of factors. In some ways it mimics embryonic development whereas in other ways it appears to be governed by the rules underlying tissue repair. In fact, it is likely a unique process governed by its own set of laws. The type of cells that are implanted and their interaction with the surrounding environment determine the type of tissue that ultimately develops from the cell−scaffold complex [57].

The environment in which the construct grows will influence the histological structure and ECM formed. Researchers have approached this phenomenon from several perspectives. In one approach, the formation of tissue begins in vitro by seeding cells onto a biodegradable scaffold and then maturing the tissue in a bioreactor prior to implantation in vivo. Using this approach, the scaffold is used as a cell delivery system and implanted in vivo shortly after cell attachment has taken place [58]. This approach uses a cell−scaffold construct to provide the initial structural integrity necessary to provide temporary physiological function until neotissue grows and remodels. The technique proposes that appropriate environmental signals for tissue repair and remodeling are inherently present in the in vivo milieu. In addition, in vivo biomechanical environmental forces provide

important stimuli that affect the formation of ECM and direct the biomechanical properties of the developing neotissue. The key steps in this process include [1]:

1. Cell proliferation and migration,
2. ECM production and organization,
3. Scaffold degradation, and
4. Tissue remodeling.

The mechanical and biological signals underlying neotissue formation remains an area of focused research. However, a lack of small animal models for TEHVs, which have the benefit of genetic control and large sample numbers compared to large animal models, has hindered direct mechanistic investigation into TEHV neotissue development. Much of the work in mechanisms of neotissue formation in cardiovascular tissue engineering has been done using murine and ovine models of tissue engineered vascular grafts (TEVGs), and will be discussed here. The recent development of a murine model for TEHV implantation may lead to more direct evaluations of TEHV development mechanisms in the near future [110–112].

The wide range of synthetic and natural materials used to fabricate TEHVs has led to a plethora of studies into the effects of the physical properties of the materials on neotissue formation [113]. Interestingly, recent findings suggest that microstructure morphology differences can have a profound effect on the in vivo response, in some cases being a stronger factor than the material used [114]. Utilization of a smaller fiber size was shown to reduce activation of contacting blood products [114]. Studies evaluating the effect of surface topography on platelet activation have found that a micropatterned rough surface is far less thrombogenic than a smooth surface [115]. Electrospun polytetrafluoroethylene (PTFE) demonstrated more smooth muscle cell growth and fewer adhered platelets than a flat PTFE surface [116]. In a rat aortic graft model, aligned fibers showed significantly higher patency and less thrombus formation than a graft with a smooth topography, despite similar cellular adhesion rates to both graft types [117].

Pore size has been shown to affect cell migration, with pore sizes larger than the cells encouraging migration through the scaffold, and pore sizes significantly smaller than the cells promoting cells to adhere to the surface of the graft [118]. Degradation rate is also a critical variable to consider in the development of a tissue engineered construct; a scaffold that degrades too quickly will lead to early mechanical failure, while a scaffold that degrades too slowly may lead to stiffening and inadequate neotissue formation [113]. The mismatch of the mechanical properties between an implanted graft and the surrounding vasculature has been implicated in a number of studies as a risk factor for poor outcomes [119]. Interestingly, the adjacent vasculature has also been shown to undergo significant remodeling following graft implantation, becoming stiffer and less compliant to more closely match the properties of the graft [120,121].

Recent studies of TEVGs in murine and ovine models have demonstrated that seeded mononuclear cells stimulate a robust infiltration of host macrophages during early timepoints [122]. Additional evidence suggests that circulating host bone marrow-derived cells are active in the acute inflammatory phase but do not represent a source of mature neotissue. Rather, macrophages appear to initiate an inflammatory cascade to drive vascular remodeling and neotissue ingrowth from the surrounding native vessel [123]. Other pathways specific to heart valve physiology may also be vital to understanding neotissue formation. One key process in the development of the heart valve is EMT. It has been demonstrated that EMT pathways involving TGF-β3, BMP2 and VEGFA are activated and localized in TEHV remodeling [124]. Many groups believe that the identification of biomaterials that can induce EMT and direct cellularization of TEHVs will be invaluable to the field [59].

TEHVs have been evaluated biochemically, molecularly, histologically, physiologically, biomechanically, and morphologically (Fig. 34.3). In each type of analysis, the tissue engineered valve has been compared with the native valve [93]. These data can then be used to identify shortcomings in the TEHV and aid in the rational design of an improved version. One challenge that remains is the identification of good biomarkers or methodologies for the noninvasive study of the structural remodeling and functionality of in vivo constructs so that a tissue engineered valve can be followed over time [125].

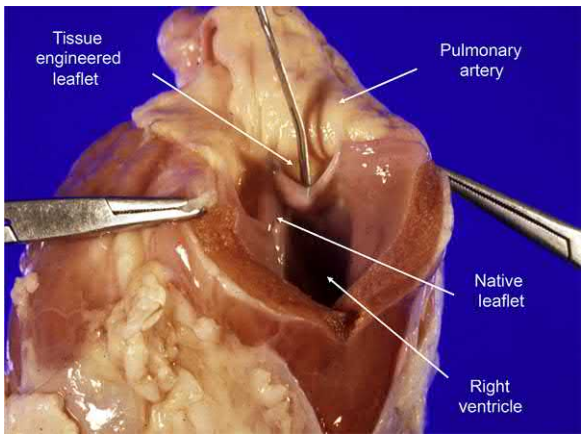

FIGURE 34.3 Photograph of a tissue engineered valve in a sheep heart.

Clinical applications of the tissue engineered heart valve

Dohmen et al. reported the first successful use of a TEHV using a decellularized cryopreserved pulmonary allograft [89]. Since then, Dohmen et al. have published long-term data on a series of 11 patients who underwent the Ross operation with a TEHV to surgically reconstruct the right ventricular outflow tract. In each case, the allograft was seeded in a bioreactor with autologous vascular endothelial cells that had been isolated from a segment of forearm vein 2–4 weeks prior to the operation. At 10 years follow-up, the TEHVs showed excellent hemodynamic function. All patients remained in New York Heart Association class I heart failure and computed tomography showed no evidence of calcification or valve degeneration (Fig. 34.4) [126]. Despite the lack of a control group, the small sample size, and the lack of long-term biochemical or tissue samples, this study is a significant advance in the clinical application of TEHVs. Re-analysis of the group of patients at 15 and 20 years postimplantation will offer insight into the effect that autologous cell seeding has on allografts in preventing long-term complications that are seen in unseeded allografts and homografts, such as calcification and valve degeneration.

Other investigators have used decellularized scaffold implantations with autologous cell seeding to tissue engineer cardiac valves. While this technique does not include any ex vivo cell seeding typical of tissue engineering approaches, this method holds the promise of valve implantation of allogenic or xenogenic tissue with a decreased host response to donor antigens. In lieu of data that host antigen recognition and antibody development may be linked to early tissue calcification and degeneration, the advantage of decellularizing a scaffold prior to implantation is that the cellular antigen burden decreases while the extracellular architecture and material properties are maintained [127].

FIGURE 34.4 Multislice computed tomography shows a normal tissue engineered pulmonary valve, without evidence of calcification or degeneration after 10 years in a male patient who was operated on at age 46 [126].

Use of xenografts in this fashion was halted in 2003 after Simon et al. reported failure of SynerGraft decellularized porcine valves implanted in four children as pulmonary valves for right ventricular outflow tract reconstruction. In this study, two valves were severely degenerated at 6 weeks and 1 year after implantation, and one valve ruptured 7 days after implantation, ultimately resulting in three deaths and the fourth child's valve was explanted prophylactically [73]. Since then, focus has turned to allogenic decellularized pulmonary valves using the SynerGraft process with results so far showing promise for this technique over standard cryopreserved allogenic valves. Studies published to date comparing SynerGraft decellularized allogenic valves with standard cryopreserved valves show in the SynerGraft valves decreased short-term stenosis or regurgitation, decreased clinically significant insufficiency, lower peak valve gradients, and fewer interventions [128]. Brown and colleagues performed a multicenter retrospective cohort study of 342 patients undergoing right ventricular outflow tract reconstruction with SynerGraft or standard cryopreserved valves and showed decreased regurgitation in the SynerGraft group and overall safety and efficacy at 4 years postimplantation [52].

In contrast to the enzymatic decellularization technique utilized by Synergraft, the Matrix P and Matrix P Plus xenografts were decellularized using only detergents, including Triton X-100, sodium dodecyl sulfate, and sodium deoxycholate, in the presence of protease inhibitors [129]. Early studies with Matrix P and Matrix P Plus in right ventricular outflow tract reconstruction, using TEHVs made from decellularized porcine pulmonary valves, demonstrated 87% freedom from intervention at 1 and 3 years postoperatively [129]. However, further studies showed a freedom from failure and dysfunction rates of 60% and 77% at 2 years and less than 20% freedom from failure at 3 years, with the most common cause for failure being conduit stenosis. Histological samples of explanted valves revealed poor cell growth into the scaffold and an abundance of inflammatory giant cells. Age less than 1 year at implant was associated with poorer outcome [130]. Further studies showed the grafts elicited a strong foreign body reaction of innate and adaptive immune cells, as well as a low neovascularization and high fibrotic deposition. These studies also showed that the grafts may have been incompletely decellularized, increasing their immunogenicity [131].

The complications of several early clinical trials with TEHVs have led to a resurgence of large animal research into TEHV neotissue development using a wide range of candidate materials, including decellularized valves, porcine small intestinal submucosa, and a PC-BU polymer seeded with a fibrin gel [132–134]. As these studies continue to provide more insight into the mechanisms of successful valve development and possible failure modes, there is hope for a new wave of TEHVs to begin to approach the clinic.

To date, synthetic scaffolds have not been used to fabricate a replacement heart valve for clinical use. However, the principles of tissue engineering outlined thus far and the approach of identifying and isolating a cell source, choosing a scaffold, and seeding the cells on to the scaffold were applied by Shinoka et al. in the first human clinical trial investigating TEVGs in children with complex congenital heart disease. The study began in 2001 and included 25 patients with an average age of 5 years undergoing extracardiac total cavopulmonary connection using the TEVG as a conduit. The synthetic scaffold used was a copolymer of polyglycolic acid and ε-caprolactone reinforced with poly-L-lactide. The scaffolds were seeded with autologous bone marrow-derived mononuclear cells. At 1 month postimplantation, all patients were alive and symptom free, and radiographic studies demonstrated no cases of TEVG aneurismal dilatation, thrombosis, or stenosis. Patients were followed serially with angiography, computerized tomography, or magnetic resonance imaging examinations. At 1 year there was one patient diagnosed with partial mural thrombus who was treated successfully with anticoagulation [135]. At mid-term follow-up (average 5.8 years postimplantation), four patients had died of causes unrelated to the TEVG and four patients had developed TEVG stenosis requiring balloon angioplasty or stenting [136]. At a late-term follow-up (average 11.1 years postimplantation) there were still no cases of graft related mortality in any of the 25 patients. In total, seven of the twenty-five patents (28%) developed asymptomatic stenosis that was treated with angioplasty [137]. Overall, the tissue engineered vascular conduits had reduced incidence of calcification, no risk of rejection because of autologous cell seeding, minimal risk of infection, and potential for growth [138]. Following the excellent results of Shinoka et al., the first FDA-approved human clinical trial investigating use of TEVGs in children with congenital heart disease was recently completed. Shinoka's results prove that the application of tissue engineering principles to vexing clinical problems has the potential to dramatically improve outcomes and lessen the morbidity and mortality of disease. All of these potential benefits would hold true for a TEHV.

As the field of cardiovascular tissue engineering continues to expand, so too will the desire to apply new devices, methods, and models in human clinical trials. It is essential for investigators to have thoroughly established the efficacy of techniques in large animal and preclinical models prior to translation into humans. Issues of bacterial contamination, insufficient cell seeding, and rapid degeneration of scaffold are common complications of tissue engineered devices and therefore strict protocols must be in place and adhered to in order for this promising field to expand clinically in an effective and responsible manner. While randomized clinical trials are the gold standard, it is not always possible to utilize this trial design, particularly for orphan applications such as TEHVs. Most importantly, though, for physicians, scientists, regulators, and engineers, is to apply this promising technology in a responsible manner, placing the safety and well-being of the patients as the top priority in all instances.

Conclusion and future directions

Successful development of a tissue engineered replacement heart valve holds the key to better treatment and improved clinical outcomes for end-stage valvular disease. Although significant progress has been achieved since its inception in the early 1990s, the field is young and many key issues have yet to be resolved. We are still exploring the cellular and ECM biology that govern the maintenance of a normal valve. Better characterization of valve cells like VECs and VICs may offer clues to optimize cell seeding. Recently developed small animal models for heart valve implantation may lead to deeper understandings of the mechanisms involved in valve repair and the formation of neotissue into a functioning valve. Moreover, advances in other fields of tissue engineering and stem cell biology may provide new cell types and processing strategies that could transform either the cell source or cell seeding technique used in TEHVs.

While still in its infancy, there has been some investigation into the use of TEHVs in fetuses at risk for hypoplastic heart syndromes. Hypoplastic heart syndromes are believed to arise because of poor intracardiac blood flow in-utero. Severe aortic stenosis leads to left ventricular dilation, dysfunction, and ultimately left ventricular growth arrest [139–142]. In fetuses with aortic stenosis, aortic valvuloplasty has been shown to restore flow and enable postnatal biventricular circulation in patients who otherwise have a high likelihood of developing hypoplastic left heart syndrome [143,144]. After birth, however, patients treated with valvuloplasty are at risk for aortic regurgitation and may require additional procedures such as valve replacement, which the neonate is likely to

outgrow several times during his or her development. A preferable paradigm would be to utilize tissue engineering principles to prevent the progression of ventricular growth arrest to allow for biventricular circulation, while simultaneously providing a competent TEHV that grows with the fetus.

The success of transcatheter heart valve implantation is well-established, and fetal aortic valvuloplasty has recently reached use in the clinic. Although some investigators have begun establishing animal models, there is little existing literature on the combination of these techniques towards transcatheter implantation of stents and heart valves in fetuses. Weber et al used a hybrid approach in which pregnant ewes underwent a midline laparotomy, followed by fetal heart cannulation and guidewire placement through the ductus arteriosus into the aorta. A 14-French delivery system was then advanced to the pulmonary artery where a stent was successfully deployed [145]. This demonstrated the feasibility of prenatal stent delivery into the pulmonary artery using a hybrid trans-apical technique in a sheep model. Our group's preliminary experience with endovascular interventions in fetal lambs suggests that percutaneous delivery is feasible. In ongoing preclinical work, we have successfully percutaneously implanted TEHVs in the right ventricular outflow tract of fetal sheep, using a 17-gauge trocar needle introduced through the maternal abdomen. The work thus far is promising and the prospect of introducing TEHVs into the fetal milieu holds considerable promise for the clinic, as well as innovating ways to harness fetal development for tissue engineering.

Development of surgical techniques for valve implantation in the fetus may allow for better outcomes, as the fetal milieu is known to have a higher regeneration potential. Transcatheter valve deployment approaches have the benefit of being much less invasive than standard open surgical techniques, allowing for more intact native environment for tissue engineered valve remodeling. Traditional stents do not degrade over time, limiting their usefulness in tissue engineering approaches. However, recent developments and research into degradable stents may allow transcatheter deployment of tissue engineered valves. Similarly, growth in other fields like 3D printing or quantification of flow using magnetic resonance imaging may eventually find clinical applications in the technologic advancement of TEHVs. To that point, it is clear that tissue engineering is a multidisciplinary, multifaceted field that requires cooperation, coordination, and collaboration between experts in a variety of different specialties. Fostering these types of relationships using unique funding mechanisms and programs will help move this field forward and will ultimately benefit the patients that depend upon its growth.

Introduction

Diabetes mellitus caused by the destruction of β-cell through autoimmune-mediate attack has become the most serious, chronic, and expensive disease. The related glucose homeostasis disruption leads to acute complications or death if left untreated. As the only available treatment for diabetes consist of exogenous insulin supply and while islet transplantation temporarily confers normoglycemia to patients, the lack of a renewable source of insulin-producing β-cells hampers the use of this treatment option. Although significant hurdles remain, in the last decade, tremendous progress has been made in generating insulin-producing cells from both mouse and human pluripotent stem cells. Following the principles that guide pancreas embryonic development is a common aspect in all differentiation protocols with considerable success in generating β-like cells in vitro. Greatest outcome of the refined protocols became apparent in the first clinical trial announced by the ViaCyte, Inc. in October 2014 and recently in Europe by the Center for Beta Cell Therapy in Diabetes (Brussels) in January 2019, based on the implantation of pancreatic progenitors (PPs) that would further mature into functional insulin-producing cells inside the patient's body. In this chapter, we will update and discuss the state-of-the-art in β-cell−replacement therapies based on the differentiation of pluripotent stem cells into glucose-response and insulin-producing cells of potential use in the treatment of type I diabetes.

State-of-the-art

A first breakthrough for in vitro differentiation and selection strategies was reported by Soria et al., when it was showed for the first time that the process was doable [1]. Combination of directed differentiation with gene-trapping strategies succeeded in the manufacture of insulin-producing cells derived from rodent embryonic stem cells that normalize blood when implanted into streptozotocin diabetic mice [1]. Further reports improved the system introducing new differentiation strategies, such as inhibiting sonic-hedgehog, or selecting cells that express a gene also expressed in islet progenitor cells (Nkx6.1) [2]. It was also shown that differentiated cells do not form teratomas [2,3], mature after 30 days inside the host [2], and effect on animal models in dose-dependent [4]. A definitive breakthrough was the demonstration that the process may be translated into human cells [5−8]. In vitro differentiation protocols for human embryonic stem cells (hESCs) or human induced pluripotent stem cells (hiPSCs) succeeded in generating definitive endoderm by using Activin A [5,6,8]. From then a tremendous list of protocols has been published that ends with insulin-producing cells derived from pluripotent stem cells. The limited space of this commentary does not allow acknowledging the full amount of contributions. However, in vitro differentiation protocols reached a non-return outcome in October 29, 2014 when the first clinical trial was announced by ViaCyte, Inc., San Diego, CA [9]. The strategy of ViaCyte, Inc. consists in implanting β-cell progenitors subcutaneously into a biocompatible capsule that may eventually be removed. The pilot study (ClinicalTrials.gov Identifier: NCT02239354) approved by the Food and Drug Administration is currently recruiting participants; however, no information has been made public yet on the evolution of the implanted patients.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00036-8

After the proof of concept was established in rodent embryonic stem cells (ESCs) [1] and hESC [5–8], more than 100 papers reported the conversion of different stem cells and progenitors into the insulin-producing cells. Here we will discuss the consolidated knowledge using mammalian embryonic stem cells as well as innovative concept of islet cell regeneration giving support to a new era in the treatment of diabetes mellitus.

The current success in generating pancreatic cell lineages from hESCs relies on recapitulating the key events that regulate pancreatic lineage commitment in the embryo. The advances in our understanding of the key transcription factors and signaling pathways that govern pancreas development and β-cell formation have been crucial for the design of new protocols for generation of in vitro insulin-producing cells from ESCs. Our knowledge of human pancreas development is derived largely from models of animal, such as rats, chicks, fish, and mainly mice, and it assumes that the molecular and cellular aspects of pancreas development are conserved, although some aspects of the mouse ESCs differentiation protocols may differ from those applied to hESCs differentiation protocols.

The challenge of making a β-cell

Tremendous progress has been made in the field of pancreas development, and it has been extensively reviewed [10,11]. Here, we will focus on the main transcription factors that govern different stages of islet development and β-cell fate; thus the common approach to differentiate hESC and human-induced pluripotent cells toward β-cells is based on a multistaged protocol attempting to reproduce in vivo pancreas development. Protocols aim to induce hESCs and hiPSCs to follow a sequential transition through mesendoderm, definitive endoderm, gut-tube endoderm, pancreatic endoderm, and endocrine precursor stages, to finally obtaining functional insulin-expressing cells [12–16]. Reported signaling pathways and factors required to direct pluripotent stem cells differentiation toward functional insulin-secreting cells are the result of years of investigation. However, due to the complexity of the aim, a highly efficient differentiation protocol is still missing.

Recent reports have detailed strategies that overcome prior hurdles to generate β-like cells from hESC and hiPSCs cells in vitro [12,13]. As the field progresses toward generating therapeutic β-cells from stem cell precursors, there are several hurdles to overcome. First, the cells must sense glucose and respond with appropriate insulin secretion. Over the last 10 years, improved protocols to direct the differentiation of hESCs into the pancreatic lineage have been established using combinations of small cell permeable molecules (growth and differentiation factors), such as retinoic acid, kinase C activator (Indolactam V, PdBU), fibroblast growth factors (bFGF), TGFb pathway inhibitors (Alk5 inhibitor, Dorsomorphin, or Noggin), BMP inhibitors, Sonic hedgehog pathway inhibitors (KAAD-cyclopamine or SANT-1), nicotinamide, thyroid hormone, nitric oxide (NO), and resveratrol or miRNAs (miR-7) [14–19]. However, in a typical multistage protocol, the final cell population has about 20%–30% stem cell–derived β-cells. Therefore improving the efficiency remains an important challenge. The necessity to obtain mono-hormonal insulin (C-peptide)-positive cells with high efficiency has led, in addition, to the identification of new molecules that not only triggered maturation of pancreatic endocrine precursors toward a β-cell phenotype but also improved glucose-stimulated insulin secretion in differentiated β-cells. Kieffer's group described a seven-stage in vitro differentiation protocol that efficiently converts hESCs into insulin-producing cells. Their so-called Stage-7 cells expressed key markers of mature pancreatic β-cells and also displayed glucose-stimulated insulin secretion similar to that of human islets of β-cells during static incubations in vitro [13]. Most recently, this approach reached an outstanding challenge by showing that upon transplantation into immunocompromised mice, the cell transplanted restored glycemia within months [3] or weeks [12,13] of the transplantation. Something that seems to depend on the state of maturation of the cells, since one of the great dilemmas is the full cell maturation that may be possible in vitro or may occur shortly after transplantation. In addition, the protocols take a huge economic and time commitment that is nontrivial.

Recent achievements (first generation of pancreatic progenitors used in the clinic)

The first pioneering study focused on hESC to make PP cells that can turn into insulin-producing cells, providing the first compelling evidence that implantation of hESC-derived pancreatic cells into mice resulted in the generation of glucose-responsive insulin producing cells. These results laid the foundations for the beginning of a prospective, multicenter, open-label, first-in-human phase 1/2 clinical trial (NCT02239354) in 2014, conducted by ViaCyte, Inc. to deliver the PP cells in an immunoprotective device product, PEC-Encap (also known as VC-01), in subjects with T1D. Next, in 2017, a clinical trial was started (NCT03163511), testing ViaCyte's PEC-Direct product (also known as VC-02), a new open device allowing direct vascularization of stem cell–derived PEC-01 PP cells, but that requires immunosuppressant drugs, and recently, in January 21, 2019, the Center for Beta Cell Therapy in Diabetes, coordinator of an international consortium in translational medicine in diabetes, and

ViaCyte, Inc. announced that VC-02 has been implanted in type 1 diabetes patients at a subtherapeutic dose. These are the first patients in Europe to receive PEC-Direct, an encapsulated PP cell product candidate designed to replace lost insulin-producing β-cells and restore blood glucose control for type 1 diabetes patients who fulfill entry criteria for a β-cell replacement therapy. Therefore the long-term function of these cells in vivo is still unclear, highlighting the presence of survival issues of encapsulated cells in human. In this scenario, to keep the graft viable in long-term patients after cell transplantation further strategies that improve both cell retention and long-term cell viability should be implemented. Their longevity in vitro and in vivo has not been clearly studied. To achieve a high ratio of survival and glucose response of transplanted β-like cells in vivo, several major issues should be considered, such as, determining an optimal transplant site in the body [20,21], accelerating maturation of transplanted β-like cells in vivo [22–24], protecting transplanted β-like cells from immune attack and inflammatory reactions in the patient [25–27], and facilitating the vascularization of the transplanted β-like cells and the release of insulin [28]. Besides, reliable assays are critically needed to monitor graft potency in hESC-derived pancreatic cells transplantation. These cells must show many of the key features and functional similarities to human β-cells in terms of gene expression [29,30], insulin content [1], glucose-stimulated human c-peptide/insulin secretion [12], ultrastructure of insulin granules [12], and glycemia modulation in streptozotocin (STZ)-induced diabetes models [3,12,13]. Several methods have been proposed to monitor qualitative or quantitative characteristics of hESC-derived PP. Global gene expression analysis is used to assay the expression of several endocrine cell markers for the initial evaluation of hESC differentiation capacity. Clusters with PDX1 + /NKX6-1 + cells can be transplanted into mice to generate glucose-responsive cells in vitro and in vivo.

Need of late maturation: cabimer protocol

Over the past decade, much has been published about the differentiation protocols for the generation of insulin-producing cells from hESCs and/or hiPSCs, in the pursuit for the recipe to make the best insulin-producing cells. Although essential growth and differentiation factors have been identified, an appropriate response to glucose in terms of insulin release was not obtained until the cells were transplanted, when subsequently matured into functional β-like cells in vivo.

Several groups are working to refine the recipe [12,13,31]. As a result, refined protocols are being elaborated to turn immature pancreatic endocrine precursors into functionally mature glucose-responsive β-cells before transplantation. In line with this proposal, different factors, that influence the maturation, enable glucose-stimulated insulin secretion in vitro, and obviate the need for in vivo "maturation" to achieve functionality, were proposed. Among various tested compounds a few small molecules, stimulating sirtuin activity, such as resveratrol, that has been demonstrated improves glucose homeostasis, decreases insulin resistance, protects pancreatic β-cells, improves insulin secretion, and ameliorates metabolic disorders [32]. Therefore this function can be harnessed in the later stages of β-cell differentiation in vitro. Resveratrol yields functional and transplantable insulin-producing cells capable of restoring glucose homeostasis diabetic mice [14]. Recent evidence reveals that miRNAs acts as switch in the maturation of insulin-producing cells by regulating the expression of targets to affect insulin synthesis and secretion [33]. A number of miRNAs are important regulators of β-cell differentiation and function, including miR-375 [34], miR-24, miR-148 [35], miR-200, miR-30d, miR-124a [36], miR-9, miR-15a, miR-16, miR-146a, miR-29a, miR-34 [37,38], and miR-7, the latter being a key regulator to regulate functional aspects of glucose-stimulated insulin secretion [15]. Therefore miRNAs involved in the formation of hESC-derived pancreatic cells, should be considered for improvement in the regulation of insulin synthesis and secretion. These studies reveal that metabolic maturation could be conducted in vitro without the need for in vivo maturation. Efficient assays for control points at each pancreatic development stage are essential to characterize the transcripts that are expressed in a stem cell–derived pancreatic β-like cell. While insulin is the "sine qua non" of the β-cell, insulin expression alone does not suffice to convey mature β-cell identity. Additional traits in the resulting cell population such as, glucose-sensing, cell excitability, insulin synthesis, packaging, and secretion, are required to transform a mere insulin-expressing cell into a mature and functional β-cell capable to release insulin in a pulsatile fashion [39]. A network of transcription factors underlies the regulation of a number of genes required for these functional traits, including PC1/3, NKX6.1, PDX1, PAX4, NKX2.2, NEUROD, PAX6 ISL1, and MAFA specific markers of β-cell lineage [40–46] (Fig. 35.1).

Strategies to maintain cell viability

One of the main challenges affording cell therapy for patients with diabetes consist of finding the way to enhance the ability of transplanted cells to integrate into tissues, to survive, and to induce healing and growth. Securing an optimized in vitro differentiation protocol, the field must now turn toward how to address

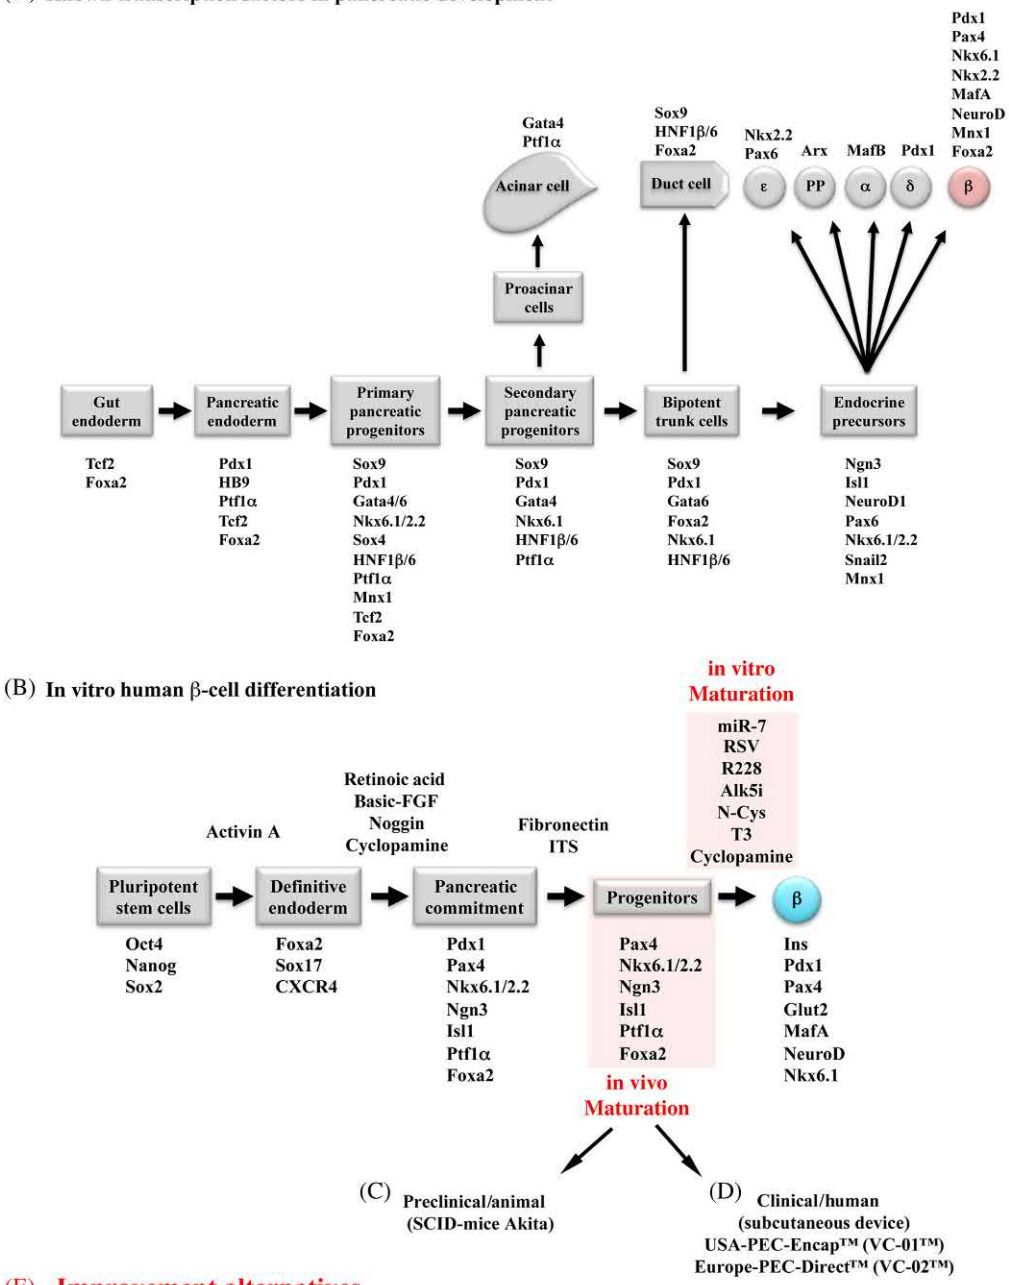

FIGURE 35.1 Simplified model of pancreas organogenesis, differentiation and maturation strategies, and alternatives to obtain a functional β-cell. (A) Transcription factors required during the development of the islets of Langerhans. (B) Sequential expression and temporal variation of genes during in vitro differentiation protocols. (C) Pancreatic progenitors to specialize into functional β-cells through maturation after transplantation into STZ-induced hyperglycemic mice. (D) Strategy for subcutaneous implantation of encapsulation devices with β-cell progenitors that can mature inside the patient's body and, eventually, control blood glucose and protect from immune insult. (E) Strategies to be considered to improve the process. *Adapted from Soria B, Gauthier BR, Martín F, Tejedo JR, Bedoya FJ, Rojas A, et al. Using stem cells to produce insulin. Expert Opin Biol Ther 2015;15(10):1469–89.*

immunological barriers for transplantation? And thus, to deal with immunosuppression, encapsulation, cell delivery, and to take advantage of gene editing. The first possibility for the allogenic transplant requires lifelong immunosuppression to control both alloimmunity and autoimmunity and to prevent the rejection of the graft [47], although the possibility of using a patient-specific induced pluripotent stem cells (iPSC)-based personalized-medicine strongly arise [48]. In addition, the immunosuppressive regimen required for pancreatic stem cell−replacement affect at the same time the proliferation and survival of the transplanted cells [49]. Though, the best way to improve cell survival is to build an artificial niche that mimics the extracellular matrix in vivo, from this starting point, one can add additional features, such as molecular signals, that enhance cell resistance or structures that protect cells from host's hostile. Therefore the β-like cells must be protected and isolated by a physical barrier to escape the immune system attack. Still, the long-term viability and functionality of the cells depend on the physiological microenvironment conditions of the host. Transplantation of β-like cells into humans must also involve encapsulation technology, not only to prevent destruction of the grafted cells by the immune system but also to contain the graft itself [50]. Examples of extravascular macrocapsule technologies, that display promise for PP cell transplantation, includes the TheraCyte and ViaCyte implant systems [25−27] and the polymer encapsulated with alginate derivatives [51]. So far, no approach has succeeded to prevent immunologic rejection of cells. A recent strategy to evade the immune rejection is based on the possibility of genetically modified cells to evade the immune system. CRISPR gene editing has the potential to protect the transplanted cells from the patient's immune system via ex vivo editing of immune-modulatory genes within the stem cell line that is used to generate the pancreatic-lineage cells. In this regard, CRISPR-Cas9 genome editing is used to specifically switch off antigenic determinants of the cell surface and therefore to escape postimplantation rejection [52−54].

Encapsulation and tolerogenic strategies

The next major challenge is the difficulty in maintaining graft functionality in spite of immune rejection by recipients. Cellular encapsulation technologies are an attractive strategy to protect transplanted β-like cells from immune attack, being able to prevent both allogeneic rejection and autoimmune attack. Encapsulation strategies are based on embedding insulin producing cells in solid matrices, creating a semipermeable environment around β-cell-like cells capable of immune-protection, but also allowing for efficient mass and oxygen transfer [50,55,56]. Based on published records, we can affirm that mature pancreatic cells delivered in a cell encapsulated−based systems accelerate the development of glucose-sensitive for β-like cells and warrant further investigation, given that, successful development of cell therapies will require consideration of processes controlling both β-cell development and mature function [15,57]; success of these cell strategies also include how amenable the protocols are to scaling-up in order to generate the hundreds of millions of cells required per patient [58,59], and encapsulation of β-like cells has demonstrated efficacy long-term control of blood glucose levels with a single minimally-invasive outpatient implant [60,61]. These approaches face challenges, including oxygen and nutrients limitations, due to the lack of vascularization and the possibility of a fibrosis coating the graft as a foreign material [62]. Vascularization is the major factor that determines whether the transplanted graft can survive and respond to the glucose fluctuations in vivo. Both healing and vascularization around the grafts are considered as important variables; a previous vascularizing pretreatment at the implant site may be essential for success in the correction of hyperglycemia through its increases and/or maintains cell survival, endocrine differentiation, and/or β-cell maturation [28,63]. Innovative biomaterial coatings and novel encapsulation design are being developed to overcome these challenges toward long-term cell function or survival after transplantation and to enable clinical success and minimize risks of encapsulated β-like cells or islets.

The concept of cellular medicament

Regulatory authorities, such as the US Food and Drug Administration (United States), the Public Health Agency of Canada (Canada) and the European Medicines Agency (Europe), established that when cells are used to treat diseases, they have to be considered "cellular medicaments" and fulfill the same criteria of small molecules and biologicals [64]. So far, the only established cell therapy is bone marrow transplantation. Cell therapy of diabetes is still an experimental "cellular medicament" and has to follow the well-established pattern of Phase I (safety and viability), II (efficacy), and III (efficiency). Before authorization of use and possible commercialization, the dossier has to be approved by the Regulatory Agencies. Our impression is that there is still room to improve these cellular medicaments by iterative preclinical and clinical research. Since we are aware of the high cost of this development and that both ViaCyte, Inc. and BetaLogics are subsidiaries of Janssen Pharmaceutical (Johnson and Johnson group), we wonder whether these medicaments will be cost-effective and affordable for the millions of people that suffer diabetes.

Conclusion

Despite the positive outlook for the future of stem cell–derived treatments for insulin-dependent diabetes, there is still two major challenges to overcome, the first is the need for better control over the methods that make β-cells from stem cells and the second is preventing an autoimmune attack after transplanting the stem cell–derived β-cells into patients. In this scenario, further studies are required to generate new transplantable insulin-producing cells that are safe and able to mimic closely the complex functions of an endogenous β-cell and to overcome several hurdles; the list is too long, but we summarize the following to be solved: in vitro differentiation strategies to generate either mature postmitotic β-cells or β-cell progenitors that may be safely implanted into the host; cell-selection methods to end with a pure β-cell population; election of the best encapsulation device to implant the cells that favors oxygen supply, promotes neoangiogenesis, and displays tunable injectability, porosity, stiffness, avoiding the foreign body reaction, and mimicking the extracellular matrix natural microenvironment; elucidation of mechanisms underpinning the therapeutic effects in preclinical representative animal models; and validation of cell–host interactions. Besides, given the enormous task that we are facing, we also suggest that a private–public international consortium with transparent rules may be a more efficient way to reach a safe, effective, and affordable cure for diabetic patients.

Chapter 36

Bioartificial pancreas: challenges and progress

Paul de Vos

Section of Immunoendocrinology, Department of Pathology and Medical Biology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands

Introduction

Type I diabetic (T1D) patients have lost the majority of their insulin-producing cells due to an autoimmune disease [1]. As a consequence, the patients depend on daily insulin injections for their regulation of glucose levels. Although this therapy is lifesaving, it does not regulate glucose-metabolism as tightly as the endocrine pancreas. Patients may therefore still suffer not only from diabetic complications such as nephropathy and retinopathy but also from vascular issues responsible for cardiac and brain damage [2–5]. The chances of these complications do decrease when glucose levels are intensively regulated by regular measurements of glucose levels and injection of insulin according to the patients' needs, but this therapy is associated with regular hypoglycemia and disabling hypoglycemic unawareness [3,4].

A better therapy is highly needed in order to improve the quality of life of T1D patients. An option is to transplant the endocrine pancreas [2]. Basically, there are two options: transplantation of the whole pancreas or only the endocrine pancreas. Transplantation of the whole pancreas is done in specialized centers in patients that as the consequence of end-stage renal failure receive a kidney transplant [6,7]. Although the grafts are in most cases successful in inducing normoglycemia and insulin independence, the procedure is associated with major surgery, some morbidity and severe complications may occur [7]. This makes the procedure limited to those patients that suffer from end-stage diabetic complications. Transplantation of only the endocrine pancreas, that is, the insulin-producing pancreatic islets is not associated with major surgery as it involves not more than infusion of tissue via the portal vein and in principle can be applied in a far larger group of T1D than patients that currently qualify for whole pancreas transplantation.

Transplantation of only the endocrine pancreas experienced a major breakthrough in 2000 with the introduction of the so-called Edmonton protocol that involved the introduction of immunosuppressive protocols lacking steroids [8,9]. With this protocol the majority of the T1D recipients of an islet graft became normoglycemic and insulin independent. Most patients remained insulin independent for more than a year, but after 2 years, 50% of the patients were still insulin independent [10]. The 50% that became insulin dependent still experienced improvement in quality of life as hypoglycemic events or unawareness were virtually absent in this group compared to the pre–transplant period. The technique has further evolved in the past two decades. Some experienced groups are able to successfully transplant islets from one single donor by controlling the parameters known to influence the islet yield [11,12].

Although important advances have been made in clinical islet transplantation programs, the procedure still requires lifelong administration of immunosuppressive medication. This is a major obstacle for wide application in T1D patients as immunosuppressive protocols have serious side effects in recipients [13,14]. It is unlikely that immunosuppression will ever be an acceptable alternative for insulin therapy in T1D. This is the main reason why the scientific community is searching for approaches to allow transplantation of islets in the absence of chronic immunosuppression. This is how the bioartificial pancreas was introduced. By packing insulin-producing cells in semipermeable but immunoprotective membranes islets

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00037-X

can be protected from the host immune system while regulating glucose metabolism on a minute-to-minute basis.

History of the bioartificial pancreas

The development of encapsulation technologies to immunoprotect cells has a long history and dates back to 1933 [15]. In the groundbreaking publication of Bisceglie [15], tumor cells were encapsulated and implanted in the peritoneal cavity of pigs to follow the fate of the cells when free floating in the device in the absence of vascularization (Fig. 36.1). Bisceglie [15] applied amnion tissue to encapsulate the cells. Already at that time it was recognized that these tissues have semipermeable properties and some degree of immunoprotection. The authors demonstrated prolonged survival of the encapsulated tissue and therewith introduced the concept of cell-encapsulation for prevention of graft rejection. However, it took till 1950 when Algire et al. [16] recognized the potential of the technology for the cure of endocrine diseases. They [16] created artificial polymeric diffusion chambers in which therapeutic cells were encapsulated with the aim to create an immunoprotected microfactory involving cells that release therapeutics upon demand. The proof of principle was demonstrated but Algire et al. [16] also demonstrated the importance of application of fully biocompatible materials and the need for defining permeability properties. Since the 1980s numerous devices have been published in different conformations with applications of many different polymeric biomaterials of different compositions. It has let to testing of the devices in many disorders where management of the disease needs a minute-to-minute regulation of metabolism such as in hemophilia B [17], anemia [18], dwarfism [19], kidney [20] and liver failure [21], pituitary disorders [22], central nervous system insufficiency [23], and diabetes mellitus [24]. In the past two decades, important advances have been made in the technology of cell-encapsulation. Many of those studies focus on application in T1D as the disease is affecting 1.25 million individuals in the United States alone and is associated with $9.8 billion on health care cost [25]. These costs can be heavily reduced if a therapy is developed that tightly regulates glucose levels. Encapsulation of cells is considered to be such an approach.

Replenishable cell sources and encapsulation

During the past 5 years, encapsulation technologies have received much attention by the scientific community. One of the leading reasons for this is the advances in replenishable insulin-producing cell sources (Fig. 36.2). In principle, these cell sources provide an inexhaustible source for insulin-producing cells for the large group of T1D patients. As most encapsulated grafts still demonstrate limited survival times such a replenishable cell source may also allow replacement of the graft after cease of function, which also may facilitate application of the technology in a wider group of patients.

Most of the replenishable cell sources are of allogeneic or xenogeneic origin and require an encapsulation technology to prevent rejection of the cells. There are several reports demonstrating the usefulness of encapsulation for immunoprotection of replenishable cell sources. Pagliuca et al. [26] developed glucose-responsive stem cell–derived β cells that in another study were encapsulated in alginate-based microcapsules and were implanted in T1D mice models, which induced normoglycemia for up to 174 days [27]. The protocols for maturation of human stem cell–derived β cells has

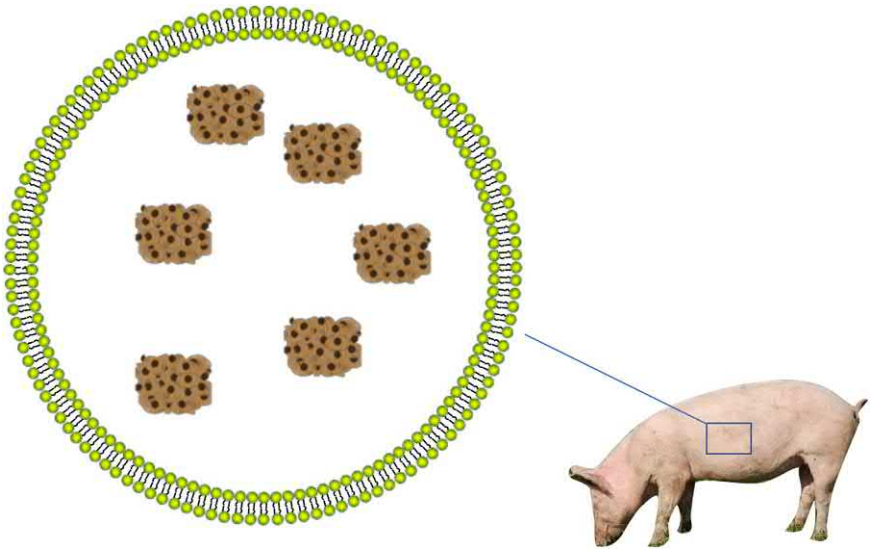

FIGURE 36.1 The concept of cell-encapsulation for immunoprotection was introduced as far back as in 1933. Bisceglie [15] implanted tumor cells after encapsulation in an amniotic sac into the peritoneal cavity of pigs to study the behavior of the cells in the absence of immunosuppression. Bisceglie did not recognize the impact of this approach for treatment of disease.

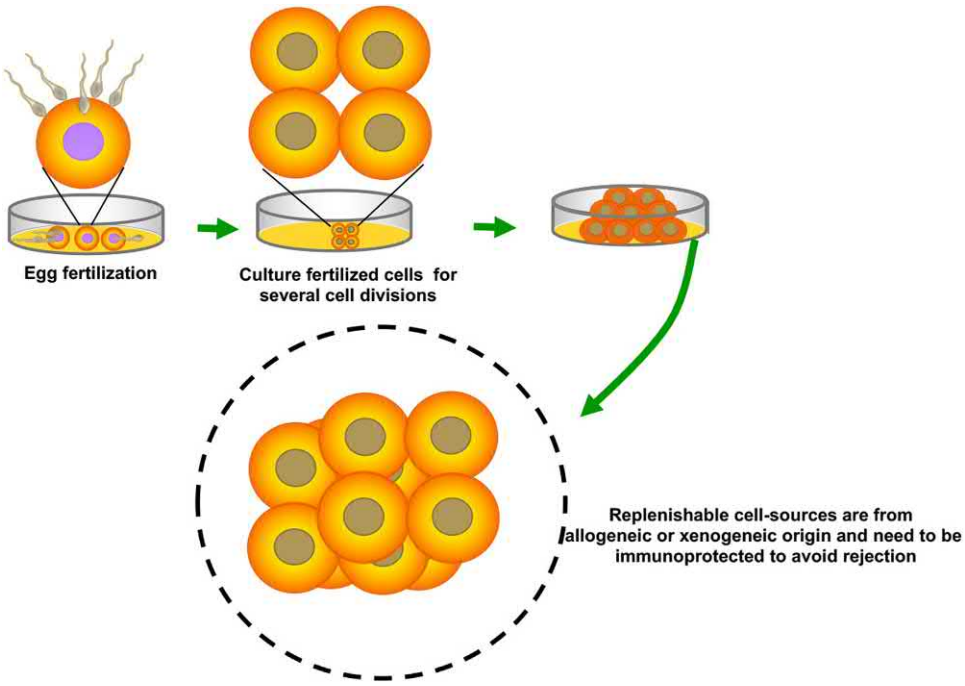

FIGURE 36.2 Replenishable insulin producing cell sources such as cells obtained from embryonic stem cell sources are either from allogeneic or even xenogeneic origin. To prevent graft rejection immunoisolation by encapsulation might be necessary.

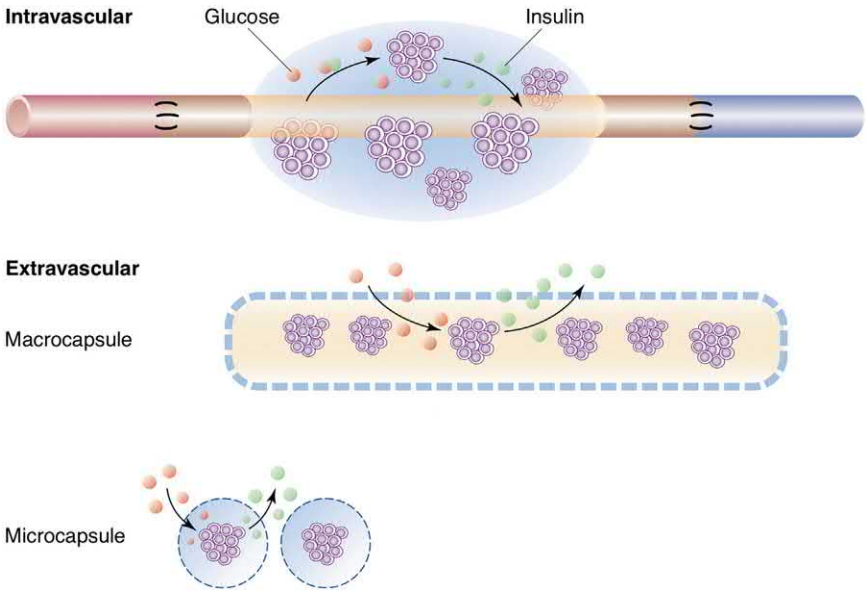

FIGURE 36.3 The bioartificial pancreas exist in three concepts. The intravascular macrocapsules, which allow fast exchange of glucose and insulin due to direct vascular access. The extravascular macrocapsules which can be implanted in the peritoneal cavity or under the skin and the extravascular microcapsules with an optimal volume to surface ratio that usually are implanted in the peritoneal cavity.

improved tremendously and some matured cells have near normal glucose-induced insulin release as early as 3 days after transplant [28]. There are however also other replenishable cell sources in development in which encapsulation might be helpful. For example, genome-editing technologies might also lead to new insulin-producing cell sources [29].

Macro- or microedevices

Currently there are three categories of devices under development for immunoprotection of insulin-producing cells: intravascular macrocapsules, extravascular macrocapsules, and extravascular microcapsules [30–32] (Fig. 36.3). All approaches have their pros and cons as will be discussed in the next section.

In intravascular devices, groups of islets are enveloped in relatively large diffusion chambers that protect the cells from the effector arm of the immune system. Intravascular devices are connected to the recipient's vascular system by anastomosis in most cases as arteriovenous shunt [33,34]. An advantage of intravascular devices is the fast exchange of nutrients, glucose, and insulin, which make a near

normal regulation of glucose metabolism possible. Because of these advantages the technology has received much scientific attention and was tested in both small and large mammals [35–39]. An issue with this approach is the chance of development of thrombosis, which might interfere with the patency of the device, and it might even happen that thrombosis occurs distant from the device [30,35]. High anticoagulation medication as well as the application of large bore devices was necessary to avoid patency issues and to guarantee flow-rate through the devices [40]. Especially the need for systemic and chronic anticoagulation therapy and also the relatively large size needed for the device were considered to be issues for clinical application. Development of these devices was stopped for almost two decades because of these issues but recently revisited. Recent developments in the field of lab-on-chip has led to the development of ultrafiltration membranes that provide better hydraulic permeability and an optimal permeability than could ever be achieved with the classical membranes that up to now were being applied in the intravascular bioartificial pancreas. With prototypes of these devices, clinically relevant numbers of islets could be kept viable and functional for prolonged periods of time [33]. The devices are proposed to be connected as arteriovenous shunt and should due to a difference in pressure between the artery and the vein result in an ultrafiltrate flowing through the device containing glucose and nutrients that flow through the small islet chamber inducing insulin release and adequate nutrition of the tissue. In vivo results are not available yet, but considering the enormous advances made in lab-on-a-chip technologies combined with the evolution of ultrafiltration techniques creates optimism about novel developments in the area of intravascular devices.

Extravascular devices in contrast to intravascular devices are not connected to the blood stream but implanted under the skin or in the peritoneal cavity without direct vascular access. For nutrition the cells in the device depend on free diffusion from the surroundings or on diffusion out of capillaries that grow in some concepts toward the surface of the device [30,41–43]. Extravascular devices are produced as macrocapsules or microcapsules. Macrocapsules can be produced from different types of polymers in the geometry of cylinders or disks or even as strings to which the islets are attached [43]. The macrocapsules usually contain groups of islets, which are enveloped in the device and subsequently implanted. For adequate nutrition, blood vessels should not be further away that 150–200 μm [44,45] to avoid formation of necrotic or necroptotic cells, which might leak immunogenic components into the surrounding. The technology is associated with not more than minor surgery and therefore considered to be a feasible approach for treatment of T1D. A major challenge, however, has been adequate oxygen supply toward the islets in the macrocapsules. Metabolic active islets require a high oxygen supply, which in most concepts of extravascular macrodevices is cumbersome due to an unfavorable surface-to-volume ratio. The competition for essential nutrients between islet cells in the device worsens this issue. As a consequence, with conventional macrodevices, the seeding density cannot exceed 5%–10% of the internal volume of the devices [46], which is a serious issue for clinical application as extremely large or several devices have to be implanted in human recipients to achieve efficacy.

This disadvantage of extravascular macrocapsules has partly been solved by inclusion of an external oxygen supply unit. The best studied approach with an external oxygen supplier is the so-called Beta-O2 device (Fig. 36.4). This device consists of two chambers. The inner chamber is the unit containing the insulin-producing cells, which are surrounded by the second chamber in which oxygen can be infused with a manually operated pump that funnels to the skin [47–50]. The inner chamber comprises a multilayer membrane providing immunoprotection. This membrane consists of a polytetrafluoroethylene mesh embedded in a high mannuronic acid alginate gel and a silicon rubber [45]. The multilayer membrane is freely accessible for essential nutrients such as oxygen and allows free exchange of glucose and insulin while providing immunoprotection [47]. In principle, this approach overcomes the issue of the low seeding density of the device and the need to use several or extremely large devices. Due to the versatile oxygen supply islet density can be increased and is much higher than in conventional extravascular macrocapsules. In the initial concept, 2400 IEQ/device were placed at a density of 1000 IEQ/cm^2 with refueling every 2 hours with O_2 [49]. This induced normoglycemia in diabetic rat

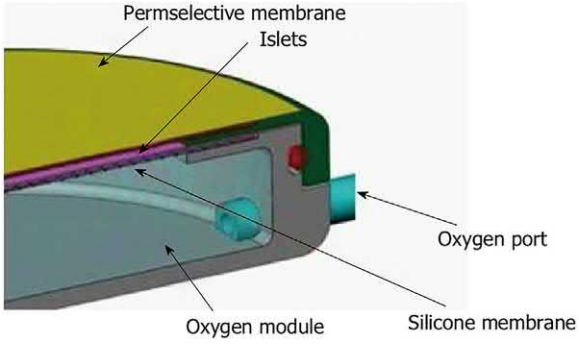

FIGURE 36.4 Schematic presentation of the Beta-O2 device. Within this concept islets are in larger groups encapsulated in semipermeable membranes. By inclusion of an oxygen chamber which can be refueled islets are provided with sufficient oxygen to generate adenosine triphosphate (ATP) and insulin. This allows higher seeding densities of islets than with conventional extravascular devices. This concept has successfully been tested in humans.

recipients for periods up to 240 days. In mini-pigs, which have a more complicated animal model with higher demands for both the device and the enveloped islets, efficacy was shown with a mass of 6730 ± 475 rat IEQ/kg [49]. Minimal responses against the devices were observed, and viable islets were retrieved after 3 months of implantation demonstrating the feasibility of the approach. During recent years, efficacy of the technology was shown in a human in an allogeneic setting and in nonhuman primates with xenogeneic porcine islets at a dose of only 20,000 islets/kg BW [51,52]. During reduction of exogeneous insulin supply, stable glycemic control was maintained for periods up to 190 days after which the devices were explanted [49]. After retrieval the devices showed optimal biocompatibility even in the human recipient and the device containing blood vessels in the immediate vicinity of the device [49]. It should be mentioned that the lower efficacy in larger animal models should not only be attributed to device issues but also to issues with islet-quality as finding suitable and high-quality islet sources for these types of experiments is still an issue and makes efficacy testing of the devices in larger mammals and humans complicated. Despite this, important advances have been made with macrocapsules, and supply of nutrients to the enveloped islets has created enthusiasm for human application of the technology when replenishable cell sources become available.

The other category of extravascular approaches is the microcapsules in which individual islets are enveloped in their own individual microcapsule. Microcapsules do suffer much less from oxygen supply or of lack of supply of other nutrients because of the more optimal surface-to-volume ratio. In our hands, if islets smaller than 150 μm are used, we observed no necrosis and optimal function for several months after implantation in the peritoneal cavity [53–56] (Fig. 36.5). Only larger islets (>250 μm) gradually develop central necrosis and cease to function after prolonged periods of implantation or culture [53–56], which might be prevented by reaggregating islets into smaller clusters [57]. Another advantage of microcapsules is that they can be made small enough to fit into organ structures with high vascularization degrees such as in the omental pouch although protrusion of cells is a challenge that needs to be solved in these approaches. Finally, microcapsules are because of their spherical small shape usually mechanically stable, and encapsulation can be done with nontoxic molecules and reagents [58] avoiding loss of valuable and rare donor tissue. This latter, that is, avoiding toxic reagents, is often an issue with macrocapsules and might lead to loss of tissue.

FIGURE 36.5 Neonatal pig islets after retrieval from a mice recipient at 8 weeks after implantation. If islets are smaller than 150 μm we do not observe any development of necrotic zone in islets.

The majority of studies addressing microencapsulation technologies use alginate as core material for the capsules. Alginates are available with different quantities of mannuronic acid (M) and guluronic acid (G), and suitability of different alginates depends on the system applied. To enhance permselectivity and mechanical stability, alginates are often coated with polyamide. Typically, for these systems a critical number of G–M polymers should be present as these G–M polymers are responsible for the binding of the polyamide structures on the surface of the capsules [59–61]. If cationic-based systems are used, other prerequisites apply to the alginate source. G–G blocks in alginate bind constitutive alginate molecules in a so-called egg-box model. These binding structures are responsible for the mechanical strength and stability of the system and therefore alginates with relatively high-G content are preferred. If, however, cations are applied with a higher affinity for alginate such as barium, it is not required to use high-G alginates as these cations bind both G–G and M–M. Typically, high-M alginates can only successfully be used with higher affinity cations such as barium [62]. This choice for the alginate type matching the system is an example of the complexity of the systems, which unfortunately in the field is not always acknowledged. This is one of the major reasons for the large variation in success rate of encapsulation systems when comparing different results of different labs. In many cases the type of polymer applied is not even documented or published illustrating a fundamental issue in this line of work [30,63].

Factors contributing to biocompatibility of encapsulation systems

In the past decade, many factors have been described, which contribute to prevention or are causing tissue responses against encapsulated cellular grafts. Biocompatibility is usually defined as “the ability of a biomaterial to perform with an appropriate host response

in a specific application." This definition was originally introduced for fully artificial organs, such as artificial prostheses [64]. Within the application of prostheses, a strong and immediate immune response is desired as it induces fibrosis of the prosthesis and integration into the surrounding tissue. The host response is desired as it allows integration of the prosthesis into the host tissue. For this reason, it is considered an "appropriate host response." For bioartificial organs such as the bioartificial pancreas that contain living cells, it is much more difficult to define "the appropriate host response." Fibrosis or integration into the surrounding tissue for extravascular devices is highly undesirable as it interferes with the nutrition of the enveloped tissue. Even a slight activation of the innate immune system may result in release of deleterious cytokines that might be harmful for encapsulated cells and should be avoided [65]. Preferably, the immune responses should be as minimal as possible to prevent massive cell-death, and to manage this response is far from easy [53,66–69].

In the past decade, much progress has been made in the field, and novel approaches to reduce or delete these responses have been published. These advances involve application of polymers/devices that lack proinflammatory residues, rational choices (combinations) of biocompatible polymers, insights into chemical conformations of surfaces to reduce host responses, and novel approaches for antibiofouling or immunomodulating biomaterials and application of polymers that form polymer brushes. These new developments will be discussed later.

Avoiding pathogen-associated molecular patterns in polymers

The role of pyrogenic contaminants and endotoxins in polymers in tissue responses against extravascular devices has been recognized for more than two decades [70,71] but is still influencing outcome of encapsulated islet grafts [41,68,72]. In recent years, we have developed a technology platform to identify possible immunogenic factors in polymers applied for cell-encapsulation and found that all currently commercially available polymers contain so-called pathogen-associated molecular patterns (PAMPs), including flagellin, lipopolysaccharide, peptidoglycan, lipoteichoic acid, and polyphenols [72]. The molecules are remnants of Gram-positive and -negative bacteria that come into the polymer preparation during processing, synthesis, or even during lyophilization procedures [72]. Some of these PAMPs classify as endotoxin but classical methods to quantify endotoxins such as the limulus amebocyte lysate assay does not react on many of these PAMPs and are consequently missed. Although regulations exist to which extend endotoxin levels are allowed in medical devices [63,67,73], we have the experience that these thresholds are far too high for bioartificial organs. Only devices with PAMP levels below the detection level did not provoke responses after implantation of the capsules in mice and rats.

PAMPs induce inflammatory responses in recipients either by diffusing out of the capsules or by being present at the capsule surface. This happens primarily by binding of the PAMP to pattern-recognition receptors (PRRs) on immune cells [74–76]. After the activation of PRRs on immune cells translocation of nuclear factor kappa-light-chain-enhancer of activated B cells occurs with inflammatory cytokine secretion as a consequence. This ultimately leads to adhesion of cells on the capsule surface and death of islet cells [77–80]. However, it should be emphasized that not only contaminants but also polymeric components can trigger these responses via PRRs. If wrong choices are being made for alginate sources uncross-linked mannuronic acid polymers can trigger immune activation via binding to Toll-like receptors (TLRs) [81]. These important novel insights have led to a broad acceptance that the field needs quality assessment systems for purity and immunogenicity of polymers applied in the devices [68,72].

Natural and synthetic polymers

Polymers applied in the bioartificial pancreas are both from natural or synthetic sources. As natural source it is mostly polysaccharides that are used in cell-encapsulation. The polysaccharides applied offer the advantage that they allow encapsulation of the cells under relatively mild conditions without affecting islet–cell viability [67]. Another reason why many favor polymers from natural sources is because hydrogels are formed that are as flexible as the surrounding tissue and still mechanically stable [82], while provoking minor or no host responses [20]. Synthetic polymers are also widely used and by some preferred because synthetic polymers hold the promise to allow reproducible production without batch-to-batch variations. Another reason why synthetic polymers are preferred is the ease by which they can be modified and tailor-made to improve biocompatibility or to generate other desired properties [83]. The type and suitability of different polymers applied in the field has extensively been reviewed [67,84–87] and will not be discussed in this chapter. Here we focus on the conformation of the molecules and how they can contribute to prevention of tissue response. Often this approach combines natural and synthetic polymers.

Multilayer capsule approaches

Many approaches where only one type of polymer was applied have significant shortcomings. For example, with

alginate, that is, the most commonly used polymer for cell-encapsulation, it was shown that when applied in low concentrations it was too porous to prevent ingress of immunoglobulin G [88,89]. Also, some systems with a monopolymeric approach were associated with low mechanical stability, higher surface roughness, and cell protrusions [58,90]. Because of these issues layer-by-layer systems were developed [91–93]. For alginate-based systems, mostly cationic polymers were applied to reduce permeability or enhance mechanical stability. This has evolved to development of layer-by-layer systems such as alginate-based systems coated with poly-L-lysine (PLL) [94], poly-L-ornithine [95,96], poly(ethylene glycol) (PEG) [97–99], chitosan [100–102], or agarose [103–107].

There is much misunderstanding and often lack of knowledge on the complexity of building an adequate polycationic membrane around alginate-based system. For example, for many years, PLL was considered to be a proinflammatory molecule leading to foreign body reactions [108–111]. New technologies in the field such as Fourier-transform infrared spectroscopy, X-ray photoelectron spectroscopy, and time-of-flight secondary ion mass spectrometry has revealed the essence of forcing PLL in certain complexes to avoid tissue responses [59,61,112–120]. First PLL-based system need alginates with an adequate number of G–M polymers as these are the molecules responsible for PLL binding. These alginates should first be gelified in a calcium solution and subsequently be treated with a buffer low in calcium but high in sodium. During this procedure the calcium at the surface is replaced by sodium which has a lower affinity for alginate than PLL. This facilitates binding of PLL in the next step that requires incubation in the absence of any divalent cations. If done properly this results in the formation of three layers: (1) random coil formations between alginate and PLL, (2) α-helicoidal structures between amide groups of PLL, and (3) antiparallel β-sheet structure between amide groups of PLL [59,113,121]. It is important that these formations are formed as these surfaces are not activating immune cells in the host. Any disturbance in the formation process can result in unbound cationic PLL structures at the capsule surface, which will lead to cell adhesion, immune activation, and inflammatory responses. We consider the insight in chemical structures responsible for induction of responses of uttermost importance as it leads to reproducible protocols to avoid these responses. For many systems it is still unknown which factors are critical, but we feel this should be a major focus for future research.

Antibiofouling approaches

Biofouling [122] is the process that every encapsulation device has to endure after implantation. It is the process that involves nonspecific adsorption of host proteins and subsequent immune cell and fibroblast adhesion. In most applications of encapsulation of insulin-producing cells, this process should be as minimal as possible as it affects viability of the enveloped cells. Ongoing research focuses on identifying molecules that can be grafted on the capsule surfaces that serve as so-called antibiofouling layer. Most strategies involve application of hydrophilic polymers that reduce protein adsorption [123]. One such molecule is PEG that in specific conformations is associated with low protein adsorption [124,125]. Efficacy depends on chain density, length, and conformation. Avoidance of protein adsorption of a PEG surface increases with higher polymerization degree. PEG has been successfully applied on alginate-based capsules as antibiofouling layer [91,126]. In this approach the PEG backbone was charged with amine groups (NH_3^+), in order to allow interaction with the negatively charged alginate. The antibiofouling PEG coating reduced fibrosis of the capsules and improved performance [126] but could not prevent graft failure. In another series of experiments the antibiofouling properties of PEG was applied by creating copolymers with PEG. PEG-block-poly(L-lysine hydrochloride) was used to bind to an alginate-based system. The PEG was protruding from the capsule surface, while the PLL was responsible for binding to the alginate. This approach significantly reduced proinflammatory responses [127]. The PEG of the diblock copolymer masked the proinflammatory PLL that was not bound in the above-described conformation and successfully formed an antibiofouling outer layer.

Formation of polymer brushes

Polymer brushes are polymeric chains that are densely packed and stretch on a surface [128]. Polymer brushes have been shown to reduce protein adsorption and cell adhesion in other fields of biomaterial research. It can be used to enhance biocompatibility but also to give surfaces of devices new functionalities [129]. Spasojevic et al. made polymeric brushes on capsule surfaces by applying novel diblock polymers such as diblock copolymers of PEG-block-poly(L-lysine hydrochloride) (PEG454-*b*-PLL100) [127,130] (Fig. 36.6). The copolymers are composed of a relatively small PLL tail that penetrates and binds onto the alginate network of capsule surfaces. The long PEG tail is at the outer surface after PLL binding onto the alginate network. At high densities the PEG is forced to stretch and form a brush. Only in certain combinations of molecular weight of PLL and PEG the brush can successfully be formed. This leads to a better biocompatibility and absence of cell adherence to the surface [127,130]. Other approaches to form brushes involves the use of a chitosan core on which polymer brushes of oligo

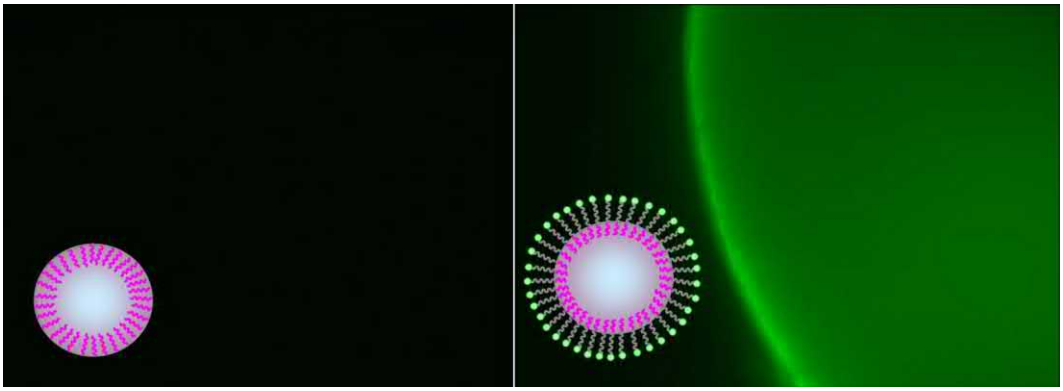

FIGURE 36.6 Confocal microscopy images after immunostaining of PEG blocks. Left are alginate-PLL100 capsules and right alginate-PLL100-PEG454-*b*-PLL50 capsules with a PEG454 brush. The illustration depicts the way the molecules are bound on the capsule surface. By using long molecular weight PEG a polymer brush is formed. Original magnification 10 ×. *PEG*, Poly(ethylene glycol); *PLL*, poly-L-lysine.

(ethylene glycol) methyl ether methacrylate and 2-hydroxyethyl methacrylate are formed by photopolymerization [131]. This brush reduced protein adhesion and eliminated platelet activation and leukocyte adhesion [131,132]. Although the formation of a brush is chemically challenging, the approach is reproducible and prevents influences on tissue responses of contamination of the polymers or inadequate formation of polycation layers [115,127]. For that reason, it holds many promises for future application in encapsulation devices.

Immunomodulatory materials

In the past decade the field of biomaterials has made important advances from which also the bioartificial pancreas does or will profit. Some biomaterials have been shown to modulate the immune system and by that can prevent undesired tissue responses [133–137]. One such an approach is the application of Staudinger ligation chemistry to link immunomodulatory molecules on, for example, PEG. This technology cross-links azide- and phosphine-labeled molecules and can be applied to couple biofunctional molecules with encapsulation polymers [138]. By this approach, immunomodulating thrombomodulin (TM) was coupled to PEG and immobilized on islet-cells through streptavidin–biotin interactions. TM inhibits proinflammatory cytokine production in macrophages and thereby reduces responses against coated mice pancreatic islets [139]. In another study, hemoglobin (Hb-C) was cross-linked with PEG to scavenge nitric oxide (NO) to reduce NO toxicity after immune activation [140,141]. Also, inclusion of silk has been reported to induce immunomodulation as after interaction with immune cells it decreased production of proinflammatory cytokines in vitro [142,143]. Silk in macrocapsules was able to change polarization of macrophages from a proinflammatory status to a regulatory M2 phenotype. This field is still in progress and more molecules applicable for the bioartificial pancreas will probably become available in the coming years.

Intracapsular environment and longevity of the encapsulated islet graft

It is broadly recognized that islet-derived factors released during the first phase after implantation negatively impacts the tissue responses with significant loss of islet cells as a consequence. This has led to new approaches in the past 5 years to preserve islet function and survival by inclusion of "survival" factors in the intracapsular milieu.

Tissue responses against an encapsulated graft already start with the mandatory implantation procedure. Although it is a minor surgery, it does lead to the release of proteins and cytokines to attract immune cells to delete possible pathogens that might be introduced during surgery. Under normal circumstances, this proinflammatory environment will soon be neutralized by IL-10 produced by other immune cells, but in case of implantation of a bioartificial pancreas, this process might get disturbed. Cells in the encapsulated graft not only release different types of molecules such as cytokines but also the so-called danger associated molecular patterns (DAMPs) that activate the local immune response [43,67,68,144–146]. These DAMPs are released by cells in the graft that are dying by necrosis or necroptosis [147,148]. Typical molecules that classify as DAMP are intracellular components such as DNA, RNA, and HMGB1 that bind to specific receptors on immune cells [149,150]. These receptors are called PRRs such as TLRs, nucleotide-binding oligomerization domain-like receptors, and C-type lectins [151–155]. The DNA, RNA, and HMGB1 that leak out of the capsules are very strong stimulators of PRRs and can enhance immunity and destruction of the graft [144]. These are all recent insights [144] that have demonstrated

that prevention of responses against bioartificial organs is not only determined by the biomaterials applied. Some modification of the capsules such as reducing permeability below 100 kDA can prevent leakage of some DAMPs, but despite this immune activation could not be completely prevented. Lower molecular weight DAMPs probably still diffuse out and induce immune activation [144]. Conceivable solutions to improve viability and reduce DAMP release are changing the intracapsular environment. It has been shown that inclusion of a necroptosis blocker called NEC-1 which is suppressing necrosis and necroptosis [144] reduces DAMP release and attenuates immune activation [144].

Another strategy to improve functional survival of cells in capsules is by inclusion of appropriate extracellular matrix (ECM) in the intracapsular environment. Islets are equipped with many integrins that interact with the ECM in their surroundings [156]. These interactions are essential for survival and serve many functions. ECM cannot only regulate via integrins the glucose-induced insulin release, proliferation, prevent or stimulate death signals but can also serve as a buffer for released cytokines and thereby conserve viability during immune attack [157–160]. A number of groups have applied laminin sequences such as tripeptide Arg-Gly-Asp (RGD) in their concept of encapsulation [161,162] and have reported long periods of graft survival in small as well as large animal models. We recently found that human pancreatic islets function longer and produce more insulin when they are encapsulated in a matrix containing collagen IV in combination with specific laminin sequences [57,163]. These combined observation illustrates that modifying the intracapsular environment is a feasible approach [156,163–165] to support functional survival of cells and prolong survival and diminish effects of immune responses against encapsulated grafts.

Concluding remarks and future considerations

In this chapter, we have reviewed some of the advances that have been made with the bioartificial pancreas. All three concepts, that is, intravascular devices, extravascular macrocapsules, and microcapsules, have undergone significant improvements in the past decade, and still all three might be developed in realistic approaches for treatment of T1D. An issue for many decades has been the undesired tissue responses against the devices that might lead to cellular overgrowth, which interferes with the functional survival of the cells. However, the introduction of novel polymeric approaches such as multilayer systems combining beneficial properties of several polymers but also the concept of polymer brushes and introduction of immunomodulating biomaterials has brought optimism that tissue responses can be reduced or even deleted. Unfortunately, there is still a large lab-to-lab variation in

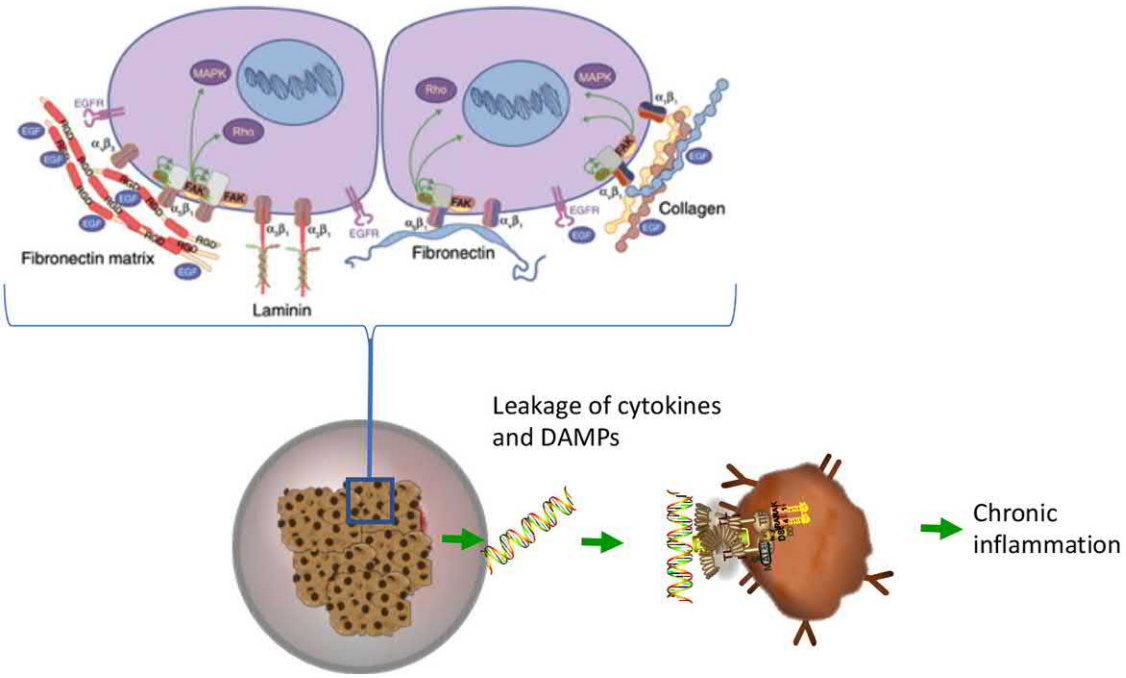

FIGURE 36.7 Cells in capsules need interactions with extracellular matrix molecules for cell homeostasis and survival. If interactions are not adequate cells may die and release danger associated molecular patterns (DAMPs) such as DNA, RNA, or HSP that bind to Toll-like receptors and other pattern-recognition receptors to induce proinflammatory responses. *DAMPs*, Danger associated molecular patterns.

outcome of encapsulated graft. This seems to be caused by lack of understanding of the need for application of specific molecules in specific systems and poor documentation of the procedures applied which make data comparison between labs cumbersome [30,63].

In recent years also, the intracapsular needs of islet-cells has gained attention. Current research efforts confirm that this is an essential, overlooked area in the transplantation field. Islets are equipped with integrins that need ECM contact. Many ECM molecules are destroyed during the enzymatic isolation of islet cells from the pancreas [166]. These molecules are required to allow survival of islets and also makes them more resistant to cytokine stress that is very common during the first week after implantation [164,167]. Significant improvements in functional survival of encapsulated islet cells are to be expected if specific combinations of ECM molecules are included in the intracapsular environment (Fig. 36.7). It has also recently been shown that many polymers used in biomedicine are poorly tolerated by islet-cells and may lead to dedifferentiation, lower glucose-induced insulin release profiles, and even cell-death [168,169]. This has received in the encapsulation field not more than minor attention but should be taken into account.

There are a few trends in the encapsulation field that need a critical debate. One of these is the current regulatory trend in the United States that some groups consider nonhuman primates the ultimate model for human application. As recently reviewed, this might be an essential mistake [72]. Nonhuman primates have innate and adaptive immune responses that are very different from human responses against cellular grafts. Especially, the innate immune pathways are different in nonhuman primates [72]. Much more information can be obtained from rodent studies with a humanized immune system and from small clinical trials.

We have reviewed in this chapter not only the progress but also remaining challenges for human application. These challenges are not all related to the capsules or biomaterials. A major challenge is to find adequate sources for insulin-producing cells. Many groups, including ours, wish to start human trials but adequate insulin-producing cell sources are lacking. High-quality human islets are difficult to obtain in sufficient amounts to do human trials. Pig islets and insulin-producing cells obtained from progenitor cells and stem cells still have functional limitations. This also limits the preclinical and clinical testing of the devices. Several concepts have a fair chance on success but adequate insulin-producing cell sources are required to come to testing and wide-scale application of the bioartificial pancreas.

Structure and morphology of the thymus

The mature thymus is a highly dynamic cellular environment. Developing T lymphocytes (thymocytes) make up over 95% of its cellularity, with the remaining few percent comprising the complex stromal compartment, which is composed of mesenchymal cells, bone marrow (BM) derived macrophages and dendritic cells (DCs), vasculature, and the uniquely specialized thymic epithelium (TE) [1]. The organ is encapsulated and lobulated and contains three principal histologically defined regions, the cortex, the medulla, and the subcapsule (Fig. 37.1). The capsule and trabeculae consist of a thick layer of connective tissue and are separated from the cortex by the subcapsule, a thin layer of simple epithelium [1]. The cortex and medulla each contain open networks of epithelial cells that are densely packed with thymocytes [1–3], and each of the cortical and medullary regions contains several different distinct epithelial subtypes (as discussed later). These cortical and medullary thymic epithelial cells (cTEC and mTEC, respectively) are key elements of the thymic stroma, providing many of the organ's specialist functions. The outer cortex also contains fibroblasts, with further complexity of the thymic fibroblast compartment beginning to emerge. The organ as a whole is heavily vascularized. BM-derived stromal cells also exist and are found in both compartments, macrophages being distributed throughout the organ, while thymic DCs—which are required for imposition of tolerance on the emerging T cell repertoire—are found predominantly at the corticomedullary junction (CMJ) and in the medulla [1].

Thymus structure is intimately linked to its function, which is to support development of a functional, self-tolerant T cell repertoire. This encompasses the linked processes of T cell differentiation and T cell repertoire selection, which together ensure that the peripheral T cell repertoire is predominantly populated by T cells that respond to antigens in the context of self-major histocompatibility (MHC) antigens, but which are not activated by binding self-peptides.

T cell development has been extensively reviewed elsewhere [4–11] and is not discussed in detail herein. In brief, thymocyte progenitors enter the postnatal thymus through blood vessels at the CMJ, and subsequent T cell development is then regulated such that thymocytes at different stages of development are found in different intrathymic locations. The earliest thymocyte progenitors do not express the CD4 or CD8 coreceptors [part of the T cell receptor (TCR) complex] and are referred to as double negative (DN) cells. DN thymocyte progenitors undergo a highly ordered series of maturation stages in the thymic cortex and upregulate expression of CD4 and CD8 to become the major double positive (DP) thymocyte subset. The cortex itself can be subdivided into four regions based on the localization of thymocyte populations at different stages of development. Thus zone 1 contains the colonizing population of thymocyte progenitor cells; these early thymocytes undergo proliferative expansion in zone 2; T cell lineage commitment is completed in zone 3; and in zone 4, thymocytes differentiate to the DP stage of development, characterized by expression of both CD4 and CD8 coreceptors [12,13] (see Fig. 37.1). Only DP thymocytes expressing TCRs that mediate low affinity interactions with self-peptide/MHC complexes, presented on cTEC, are positively selected. These positively selected thymocytes survive and mature into $CD4^+$ or $CD8^+$ single positive (SP) cells. Thymocytes that have been positively selected then migrate into the medulla [14,15]. The remaining DP thymocytes, which fail

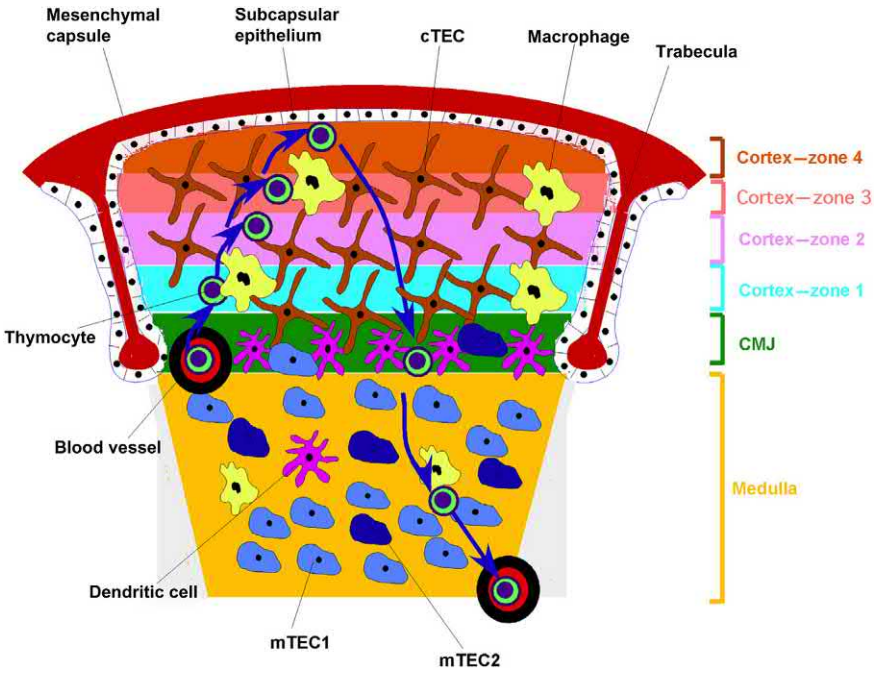

FIGURE 37.1 Histology of the postnatal thymus.
The postnatal thymus is surrounded by a capsule consisting of mesenchymal cells and connective tissue, which penetrates into the thymus at regular intervals to form trabeculae. Underlying the capsule and trabeculae is the subcapsular epithelium consisting of a layer of simple epithelium, which overlies the outer cortex. The cortex is populated with cTEC, macrophages, and developing thymocytes at the DN and DP stages of development. Thymocytes enter the thymus at the CMJ via the vasculature and migrate through the cortex to the subcapsule as they differentiate. The cortex can be divided into four zones based on the differentiation status of thymocytes that reside within it. Thus zone 1 contains the most immature DN1 thymocytes and zone 4 contains thymocytes undergoing the DN4-DP transition. DP thymocytes are then screened for propensity to recognize self-MHC, a process termed "positive selection," and those selected to mature into $CD4^+$ or $CD8^+$ SP cells migrate into the medulla, where they undergo the final stages of maturation before being exported to the periphery. Central tolerance is established by deletion of self-reactive thymocytes in a process termed "negative selection" and occurs principally at the CMJ and in the medulla: negative selection is mediated both by thymic dendritic cells and medullary TECs. Medullary TECs are also required for the generation of $CD4^+CD25^+$ T regulatory (Treg) cells and natural killer T cells, both of which actively repress self-reactive T cells. *CMJ*, Cortico-medullary junction; *cTEC*, cortical thymic epithelial cells; *DN*, double negative; *DP*, double positive; *MHC*, major histocompatibility; *SP*, single positive; *TEC*, thymic epithelial cell.

positive selection, die by apoptosis [16]. Intrathymic migration of thymocytes is at least partly a regulated process. Both the outward migration of thymocytes from the CMJ to the outer cortex [17] and the migration of positively selected cells from the cortex into the medulla [5,15,18–21] are controlled by chemokines.

In the medulla, a wide array of self-antigen/MHC complexes presented by mTECs and/or DCs induce apoptosis of those SP thymocytes that express TCRs with high affinity for self-antigens [22–24]. This process, termed "negative selection," is essential to reduce the frequency of autoreactive T cells in the peripheral T cell repertoire. SP thymocytes proliferate and undergo the final stages of T cell maturation in the medulla before emigrating from the thymus to enter into the peripheral immune system. Some high affinity self-reactive thymocytes escape negative selection and instead differentiate into T regulatory (Treg) cells, which suppress autoreactive T cells in the periphery and are therefore an important component of self-tolerance [25–27].

Thymic epithelial cells

Complexity of the thymic epithelium compartment

The TE is highly heterogeneous in terms of immunophenotype and function, and recapitulation of this heterogeneity is likely to prove essential for the development of a truly functional engineered thymus. Ultrastructural and immunohistochemical analyses initially revealed six different subtypes of TEC [28–31], as well as large complexes of TECs and developing thymocytes [31] termed "thymic nurse cells" [32,33]. In addition, some epithelia identified in small isolated clusters at the CMJ were classified as undifferentiated [31] and proposed as precursors of differentiated TEC [34]. Different TE subpopulations can be defined by differential expression of cytokeratins (K) and other markers including MHC Class II, CD40, and CD80. All TEC express MHC Class I, while MHC Class II, CD40, and CD80 expression is variable [35–38]. In both the cortex and the medulla, high levels

of CD40 and surface MHC Class II are thought to identify the most mature TECs [39–41].

Two cTEC populations have been identified based on cytokeratin expression—a predominant $K5^{-}K14^{-}K8^{+}K18^{+}$ subset and a minor subset consisting of $K5^{+}K14^{-}K8^{+}K18^{+}$ cells that is found at the CMJ and scattered throughout the outer cortex [42]. Most if not all cTECs also express the determinants recognized by mAbs Ly-51 [43], which recognizes the homodimeric cell surface glycoprotein BP-1, and CDR1 [44], the target of which is not yet biochemically defined. cTEC additionally express the endocytic receptor CD205 [45–47], and the TEC-specific catalytic proteasome subunit, β5t [48–50].

Most medullary (m) mTEC are $K5^{+}K14^{+}K8^{-}K18^{-}$ [42] and also bind mAb MTS10 [30], while a minor $K5^{-}K14^{-}K8^{+}K18^{+}MTS10^{-}$ mTEC subset also exists [42]. mTECs also express high levels of epithelial cell adhesion molecule (EPCAM) as determined by immunohistochemistry [51] (all TEC are $EPCAM^{+}$ by flow cytometry) and bind the lectin *Ulex europaeus agglutinin-1* (UEA-1) [52], with a subset of $K14^{-}$ mTECs binding UEA-1 at high levels. mTECs can be further subdivided based on CD80 expression, the level of which correlates with degree of functional maturation as for MHC Class II [40,53]. The lineage relationships between these different TEC subsets remain incompletely defined (see later). Furthermore, while these analyses give an indication of the complexity of the TE, they underestimate the number of TEC subtypes present in the adult thymus based on recent transcriptome analysis [54–56].

Functional diversity

The functional dichotomy between the cortical and medullary compartments of the mature thymus (see the "Structure and morphology of the thymus" section) is reflected in functional differences between cTEC and mTEC. cTEC express Delta-like 4 (DLL4), the Notch ligand required throughout the lifespan for commitment of thymocyte progenitors to the T cell lineage;[57–59] membrane-bound Kit ligand (mKITL), required by DN2 thymocytes (note that mKITL presented by cortical vascular endothelial cells is also required at the DN1 stage); [60] and the chemokine CXCL12 [also known as stromal cell-derived factor 1 alpha (SDF1α)], a regulator of the β-selection checkpoint that controls progression from the DN to the DP stage of thymocyte development [61–63]. In addition, cTEC express ligands required for positive selection [64]. Notably, β5t expression in cTEC is required for generating an optimally selected $CD8^{+}$ T cell repertoire. The β5t-containing "thymoproteasome" generates a specific set of self-peptides for presentation by MHC Class I, and in the absence of β5t, a depleted, functionally deficient $CD8^{+}$ T cell repertoire is selected [49,65–72]. Similarly, expression of Cathepsin L (Cathepsins L and V in human) in cTEC is required for optimal positive selection of the $CD4^{+}$ T cell repertoire [73–76].

mTECs play an essential role in the development of central tolerance, by mediating both negative selection of the T cell repertoire and development of Tregs. In addition, they regulate the migration of positively selected thymocytes into the medulla via the expression of CCL19 and 21 [15,18,19,77], with expression of CCR4 ligands by medullary DC also contributing to regulation of this process [78,79]. mTECs regulate central tolerance through expression of a broad repertoire of proteins, termed tissue-restricted antigens (TRAs), that are otherwise tissue or developmentally restricted [80–82]. Expression of a subset of these genes is regulated by the *Autoimmune Regulator, Aire*, which, within the thymus, is specifically expressed in $CD80^{hi}$ mTEC [83–89], with individual TRAs being expressed stochastically within the total $CD80^{hi}$ mTEC population [90]. mTEC-expressed TRAs are presented to medullary thymocytes by both mTECs and DCs, the latter via a cross-presentation mechanism [24,91,92]. In the absence of AIRE, mice and humans develop the broad-spectrum autoimmune syndrome, APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy) [86,87]. AIRE-independent expression of TRAs by mTECs may be regulated by the transcription factor Fez Family Zinc-finger 2 (FEZF2) which, in contrast to AIRE, is expressed in both $CD80^{lo}$ and $CD80^{hi}$ mTECs [93].

The medulla is also distinguished by corpuscular bodies of epithelial cells known as Hassall's corpuscles. These are particularly prevalent in human thymus and have been shown to express thymic stromal lymphopoietin, a signaling molecule that instructs closely associated DCs in the medulla to induce Treg cells [25,26]. In this regard, mTEC also regulate the accumulation and positioning of DCs in the medulla via the secretion of the chemokine XCL1 [94]. Further complexity in the mTEC compartment has emerged with the identification of "post-AIRE mTEC" [95,96], and through single-cell RNAseq analyses which reveal the presence of at least four major mTEC subtypes, including a subpopulation with Tuft cell–like identity [55,56].

In vitro T cell differentiation

The high level of phenotypic and functional heterogeneity demonstrated above presents a significant challenge for attempts to fully recapitulate thymus function in vitro and is also highly pertinent to cell replacement or regenerative strategies for enhancing thymus activity in vivo. Currently, it is not possible to reconstitute full thymus function in vitro or upon transplantation except in cultures

based on ex vivo thymus tissue. However, in vitro systems that fully or partly support T cell differentiation are widely used as a tool for investigating regulation of this process, and recently, the use of in vitro culture of hematopoietic progenitors to enhance lymphohematopoietic reconstitution following BM transplantation has been investigated. Current approaches to in vitro T cell generation are summarized later.

Fetal thymic organ culture (FTOC) utilizes ex vivo thymic lobes, usually derived from E15.5 to E16.5 mouse embryos or second-trimester human fetuses, to support the differentiation of T cell progenitors from endogenous or exogenous sources [97–101]. The technique of reaggregation fetal thymic organ culture (RFTOC), in which defined TEC subpopulations are obtained by cell purification techniques, reaggregated with fibroblasts, and defined lymphocyte populations, and then cultured further in vitro, was developed as an extension of FTOC and has proved invaluable for assessing the role of individual stromal components during specific stages of T cell maturation [64,102]. This approach has also been combined with grafting, typically under the kidney capsule, since grafted RFTOC typically exhibit better cortical and medullary patterning than in vitro cultured RFTOC and has been adapted for testing the potency of different fetal and adult TEC subpopulations from mouse, rat, and human [103–110]. Improved reproducibility of the RFTOC technique was demonstrated using an approach for cellular reaggregation termed Compaction Aggregation (CoROC), which also permits the juxtaposition of the different cell types included in the cellular reaggregate to be controlled [111].

A related approach demonstrated the generation of an in vitro "thymic organoid" by seeding a tantalum-coated carbon matrix with ex vivo murine thymic stromal cells [112]. When these structures were cocultured with human $CD34^+$ hematopoietic progenitors, efficient generation of mature $CD4^+$ and $CD8^+$ SP T cells was observed after 14 days. The T cells generated in this system were functional, as demonstrated by their proliferative response to mitogenic stimuli, and demonstrated TCR repertoire diversity comparable to that of peripheral blood T cells [112]. These findings established that the utilization of three-dimensional matrices in conjunction with thymic stromal cells can provide an efficient and reproducible method of in vitro T cell generation. However, this approach relies on seeding with ex vivo thymus tissue and therefore is not highly scalable.

The demonstration that transfection of the BM stromal cell line OP-9 with the Notch ligand Delta-like 1 (DL1) conferred the capacity to support T cell differentiation from a variety of hematopoietic progenitors in monolayer culture represented a major breakthrough [113,114]. Using this system, DP thymocytes can be generated efficiently from mouse fetal liver, adult BM, or embryonic stem (ES) cell-derived hematopoietic progenitors; $CD8^+$ SP T cells are also produced inefficiently although $CD4^+$ SP T cells are largely absent [113,114]. This system was also shown to support T cell development from human cord blood– and human BM–derived $CD34^+$ cells [115–118]. OP-9 cells stably transfected with Delta-like 4 (DLL4), the nonredundant Notch ligand required for T cell lineage commitment in vivo [57,58], also efficiently support the generation of DP cells [119,102]. In the OP-9 system, lower levels of DLL4 than DL1 are required for T lineage commitment [119].

Neither the OP-9-DL1 nor the OP-9-DLL4 system can be used to generate mature T cells for transplantation into patients [120] since OP-9 cells lack the cTEC and mTEC-specific gene-expression programs required to direct physiological positive and negative selection of the T cell repertoire. However, these systems have been widely used to dissect cellular and molecular regulation of T cell differentiation in mouse and human (see, e.g., Refs. [13,121]). In addition, they have been used to produce expanded pools of hematopoietic progenitor cells (HPCs) for transplantation [122–126]. In particular, adoptive transfer of OP-9-DL1-produced $CD4^-CD8^-$ DN thymocytes in a mouse model of hematopoietic stem cell (HSC) transplantation resulted in improved T cell reconstitution [122]. Similarly, the transplantation of human $CD34^+CD7^{hi}$ cells produced by in vitro culture of umbilical cord blood or adult HSC resulted in the efficient engraftment of the thymus of immunodeficient mice [123,125]. Furthermore, in preliminary clinical trial data, transplantation of OP-9-DL1-cultured HPC, together with a single unit of cord blood, resulted in more rapid recovery of neutrophil numbers following a myeloablative preparative regimen than the currently standard procedure of transplantation of a double unit of cord blood [124].

The successful application of OP9-DLL1-derived $CD4^-CD8^-$ DN thymocytes in T cell reconstitution has led to the development of stromal cell free culture systems. Culture systems based on immobilized DLL1 [127] and DLL4 [128] have shown potential to expand lymphoid precursor cells in vitro and in vivo. Cord blood $CD34^+$ HSCs cultured on immobilized DLL1 led to the expansion of $CD34^+CD7^+$ pro-T cells, capable of thymic repopulation in immunodeficient mice [127]. Expansion of $CD34^+$ hematopoietic stem/progenitor cells (HSPCs) on immobilized layers of DLL4 and VCAM-1, a potent enhancer of Notch activation, leads to the maturation of $CD7^+$ pro-T cells, capable of reconstituting the periphery of immunodeficient mice [129]. HSPCs cultured on immobilized DLL4 and VCAM-1 for 14 days prior to engraftment into immunodeficient mice were shown to have homed to the thymus by 4 weeks, and at 10–12 weeks postengraftment human $CD3^+CD8^+$ T cells were isolated from the peripheral blood, indicating that pro-T

cells developed on immobilized Notch ligands are capable of reconstituting the peripheral immune system. In addition to the OP9-based systems, a serum-free "artificial thymic organoid" (ATO) in vitro T cell differentiation system based on the mouse BM cell line MS5 transduced with human DLL1, has recently been described [130]. Three-dimensional organoids based on this cell line efficiently support human T cell development to the DP and $CD8^+$ SP stages, with some mature $CD4^+$ SP also developing probably as a result of selection on DCs within the ATO [130]. This system, in combination with an embryonic mesodermal induction step, has also recently been shown to support differentiation of human T cells from human pluripotent stem cells [131].

Thus in vitro approaches based on generating and/or expanding HPC appear poised for translation. Progress toward the goals of generating transplantable T cell repertoires in vitro, that have undergone physiological positive and negative selection, however, is likely to require a combination of stem cell–based approaches coupled with tissue engineering to pattern the resulting organoid.

Proof-of-principle studies have also demonstrated the feasibility of restoring adaptive immunity in patients by thymus transplantation [132–134]. This approach currently relies on the transplantation of human neonatal thymus tissue, and, in addition, a high proportion of recipients develop autoimmune complications [135]. These issues collectively limit the widespread use of the current thymic transplantation approach.

In this regard the use of decellularized thymic extracellular matrix (ECM) for developing transplantable tissue-engineered thymic organoids has recently been investigated. The earliest report described the use of a detergent-perfusion system to decellularize 3–4-week postnatal thymi, which were then seeded with an enriched preparation of ex vivo thymic stroma, plus HSCs [136]. However, the interpretation of the results of this study was confounded by limitations associated with experimental design and controls. The enriched thymic stromal preparation still contained a substantial (18%) population of SP thymocytes that possess the potential to populate the periphery of the haplotype-matched nude donor without undergoing a further, thymus-dependent differentiation process and may therefore be responsible for the functional effects the authors ascribed to the ECM-scaffold [136].

Subsequently, the zwitterionic surfactant 3-[(3-cholamidopropyl)dimethylammonio]-2-hydroxy-1-propanesulfonate (CHAPSO) was used to prepare an ECM gel from postnatal thymi obtained from mice at an age of 7 weeks. These CHAPSO-derived scaffolds were seeded with E14.5 $CD45^-EPCAM^+$ TEC and $CD45^-EpCAM^-$ thymic mesenchyme and were able to mediate thymopoiesis from recruited hematopoietic precursors. Compared to control RFTOC-kidney grafts, the CHAPSO-scaffolds significantly improved TEC and thymic mesenchyme proliferation and the contribution of T cells to the peripheral immune system. However, this study did not directly investigate T cell function or central tolerance induction [137].

These pioneering studies together suggest that the integration of stem cell technologies, to provide an alternative source of thymic cells, with tissue engineering may eventually allow thymus transplantation to be more widely adopted: in addition to the challenge of generating a thymus by tissue engineering, the cause of autoimmunity in current thymus transplantation protocols must be understood and addressed. In the following sections, we summarize current knowledge of molecular and cellular control of thymus development and maintenance as related to these aims. We focus primarily on the TEC compartment, based on the critical function of these cells in the thymus. We also discuss the current understanding of parathyroid development, since parathyroid replacement is also a clinically important goal.

Thymus organogenesis

Cellular regulation of early thymus organogenesis

The thymus arises from a common primordium with the parathyroid gland. This common primordium develops from the third pharyngeal pouch (3PP), one of a series of bilateral outpocketings of pharyngeal endoderm. In the mouse, outgrowth of the 3PP occurs from approximately E9.0 [138]. At this stage the epithelium of the 3PP consists of a single layer of columnar epithelium surrounded by a condensing population of neural crest cells (NCCs) that will eventually form the capsule and thymic pericyte populations [139–142]. Overt thymus organogenesis is evident from between E10.5 and E11.0, at which stage the epithelium begins to proliferate, assuming a stratified organization [143]. At E12.5 the primordia separate from the pharynx and begin to resolve into discrete thymus and parathyroid organs. The thymus primordium subsequently migrates to its final anatomical location at the midline, following the path of the carotid artery and vagus nerve, while the parathyroid primordium associates with the lateral margins of the thyroid [144,145]. In the case of the thymus, this migration is active and is regulated by NCC through EphB-ephrin-B2 interactions [146–148]. Within the common primordium the prospective thymus is located in the ventral domain of the 3PP, and the prospective parathyroid in the dorsal aspect. Patterning of these prospective organ domains occurs early in organogenesis, as the parathyroid domain is delineated by the transcription factor GCM2 as early as E9.5 (see the "Specification of the thymus and parathyroid" section).

The mesenchymal capsule surrounding the thymus primordium is derived from the migratory neural crest, a transient population formed between the neural tube and the surface ectoderm. In the mouse, NCCs migrate into the pharyngeal region from E9.0. Elegant chick-quail chimera studies provided the first evidence that NCCs are the source of mesenchymal cells in the thymus [140], which was confirmed in the mouse by heritable genetic labeling in vivo [139,141,142].

Colonization of the mouse thymus with HPCs occurs between E11.25 and E11.5 [149–151]. As vascularization has not occurred by this stage, the first colonizing cells migrate through the perithymic mesenchyme into the TE [152]. These cells have been reported to exhibit comparatively low T cell progenitor activity, while a second colonizing wave that arrives between E12 and E14 appears to display much higher levels of T cell potential upon in vivo transfer [153].

Following the formation of the thymic primordium and the commitment of the epithelial cells to the TEC lineage, the thymus undergoes a period of expansion involving both the proliferation of stromal cells and an increase in thymocyte numbers. In vitro experiments have demonstrated that both FGF7 and FGF10, which are expressed by the perithymic mesenchyme [154], can stimulate the proliferation of fetal TECs [155,156]. Furthermore, thymi in mice lacking *Fgfr2IIIb*, the receptor for FGF7 and FGF10, are severely hypoplastic although able to support T cell differentiation, and $Fgf10^{-/-}$ mutants also exhibit hypoplastic thymi [154]. Similarly, the expression of a soluble dominant negative FGFR2IIIb fusion protein by thymocytes resulted in reduced thymic size and cellularity, although thymocyte development was unperturbed [157].

Concomitant with this proliferation TEC differentiation commences with the initial stages of differentiation into cortical and medullary cell types evident by E12.5 [41,105]. The development of the two compartments then proceeds in a lymphocyte independent manner until E15.5 [158,159]. The expression of MHC Class II and MHC Class I on the surface of TEC is first detected at E12.5, and ~E16, respectively [36,41,160,161] and is followed by the appearance of $CD4^+$ and $CD8^+$ SP thymocytes at E15.5 and E17.5 [36,160]. Although a functional thymus is present in neonates, the full organization of the stroma is not achieved until 2–3 weeks postnatally in the mouse.

We note that the precise timings of developmental events varies between mouse strains, and the Blackburn lab has observed that the thymic primordium in C57BL/6 embryos is consistently developmentally retarded by at least 12 hours compared to CBAxC57BL/6 F1 embryos at E12.5. Hence, the timings reported for particular events in thymus organogenesis may vary slightly due to the variations in genetic background.

Origin of thymic epithelial cells

The precise embryonic origins of the TE were controversial for many years [104,150,162–167]. However, evidence obtained using chick-quail chimeras showed that the epithelial compartment of the thymic stroma was derived solely from the pharyngeal endoderm [164]. Subsequently, definitive evidence for a single endodermal origin in mice was provided through histological, fate, and potency analysis of the pharyngeal region [138]. In particular, transplantation of 3PP pharyngeal endoderm isolated from E8.5 to E9.0 embryos (i.e., prior to initiation of overt thymus organogenesis) established that grafting of this endodermal region was sufficient to direct complete thymus organogenesis, showing that pharyngeal endoderm alone is sufficient for the generation of both cortical and medullary thymic epithelial compartments [138].

Thymic epithelial progenitor cells

The phenotype of thymic epithelial progenitor cell (TEPC) has been of considerable interest and remains an area of ongoing investigation. Analysis of a subset of human thymic epithelial tumors initially suggested the existence of a common TEPC; these tumors contained cells that could generate both cortical and medullary subpopulations, thus suggesting that the tumorigenic targets were epithelial progenitor/stem cells [168]. In addition, ontogenic studies suggested that the early thymus primordium in both mouse and human might be characterized by the coexpression of markers that later segregated to either the cortical or medullary epithelium [169].

The first genetic indication of a TEPC phenotype was provided by a study addressing the nature of the defect in *nude* mice [170] that fails to develop a functional thymus due to a single base deletion in the transcription factor FOXN1 [171,172]. Analysis of allophenic *nude*-wild-type aggregation chimeras demonstrated that cells homozygous for the *nude* mutation were unable to contribute to the major TE subsets, establishing that the *nude* gene product (FOXN1) is required cell-autonomously for the development and/or maintenance of all mature TEC [170]. However, a few *nude*-derived cells were present in the thymi of adult chimeras, and phenotypic analysis indicated that these cells expressed determinants reactive to mAbs MTS20 [30] and MTS24 (both subsequently shown to bind a determinant on the PLET1 protein [173]) but did not express markers associated with mature TEC including MHC Class II. These findings suggested that in the absence of *Foxn1*, TE lineage cells underwent maturational arrest and persisted as $MTS20^+24^+$ progenitors [170]. This hypothesis was confirmed by clonal reactivation of a conditional null allele of *Foxn1* in the neonatal thymus, which resulted in the generation of functional

thymus tissue containing organized cortical and medullary regions [174]—demonstrating unequivocally that in the absence of FOXN1, a common TEPC persists in the thymic rudiment. A similar approach using conditional reversion of a severely hypomorphic allele of *Foxn1* subsequently demonstrated that in the absence of functional levels of FOXN1 expression, this common TEPC is stable for at least 6 months in vivo [175].

Further data regarding the phenotype of TE progenitors came from the analysis of mice with a secondary block in thymus development resulting from a primary T cell differentiation defect. The thymi of postnatal *CD3e26tg* mice, in which thymocyte development is blocked at the $CD44^{+}CD25^{-}$ TN1 stage [176,177], principally contain epithelial cells that coexpress K5 and K8 [42]—which, in the normal postnatal thymus, are predominantly restricted to the medulla and cortex, respectively, and are coexpressed by only a small population of TEC at the CMJ. Klug et al. demonstrated that transplantation of *CD3e26tg* thymi into $Rag1^{-/-}$ mice, which sustain a later block in T cell differentiation, resulted in the development of $K5^{-}K8^{+}$ cells, suggesting that the $K5^{+}K8^{+}$ cells are progenitors of cTEC [42].

The phenotypic and functional properties of $MTS20^{+}24^{+}$ cells within the fetal mouse thymus were addressed directly in several studies. Analysis of the functional capacity of isolated $MTS20^{+}24^{+}$ cells and $MTS20^{-}24^{-}$ cells via ectopic transplantation demonstrated that $MTS20^{+}24^{+}$ TEC were sufficient to direct the establishment of a functional thymus containing both cortical and medullary TEC populations [105,106]. These studies clearly identified fetal $MTS20^{+}24^{+}$ TEC as TEPC but lacked clonal evidence for the existence of a common TEPC. Expression profiling subsequently identified the target of MTS20 and MTS24 as the orphan cell surface protein PLET1 [173].

Evidence for a common TEPC has been presented in two independent studies. A short-term retrospective clonal lineage analysis demonstrated the presence of both a common TEPC able to generate both cTEC and mTEC, and cTEC-restricted TEPC, in the neonatal thymus [174]. In an elegant extension of these experiments, clonal reversion of a *Foxn1* null allele resulted in the generation of small regions of thymus tissue that contained both cortical and medullary TEC [174], providing conclusive evidence for the existence of a common progenitor in $Foxn1^{-/-}$ mice, as discussed above. In a complementary study the existence of a common TEPC in the E12.5 thymus was demonstrated by the transplantation of single E12.5 $PLET1^{+}$ TEC [108], establishing that the $PLET1^{+}$ TEC population originally identified as TEPC indeed contains a common TEPC.

The view that PLET1 is a marker for TEPC was challenged in a report demonstrating that at E14.5, both the $PLET1^{+}$ and $PLET1^{-}$ TEC compartments can form a functional thymus upon transplantation [178], in contrast to initial conclusions [106]. However, a key difference between these studies is that Gill et al. transplanted limiting numbers of $PLET1^{+}$ TEC [106], whereas in the later study, cell number was not limiting [178]. Furthermore, Rossi et al. did not provide phenotypic analysis of the input populations and therefore could not determine precursor:progeny relationships—a caveat of particular importance since the PLET1-negative TEC population at E14.5 and subsequent developmental stages is highly heterogeneous [41]. Rossi's findings could thus be consistent with the existence of intermediate progenitor populations restricted to cortical and medullary TEC fates downstream of $PLET1^{+}$ TEC in the thymic epithelial differentiation hierarchy, which can together generate a fully functional thymus. No information yet exists regarding the reversibility or otherwise of the early steps in thymic epithelial lineage differentiation, and therefore other alternative explanations for these findings are also possible.

Taken together, the available genetic and functional analyses strongly support PLET1 as a marker of the founder cells of the thymic epithelial lineage and demonstrate the loss of PLET1 expression with the onset of differentiation in the fetal thymus [41]. The lineal relationship between fetal $PLET1^{+}$ TEPC and the population of $PLET1^{+}$ mTEC of the postnatal thymus remains unclear. While the $PLET1^{+}$ TEC population isolated from the fetal thymus at stages up to and including E16.5 could initiate de novo thymus organogenesis upon ectopic transplantation, this capacity was lost by E18.5 [178,179], indicating a clear functional difference between the early fetal and late fetal/postnatal $PLET1^{+}$ TEC populations. However, recent clonal resolution data indicate that a minor subpopulation of $PLET1^{+}$ cells in the adult thymus, that coexpresses the cortical marker LY-51, contains bipotent progenitor or stem cells that can generate both cTEC and mTEC in a transplantation assay [110]. These cells are thus likely to play a role in maintaining postnatal TEC, functioning either as adult common or mTEC-restricted TEC progenitor/stem cells [110] (discussed in sections that follow). Irrespective of the differences between fetal and adult populations, the identification of the earliest fetal progenitor cells for the TEC lineage [41,105,106,173], coupled with the demonstration that these cells are common TEPC [108] and can generate an organized, functional thymus upon transplantation [105,106], points to the possibility of using TEPC as a source of TEC in the generation of in vitro thymus organoids and in thymus transplantation.

The existence of intermediate mTEC- and cTEC-restricted progenitors in the fetal and postnatal thymus has now been demonstrated by a number of studies. Analysis of MHC Class II mismatched chimeras showed

that the medullary epithelium initially forms as individual clonally derived islets, and that these coalesce later in development [104]. This study demonstrated the presence of mTEC sublineage-restricted progenitors (mTEPC) until at least E15.5 [104]. Furthermore, medullary sublineage-restricted TEPC can be isolated from E13.5 fetal thymus based on expression of Claudin 3 (CLDN3) and CLDN4 [180], and the UEA1$^+$ subset of fetal CLDN3,4$^+$ TEC was shown to represent the precursor of the clinically important AIRE$^+$ subset of mTECs [180]. Further investigation of the fetal CLDN3,4$^+$ population has shown that robust mTEC generation can initiate from an SSEA-1$^+$ subset that lacks the expression of differentiation markers such as UEA-1, MHCII, and CD40 [181]. This population also persists in the adult thymus, although its capacity for mTEC generation is significantly diminished compared to its fetal counterpart [181]. A cTEC progenitor activity has also been identified within the CD205 TEC population of the fetal thymus [47], the descendants of which are suggested to acquire more differentiated characters in a stepwise fashion. CD205 is a broad marker of cTEC in the postnatal thymus and identification of cTEC progenitors within this population is therefore an area of current investigation.

The studies described above demonstrate that TEC development during ontogeny is driven by bipotent TEPCs that give rise to distinct precursor populations that are restricted to the cTEC and mTEC lineages. Further work is needed to phenotypically define the progenitor state, or states, at which the transition from bipotent TEPC to cTEC or mTEC-restricted progenitor occurs, and the molecular mechanisms controlling this transition. In this regard, CD205$^+$ TEPC populations isolated from E15.5 thymi can generate both cTEC and mTEC lineages [182]. Consistent with this observation, mTECs have been shown to derive from cell that have previously expressed the thymus-specific proteasome subunit β5t [183–185] and the TSCOT promoter [186] and strongly suggest that in the adult thymus mTEC is maintained by sublineage restricted rather than common or bipotent progenitors [184,185].

Human thymus development

Early human thymus development closely parallels that of the mouse; the human thymus forms from the 3PP in a common primordium with the parathyroid gland. The 3PP is evident from early week 6 of human fetal development and initially develops as a tube-like lateral expansion from the pharynx, which makes contact with the ectoderm of the third pharyngeal cleft [187,188]. Since the thymus has a single endodermal origin in mice and avians [138,164] it is reasonable to assume that this is also the case in humans, although this has not formally been demonstrated. Within the human common thymus/parathyroid primordia the thymus and parathyroid domains are located ventrally and dorsally and are surrounded by condensing NCC-derived mesenchyme from the onset of development [187]. The thymus component of this primordium begins to migrate ventrally from week 7 to midweek 8, forming a highly lobulated, elongated, cord like structure. The upper part of this structure normally disappears at separation of the two organ rudiments, leaving the parathyroid in the approximate location in which it will remain throughout adulthood [187]. The bilateral thymic primordia continue to migrate toward the midline, where they eventually meet and attach at the pericardium—the permanent location of the thymus into adulthood—by midweek 8 [187]. As in the mouse [105], the human early thymus primordium appears to contain undifferentiated epithelial cells that express some markers that are later restricted to either cortical or medullary compartments [169]. Nascent medullary development is evident from week 8, and by week 16, distinct cortical and medullary compartments are present. Other cell types penetrate the thymus from week 8, including mesenchymal, vascular, and lymphoid cells, and mature lymphocytes begin to leave the thymus to seed the peripheral immune tissues between weeks 14 and 16 [189,190].

Cervical thymus in mouse and human

In addition to the thoracic thymus, that is the main site of T cell production, the presence of an additional "cervical" thymus, located anterior to the thoracic thymus, has been recorded in both animals [191] and humans [189,192,193] and is a common occurrence in at least some mouse strains [194,195]. In terms of size and cellularity the cervical thymus is much smaller than the thoracic thymus; however, the morphology of the two structures is very similar, with organized cortical and medullary regions and similar expression patterns of cytokeratin molecules [194,195]. Furthermore, the cervical thymus expresses the transcription factors FOXN1 and AIRE and can produce functional T cells that are tolerant to self-antigens [157,195], although the range of self-antigens present may be more restricted than in the thoracic thymus [194].

In mice, cervical thymi are thought to appear at around E15.5 based on *Foxn1*-reporter expression [196,197]. Their frequency increases through late gestation, leveling off at birth at about 50% of mice on the C57BL/6 background, suggesting that cervical thymi all arise at or before birth [196], similar to humans where cervical thymi are clearly present in the second trimester of fetal development. The origin of the cervical thymus has been investigated in mice using both genetic and lineage tracing analyses [196]. Cervical thymi were shown to have two lineage origins. The majority appear to arise

from 3PP cells at the thymus-parathyroid junction, which have not previously differentiated into either organ fate, and turn on *Foxn1* expression after E15.5: as cells specified to the TE lineage retain their identity in the absence of FOXN1 expression [174,175], many of these cervical thymi could arise from FOXN1-negative but thymus-fated cells. About 25% of cervical thymi have a lineage history of parathyroid cell differentiation and appear to have downregulated the parathyroid program and switched to thymus [196]. TEC in parathyroid-derived cervical thymi express lower levels of *Foxn1* than do thoracic TEC and exhibit low levels of MHC Class II and absent UEA-1. As a result, parathyroid-derived cervical thymi support a distinct thymocyte differentiation profile, similar to other *Foxn1* hypomorphic thymi [198]. Thus cervical thymi with different lineage histories generate distinct sets of thymocytes and could contribute differentially to the peripheral T cell pool.

Molecular regulation of thymus and parathyroid organogenesis

Although the regulation of thymus organogenesis is incompletely understood, studies of classical and genetically engineered mouse mutants have revealed a network of transcription factors and signaling molecules that act in the pharyngeal endoderm and surrounding mesenchyme and mesoderm to regulate thymus and parathyroid organogenesis. The principal components of this network are discussed later and summarized in Fig. 37.2.

Improved understanding of molecular regulation of early TEC development may facilitate directed differentiation of pluripotent stem cells into TEC in vitro. Indeed, by recapitulating the stepwise restriction of differentiation potential observed in vivo, a highly enriched anterior foregut endoderm population can be obtained from pluripotent stem cell–derived definitive endoderm [199–204]. Some progress toward generating TEC from pluripotent stem cells has been reported [205–210], although production from pluripotent stem cells of TEC that can contribute to all normal TEC subtypes has not yet been reported [211].

Molecular control of early organogenesis

The T-box transcription factor TBX1, retinoic acid (RA) signaling, and fibroblast growth factor 8 (FGFf8) signaling have been implicated as important regulators of the earliest events in thymus organogenesis, which occur prior to overt organ development and relate to molecular control of 3PP formation.

Tbx1 is the gene responsible for cardiovascular and glandular defects in *Df1* mice, which carry a large deletion of chromosome 16 [212]. *Df1* heterozygotes closely phenocopy a human condition known as 22q11.2 deletion syndrome (22q11.2DS, or DiGeorge Syndrome) in which a deletion in chromosome 22 covering an interval of approximately 30 genes [213], results in a range of defects including thymus aplasia or, more frequently, hypoplasia [214,215].

During development, *Tbx1* is expressed in the pharyngeal endoderm and the core mesenchyme of the pharyngeal arches from approximately E7.5 and continues to be expressed in a variety of structures until E12.5 [216–218]. *Tbx1* mutants have severe defects throughout the pharyngeal region, including abnormal patterning of the first pharyngeal arch, hypoplasia of the second arch, and absence of the third and fourth arches and pouches [219]. As a result, $Tbx1^{-/-}$ mutants lack both thymus and parathyroids and display a spectrum of cardiovascular abnormalities and craniofacial defects [219].

The phenotype of $Tbx1^{-/-}$ animals suggests an important role in the segmentation of the pharyngeal region. Support for this hypothesis was provided by an elegant study addressing the temporal requirement for *Tbx1* in the development of the pharyngeal region. Deletion of *Tbx1* at E8.5, during the formation of the 3PP, resulted in complete absence of thymus and parathyroid, and complementary fate-mapping experiments demonstrated that cells that express *Tbx1* at E8.5 contribute significantly to the thymic primordium [220]. However, although deletion of *Tbx1* at E9.5/E10.5 (after initial formation of the 3PP) caused morphological defects in the thymus, these were not as severe as the aplasia seen after deletion at E8.5, and fate mapping of cells expressing *Tbx1* at E9.5/E10.5 revealed only a small contribution to the thymus [220]. This is likely because *Tbx1* is downregulated in the ventral 3PP during pouch outgrowth [221,222] and, in fact, there is evidence that its expression is antagonistic to thymus differentiation. Ectopic expression of *Tbx1* in *Foxn1*-expressing cells results in *Foxn1* downregulation, with the cells remaining $PLET1^{+}$ and presumably thymus-fated [222]. Taken together, these data suggest that TBX1 is required for the formation of the 3PP but is not directly required for subsequent thymus development.

A role for RA in 3PP formation was suggested by experiments in which RA antagonist was administered to whole embryo cultures. Blockade of RA signaling at E8.0 resulted in the absence of the growth factors FGF8 and FGF3 in the 3PP endoderm and impaired NCC migration to the third and fourth pharyngeal arches [223]. Expression of the transcription factor PAX9 (see later) was also absent in the 3PP but was expanded in the 2PP endoderm. These data suggest that RA signaling is required for the specification of the 3PP, which confers subsequent competence to support NCC migration. Genetic evidence for a role for RA signaling was subsequently provided by the finding that fetal mice lacking RA receptors α and β display thymus agenesis and

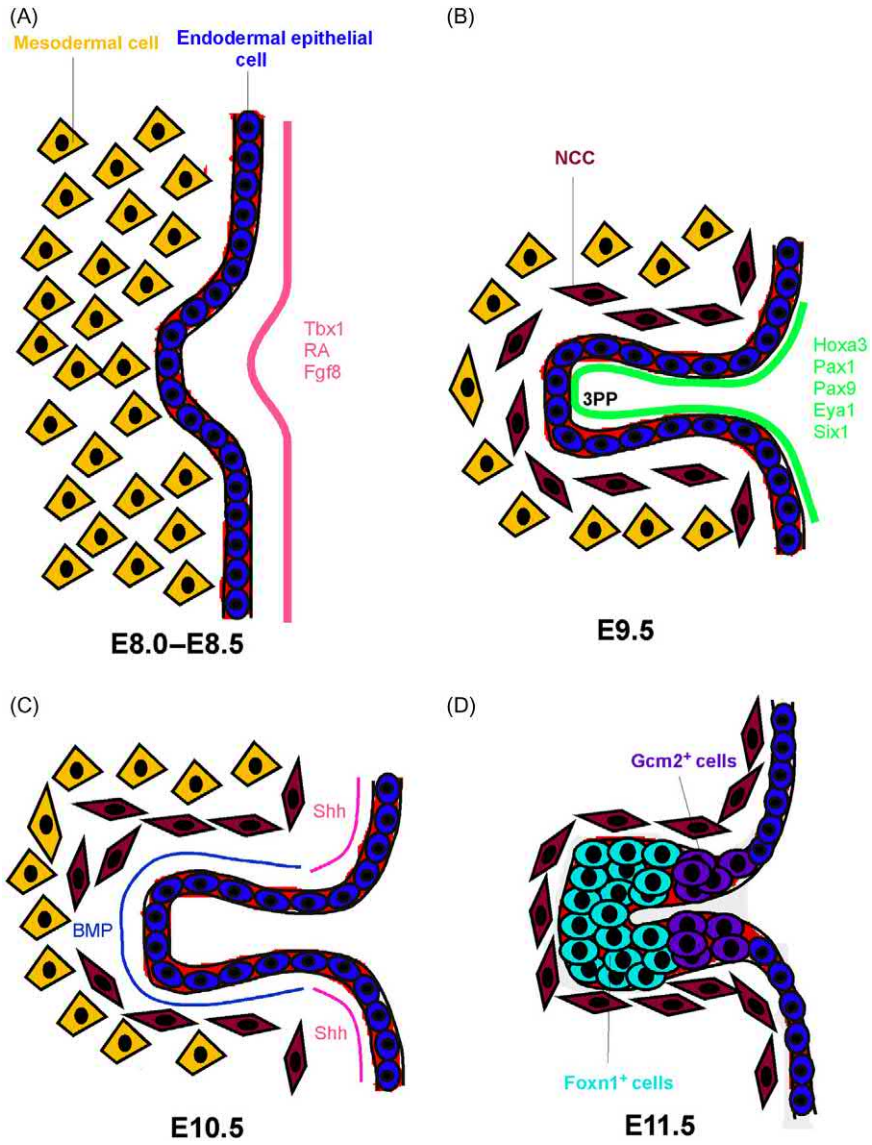

FIGURE 37.2 Molecular regulation of early thymus organogenesis.
(A) At approximately E8.0−E8.5 the formation of the 3PP is initiated in the pharyngeal endoderm and is dependent on the expression of TBX1 and RA, and on FGF8 signaling (pink). (B) At E9.5 the 3PP has formed and is surrounded by mesenchymal cells of mesodermal and NCC origin. Continued development is dependent on the expression of the transcription factors HOXA3, PAX1, PAX9, EYA1, and SIX1 (green). (C) BMP (blue) and SHH (pink) signaling occur at E10.5 in the 3PP endoderm in the ventral and dorsal aspects, respectively. These factors may be involved in the specification of the 3PP into thymus and parathyroid specific domains. (D) At E11.5 epithelial cells in the ventral domain of the 3PP express the transcription factor FOXN1 (light blue) and will form the thymic epithelium. Epithelial cells in the dorsal domain express the transcription factor GCM2 (purple) and will form the parathyroid gland. The differentiation and maintenance of both of these cell types are dependent on these factors. Note that throughout this figure, gene-expression domains are annotated only for the endoderm. Many of the factors shown are also expressed in the mesoderm and/or mesenchyme of the pharyngeal arches, and/or in the pharyngeal ectoderm, as described in the text. *3PP*, third pharyngeal pouch; *BMP*, Bone Morphogenetic Protein; *FGF8*, fibroblast growth factor 8; *NCC*, neural crest cell; *RA*, retinoic acid; *SHH*, sonic hedgehog.

ectopia [224]. Furthermore, exposure to excess RA also resulted in defects in third and fourth PP formation, altered NCC migration, and subsequent thymus development defects, which were associated with altered *Hoxa3* and *Pax1* expression [225].

FGF8 is also required during the early stages of thymus and parathyroid development. This growth factor is expressed in the early gut endoderm and in the endoderm and ectoderm of the pharyngeal pouches and clefts. Mice carrying hypomorphic alleles of *Fgf8* show defects in thymus development ranging from hypoplasia to complete aplasia [226,227]: the initial impairment in thymus and parathyroid organogenesis is likely to occur at an early stage in the development in these mice, as the third and fourth pharyngeal arches and pouches are usually hypoplastic/aplastic, in addition to other abnormalities in the pharyngeal region [226,227].

In terms of the cell types affected by impaired FGF8 signaling, similarities between the phenotype of FGF8 hypomorphs and the spectrum of abnormalities found during experimental NCC ablation [228,229] suggest that the glandular defects may result from defective NCC migration/differentiation or survival. In support of this, NCC of FGF8 hypomorphs show increased levels of apoptosis [226,227] and reduced expression of *Fgf10*, which mediates the expansion of the thymic primordium from E12.5 [154], in the neighboring NCC mesenchyme [227]. There is also a mild reduction in the expression of genes associated with differentiated NCC [226] suggesting that the maintenance of NCC is perturbed.

Taken together, these data implicate FGF8 in maintaining a competent NCC population that can contribute to thymus organogenesis. However, FGF8 may also act specifically on the 3PP endoderm, since ablation of FGF8

in the endoderm and ectoderm, or ectoderm alone, results in different phenotypes. Ablation in the ectoderm alone causes vascular and craniofacial defects as seen in FGF8 hypomorphs [230], whereas when FGF8 is also deleted in the endoderm, glandular defects are evident, including thymus hypoplasia and ectopia [230]. The NCC defects were the same in both cases.

Further insight into the role of FGF signaling was provided by a detailed study of FGF signaling components during thymus organogenesis. This revealed a complex picture in which FGF signaling is modulated by the expression of Sprouty 1 and 2, such that although the 3PP expresses both FGFs and FGFR, signaling in the endodermal component of the thymus is restricted by Sprouty 1 and 2 [231]. Thus while the importance of FGF8 signaling in regulating development of the 3PP is clear, further studies are required to understand the temporal requirements for this pathway and its interplay with other signaling pathways involved in thymus and parathyroid organogenesis.

Transcription factors and regulation of third pharyngeal pouch outgrowth

After initial 3PP formation, continued development of the common primordium is dependent on a complex networks of transcription factors, including HOXA3, PAX1, PAX9, EYA1, SIX1 and SIX4; all of these factors are expressed in the 3PP endoderm from E9.5 to E10.5 and, with the exception of PAX1 and PAX9, are also expressed in associated NCC and ectoderm.

Hoxa3 mutants are both athymic and a parathyroid [145,232], and analysis of both null and tissue specific null mutants together reveals a complex role for HOXA3 in thymus development [233]. Initial 3PP formation is normal in *Hoxa3* null mutants, but the location and timing of regionalized markers including *Bmp4, Tbx1*, and *FGF8* is altered. *Gcm2* is initially expressed in the correct parathyroid domain but is then downregulated with the cells undergoing apoptosis, consistent with the *Gcm2* null phenotype [234]. In the thymus domain of $Hoxa3^{-/-}$ mice, *Foxn1* expression is delayed but subsequently reaches normal expression levels; however, the entire thymus primordium undergoes rapid apoptosis soon after and is completely ablated by E12.5. Conditional deletion in the endoderm or NCC or both showed that expression in each tissue contributes uniquely to thymus development, and that expression in either tissue is sufficient for thymus survival. A further study using temporally controlled global *Hoxa3* deletion showed that *Hoxa3* is not required in the thymus after E12.5 [233]. Thus HOXA3 function is required in both NCC and endoderm for proper timing of thymus differentiation, and its expression in either cell type is sufficient for survival of the thymus primordium.

Deletion of *Eya1* results in the failure to initiate overt thymus and parathyroid organogenesis once the 3PP has formed, revealing the essential roles of these factors [144,145,235,236]. *Tbx1* and *Fgf8* are both downregulated in the 3PP of $Eya1^{-/-}$ mice at E9.5 [236], indicating that EYA1 plays a role in regulation of these factors. Lack of SIX1 and SIX4, PAX1, or PAX9 causes much less severe phenotypes. The common primordium begins to develop in $Six1^{-/-}$ mice, and patterning into thymus and parathyroid domains (see the "Specification of the thymus and parathyroid" section) is initiated. However, subsequent apoptosis of endodermally derived cells in the common primordium leads to complete disappearance of the organ rudiment by E12.5 [236]. A similar phenotype is evident in $Six1^{-/-}$; $Six4^{-/-}$ embryos, though the size of the primordium is further diminished in the double mutants indicating synergy between these gene products [236]. *Pax9* loss of function mutations result in the formation of ectopically located thymic primordia, which form within the laryngeal cavity, rather than within the pharyngeal arch mesoderm. These primordia fail to migrate to the mediastinum and exhibit severe hypoplasia from E14.5. However, the thymic lobes are vascularized, contain both thymocytes and mesenchymal cells, and express *Foxn1* [237]. $Pax1^{-/-}$ mutants show relatively mild thymus hypoplasia and aberrant TEC differentiation [146,238,239]. Since *Pax1* and *Pax9* are highly homologous, these phenotypes may reflect functional redundancy, as demonstrated in other tissues [240,241].

Expression of *Hoxa3*, *Eya1*, and *Six1* in multiple germ layers complicates interpretation of the respective null phenotypes for these genes. However, HOXA3 appears to regulate *Pax1* and *Pax9* either directly or indirectly, since *Pax1* and *Pax9* expressions are initiated normally in $Hoxa3^{-/-}$ mutants but fails to be maintained at wild-type levels beyond E10.5 [145]. Furthermore, $Hoxa3^{+/-}$; $Pax1^{-/-}$ compound mutants show delayed separation of the thymus/parathyroid primordium from the pharynx, resulting in thymic ectopia and a more severe hypoplasia than that seen in $Pax1^{-/-}$ single mutants [146], indicating that these factors function in the same network.

It has been suggested that EYA1 and SIX1 act downstream of the *Hox/Pax* genes, as $Eya1^{-/-}$ embryos show normal expression of *Hoxa3*, *Pax1*, and *Pax9* but reduced expression of *Six1* in the endoderm of the third and fourth PP and ectoderm of the second, third, and fourth pharyngeal arches [235]. However, while it is likely that SIX1 acts downstream of EYA1, more recent evidence indicates that EYA1 and SIX1 are not regulated by the PAX genes since $Pax9^{-/-}$ and $Pax1^{-/-}Pax9^{-/-}$ mutants show normal expression of *Eya1* and *Six1* in the 3PP. Interestingly, $Eya1^{-/-}$ and $Six1^{-/-}$ double mutants lack the expression of *Pax1* in the E10.5 3PP, while *Pax9* expression is unaffected [236]. It remains possible that

Eya1 and *Six1* may be regulated by HOXA3 independently of PAX1 and PAX9 function.

Mice homozygous for a null mutation in *Ripply3*, an RA signaling target, have ectopic and hypoplastic thymi, with the thymic lobes of *Ripply3*$^{-/-}$ embryos being located in the oropharynx, similar to *Pax9* null thymi [242,243]. *Ripply3* was shown to repress *Tbx1* transcription in an in vitro Luciferase assay system, and the expression domain of *Pax9* was increased in the pharyngeal region of E9.5–E10.5 *Ripply3*$^{-/-}$ mice [242]. Furthermore, a 3.7 kb promoter region of *Pax9* was shown to be TBX1 responsive in a Luciferase assay. These studies together suggest that the expression of *Tbx1* may regulate *Pax9* expression.

Overall, the complexity of these data suggests it is likely that all or some of these factors form a stable network, which is sustained by complex feedback and autoregulatory loops. Further work is required to elucidate exactly how these and other transcription regulators cooperate in the development of the 3PP endoderm and to determine the precise role of each of these factors at the cellular level.

Specification of the thymus and parathyroid

Prior to the overt the formation of the thymus and parathyroid primordia, the 3PP is specified into organ-specific domains. At E9.5, epithelial cells within the anterior dorsal aspect initiate expression of GCM2 [244], a transcription factor required for the development of the parathyroid [245]. *Gcm2* is downregulated in *Hoxa3*$^{-/-}$, *Eya1*$^{-/-}$ and *Hoxa3*$^{+/-}$;*Pax1*$^{-/-}$ compound mutant mice [146,165,235], suggesting that GCM2 acts downstream of EYA1 and HOXA3. *Gcm2* is also directly regulated by GATA3; in E11.5 *Gata3*$^{+/-}$ mice, a lower proportion of cells in the 3PP expresses *Gcm2* [246]. The first known thymus specific transcription factor, FOXN1, is expressed at functionally relevant levels in the ventral domain of the 3PP from approximately E11.25, although low levels can be detected from E10.5 [244,247]. FOXN1, a forkhead class transcription factor, is required for TEC differentiation and hair development, and is discussed in more detail in the "FOXN1 and regulation of thymic epithelial cell differentiation" section.

The expression patterns of *Foxn1* and *Gcm2* clearly define the thymus and parathyroid domains of the 3PP. However, these factors do not appear to be responsible for specification of their respective organs, indicating that specification must be mediated by an upstream factor or factors. Three lines of evidence support this model. First, the epithelial cells in the ventral domain of the E11.5 3PP express interleukin 7 (IL-7), a cytokine required for thymocyte differentiation [248], making IL-7 one of the earliest currently identified markers of thymus identity. The thymus primordium *Foxn1*$^{-/-}$ embryos show normal *IL-7* expression [248], indicating that TE identity is specified in the absence of FOXN1. Second, the transplantation of the E9.0 pharyngeal endoderm, which does not express functionally relevant levels of *Foxn1*, gives rise to a functional thymus when grafted ectopically [138], indicating that at this developmental stage, some pharyngeal endoderm/3PP cells are already specified to the TE lineage. Third, the 3PP cells of mice carrying revertible null or revertible hypomorphic alleles of *Foxn1* retain their identity as TEPC until at least postnatal day 14 and 6 months of age, respectively, and are induced to initiate the TEC differentiation/organogenesis program simply by reversion of the null or hypomorphic allele [174,175].

Similarly, our studies conclude that GCM2 is not required for the specification of the parathyroid, as other parathyroid-specific markers, including *Tbx1*, *Ccl21*, and *CaSR*, are initiated in *Gcm2*$^{-/-}$ mice, although this domain undergoes rapid and coordinated apoptosis in the absence of GCM2 [249]. Thus GCM2 may play a somewhat analogous role in parathyroid development to that of FOXN1 in the thymus, although the thymus rudiment does survive in the absence of *Foxn1*.

Upstream regulation of *Foxn1* is currently not well understood. *Eya1*$^{-/-}$ embryos do not express *Foxn1*, but this is likely due to the block in primordium formation prior to the onset of *Foxn1* expression in each of these mutants. Although *Foxn1* expression is unaltered in *Pax9*$^{-/-}$and *Hoxa3*$^{+/-}$, *Pax1*$^{-/-}$ mutants [237,239], PAX1 and PAX9, are known to be functionally redundant in other cell-types, as expected from their high homology level. Furthermore, while *Six1*$^{-/-}$ mutants display reduced *Foxn1* expression, the 3PP exhibits increased cell death in the absence of *Six1* [236], and therefore, the reduced expression of *Foxn1* may reflect poor survival of FOXN1^{+} cells rather than a direct interaction between *Foxn1* and SIX1. Further studies are required to determine whether a regulatory relationship exists between these genes and *Foxn1*.

Several candidate regulators of thymus specification have been identified based on their expression in the 3PP prior to initiation of *Foxn1* [250]. These include NKX2.5, NKX2.6, ISL1, GATA3, and FOXG1. *Nkx2.5*, *Nkx2.6*, *Isl1*, and *Gata3* are expressed in the developing 3PP at E9.5 and are restricted to the ventral portion of the 3PP endoderm at E10.5. *Foxg1* is not expressed in the 3PP at E9.5 but at E10.5 is expressed in two discrete regions, one dorsal and the other ventral. By E11.5, when *Foxn1* is first activated in the 3PP, *Foxg1* and *Isl1* are already restricted to the thymus domain. These factors continue to be expressed in TECs throughout late fetal and postnatal differentiation. However, it remains unknown whether they transcriptionally activate *Foxn1* or instead regulate

FOXN1-independent aspects of thymus development. The transcription factors E2F3 and E2F4 have been shown to play a role in promoting FOXN1 expression in the adult thymus [251]. E2F family transcription factors are associated with cell cycle progression and are negatively regulated by Retinoblastoma (RB) tumor suppressor proteins. Both E2F3 and E2F4 have been shown to bind to their consensus motifs in the presumptive FOXN1 promoter and genetic ablation of the Retinoblastoma tumor suppressor proteins in adult mice results in increased E2F3 activity and a concomitant increase in FOXN1 expression in TEC [251]. As a result of perturbed RB activity, these mice exhibit thymic hyperplasia, which can be reversed by genetically suppressing FOXN1, strongly suggesting that the effects observed reflect E2F mediated regulation of FOXN1.

The T-box transcription factor TBX1 has also been implicated in the regulation of FOXN1 expression. As discussed above, overexpression of TBX1 in 3PP in mice leads to reduced FOXN1 expression and maturational arrest of TEC differentiation at an early progenitor stage, characterized by expression of PLET1 [222]. This indicates that TBX1 negatively regulates FOXN1 expression, although further work is required to establish if this effect is direct or indirect.

Further insight regarding the regulation of *Foxn1* expression may be drawn from analysis of the cutaneous epithelium, which also requires FOXN1 for normal development. There is some evidence to suggest that HOXC13 is involved in *Foxn1* regulation in hair follicles [252], although at present it has not been determined if this factor performs a similar function in TEC.

How then are the thymus and parathyroid domains within the 3PP established? Evidence suggests that opposing gradients of bone morphogenetic proteins (BMPs) and sonic hedgehog (SHH) may play an important role in this process. During thymus development, *Bmp4* expression is first detected at E9.5 when it is expressed by a small number of mesenchymal cells in the third pharyngeal arch [253]. By E10.5, the *Bmp4* expression domain has expanded to include the ventral 3PP endoderm and the adjacent mesenchyme but remains absent from the dorsal 3PP. This expression pattern is maintained at E11.5 and by E12.5 *Bmp4* is expressed throughout the thymic primordium and the surrounding mesenchymal capsule [253].

In vivo evidence of a role for BMPs in thymus organogenesis was provided by a series of studies in which the expression of the BMP inhibitor *Noggin* was driven by the *Foxn1* promoter, thus impairing BMP signaling in the thymic stroma [254–256]. *Foxn1-Noggin* mice developed hypoplastic and cystic thymi that failed to migrate to their normal position above the heart. It is highly likely that this is due to a direct effect on the thymic stroma, although mediators of BMP signaling such as *Msx1* and phosphorylated SMAD proteins were downregulated in both the epithelium and surrounding mesenchyme. Interestingly, *Foxn1* expression was only partially blocked in this transgenic model [254]. However, *IL7* expression was also absent in the cells that had downregulated *Foxn1*, suggesting that thymus fate, rather than solely *Foxn1*, may have been affected [255]. A caveat for interpreting these data is that the inhibition of BMP signaling was driven by the *Foxn1* promoter and thus occurred after initiation of *Foxn1* expression. Furthermore, the addition of a BMP inhibitor did cause loss of *Foxn1* in a zebra fish model [255]. A further study showed that BMP signaling is necessary for *Foxn1* initiation in cocultures of qE2.5 quail pharyngeal pouch endoderm and chick mesenchyme. BMP is required only during a narrow time window, however, as addition of Noggin has no effect on *Foxn1* initiation in cocultures containing qE3 endoderm. *Gcm2*, in contrast to *Foxn1*, is initiated in the absence of mesenchyme and maintained in the presence of Noggin [257]. Furthermore, transient inhibition of BMP signaling during early/mid thymus organogenesis led to reduced *Foxn1* expression, with concomitant reduced functionality also observed in $Foxn1^{+/-}$ TEC [256].

Conditional deletion of *Bmp4* in the pharyngeal endoderm (and, with variable efficiency, in the surrounding mesenchyme) using *Foxg1-Cre* indicates that expression of *Bmp4* is required for thymus and parathyroid morphogenesis. In E11.5 *Foxg1-Cre*; $Bmp4^{F/F}$ embryos, the thymus-parathyroid primordium is hypoplastic, but the expression of *Foxn1* and *Gcm2* is normal as detected by in situ hybridization, demonstrating proper specification and patterning of the thymus and parathyroid domains. However, delayed separation of the two organ primordia and reduced migration of the thymus primordia are evident at E12.5 and E13.5 [258]. *Wnt1-Cre* or *Foxn1-Cre* mediated the deletion of *Bmp4* has no effect on thymus and parathyroid morphogenesis, suggesting that BMP4 signaling is required in the pharyngeal epithelium during a narrow time window prior to the onset of *Foxn1* expression. However, as the thymic primordium expresses BMP2 and BMP7 (CCB and NRM unpublished data), which signal through the same receptor as BMP4, redundancy is an issue for interpreting these results.

During the development of the 3PP, expression of the secreted glycoprotein SHH is restricted to the region of 3PP immediately adjacent to the pharyngeal endoderm at E10.5 and E11.5, although its receptor Patched1 is expressed by cells in close proximity to this region [259,260]. Analysis of $Shh^{-/-}$ embryos revealed expanded expression domains for both *Bmp4* and *Foxn1* in the 3PP, while the corresponding $Gcm2^{+}$ parathyroid domain was lost in these mutants [259]. Consistent with these observations, cyclopamine treatment of chick embryos at HH14–16 blocked *Gcm2* initiation and led to

enhanced *Bmp4* expression in the caudal pharyngeal pouches. However, loss of SHH signaling at a later stage (HH21) caused ectopic expression of *Gcm2* and *CaSR* in the anterior first ectodermal cleft and posterior second arch and had no effect on *Gcm2* transcription in the 3PP [260]. Thus at early developmental stages, the role of SHH in thymus organogenesis may be to oppose the action of BMP4 to allow the specification and development of the parathyroid. At later stages, SHH signaling may also restrict parathyroid development to the caudal pharyngeal pouches.

SHH is also implicated in both thymocyte and TEC development [261]. In the mouse, $Shh^{-/-}$ results in embryonic lethality at E15.5. Analysis of thymic cellularity at E15.5 revealed a decrease in both the EPCAM and CD45 expressing compartments and, when cultured as FTOC for 7 days, displayed a lower mTEC to cTEC ratio than $Shh^{+/+}$ controls. To isolate the effect of SHH on TEC development from the above-described effect upon 3PP specification, the authors employed a conditional SHH knockout model, *Foxn1-Cre*; $Shh^{F/F}$, in which *Shh* is only deleted in *Foxn1* expressing TEC (and skin). At E15.5 the model displayed reduced total thymic and TEC cellularity compared to *Cre*-controls. When cultured in FTOC, similar perturbation of the medullary compartment was observed as in the constitutive *Shh* knockout model. Examination of maturity markers in conditional *Shh* knockout TEC showed that mTEC expressed significantly more MHCII but that fewer cells developed AIRE expression. Collectively, these data indicate that SHH is required for 3PP specification and is antagonistic to thymus development during initial organogenesis but has subsequent effects on TEC development.

WNT glycoproteins may also be important in regulating *Foxn1* expression. WNTs are expressed by the thymic stroma and by lymphoid cells, with WNT receptors being expressed by TECs [247] and some other intrathymic cell-types including DCs. The earliest reported expression of WNT family members during thymus development is at E10.5, immediately prior to strong *Foxn1* expression, when the epithelium of the 3PP and adjacent cells express *Wnt4* [247]. Given this expression pattern and the finding that TEC lines that overexpress WNT4 display elevated the levels of *Foxn1* [247], it is possible that WNT4 cooperates with BMP4 to regulate *Foxn1*. However in vivo models fail to provide evidence of this. $Wnt1^{-/-}$, $Wnt4^{-/-}$, $Wnt1^{-/-}$, *and* $Wnt4^{-/-}$ mice all exhibit hypoplastic thymi characterized by reduced T cell numbers but normal thymocyte developmental progression, indicating that *Foxn1* is activated in the absence of these WNT signaling cascades [107,262].

Analysis of $Wnt4^{-/-}$ mice suggests that WNT4 controls thymus size by modulating the expansion of both TECs and immature thymocytes. By E15.5, $Wnt4^{-/-}$ thymi contained fewer TECs than wild-type thymi, and at E18.5, histological analysis revealed smaller medullary areas and reduced the expression of medullary markers and disorganization of the CMJ. In addition, mouse models have been engineered to knock out the canonical, β-catenin-dependent and noncanonical, Nlk-dependent ($Nlk^{-/-}$) intracellular signaling cascades [263], with TEC- and skin-specific knockout of β-catenin (*Foxn1*-Cre; $Ctnnb^{fl/fl}$) resulting in neonatal lethality. At E15.5, both models led to hypocellular thymi, similar to $Wnt4^{-/-}$ mice but with histologically normal TEC patterning and robust *Foxn1* expression. The authors also explored the effects of WNT overactivation in TEC using *Foxn1*-driven expression of β-catenin (*Foxn1:Ctnnb*) and WNT4 (*Foxn1:Wnt4*). In both models, thymic organogenesis was severely perturbed, characterized by ectopic, and hypocellular thymi with reduced *Foxn1* expression compared to wild-type controls. In the β-catenin overexpression model, TEC were unable to form a reticulated architecture, the thymus was not colonized by T cells, and adult mice were severely T cell hypoplastic [263]. The WNT4 overexpression model produced comparatively larger thymi with reticulated TEC architecture but still presented disrupted differentiation [263]. These observations are consistent with a previous analysis, that also showed restricted immigration of thymocytes, as well as a block in thymocyte development at the DN1 stage, in a β-catenin overexpression model [264]. The mutant TE contained a central core of cells that initially appeared committed to a thymus fate but later downregulated expression of FOXN1, K8 and K5, and expressed involucrin [264]. Similarly, the deletion of the WNT signaling repressor *adenomatous polyposis coli* (*Apc*) in K14-expressing cells (using *K14-Cre*; $Apc^{CKO/CKO}$ mice) revealed a hypoplastic thymus characterized by variable disruption of epithelial organization, exclusion of lymphocytes, and the presence of enlarged structures expressing keratinocyte markers such as involucrin [265].

Collectively, these data suggest that WNT acts as a negative regulator of *Foxn1* and inhibits migration of the thymic rudiment. Analysis of a double transgenic model in which both β-catenin and the BMP4 inhibitor NOGGIN were overexpressed in TEC (*Foxn1:Ctnnb*; *Foxn1:Noggin)* revealed that the inhibition of BMP4 further exacerbated the β-catenin overexpression phenotype. However, later in development WNT appears essential for thymic organogenesis as its absence perturbs thymic cellularity and TEC differentiation [263].

Evidence also suggests that WNT signaling is also required for the maintenance of the postnatal thymus. Deletion of the WNT antagonist Kremen resulted in the development of large epithelial-free zones in the TEC network [266]. Tetracycline-regulated the overexpression of the canonical WNT inhibitor Dickkopf related protein 1

(encoded by *Dkk1*) in cortical, and medullary TECs of postnatal mice resulted in dramatic thymus degeneration [267]. A decrease in the number of $K5^{+}K8^{+}$ cells at the CMJ and reduced proliferation in the MHC Class II^{lo} compartment was observed in this model, perhaps implicating WNT in the regulation of progenitor TEC. Consistent with this idea, these phenotypes were reversed by the withdrawal of Doxycycline, and restoration of thymus size correlated with recovery of the $K5^{+}K8^{+}$ TEC population [267].

Foxn1 and regulation of thymic epithelial cell differentiation

As discussed in the "Origin of thymic epithelial cells" and "Thymic epithelial progenitor cells (TEPC)" sections, the existence of a common TEPC, able to generate both cortical and medullary TECs, and of downstream cortical and medullary thymic epithelial sublineage-restricted TEPC, is now clearly established. Understanding the mechanisms controlling TEC sublineage differentiation from the common progenitor, and the maintenance of differentiated TEC subtypes, is thus important for tissue-engineering strategies.

The transcription factor FOXN1, introduced in the "Thymic epithelial progenitor cells" section, regulates the differentiation of TEC in both the mTEC and cTEC sublineages in the fetal and adult thymus. TEC undergo developmental arrest at the founder/fetal progenitor cell stage of development in the absence of functional FOXN1 expression [41,174]. FOXN1 is required cell autonomously for development of all mature TEC subtypes from the common TEPC [170] and also regulates TEC proliferation in the fetal thymic rudiment [143]. Thus while TEPCs form independently of FOXN1, their proliferation and differentiation into mature c- and mTEC is FOXN1-dependent. However, analysis of the $Foxn1^{-/-}$ fetal thymus revealed the presence of $K5^{hi}CLDN4^{hi}$ regions corresponding to presumptive progenitor mTEC suggesting that, during organogenesis, FOXN1 is not required for divergence of the mTEC lineage from the common TEPC [41]. This was corroborated by the finding that $Cldn3,4^{hi}SSEA1^{+}$ mTEC stem cells could be identified in $Foxn1^{-/-}$ fetal thymi, albeit at reduced numbers compared to wild-type controls [268].

FOXN1 is expressed by most if not all differentiating and mature TECs throughout fetal development and, postnatally, is also expressed in most TECs throughout the lifespan [171]. $FOXN1^{lo/negative}$ populations arise in the postnatal thymus from TEC that have previously expressed FOXN1 [269,270] with this progressive postnatal downregulation of FOXN1 occurring first in cTEC, coincident with the onset of age-related thymic involution [269]. The role of FOXN1 beyond the fetal TEPC stage is incompletely understood. FOXN1 is required in a dosage-dependent manner to regulate multiple stages of differentiation in both the c- and mTEC sublineages in the fetal and adult thymus. In both sublineages, FOXN1 is required throughout differentiation, from exit from the earliest TEPC state to terminal differentiation of both cTEC and $AIRE^{+}$ mTEC [41]. FOXN1 also plays a role in regulating cross talk between developing TEC and thymocytes, which is required for the expansion and maturation of the medullary compartment [198,271].

Importantly, a subfunctional thymus can be generated at suboptimal levels of FOXN1 expression or function, indicating that full thymus function is generated only in a relatively narrow *Foxn1* dosage range [41,198,272–274]. This conclusion is also supported by the analysis of FOXN1 function in the postnatal thymus, which shows it is required in a dosage-sensitive manner to maintain thymus homeostasis [275], and that complete loss of either FOXN1 expression or FOXN1-expressing TEC postnatally results in loss of thymus function [197,276,277]. Furthermore, downregulation of FOXN1 expression in TEC is a key hallmark of thymic involution [278–280]. Restoration of FOXN1 expression is sufficient to reverse this process in aged mice [280], and the upregulation of FOXN1 is also observed in some models of thymus regeneration [270]. Collectively, these data highlight the importance of understanding the intrinsic and extrinsic mechanisms that regulate FOXN1 expression, and the downstream mechanisms regulated by FOXN1, in vivo.

As discussed above, little information exists regarding the transcriptional regulation of *Foxn1* expression. However, direct or indirect transcriptional targets of FOXN1 itself have been described in a number of studies [25,41,197,272,275,280–284]. Recently, high-confidence direct FOXN1 targets in postnatal cTEC have been identified by chromatin immunoprecipitation sequencing (ChIPseq) [284]. Since the set of FOXN1-regulated genes identified to date includes factors with diverse functions in thymus development and the TEC-mediated support of T cell development, FOXN1 can be considered a "master regulator" of TEC differentiation, rather than a regulator of a specific aspect of thymus development.

In addition to its expression in TEC, FOXN1 is also expressed in skin and hair follicle keratinocytes, where it regulates normal development. In these cutaneous epithelial lineage cells, FOXN1 is believed to regulate the balance between proliferation and differentiation [285–287]. However, while some parallels may exist between FOXN1 function in skin and thymus, FGF2, a known direct target of FOXN1 in cutaneous epithelium [287], is not expressed in TEC [41], suggesting FOXN1 may regulate different target genes in the cutaneous and thymic epithelial lineages.

Medullary development and expansion

The development of mature mTECs depends on the activation of the noncanonical NF-κB-signaling pathway that culminates in RELB activation. mTEC development is severely compromised in RELB deficient mice [288,289]. In addition, a range of medullary defects occurs in mice deficient in components upstream of RELB in the alternative NF-κB-activation pathway. Mice with a naturally occurring mutation in NF-κB-inducing kinase (*NIK*), and *Ikkα* knockout mice, display abnormal thymic architecture with small, hypocellular medullary regions associated with reduced *Aire* and TRA expression [290–292]. A similar phenotype is found in *TRAF6* knockout mice, indicating that the classical NF-κB-signaling pathway also plays a role in formation of functional medullary regions [293]. Interestingly, each of these mutant strains develops autoimmune manifestations consistent with a breakdown in the establishment of central tolerance due to a deficiency of $AIRE^+$ mTECs.

Signals from positively selected thymocytes play an important role in expanding the medullary region in adult thymi, a mechanism often referred to as lympho-epithelial cross talk. Small medullary regions containing sparse mTEC subsets are found when thymocyte development is blocked at the DP stage, as occurs in *TCRα* deficient mice or in mice lacking both MHC Class I and MHC Class II molecules [294,295]. Despite the paucity of mTECs, the medullary regions in these mice nevertheless express *Aire* and TRAs, indicating that mTEC expansion is affected to a greater extent than differentiation. Positively selected DP thymocytes differentiate into SP thymocytes that migrate into the medulla, and these SP cells express various tumor necrosis factor superfamily (TNFSF) ligands, including receptor activator of NF-κB ligand (RANKL), CD40 ligand (CD40L), lymphotoxin-α, and lymphotoxin-β [296–299]. Binding of these ligands to their receptors on mTEC activates NF-κB signaling, to promote mTEC proliferation and differentiation: ligand engagement of the TNFSF receptors activates NIK, which phosphorylates homodimers of the downstream kinase, Ikkα. Activated Ikkα in turn phosphorylates the C-terminal region of NF-κB2 (p100) leading to ubiquitin-dependent degradation and release of the N-terminal polypeptide, p52. The formation of RELB/p52 heterodimers permits shuttling of RELB from the cytoplasm into the nucleus where it functions as a transcriptional regulator [300].

Thus *RANK* or *RANKL* deficient mice have small, poorly developed medullary regions in which mTEC cellularity is decreased and *Aire* expression is reduced [298,301]. Targeted disruption of the *Ltbr* gene also results in disorganized medullary regions that contain reduced numbers of mTECs [299]. Signaling via the LTBR is required to upregulate RANK expression on fetal TECs, implying cooperation between these two TNFSF receptors in mTEC development [302]. Furthermore, it has been reported that LTBR signaling regulates *Fezf2* expression in mTECs [93], suggesting a possible mechanism by which this signaling cascade regulates self-tolerance. However, a subsequent report found that neither *Aire* nor *Fezf2* expession was altered by loss of LTBR signaling [303]. The reason for the discrepancy in these two reports is not clear.

Recently, two studies have indicated a hierarchy of intermediate progenitors specific for the mTEC (MEC) sublineage, based on detailed genetic analyses of NF-κB pathway components [268,304]. These studies strongly suggest that RANK signaling promotes two distinct stages of mTEC development, initially cooperating with LTBR to induce "pro-pMEC" ($UEA\text{-}1^+RANK^{lo}MHC\ II^{lo}CD24^{hi}$) from the putative $Cld3,4^{hi}SSEA\text{-}1^+$ mTEC stem cell via RELB [268,304] and subsequently stimulating "pro-pMEC" to differentiate into "pMEC" ($RANK^+UEA\text{-}1^+MHC\ II^{mid}CD80^-$) and then $AIRE^+$ MEC via TRAF6 [304]. HDAC3 has also emerged as an essential regulator of mTEC differentiation [305], and a role for STAT3 signaling has been demonstrated in mTEC expansion and maintenance [306,307]. Despite these advances, the molecular mechanisms operating in thymus organogenesis to govern the emergence of the earliest cTEC- and mTEC-restricted cells are not yet understood [180].

Interestingly, medullary region development is initiated in the fetal thymus prior to the appearance of SP thymocytes. This is at least partly due to the presence of lymphoid tissue inducer (LTi) cells that express RANKL, but not CD40L. RANKL signaling induces the generation of $AIRE^+$ mTECs before fetal thymocytes of the αβ TCR lineage have matured to the SP stage [301,308]. The early fetal thymus also contains thymocytes expressing invariant Vγ5 Vδ1 TCRs. These cells, which are present prior to the development of αβ lineage thymocytes, also express RANKL and play a role in the development of $AIRE^+$ mTECs [309]. In addition to αβTCR and γδTCR expressing thymocytes, group 3 innate lymphoid cells (ILC3) and invariant natural killer cells also express RANKL and, therefore, contribute to mTEC differentiation.

Maintenance and regeneration of thymic epithelial cells: Progenitor/stem cells in the adult thymus

The identity of the progenitor and/or stem cell populations that maintain postnatal TECs during homeostasis has been the subject of intense investigation. Efforts to track down postnatal TEPC have focused on determining the potency of TEC subpopulations in the adult mouse thymus, using the combination of in vitro and in vivo assays. Perhaps

the most salient question in this regard is whether a multipotent stem/progenitor cell exists that can maintain the highly heterogenous TEC population or if distinct compartments are exclusively sustained by precursors that are lineage restricted. This question is particularly important with respect to strategies that aim to reconstitute thymus function.

The existence of an mTEC-restricted progenitor cell in the adult mouse thymus has been suggested by both transplantation-based assay and lineage tracing studies [181,184,185]. In particular, Sekai et al. identified a rare mTEC population in the postnatal mouse thymus that exhibited a similar phenotype to fetal mTEC restricted precursors (SSEA-1^+CLDN3,4^{hi}, $MHCII^-UEA\text{-}1^-$). Purified populations of these cells could contribute to mature mTECs within transplanted reaggregate fetal thymic organ cultures (RFTOCs) based on E14.5 WT thymi, although this capacity was significantly reduced compared to cells isolated during embryonic and neonatal stages [181]. Importantly, contribution to the cTEC lineage was not detected. Interestingly, the authors found that this decline in progenitor mTEC activity was associated with the presence of thymocytes at advanced differentiation stages, as SSEA-1^+ cells isolated from $RAG2^{-/-}$ mice, in which later stages of thymocyte development are blocked, retained a higher capacity for mTEC reconstitution. The mechanistic reason for this is unclear, although it may reflect the developmental arrest of mTEC precursors as a consequence of impaired formation of the $RAG2^{-/-}$ thymic medulla.

Evidence of bipotent TEPCs in the adult thymus has also recently emerged. One study has identified an $EPCAM^+UEA\text{-}1^-MHCII^{lo}Ly51^{lo}$ population that resides at the CMJ and can contribute to both cortical and medullary lineages upon transplantation [310]. However, these experiments used high input cell numbers (7.5×10^4–1×10^5), limiting the utility of the assay with respect to determining lineage contribution from single cells. A more recent study identified an $EPCAM^+PLET1^+MHCII^{hi}Ly51^+UEA\text{-}1^-$ population, also residing at the CMJ in adult thymus, that could contribute to both cTEC and mTEC lineages, a capacity that persisted for at least 9 months [110]. Importantly, this ability was evident with input cell numbers as low as 129/graft, with limiting dilution analysis predicting the frequency of bipotent cells within the population at around 1:90. Furthermore, the long-term contribution exhibited by this population points to a possible stem cell activity. Interestingly, this study also found cTEC-restricted lineage potential in a cell type that overlaps phenotypically with the $EPCAM^+UEA\text{-}1^-MHCII^{lo}Ly51^{lo}$ population [310], providing a possible explanation for the multilineage contribution observed for the $MHCII^{lo}Ly51^{lo}UEA\text{-}1^-$ compartment [110].

A thymic epithelial stem cell (TESC) population with multilineage potential has also been reported [311]. This study assayed the ability of adult thymic stromal cells to develop in vitro spheroids, an approach that has been employed for other self-renewing epithelia such as the mammary gland. The authors found that the spheroids, termed "thymospheres," were clonally derived, displayed some degree of self-renewal and exhibited multilineage potential [311]. However, the main conclusions have been refuted in a recent study that showed that $FOXN1^-$ thymic mesenchymal cells initiate thymosphere formation by recruiting $FOXN1^+$ TECs [312], providing insight into the role of nonepithelial thymic stroma in supporting thymus development and function.

Strategies for thymus reconstitution

Reconstitution of thymus function is essential for strategies that aim to restore immune function in a number of clinical settings. In particular, optimal regeneration of a functional T cell repertoire following BM transplantation depends on robust thymus function, which is impaired in many patients as a consequence of thymic involution. Several approaches may be considered to achieve this end. In vitro generation of a functional thymus is one strategy, which could be employed to either facilitate the production of a T cell repertoire for adoptive transfer or to provide a source of engineered tissue for transplantation. An alternative approach is to restore endogenous thymus function by reversing thymic involution. In the former, a scalable source of cells that can generate the full range of functional TEC is essential, while for the latter, an intricate knowledge of how TEC maintenance and function is regulated at the molecular level is required. The advances in our understanding of thymus biology discussed in this review have led to significant developments in each of these areas, making the goal of thymus reconstitution a tangible reality.

One possible source of TEC are pluripotent stem cells, which have the capacity to generate all cell lineages that constitute functional tissues and organs. This approach can utilize either ES cell lines derived from blastocysts or induced pluripotent stem cells (iPS) generated by reprogramming somatic cells. The use of iPS cells has the key advantage of enabling the generation of cells that are genetically identical to individual patients, thus circumventing the need for immunosuppression. The viability of this approach depends on the ability to efficiently direct the differentiation of PSCs to the TEC lineage. In this regard, several studies have now reported progress toward generating TEC-like cells derived from in vitro cultures of PSCs [206–210]. Notably, two studies have used in vitro protocols that promote the stepwise differentiation of human ESC lines into definitive endoderm, foregut endoderm, pharyngeal endoderm and subsequently epithelial cells bearing hallmarks of TEPCs, including *Foxn1*

expression [209,210]. When grafted into athymic nude mice, these TEPC-like cells were able to differentiate into cells that expressed markers associated with cTECs and mTECs, as well as support some level of thymopoiesis. However, the grafts derived from TEPC like cells did not display the tissue architecture typical of the functionally mature thymus, with no distinct cortical or medullary regions apparent. This is important as the spatial organization of the TE is critical to ensure that T cell−development proceeds through the correct sequence of events. Furthermore, the induction of the distinct cortical and medullary architecture itself depends on reciprocal interactions with developing thymocytes that have transitioned through the various stages of maturation. The highly ordered spatial organization of TECs is therefore indicative of functional thymopoiesis, and the lack of an organized TE in grafts derived from TEPC-like cells suggests that thymus function has not been fully recapitulated and/or sustained. Thus while this avenue of research is promising, further progress is needed to establish if TEPC-like cells derived by these methods can fully reconstitute thymus function.

Recently, two studies have revealed that the manipulation of FOXN1 expression presents a powerful means of both restoring thymus function in the aged thymus [280] and directly reprogramming cells into functional TEC [283]. In the former, induction of FOXN1 expression in TECs of aged mice was sufficient to reverse thymic involution and restore cortical and medullary organization to close to that observed in the young, preinvolution thymus. Consistent with this, thymopoiesis was restored, demonstrated by the presence of thymocyte subsets and newly generated peripheral T cells. Strikingly, this effect could be elicited in mice as old as 2 years. The significance of this study is it reveals that targeting a single transcription factor is sufficient to reverse thymic involution and validates FOXN1 as a target for thymus regeneration, further highlighting the importance of understanding how this transcription factor itself is regulated.

In the second study, FOXN1 expression was induced in in vitro cultures of murine embryonic fibroblasts [283]. This resulted in the generation of cells with TEC-like characteristics, including the expression of genes required in TEC to promote T cell commitment and development, such as DLL4, CCL25, and KITL, as well as the endogenous FOXN1 locus. Consistent with this, these induced TEC (iTEC) could support in vitro thymocyte development in a similar manner to the OP9-DLL4 system. Strikingly, when iTECs were grafted into athymic nude mice, they could generate a fully functional thymus that supported thymopoiesis and the generation of peripheral T cells. Critically, thymus tissue derived from iTECs displayed the cortical and medullary architecture typical of the functionally mature gland, and the phenotypic heterogeneity expected of fully mature cTEC and mTEC. The generation of iTEC by forced expression of FOXN1 identifies for the first time a means of directly reprogramming cells to the TEC lineage. This represents a strategy that could enable the generation of transplantable thymus tissue from a highly scalable source of cells and thus is highly significant with respect to restoring immune function. In this regard it will be important to determine which cell types are competent to form iTEC in response to forced FOXN1 expression.

Collectively, our understanding of the cellular and molecular mechanisms that regulate TEC development and maintenance have led to significant progress in developing strategies that will enable the reconstitution of thymus function. Continued advances in our knowledge of thymus biology will accelerate this progress toward therapeutic strategies that can be utilized in the clinic.

Summary

Thymus organogenesis is a complex process in which a dynamically regulated, three-dimensional organ forms from the endoderm of the 3PP. The TE, a critical regulator of thymopoiesis, is comprised of many subtypes of TEC, all of which arise from a common progenitor. Importantly, T cell development depends on interactions with both cortical and medullary TEC subtypes, which mediate different aspects of T cell differentiation and repertoire selection. Therefore the development of functional in vitro or transplantable thymic organoids requires the ability to recapitulate all of these functions, with appropriate spatial and temporal constraints. Recent studies have begun to clarify the lineage relationships of the different TEC subtypes, and to unravel the molecular networks that govern thymus and parathyroid organogenesis. However, with respect to the goal of developing in vitro or transplantable thymi for therapeutic purposes, several significant questions remain unresolved:

- What factor or factors specify thymus and parathyroid lineages within the 3PP?
- How does the network of transcription factors and signaling molecules that are expressed in the endoderm and surrounding mesenchyme/mesoderm control subsequent thymus and parathyroid development, including the maintenance, proliferation, and differentiation of thymic epithelial and parathyroid progenitor cells?
- How is *Foxn1* regulated in fetal and adult TEC?

In addition, further identification of the transcriptional networks in which FOXN1 operates to control development and function of c- and mTEC, is an important goal. The potential of factors downstream of FOXN1 to facilitate engineering of HPC niches ex vivo has already been demonstrated by transgenic expression of varying

combinations of *Ccl25*, *Cxcl12*, *Scf*, and *Dll4* in *Foxn1*-deficient TE [313]. It is likely that the knowledge of both additional FOXN1-regulated genes and proteins required in conjunction with FOXN1 to regulate specific functions in TEC may prove useful for manipulating or engineering thymus function(s) in vitro or in vivo.

Finally, a deeper understanding of the mechanisms that mediate the homeostatic maintenance of the mature thymus is critical for developing the strategies for thymus regeneration or replacement. Of particular importance is continued delineation of both the stem/progenitor cell types responsible for replenishing TEC in the adult thymus, and of the mechanisms that operate on TEC to induce thymic involution. Progress in each of these issues is likely to facilitate rational design of strategies for therapeutic reconstitution of the adaptive immune system. The development of such strategies should significantly impact the health of the aging population, and other immunocompromised individuals.

Introduction

The intestinal epithelium performs multiple complex functions, including absorption of nutrients and providing a barrier against pathogens. These epithelial cells are exposed to a harsh luminal environment, necessitating constant self-renewal and replenishment of the majority of the epithelium every 4−8 days. The intestinal stem cell (ISC) long remained elusive, but over the past few decades considerable advances have been made to identify progenitor populations and develop a more cohesive understanding of intestinal renewal.

Stem cells are, by definition, capable of both self-renewal and differentiation, with enormous potential for future therapies. The identification of different stem cell populations in the crypts, and insight into the complex network of signaling molecules that sustain them, has led to the advent of techniques that take advantage of these properties. Tissue engineering may capitalize on native regenerative populations or strategies to recapitulate aspects of development. Following the identification of native stem/progenitor populations, tissue-engineered intestine (TEI) has been produced from multiple sources. TEI might have the potential to restore enteral independence in patients with short bowel syndrome (SBS), a devastating condition that results from extensive loss of the absorptive capacity of the epithelium, resulting in partial or total dependence on intravenous, or parenteral, nutrition for survival. Here we will discuss the stem/progenitor cells of the gastrointestinal tract, chemical messengers that maintain the stem cell niche, and future applications for tissue engineering that might apply these concepts in order to develop future human therapies.

Stem cells of the intestine

Cell types of the epithelial layer

The intestinal epithelial layer is the most rapidly cycling tissue in mammals and is structurally adapted to provide maximum absorptive surface area. The wall of the intestine is composed of four layers, the innermost mucosa, submucosa, muscular layer, and outer serosa (Fig. 38.1). The microscopic anatomy consists of the invaginated crypts of Lieberkühn surrounding the finger-like villus projections (Fig. 38.2A). Intestinal epithelial cells can be divided into two distinct lineages: absorptive and secretory (Fig. 38.2A). The absorptive cells or enterocytes function in uptake of nutrients and are localized to the villi. There are several types of secretory cells which aid in protecting and optimizing the function of this absorptive surface. The goblet cells secrete mucus that helps one to protect the enterocytes and serves as a passive barrier

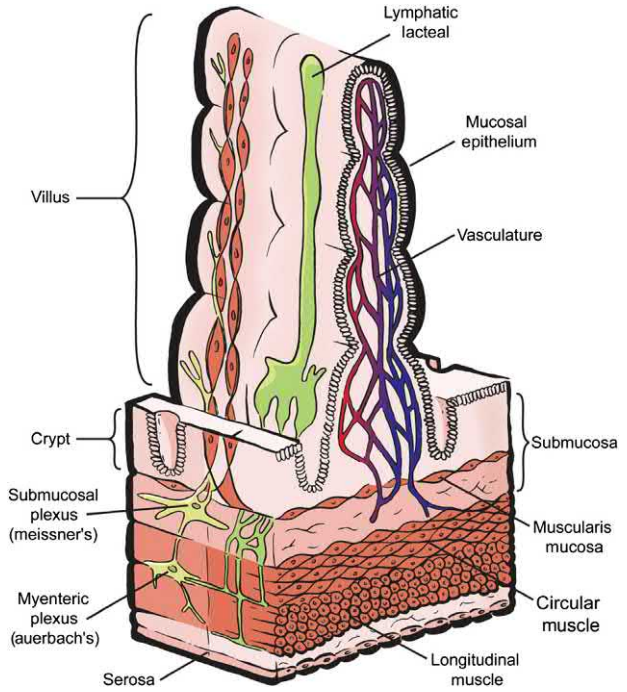

FIGURE 38.1 Structure of the small intestinal villus. A cross section of an individual villus and surrounding crypts depicts the vasculature, lymphatic, and neuromuscular structures. Small intestinal villi are finger-like projections covered in absorptive enterocytes with dense microvilli that provide an extensive absorptive area for extracting nutrition from the gastrointestinal lumen. Arterial vessels feeding the muscular and mucosal layers originate from the arterial plexus of the submucosa, with the mucosal layer receiving roughly 80% of the intramural blood flow. Submucosal arterioles are eccentrically located within the villi, which pass to the villus tip forming a capillary network with multiple anastomoses and egress as a single eccentrically located venule. The lymphatic system of the small intestinal villus comprises a centrally located lacteal with the apical portion containing endothelium that provides propulsion of absorbed luminal contents toward the collecting lymphatics when the villus contracts. The neuromuscular interface not only promotes contractility from ganglia within the myenteric and submucosal plexuses within the villus, but enteric neural connections with neuropods of enteroendocrine cells establish a neuroepithelial networks allowing propagation of luminal signaling to the nervous system.

against pathogens [1]. M cells overlie Peyer's patches and serve as antigen sampling cells that aid in initiating the adaptive immune response and act as an active barrier to infection [2]. Enteroendocrine cells produce and secrete numerous hormones involved in regulating a wide range of physiologic processes, including intestinal motility and metabolism [3]. The function of tuft cells has not been well elucidated, but among other possible purposes, they appear to function as chemosensors [4,5] and local sources of prostaglandins [6]. Finally, Paneth cells are found within the crypts between villi, secrete antimicrobial peptides, and provide essential Wnt and epidermal growth factor (EGF) ligands for the crypt base progenitor stem cells [7].

Stem and progenitor cell types

Due to continuous exposure to harsh luminal conditions, routine turnover and self-regeneration are important for the maintenance of the epithelial barrier. Intestinal homeostasis is a delicate balance between proliferation within the crypts and shedding of mature cells from the upper third of the villi. Several foundational lineage-tracing studies have localized intestinal progenitor or stem cells (ISCs) to the base of the crypts, with daughter cells differentiating and migrating out of the crypt. Cell expansion and the beginning of differentiation occur within the so-called transit amplifying (TA) zone beginning at the +5 region, or five cells above the base of the crypt (Fig. 38.2B and C). With the exception of Paneth cells (see later), cells differentiate as they move out of this region and up the villi until they are shed at the end of their life cycle [8–11]. The intestinal progenitor/stem cells located within the crypt are drivers of cell repopulation through proliferation.

Historically, there have been two competing models of ISC identity: "the stem cell zone model" and the "+4 model" [12]. The "stem cell zone" model was first postulated by Cheng and Leblond who noted wedge-shaped crypt base columnar (CBC) cells interspersed between Paneth cells at the crypt base [13,14]. Lineage labeling, performed by tracking phagocytosed debris from injury caused by tritiated thymidine injection, demonstrated that these cells could give rise to other, differentiated, cell types [14]. Further work, including mutagenesis lineage tracing, revealed both long- and short-lived cells within the crypt; the long-lived cells, thought to be the multipotent CBC cells, gave rise to various daughter cells. The central premise of this model is that the CBC cells reside in the stem-cell permissive crypt and the daughter cells migrate to the +5 position where local signals induce lineage commitment and differentiation [15–17]. The CBC cells represent a rapidly cycling ISC population that can be identified morphologically based on their unique shape, biochemically based on molecular markers (see below), and functionally by their persistence in an undifferentiated self-renewal state with the ability to produce all mature intestinal epithelial cell types [8].

The first widely accepted ISC marker, leucine-rich repeat-containing G-protein coupled receptor 5 (LGR5), marks the CBC cells. Studies using mouse models and organoid cultures showed that Lgr5+ cells have the essential characteristics of stem cells, including the ability to self-renew and persist, rapidly cycle, and to give rise to all mature intestinal cell types [18,19]. Lgr5 is a G-protein coupled receptor that binds R-spondin and serves as a Wnt signaling amplifier [20,21]. Lgr5+ ISCs also express achaete-scute family bHLH transcription factor 2 (ASCL2). *Ascl2* knockout studies performed in mice

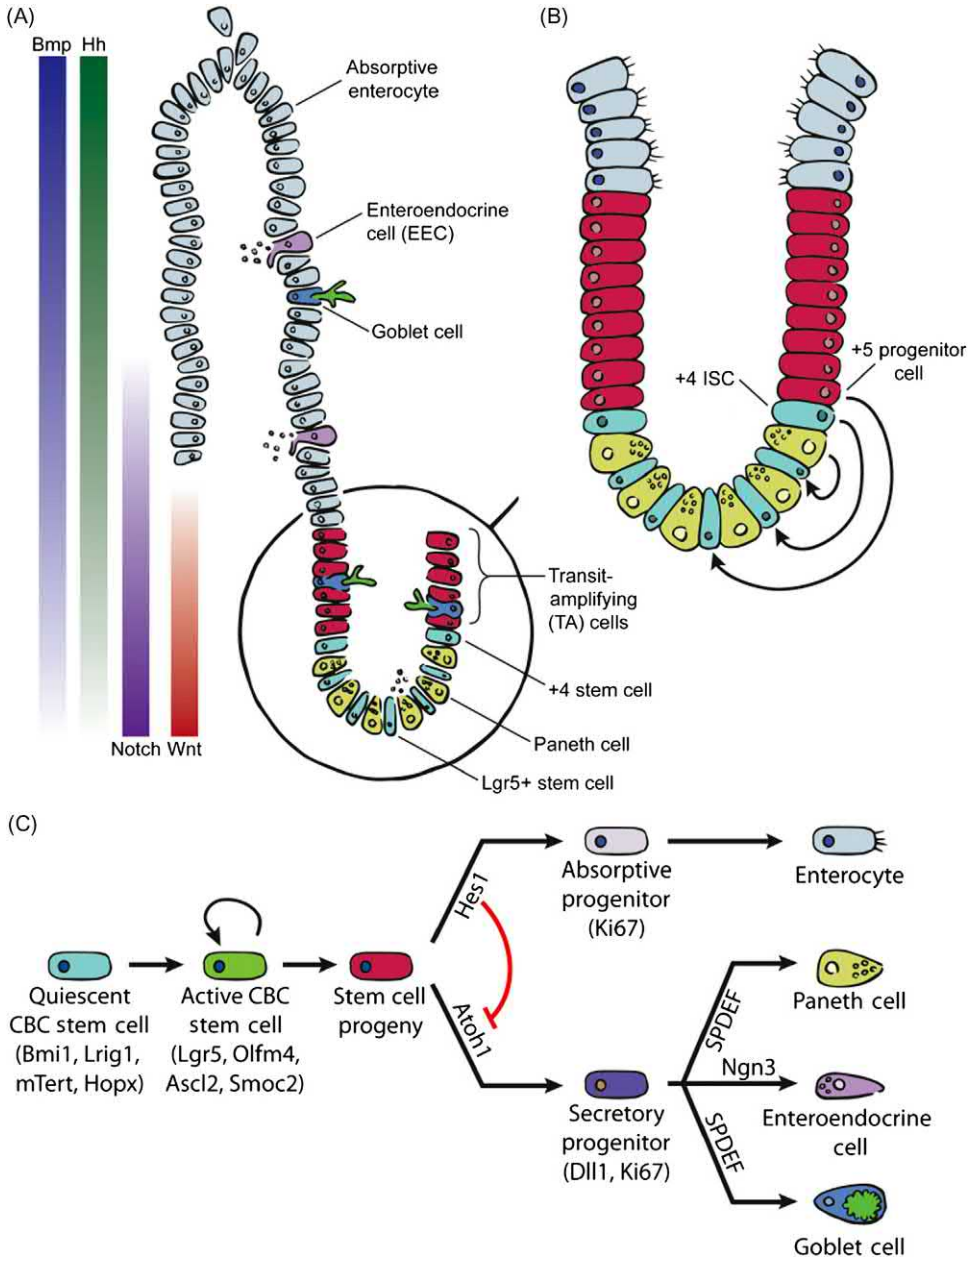

FIGURE 38.2 **Small intestinal epithelium and the stem cell niche.** (A) The villus and crypt contain the epithelial cell types necessary for mature function and self-renewal of the small intestine. The villus contains absorptive and secretory enterocytes. The secretory cell−type goblet cells (blue), enteroendocrine cells (purple), Paneth cells (yellow) are located within the crypt base. Maintenance and activation of the ISC pool involves a complicated interplay of signaling between pericryptal stromal and adjacent epithelial cells. A relatively high expression of Bmp, Hedgehog (Hh) restrict the stem cell population to the base of the crypts. Within the TA zone and crypt, high levels of Notch and Wnt maintain stemness and promote proliferation of ISCs within the crypt. (B) The ISC compartment of the small intestine contains CBC cells interspersed among protective Paneth cells in the active stem cell zone. The quiescent label-retaining ISC resides near the bottom of the crypt in the +4 position (quiescent stem cell zone) just above the interspersed Paneth cells. Acute injury results in the loss of the proliferating Lgr5+ stem cells but preserves the relatively resistant Paneth cell precursors, +4 stem cells, and niche cells. When ISCs are damaged or die, neighboring +4 ISC can repopulate CBC within the crypt base. Alternatively, Paneth cells and absorptive/secretory progenitors within the TA zone can undergo dedifferentiation in order to restore the ISC population within the crypt. This remarkable plasticity allows for survival and regenerative capacity of intestinal epithelium even under the harshest of conditions. (C) Identification of distinct and overlapping ISC markers has relied on intricate lineage-tracing studies. Active-cycling ISC (green) and quiescent ISC (cyan) express distinct stem cell markers, although some overlaps have been demonstrated for Bmi1, Hopx, mTert, and Lrig1. The +5 progenitor cell undergoes cell lineage fate decisions through expression of Atoh1 or Hes1. Absorptive progenitor cells arise from Hes1 expression, which has an inhibitory effect on Atoh1 and subsequent production of secretory enterocytes. Although many of the factors responsible for specific epithelial cell differentiation have yet to be elucidated, SPDEF and Ngn3 (neurogenin 3) promote the formation of selected secretory enterocytes. *CBC*, Crypt base columnar; *ISC*, intestinal stem cell; *TA*, transit amplifying.

identified a concomitant loss in Lgr5 + CBC cells, suggesting that Ascl2 is essential for stem cell survival or identity [22]. In addition, Ascl2 has been recently identified as a transcriptional switch that is regulated in a direct Wnt-responsive loop, driving genes crucial to maintaining the stem cell state [23].

In contrast, the "+4" ISC model was proposed by Potten after identifying radiosensitive, label-retaining cells (LRCs) located immediately above the Paneth cell position, usually four cells above the lowest point in the crypt [12]. Theoretically, ISCs that were LRCs could retain label through asymmetrical inheritance of chromosomes, retaining an "immortal strand" and preventing radiation-induced damage from exerting a lasting effect on the genome [24–26]. However, asymmetrical division of ISCs is highly controversial [27] and does not appear to occur in the rapidly cycling CBC cells [28]. The +4 cells are now thought to represent a reserve population of quiescent stem cells as opposed to the rapidly cycling CBC cells which provide the major source for homeostatic cell turn over [12,14,29]. Interconversion between these populations has been an evolving puzzle, with Lgr5 + cells shown to produce +4 cells and cells in the +4 position producing CBC cells in special conditions [30,31].

Lineage-tracing studies initially identified *Bmi1*, *Hopx*, *Lrig1*, and *mTert* as potential markers distinguishing the slowly cycling +4 ISCs from the rapidly cycling CBCs [32–35]. The Capecchi lab found *Bmi1* expressed discretely in the +4 position, and like LGR5 + cells, +4 cells differentiated into all of the epithelial cell types [33]. Bmi1 + cells have been shown to revert to Lgr5 + ISCs after ablation of the Lgr5 + CBCs and have been posited to play a role in epithelial regeneration after radiation damage [36,37]. However, these markers have not been definitively validated as further studies have found that *mTert* and *Bmi1* are expressed throughout the crypt, while *Hopx* and *Lrig1* expression is actually highest in Lgr5 + cells [38,39].

In addition to the two "traditional" ISC populations, recent evidence shows that much of the epithelium can undergo reversion to an Lgr5 + stem phenotype when necessary. For example, alkaline phosphatase-expressing cells (absorptive enterocyte lineage) can dedifferentiate and become Lgr5 + ISCs [40]. Secretory progenitors and enteroendocrine cells can revert after injury, as can Paneth cells [40–43]. A role for Paneth cells in replenishing lost ISCs is particularly interesting given the unique nature of this population; while most cells migrate up out of the TA zone as they differentiate, Paneth cells migrate down to the bottom of the crypt where they are intercalated with CBC cells. They are longer lived than other terminally differentiated intestinal epithelial cells, with a turnover time of approximately 57 days [44]. They provide factors that maintain the stem cell niche, particularly Wnt, and organoid cultures with coplated Lgr5 + cells and Paneth cells have greatly increased growth efficiency [7]. Inhibition of glycolysis in Paneth cells impairs organoid growth, indicating that they may also provide metabolic substrates such as lactate to Lgr5 + stem cells [45]. Furthermore, while they are able to dedifferentiate and regain multipotency, they only seem to be competent to do this after an injury [46]. Together, these studies and others show that the stem cell niche is a complex environment sustained in part by interconversion of cell types. A deeper understanding of the cues that can drive this cell plasticity could lead to translationally relevant approaches for improving tissue-engineered small intestine (TESI) yields.

Signaling pathways in the intestinal epithelium

The complex homeostatic mechanisms of the stem cell niche, which maintain the balance between proliferation and differentiation, have yet to be fully elucidated. While epithelial–epithelial interactions play a vital role in gut homeostasis, there is also significant crosstalk between the mesenchyme and epithelium [47,48]. ISCs are essential to the intestine's response to injury, and while reserve ISC populations appear to be integral to this process, the exact mechanism by which this occurs is poorly understood [32,36,43]. For reviews of intestinal development, see Chin et al. [49] and Le Guen et al. [47]. Here, we focus on a few of the known signaling pathways that control the stem cell niche and contribute to growth and differentiation, particularly Wnt, Notch, ErbBs, Hedgehog, and BMP.

The Wnt pathway

Wnt signaling is a critical stimulus for stem cell proliferation. There are two primary ways the Wnt pathway can be activated: via a β-catenin/T-cell factor (TCF)–dependent mechanism (the canonical pathway) and a β-catenin/TCF-independent mechanism (the noncanonical pathway) which is reviewed elsewhere [50,51]. The canonical pathway is required for maintenance of the proliferative zone and Lgr5 + ISCs in the crypt [52,53] and regulates Paneth cell differentiation [54]. Wnt ligands bind to the Frizzled receptor and its coreceptor LRP5/6 in order to inhibit the formation of the Axin, APC, CKI, and GSK3β complex that usually degrades β-catenin [48,55]. The inhibition of this routine destruction allows β-catenin to accumulate and travel to the nucleus, forming a complex with heterodimer lymphoid enhancer factor and TCF. This complex of transcription factors activates the expression of Wnt target genes, including Axin2, cMyc, CD44, Ccnd1, Sox9, Lgr4/5, and Cdx1, among others [55,56],

which are involved in driving cell proliferation and self-renewal.

Constitutive activation of the Wnt pathway via APC mutation results in polyposis and epithelial hyperproliferation [48,56]. On the other hand, a loss of Wnt function results in the absence of intestinal crypts and the sole presence of differentiated epithelial cells. Pharmacological deletion of Porcn, a protein important in the palmitoylation and proper secretion of Wnt for paracrine signaling, results in a decrease in Lgr5 + ISCs and the loss of the Wnt-induced marker of OLFM4 + CBC cells [55]. Looking downstream from Wnt, the loss of Wnt effectors and target genes alters crypt formation, size, and proliferation in adulthood [55,57]. Wnt is also an important mediator of other signaling pathways, including Eph/Ephrin, Notch, and BMP [48].

Wnt signaling components are expressed, possibly redundantly, within the epithelium and the mesenchyme; for example, both Paneth cells and subepithelial telocytes express Wnt ligands [58,59]. Wnt activity thus exists in a gradient along the crypt-villus axis, with the strongest signal at the crypt base. Paneth cells produce Wnt3 that has been shown to establish a short-range gradient within the crypt, and the presence of Paneth cells augments the growth of organoids [7,60]. However, single Lgr5 + cells have been observed to form organoids without Wnt supplementation, albeit with very low efficiency, and demonstrate growth arrest with Wnt inhibition [7,61]. Several in vivo studies have shown that development and homeostatic turnover can proceed without *Wnt3* or Paneth cells [59,62,63], though in the absence of this support the ISCs respond poorly to injury, demonstrating a critical role for Paneth cells and their products in maintaining the stem cell niche in the face of a challenge [64].

The Notch pathway

Notch proteins represent a highly conserved set of transmembrane signaling molecules that aid in cell−cell communication and cell differentiation. In the intestine, Notch regulates crypt cell proliferation while maintaining the balance of secretory and absorptive cells. Notch activity requires cell−cell interaction and specifies cell fate in adjacent cells through lateral inhibition [65,66]. Binding Notch ligand Jagged or Delta-like (Dll1/4) causes the Notch receptor on adjacent cells to be proteolytically cleaved. ADAM10 is responsible for cleaving the extracellular portion, while γ-secretase releases an intracellular fragment, termed the Notch intracellular domain (NICD). NICD travels to the nucleus and, along with cofactor RBPJK, induces expression of *Hes1/5/7*, *Hey1/2*, and other targets [65,67]. In cells receiving Notch signaling, the expression of Notch ligands Dll1/4 and Jagged is inhibited by Notch target genes. Therefore Notch-receiving cells cannot themselves transmit the Notch signal.

In the crypt base the combined presence of Notch and Wnt signals maintains stemness [56,65]. Traveling up the crypt, decreased exposure to Wnt and Notch, results in an absorptive fate in differentiated cells [68]. In contrast, Wnt signaling in the absence of Notch results in development toward secretory fate. In the absence of Wnt, the presence/absence of Notch signaling is sufficient to determine absorptive/secretory fate of intestinal cells [69]. Indeed, the expression of Notch target *Hes1* represents a precursor of absorptive fate in the intestine [65].

Epidermal growth factor receptor/ ErbB signaling

EGF receptor (EGFR/ErbB1) is the prototypic member of a family of four receptor tyrosine kinases that also includes ErbB2/HER2, ErbB3, and ErbB4 [70]. These receptors recognize and are activated by, with varying specificity and affinity, a broad panel of ligands, including EGF, heparin-binding-EGF-like growth factor, epiregulin, betacellulin, amphiregulin, transforming growth factor-alpha, and the neuregulin/heregulin peptides. Ligand binding stabilizes receptor homo- and/or heterodimers, resulting in increased tyrosine kinase activity and phosphorylation on c-terminal tyrosines that in turn provide docking sites for downstream substrates and signaling partners [70,71]. ErbBs can activate a wide array of signaling pathways, such as Ras/Raf/MEK/ERK, PI3K-Akt, JNK, JAK-Stat, Src, Rho/Rac, and PLC-γ/PKC [72,73], with bias in the downstream pathways providing part of the selectivity in response [74,75]. Specificity in responses is likely driven by ligand−receptor affinity together with the balance of available ligands and receptors expressed in a cell.

ErbB signaling supports the maintenance of stem/progenitor cells in the gut. Ligand-secreting mesenchymal cells reside along the bases of the intestinal crypts, and Paneth cells secrete EGF. Isolated ISCs require exogenous EGF to efficiently survive and expand ex vivo [76], underscoring the importance of EGFR/ErbB1. Deletion of another family member, ErbB4, compromises the ISC niche and Paneth cell compartment in expanding enteroid cultures [77,78]. In addition, ErbBs strongly activate the PI3K-Akt pathway, and Akt signaling can lead to activation of the canonical Wnt pathway by way of β-catenin phosphorylation [79]. Prolonged activation of PI3K-Akt by PTEN deletion promotes ISC activity, crypt fission, and intestinal polyp formation [80]. Taken together, the literature supports key roles for ErbB receptors in the proliferation and survival of ISCs.

The Hedgehog pathway

The Hedgehog (Hh) pathway drives an epithelial−mesenchymal signaling loop that decreases epithelial proliferation in the crypt [56,66]. Vertebrate Hedgehog genes, including *Indian hedgehog* (*Ihh*), *Sonic hedgehog* (*Shh*), and *Desert hedgehog* (*Dhh*), are expressed in the intestinal epithelium and signal the mesenchyme in a paracrine fashion [48,81]. Hh precursors are cleaved and lipid modified in Hh-expressing cells to be released through the activity of dispatched (Disp). Hh molecules then bind to the Patched receptor (Ptch1/2) and coreceptors Cdo, Boc, and Gas1 resulting in a relief of inhibition of Smo. This induces a signal cascade resulting in the dissociation of Gli1/2/3, which are the transcriptional inducers of the Hedgehog pathway. Hh targets include *Ptch1/2*, *Gli1*, *Cyclin D*, and *Hhip*, among others [81−84].

Shh in the adult intestine is most highly expressed in the crypt, where it marks undifferentiated epithelial cells [48,67]. Hh signaling is required for orderly formation of villi and for regulation of crypt density. Overexpression of *Hhip*, a target of Hh signaling and also a Hh inhibitor, results in a lack of villi, crypt hyperplasia, and incomplete epithelial differentiation [48,81]. A decrease in Ihh results in increased wound healing responses due to intestinal epithelial proliferation and crypt fissioning [85]. Hh signaling is thus important in the maintenance of the mesenchymal and epithelial homeostasis.

The BMP pathway

BMPs are part of the TGF-β family of signaling molecules and targets of both Wnt and Hh signaling [48,56]. BMP activation results in the phosphorylation of SMAD 1/4/5/8, which then form a heterodimer (SMAD4 with SMAD 1, 5, or 8) that travels to the nucleus to induce the transcription of target genes [47,48,67]. BMP ligands are primarily expressed in the mesenchyme, where Hh signaling from the epithelium induces their expression; conversely, the primary activity of BMP ligands expressed by the mesenchyme is to signal through receptors located in the epithelium [48].

BMPs are expressed most strongly in the intervillus mesenchyme, where their localized activity is restricted by the concomitant expression of BMP inhibitor Noggin at the +4 position, just above the intestinal crypt proper. Ectopic cryptogenesis is seen when intestinal BMP is inhibited in a mouse model, a finding likely associated with a relief of inhibition of the canonical Wnt pathway [86,87]. Both of these signals are important in the maintenance of ISCs, and their crosstalk and patterning suggest a role for BMP expression in normal villification/cryptogenesis [88]. Indeed, studies show that molecules, including BMP4, cluster beneath developing villus tips that act to restrict ISCs to the developing crypt region [88,89].

Tissue engineering the intestine with stem/progenitor cells

With the identification of the ISC and associated growth factors, manipulation of ISC to generate TEI has become possible. Many tissue-engineering approaches include delivering various stem/progenitor cells on synthetic or biological scaffolds in vivo with the long-term aim to reproduce a construct that is similar in structure and function to native intestine that could eventually replace enough lost intestinal digestive/absorptive surface area to reduce the complications from SBS and its therapies (Fig. 38.3).

We apply the term TESI to tissues that recapitulate all of the key components of the intestine and have proposed various other terminology to reflect the regions of the gastrointestinal tract that can also be produced, such as tissue-engineered esophagus (TEE), tissue-engineered liver (TELi), tissue-engineered stomach (TES), and tissue-engineered colon (TEC) [90−100]. The overall concept of TEI, which may be from any region, is commonly termed TEI. These terms ought not to be applied to biologic constructs that lack function (although physiologic function may not be exactly replicated) and do not support the key cell populations required for function, such as systems, in which epithelium or mesenchyme survives alone. We distinguish these TEI variations versus disease in a dish or organ-on-a-chip systems, which may be informative, but lack important components of the desired gastrointestinal tissue as well as systemic influences. Macroscopically, in order to eventually be a long-term solution for patients with SBS, TESI must recapitulate native intestinal epithelial mucosa, submucosa, smooth muscle, and serosa in the correct orientation. Intestinal motility, digestion, absorption, secretion, and excretion also require reconstitution of an enteric nervous system (ENS) which is not derived from ISCs but from the vagal neural crest [101]. In addition, an adequate vascular and lymphatic supply is required for oxygen, nutrient, and waste exchange [102]. On a subcellular level, appropriate barrier function, digestion, and absorption depend on the correct localization of enzymes and membrane proteins [103].

Organ-specific stem cell progenitors versus pluripotent stem cells

Pluripotent stem cells, multipotent progenitor cells, terminally differentiated cells, or a combination of these have been investigated for the generation of TEI

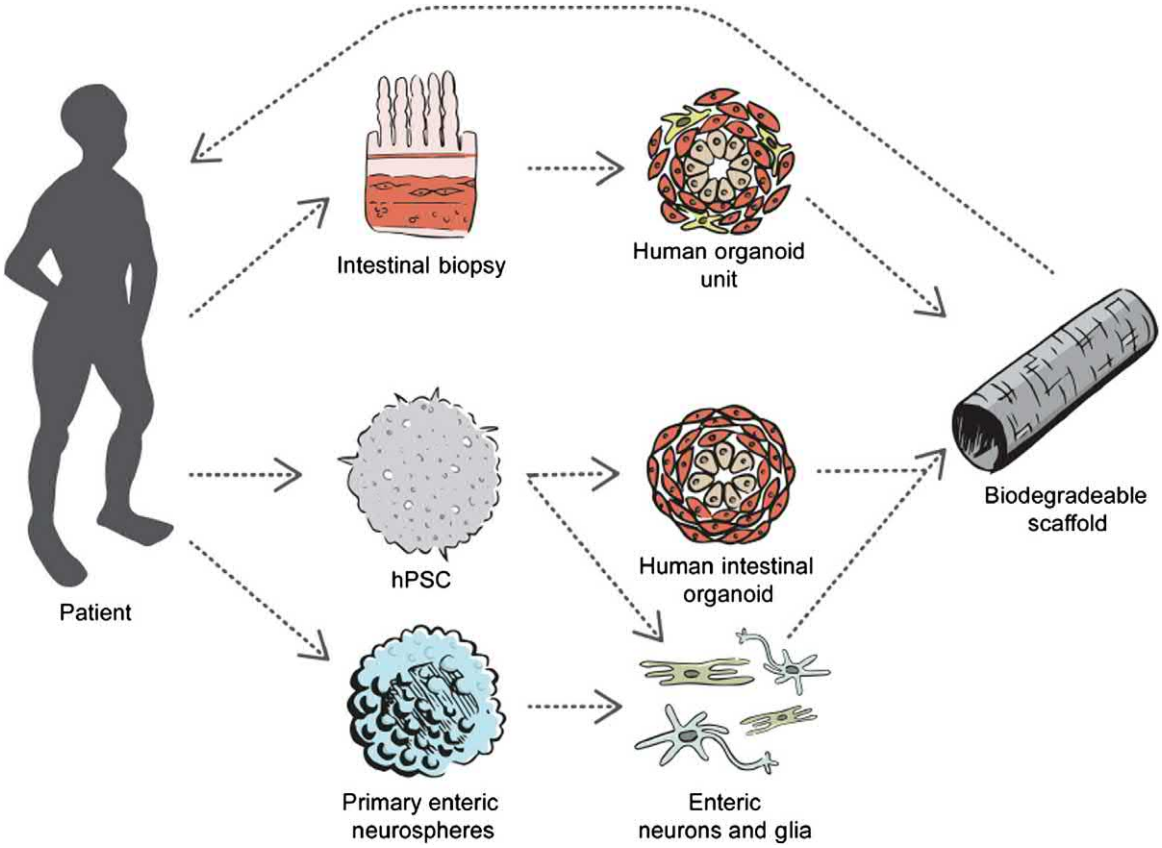

FIGURE 38.3 Methods for creating tissue-engineered small intestine. TESI can be created via different approaches. Primary intestinal biopsies obtained through minimally invasive endoscopic approaches could be mechanically dissected and enzymatically dissociated to form epithelial/mesenchymal cell clusters termed hOU. hOU contain all of the necessary cell types required for intestinal absorption and mechanoluminal function, including mature epithelial cell types, myofibroblasts, and cell types of the ENS. Small intestinal hOU can be cultured or directly placed onto biodegradable scaffolds that, once implanted into the omentum, mesentery or other highly vascularized intraabdominal sites, can produce TESI that can be anastomosed to native intestine. Another recent approach is to generate TESI derived from patient-specific iPSCs (hiPSC) or human leukocyte antigen-matched human embryonic or iPSC banks to generate TESI. With directed differentiation methods, hPSC can be directed in culture to form HIO that contains many of the necessary cell types of the intestine. However, in contrast to primary intestinal-derived OU, HIO fails to generate ENS cell types. Therefore in order to restore function to these constructs, ENCC derived from hPSC or enteric neurosphere extraction from primary intestinal biopsies must be added back to developing HIO-derived TESI. A combination of HIO and ENCC derived from hPSC or enteric neurospheres loaded onto biodegradeable scaffolds can be implanted into the omentum, mesentery, or other highly vascularized locations within the patient to allow for ENCC-HIO-TESI to grow and later be connected to native intestine. The benefit of these approaches is that they are amenable to genetic manipulation prior to implantation. With the advent of highly specific targeted genetic manipulation through CRISPR/Cas9, ZFNs and TALENS, OU, attributes important to intestinal absorption may be enhanced. This approach may become a crucial addition to enhancing the function of tissue-engineered organs. *ENCC*, Enteric neural crest cells; *ENS*, enteric nervous system; *HIO*, human intestinal organoids; *hOU*, human organoid units; *iPSCs*, induced pluripotent stem cells; *OU*, organoid units; *TESI*, tissue-engineered small intestine, *hiPSC*, human induced pluriopotent stem cells.

[94,104–108]. Much of the initial works performed in initial experiments employed organoid units (OU), which are made by mechanically and chemically digesting native intestine [109]. They are distinct from organoids or enteroids in that they contain both epithelial and mesenchymal elements. Yet other approaches focus on implanting cultured enteroids, clusters of intestinal-derived epithelial cells, that were genetically altered to enhance digestive and absorptive function. Pluripotent stem cells, either induced pluripotent stem cells (iPSCs) or embryonic stem cells, can be differentiated into all of the layers of the small intestine, excepting the ENS, and these are termed human intestinal organoids (HIO) [110].

Synthetic and biological scaffolds

The most common approach to tissue engineering small intestine starts with creating a structural template with a scaffold for cellular growth. The scaffold is a biological or synthetic biodegradable matrix that must maintain its shape, provide an appropriate surface for tissue growth and organization, and be porous enough to allow for

angiogenesis and vasculogenesis [111,112]. Scaffolds provide three-dimensional mechanical support for cells that recapitulate the microcellular environment thereby guiding reorganization into functional tissues. Scaffolds can be designed from several synthetic polymers or extracted from primary tissues through decellularization of native organs [111,112].

We have routinely noted poor tissue growth in decellularized tissues as well as in other relatively nonporous polymers and have demonstrated that high porosity is associated with improved stem/progenitor cell growth [99]. Further modifications can provide additional signaling factors or extracellular matrices, such as collagen, laminin, heparin sulfate, and others, that may influence cellular proliferation, differentiation, and migration [112,113]. The scaffold commonly employed in our laboratory is polyglycolic acid/poly-L-lactic acid (PGA/PLLA), a synthetic fiber that can be woven or felted into porous sheets and coated with extracellular matrices and growth factors which permit initial nutrient support and oxygen diffusion required for cell survival prior to neovascularization [111,112]. Engineered tissues have been derived from small intestine, colon, esophagus, stomach, and liver by delivering cells on this material and the generation of TESI will be described in more detail later [90,93–97,100,104]. As cells proliferate, secrete extracellular matrix, and establish appropriate organization through cell-to-cell interactions within the developing engineered tissue, the supportive scaffold is gradually degraded by hydrolysis.

Primary intestinal-derived organoid units

Strategies to generate TESI began with a study by Vacanti et al., in which murine enterocyte preparations were seeded onto synthetic polymers [114]. Small intestine-derived enterocyte-seeded scaffolds were cultured for 4 days and remained viable and continued to proliferate. Direct omental implantation of these constructs in conjunction with partial hepatectomy induced engraftment and growth in 3 out of 23 implants with mature epithelial cell types and submucosal mesenchyme lining a neovascularized cystic structure with mucous and cellular debris within the lumen [114]. This pioneering study demonstrated the efficacy of combining primary cells with a synthetic scaffold as a viable approach to regenerating tissue with the potential for in vivo growth and development (Fig. 38.3). Vacanti's group later modified this approach to include mesenchymal cell types as well intestinal epithelium, and modifications of this approach now have much improved outcomes. We and others have demonstrated that the implantation of human and murine-derived OU embedded onto biodegradable scaffolds in immunocompromised mice results in successful growth of TES, TELi, TEE, TESI, TEC, etc. after 2–6 weeks [90,93–97,100,104].

By gross histology, TESI develops with a luminal facing epithelium and surrounding mesenchyme. The vascular supply is dually contributed to by de novo vascularization from donor endothelial progenitor cells and neovascularization from the host, and although capillary formation remains attenuated and rudimentary, the lymphatic network continues to grow [115,116]. The epithelial surface can range in architecture from a flat epithelium to alternating villus and crypt-like structures similar to mature native small intestine. Immunofluorescent staining for markers of mature epithelial and mesenchymal cell types demonstrates the ability of OU to restore ISCs, secretory and absorptive epithelial cells, and numerous mesenchymal support cells [95]. CBC cells retain their ability to proliferate as demonstrated by cellular division marker Ki67. At 4 weeks, human and murine TESI demonstrate the formation of microvilli with restoration of tight junctions, transporters, and functional brush-border enzymes in the correct apical and basolateral expression [93]. In addition, measurements of transepithelial resistance of rat-derived TESI show that while TESI has decreased active ion transport compared to native rat ileum, it does have similar epithelial barrier integrity [113]. Restoration of immunocyte populations is achieved only after TESI undergoes anastomoses to host bowel [117]. Although these data suggest that immune system maturation is dependent on luminal stimuli and time, they also show that engineered intestine can develop and recruit this crucial subpopulation of cells.

Numerous studies have investigated alterations to the protocol in order to enhance growth and function of TESI. Performing concurrent small intestinal resection stimulates intestinal adaptive changes as reflected by increased TESI size and diameter [107]. Anastomosis of TESI to native small intestine after the initial maturation period results in greater villus number, villus height, crypt number, and mucosal surface length, suggesting that mechanoluminal signaling factors may drive additional intestinal development [106,118]. The stimulatory signals have not been clearly identified but may include factors that are found at higher concentration in native intestine, such as VEGF, EGF, GLP-1/2, and other growth factors. FGF10 overexpression in a murine model generated heavier and larger sized TESI with more proliferating epithelia cells and longer villi and deeper crypts [119]. In addition, in a VEGF overexpression mouse model, submucosal capillary density was also improved, implying that neovascularization can be enhanced with the addition of growth factors [120]. Intestinal anastomosis and treatment with GLP-2 increases villus height and crypt depth in TESI, supporting the potential use of human-derived TESI as a useful model for testing emerging therapeutic

interventions aimed at stimulating structural and functional adaptation that may not be possible in controlled human clinical trials [121].

A significant limiting factor in the clinical translation of TESI is the need for generating a sizeable construct with a patent lumen that can be successfully anastomosed to the native intestine and can provide enough digestive and absorptive surface to allow the patient to gain weight and wean from PN. Animal models thus far have been encouraging. While rats with anastomosed TESI lost more weight initially than control rats without TESI, they regained weight more quickly and returned to 90% of preoperative weight by day 40 [98]. TESI generated from both murine and human OU has been demonstrated to recapitulate not only the structure of mature intestine but its digestive function as well. TESI bears active brush-border disaccharidases and demonstrate nutritional absorption [122]. Furthermore, both human and murine OU can be maintained in long-term culture without growth factor supplementation and these OU retain the ability to generate TESI with all mature intestinal epithelial cell types as well as ENS and mesenchymal cell types [123].

Pluripotent stem cell approaches—human intestinal organoids

Spence et al. defined a protocol to generate all of the components of the intestine except for the ENS from either human embryonic or iPSCs that were exposed to a temporal cocktail of growth factors, including Activin-A, FGF10, Wnt3a, Rspo, and others, to form spherical organoid structures with a luminal epithelium and surrounding mesenchyme, termed HIO [110,124]. In vitro, HIOs contain immature villus-like structures that lack lamina propria in their central core and fail to develop crypts with an extensive mesenchymal layer, as in mature intestine [110]. However, implantation into the kidney capsule and growth up to 16 weeks led to significant maturation of transplanted HIOs (tHIO) [108], demonstrating that the grafts have the capacity to differentiate in the presence of appropriate cues. Increased proliferation was observed in the intestinal crypts of tHIO, with restriction of Lgr5-positive ISCs and Paneth cells to the base of the crypts and mature absorptive/secretory epithelium throughout the villus, similar to native human small intestine. Several brush-border enzymes, such as sucroisomaltase, lactase, trehalase, and maltase-glucoamylase, had higher mRNA expression compared with in vitro HIOs and appropriate polarity was demonstrated by apical staining of sucroisomaltase, which was absent in in vitro HIOs. Moreover, intraluminal injections of small peptides were absorbed in tHIO. Increased organization of the mesenchyme occurred in tHIO, as platelet-derived growth factor receptor alpha-positive cells lined the basal side of villus epithelium and smooth muscle actin-positive myocytes condensed into a prominent band within the submucosa nearly identical to native human intestine. Compared to OU, the vasculature- and lymphatics-supporting tHIO are solely of mouse origin.

To test if tHIO respond to humoral factors and undergo intestinal adaptation as seen in postintestinal resection models of native intestine, mice transplanted with HIOs after 6 weeks then had an ileocecal resection with anastomosis and were harvested 1 week later. Similar to OU, significant intestinal adaptation occurred in tHIO following postileocecal resection as demonstrated by increased villus height/crypt depth, crypt fission, and thickness of the smooth muscle compared to surgical sham tHIO. These data suggest that HIOs respond to intrinsic cues that augment intestinal adaptation. Although tHIOs display significant features of maturation beyond that observed in HIO in culture, comparative unsupervised hierarchical clustering of RNA-sequencing data of tHIO compared to human fetal and adult small intestine demonstrated that tHIO more closely resemble fetal small intestine rather than mature adult small intestine [125]. The implantation of HIO-seeded PGA/PLLA scaffolds into the omentum of immunosuppressed mice, similar to OU, has yielded promising results: generating HIO-TESI after 3 months that is nearly indistinguishable to native intestine [104].

Although HIOs provide a potential platform for generating limited amounts of patient-specific intestinal tissue, they lack a critical element intrinsic to OU that are required for peristalsis, an ENS. There are two approaches to derive enteric neural crest cells and their derivatives: from primary intestinal biopsies and directed differentiation of hPSCs (Fig. 38.3) [126–129]. Coimplantation of HIO-TESI with murine OU repopulates cell types of the ENS as demonstrated by nerves and glia adjacent to HIO-derived epithelium and within the myenteric layers [104,130]. HIOs cocultured with vagal neural crest cells derived from hPSCs for 4 weeks and implanted into the kidney capsule demonstrate immature restoration of ENS components [131]. Submucosal and myenteric ganglia are restored with retention of inhibitory neurons; however, excitatory choline acetyltransferase was lost after transplantation and restoration of a neuroepithelial circuit necessary for transmission of intraluminal sensory information was not restored as neurons lacked synaptic formation with neuropods of enteroendocrine cells. Applying an alternate differentiation protocol to generate the PSC-derived neural crest cells, we were able to retain important ENS subtypes and functional contraction of HIO-TESI with restoration of key components of the ENS, including neuroepithelial connectivity and neuron-dependent smooth muscle contractility and relaxation [130].

Remaining barriers to the generation of tissue-engineered intestine

Several barriers remain to be overcome before intestine can be routinely tissue-engineered from stem and progenitor cells. First, tissues grown from stem/progenitor cells often form disorganized tissue of a more primitive histologic type. TESI from multiple donor origins contains a spectrum of tissue organization, with only a portion recapitulating organized crypts and villi. Second, although generation of an entire organ may not be necessary in order to replace sufficient function, tissue of adequate size and development must be generated. This will require upscaling protocols, large animal models, and perhaps the addition of small molecules that will be acceptable to regulatory bodies. Third, as the volume of tissues generated increases, the issue of blood flow must be addressed, either through concomitant angiogenesis or via an engineered or autologous graft. Furthermore, the first in human clinical trials must proceed with thoughtful and thorough regulatory and ethical guidance, and data should be derived from all attempts to translate by careful reporting. There is a tremendous opportunity for TEI therapies to be appropriately studied and reported through preregistered trials.

Conclusion

Multiple populations of stem/progenitor cells have been identified in the intestinal crypts, including rapidly cycling Lgr5+ CBC cells, a quiescent +4 population, and/or progenitor and differentiated cells capable of reverting to a stem phenotype. Any of these may have the potential to generate de novo intestine. The stem cell niche is maintained by a complex network of signaling molecules which, although not completely understood, involves a modulated interaction of multiple factors, including Wnt, ErbBs, Notch, Hedgehog, and BMP. Advances in understanding ISC and the ISC niche have offered possibilities to harness these regenerative processes for the generation of TEI. TESI has been generated from multiple sources of stem/progenitor cells such as OU from intestinal biopsies or HIO from iPSC. While multiple barriers still exist, there has been rapid progress toward future clinical applications of TEI based on foundational principles discovered in developmental biology and rigorous scientific study of an elegant stem cell niche.

Chapter 39

Liver stem cells

Dagmara Szkolnicka[1] and David C. Hay[2]
[1]Division of Gastroenterology and Hepatology, Centre Hospitalier Universitaire Vaudois, University of Lausanne, Lausanne, Switzerland,
[2]MRC Centre for Regenerative Medicine, University of Edinburgh, United Kingdom

Introduction

The liver is a complex organ that performs a wide range of different metabolic processes essential for body function [1]. Although liver possesses unique regenerative capacities, upon serious injury scarring occurs, and liver repair is often compromised. Significant loss of liver function may lead to serious consequences for the patient [2–4]. Currently, orthotopic liver transplantation is the only effective treatment for acute or end-stage liver failure. However, the decreasing number of organ donors and complications associated with lifelong immunosuppression requires us to develop alternative therapies for patients [5].

Donor adult hepatocytes have been successfully transplanted to treat metabolic liver diseases [6]; however, the graft is eventually cleared by the immune system and is further compounded by the scarcity of the liver tissue [7]. Therefore new sources of liver tissue such as adult progenitors and pluripotent stem cell (PSC)–derived somatic cells represent attractive cell-based systems to support failing liver function in humans and to better model liver biology "in a dish."

Liver architecture and function

The liver is the largest internal organ providing different metabolic, endocrine, and exocrine functions such as drug detoxification, glycogen storage, production of serum proteins, and bile secretion [1,8]. The organ is composed of four lobes that are further divided into lobule structures—the basic architectural unit of the liver. Liver lobules are hexagonal in appearance, with each corner demarcated by the "portal triad," consisting of the portal vein, bile duct, and hepatic artery [8]. Hepatocytes are the parenchymal cells of the liver that make up approximately 70%–80% of the organ mass and carry out most of the metabolic functions. Hepatic function is supported by the nonparenchymal cells (NPCs) that consist of numerous cell types such as cholangiocytes, sinusoidal endothelial cells, natural killer cells, Kupffer cells, and stellate cells [9]. Hepatocytes are highly polarized epithelial cells, where their basolateral surface is directly connected with sinusoidal endothelial cells to facilitate the exchange of materials between hepatocytes and blood vessels. Tight junctions between hepatocytes allow for the canaliculus formation. The bile canaliculi collect bile salts and acids that are transported across the apical side of hepatocytes to bile ducts, where they are finally stored in gall bladder before release into duodenum [10].

Liver development

Several animal studies have proven regulatory pathways during liver organogenesis to be evolutionary conserved [11]. During gastrulation the endoderm germ layer is established and forms a primitive gut tube that is further subdivided into foregut, midgut, and hindgut regions [11]. The foregut gives rise to hepatic diverticulum, where the anterior portion of it forms liver and posterior portion allows formation of the gall bladder and extrahepatic bile ducts. Liver specification is induced by fibroblast growth factor (FGF) signaling from the cardiac mesoderm and bone morphogenetic protein (BMP) signaling from the septum transversum mesenchyme (STM) [12–14]. Once hepatic specification is established, hepatic epithelium pseudo stratifies, delaminates and the newly formed hepatoblasts invade the STM, where they recruit mesenchymal cells prior to liver bud formation [15]. Once specified, the bipotential hepatoblasts express markers of fetal (AFP) or adult hepatocytes (HNF4α, HNF6, and ALB) and biliary epithelium (CK7 and CK19) [8]. Hepatoblast differentiation toward hepatocytes versus biliary epithelial cells (BECs) is regulated by an activin/TGF beta-signaling

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00040-X

gradient [16–18]. Furthermore, upon colonization of the nascent liver bud, hematopoietic cells secrete oncostatin M, which in combination with glucocorticoid hormones, hepatic growth factor (HGF), and Wnt promotes hepatocyte differentiation, proliferation, maturation, and liver zonation [19–22]. Regulatory signals from periportal mesenchyme such as Wnt, TGFB, and Notch are involved in biliary development [8]. In response to mesenchyme signals, bipotential hepatoblasts downregulate hepatic factors (HNF4α, Tbx3, C/EBP) and increase expression of transcription factors, such as HNF6 and HNF1β, to stimulate cholangiocyte formation [16,23–25].

Fetal liver stem cells

Several studies using different culture systems have demonstrated the evidence for the presence of a potential liver "stem cell" in the fetal liver, which has a capacity for unlimited proliferation and multilineage differentiation [10]. Due to their unique features, it has been suggested that hepatic stem cells (HpSCs) may become an alternative cell source to primary hepatocytes for future clinical applications [26]. Therefore several studies have tried to isolate, purify, and characterize liver stem cells from human and rodent livers using flow cytometry. It has been demonstrated that isolated HpSCs expressed markers of stem cell origin such as CD13 [27], CD29 and CD49f [28], CD133, CD117, Epcam [29], and DLK [30], markers of hepatocyte and cholangiocytes [31] as well as markers of both hematopoietic and mesenchymal stem cells (MSCs) [32,33]. Recently, Zhang et al. [26] have identified CUB domain-containing protein 1 (CDCP1) to be an important marker for HpSCs isolation from the human primary fetal liver. Flow cytometry permitted the isolation of the $CDCP1^{+}CD90^{+}CD66^{-}$ subpopulation that exhibited remarkable clonal expansion and self-renewal capability. Moreover, in vivo studies demonstrated that this subpopulation repopulated over 90% of the mouse liver and differentiated to metabolically functional hepatocytes 1 month after transplantation. Dan et al. [34] reported the isolation of a population of human fetal liver multipotent progenitor cells called "hFLMPCs" that exhibited capacity to differentiate to liver cells and repopulate in a mouse liver injury model. These cells expressed several stem cell-related markers such as CD90, c-Kit, CD44h, and EpCAM but did not express hepatic markers such as AFP or ALB. This was further confirmed by Schmelzer et al. [32]. Recently, the same group [35] isolated a similar subpopulation of cells expressing mixed endodermal–mesenchymal markers, as had been reported by other groups [36,37]. The cells were capable of differentiating into mesenchymal lineages of bone, cartilage, endothelium, and fat. Furthermore, upon engraftment into a mouse $Rag2-/-\gamma c-/-$ model, cells acquired de novo progenitor state and were able to proliferate and differentiate into functional hepatocytes in vivo.

Although human HpSCs from fetal and postnatal human liver have been demonstrated to self-replicate and differentiate to adult hepatic tissue [26,32], the source of these primed stem cells is still limited and is not available commercially. Furthermore, use of these cells for hepatocyte transplantation is still questionable due to their origin; and therefore long-term safety assessments should be performed in order to determine their potential off-target effects.

Hepatocytes and liver progenitors in organ regeneration

The liver is a remarkable regenerative organ; however, the cellular source for hepatocyte regeneration in injured parenchyma remains complex. It has been demonstrated that during liver homeostasis or its mild injury, regeneration occurs through self-replication of hepatocytes [38–40]. However, under severe liver injury conditions, when parenchymal cell proliferation is impaired and high levels of senescence are detected, liver progenitor cells (LPCs) derived from BECs play an essential role in liver regeneration [41].

Molecular signaling and processes involved in liver regeneration

Liver regeneration is a complex process, with different molecular signaling pathways playing key roles in orchestrating organ regeneration. It has been widely documented that involvement of Wnt/β-catenin signaling is essential for the liver regeneration in zebrafish, rodents, and humans (see Ref. [40] review for details). During the early stages of partial hepatectomy (PHx), β-catenin translocates to the nucleus, where it activates essential proliferative genes such as cyclin D1. This has been confirmed by ablation or knockout of β-catenin, which severely delays liver regeneration [42,43]. Furthermore, R-spondin-1 (Rspo-1), strongly potentiates canonical Wnt-signaling pathway by acting as a ligand for leucine-rich repeat-containing G protein coupled receptors 4–6 (LGR4–6), promoting liver regeneration [44]. One of the most important signaling pathways is the Hippo/Yes-associated protein 1 (Yap) that orchestrates liver homeostasis by regulating organ size and cell fate [45,46]. Furthermore, Yap has been demonstrated to be a downstream effector of the Hedgehog pathway, resulting in increased proliferation of hepatocytes and stellate cells under liver injury conditions [47]. Recent studies by Li et al. [48] reported that chromatin remodeling gene

Arid1a endows hepatocytes with a competence to respond to the Hippo/Yap signal, which activates the expression of liver-progenitor-like cell genes and renders them competent to respond to injury-associated regenerative signals. In support of this, Planas-Paz et al.'s [49] CRISPR screen identified that contrary to RSPO-LGR4/5-mediated WNT/β-catenin activity, mTORC1 and YAP signaling are important in promoting ductular reaction and liver regeneration. Hedgehog signaling has been reported to induce Gli transcription factors that activate target genes responsible for regulating cell proliferation, survival, and differentiation [50,51].

Recently, it has been described that among factors released immediately after PHx, different prosurvival antiapoptotic functions are activated during liver regeneration process [52]. Several studies reported that cellular oxygen sensor [52], bile acids (BA) [53,54], and CCAAT/enhancer binding protein [55] are important factors that promote liver repair and impairment of these factors may have deleterious effects on liver regeneration. Furthermore, Liu et al. [56] and Wahlström et al. [57] demonstrated the impact of microbiota on liver regeneration. Although the interplay between microbiota and BA is not well understood in the process of organ regeneration, it has been hypothesized that gut microbiota regulates BA homeostasis. Therefore further research on probiotics may open a new therapeutic opportunity and allow for further understanding of the processes involved in liver disease and regeneration [40].

Hepatocytes' role in liver regeneration

Although hepatoblasts are precursors for functional hepatocytes and cholangiocytes during liver development, their existence post birth is questionable. Therefore adult liver maintains homeostasis by division of hepatocytes [38,39]. It has been reported that hepatocytes are functionally heterogeneous, and metabolic zonation determines different hepatic populations capable of proliferating and self-renewing to maintain homeostasis (see review by Ref. [40]). Lineage-tracing experiments in mice identified a population of proliferating and self-renewing hepatocytes in the centrilobular zone 3. These cells, expressing early liver progenitor markers such as Axin2 and Tbx3, were able to recover one-third of the mouse liver lobule [38]. Although promising, recent studies reported the lack of evidence of a hepatocyte niche around the central vein that would be responsible for liver homeostasis; therefore a more detailed analysis is required to probe these differences. Furthermore, Font-Burgada et al. [58] identified a population of Sox9/HNF4α-positive hepatocytes in the periportal zone. These hybrid hepatocytes were able to replenish liver mass upon damage; however, they were not participating in normal liver homeostasis. Recent lineage-tracing studies discovered periportal Mfsd2a [59] and telomerase [60] expressing hepatocytes were capable of recovering liver mass after chronic injury or able to generate small clones scattered throughout the liver lobule following transplant.

Cholangiocytes and liver stem cells in liver regeneration

Although hepatocytes are capable of proliferation during homeostasis or even after surgical removal of two-thirds of the liver (PHx) [10,61], the regenerative capacity of these cells is significantly reduced in the presence of noxious agents. Despite toxic injury, the liver is still capable of regeneration and led to the theory of an adult stem/progenitor compartment ([62,63]; see review by Ref. [64]). It has been widely believed that these facultative progenitors are derived from a subpopulation of the duct/biliary cells (oval cells) from the liver compartment [65]. The early studies have reported that cholangiocyte-like oval cells, upon liver injury, become liver stem cells capable of regenerating both hepatocytes and cholangiocytes [66]. Several groups have indeed reported similar results, where oval cells expressing Epcam, FoxL1, Lgr5, or Sox9 have been regarded as bipotential facultative stem/progenitor cells [67–71]. This theory has been further supported by experimentation demonstrating that during hepatocyte death and senescence, bile duct–derived progenitor cells contribute to liver reconstitution in vivo [72]. More recently, Raven et al. [41] confirmed these findings and demonstrated that blocking hepatocyte proliferation, by overexpressing p21 or inhibiting Itgb1, resulted in the generation of new hepatocytes from biliary epithelia.

Although the theory of hepatocytes being derived from liver stem cells of bile duct origin has been widely accepted by the field, certain studies have questioned this rationale. Several recent lineage-tracing approaches failed to support stem cell progenitor existence and demonstrated that the repair of damaged liver relies predominantly on the hepatocyte compartment [39,73]. These differences in cell plasticity are important and are likely the product of the environment created in vivo [74]. Studies by Yimlamai et al. [46] have reported that downregulation of Hippo signaling efficiently converted hepatocytes to panCK + /Sox9 biliary cells and MIC1-1C3 + oval cells. Recently, Schaub et al. [75] demonstrated a successful transdifferentiation of hepatocytes to cholangiocytes by TGF-β signaling without the need for Notch activity. These results provided evidence of hepatocyte plasticity with a formation of stable biliary system that might reveal opportunities for the treatment of Alagille syndrome (ALGS) and other cholestatic liver diseases. What is more, Deng et al. [76] further confirmed direct

lineage conversion without the progenitor status. The studies described that BECs largely contribute to hepatocyte regeneration upon chronic liver damage. The converted BECs gained an HNF4α + CK19 + biphenotypic state and replenished ~55.7% of the liver parenchyma upon 3.5 diethoxycarbonyl-1,4-dixydrocollidine (DDC) treatment. The authors discussed that former studies on bile duct–derived progenitor cells used relatively short-term liver injuries, which could not assess whether NPCs or BECs contribute to hepatocyte regeneration. Furthermore, the study by Deng et al. [76] indicated that Sox9 expression does not distinguish BECs from LPCs, and markers of progenitors were not detected during cholangiocyte-to-hepatocyte conversion as previously published in Raven et al. [41] studies.

Pluripotent stem cell–derived hepatoblasts and hepatocytes

Although organ transplantation is the only longterm treatment for end-stage liver disease and inborn errors in metabolism, availability of donors is severely limited; hence, only a minority of eligible patients will receive a transplant [77]. Therefore liver cell transplantation is an alternative option with a potential to cure congenital liver diseases as well as acute-on-chronic liver failure. As such treatment is considered minimally invasive, it has several advantages over the whole organ transplantation such as faster recovery time and cost savings [77]. Although preliminary clinical studies on primary hepatocytes as well as hematopoietic and MSCs provided evidence of their potential suitability for cell engraftment [78,79], longterm expansion capacity of these cells led to search for a new source of engraftable and functional liver cells.

In addition to transplantation, a renewable source of liver tissue for modeling human response "in a dish" is vital to model disease, repurpose drugs and improve the efficiency of the drug development process. Recent research analyses indicated that drug development takes over 12 years and requires a cost of $2.6 billion [80,81]. Unfortunately, high percentage of drug failure during clinical phases II and III leads to significant drug attrition during the development process. As toxic effects in the liver are usually detected at later stages of the drug development, there is a need to improve screening platforms and preclinical models [82,83]. Currently, industry heavily relies on different types of cell-based systems. Primary human hepatocytes (PHH) are considered as a gold standard model to study drug metabolism; however, their rapid loss of phenotype, isolation from transplant rejected organs, and loss of function limit their use for long-term drug toxicity studies in vitro [84]. Therefore researchers have searched for more accessible and cheaper alternatives such as cancer-derived cell lines. The immortalized lines such as HepG2, Huh-7, Hep3B, Fa2N-4, and HepaRG have been widely used in the industrial setting displaying a moderate potential to metabolize different drugs [85]. Despite having advantages, their cancer origin offers limited biological relevance when compared to primary organ or cell type. Therefore stem cell technology has been proposed as a suitable alternative to overcome limitations associated with primary hepatocytes or cancer cell lines (see review by Ref. [86]). Human PSCs (hPSCs) include human embryonic stem cells (ESCs) (hESCs) and human-induced PSCs (iPSCs) (hiPSCs), have the ability to self-replicate and differentiate into all types of body cells, including functional hepatoblasts and hepatocytes [87–92]. Therefore hPSC-derived hepatoblasts or hepatocyte-like cells are an attractive cell source to provide unlimited number of functional hepatocytes for liver transplantation and improved in vitro modeling.

Research has produced a number of efficient hepatocyte differentiation procedures from PSCs using different growth factors or small molecules [5,93–107]. Recent advances in generating functional hepatocytes from stem cells allows one to model different diseases such as metabolic disorders [108,109], nonalcoholic liver diseases [110,111], and drug or tobacco-induced liver injuries [112,113]. Although stem cell–derived hepatocytes have been useful for drug toxicity studies and disease modeling, further improvements of these models are required to understand cell–cell interactions or cell–ECM signaling that usually affects liver functions in vivo [86]. Several engineering tools such as biomaterial scaffolds [114,115], cellular microarrays [116], protein micropatterning [117–119], microfluidics [120], and bioprinting (see review Ref. [121]) have been developed to control cellular microenvironment and hepatic niche (Fig. 39.1).

Despite advances in hepatic differentiation protocols, the procedures are often considered as time-consuming, expensive, and generate mixed populations of hepatocytes and other cell types [134]. Indeed, recent genome-wide expression studies demonstrated significant differences in gene expression between stem cell–derived hepatocytes and their target cells (i.e., primary hepatocytes) [101,135]. Distinct gene expression and epigenetic signatures were also observed between hepatocytes generated from the same donor using different strategies [136]. Therefore application of Omics technologies is essential to generate high fidelity hepatocytes for cell based modelling [137,138].

Studies have focused on the generation of LPCs from PSCs. Although potentially promising, efficient methodologies for maintaining hepatoblasts or LPCs under suitable conditions in vitro remain challenging. Several groups have reported an establishment of proliferative PSC-derived LPCs that were capable of differentiation to

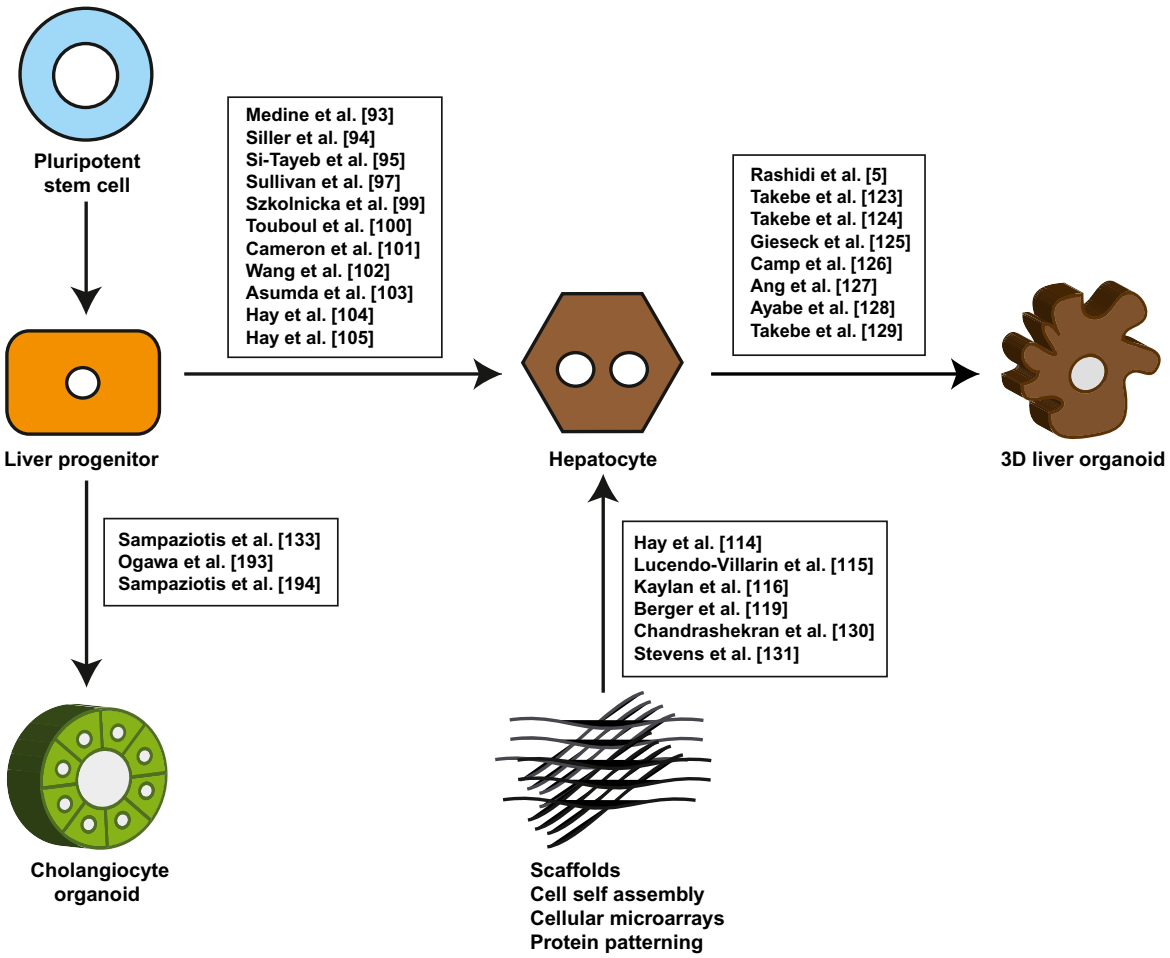

FIGURE 39.1 Established hepatic and cholangiocyte differentiation protocols from pluripotent stem cells: liver progenitor→hepatocyte—for details see Refs. [93–95,97,99–103,105–106,122]; hepatocyte→3D liver organoid—for details see Refs. [5,123–129]; scaffolds cellular microarrays protein micropatterning→hepatocyte—for details see Refs. [114–116,119,130,131]; liver progenitor→cholangiocyte organoid—for details see Refs. [133,193,194].

both hepatocytes and cholangiocytes [139,140]. However, to isolate and characterize these cells, a combination of cell surface markers was used, which were not specific to the liver [141]. To improve LPCs isolation and expansion, several studies have used specific extracellular matrices or cell surface markers. Takayama et al. [142] generated PCS-derived LPCs on human recombinant laminin 111 (LN111) matrix. Cells cultured on LN111-coated dish were maintained for 3 months in vitro as a bipotential population. Although promising, the authors applied adenovirus-mediated gene transfer to generate hepatic lineage that may also induce changes in the host cell. Two years later, Kido et al. [143] identified carboxypeptidase M as a novel marker to isolate hiPSC-derived LPCs that demonstrated self-renewal capacity and bidirectional differentiation. Furthermore, Zhang et al. [144] generated self-renewing hepatoblasts from hESCs by a stepwise induction strategy. The human hepatoblasts were successfully maintained in a specific ECELS medium supplemented with epidermal growth factor, glycogen synthase kinase-3 inhibitor (CHIR99021), transforming growth factor B receptor inhibitor (E-616452 or SB431542), lysophosphatidic acid, and sphingosine 1-phopshate [145]. Upon specific hepatic signals, hepatoblasts were able to differentiate to mature hepatocyte and displayed bile duct-like structures in Matrigel-embedded 3D culture.

3D liver organoids and expansion

Despite extensive investigation and optimization of different cell culture systems, the long-term in vitro amplification of hepatocytes remains very challenging due to the loss of their features and their proliferation capacity in culture. Tissue engineering has received a lot of attention and opened new perspectives to develop new culture cell models to improve their stability and functionality in vitro. Hepatocytes derived from PSCs, either from

iPSCs [95,146,147] or hESCs [101,105,106,122,148], have shown great promise. Although the results obtained with stem cell–derived hepatocytes have been encouraging, the cost and time needed to maintain and differentiate cells into a particular lineage are some of the limitations that restrict the current use of these cells for clinical applications. What is more, the widely used 2D hepatic differentiation protocols do not recapitulate organ morphogenesis or tissue organization, which can compromise their application [5]. Therefore novel strategies such as 3D culture systems have been generated to reconstitute more faithfully the in vivo hepatic environment that would improve long-term maintenance and large-scale production of cells.

Pluripotent stem cell–derived liver organoids

During liver development, progenitor liver cells delaminate and migrate into the STM to form highly self-organized and vascularized liver bud [15,149]. As the process of formation and growth of the hepatic diverticulum requires various signals from endothelial and mesenchymal cells, understanding the key-cross signaling pathways among cells is essential to fully comprehend hepatogenesis and function [150]. To generate 3D functional liver tissue iPSCs-derived hepatocytes, human umbilical vein endothelial cells, and MSCs were aggregated [123,124]. Although the authors were able to generate liver tissue that mimics the in vivo equivalent, the system was not suitable for scaled-up production. Alternative approaches to generate functional liver tissue and to better understand multilineage communication have also been developed by Gieseck et al. [125], Camp et al. [126], Ang et al. [127], Ayabe et al. [128], and Lucendo-Villarin et al. [92]. However, in order to produce stable liver spheres or organoids for application, challenges associated with scale and reproducibility have to be overcome. Recently, to facilitate the future therapeutic application of organoid-based approaches, Takebe et al. [129] established reproducible, functional and vascularized human liver buds from human iPSCs. Such studies provide an advance in the quest to build human liver tissue for the clinic and to study disease. More recently, Rashidi et al. [5] developed a defined 3D hepatosphere system that permitted the specification and culture of functional liver tissue for over a year in vitro, provided liver support in vivo, even in immunocompetent recipients. Although challenges still exist, these studies have opened up new experimental avenues for human translational medicine.

Bile duct–derived organoids

While PSC-derived hepatocytes hold a great promise for translational applications, further safety and optimization of 3D differentiation protocols are required before they are ready for the clinic [151,152]. Therefore parallel studies have focused on the stable expansion of nontransformed cell types for regenerative therapies and in vitro modeling (Fig. 39.2). Several studies have demonstrated that liver displays a remarkable regenerative capacity, where different modes of response occur depending on the type of damage. Lineage-tracing studies have demonstrated that under steady-state conditions in vivo, Axin + pericentral hepatocytes are able to self-renew and proliferate [38,60]. What is more, upon PHx, hepatocytes are capable of regenerating the whole liver within 2 weeks after damage without dedifferentiation into progenitor/stem cell–like state [10]. However, under severe or chronic, the stem cell compartment is activated [66]. Several studies have described the generation of long-lived 3D liver spheres that mirror oval cell in terms of their plasticity [71,153]. Under specific Rspo-1 growth-factor conditions, single mouse Lgr5 + liver stem cells were demonstrated to be clonally expanded as organoids for over multiple months and could be induced to functional hepatocytes both in vitro and in vivo [71]. Soon after, Epcam + bile duct–derived bipotent progenitor cells from human liver biopsies were established and displayed long-term proliferation and genetic stability. Furthermore, using this technique, the authors generated 3D organoids from patients with alpha 1-antitrypsin deficiency and ALGS and were able to model the effects of those mutations in vitro [153].

Hepatocyte-derived organoids

The work of Huch et al. [71,153] has greatly improved liver organoid formation from BECs and primary liver cancer (PLC) cells [157]. Despite progress, it has been challenging to culture and stably expand healthy mature hepatocytes in vitro from cholangiocyte-derived organoids. To overcome this issue, several studies have described generation of long-term culture system for proliferative hepatocyte spheroids. It has been reported that hepatocyte-derived progenitors generate 60 times more hepatocytes than progenitors derived from cholangiocytes [159]; therefore use of solely primary hepatic tissue could be a preferred source to establish 3D models for in vitro expansion. Several studies have described the importance of injury-invoked regenerative signals during liver damage [160,161]. Recently, Peng et al. [151] generated long-term 3D mouse organoids by inducing tumor necrosis factor α (TNFα). The injury-induced inflammatory cytokine secreted by Kupffer cells has been reported to play an essential role in initiating liver regeneration [160]. Therefore given its role in tissue repair, the authors asked whether such inflammatory signals could promote primary hepatocyte proliferation. Single-cell RNA sequencing (RNA–seq) studies on 3D mouse organoids revealed a

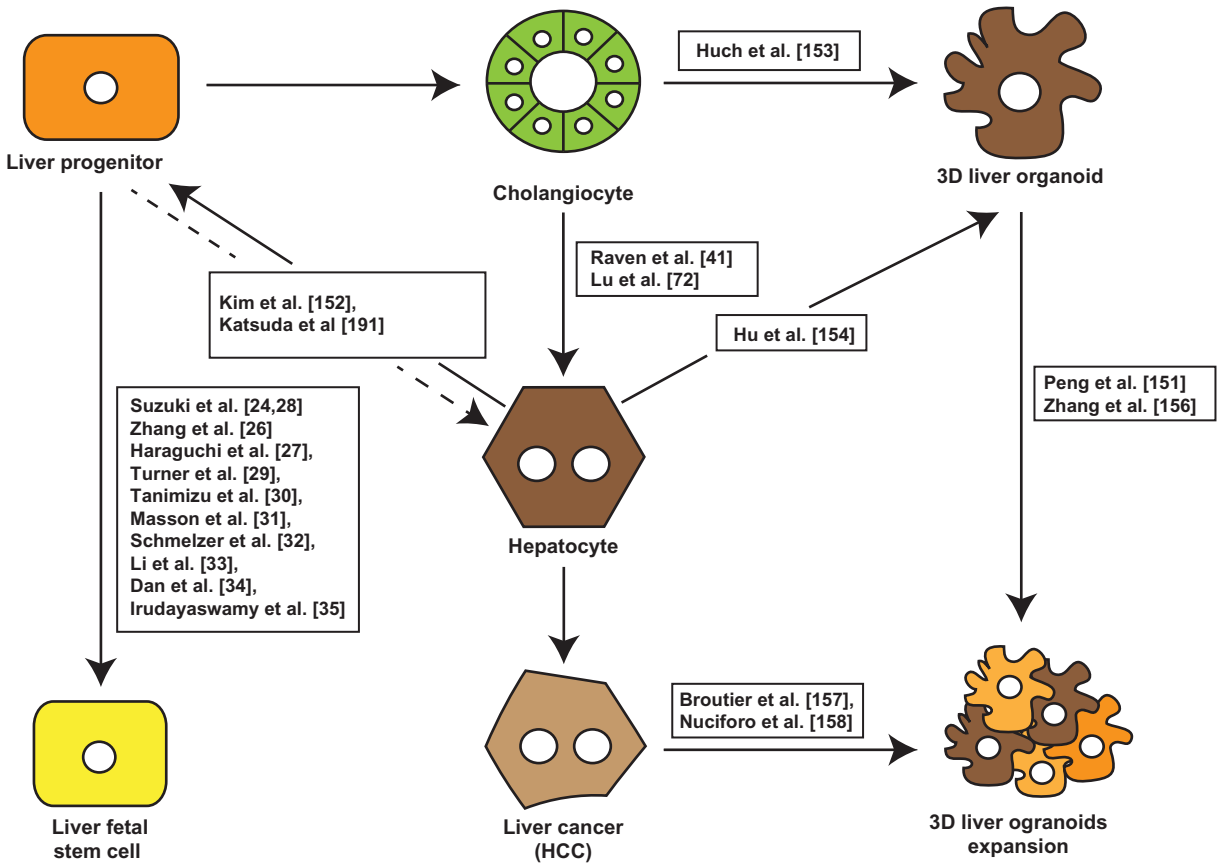

FIGURE 39.2 Recent advancements in generating hepatic cells from primary liver tissue: cholangiocyte→3D liver organoid—for details see Ref. [153]; cholangiocyte→hepatocyte—for details see Refs. [41,72]; hepatocyte→3D liver organoid—for details see Ref. [154]; hepatocyte→liver progenitor—for details see Refs. [152,191]; liver progenitor→liver fetal stem cell—for details see Refs. [24,26–28,30–35]; 3D liver organoid→3D liver organoids expansion—for details see Refs. [151,156]; liver cancer (HCC)→3D liver organoids expansion—for details see Refs. [157,158].

broad expression of hepatic but not biliary markers, and cells extensively repopulated injured liver of FAH −/− mice. Therefore harnessing tissue repair signals may be a powerful approach to manipulate hard-to-culture cell types for different medical implications. The same year, Hu et al. [154] described successful generation of long-term 3D organoids derived from mouse and human primary hepatocytes. The authors reported establishment of hepatic 3D system from single hepatocytes that were capable of growing for multiple months in vitro, retained key morphological and functional features as well as repopulated damaged liver in Fah −/− NOD Rag1 −/− Il2rg −/− (FNRG) mice. It has been suggested that the combination of the two protocols [151,154] could be essential for further clinical development. Lastly, remarkable in vitro expansion of PHH was achieved by Zhang et al. [156] using defined medium conditions. The authors generated proliferating human hepatocytes (ProliHHs) that displayed both hepatic and progenitor features could be serially passaged and expanded by 10,000 fold. Bipotent ProliHH organoids could be reverted to mature phenotypes and were able to repopulate damaged mouse liver up to 60%. The work of Zhang et al. provides an efficient protocol for large-scale production of cells suitable for treating human liver disease and drug metabolism studies.

Novel scaffolds for liver organoids

Although promising, those techniques often suffer from limitations that do not allow the use of these cells for clinical application. The use of animal-derived components such as Matrigel cannot be used for large-scale production under good manufacturing practice conditions. To overcome the problem of xeno-derived components, novel engineered scaffolds [162], naturally occurring [163] or synthetic material [164], are under scrutiny to improve organoid-differentiation. In the future the use of biocompatible scaffolds in combination with organoid-based systems could provide a safe and efficient source of functional cells for transplantation until the patient

receives an organ transplant or the native liver recovers. Recently, Chandrashekran et al. [130] generated liver organoids from human umbilical cord–derived MSCs and human cadaveric donor–derived hepatocytes that were cultured on methylcellulose scaffolds. Methylcellulose is a synthetic chemical product derived from cellulose [165] and is widely used in industry and clinical settings [166–168]. Although the authors demonstrated the methylcellulose-based liver organoids to be functional in vitro, the results obtained were still significantly lower than of Matrigel cultures. Nevertheless, establishment of liver organoids in methylcellulose and further encapsulation of these aggregates in alginate-methylcellulose 3D scaffolds may enable clinical grade expansion and may be highly applicable in the treatment of acute liver failure in the future. In order to tackle tissue architecture and scale issues, Stevens et al. [131] took a different approach and developed SEEDs (in situ expansion and engineered devices). This approach used primary parenchymal, vascular, and stromal cells and arranged those in a specific architecture in the biodegradable hydrogel. The bioencapsulated organoids expanded in vivo in response to regenerative cues, expanding up to 50-fold in animals with liver injury. Recent studies by Rashidi et al. [5] have provided evidence for successful subcutaneous implantation of scaffold-based 3D liver organoids. The FDA-approved material, polycaprolactone, was selected to develop an implantable liver graft that demonstrated vascularization and function upon transplantation into immunocompetent and deficient recipients. The implantation of 3D hepatocytes–loaded scaffolds resulted in significant body weight recovery and increase in hepatic functions over 14 days in vivo. As subcutaneous transplantation of the scaffold is a simple procedure, it may reduce the need for general anesthesia and invasive abdominal operations in the future to treat failing liver function in humans.

Organoids as a model to study liver cancer disease

Currently, hepatocellular carcinoma (HCC) and cholangiocarcinoma (CC) represent the most common PLCs in the world [169]. Despite much progress in drug research [169,170], most of the cancer drugs fail to meet clinical end points in phase III trials [171]. Recently, the newly developed multikinase inhibitor regorafenib [172] and monoclonal antibody nivolumab [173] have been demonstrated to display efficacy for advanced HCC. However, the effective treatments against PLCs are still limited; therefore new anticancer therapies are urgently needed. The development of new human models that recapitulate key features of tumors such as their tissue structure and cellular heterogeneity are essential in these endeavours [158,174]. The development of new organoid-based technologies has aided cancer research, studying prostate [175], pancreatic [176], colorectal [177], breast [178], and bladder [179] cancers. Recently, Broutier et al. [157] described a new organoid culture system to propagate human PLC–derived organoids that would be suitable for disease modeling and drug screening. The 3D organoids were derived from patients suffering from HCC, CC, or combination of both tumors and preserved their histological architecture, gene expression and could be expanded over time in vitro that allowed to identify an ERK inhibitor SCH772984 as a potential therapeutic agent against PLCs. A year later, a similar study performed by Nuciforo et al. [158] generated long-term organoid cultures from tumor needle biopsies of HCC patients and demonstrated sorafenib inhibitor sensitivity. These studies evidence the importance of 3D systems in drug development and establishing personalized medicines.

Reprogramming of human hepatocytes to liver progenitors using different culture conditions

Currently, hepatocyte transplantation represents the only possible alternative to whole liver transplantation for patients with end-stage liver diseases. Although promising, cell transplantation results in a partial and relatively short-term correction of liver dysfunction. Furthermore, it has been severely hampered by different issues related to shortage of donor tissue, insufficient hepatocyte proliferation in vitro, or low engraftment efficiency of hepatocytes in vivo. To overcome these issues and to further develop cell-based therapies, much effort has been directed toward the potential use of stem cells capable of self-renewal, including ESCs, iPSCs, MSCs, and LPCs [101,147,180,181]. Despite the great promise of stem cell–derived hepatocytes in the field of regenerative medicine, their use in clinic is impeded by their differentiation potential [96], poor engraftment [182], likelihood of immune rejection [183], or the risk of cancer development [182,184,185].

Recently, several groups have reported that adult mature hepatocytes can be reprogrammed into bipotent and proliferative LPCs in response to chronic liver injury [39,46,159,186]. Therefore conversion of mature hepatocytes to LPCs could serve as a novel cell source that can be used in liver regenerative medicine [6] and would allow one to further understand molecular processes involved in cell reprogramming during liver disease/dysfunction. Recent developments in small molecules have successfully replaced the use of growth factors and contributed to the induction and maintenance of stem cells as

well as to their differentiation into distinct tissue lineages [94,187–189]. Kawamata and Ochiya [155] have identified that a combination of four small molecules Y-27632 (Rho-associated kinase inhibitor), PD0325901 (mitogen-activated protein kinase inhibitor), A83-01 (type 1 transforming growth factor−β receptor inhibitor), and CHIR99021 (glycogen synthase kinase-3 inhibitor) allowed for stable culturing of multiple types of rat stem/progenitor cells, including ESCs, CD63 + /Ck14 + mammary gland progenitor cells, and multipotent mammary tumor cells. The positive results from this study have led to the generation of chemically induced liver progenitors (CLiPs) from mature rat hepatocytes using the same four-molecule cocktail [190]. CLiPs displayed stable expression of liver stem cell features in long-term culture in vitro and were able to differentiate both to hepatocytes and functional cholangiocytes, as well as extensively repopulate chronically injured liver tissue. Although promising, rat CLiPs were demonstrated to exhibit chromosomal translocation under long-term culture. In addition, the YAC cocktail used to reprogram animal hepatocytes was not able to induce conversion in human mature hepatocytes. A year later, the same group was able to generate human CLiPs (hCLiPs) obtained from human infant hepatocytes using a similar strategy. The newly produced hCLiPs demonstrated significant repopulative capacity following transplantation into injured mice and upon redifferentiation in vitro exhibited enzymatic activities [191]. In addition, other groups have also reported different methods for in vitro generation of liver progenitors from human hepatocytes. Kim et al. [152] used a combination of similar small molecules (A83-01 and CHIR99021) and HGF to generate hepatic progenitors from human PHH. Those progenitors were highly proliferative and were capable of hepatic and biliary differentiation in vitro and in vivo. Contrary to those studies, Zhang et al. [156] observed that replacement of Wnt growth factor with CHIR99021 could not induce proliferation of hepatic cells in their 3D organoid system. More recently, Fu et al. [192] reported efficient expansion and differentiation of human hepatocyte−derived liver progenitor-like cells in vitro by activating NAD + dependent deacetylase signaling using specific transition and expansion medium formulations.

Conclusion

Recent advances in stem cell technologies and tissue engineering have resulted in the generation of prototype human liver tissue. These tissues display appropriate levels of liver function in vitro and in vivo, which evidences their potential. These advances, in combination with tissue engineering, microfabrication, and microfluidics, promise new opportunities to develop perfused human tissue for the clinic and the laboratory. Going forward, further development of 3D bioprinting techniques will help to refine tissue organization, vascularization, stability, and scale-up. We believe that advances in this scientific area will provide defined, renewable, and functional human liver tissue for translational medicine.

Liver disease burden

Fatal liver disease accounts for ~2 million deaths annually worldwide and has steadily increasing rates over the years [1]. Liver failure can be divided into three major categories: (1) acute liver failure (ALF) that presents as a rapid loss of liver function in patients without preexisting liver disease, (2) chronic liver disease due to metabolic dysfunction, and (3) chronic liver failure accompanied by tissue remodeling and scarring.

ALF is a rare syndrome with an annual incidence of less than 10 cases per million people in the developed world. In the United States, ~2000 cases of ALF are diagnosed each year [2]. It commonly develops in healthy adults in their 30s. Patients with ALF usually present with abnormal liver biochemistry, coagulopathy, and encephalopathy. The causes vary geographically. Damage due to drug exposure (e.g., acetaminophen) is the most common cause in the West, while in large parts of the East, viruses (e.g., Hepatitis A and E) are the most prominent cause of ALF [3]. Clinically, ALF can be subdivided based on the period of time between the appearance of jaundice and onset of hepatic encephalopathy. Data from O'Grady et al. proposed the following classification: hyperacute for periods between 0 and 7 days, acute for periods between 7 and 28 days, and subacute for periods between 4 and 12 weeks [4]. In hyperacute cases the cause is usually acetaminophen toxicity or viral infection. Subacute cases that evolve slowly often result from idiosyncratic drug-induced liver injury (DILI). Even though patients with a subacute presentation have less coagulopathy and encephalopathy, paradoxically they have a consistently worse medical outcome than those with a more rapid onset of the disease [5].

Chronic liver disease develops on the background of a constant injurious insult, either resulting from a metabolic disorder or a number of etiologies that lead to widespread tissue remodeling and pathologic deposition of extracellular matrix (ECM). Inborn liver-based errors of metabolism are life-threatening conditions caused by genetic defects in single enzymes or transporters and lead to blockade of a specific metabolic pathway. While they can be accompanied by progressive fibrosis and cirrhosis, such as in the case of α1-antitrypsin ZZ deficiency, hemochromatosis, Wilson's disease, and hereditary tyrosinemia [6], the liver parenchyma often remains intact. Some examples of metabolic disorders with an intact parenchyma include hypercholesterolemia, Crigler–Najjar syndrome, ornithine transcarbamylase deficiency, organic acidurias, and hyperoxaluria [7]. In a biopsy the lack of parenchymal destruction often leads to a delayed diagnosis, exposing the patient to sequelae. In all cases of liver disease the lack of FDA-approved noninvasive biomarkers makes it challenging to diagnose and treat liver diseases.

Chronic liver disease occurs in the setting of nonalcoholic fatty liver disease (NAFLD). NAFLD is marked by hepatic steatosis and is related to the presence of metabolic syndrome in association with obesity, diabetes, and/or arterial hypertension [8]. A subset of NAFLD patients

* These authors contributed equally.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00041-1

will develop signs of nonalcoholic steatohepatitis (NASH), a more severe condition associated with lobular inflammation and hepatocellular ballooning and can lead to fibrosis and cirrhosis [9]. In NAFLD the liver is unable to utilize carbohydrates and fatty acids properly, leading to toxic overaccumulation of lipid species. These metabolites induce cellular stress, injury, and death, which predispose the liver to sequelae such as cirrhosis and hepatocellular carcinoma [10].

In the United States the number of NAFLD cases is projected to expand from 83.1 million in 2015 (~26% of the population) to 100.9 million by 2030 (~28% of the population) [11]. An increasing percentage of these cases are projected to be classified as NASH, rising from 20% to 27% of adults with NAFLD during this interval [12]. While diagnosing NASH at an early stage remains a challenge, multiplexed protease-activated nanosensors have demonstrated utility in monitoring NASH progression and treatment response in a 3,5-diethylcarbonyl-1,4-dihydrocollidine model of fibrosis in mice. With further development, these noninvasive readouts can be used to diagnose disease.

Current state of liver therapies

In order to mitigate the clinical burden of liver disease, several therapeutic strategies have been undertaken (Fig. 40.1).

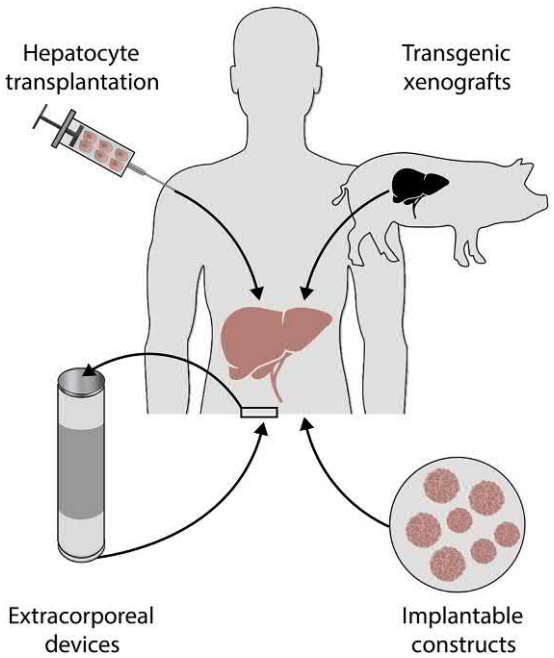

FIGURE 40.1 Cell-based therapies for liver disease. Extracorporeal devices perfuse patient's blood or plasma through bioreactors. Hepatocytes are transplanted directly or implanted onto scaffolds. Genetically modified large animals can be used for xenotranplantation.

Extracorporeal liver support devices

Liver failure is associated with abnormal accumulation of numerous endogenous substances such as bilirubin, ammonia, free fatty acids, and proinflammatory cytokines [13]. Extracorporeal liver support devices have been developed to detoxify the blood and plasma in order to bridge patients to liver transplantation (LT) or allow the native liver to recover from injury. Artificial liver (AL) devices use nonliving components for detoxification, such as membrane separation or sorbents, to selectively remove toxins but have limited clinical use because they do not replace the synthetic and metabolic roles of the liver [13]. Bioartificial liver (BAL) devices, on the other hand, contain a cell-housing bioreactor that aims to provide the detoxification and synthetic functions of the liver and are an ongoing topic of clinical investigation. Current versions are either based on hollow fiber cartridges [14–16] or on perfused three-dimensional (3D) matrices [17]. BALs, just like other hepatocyte-based therapies, face many challenges, such as the lack of readily available functional cell sources and the loss of cell viability and phenotype during the treatment process.

Biopharmaceuticals

In the setting of ALF, *N*-acetyl cysteine (NAC) is FDA-approved to reduce the extent of liver injury after acetaminophen overdose [18]. In the setting of chronic liver disease, however, most of the FDA-approved therapies are for hepatitis A, B, and C. A detailed listing can be found in Table 40.1. While a few treatments have shown moderate efficacy, there are currently no biopharmaceuticals that are approved for NAFLD, NASH, or cirrhosis. Glitazones, for example, upregulate adiponectin, an adipokine with antisteatogenic and insulin-sensitizing properties [19]. Vitamin E, an antioxidant, can prevent liver injury by blocking apoptotic pathways and protecting against oxidative stress [19]. Despite clinical studies of a large number of therapeutic candidates, no single agent or combination has shown improvement to liver-related morbidity and mortality in patients with NASH. Until a drug is FDA-approved for NASH indications, lifestyle modifications and optimizing metabolic risk factors are the best medical-treatment options for these patients.

Liver transplantation

The first attempt at human LT took place at the University of Colorado on March 1, 1963 but turned out to be unsuccessful [20]. Based on the pioneering work of Thomas Starzl, the first extended survival of a human recipient after LT was achieved on July 23, 1967 with a 19-month-old female patient with hepatocellular carcinoma who survived

TABLE 40.1 List of FDA-approved therapies for chronic liver diseases.

Drug name	Year approved	Indication(s)	Mechanism
Heplisav-B	2017	Hepatitis B	Combines hepatitis B surface antigen with a proprietary Toll-like receptor 9 agonist to enhance the immune response
Mavyret	2017	HCV genotype 1–6	Fixed-dose combination of glecaprevir, an HCV NS3/4A protease inhibitor, and pibrentasvir, an HCV NS5A inhibitor
Vosevi	2017	Hepatitis C	Fixed-dose combination of sofosbuvir, an HCV nucleotide analog NS5B polymerase inhibitor, velpatasvir, an HCV NS5A inhibitor, and voxilaprevir, an HCV NS3/4A protease inhibitor
Ocaliva	2016	Primary biliary cholangitis	FXR agonist
Zepatier	2016	HCV genotype 1 or 4	Fixed-dose combination product containing elbasvir, an HCV NS5A inhibitor, and grazoprevir, an HCV NS3/4A protease inhibitor
Cholbam	2015	Bile acid synthesis and peroxisomal disorders	Primary bile acid synthesized from cholesterol in the liver
Daklinza	2015	HCV genotype 3	Inhibitor of NS5A, a nonstructural protein encoded by HCV
Technivie	2015	HCV genotype 4	Fixed-dose combination of ombitasvir, an HCV NS5A inhibitor, paritaprevir, an HCV NS3/4A protease inhibitor, and ritonavir, a CYP3A inhibitor
Olysio	2013	Hepatitis C	Small molecule orally active inhibitor of the NS3/4A protease of HCV
Sovaldi	2013	Hepatitis C	Inhibitor of the HCV NS5B RNA-dependent RNA polymerase
Incivek	2011	HCV genotype 1	Inhibitor of the HCV NS3/4A serine protease
Victrelis	2011	HCV genotype 1	Inhibitor of the HCV NS3 serine protease
Viread	2008	Hepatitis B	Oral nucleotide analogue DNA polymerase inhibitor
Tyzeka	2006	Hepatitis B	Inhibitor of HBV DNA polymerase
Baraclude	2005	Chronic hepatitis B with evidence of active viral replication	Small-molecule guanosine nucleoside analog with selective activity against HBV polymerase
Hepsera	2002	Chronic hepatitis B with evidence of active viral replication	Inhibitor of HBV DNA polymerase
Pegasys	2002	Chronic hepatitis C with compensated liver disease	Binds to and activates human type 1 interferon receptors
Peg-intron	2001	Chronic hepatitis C	Binds to and activates human type 1 interferon receptors
Ribavirin	2001	Chronic hepatitis C	Synthetic nucleoside analog with antiviral activity
Twinrix	2001	Hepatitis A and B	Recombinant vaccine

FXR, Farnesoid X receptor; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *NS3*, nonstructural protein 3.

13 months before succumbing to metastatic disease [21]. After the initial success of the surgery, advancements were made to improve donor organ quality, recipient selection, operative and perioperative management, immunosuppression and infectious complications. These advancements have made orthotopic LT the primary treatment for end-stage liver disease and certain cancers. These transplants have 1-year patient survival rates over 80% [22]. However, many challenges remain, including donor organ shortages, recipients with more advanced disease at transplant, a growing need for retransplantation, and adverse effects associated with long-term immunosuppression. To overcome a growing imbalance between the supply and demand of donor livers, transplant centers have developed strategies to expand the donor pool. These strategies include live donor LT [23], split-LT [24], and extended criteria for donor livers [25]. Despite all these efforts, the number of liver transplants has not increased in the last decade.

An alternative to human LT is xenotransplantation, though it has been clinically intractable due to concerns about immunological rejection and zoonotic pathogen transfer. With the advent of accessible genetic engineering technologies to circumvent the aforementioned challenges, the breeding efficiency of animals can be leveraged to mass-produce tissue for human organ transplants. Niu et al. applied CRISPR-Cas9 to inactivate all 62 copies of porcine endogenous retroviruses, thus paving the way for pig-to-human transplants [26]. Relatedly, Längin et al. genetically engineered porcine heart xenografts and demonstrated long-term pig-to-baboon orthotopic transplantation [27].

Hepatocyte transplantation

Given the several drawbacks of LTs, alternative strategies have been pursued. A potential alternative to LT is allogeneic hepatocyte transplantation (HT). Transplanted cells can provide the missing or impaired hepatic function once engrafted. Given their synthetic and metabolic capabilities, mature hepatocytes are the primary candidates for liver cell transplantations. HT offers several advantages over LT. It is less invasive and can be performed repeatedly to meet metabolic requirements. Furthermore, multiple patients can be treated with a single dissociated donor tissue, and harvested cells can be cryopreserved for later use on an as-needed basis.

The first experimental attempt of HT was done in 1976 to treat an animal model for Crigler–Najjar syndrome type I [28]. Along with other observations, it led to the first transplant of autologous hepatocytes in 10 patients with liver cirrhosis in 1992 in Japan [29]. Since then, reports have been published on more than 100 patients with liver disease treated by HT worldwide [30]. Human HT has resulted in partial correction of a number of liver diseases, including urea cycle disorders [31], factor VII deficiency [32], glycogen storage disease type 1 [33], infantile Refsum disease [34], phenylketonuria [35], severe infantile oxalosis [36], and ALF [37]. HT faces several limitations: limited supply of high-quality mature hepatocytes, freeze–thaw damage due to cryopreservation, poor cellular engraftment (estimated to be from 0.1% to 0.3% of host liver mass in mice after infusion of 3% − 5% of the total recipient liver cells) [30], and allogeneic rejection.

Clinically, the most widely used administration route for HT is through the portal vein or one of its branches. Hepatocytes traverse the sinusoidal vasculature and create transient occlusions. The occlusions lead to vascular permeabilization which allows transplanted cells to reach the liver parenchyma [35]. The number of cells that are injected intraportally and subsequently engraft is a function of portal pressure and liver architecture. Thus other administration routes have been explored for patients with cirrhosis who have high portal pressures due to fibrosis.

In animal studies, hepatocytes transplanted into the spleen proliferate for extended periods of time and display normal hepatic function. The spleen has been shown to be well-suited for hepatocyte engraftment because it functions as a vascular filter and provides an immediate blood supply [30]. The peritoneal cavity represents an attractive administration route as it is easily accessible and can house a large number of cells. Due to cell number requirements associated with metabolic compensation, it has been used in patients with ALF [38]. As an alternative to the portal vein, spleen and peritoneum, the lymph node (LN) has also been shown to demonstrate engraftment of donor hepatocytes [39,40]. While this strategy has not been utilized in the clinic yet, the preclinical data is promising.

Current clinical trials

Several pathways have been implicated in the biology and pathogenesis of NAFLD development: insulin resistance, lipotoxicity, oxidative stress, altered immune/cytokine/mitochondrial functioning, and apoptosis. New therapeutic modalities are being developed to target many of these pathways. For a detailed overview of NAFLD-targeted drugs that are currently in the clinical trial pipeline, please refer to Younossi et al. [41].

In vitro models

To build high-fidelity cellular models and therapies, components of the native liver microenvironment must be incorporated (Fig. 40.2). The liver's highly organized structure is key to its role as a complex tissue supporting myriad synthetic and metabolic functions. In addition to hepatocytes the main parenchyma of the liver, there are several nonparenchymal cell types such as liver sinusoidal endothelial cells, Kupffer cells, cholangiocytes, and stellate cells. In each lobule of the liver an array of parallel hepatocyte cords are sandwiched between the sinusoid, carrying circulating blood, and the bile duct, carrying hepatocyte-secreted bile acids. Notably, this arrangement dictates a unique set of architecturally driven cell–cell and cell–matrix cues, which gives rise to liver-specific phenotypes. Gradients of physicochemical stimuli along the sinusoid drive zonal phenotypes with disparate metabolic and synthetic functional profiles [42]. Interrupting the natural order of cell arrangement in the liver is directly connected with diseases discussed in the "Liver disease burden" section. In this chapter, we will primarily focus on human platforms, which are biologically distinct from animal-derived cell models of the liver that are reviewed more in depth elsewhere [43].

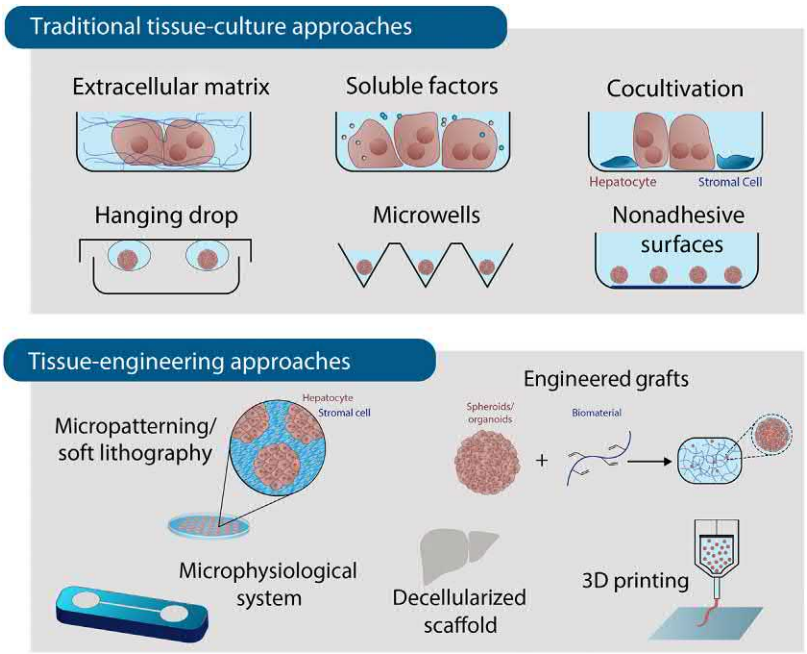

FIGURE 40.2 Advances in hepatic tissue engineering. Traditional tissue culture approaches such as the addition of extracellular matrix, soluble factors, cocultivation with supporting cell types, hanging drop, microwell molding, and nonadhesive surfaces have enabled the early study of hepatocyte phenotype in vitro in both 2D and 3D cultures. The advent of technologies from disciplines such as chemical engineering and electrical engineering has led to a new level of control for hepatic tissue cultures, such as micropatterning to template cell interactions, microphysiological systems to study the impact of bioactive perfusate, polymeric biomaterials for constructing 3D cell-laden grafts, perfusion technologies for decellularization/recellularization strategies, and 3D printing for scalable engineering of cellular grafts. *2D*, Two-dimensional; *3D*, three-dimensional.

Two-dimensional liver culture

Hepatocytes are responsible for more than 500 metabolic and synthetic functions of the human body, often categorized broadly as protein synthesis and secretion, detoxification, bile synthesis, and nitrogen metabolism. Primary hepatocytes quickly lose their phenotype and function after a few days in traditional monolayer culture and require a collagen-coated surface for adherence and survival [6]. In contrast, when primary human hepatocytes (PHHs) are cultured between two layers of collagen gel (i.e., sandwich culture configuration), they retain viability, polarity and many axes of relevant metabolic and synthetic function [44,45]. Guguen-Guillouzo et al. found that a random coculture with a liver epithelial cell line was sufficient to support hepatic albumin secretion, suggesting the importance of heterotypic cell interactions for long-term ex vivo culture [46]. Bale et al. demonstrated that other nonparenchymal liver cells can better recapitulate hepatic response to inflammatory stimuli, through higher order intercellular interactions captured in a multicellular platform [47]. It was later discovered that a micropatterned architecture consisting of hepatocyte-filled islands surrounded by a nonbiomimetic cell type and mouse fibroblasts can also stabilize hepatocytes, suggesting the existence of conserved coculture signals across species. These micropatterned cocultures (MPCCs) enable the study of DILI and hepatotropic pathogen infection for several weeks in vitro [48–50]. Furthermore, Davidson et al. added hepatic stellate cells to the traditional MPCC to create an in vitro model of NASH [51].

Despite the utility of two-dimensional (2D) hepatic cultures in screening assays, a wealth of literature suggests that they are dissimilar to hepatocytes in vivo. Specifically, 2D formats, even with overlaid collagen matrix, are more flattened than their native cuboidal architecture. On a subcellular level, this translates to major differences in cytoarchitecture, which is linked to aberrant polarization and nonphysiological behavior [52,53]. Griffith and Swartz have described the improved presentation of relevant biochemical and mechanical cues in 3D cultures, typically cell-laden hydrogels, compared to traditional 2D cultures [54].

Three-dimensional liver constructs

Commonly, 3D hepatic cultures consist of primary cell or induced pluripotent stem cell (iPSC)-derived spheroid and organoid cultures, which are typically embedded in ECM-based hydrogels [55]. Spheroids and organoids can be manufactured using a variety of techniques, such as microwell mold-based technologies, which offer a high degree of composition and size control but are difficult to scale. Spinning flasks and bioreactors can produce large populations of spheroids, though they are typically nonuniform in size and function. Bell et al. showed that primary human hepatic spheroids fabricated and cultured in microwell plates serve as useful models of hepatotoxicity and multiple liver pathologies [56].

Toward transplantable cell therapies, Stevens et al. used microwell molds to create 3D hepatic spheroid

cocultures of PHHs and fibroblasts, which can be embedded in agarose, fibrin, or polyethylene glycol hydrogel scaffolds. The resulting tissue constructs support hepatic function in vitro and in vivo after ectopic transplantation into the peritoneal cavity [57]. Furthermore, Stevens et al. demonstrated that implanting a tissue seed, consisting of hepatic aggregates and vascular cords, into an FRNG [fumarylacetoacetate hydrolase-deficient ($Fah^{-/-}$), recombinase activating gene-deficient ($Rag1^{-/-}$), nonobese diabetes (NOD), and interleukin-2 receptor γ chain-deficient (Il2rγ-null)] mouse model of hereditary tyrosinemia leads to a 50-fold expansion in serum human albumin and formation of perfusable vessels after 80 days of cycled exposure to regenerative stimuli [58]. Relatedly, Takebe et al. constructed liver buds consisting of iPSC-derived hepatocyte-like cells (HLCs), mesenchymal stem cells, and human umbilical vein endothelial cells; mesenteric transplantation of these human liver buds resulted in vascularization and rescued a lethal TK-NOG mouse model of liver injury [59].

To create clinically viable engineered liver constructs, cell sourcing (discussed further in the "Cell sourcing" section), and clinical-scale manufacturing of organoids and spheroids must be addressed. Toward this end, Takebe et al. constructed a large-scale liver bud microwell culture platform, enabling the formation of 10^8 liver buds [60].

Physiological microfluidic models of liver

Despite improvements to in vitro liver platforms as model systems and implants, static cultures lack physiologically relevant dynamic components. The native liver's dynamic physiology arises from blood circulation and multiorgan cross talk. Thus to improve biological fidelity, many have attempted to create microfluidic models of the liver [61]. By leveraging techniques from the semiconductor manufacturing industry such as soft lithography, groups have fabricated microphysiological systems with preformed channels to allow for perfusion of nutrients and to aid in waste removal [62–67]. These so-called liver-on-chip platforms allow for the study of biochemical and mechanical cues such as growth factor gradients and shear stress. Lee et al. demonstrated that the presence of human stellate cells and application of shear via flow enabled the formation of stable hepatic spheroids on chip [68]. Furthermore, by linking microfluidic channels between multiple tissue models, multiorgan phenomena such as drug metabolite toxicity and disease progression can be captured in vitro, which is not possible in traditional cultures [69–71].

Controlling three-dimensional architecture and cellular organization

Another approach to improving the functionality of tissue-engineered constructs is to more closely mimic in vivo microarchitecture by generating scaffolds with a highly defined material and cellular architecture, which would provide better control over the 3D environment at the microscale.

A range of rapid prototyping and patterning strategies have been developed for polymers using multiple modes of assembly, including fabrication using heat, light, adhesives, or molding, and these techniques have been extensively reviewed elsewhere [72]. For example, 3D printing with adhesives combined with particulate leaching has been utilized to generate porous poly(lactic-co-glycolic acid (PLGA) scaffolds for hepatocyte attachment [73], and microstructured ceramic [74] and silicon scaffolds [75,76] have been proposed as platforms for hepatocyte culture. Furthermore, molding and microsyringe deposition have been demonstrated to be robust methods for fabricating specified 3D PLGA structures toward the integration into implantable systems [77].

Microfabrication techniques have similarly been employed for the generation of patterned cellular hydrogel constructs. For instance, microfluidic molding has been used to form biological gels containing cells into various patterns [78]. In addition, syringe deposition in conjunction with micropositioning was recently illustrated as a means to generate patterned gelatin hydrogels containing hepatocytes [79]. Patterning of synthetic hydrogel systems has also recently been explored. Specifically, the photopolymerization property of poly(ethylene glycol) (PEG) hydrogels enables the adaptation of photolithographic techniques to generate patterned hydrogel networks. In this process, patterned masks printed on transparencies act to localize the ultraviolet exposure of the prepolymer solution and, thus, dictate the structure of the resultant hydrogel. The major advantages of photolithography-based techniques for patterning of hydrogel structures are its simplicity and flexibility. Photopatterning has been employed to surface pattern biological factors [80], produce hydrogel structures with a range of sizes and shapes [81,82], as well as build multilayer cellular networks [83,84]. Consequently, hydrogel photopatterning technology is ideally suited for the regulation of scaffold architecture at the multiple length scales required for implantable hepatocellular constructs. As a demonstration of these capabilities, photopatterning of PEG hydrogels was utilized to generate hepatocyte and fibroblast coculture hydrogels with a defined 3D branched network, resulting in improved hepatocyte viability and functions under perfusion [85]. More recently, a "bottom-up" approach for fabricating multicellular tissue constructs utilizing DNA-templated assembly of 3D cell-laden hydrogel microtissues demonstrates robust patterning of cellular hydrogel constructs containing numerous cell types [86]. Also, the additional combination of photopatterning with dielectrophoresis-mediated cell patterning enabled the construction of hepatocellular hydrogel

structures organized at the cellular scale. Overall, the ability to dictate scaffold architecture coupled with other advances in scaffold material properties, chemistries, and the incorporation of bioactive elements (discussed further in the "Extracellular matrix for cell therapies" section) will serve as the foundation for the future development of improved tissue-engineered liver constructs that can be customized spatially, physically, and chemically.

In vivo models

While there have been impressive advances in cell culture models of the human liver, experimental animal models still play an important role in the effort to engineer liver therapies. Commonly performed surgeries such as bile duct ligation and partial hepatectomy are experimentally tractable models of acute liver injury, yet they are of little clinical relevance. Drug-induced (e.g., carbon tetrachloride, acetaminophen, or thioacetamide) hepatotoxicity to induce necrotic lesions is more recapitulative of human pathophysiology, but the phenotype is difficult to reproduce [87]. In addition, modeling chronic liver injury in animal models is problematic because they tend to rapidly correct severe hepatic damage after a few days, which is not representative of human disease progression and resolution [88].

In order to model a human-like context for liver injuries, it is necessary to develop improved, controlled models of human liver injury. Such animal models can be useful for the evaluation of human liver biology and the preclinical performance of candidate therapies and drugs [89,90]. To accomplish this, human hepatocytes can be transplanted orthotopically in immunocompromised mice with no liver injury via the injection of a cell solution and are useful for modeling human-specific drug metabolism, liver injury, and hepatotropic infections. However, on average, HT exhibits poor levels of engraftment ($\sim$10%–30%) [91].

Transplanted hepatocytes have the ability to expand preferentially if the host is compromised by injury or genetic modification. The first genetically engineered mouse model to demonstrate this was the Alb-uPA mouse that carries a uroplasminogen activator under an albumin promoter, causing liver injury and failure [92]. Aiming to improve on the Alb-uPA system, a transgenic model of hereditary tyrosinemia I was developed, in which a genetic knockout of FAH leads to the hepatotoxic accumulation of fumarylacetoacetate [93]. FAH knockout mouse injury initiation and duration can be controlled through the administration of a small molecule drug [2-(2-nitro-3-trifluoro-methylbenzoyl)-1,3-cyclohexanedione] in the drinking water. Another inducible model called TK-NOG, which expresses thymidine kinase under an albumin promoter, causes hepatocyte ablation following activation by ganciclovir treatment [94]. In the AFC8 injury model, induction by the small molecule AP20187 drives caspase-8-initiated apoptosis of hepatocytes modified to express FK506 under an albumin promoter [95]. For all of the above models, engraftment rates surpassing 70% have been observed.

A classical study in parabiotic rats in the 1960s revealed that hepatic injury results in the expression of systemic, soluble signals that have the potential to drive liver regeneration [96]. Despite decades of research, the complex signaling cascade driving liver regeneration is still not well understood but has found utility in ectopic humanized mouse models. Chronic liver injury often presents with high portal pressures, which can reduce engraftment levels during an orthotopic transplantation. Thus transplantation to ectopic sites is clinically attractive. Ectopic grafts that anastomose to the host vasculature can interact with regenerative stimuli from the host liver, causing expansion and proliferation of the transplanted human hepatocytes. Initially, ectopic transplantation was demonstrated in the LN [40] and spleen [97], and later in the subcutaneous space and mesenteric fat pad, both of which offer ease of accessibility for manipulation and noninvasive imaging [58,59,98].

Taken together, the range of liver injury animal models are an essential tool for studying various perturbations to normal liver biology and building implantable tissue constructs to address acute and chronic liver failure. The field is just beginning to uncover mechanisms that control liver regeneration in various disease and injury contexts. The discovery of new soluble regenerative signals will be central to advancing therapies that have the potential to improve the supply of donor tissue.

Cell sourcing

Cell number requirements

The development of cell-based therapies poses myriad challenges, partially stemming from the scale of the liver. An adult human liver is estimated to possess 241 billion hepatocytes, 24 billion stellate cells, and 96 billion Kupffer cells [99]. Sourcing such enormous cell numbers using current technologies is not feasible.

However, many human HT studies suggest that clinical intervention is possible with a fewer number of cells and offer critical insights to help us determine minimum cell numbers. In a review, Fisher and Strom cataloged 78 different human HT studies, detailing both the input cell number and a qualitative description of functionality [30]. Correlating these, we can broadly surmise that to correct inborn errors of metabolism, at least 1–10 billion hepatocytes are needed. However, for ALF, that number grows to 5–20 billion cells. For liver cirrhosis, HTs have largely been unsuccessful (discussed further in the "Hepatocyte transplantation" section); therefore it is unclear what the

cellular requirements for cirrhosis are. While injection of hepatocytes is not the same as implantation within a scaffold, these studies serve as useful inputs into more complex physiological models.

In order to get us closer to these numbers, many different cell sources have been explored.

Immortalized cell lines

Immortalized hepatocyte cell lines can be derived from liver tumor tissue or directly from primary hepatocytes in vitro. The prominent lines utilized today are HepG2, derived from hepatocellular carcinoma; HepaRG [100], a human bipotential progenitor cell line; C3A, derived from HepG2s; and Huh7, derived from liver tumor [101]. Several other fetal and adult hepatic cell lines have also been established, typically using a combination of viral oncogenes and the human telomerase reverse transcriptase protein [102]. However, these cell lines lack the full functional capacity of primary adult hepatocytes and there is a risk that oncogenic factors could be transmitted to the patient, limiting their use as a cell source for transplantation therapies.

Primary cells

Unlike immortalized lines, PHHs can provide a whole host of human liver-specific function. PHHs, however, are limited in supply, and their phenotype is difficult to maintain in vitro. Many methods have been developed for maintaining long-term functionality of hepatocytes through the use of a variety of configurations and biomaterial constructs, which are further discussed in the "In vitro models" section. Due to limitations in the supply of mature human hepatocytes, many groups have attempted to promote the expansion and proliferation of PHHs in vitro. Peng et al. have shown that TNFα promotes the expansion of hepatocytes in 3D cultures and enables serial passaging and long-term culture for more than 6 months [103]. In a similarly notable study, Hu et al. identified an optimal cell culture cocktail consisting of B27 supplement (without vitamin A), R-spondin, CHIR99021 (a Wnt agonist), NAC, nicotinamide, gastrin, epidermal growth factor (EGF), TGFα, fibroblast growth factor (FGF)7, FGF10, HGF, a TGFβ inhibitor (A83-01), and ROCK inhibitor that led to long-term 3D organoid culture of PHHs [104].

Fetal and adult progenitors

Given their ability to differentiate into diverse lineages both in vitro and in vivo, iPSC and human embryonic stem cell cultures can also be utilized to generate HLCs. Various differentiation protocols have been applied to these cultures to yield cell populations that exhibit some phenotypic and functional characteristics of hepatocytes [62,105–108]. These populations are termed HLCs because of their expression of fetal proteins and fetal-like cytochrome P450 profiles [109]. While they are distinct from mature adult hepatocytes, HLCs can still serve as a potential cell source in very specific contexts.

In addition to pluripotent cells, bipotential progenitor cells can also serve as a source for hepatocytes. Huch et al. delineated conditions that allow for long-term expansion of adult bile duct-derived EpCAM + bipotential progenitor cells from the human liver [110]. The expanded cell population attained using their protocol is stable at the chromosomal level and can be converted into functional HLCs in vitro and in vivo [110].

Reprogrammed hepatocytes

HLCs can also be generated using direct reprogramming of mature cell types. For example, several groups have demonstrated the feasibility of reprogramming fibroblasts into HLCs without a pluripotent intermediate [111–113]. Cheng et al. demonstrated that a combination of nuclear factors can stimulate the conversion of hepatoma cells to HLCs [101]. These findings raise the future possibility of deriving human HLCs directly from another adult cell type.

Extracellular matrix for cell therapies

The ECM of the liver provides a structural scaffold with bioactive cues that modulate hepatic function and promote vascularization. Collagen and fibronectin are the major structural components of the liver ECM. Along with other nonstructural proteins, these components participate in integrin-mediated signaling between cells and their surrounding matrix. Hepatocytes are sensitive to their ECM, and it has been demonstrated that the presence of abnormal amounts and/or types of ECM components correlates with the onset and progression of liver fibrosis [114].

ECM scaffolds for hepatic tissue engineering are useful for constructing 3D tissue models and as a delivery vehicle for implants. Polymeric biomaterial hydrogels gained popularity as an engineering tool for recapitulating a physiologically relevant 3D tissue niche. Aside from creating a permissive environment for hepatocyte survival and growth, ECM scaffolds for hepatic tissue engineering also enable the formation of biliary and vascular networks that will be further discussed in the "Vascular and biliary tissue engineering" section. Broadly speaking, ECM scaffolds can be constructed using synthetic and/or naturally derived polymers.

Natural scaffold chemistry and modifications

A wide range of natural biomaterial polymers spanning polysaccharides (e.g., dextran and chitosan), peptides (e.g., collagen and fibrin), decellularized ECM (dECM), and composites of these have been employed as hepatic tissue−engineering scaffolds [55,57,58,115−121]. The advantages of biologically derived materials include their biocompatibility; naturally occurring cell adhesive moieties; and, in the case of decellularization, native architectural presentation of ECM molecules. However, naturally derived biomaterials have several barriers to use in the clinic, primarily due to lot-to-lot variability and xenogeneic origin.

The choice of material determines the physicochemical and biological properties of the scaffold. For example, early efforts in developing implantable hepatic constructs utilized collagen-coated dextran microcarriers that enabled hepatocyte attachment since hepatocytes are known to be anchorage-dependent cells. The intraperitoneal transplantation of these hepatocyte-attached microcarriers resulted in successful replacement of liver functions in two different rodent models of genetic liver disorders [122]. Subsequently, collagen-coated or peptide-modified cellulose [120,123], gelatin [124], and gelatin−chitosan composite [125] microcarrier chemistries have also been explored for their capacity to promote hepatocyte attachment. On the other hand, materials that are poorly cell adhesive such as alginate [115] have been exploited for their utility in promoting hepatocyte−hepatocyte aggregation (i.e., spheroid formation) and phenotypic stabilization within these scaffolds. Collectively, the size of engineered tissues created by these approaches is limited by oxygen and nutrient diffusion to only a few hundred microns in thickness.

To address this constraint, recent work has sought to use decellularized whole organ tissue as a matrix for liver tissue engineering. The decellularization process utilizes perfusion-based technologies to remove cells from donor tissues but preserve the structural and functional characteristics of the native underlying tissue. Recent advances in decellularization protocols have yielded scaffolds with native liver ECM composition, growth factor presentation, vascular structure, and biliary network architecture [126−128]. To date, seeding protocols have achieved up to 95% efficiency of recellularization with relevant cell populations (e.g., hepatocytes, vascular cells and bipotent hepatic progenitors); resulting recellularized grafts exhibited liver-specific function, and survival after transplantation in rodents [121,126,129]. Furthermore, cell-laden, xeno-derived dECM scaffolds are compatible with immunocompetent animal models [128]. However, given the shortage of donor tissue, the wide use of dECM scaffolds is unlikely.

Synthetic scaffold chemistry

In contrast to biologically derived material systems, synthetic materials enable precisely customized architecture (porosity and topography), mechanical and chemical properties, and degradation modality and kinetics, which are known to drive cell behavior. Synthetic materials that have been explored for liver tissue engineering include poly(L-lactic acid) (PLLA), PLGA, poly(ε-caprolactone), and PEG [85,98,130−135]. Polyesters such as PLLA and PLGA are the most common synthetic polymers utilized in the generation of porous tissue-engineering constructs. These materials are biocompatible, biodegradable, and have been used as scaffolds for HT [132,136]. A key advantage of PLGA is the potential to finely tune its degradation time due to differences in susceptibility to hydrolysis of the ester groups of its monomeric components (lactic acid and glycolic acid). However, the accumulation of hydrolytic degradation products has been shown to produce an acidic environment within the scaffold which initiates peptide degradation and stimulates inflammation, which may affect hepatocyte function [137]. Consequently, as alternatives to macroporous scaffold systems, approaches aimed at the efficient and homogeneous encapsulation of hepatocytes within a fully 3D structure have been explored. In particular, hydrogels that exhibit high water content and thus similar mechanical properties to tissues are widely utilized for various tissue-engineering applications, including hepatocellular platforms. Synthetic, PEG-based hydrogels have been increasingly utilized in liver tissue-engineering applications due to their high water content, hydrophilicity, resistance to protein adsorption, biocompatibility, ease of chemical modification, and the ability to be polymerized in the presence of cells, thereby enabling the fabrication of 3D networks with uniform cellular distribution [138]. PEG-based hydrogels have been used for the encapsulation of diverse cell types, including immortalized and primary hepatocytes and hepatoblastoma cell lines [85,98,135]. The encapsulation of primary hepatocytes requires distinct material modifications [e.g., 10% w/v PEG hydrogel, inclusion of RGD adhesive motifs] as detailed below, as well as, analogous to 2D coculture systems, the inclusion of nonparenchymal supporting cell types such as fibroblasts and endothelial cells [135].

Modifications in scaffold chemistry

The relatively inert nature of synthetic scaffolds allows for the controlled incorporation of chemical/polymer moieties or biologically active factors to regulate different aspects of cellular function. Chemical modifications such as oxygen plasma treatment or alkali hydrolysis of PLGA [139,140], or the incorporation of polymers such as

poly(vinyl alcohol) or poly(*N*-*p*-vinylbenzyl-4-*O*-β-D-galactopyranosyl-D-glucoamide) (PVLA) into PLGA or PLLA scaffolds [132,141,142] have improved hepatocyte adhesion by modulating the hydrophilicity of the scaffold surface [143]. Biological factors may include whole biomolecules or short bioactive peptides. Whole biomolecules are typically incorporated by nonspecific adsorption of ECM molecules such as collagen, laminin, or fibronectin [139,144]; covalent conjugation of sugar molecules such as heparin [145,146], galactose [131,147], lactose [145] or fructose [148]; or growth factors such as EGF [149]. Alternatively, short bioadhesive peptides that interact with cell surface integrin receptors have been extensively utilized to promote hepatocyte attachment in synthetic scaffolds. For example, conjugation of the RGD peptide to PLLA has been shown to enhance hepatocyte attachment [150], whereas RGD modification significantly improved the stability of long-term hepatocyte function in PEG hydrogels [98,135]. The additional incorporation of adhesive peptides that bind other integrins may serve as a way to further modulate and enhance hepatocyte function within synthetic polymer substrates. Moreover, Stevens et al. demonstrated that integration of matrix metalloproteinase-sensitive peptide sequences into hydrogel networks as degradable linkages has been shown to enable cell-mediated remodeling of the hydrogel [151].

The capacity to modify biomaterial scaffold chemistry through the introduction of biologically active factors will likely enable the finely tuned regulation of cell function and interactions with host tissues important for implantable systems.

Porosity

A common feature of many implantable tissue-engineering approaches is the use of porous scaffolds that provide mechanical support, often in conjunction with cues for growth and morphogenesis. Collagen sponges, various alginate and chitosan composites, and PLGA are the most commonly used porous scaffolds for hepatocyte culture and are generally synthesized using freeze-dry or gas-foaming techniques. Pore size has been found to regulate cell spreading and cell−cell interactions, both of which can influence hepatocyte functions [116], and may also influence angiogenesis and tissue ingrowth [152]. Porous, acellular scaffolds are normally seeded using gravity or centrifugal forces, capillary action, convective flow, or through cellular recruitment with chemokines, but hepatocyte seeding is generally heterogeneous in these scaffolds [153,154].

Vascular and biliary tissue engineering

Beyond compatibility with hepatic cell types, scaffolds should also be conducive to vasculature formation. Relying on vascularization by the host is not sufficient for large tissue constructs required for the clinic, because cells that are not near capillary structures ($>150-200\ \mu m$) are at a risk for necrosis after a matter of hours due to a lack of oxygen, nutrient availability, and waste transport. In this section, we discuss composite approaches toward building scalable, vascularized constructs.

Vascular engineering

Approaches to engineering vessels can generally be categorized as bottom-up induction of vascular assembly and top-down fabrication of vascular conduits [155]. Bottom-up vascular engineering approaches are built upon the idea of neovascularization, or new vessel formation. Vessel formation can occur by angiogenic sprouting, the formation of vessels branching off of an existing blood vessel, or vasculogenesis, the self-assembly of single endothelial cells or progenitor cells into lumenized vessels. Despite the ability of single vascular cells to coalesce to enable self-assembly, vasculogenesis is accelerated by coculture with supporting stromal cells, such as fibroblasts, mesenchymal stem cells, and pericytes [155−157]. Studies exploring angiogenesis and sprouting events suggest that chemical gradients, fluid-driven shear stress, and a hypoxia are key players in vessel formation [158−161].

Top-down fabrication approaches dictate geometry and architecture, rather than driving self-assembly. Polymer molding using microetched silicon has been shown to generate extensive channel networks with capillary dimensions, though it is not amenable to high-throughput manufacturing [162]. While direct printing of cells can be cytotoxic, 3D printing has become a popular approach for fabricating hollow channels that enable vascular cell seeding. The challenge lies in using this approach to build patent capillary beds, which are $5-10\ \mu m$ in diameter. While two-photon polymerization has an impressively high feature size resolution at 100 nm, the trade-off between build volume (i.e., building constructs large enough for clinical impact), build speed (i.e., impacting manufacturability), and printer resolution renders it inappropriate for most applications in tissue engineering. Alternate printers using direct-ink writing (DIW) of viscoelastic materials have emerged as a powerful tool for the fabrication of patterned hydrogel constructs. DIW can achieve minimum feature size resolutions from 1 to 250 μm, depending on the ink "building block" size [163]. However, DIW printing requires yield-stress fluid inks with restrictive viscosities (10^2-10^6 mPa s), such that they fluidize under stress but regain the original shear elastic modulus after printing [163]. Kolesky et al. demonstrated that DIW and fugitive inks were useful for multimaterial printing as well as

construction of thick (>1 cm), vascularized tissues [164,165]. Miller et al. demonstrate the use of thermal microextrusion approach to create sacrificial sugar glass lattices that can be embedded in various cell-laden biomaterials, evacuated and subsequently lined with vascular cells [166].

Taken together, self-assembly driven formation of a capillary bed can be combined with printing of larger vessels to enable the fabrication of a fully vascularized tissue construct. Song et al. used 3D printing to create curved vascular channels using a fugitive ink [159]. The vascular cells lining the channel were able to degrade the surrounding hydrogel matrix and undergo sprouting when exposed to angiogenic factors. They further demonstrated that the curvature and complexity of printed vasculature impacted the extent of sprouting, which will be an important consideration for vessel patterning in future clinical applications [159].

Host integration

For vascularized constructs to survive after implantation the engineered vessels must anastomose with the host vasculature. To date, the exact mechanism that drives integration with the host is not well understood [155]. A number of studies have elucidated the contribution of cytokines important in angiogenesis and recruitment of host vasculature in implant constructs, such as vascular EGF (VEGF) [136], basic FGF [167], and VEGF in combination with platelet-derived growth factor [168]. Furthermore, preimplantation of VEGF releasing alginate scaffolds prior to hepatocyte seeding was demonstrated to enhance capillary density and improve engraftment [169]. In addition, while building an AL tissue construct, Stevens et al. demonstrated that the coimplantation of parallel endothelial cell cords with PHH and fibroblast spheroids led to better hepatic performance and survival when compared to an implant with nonpatterned endothelial cells, suggesting that there may be an optimal templated endothelial geometry that enables vascularization and host integration in vivo [58]. Surgical anastomosis poses an alternative to biologically driven anastomosis, though this approach requires invasive surgery and access to suture-able vessels both in the graft and in the host. Strategies to incorporate vasculature into engineered constructs include the microfabrication of vascular units with accompanying surgical anastomosis during implantation [75,170].

In addition to interactions with the vasculature, integration with other aspects of host tissue will constitute important future design parameters. For instance, incorporation of hydrolytic or protease-sensitive domains into hepatocellular hydrogel constructs could enable the degradation of these systems following implantation [151]. Of note, liver regeneration proceeds in conjunction with a distinctive array of remodeling processes such as protease expression and ECM deposition. Interfacing with these features could provide a mechanism for the efficient integration of implantable constructs. Similarly to whole liver or cell transplantation, the host immune response following the transplant of tissue-engineered constructs is also a major consideration. Immunosuppressive treatments will likely play an important role in initial therapies, although stem cell–based approaches hold the promise of implantable systems with autologous cells. Furthermore, harnessing the liver's unique ability to induce antigen-specific tolerance [171] could potentially represent another means for improving the acceptance of engineered grafts.

Biliary network engineering

Importantly, future iterations of hepatic grafts should include a biliary system, which is responsible for excretory functions. In a similar vein, we envision that a combination of "top-down" manufacturing, such as the aforementioned technologies for generating patent vascular conduits, and "bottom-up" approaches, which could involve leveraging biological phenomena that drive biliary morphogenesis, will be useful for building a biliary network.

The biliary tree is a complex, 3D network of tubular conduits of various sizes and properties. The liver contains an intrahepatic compartment that is lined by biliary epithelial cells, termed cholangiocytes, that aid in the modification and removal of hepatocyte-secreted bile. Even though the blood vessel–fabrication approaches delineated above have not yet been applied to engineering bile networks for implantable liver constructs, advancements in cholangiocyte sourcing methods have made it feasible. Sampaziotis et al. identified a protocol for directed differentiation of human iPSCs into cholangiocyte-like cells [172]. In 2017 the same group provided the first proof-of-concept study to reconstruct the gallbladder wall and repair the biliary epithelium using human primary cholangiocytes expanded in vitro [173]. Furthermore, current studies are focused on the development of in vitro models that exhibits biliary morphogenesis and recapitulates appropriate polarization and bile canaliculi organization [174–176], as well as platforms for the engineering of artificial bile duct structures [177,178].

Conclusion and outlook

Traditionally, hepatic tissue–engineering research has focused on designing the microenvironment to support a stable hepatic phenotype. As concomitant advances in pluripotent cell research and polymer chemistry have been actualized, new cell sources and extracellular

matrices have been added to the pipeline. This interdisciplinary synergy has been the driving force behind the development of tissue-engineered grafts with long-term survival and growth. In order to inch closer to the regenerative medicine north star of an ex vivo engineered graft that can serve as a replacement for the native organ, there are several areas to consider for improvement: (1) vascularization of thick, dense grafts through a combination of self-assembly and bioprinting; (2) engineering of the hepatic graft to prevent immune rejection in allogeneic and xenogeneic settings; (3) improved understanding of metabolic and cellular requirements of various liver diseases; (4) development of scalable, renewable cell sources that do not compromise the functional capabilities of cells; (5) leveraging of animal injury models as bioreactors for cell sourcing; and (6) upscaling of grafts in a manner that is compatible with FDA's Good Manufacturing Practice standards.

Introduction

Transplantation of hematopoietic stem cells (HSCs) shows promising prospect for broad-spectrum hematological disorder therapy, owing to their potential to generate the entire hematopoietic lineages [1,2]. However, the limited number of HSCs in either bone marrow (BM) or umbilical cord blood (UCB) limits their widespread use [3]. Hence, there is great interest in developing methods for ex vivo expansion and thus self-renewal of HSCs [4,5]. Strategies based on nanomaterials or nanotechnologies seem hopeful to expand HSC numbers more efficiently and tune their properties ex vivo [6,7]. In this chapter, we focus on recent advances in biomaterials-based tissue engineering studies of HSCs, such as hematopoietic niche mimic, functional regulation, and other potential applications. Moreover, we proposed the future scientific issues to be solved in advancing the preclinical translations.

Hematopoietic stem cells and hematopoietic stem cells niche

As the best characterized adult stem cells that had been identified nearly 60 years ago [8], HSCs own remarkable characteristics, including continuous self-renewal and differentiation into cells of all mature blood lineages [9]. Over past years, multiple surface markers have been used to identify, isolate, and purify HSCs [10]. For example, long-term HSCs (LT-HSCs) have been phenotypically defined as Lin-Sca-1 + c-Kit + Flt3 − CD34 − CD150 + CD48 − in mouse [11] and Lin-CD34 + CD38 − CD45RA − CD90 + CD49f + in human [12].

Due to progress in the understanding of the molecular mechanisms involved in regulating maintenance and expansion of hematopoietic stem/progenitor cells (HSPCs), a number of cytokines have been reported to play crucial roles in the proliferation, differentiation, and self-renewal of HSCs. These include stem cells factor (SCF), thrombopoietin (TPO), Angipoietin-1, Jagged-1, CXCL12 (also known as stromal cell-derived factor-1, SDF-1), IL-1, IL-3, IL-6, IL-11, IL-12, granulocyte colony-stimulating factor (G-CSF), and granulocyte−macrophage colony-stimulating factor (GM-CSF), which are reviewed in Refs. [13,14]. In addition to the hematopoietic cytokines, signaling pathways have also been shown in various models involved in the proliferation, differentiation, and self-renewal of HSCs, including Notch [15], Wnt [16], BMP [17], Hedgehog [18], Jak-Stats [19], Polycomb-group (PcG) proteins [20], and Homeobox (Hox) family [21].

HSCs are rare cells (about 0.005%−0.01%) normally located in BM [22], and they can migrate through the blood circulation into other tissues under certain conditions [23]. Two hematopoietic growth factors, G-CSF and GM-CSF, are commonly used as HSC mobilizing agents [24]. G-CSF treatment for mobilization of HSCs is the most efficient way to collect HSCs for clinical BM transplantation. Previous study demonstrated that murine HSCs increased within the central BM region after 4 days G-CSF administration, but not within the endosteal region [25]. This study suggested that HSCs respond differently to G-CSF, which is dependent on their locations. Homing of HSC to BM is also facilitated by chemokines [26]. The perivascular stromal cells of sinusoidal vessels produce CXCL-12 (SDF-1), while CXCR4 (receptor of CXCL-12) is expressed on HSCs. The SDF-1/CXCR4 pathway is essential for HSCs migrating from fetal liver to BM during development and plays a major role in directing the migration of

HSCs [27]. Mobilization and homing processes provide theoretical basis for transplantation of HSCs.

HSCs transplantation have already been used in the clinic to treat various hematopoietic malignancies [28], such as leukemia [29], multiple myeloma [30], lymphoma [31], anemia, and myelodysplastic syndrome [32]. The source of transplanted HSCs can be isolated from BM, UCB, or mobilized peripheral blood of either patient's own (autologous) or a HLA-matched donor (allograft) [28], and the number of HSCs correlated with successful engraftment and patient survival [30]. High numbers of CD34 + cells (3×106/kg body weight) are clinically required for a successful transplantation, but the number of HSCs in a given graft may not be sufficient for transplantation proceeding [33]. Therefore methods for HSCs expansion ex vivo would be highly desirable.

However, HSCs rapidly differentiate and lose their self-renewal ability in vitro due to the lack of suitable microenvironment [34]. The local environment of HSCs in BM is referred to as stem cell niche, which is composed of extracellular matrix (ECM), stromal cells, and other cells (Fig. 41.1) [35,36]. Signals from niche components are essential for the regulation of HSC self-renewal and differentiation [37]. Cytokines including SCF, TPO, Jagged-1, SDF-1α, fms-related tyrosine kinase 3-ligand (Flt3L) are known molecular signals for self-renewal, quiescence, and engraftment in vivo [38–40]. These factors are usually secreted by other niche cells, such as osteoblasts, megakaryocytes, and perivascular cells (Table 41.1). ECM components distributed throughout the HSCs niche, such as fibronectin, collagens, and proteoglycans, can be sensed by HSCs through interaction with integrins, contributing to regulate HSCs [41–43]. Furthermore, ECM actively allows binding of cytokines and therefore favoring localization of HSCs [44,45]. Both cellular and extracellular components are key parts in the HSCs niche, and development of a functional hematopoietic microenvironment in vitro cannot ignore either of them.

Effects of biomaterials on hematopoietic stem cells

Biomaterials are natural or synthetic materials to replace or interact with biological system [60,61]. Extensive attempts to recreate HSCs niche by biomaterials in vitro had been reported (Table 41.2). As the HSCs niche is a fully 3D tissue, recent focus mainly aimed at developing 3D biomaterials to achieve niche-inspired signals. The use of biodegradable hydrogels for HSCs niche mimicking has increased, because they provide a 3D system that supports cell adhesion and mechanosensing [62,63]. Hydrogels can be made from natural (collagen [64], chitosan [65], hyaluronic acid [66], etc.) and synthetic (Polyethylene glycol (PEG) [67], Poly-L-lactic acid (PLLA) [68], etc.) polymers. Specific growth factors or molecules can be conjugated to hydrogel [69]. Conjugation of the PEG hydrogel with SCF and IFN-γ increased the total HSC population by maintaining stemness [70]. Another 3D platform for HSCs expansion is sponge-like porous scaffolds with interconnected network of pores to allow the exchange between nutrients and cells, and several materials have been used to construct porous scaffolds, such as collagen [71], PEG [72], and Polyurethane [73]. Moreover, nanofiber-based platforms have also been used to study HSCs. Carboxylic acid

functionalized carbon nanotubes (CNT-COOH) was reported to increase the viability and support ex vivo expansion of HSCs in human UCB-derived mononucleated cells without adding any cytokine, particularly of CD45 + CD34 + CD38 − population and GM unit [74].

However, the safety and effectiveness of biomimicking materials to HSCs were often neglected. For maintaining clinical HSCs standard, both the starting and constructed materials should not show any negative effect on self-renewal, differentiation, migration, or cytotoxicity to HSCs [85]. But such data were wholly or partially absent in most of the related studies. In vitro expansion and differentiation potentials are major focused effects of biomimicking materials to HSCs. More completed data about interaction between HSCs and biomaterials-based ex vivo expansion system would promote us to design more suitable and effective expansion system for clinical application.

Applications

Engineering hematopoietic stem cells niche for in vitro expansion

Except for combining 3D platforms and cytokines (SCF, TPO, Flt3L, IL-3, etc.), other factors such as interacting cells and physical cues in engineering HSC niche have also been reported in the ex vivo expansion of HSCs. The coculture of HSCs with other niche cell populations, such as MSCs, osteoblasts, and megakaryocytes, is commonly

used to support HSCs growth and differentiation in vitro. In a previous study, HSCs were cocultured with mesenchymal stem cells (MSCs) and/or osteoblasts in decellularized bone scaffolds. The efficiency of expansion of HSCs in mixed cells (MSCs and osteoblasts) was much higher than those of individual MSCs or osteoblasts [86]. However, it is more difficult to separate HSCs from other cells in the mixed coculture system. Thus a noncontact coculture system should be established. For example, two types of cell can be placed on two sides with an efficient exchange of growth signals by using nanofiber platforms [87].

Moreover, modulation of physical factors, such as stiffness, dimensionality, and topography, has also been evaluated. Glycosaminoglycan was employed to modulate stiffness of hydrogel, and results showed HSCs formed less proliferative clusters in stiff cultures, compared to the soft hydrogel [88]. A range of fabrication cues can be used to manipulate architecture of scaffolds, such as electrospinning [89], lyophilization [90], and laser sintering [91]. Commonly, 3D culture systems have resulted in increase in HSC expansion compared to 2D cultures, and this was further enhanced by TPO and Flt3 supplementation [84]. In addition, fibronectin-immobilized positron emission tomography (PET) scaffolds led to a 100-fold expansion of human HSCs [92].

The most recent system for ex vivo expansion of HSCs is the BM-on-a-chip [93]. A poly(dimethylsiloxane) device with a central cylindrical cavity was microfabricated and filled with collagen gel and then perfused with culture medium in a microfluidic device. The engineered BM facilitates maintenance of a significantly higher proportion of LT-HSCs in vitro and retains hematopoietic stem and progenitor cells in normal in vivo-like proportions for at least 1 week. This technique provided an improved platform for producing HSCs naturally.

Considering the vasculature is critical in HSCs maintenance [94], the major caveat in mimicking HSCs niche is the lack of precise vascular structure. To overcome this issue the precise roles of each type of vessels should be explored. Moreover, the achievement of sustainable culture by developing vascular-on-a-chip should provide a clue [95] (Fig. 41.2).

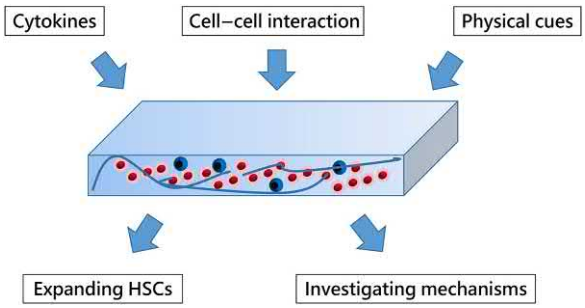

FIGURE 41.2 Current approaches for engineered HSCs niche. *HSCs*, Hematopoietic stem cells.

Manipulation of the multilineage differentiation of hematopoietic stem cells

By the construction of biomimic HSCs niche, we can also study the interactions between HSCs and the niche, more than just expanding clinical cell populations. BM is composed of two distinct niche (endosteal and vascular niches) that vary in a few properties including stiffness, types of feeder cells, oxygen concentration and distribution of cytokines [96,97]. The endosteal niche, closer to the trabecular bone, is home to quiescent HSCs by maintaining stemness, whereas primed HSCs are located more actively in the vascular niches [36]. Thus the differentiation of HSCs could be manipulated in vitro based on this theory.

In a previous study, when HSCs were seeded on a collagen hydrogel embedded with MSCs, HSCs' population migrated inside the hydrogel and presented a high level of primitive HSCs, while the HSCs that stayed above the hydrogel were differentiated [71]. Migrated HSCs received the majority of the cytokines provided by MSCs, while HSCs on the surface received much less, which suggested that the gradients of cytokines or other signals affect the fate determination of HSCs. Another study also reported that hydrogels with a high diffusivity can increase the paracrine signals between cocultured HSCs and Lin + fraction of BM cells, which caused the differentiation of HSCs into myeloid and lymphoid progenitor cells [75]. On the contrary, hydrogels with low diffusivity increased the number of primitive HSCs. Generally, a lower diffusivity required a higher concentration of starting materials, and thus a stiffer hydrogel promotes the stemness of HSCs because of the increased autocrine signals. Furthermore, 3D polyvinyl formal resin scaffolds with low oxygen led to maintenance of primitive HSCs, whereas hypoxia environment led to higher expansion [92]. In addition, feeder cells are commonly used to manipulate the differentiation into multiple lineage, such as myeloid, lymphoid, and megakaryocytic cells.

However, an adequate BM mimicking platform with the same variations between endosteal and vascular is challenging. Microfluidic-based systems have been widely used to generate gradient distribution of cytokines and ECM proteins in hydrogels [98]. A previous study demonstrated the effect of the gradient conjugation of SCF in hydrogel to the HSCs via a microfluidic system, and the gradient of cocultured osteoblasts and HSCs can also be generated [82,99]. Scaffolds with gradient in other cytokines and feeder cells should also be constructed and evaluated in future.

In vivo tracking hematopoietic stem cells

Although HSCs transplantation was successfully used in clinical therapies, numerous important issues remain lack of study. How many transplanted HSCs home into BM and contribute to hematopoiesis in a given time? How often the HSCs divide and how about their fate determination in vivo? Several groups have established different techniques to track the transplanted HSCs.

Many studies analyzed HSCs cell cycle by labeling cells with DNA dyes [100,101]. For example, BrdU was given orally or by intraperitoneal injection, and the kinetic of BrdU could be detected by fluorescent-activated cell sorting to provide information about cell division [102]. By doing this, it is estimated that about 8% of a population enriched by surface marker of HSCs randomly enter into cell cycle per day, and all HSCs enter into cell cycle on every 57 days. However, BrdU-mediated DNA labeling requires cell fixation, which prohibits testing of the functionality of labeled HSCs. Methods for labeling cell surface or cytoplasmic protein can trace cells real time; however, labeled cells would be diluted as cell division [103,104]. For example, a previous study reported biotin−avidin-labeled HSCs were mainly found in BM after 1 week, and primitive HSCs showed higher label signals than other mature hematopoietic cells [105]. However, low divisional resolution could distinguish maximally to only four divisions, which limited the long-term in vivo tracking.

In addition, current approaches for HSCs in vivo tracking were based on bioluminescence imaging (BLI) [106]. However, the limitation of light transmission through tissue restricts the applications of BLI in small animal models, because light signal can hardly penetrate large tissues in human [107]. In contrast, magnetic resonance imaging (MRI) can provide high penetration signal and 3D information, which appears to be a useful way for in vivo tracking of HSCs [108]. Magnetic labeling is required in MRI, and the magnetic contrast agents are safe to HSCs. The same goes for nuclear imaging (NI), such as PET and single-photon emission computed tomography, but the use of radioactive substances which lead to genotoxicity lacks study. However, multimodality imaging combines BLI, MRI, and/or NI, which provides dual benefits of high sensitivity and resolution [109].

Future perspectives

Over past decades, growing evidences indicated that HSC expansion in vitro might actually be achievable. This is based on a better understanding of HSCs niche and niche-HSCs interaction for regulating HSCs in vivo, which have led to novel strategies to expand HSCs ex vivo. However, we are currently in an early stage for moving forward the clinical applications of HSCs-based tissue engineering, and there is still abundant future work to be completed.

First, the safety and effectiveness of biomimicking materials to HSCs should be focused to meet clinical standard. Next, combination of 3D scaffolds, cytokines, feeder cells, and appropriate physical condition might provide a robust option for HSCs expansion ex vivo. Engineered HSCs niche also offered a tool to study the interaction mechanisms of HSCs and niche in vivo. Extensive mechanistic studies would further guide the design of engineered HSCs niche, which is necessary as a first essential step for clinical translation. Besides, more clinical approved contrast agents can be used in HSCs labeling for in vivo tracking real time, and multimodality imaging methods should be developed. Despite the numerous challenges faced when exploring the clinical translations, more in vitro and in vivo experiments are still essential to reduce clinical cost, and all these efforts will accelerate the development of HSCs-based tissue engineering in the future.

Acknowledgments

This work is supported by grants from the National Key R&D Program of China, Stem Cell and Translation Research (NO. 2018YFA0109300), the National Natural Science Foundation of China (NO. 81870080), the Outstanding Youth Project of Zhejiang Natural Science Foundation (NO. LR19H080001), China Postdoctoral Science Foundation (2019M662030), Stowers Institute for Medical Research (SIMR-1004), and NIH National Cancer Institute grant to University of Kansas Cancer Center (P30 CA168524).

Introduction and history of modern hematology

Hematopoiesis is a highly regulated, dynamic process for the generation and maintenance of all mature blood cell types. The discovery of the major cell types within the blood and their importance for human health was recognized many centuries ago. In the mid-1600s, Jan Swammerdam first reported the presence of red blood cells (RBCs) while examining samples under the microscope. Two hundred years later, in the mid-1800s, French physician Gabriel Andral and British physician William Addison first reported the discovery of white blood cells (WBCs). During this same era, French physician, Alfred Donne described the discovery of platelets [1]. Initial attempts to transfuse blood between humans occurred in the early 1800s; James Blundell first experimented with transfusing blood in up to 10 patients [2]. Even though little was known about blood typing at the time, he was successful in half of these cases, which prompted others to continue exploring the practice. In the early 1900s the Austrian physician, Karl Landsteiner, discovered the A, B, and O blood groups and the importance of matching blood types for successful and safe transfusion. He also helped discover the Rhesus (Rh) blood group system as another important consideration for ensuring safe transfusions [3]. These discoveries helped lead to further improvements in blood typing, collection, storage, fractionation, and transfusion practices over the course of the 20th century to treat various blood disorders, including hemophilia, hemorrhaging bleeding, and anemia. In the 1950s, both chemotherapy and bone marrow (BM) transplantation emerged as therapeutic options to treat hematologic malignancies. In 1956, Thomas was the first to successfully perform BM transplantation; he treated a boy with leukemia using BM collected from the boy's identical twin [4]. Later research highlighted the importance of and guidance for human leukocyte antigen (HLA) matching between donor and recipient for success of BM transplant and avoiding immune rejection and graft versus host disease [5]. It is now recognized that the hematopoietic stem cell (HSC) is the most critical component of BM for transplantation as it can give rise to all mature blood cell types. Today, more than 50,000 HSC transplantations (HSCTs) are performed each year [6], highlighting the importance of this procedure for treating hematologic diseases.

Long-term HSCs reside in the BM and sit at the top of the hematopoietic hierarchy. They give rise to short-term HSCs, which then further differentiate into early stage myeloid and lymphoid progenitors (Fig. 42.1).

Extrinsic cytokines and growth factors stimulate transcription factor activity to further drive lineage-specific differentiation programs, and through a multistep process, eventually generate the diversity of cell types seen in the peripheral blood (PB). Myeloid lineage progenitors give rise to erythrocytes, megakaryocytes (MKs)/platelets, monocytes, and granulocytes, while lymphoid lineage progenitors give rise to T, B, NK, and NKT cells (Fig. 42.1). As we discuss below, these cells each play a unique and vital role in maintaining human health; therefore the ability to replace or repair elements of the hematopoietic system during injury or disease is a major medical focus.

Red blood cells

Erythrocytes or RBCs are the most abundant cell type in the PB with an average of 5×10^{12} cells/L (Fig. 42.2). They represent 40%–45% of the total blood volume and have the critical role of binding and transporting oxygen

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00043-5

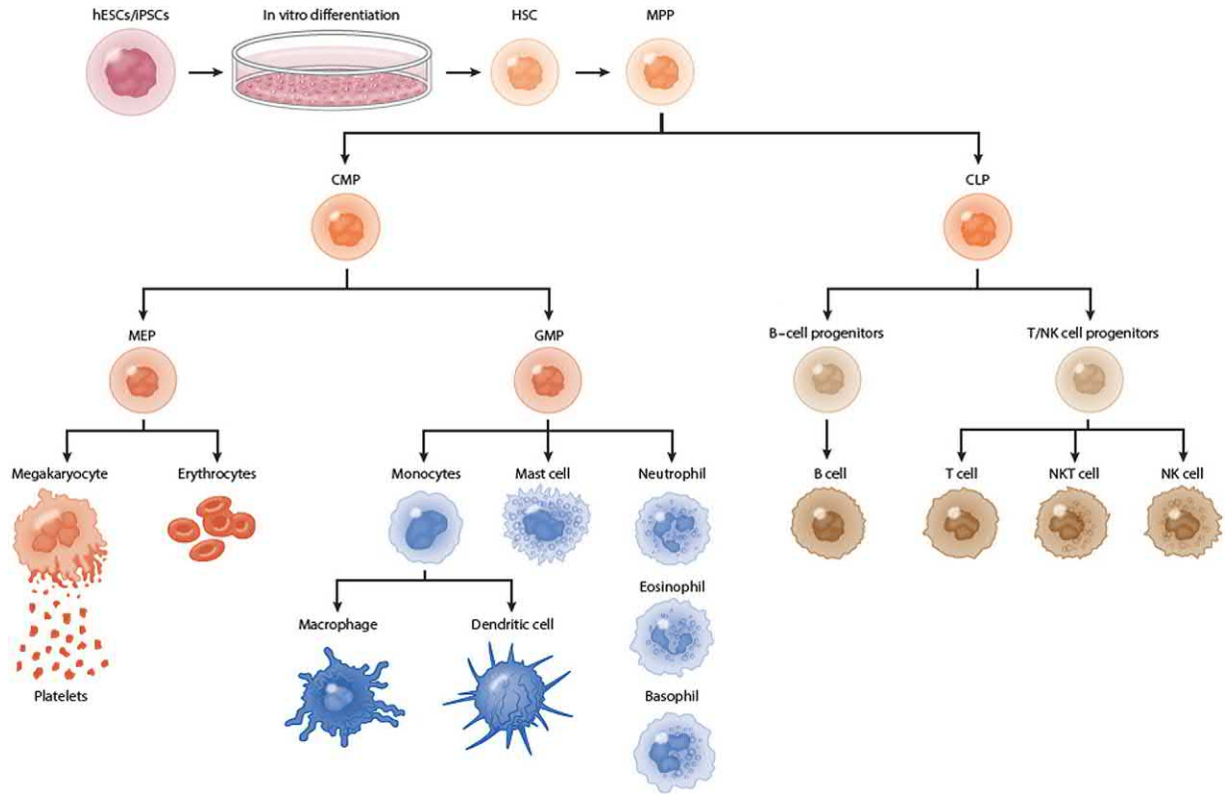

FIGURE 42.1 Hematopoietic hierarchy. All mature blood cell types within the adult hematopoietic system arise from HSCs in the bone marrow. hESCs/iPSCs can be induced to differentiate down the hematopoietic lineage in vitro with the goal of producing blood components that mimic those found naturally in the body. *hESCs*, Human embryonic stem cells; *HSC*, hematopoietic stem cell; *iPSCs*, induced pluripotent stem cells.

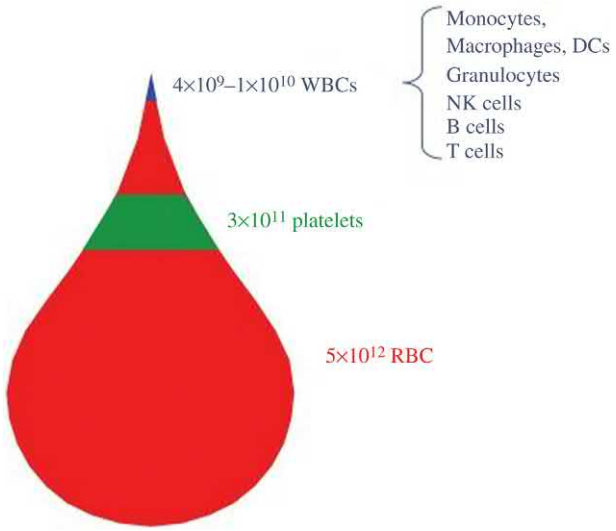

FIGURE 42.2 Number and types of cells per liter of human peripheral blood. PSCs can be differentiated toward these mature blood cell types in vitro. Ongoing efforts are aimed at improving the efficiency of differentiation and/or the maturation of PSC-derived blood components. *PSCs*, Pluripotent stem cells. *Reprinted with permission from Kimbrel EA, Lu SJ. Potential clinical applications for human pluripotent stem cell derived blood components. Stem Cells Int 2011;2011:273076.*

to tissues of the body. More than 14 million units of whole blood and apherised RBCs were collected for transfusion purposes in the United States in 2013 according to the National Blood Collection and Utilization Survey. This represents a 9% decline from previously reported numbers in 2011, likely due to improved patient blood management practices and alternative medical options for patients that used to be treated with transfusions [7]. Despite this trend, there is still a great demand for blood donation for the purpose of replacing RBCs in patients that have lost significant amounts of blood or are severely anemic. Moreover, universally immunocompatible blood, that is, (O) Rh − is perennially in short supply due to the low frequency of this blood type in the general population, with less than 8% of people in Western countries and less than 0.3% of people in Asia with this type.

RBCs contain hemoglobin, a 4-subunit, 4 heme-group containing protein that binds iron, which in turn binds oxygen. During early development, primitive, yolk-sac-derived RBCs contain embryonic hemoglobin (hemoglobin ε, epsilon). Further embryonic development leads to the initiation of definitive hematopoiesis within the fetal liver and the production of enucleated RBCs containing

fetal hemoglobin (HbF). The transition from fetal to adult globin occurs within the first few months of life [8]. HbF comprises two alpha and two gamma subunits, while adult hemoglobin (HbA) contains two alpha and two beta globin subunits. Sickle cell anemia and beta-thalassemia are two commonly inherited blood disorders that involve defects in HbA. Beta-thalassemia involves a defect in the production of beta globin, leaving its alpha counterpart unpaired, causing the death of erythrocyte precursors. Sickle cell disease involves the mutation of the beta globin gene, which causes hemoglobin to polymerize and distort RBCs into a "sickle" or crescent shape. These abnormally shaped cells can lead to clogging in blood vessels, pain, and impaired oxygen delivery to tissues. It is estimated that 300,000 children are born with these diseases each year, translating to several million people living with these disease worldwide [9]. In both situations, transfusion of normal RBCs can help.

In the adult BM, erythropoiesis involves the differentiation of the common myeloid progenitor (CMP) to an MK−erythroid progenitor, which then further differentiates and gives rise to the lineage-restricted preerythrocyte, followed by early, intermediate, and late erythroblast stages. At this point, the nucleus is extruded, and the cell is called a reticulocyte. Reticulocytes enter the PB, further mature into an RBC, and circulate for ~120 days prior to being phagocytosed by macrophages [10]. Stem cells within cord blood (CB), PB, and BM can all be induced to generate erythrocytes through cytokine-driven in vitro culture. Supplementation of culture media with erythropoietin (EPO), stem cell factor (SCF), and interleukin-3 (IL-3) facilitates this differentiation; coculture with stromal feeders, such as MS-5 or human mesenchymal stromal cells (MSCs), helps facilitate enucleation [11−13]. In a recent example, CB-derived CD34 + cells were differentiated ex vivo into RBCs using a four-step differentiation protocol. Here, SCF, thrombopoietin (TPO), and fms-like tyrosine kinase 3 (Flt3) ligand helped with initial expansion, while the combination of SCF, EPO, IL-3, granulocyte−macrophage colony stimulating factor, and Flt-3 ligand (FL) was used in the last stage of the 21-day protocol to facilitate the expansion and maturation of erythrocyte progenitors. Using this method, 1 million CD34 + CB cells gave rise to 2.9×10^{11} RBCs, with 90% expressing CD235a and 50% enucleated. Upon injection into immunodeficient NOD/SCID mice treated with sublethal irradiation, these RBCs survived for 3 days, similar to primary human RBCs, further matured, and enucleated. In a nonhuman primate model of hemorrhagic anemia, these RBCs enhanced hematologic recovery without adverse effects [14]. Only one study has tested clinical use of ex vivo produced RBCs. Here, PB CD34 + cells were differentiated into RBCs and reinfused into the patient without adverse effects [15]. These approaches, while feasible, are still limited by their donor-dependent sources and are expensive to produce for autologous use.

Pluripotent stem cells (PSCs) may serve as an off-the-shelf alternative to donated or ex vivo derived RBCs, particularly if starting from a universally immunocompatible (O) Rh − PSC line. Early studies have demonstrated the feasibility of using human embryonic stem cells (hESCs) for this purpose [16−20], and additional studies have shown similar proof of concept using induced PSCs (iPSCs) [21−24]. For example, in one such study, our group demonstrated that it was possible to obtain functional, oxygen-carrying erythrocytes from various starting PSC lines on a large scale [17] (Fig. 42.3). Another approach involves the use of ectopically expressed transcription factors to drive direct conversion of fibroblasts to hematopoietic progenitors and further differentiation into erythroid cells [25,26] or conversion of B cells to erythroid lineage cells [27]. Although several different approaches were used in the above studies, none were able to completely overcome two issues: inability of most cells to express beta globin (i.e., inability to undergo "globin-switching") and inefficient enucleation.

More recent studies are beginning to unravel the intricacies of these cellular events and finding ways to overcome the hurdles. Proteomic comparison of iPSC−RBCs with adult RBCs showed that although there was considerable overlap in the expression of more than 30 key erythroid markers, there were differences in the expression of cytoskeletal proteins, which the authors suggest could account for inefficient enucleation of the iPSC-derived RBCs [28]. In other studies, gene expression signatures during iPSC differentiation of RBCs were compared to that of adult, CB progenitors and/or K562 erythroleukemia cells. The pattern of gene expression for iPSCs differentiating into RBCs differed from these comparators. Among the differences, the key erythroid markers, Sox6, MYB, BCL11A, and KLF1 were downregulated, while embryonic hemoglobin ε was upregulated in iPSC derived versus the other sources of erythroid cells [29,30].

A strategy to overcome the block in globin switching for PSC-derived RBCs may be manipulating the expression levels of factors involved in globin switching [31,32]. In one study, increasing expression of BCL11A in an iPSC erythroid cell line called HiDep-1 was helpful for increasing beta globin levels, as BCL11A binds to locus control region and intergenic regions between gamma and beta globin to upregulate beta globin. This strategy worked in HiDep-1 cells likely because they already express high levels of KLF1, another critical factor involved in globin switching [29]. In another study, manipulation of globin switching regulatory genes promoted reversion of beta globin to gamma. Here,

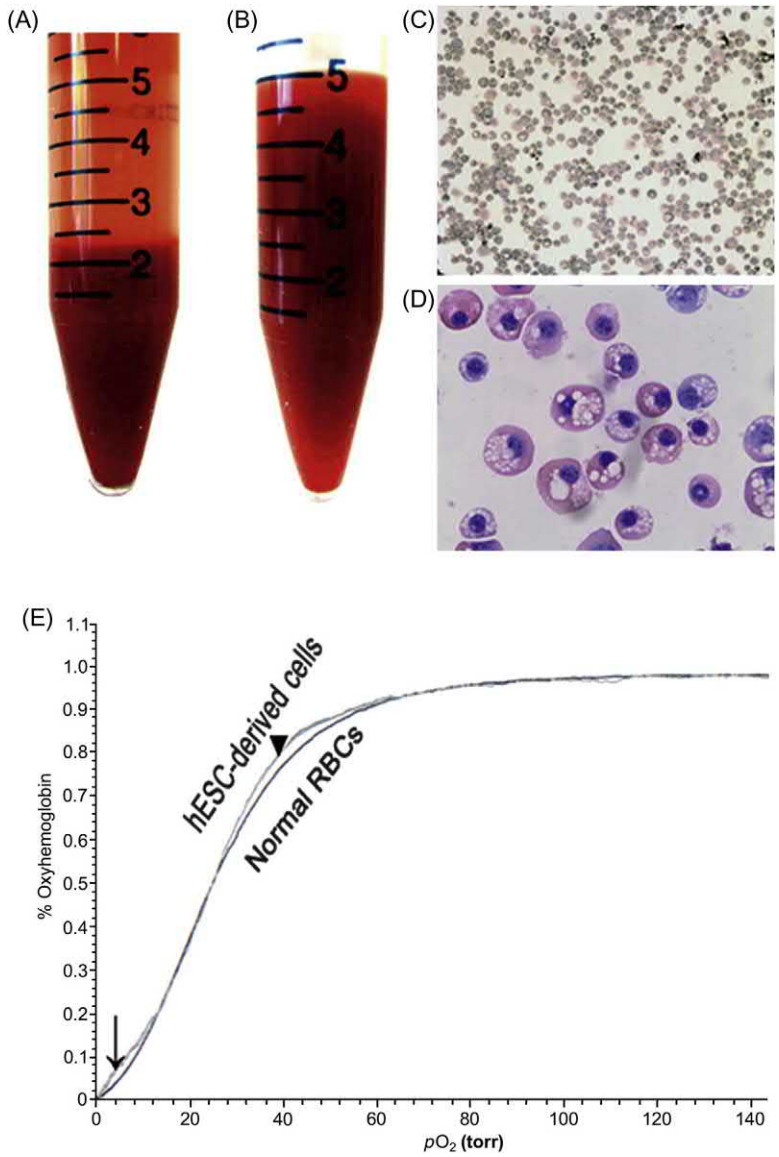

FIGURE 42.3 Large-scale production of erythroid cells from hESCs. (A) Erythroid cells (pellet) derived from 2×10^6 hESCs; (B) erythroid cells from panel a were resuspended in equivalent hematocrit of human whole blood; (C and D) morphology of erythroid cells derived from hESCs (C, ×200; D, ×1000); (E) functional characterization of hESC-derived erythroid cells. Oxygen equilibrium curves of normal human erythrocytes and hESC-derived erythroid cells. The two curves are virtually indistinguishable at their midpoints, whereas the curve of hESC-derived erythroid cells are leftward shifted at low (→) and high (▼) oxygen saturation percentages. *hESCs*, Human embryonic stem cells. *This research was originally published in Lu SJ, et al. Biologic properties and enucleation of red blood cells from human embryonic stem cells. Blood 2008;112:4475–84. © The American Society of Hematology.*

knockdown of mi2beta increased gamma globin expression in erythrocytes derived from CD34+ progenitors [33]. Mi2beta is a component of the NuRD complex normally involved in enhancing expression of KLF1 and BCL11A. Reducing levels of mi2beta or BCL11A decreases beta globin while increasing gamma globin, which is a useful therapeutic strategy for sickle cell disease or beta thalassemia [34]. Further work to manipulate this system in the opposite direction may be beneficial for driving beta globin expression and reducing gamma globin in PSC–RBCs. Toward this end, Yang et al. used a tamoxifen-ER-inducible system to drive EKLF/KLF1 at the AAVS1 safe-harbor locus in iPSC differentiating to erythrocytes. This slightly enhanced enucleation, shape, and stability of the resulting RBCs by increasing the generation of CD71+/CD235a+ cells from 30% up to 65%. Yet surprisingly, it did not induce globin switching to beta globin [35], suggesting that further work still needs to be done to optimize globin switching. In another study, an ES-sac culture method was used to enhance RBCs from hESC/iPSC, increasing the expression of beta globin over time, going from 0% at day 9 to 18% at day 18 [36]. In another study the use of microcarriers followed by coculture with MSCs helped drive a 6-fold increase in hematopoietic progenitors and an 80-fold increase in RBCs with improved maturation and enucleation [37]. Continuing efforts like these are still focused on improving beta-globin switching, enucleation, and importantly, large-scale manufacturing to enable clinical application of PSC–RBCs.

Megakaryocytes/platelets

MK are large (~50−150 μm in diameter), polyploid (up to 128N) cells that generate platelets. Platelets are the second most abundant cell type in the blood, with $\sim 3 \times 10^{11}$/L (Fig. 42.2). These small, disk-shaped, anucleate cell fragments play a key role in thrombogenesis (i.e., clot formation), hemostasis, and vascular repair [38]. Compared to RBCs, platelets are relatively short lived, lasting only 7−9 days in circulation. Although each MK has the capacity to generate between 2000 and 10,000 platelets, thrombocytopenia, a condition where counts drop below 150,000/μL (1.5×10^{11}/L) may occur if platelet production is impaired [39]. This is often the case in patients with liver failure or leukemia. Thrombocytopenia may also occur if platelets are destroyed, as is the case during chemotherapy. Low platelet counts can be quite serious as it may put a person at risk of uncontrolled bleeding with a fall or skin laceration. Transfusion of platelets can help alleviate thrombocytopenia but high demand and limited shelf life put transfusable platelets in constant demand. Moreover, refractoriness, largely due to HLA alloimmunization occurs in ~1/3 of transfusion patients [40]. The use of PSCs as an alternative source of platelets to donated blood may help alleviate these issues.

Proof of principle for the use of hESCs dates back to 2008, where an ESC-derived sac-like structure gave rise to hematopoietic progenitors, which further differentiated into MK and platelets through the use of TPO, SCF, and heparin [41]. In another method developed by our group, hemangioblasts derived from hESCs were used in a serum and feeder-free method to drive MK and platelet production [42]. Here, differential interference contrast and electron microscopy showed that ultrastructural and subcellular features of hESC-platelets were identical to those of primary, adult PB platelets. Various in vitro assays demonstrated that these hESC-platelets have functional properties similar to those of PB platelets as well, including responsiveness to thrombin stimulation, microaggregation, and clot formation/retraction upon stimulation with physiological activators (Fig. 42.4). Moreover, these hESC-platelets participated in developing mouse platelet thrombi at the site of laser-induced arteriolar wall injury in vitro similar to normal human PB platelets [42]. iPSCs have also been used to generate MKs and platelets with these two initial methods [43,44] to a similar degree as with hESCs. However, with less than 20 platelets

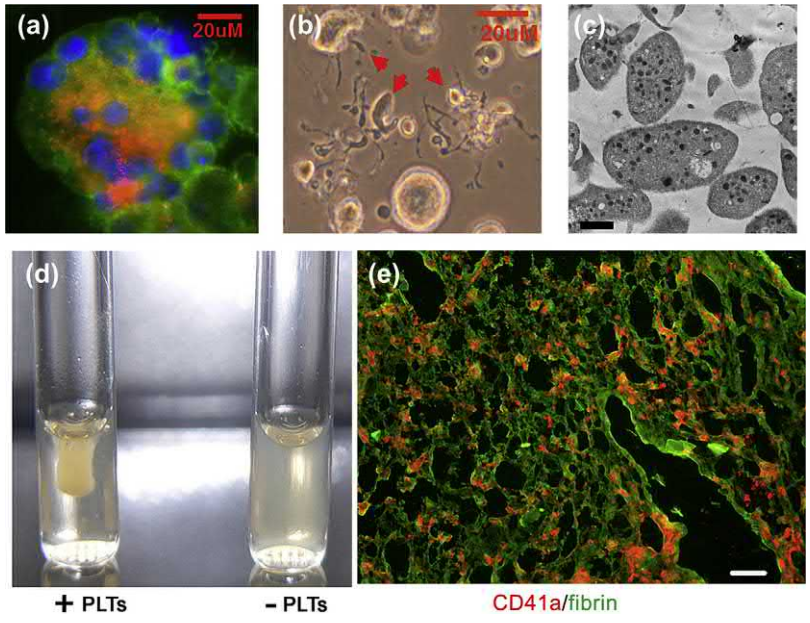

FIGURE 42.4 Generation and characterization of MKs and platelets derived from hESCs. (A) Immunofluorescence of vWF (red) and CD41 (green) proteins in MKs derived from hESCs. vWF is localized in the cytoplasm in a punctate pattern, which is typical for MKs. CD41 is expressed on the surface. 4′,6-diamidino-2-phenylindole (DAPI) (blue) stain shows polynuclei (polyploidy); (B) phase contrast image of proplatelet forming MKs derived from hESCs; (C) thin-section transmission electron microscopy of platelets generated from hESCs, Bar = 1 μm; (D) in vitro functional characterization of platelets generated from hESCs. Platelet-depleted human plasma was added with (+PLTs) or without (−PLTs) hESC-platelets (1.5×10^7/mL), and thrombin (2 U/mL) and CaCl2 (10 mM) were then added to the suspensions to induce clot formation/retraction. No clot formation/retraction was observed without addition of hESC-platelets (−PLTs); (E) clot cryo-sections were stained with antihuman CD41 (red) and antihuman fibrin (green) antibodies. Images were taken under a fluorescence microscope. Bar = 50 μm. *MKs*, Megakaryocytes; *hESCs*, human embryonic stem cells; *vWF*, von Willebrand factor. *This research was originally published in Lu SJ, et al. coming from each MK, the production is still several orders of magnitude less than the 2000–10,000 platelets per MK made in the body.

To enhance generation of platelets from iPSC-MKs, Thon et al. report the use of a shear force system to recapitulate their native BM environment [45]. This system nearly doubled the number of platelets per MK that had previously been reported, yet it still fell short of physiologically relevant numbers. In another study, Moreau et al. used three transcription factors (GATA1, FLI1, and TAL1) to drive megakaryocyte commitment, starting with a 10-day-cytokine–supplemented, embryoid body (EB)-based differentiation system. EBs were subsequently dissociated into single cells and plated onto tissue culture–treated plates. At this stage, supplementation with low TPO and SCF helped maintain cultures for 90+ days with enhanced MK yield and purity, generating up to 2×10^5 MK per input iPSC. This was a noted improvement over the 1300 MKs per iPSC yield that was achieved when using high TPO and IL1β supplementation [46]. Importantly, the optimized protocol enabled large scale expansion and cryopreservation of MKs. Platelets derived from such optimized MKs participated in clot formation in vivo in a laser-induced vascular injury model, yet similar to other studies, the yield of platelets was still much lower than that achieved in vivo. Direct conversion approaches have also been explored for generating MKs and platelets from primary cell sources without having to go through a pluripotent stage. Pulecio et al. describe the use of a six-transcription factor cocktail consisting of GATA1, GATA2, RUNX1, TAL-1, LMO2, and c-MYC to directly convert fibroblasts to CD41+ MK cells. These could further give rise to platelets in vitro or upon transplantation into mice [47]. Another group reported the use of p45NF-E2, MAF G, and MAF K to convert human dermal fibroblasts into CD41+ MKs. In vivo transplantation of these "iMKs" produced platelets, which upon recovery could participate in an ex vivo thrombus formation assay [48]. Improvement in MK production from CD34+ cells has also described using a three-step system involving increasing pH, oxygen content, and differential application of cytokines. High ploidy MKs were produced, yet platelet production was still inefficient, suggesting that the in vitro culture environment rather than issues with the starting material may be responsible for low platelet production [49]. Newer culture systems are needed to augment in vitro production of platelets in more physiologically relevant quantities from MKs. In addition, further work is needed to determine how best to isolate, increase shelf-life, and ship platelets on a commercial scale without damaging their functional properties.

White blood cells

WBCs represent only ~1% of circulating cells in the PB (Fig. 42.2), yet they play extremely important roles in providing both innate and adaptive immunity against viruses, bacteria, parasites, and the outgrowth of cancer. Three main classes of WBCs are lymphocytes [containing T, B, NK, NKT, and plasmacytoid dendritic cells (DCs)], monocytes (which can differentiate into macrophages and myeloid-derived DCs), and granulocytes (containing neutrophils, eosinophils, basophils, and mast cells). Lymphocytes arise from the progressive differentiation of common lymphoid progenitors (CLPs), while granulocytes and monocytes arise from the CMP, as mentioned previously (Fig. 42.1). Several studies have shown that hESCs and iPSCs can differentiate into both lymphoid and myeloid lineage WBCs, and current efforts are underway to develop these PSC-derivatives as off-the-shelf therapies to bolster innate and adaptive immune responses, as summarized later.

Lymphocytes—T cells

T cells are present at a concentration of 1×10^9/L of PB and represent about 10% of WBCs, or 0.1% of all circulating cells. As part of the adaptive immune system, T cells can be stimulated to mount antigen-specific immune responses against pathogens and cancer cells. While a detailed review of T cell biology is beyond the scope of this chapter, in brief, T-cell precursors arise from CLPs in the BM and migrate to the thymus for further differentiation and maturation. Mature T cells can be classified into six main types based on their unique immunophenotype and function: helper CD4+ T cells that secrete specific cytokines in response to MHC II-presented antigens; cytotoxic CD8+ T cells that release cytotoxic enzymes in response to MHC I-presented antigens; long-lived CD4+ or CD8+ memory T cells; immunosuppressive CD4+CD25+FoxP3+ regulatory T cells (Tregs); skin, gut, or lung-resident γδ T cells; and rare, CD1d-restricted NKT cells. Clinical use of primary T cells dates back to the late 1980s when it was found that autologous T cells could be isolated, expanded ex vivo, and then adoptively transferred back into patients to treat melanoma [50]. Since then, many improvements have been made and are still being made to increase the utility, safety, and efficacy of adoptive T cell therapy (ACT) protocols [51–54].

Arguably, the most significant improvement made to ACT has been the creation and use of engineered, chimeric antigen receptors (CARs) to increase specificity against tumor antigens. First, CAR technology enables antigen-specificity to be delivered in an MHC-independent manner and second, it obviates the need for

isolating patient-specific, tumor-infiltrating T-cell clones. The concept of using CARs to provide greater antigen specificity for target cell killing was first proposed in 1989 by Gross et al. Here, they fused the antibody variable heavy and light chains (Fab′ fragments) to the T-cell receptor (TCR) constant domain to create a chimeric TCR [55]. This chimeric TCR conferred antigen-specific IL-2 production and cytolytic responses from the engineered cells to cellular targets displaying 2,4,6-trinitrophyenyl haptens. Further refinement of this engineering approach in 1993 led to the use of a single-chain variable region, single-chain variable fragment (scFv) fused through a spacer and transmembrane domain to the gamma (γ) or zeta (ζ) chains of CD3 for downstream signaling [56]. This simplified design employing scFv and a CD3 ζ chains is viewed as the first generation of modern CAR technology. First generation, anti-CD20 CAR T cells were tested in clinical trials for non-Hodgkin lymphoma and mantle cell lymphoma [57] and first generation anti-alpha folate receptor CAR T cells were tested in clinical trials for ovarian cancer [58]. Neither of these trials showed much clinical success and thus first generation CARs were quickly replaced with second generation versions containing costimulatory domains such as CD28 [59,60] or 4-1BB [61,62]. Second generation CAR T cells have proven much more efficacious than their first generation counterparts with numerous clinical studies reporting efficacy using anti-CD19 CAR T cells to target B-cell malignancies. These include relapsed or refractory acute lymphoblastic leukemia (ALL) in both pediatric and adult cases, diffuse large B-cell lymphoma, chronic lymphocytic lymphoma, and follicular lymphoma [63–72]. Success with second generation CAR T cell therapy led to the approval of tisagenlecleucel (Kymriah, Novartis) in August 2017 for B-cell ALL in patients up to 25 years of age, followed shortly thereafter with the approval of axicabtagene ciloleucel (Yescarta, Kite Pharma) in October 2017 for adults with relapsed or refractory diffuse large B-cell lymphoma. Kymriah's approved indications were expanded to include adult relapsed or refractory diffuse large B-cell lymphoma in May 2018. The most common side effects reported for CAR T cell therapies include cytokine release syndrome (CRS) and neurologic toxicity. CRS involves increased release of proinflammatory cytokines by the activated CAR T and other immune cells within close proximity. It can be controlled with steroids and anti-IL-6 therapy, while corticosteroids are often given to deal with neurologic toxicity even though it is generally more difficult to control than CRS [73].

The CAR technology field is still rapidly evolving. Antigen specificity of CARs in clinical trials has now greatly expanded beyond CD19 to include other hematologic targets such as CD22 for leukemias and lymphomas and BCMA for multiple myeloma. In addition, CARs with specificity against solid tumor antigens are also in clinical trials. Examples include epidermal growth factor receptor (EGFR) for treatment of glioblastoma, mesothelin for pancreatic, cervical, breast, and hepatocellular cancers, and MUC1 for lung, gastric, pancreatic, and colorectal cancers (these and others reviewed in Ref. [74]). Moreover, further improvements to CAR design features have led to the creation and subsequent clinical testing of third generation CAR technology. This involves using two additional costimulatory domains, such as various combinations of CD28, 4-1BB, ICOS, OX40, and/or CD27 in addition to the standard CD3ζ in order to increase the persistence of CAR T cells within circulation [75–77] (Fig. 42.5).

Fourth generation CAR technology has also been in development and involves transgenic expression of proinflammatory cytokines such as IL-12 and IL-15 to augment antitumor efficacy of second generation CARs. Fourth generation CARs are also referred to as T cells redirected for universal cytokine killing, or "TRUCKs," and may be helpful for targeting heterogeneous tumors that are difficult to kill with a single targeted CAR moiety or as a therapeutic option to treat diseases other than cancer, such as autoimmune or metabolic disorders [78]. Next generation

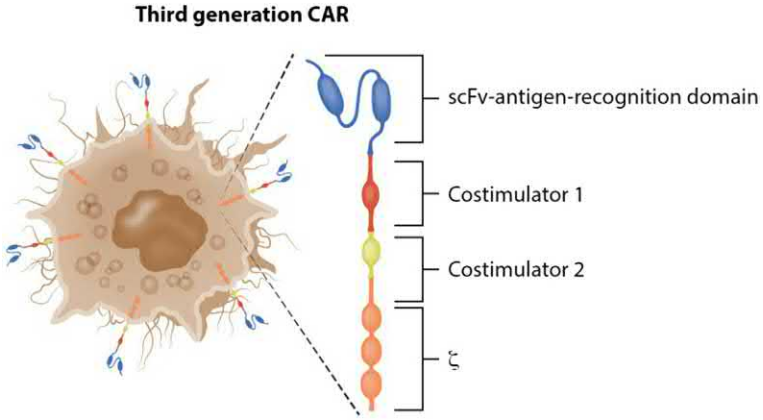

FIGURE 42.5 Features of third generation CAR constructs. An scFv antigen-recognition domain is coupled to two costimulatory domains, followed by the intracellular signaling domain of CD3, zeta (ζ) chain. CAR technology is now being applied to PSC-lymphocyte derivatives. *CAR*, Chimeric antigen receptor; *PSC*, pluripotent stem cell; *scFv*, single-chain variable fragment.

CAR technology goes beyond the fourth generation to improve the scope, precision, and utility of CAR technology through at least nine other types of engineering approaches. Examples include "self-driving" CARs that involve the use of a chemokine receptor to promote better tumor binding, "armored" CARs whose engineering makes them resistant to immunosuppression, and "self-destruct" CARs that use transient mRNA transfection of the CAR gene to limit the expression of the CAR instead of using a more conventional, integrating, retrovirus-based approach. Another approach to limit CAR expression involves the use of an inducible suicide gene, such as iCasp9 or CD20 to control persistence of the CAR-containing cells upon administration of a small molecule or antibody. Other engineering approaches include the "conditional" CAR, whose full activation is only achieved upon providing a small molecule as well as the "tanCAR" or tandem approach which involves the use of two scFvs with different affinities to provide more specific targeting of tumors and avoiding on-target, off-tumor effects (these and others reviewed in Ref. [79]). Nonengineering approaches are also being developed to increase CAR T-cell persistence. These include the use of lymphodepletion to remove Tregs, infusion of cytokines to support the viability of CAR T cells in vivo, and the use of T cells that are specific for chronic viral infections [e.g., cytomegalovirus (CMV) or Epstein–Barr virus (EBV)] as the starting material for CAR T-cell generation. In the last example, vaccination with CMV or EBV viral peptides has been found to stimulate the proliferation of the resulting CAR T cells for longer term specificity against a tumor antigen, such as CD19. These approaches are being tested in clinical trials as a way to enhance long-term survival of CAR T cells [80].

Most studies to date have relied on the use of autologous cells for CAR T cell therapies; however, the use of autologous cells is very expensive and also requires time for individual engineering of the CAR cells. Use of allogeneic cells would help with the production of off-the-shelf CAR-engineered cells, drive down costs, and make these therapies immediately available for patients in need. A couple of studies have already explored the use of allogeneic CAR T cells clinically and surprisingly, found they could be used without eliciting graft versus host disease [81,82]. This may be due to the rapid stimulation and immediate exhaustion kinetics of first generation CAR T cells [83]. These studies also pave the way for alternative allogeneic sources, such as PSCs, to be considered as starting material.

The first studies demonstrating that PSCs can differentiate into T cells were published in the mid-2000s. Galic et al. published two papers in 2006 and 2009 showing that hESCs, cultured either on OP9 stromal cells or as EBs with hematopoietic cytokine cocktails, could be induced to differentiate into CD34 + hematopoietic progenitors capable of giving rise to T cells upon their transplantation into a Thy/Liv organ implant within SCID or RAG2 deficient mice [84,85]. In the EB-based method, the Thy/Liv implant environment facilitated the generation of CD4/CD8 double positive T cells within 4 weeks and single positive CD4 and CD8 T cells that had undergone TCR rearrangement by 8 weeks after transplantation [85]. Subsequent studies by Timmermans et al. showed that hESCs could differentiate into mature T cells using a completely in vitro system. Here, hESCs were cultured on OP9 to produce hematopoietic progenitors and then transferred onto OP9 cells expressing delta ligand 1 (DL1) for another 5–7 weeks with FL, SCF, and IL-7 supplementation. Within 30 days, CD3 + T cells that had undergone TCR rearrangements emerged and could be induced to secrete IFNγ in response to PHA induction, similar to primary T cells [86]. Similarly, Kennedy et al. used an EB-based method to isolate $CD34^{+}$, $CD43^{lo/-}$ progenitors and could induce their differentiation toward T-cell lineage by coculturing them on OP9 expressing DL4. Here, CD5 + CD7 + cells emerged within the first 14 days on the DL4-expressing stroma, followed by CD4/CD8 double positive T cells by day 28, and CD3 + TCR$\alpha\beta$ or TCR$\gamma\delta$ cells by day 42. Genomic DNA sequencing showed that these cells had undergone TCR rearrangement [87]. In 2014, two other papers reported the generation of T cells with broad TCR diversity. One study used both hESCs and skin biopsy–derived iPSCs as the starting material. Here, PSCs were initially plated onto OP9 cells for 18 days to generate cell clumps containing CD34 + cells, which were then affinity-purified and replated onto OP9-DL4 with FL, SCF, and IL-7 for up to an additional 35 days. $\gamma\delta$T cells were first to emerge after 14 days on OP9-DL4, followed within a week by $\alpha\beta$ T cells, thus mimicking in vivo T-cell development. In vitro characterization confirmed that stimulation with PMA/ionomycin or CD3/CD28 beads induced expected activation responses in these T cells. They upregulated CD25 and CD69 expression and increased production of IL-2, IFNγ, TNFα, as well as the degranulating enzymes perforin and granzyme B [88]. Another study in 2014 avoided the use of OP9 cells for initial hematopoietic differentiation of hESCs as well as fibroblast- or BM-derived iPSCs. They demonstrated that tenascin C is a critical hematopoietic-inducing factor secreted by OP9 which mimics the extracellular matrix of in vivo HSC niches. In their study, PSCs were initially differentiated on a tenascin C substrate for 9 days, at which time CD43 + cells were replated onto OP9-DL4 to induce lymphoid lineage differentiation. Within 3 weeks, CD4 + /CD8 + double positive T cells emerged and showed evidence of polyclonal VDJ recombination [89].

During the early 2010s, efforts were underway to determine if iPSCs could be made from PB cells instead of reprograming dermal fibroblasts back to a pluripotent state. Not only is blood cell collection less invasive than a skin biopsy but the number of cells that can be collected is relatively high. Moreover, the use of blood cells for reprograming into iPSCs and then differentiating back again into blood cells may be beneficial due to epigenetic memory of the starting material and, in the case of T cells, can make use of preexisting TCR rearrangements and antigen specificity of the starting T cells. Toward that end, Loh et al. showed in 2010 that PBMCs could be reprogramed to iPSCs and more specifically, that mature T cells within the blood could give rise to iPSC clones [90]. This observation was followed by studies showing that antigen-specific, isolated, cytotoxic T lymphocytes (CTLs) could be reprogramed to iPSCs, expanded, and then redifferentiated back into CTLs while preserving the TCR repertoire and antigen specificity of the source material. For example, Nishimura et al. reprogramed antigen-specific CD8 + T cells from an HIV patient back into iPSCs. These were initially differentiated for 15 days on CH3H10T1/2 stroma with VEGF, SCF, and FL to give rise to CD34 + cells, which were then transferred onto OP9-DL1 in the presence of FL and IL-7 for up to an additional 30 days to differentiate into T cells. Stimulation of these developing T cells with CD3/CD28 beads or PHA followed by coculture with irradiated PBMCs plus IL-7 and IL-15 pushed them to generate memory CD8 + cells that were capable of mounting a cytotoxic response upon exposure to a specific HIV antigen. The stimulation/coculture step also enabled a $\sim 100-1000\times$ expansion of the iPSC-T cells as compared to parental T-cell clones under this condition, which were only able to expand $20\times$ [91]. The authors noted that these cells had elongated telomeres compared to the initial T-cell clone, helping one to explain their greater proliferative capacity. Another study demonstrated the use of melanoma epitope MART-1-specific CTLs to generate iPSCs. Coculture of the differentiating iPSCs on OP9-DL1 gave rise to CD4 + CD8 + double positive T cells expressing TCRβ, with roughly 70% being positive for MART-1 specificity, as evidenced by tetramer staining. Stimulation of these cells with anti-CD3 for 6 days induced a $300\times$ expansion of CD8 + and increased the percentage of MART-1-specific cells to >95%. Subsequent exposure to MART-1-expressing antigen-presenting cells (APCs) induced them to secrete IFNγ, as expected [92].

Encouraged by the recent clinical success of CAR engineering in primary T cells, CAR technology is now also being applied to PSC-derived lymphocytes. The generation of CAR-expressing PSC-derived lymphocytes could provide a readily available, highly effective therapy in situations where isolated T cells have not expanded well for patients or who do not respond well to donor lymphocytes. In a 2013 study by Themeli et al., PB T cells were first reprogramed into iPSCs using retrovirus and then subjected to lentiviral transduction of a second generation CAR construct, 19−28z. The 19−28z CAR construct has antigen specificity for CD19 and a dual CD28, CD3ζ internal signaling domain. These CAR-containing iPSCs were differentiated to EBs for 10 days, whereby the resulting CD34 + cells were isolated and transferred to OP9-DL1 coculture containing SCF, FL, and IL-7. After 30−35 days, mRNA profiling indicated that the resulting T cells were most similar to primary γδ T cells, despite their premature expression of TCRαβ. Exposure to CD19-expressing 3T3 cells resulted in upregulation of CD25 and CD69 as well as secretion of TNFα, IL-2, and IFNγ. Exposure to CD19-3T3 cells was also leveraged to induce their expansion, such that 3 weekly stimulations enabled a $1000\times$ expansion. The expanded T cells were able to mount CD19-specific cytotoxic responses against CD19-expressing EL-4 and Raji cells in a manner similar to that of primary γδ T cells as shown in an in vitro chromium release assay and an in vivo xenogenic tumor model, respectively [93]. The expression of CARs in PSC-derived T lymphocytes has great therapeutic potential, and we are likely to see further development of such therapies in the future.

Lymphocytes—NK cells

NK cells are a component of the innate immune system that accounts for $\sim 5\%-15\%$ of circulating lymphocytes. They can also be found in peripheral tissues such as the thymus, lymph nodes, spleen, liver, and lung [94,95]. NK cells circulate for roughly 2−4 weeks during which time they are able to provide rapid, nonspecific defense against various microbial infections and aid in the detection and elimination of tumor cells [96]. Cytokine release, granule-mediated natural cytotoxicity, target-cell apoptosis via membrane-bound Fas ligand and TRAIL expression, and antibody-dependent cellular cytotoxicity (ADCC) are the main mechanisms by which NK cells provide this defense. A balance between inhibitory and activating signals are required for NK cells to elicit each specific function. For example, the NK activating receptor NKG2D is involved in surveying MHC I−associated proteins and activating the NK cell if it determines that there is insufficient MHC I expression. Similarly, the activating receptor DNAM-1 is involved in the detection of stress signals such as CD112 and CD155 on the surface of tumor cells or infected cells to help trigger NK cell activation. Other activating receptors include natural cytotoxicity receptors such as NKp30, p44, p46, and heterodimers CD94/NKG2C, CD94/NKG2E as well as CD16, which

recognizes the Fc portion of antibodies and is involved in mediating ADCC. The CD94/NKG2A heterodimer is a major inhibitory receptor, while various types of killer cell-immunoglobulin like receptors (KIRs) are also present on the surface and can be either activating or, in most cases, inhibitory. In general, CD56 bright, CD16 low, KIR low, CD94 − immature NK cells are the principal cytokine secretors and reside mostly in lymph nodes while CD56 dim, CD16 high, KIR high CD94 + mature NK cells are largely responsible for cytotoxic responses and are found in the circulation [95,97].

Groundbreaking work in the 1980s by Rosenberg et al. stimulated considerable interest in and a variety of approaches for harnessing the cytotoxic capabilities of NK cells [98,99]. Autologous NK therapies are currently used in the clinic to help treat a variety of cancers including metastatic melanoma, renal cell carcinoma, and hematologic malignancies. In 2004, allogeneic NK cells were first tested for clinical use as an adjunct immunotherapy after HSCT for myeloid malignancies [100]. Since then, a variety of studies have confirmed that allogeneic NK cells are safe to use and therapeutically beneficial in the context of both combination therapies and monotherapies for various hematologic malignancies, Ewing sarcoma, breast and ovarian cancer, melanoma, renal carcinoma, and non-small cell lung cancer (reviewed in Ref. [101]). Interestingly, evidence suggests that allogeneic NK cells may be more effective than autologous ones, in part, perhaps because they avoid inhibitory signals from self-MHC receptors on autologous cells [102]. Currently, there are hundreds of ongoing clinical studies, sponsored by both academic groups and biotechnology companies such as Glycostem, Green Cross Lab Cell, and NantKwest to further explore the therapeutic utility of allogeneic NK cells from umbilical CB, unrelated PBMC donors, and the cell line, NK-92 (clinicaltrials.gov). Moreover, additional efforts are focused on enhancing the cytotoxic functionality of NK cells, improving their ex vivo expansion, and priming them before being adoptively transferred. For example, Genentech and Kyowa Hakko Kirin are conducting clinical trials to test monoclonal antibodies with enhanced affinity for CD16 in an effort to facilitate NK ADCC. AvidBiotics and Affimed are conducting preclinical and clinical studies using bispecific antibodies to recruit NK cells to tumor sites, and Innate Pharma is running clinical studies to test antibodies that bind to and block inhibitory receptors on an NK-cell surface [101]. Efforts to improve the expansion capability of NK cells are also being explored; membrane-bound IL-21 and nicotinamide have each been found to enhance ex vivo NK proliferation [103−105]. Preexposure of NK cells to cellular lysates from leukemia cell lines or to peptides from tumor-associated hsp70 (before they are infused into patients) are both being tested in clinical trials as potential ways to prime NK cells for greater in vivo efficacy [106,107].

A notable recent advancement for NK-based therapeutics is the adoption of CAR technology. First, second, and third generation CARs have all been engineered within NK cells or NK cell lines to target various cancer-associated antigens. Examples include targeting of CD19 and CD20 on leukemia and lymphoma cells, GD2 on glioblastoma, CS1 or CD138 on multiple myeloma, ErbB2 on breast, ovarian, and squamous cell carcinoma and CD5 on T-cell leukemias (reviewed in Refs. [108,109]). Second generation CARs, with multiple intracellular signaling domains, appear to work better than first generation CARs in NK cells [110] and 4-1BB (from CD137) appears to work better than CD28 as a costimulatory intracellular signaling domain [111]. CAR-NK cells may also have therapeutic advantages over CAR T cells due to their greater diversity of activating enzymes, various cytotoxic mechanisms of action, and shorter half-life [112]. Indeed, CAR-NKs can be designed to overexpress their natural activating receptors for improved cytotoxic effects rather than being designed to only target a single antigen. This is particularly advantageous in situations when a tumor has downregulated antigen expression and CAR T cells directed toward that antigen begin to elicit on-target but off-tumor effects. Chang et al. retrovirally introduced an NKG2D-DAP10-CD3z construct to enhance NK cell−mediated antitumor effects [113]. These engineered NK cells released a variety of cytokines and toxic enzymes through degranulation for improved cytotoxicity against a variety of cancer types in an antigen-independent manner. Another study reported that CAR NK cells were engineered with a TGFβ type II receptor fused to a transmembrane domain and intracellular signaling domain from NKG2D to allow them to be activated instead of inhibited by high TGFβ in the tumor microenvironment. These TGFβIIR-engineered NK cells migrated to TGFβ-producing tumors and increased IFNγ secretion for enhanced killing of hepatocellular carcinoma cells in a xenograft model [114]. CAR T cells secrete a panopoly of proinflammatory cytokines and their persistence in the circulation can lead to tissue-damaging CRS, yet CAR NK−secreted cytokines have less inflammatory potential and the shorter half-life of NK cells compared to T cells also helps limit the potential for CRS [112].

There are at least 10 ongoing clinical trials examining the therapeutic potential of CAR-NK cells in a variety of indications, including leukemias, B-cell lymphomas, ovarian, and prostate cancers (clinicaltrials.gov). NK sources include both primary NK cells, for example, from CB or the use of NK cell lines, such as NK-92, each of which has its own advantages and disadvantages. Primary NK cells express a wider range of activating receptors than NK cell lines and can somewhat expand in vivo in

response to activating signals. However, primary NK cells are limited by short supply, difficulties with in vitro expansion, and although they can be isolated from other cell types, pose the risk of contaminating T cells, which could elicit GvHD. NK cell lines, on the other hand, are homogenous and can easily be expanded to a large-scale in vitro but lack certain activating receptors such as CD16 and cannot expand in response to in vivo cues due to the need to irradiate them before use.

As these studies are ongoing, there has been considerable interest in developing NK cell therapies from PSCs as an alternative source that may combine the advantages of primary NK and NK cell lines. Leading the way, Kaufman et al. have published a series of papers showing proof of concept and optimization of differentiation protocols for the generation of functional hESC- and iPSC-derived NK cells. Their initial protocol used began with coculturing PSCs on murine M210-B4 stroma for 17−20 days, isolation of the resulting CD34 + CD45 + progenitors, which represented <5% of the culture, and transfer of these progenitors onto murine AFT024 stroma in media containing SCF, FL, IL-7, and IL-15. After a 30−35-day total, CD45 + CD56 + CD94 + NK cells emerged [115,116]. A variety of in vitro assays showed these cells secreted IFNγ in response to IL-12/IL-18 stimulation, displayed natural cytotoxicity and ADCC against various cancer cell lines. In vivo xenograft studies showed they had antitumor activity [115] as well as anti-HIV activity [117]. This group has made several improvements to their protocol to make them more clinically relevant. They are now able to avoid the use of the M210-B4 stroma step by instead using an 11-day spin EB step to generate CD34 + CD45 + progenitors [118]. They subsequently transfer the entire spin EB culture (not just the isolated progenitors) to uncoated 24-well plates in the presence of IL-3, IL-7, IL-15, SCF, and FL instead of onto ADT024 stroma. They noted that the contents of the spin EB culture contain cells that attach to the 24-well plate to provide its own stromal layer. Within 4 weeks, the culture produces CD45 + CD56 + CD94 + NK cells expressing a variety of other NK markers that are comparable to those generated in their original protocol. Moreover, these cells similarly can be induced to secrete IFNγ, display natural cytotoxicity and ADCC against a variety of cancer cell types [118]. The group was also able to use a K562-based, membrane-bound IL-21 expressing artificial APC line to help expand their PSC-NK cells 2 to 3 logs. These various improvements to PSC-NK differentiation protocols have resulted in clinical realization of the technology. In November 2018, Fate Therapeutics announced that it had received FDA approval to begin a Phase 1 clinical trial (NCT3841110) testing iPSC-derived NK cells for the treatment of advanced solid tumors as a monotherapy or in combination with immune checkpoint inhibitors [119].

In parallel, Kaufman's group has continued to advance their platform by applying CAR technology to their PSC-NK cells [120]. In a recent study, they screened nine different CAR constructs containing an scFv with specificity for the tumor-associated antigen, mesothelin and various options for cotransmembrane and costimulatory domains in NK92 cells to determine which may be most efficacious in their PSC-NK cells. The screen indicated that a novel construct with the transmembrane domain of NGK2D, 2B4 costimulatory domain (from CD244), and the CD3ζ signaling domain, which is also a domain expressed within CD16, worked best in an NK-cell background. They engineered iPSCs to carry this CAR and compared functionality of the resulting meso-specific NK CAR iPSC-NK cells to nonengineered iPSC-NK, T cells, meso-directed CD28−41BBz (CAR-T) expressing iPSC-CAR NK cells as well as meso-directed CAR T cells. They found their iPSC-CAR-NK cells were more effective in inhibiting in vivo ovarian cancer cell growth and prolonging survival of the tumor xenograft mice than the regular iPSC-NK cells, T cells, and CD28−41BBz (CAR-T) expressing iPSC-CAR NK cells. The antitumor effect was comparable to that of CAR-T cells, yet the NK-CAR iPSC-NK therapy provided longer term survival of the xenografted animals than the CAR T cells, likely due to a shorter cytokine release period and thus cytokine-induced toxicity than the CAR T cells [120]. These results suggest that the specific domains used to generate a CAR should be matched to the cell in which it is expressed for optimal therapeutic function.

Lymphocytes—NKT cells

NKT cells are another lymphocyte population with therapeutic potential and for which both PSC and CAR technologies are being applied. They represent ≤1% of circulating lymphocytes and have characteristics of both T cells, via expression of TCRαβ, and of NK cells, via expression of CD161 (NK1.1), CD16, and CD56. Class I NKT cells express an invariant α chain on their TCR, the Vα24 Jα18, thus accounting for the term iNKT ("invariant" NKT). They are further defined as being either CD4 + , CD8 + , or CD4/CD8 double negative. iNKT recognize lipids that are presented through CD1d on target cells, such as alpha-galactosylceramide (a-GalCer) and can be induced to secrete various cytokines to activate other immune cell populations, including CD8 + T cells, NK, and DC cells [121]. They also can produce degranulating toxic enzymes and use Fas-ligand- and TRAIL-mediated methods to induce apoptosis in target cells. Class II NKT cells are also CD1d-restricted but do not recognize a-GalCer. They have greater diversity in their TCR and recognize a wider range of antigens and are thought to be largely immunosuppressive [122]. Clinical

interest in NKT cells have therefore largely focused on class I, the iNKT cells. iNKT are able to infiltrate solid tumors better than T cells and contribute to antitumor responses by killing tumor-associated macrophages and myeloid-derived suppressor cells that normally contribute to tumor growth and immune resistance within tumor microenvironment. Evidence also suggests that they may help suppress GvHD (reviewed in Ref. [123]). Preclinical studies have suggested potential utility of primary iNKT in treating cancers ranging from leukemia and lymphoma to melanoma and colon, breast, ovarian, prostate, and lung cancers. Clinical studies have likewise tried to leverage the antitumor properties of iNKT. Approaches include direct injection of a-GalCer or injection of ex vivo, a-GalCer-pulsed CD1d-expressing myeloid-derived DCs to augment endogenous iNKT activity. Adoptive transfer of ex vivo expanded iNKT cells is also being tested as a monotherapy or in a combination with a-GalCer-pulsed PBMC to treat nonsmall cell lung cancer, head and neck cancer, melanoma and multiple myeloma (reviewed in Ref. [123]). CAR technology is also being applied to primary NKT cells. Heczey et al. showed that first, second, and third generation CARs, when expressed in NKTs, could mediate antigen-specific lysis of neuroblastoma cells and increased the survival of tumor-bearing mice, while the CAR NKT cells still retained their inherent ability to kill CD1d + tumor-associated macrophages [124]. This has led to the first wave of clinical trials testing CAR-NKT technology. A Phase 1 clinical trial for autologous GD2-specific, IL-15-expressing CAR-NKT is being conducted for neuroblastoma (NCT03294954) while another Phase 1 study using allogeneic CD19-directed CAR NKT cells is being conducted for relapsed or refractory B-cell lymphomas (NCT03774654).

Given the low numbers of primary NKT in circulation, several groups have tried to find ways to increase yields for off-the-shelf ACT. A recently reported approach involves treatment of allogeneic NKT with IL-2 and IL-21, which was found to preserve the central-memory-like phenotype and antitumor effects of the long-lived CD62L + NKT cells [125,126]. Another approach involves the use of PSCs as an alternative starting material for adoptive iNKT cell therapies. Watarai et al. developed an NKT differentiation protocol that was successfully used to generate NKT cells from both mouse ESC and iPSCs [127,128]. In their first study, mouse ESCs generated through nuclear transfer from an NKT cell were used to differentiate into NKT with the hope that the prearranged invariant TCRα gene from the NKT nucleus would allow the ESCs to differentiate better than standard ESCs. These NKT-ESC were cultured on OP9-expressing DLL1 in the presence of FL for 10 days to induce their differentiation. Suspension cells were then transferred to fresh OP9-DLL1 stroma plus FL and IL-7 every 4 days thereafter. Analysis of the various fractions showed that Notch signaling via DLL1 is important for early stage NKT development but that functional maturation out to day 20 was not impacted by DLL1. These cells helped generate antigen-specific, IFNγ-secreting CD8 + T cells in vivo. The same protocol was used to generate NKT from iPSC and these were also found to be functional as they secreted large amounts of IFNγ and reduced tumor growth in vivo. Yamada et al. adapted this OP9-DLL1-based protocol for the differentiation of human iPSCs. These iPSCs had originally been reprogramed from PB or CB Vα24 + iNKT and redifferentiation of the resulting iPSCs back into iNKT was achieved within 33 days. The newly derived iNKT were found to be Th1-skewed in nature, which lends them to therapeutic use; they showed better cytolytic activity against six different tumor lines than a reference NKT cell line. They also displayed antitumor effects using a K562-luciferase tumor model and could be expanded 4−10 × within one to two additional weeks via stimulation with a cocktail containing IL-2, IL-7, and IL-15 [129]. Another study the same year adapted a previously published T-cell differentiation protocol [91] to generate iNKT from an iNKT-derived iPSC line. They cultured the iPSCs onto C3H10T1/2 stroma in the presence of VEGF for 7 days, upon which time they added SCF and FL to induce hematopoietic differentiation. At 14 days, the hematopoietic progenitors were collected, transferred to OP9-DLL1 stroma in media with supplemental IL-7 and FL and on day 29, they added IL-2 and IL-15. The resulting iNKT-iPSC-iNKT-harbored characteristic NKT properties: they secreted IFNγ in response to a-GalCer stimulation, induced maturation of DCs and their IL-12p70 secretion, activated T and NK cells, and displayed NK-like cytotoxicity against cancer cell lines [130]. Additional studies are underway to continue developing the therapeutic potential and clinical application of PSC-NKT.

Monocyte-derived dendritic cells

Straddling the interface between innate and adaptive immunity, DCs are one of the body's three main types of APCs. Clinically, DCs may be used in the development of vaccine-based therapies to stimulate T-cell responses against a variety of disease-associated antigens [131]. Upon exposure to a suitable antigen, immature DCs undergo the process of activation and maturation, which involves proteolyzing antigen and presenting its fragments on the DC-cell surface using MHC class I or II molecules for CD8 + or CD4 + T cells to recognize, respectively. Myeloid-derived DCs arise from monocytes, secrete IL-12 in response to activating stimuli, and express toll-like receptors TLR2 and TLR4. Lymphoid-lineage-derived DCs [plasmacytoid (p)DCs] have similar functional

characteristics to mDCs but secrete IFNα and express TLR7 and TLR9 [132]. Specialized DCs called Langerhans cells are located in the skin and mucosa, while DCs can also be differentiated from CD34 + CB cells. Innovative work in the late 1990s provided the proof of concept for clinical use of DCs as studies showed that ex vivo generated DCs (from allogeneic or autologous BM or PB sources) could be loaded with melanoma-specific antigens and stimulate antitumor immune responses once injected into patients [133,134]. Since then, many different types and sources of DCs have been investigated for their utility in developing cancer vaccines. Currently, there are over 400 ongoing clinical trials testing DC-based vaccines as a monotherapy or in combination with other approaches (clinicaltrials.gov). A wide range of diseases are being targeted with monocyte-derived DC-based vaccines, including leukemia, lymphoma, melanoma, multiple myeloma, HIV, hepatitis C, glioblastoma, hepatocellular carcinoma, colorectal, ovarian, prostate cancer, and many more. The design of such studies varies considerably as DCs may be loaded in vivo or ex vivo with either a single antigen, antigenic peptide, whole killed tumor cells, tumor cell lysate, apoptotic bodies, exosomes, or tumor-derived DNA or RNA [135].

Several studies have shown that human PSCs can differentiate into DCs and may serve as a cost-effective and scalable standardized source of DCs. Two main differentiation procedures have been used to generate DCs from hESCs and iPSCs. The first method relies on OP9 coculture [136,137], while the second utilizes an EB-based approach and can be done in a serum-free or serum- and feeder-free manner [138–140]. The resulting DCs in these studies had characteristic large eccentric nuclei, spiny dendritic processes, and expressed DC surface markers, CD11c, CD40, CD45, CD86, HLA class I and II to varying degrees with two to five DCs per starting PSC being generated. Despite subtle differences compared to monocyte-derived DCs, PSC-derived DCs produced in these studies and in our own lab appear to be functional upon maturation in assays measuring IL12-p70 secretion, chemotaxis, antigen-uptake and proteolysis, induction of T-cell proliferation and stimulation of antigen-specific cytotoxic CD8 + T-cell responses ([138,140] and unpublished results). In addition, the discovery of CD141 + tolerogenic DCs in the skin [141] has led to an exploration of PSCs to generate DCs capable of resetting tissue homeostasis. Sachamitr used a 24-day DC differentiation protocol coupled with negative selection for CD1c to isolate a tolerogenic CD141 + DC population that could be used to induce tolerance to local antigens and reset homeostasis in autoimmune diseases such as type 1 diabetes [142]. Further development of such PSC-derived DCs is still needed before they may compete with donor-derived DCs.

Monocyte-derived macrophages

Macrophages are large phagocytic leukocytes that play a role in normal tissue homeostasis and local immune responses. Populations of tissue-specific macrophages are established during normal fetal development and can survive for months to years [143]. However, in response to chemotactic signals, circulating monocytes extravasate from blood vessels differentiate into macrophages and adopt tissue-specific gene expression and functions. Examples of diverse tissue-resident macrophages include liver Kupffer cells, central nervous system microglia, and lung alveolar macrophages. Macrophages engulf and digest microbes, cancer cells, and foreign substances as an innate immune defense mechanism and assist in the activation of adaptive immune responses. Interest in harnessing the defensive properties of macrophages dates back to the 1970s when Dr. Isaiah Fidler began testing the antitumor effects of isolated macrophages in mouse tumor models [144]. Subsequently, several clinical trials conducted during 1987–2010 aimed to use autologous macrophages to treat cancers, including nonsmall cell lung cancer, bladder, colorectal, and ovarian cancers, pancreatic cancer, and renal cell carcinoma (reviewed in Ref. [144]). Although such trials showed that large and frequent doses of autologous macrophages are safe and well tolerated, most had little, if any, therapeutic benefit. Recent research has revealed the complexities of macrophage polarization, optimized culture conditions, and the value of engineering for directing macrophage function in vivo, which has renewed interest in developing macrophage-based therapies for clinical use. Toward that end, the company Vericel has developed Ixmyelocel-T, an autologous BM-derived mixed cell therapy enriched for M2 antiinflammatory macrophages and MSCs to treat dilated cardiomyopathy and critical limb ischemia. In 2016 results from their Phase 2b trial for ischemic heart failure showed a 37% reduction in cardiac events for patients treated with Ixmyelocel-T [145], and in 2017 the company received FDA's Regenerative Medicine Advanced Therapy designation to facilitate expedited review of their macrophage/MSC therapy for ischemic heart failure [146]. Likewise, skewing macrophages toward an M1 subtype is thought to promote their antitumor effects [147,148]. This knowledge, combined with various engineering approaches, has provided greater control over the functions and in vivo effects of macrophage-based therapies in development. For example, a recent study shows that expressing a HER2-targeting CAR in macrophages could significantly inhibit tumor growth in a HER2-4T1 orthotopic tumor model in BALB/C mice. These CAR-macrophages helped degrade tumor extracellular matrix and enabled greater T cell infiltration into the solid tumor [149]. Abbvie has also invested in a

CAR-macrophage startup company called Carisma to target solid tumors, such as those expressing Her-2 and two other undisclosed targets [150], while various other engineered macrophage-based therapies are in preclinical development [144].

Protocols for the differentiation of PSCs into monocytes and macrophages have been developed and refined over the years. Wilgenburg et al. have described a clinically adaptable, chemically defined, serum- and feeder-free method for the generation of CD14 + CD16 low CD163 + monocytes from both hESC and iPSCs. Application of M-CSF further differentiates them into phagocytic macrophages with properties similar to those of primary macrophages [151]. Additional studies have applied genetic engineering approaches to more effectively control the in vivo effects of PSC-derived macrophages. For example, Koba et al. genetically engineered an iPSC-derived myeloid/macrophage cell line to overexpress IFNβ to treat NUGC-4 human gastric tumors, noting that the overexpression of IFNβ was essential for an antitumor effect [152]. In another example, Senju et al. engineered iPSCs with an scFv directed toward beta amyloid and showed that iPSC-derived macrophages could specifically phagocytose this Alzheimer's disease−associated protein in vitro. They also generated another iPSC line with an scFv directed against CD20 and differentiated them into macrophages cells, demonstrating these CD20-specific iPSC-derived macrophages could specifically kill BALL-1 B-cell leukemia cells both in vitro and in immunocompromised mice [137]. In follow-up studies, this group engineered iPSC macrophages to express the beta amyloid-degrading enzyme, neprilysin, which reduced soluble beta-amyloid in vivo [153]. In another example, gene editing has been performed in iPSCs from patients with hereditary pulmonary alveolar proteinosis (PAP) to correct mutation of the CSF2RA gene that is required for alveolar macrophages to properly clear surfactant protein [154−156]. Pulmonary transplantation of these gene corrected iPSC-macrophages functionally compensated for defective macrophages in a humanized mouse model of PAP [154]. These are just a few examples of how combinations of PSC and gene editing and/or CAR technologies are being applied to myeloid-lineage leukocytes. Their continued development holds great promise for future novel regenerative medicine-based therapies.

Granulocytes—neutrophils

Granulocytes are myeloid-lineage WBCs that help fight pathogenic infections and play a role in allergic reactions by mediating inflammatory responses. They harbor abundant granules in their cytoplasm containing a variety of toxic enzymes that can be released in response to environmental signals. Four main granulocyte classes (neutrophils, eosinophils, basophils, and mast cells) have varying roles in fighting bacterial, viral, and parasitic infections. They can be characterized by the distinct shape of their nuclei and hematoxylin−eosin staining patterns. Neutrophils are the most abundant leukocytes in the PB and account for 60%−70% of circulating WBCs with a concentration of roughly $2.5-7.5 \times 10^9$/L. They rapidly kill microbes, cancer cells, and other foreign entities through phagocytosis and the production of reactive oxygen species. With a half-life of 6−8 hours, neutrophils are abundantly produced on a magnitude of 5×10^{10} to 10×10^{10}/day [157].

Neutropenia describes the situation when absolute neutrophil counts are less than 1500 cells/μL and severe neutropenia occurs when counts are below 500 cells/μL. Neutropenia may be caused by chemotherapy or as a result of primary immunodeficiency, such as chronic granulomatous disease (CGD) and Kostmann syndrome [158]. Evidence suggests that rates of infection increase with increasing severity of neutropenia. Roughly, a third of severely neutropenic patients will develop rapid, life-threatening infection within a single week [159]. G-CSF (Filgrastim), pegylated G-CSG (Pegfilgrastim, which has a longer half-life), or a recently FDA-approved biosimilar (Zarxio) can be used to stimulate the production of neutrophils and represents the main therapeutic approach to treating neutropenia. Allogeneic granulocyte transplantation (Gtx) can also be used to provide rapid, short-term relief from critical neutropenia, yet the collection of procedure is time-consuming and limited by the short half-life and shelf-life of mature neutrophils. In the United States, Gtx has largely been replaced by Filgrastim and antibiotic/antifungal therapies [160]. In certain chronic situations, long-term G-CSF/Filgrastim cannot be used and HSCT is the only curative therapy. In more acute situations, such as following chemotherapy, there is still a gap where patients are at increased risk of infection even when given Filgrastim and antibiotic/antifungal medications [161]. In these situations, there is a need to increase the absolute neutrophil count through other means. Toward this end, nicotinamide-expanded CB stem cells (NiCord) have been found to shorten the time to neutrophil engraftment, reduced the incidence of severe infections, and reduced the duration of hospitalizations within the first 100 days following treatment. Their contribution to short-term recovery is likely due to the expansion of myeloid progenitors that can quickly differentiate into neutrophils for faster recovery than unmanipulated HSCs alone [162,163].

The propensity of PSCs to differentiate into myeloid progenitors and/or further differentiate down the neutrophil lineage has been explored for similar therapeutic purposes. In 2009, hESC-derived CD11b + neutrophils were

generated through an EB method and were found to be functional in three in vitro assays assessing chemotaxis, phagocytosis, and production of reactive oxygen species [164,165]. In one of these studies the hESC-neutrophils displayed IL-1b-induced chemotaxis in an air-pouch inflammatory mouse model [165]. In subsequent studies, Morishima et al. used an OP9 coculture method to generate three characteristic subsets, containing either azurophilic, lactoferrin, or MMP9-containing granules [166]. These neutrophils expressed characteristic neutrophil transcription factors, C/EBPα and ε, could phagocytose, respond to chemotaxic signals, and displayed bactericidal activity. In another study in 2016, Sweeney et al. used a four-stage, 32-day EB-based protocol to generate and expand hematopoietic stem and progenitors and then induce their differentiation into granule-expressing neutrophils with similar morphology and function to primary neutrophils [167]. Similarly in 2017, Schrimpf et al. differentiated marmoset (*Callithrix jacchus*, "cj") iPSCs into CD34 + /VEGFR2 − hematopoietic progenitors and then further into neutrophils. These cj-iPSC-derived neutrophils showed similar cell surface markers, subcellular structures, and phagocytic properties to primary neutrophils in a variety of in vitro tests and will facilitate preclinical evaluation of the technology in nonhuman primates [168].

The earlier-mentioned studies have laid down the foundation for the development of gene-edited PSC-based approaches to treat primary immunodeficiencies. In CGD, mutations in the gene for CYBA, CYBB, NCF-1, NCF-2, and NCF-4 cause disruptions in NADPH oxidase, which is needed for the production of superoxide and the antimicrobial functions of phagocytic leukocytes such as neutrophils. Patient-specific iPSCs from individuals suffering from CGD have been subjected to zinc-finger nuclease and TALENS-based editing to correct the underlying genetic mutations in X-linked CGD at the CYBB locus or through insertion of a corrective minigene at the AAV1 safe-harbor locus. Subsequent differentiation of the corrected iPSCs into neutrophils has shown the functional recovery of neutrophil activity [169−172]. Transplantation of gene-corrected iPSC derivatives offer a regenerative medicine approach to functionally compensate for defective granulopoiesis in CGD patients in the short or perhaps even long term.

Perspectives

As reviewed here, regeneration and replacement of PB components can be used to treat a variety of diseases and indications. PSCs have a limitless ability to self-renew and as such have garnered significant interest as an inexhaustible cell source for the generation of off-the-shelf myeloid and lymphoid lineage blood cells. PSC-derived RBCs and MKs/platelets may one day be used in transfusions to treat anemia and thrombocytopenias, yet further development is still needed to mature these cells and/or produce them on an exponentially larger scale. PSC-derived DCs can be developed as off-the-shelf cancer vaccines as an alternative to the primary DC-derived cancer vaccines currently being tested in more than 400 clinical trials. The success of CAR technology in primary lymphocytes has sparked interest in developing PSC-derived T, NK, NKT cells, and macrophages with a diverse array of CARs to treat hematologic malignancies, various solid tumors, Alzheimer's, and other diseases. In addition, PSCs can be used to generate neutrophils or their progenitors and may provide bridging therapies to help fight infections in patients undergoing myeloablative chemotherapy and HSCT or suffering from severe neutropenia due to other causes. Moreover, when combined with gene-editing technology, iPSCs can be used to create patient-specific gene-corrected neutrophils, macrophages, or their progenitors, thus offering a way to treat primary immunodeficiencies that impair the functions of these cells. Ultimately, PSC-based blood cell therapies have a unique opportunity to treat a wide variety of disorders and provide readily available, commercial-scale regenerative medicine to a large number of patients. Moreover, the combination of gene therapy, gene editing, and/or CAR technologies in PSCs makes them a powerful tool to drive the development of highly innovative, blood cell-specific cellular therapies.

Chapter 43

Red blood cell substitutes

Andre Francis Palmer and Donald Andrew Belcher
William G. Lowrie Department of Chemical and Biomolecular Engineering, The Ohio State University, OH, United States

Introduction

Blood type incompatibility reactions, short ex vivo storage shelf-life (42 days in the United States), and the risk of contracting unknown pathogens are some of the issues that have been associated with allogenic red blood cell (RBC) transfusion. To this end, researchers have long sought a RBC substitute that is universal, stable at ambient temperature and pressure, and nonpathogenic. Such a fluid would need to replicate the functionality of RBCs, while surpassing the aforementioned limitations associated with RBCs. Despite rigorous efforts to develop an effective RBC substitute in the late 20th and early 21st century, there is currently no clinically approved RBC substitute in either the United States or Europe. Regrettably, the inherent toxicity of RBC substitutes and their nonphysiologic performance obstructed the possible clinical applications. Complications of RBC substitutes include nonphysiologic O_2 delivery, vasoconstriction, systemic hypertension, and renal toxicity. Other strategies to produce these materials yielded safer materials but were too costly to pursue clinically. Current development of RBC substitutes now focuses heavily on design strategies that mitigate toxicity and restore physiologic performance. Other research has focused on developing materials that would make RBC substitutes closer in costs to an allogenic-packed RBC unit. Current RBC substitutes consist of either synthetic perfluorocarbons (PFCs) or a large variety of modified hemoglobin (Hb) species (Fig. 43.1) that can replicate various RBC functions.

Replicating red blood cell functions

In the circulatory system, RBCs perform a variety of functions (Fig. 43.2), including facilitating O_2 and carbon dioxide (CO_2) transport between the tissues and the lungs, Hb detoxification via encapsulation, and reduction via methemoglobin (metHb) reductase, and small molecule reductants, vascular flow modulation via shear-stress induced signaling [1–3], and nitrate reactions [4–6]. An ideal RBC substitute should have material properties that replicate each of these functions. Initially development of RBC substitutes only focused on O_2 transport. Recently developed materials have incorporated aspects of CO_2 transport and Hb detoxification. In addition to replicating the core functionality of RBCs, a practical RBC substitute must have reasonable circulatory half-life and be easily metabolized or excreted by the body. These materials must also meet or exceed the ex vivo shelf-life of a human blood unit to be applicable in a clinical setting. There are two classes of RBC substitutes that meet some of these functions: Hb-based O_2 carriers (HBOCs) that bind O_2 and synthetic PFCs that dissolve O_2.

Hemoglobin-based oxygen carriers

HBOCs represent the first major class of RBC substitutes. These O_2 carriers are derived from Hb, a 64.5 kDa metalloprotein found in RBCs that is responsible for O_2 storage and transport. Hb is composed of two $\alpha\beta$ dimers, with each α and β subunit holding a single heme prosthetic group in a hydrophobic binding pocket. The iron in the core of the heme prosthetic group is capable of reversibly binding O_2. In the lungs ($pO_2 \sim 144$ mmHg), Hb contained inside RBCs is typically 98% saturated with O_2 (1.34 mL O_2/g of Hb). When the RBCs reach the tissues ($pO_2 \sim 20–40$ mmHg) the Hb inside the RBC discharges most of its O_2. This ability to nonlinearly offload O_2 results from intramolecular interactions between O_2, heme, and the globin subunits. The release of O_2 triggers a conformational change from the high affinity oxygenated relaxed (R) quaternary state to the low-affinity deoxygenated tense (T) quaternary state (Fig. 43.3). During the transition between the T- and R-state, the structure of each globin subunit shifts conformation, which results in changes in the ion pairs at the α-β globin interface [7].

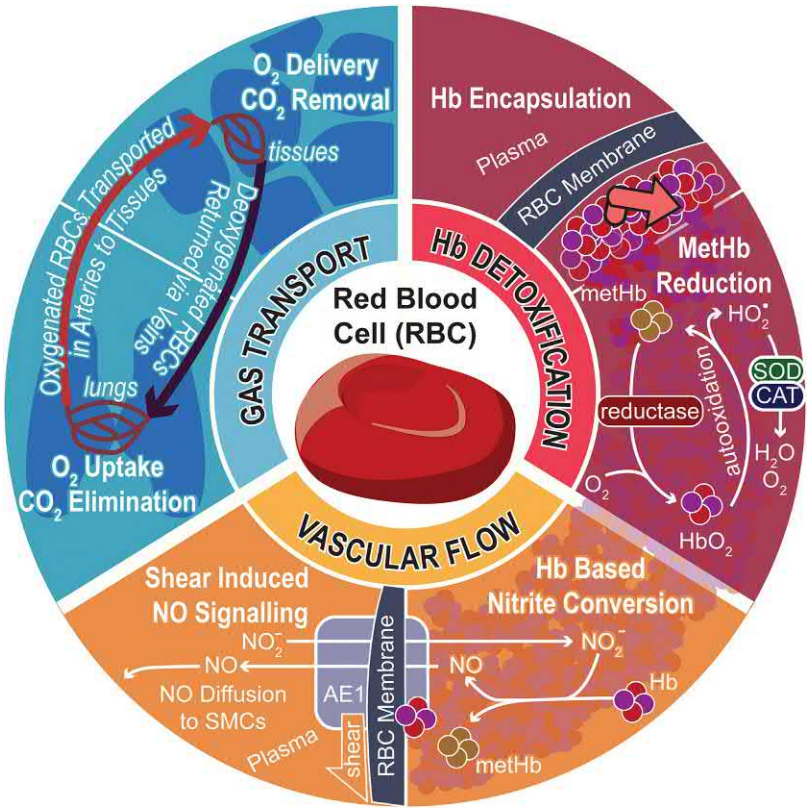

FIGURE 43.2 Functions of a red blood cell.

These conformational shifts lead to cooperative O_2 binding that facilitate O_2 offloading at physiologic conditions. This nonlinear O_2 binding is captured in the signature sigmoidal O_2 equilibrium curve of Hb. In addition to O_2, diphosphoglycerate (2−3 DPG) in RBCs can bind to deoxyhemoglobin (deoxyHb) to stabilize the tense quaternary state which decreases the O_2 affinity of Hb. Another allosteric effector is carbon dioxide (CO_2). This gaseous

ligand binds as a carbamate to the four terminal-amine groups of the protein subunits in T-state Hb further altering the O_2 affinity. This binding function also results in Hb storing and transporting 20% of the CO_2 in blood (4 mol CO_2/mol deoxyHb). Because the core functionality of the RBC (O_2 transport) depends on Hb, this protein is typically considered a key component in the formulation of many HBOCs. By isolating Hb from RBCs, blood group antigens are removed from HBOCs which eliminates crossmatching requirements and permits rapid administration. In addition, HBOCs can be stored for several years either as a dried powder or a deoxygenated solution at room temperature for use in emergency scenarios.

Hemoglobin toxicity

While purifying hemoglobin from RBCs reduces the risk of transmission of unknown pathogens, increases ex vivo storage lifetime, and eliminates blood type incompatibility reactions, administration of stroma-free Hb in the circulation is associated with renal toxicity and hypertension [8]. The mechanisms of Hb toxicity are well understood, and several mechanisms for toxicity have been proposed. The iron containing heme prosthetic group that is responsible for Hb's ability to bind O_2 is the primary component associated with the toxicity of acellular Hb. Hb can oxidize from the ferrous ($HbFe^{2+}$) form to the ferric ($HbFe^{3+}$) form known as metHb which is incapable of binding O_2. When inside RBCs, metHb accumulation is limited and protected by enzymes such as metHb reductase, catalase (CAT), and superoxide dismutase (SOD) [9]. Outside the RBC, Hb is exposed to exogenous oxidants that accelerate metHb formation. Furthermore, metHb is prone to αβ dimerization followed by the release of heme [10]. These ferric species can spontaneously form ferryl (4 + valence state) species in aqueous environments, which leads to the production of reactive oxidative species (ROS) such as superoxide and hydrogen peroxide ions. These ROS result in oxidation of lipids, protein, DNA, and mitochondria. Furthermore, the ROS produced during autoxidation drive a catalytic pseudoperoxidase cycle that oxidizes Hb to metHb and ferrylHb ($HbFe^{4+}$) [8]. The ferrylHb and its associated radical formed during the pseudoperoxidase cycle have high redox potentials (1.0 V) that further aggravate oxidative stress [11]. In the absence of allosteric effectors, most HBOCs have higher redox potentials than unmodified Hb. Despite this, most HBOCs have

increased rates of autoxidation that has been attributed to increased heme accessibility [12].

Furthermore, when in the ferric state, the iron in the heme prosthetic group no longer forms a covalent bond with the proximal histidine residue (αH87, βH92) in the hydrophobic heme binding pocket. The absence of the covalent bond results in the release of free heme that can accumulate in tissues. Of concern is the accumulation of free heme within cell membranes and the subsequent activation of Toll-like receptors which amplifies inflammatory responses [13]. To combat these effects, plasma proteins such as haptoglobin and hemopexin reduce tissue oxidation/ROS generation and aid in free Hb/heme clearance, respectively [14,15]. Unfortunately, these mechanisms are quickly exhausted due to the volume of HBOC transfusions that are typically required for emergencies.

One of the key factors linked to Hb toxicity is the protein's small molecular diameter. With a hydrodynamic diameter estimated at only 5.5 nm [16] as a tetramer (and less when dissociated into αβ dimers), Hb can freely extravasate through the vascular endothelium and into the interstitial space and tissue space [17]. Moreover, when acellular Hb extravasates through the blood vessel wall, it can inhibit NO signaling from endothelial cells to smooth muscle cells, which results in vasoconstriction and systemic hypertension [18].

The pathway for this inhibition has been well studied. In the interstitial space, HbO_2 rapidly ($\sim 10^7\ M^{-1}/s$) and irreversibly reacts with NO produced by the vascular endothelial cells to yield metHb and nitrate, effectively blocking NO uptake by the smooth muscle cells. Without the endogenously produced NO, proendothelin is converted to endothelin, which stimulates contraction of the smooth muscle cells and subsequent vasoconstriction [19]. This increased vasoconstriction then led to increased pulmonary hypertension and reduced cardiac output. In addition, the increased diffusion and subsequent endothelial interactions between nanoscale HBOCs may lead to trace NO scavenging at the endothelial wall [20].

Tissue extravasation of these acellular Hbs and the transfusion volume can lead to significant accumulation of Hb and heme within the kidney [21]. An early clinical study that attempted to transfuse acellular Hb led to rapid clearance and renal dysfunction [22]. Organ failure typically occurs due to ROS production from the accumulated Hb in the kidney. A key aspect of modern HBOC design is the mitigation of Hb's oxidative potential and vasoactivity via encapsulation, size modification, or the addition of antioxidant activity (Fig. 43.4). However, reigning in the inherent toxicity of Hb is extremely difficult once Hb is outside of the protective barrier of the RBC. Many of the approaches employed can only partially reduce the toxicity of HBOCs.

Increasing the size of HBOCs to reduce extravasation is the principal method to reduce the toxicity of acellular Hbs. Studies have found that the hydrodynamic diameter of HBOCs are inversely proportional to their vasoactivity and oxidative toxicity. Because of this, the design of many HBOCs aim to increase the stability of the Hb tetramer and the HBOC diameter [23,24]. Increasing HBOC size also increases the circulatory half-life of the materials by reducing clearance in the liver, kidney, and spleen [25] and potentially by obstructing the haptoglobin clearance pathway [26]. Many strategies to increase the size of Hb have been investigated, including polymerization, surface conjugation, and encapsulation.

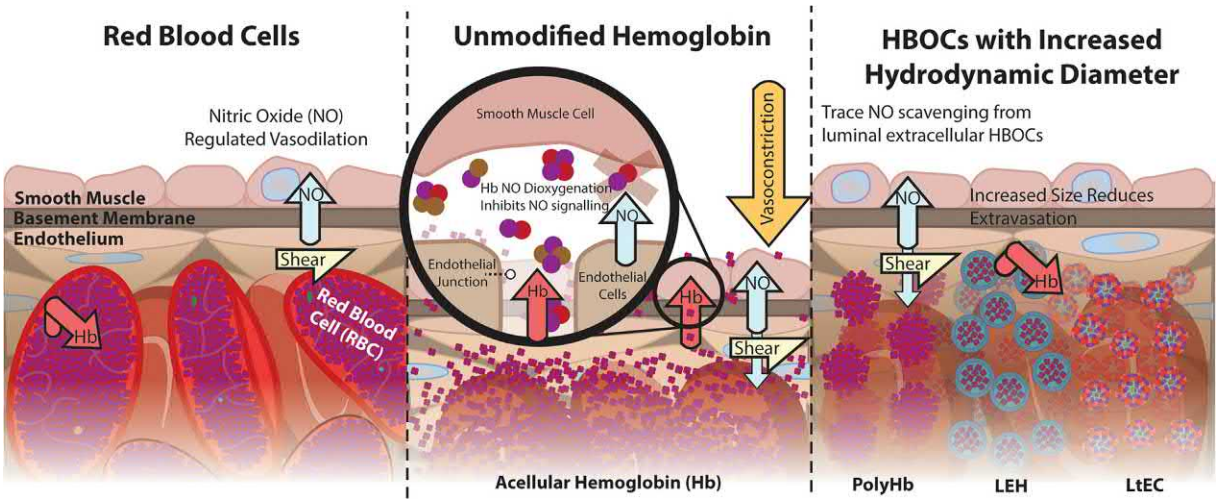

FIGURE 43.4 The role of Hb extravasation on inhibition of NO signaling from the endothelium and smooth muscle cells. HBOCs with increased hydrodynamic diameter do not extravasate, with only minimal scavenging from luminal HBOCs due to decreased contact with the endothelial vessel wall. *Hb*, Hemoglobin; *HBOCs*, hemoglobin-based oxygen carriers.

Oxygen delivery

In addition to tissue extravasation and oxidative tissue injury, the nonphysiologic O_2 offloading of many early generation HBOCs is suspected to correlate with either increased hypertension or unsuitable oxygenation. The various modifications that are employed to reduce toxicity and increase circulatory half-life alter the O_2 affinity of Hb (Fig. 43.5). In general, these modifications either increase or decrease the O_2 affinity of Hb. In some cases, where the protein conformational motion is limited by intermolecular cross-links, the cooperativity is also eliminated. Low O_2 affinity HBOCs are typically formed when HBOCs are produced under anoxic conditions ($pO_2 \sim 0$ mmHg). These species can have as little as 60% of the O_2 binding capacity of unmodified Hb at atmospheric pressure. Because of their low O_2 affinity, these HBOCs readily offload O_2 but require higher Hb or O_2 concentrations to bind an equivalent amount of O_2 compared to the Hb inside RBCs. In addition, these low O_2 affinity species may offload O_2 while in the arterioles leading to arteriolar overoxygenation autoregulatory effects [27]. High affinity HBOCs are typically produced when reacting Hb under hyperoxic conditions ($pO_2 \sim 140-700$ mmHg). In addition, other modifications can separate the Hb into $\alpha\beta$ dimers, which have characteristically high O_2 affinity like myoglobin. In contrast to low affinity HBOCs, high O_2 affinity HBOCs do not offload O_2 in arterioles and are fully saturated when in the lungs. Instead, these species retain O_2, only releasing it under ischemic or hypoxic conditions. There is still ongoing debate in the development of artificial RBCs whether low or high O_2 affinity HBOCs are more effective. Some studies have also attempted to mix low and high O_2 affinity HBOCs to establish intermediate O_2 affinities [28]. In addition, many of the chemical modifications used to prepare HBOCs eliminate or reduce the Bohr effect [26].

The potential reduction of O_2 affinity could also lead to an oversupply of O_2 that may lead to vasoconstriction. In the absence of the intraluminal diffusive barrier of the lipid bilayer present on the RBC surface, O_2 diffusion is enhanced due to the extracellular Hb species that can freely diffuse throughout the intravascular space [29,30]. This process of facilitated diffusion can lead to arteriolar vascular constriction and decreased functional capillary density due to excessive O_2 offloading to the arterioles [31,32].

Viscosity and colloid osmotic pressure

In addition to altering O_2 delivery, transfusion of a large volume of HBOC leads to altered flow in the vascular system. Transfusion of RBC substitutes reduces the hematocrit and thus apparent blood viscosity via hemodilution. Hemodilution increases blood flow velocity but decreases blood vessel wall shear stress that is necessary for mechanotransduction and subsequent regulation of functional capillary density via NO production in the endothelium [33,34]. The resultant supraperfusion increases the O_2 carrying capacity of blood, which in turn decreases transit losses to nonvital tissues and increases O_2 delivery within the capillary network [35]. Unfortunately, many of the chemical modifications used to decrease the toxicity and improve performance of HBOCs alter their viscosity and colloid osmotic pressure (COP). However, some of the strategies employed to increase HBOC size, such as Hb polymerization, can also lead to significant increases in viscosity, which impairs heart function and leads to high blood pressure. To match the COP of blood, RBC substitutes typically aim to have COPs between 20 and 25 mmHg. Application of fluids with low COP, such as saline and lactated Ringers, leads to tissue edema due to increased fluid transport into the tissue space. In contrast,

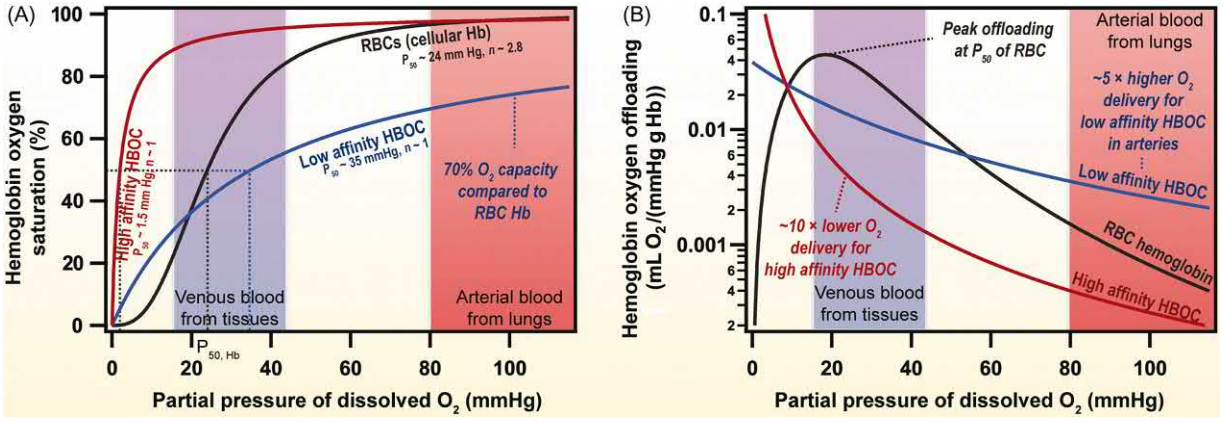

FIGURE 43.5 OEC and oxygen offloading plot for Hb inside RBCs, a low O_2 affinity HBOC, and a high O_2 affinity HBOC. *Hb*, Hemoglobin; *HBOC*, hemoglobin-based oxygen carriers; *OEC*, oxygen equilibrium curve; *RBC*, red blood cell.

transfusion of solutions with high COP leads to fluid transport from the tissue into the vasculature which can hinder nutrient delivery. However, high COP may be beneficial for reversing endothelial edema during hemorrhage [36]. To maintain the O_2 carrying capacity of blood, most HBOCs must be formulated at a concentration of at least 10 g/dL. Unfortunately, the chemical modifications that reduce toxicity typically increase the viscosity and/or COP that are directly proportional to the concentration of the HBOC. For example, poly(ethylene glycol) (PEG) surface conjugated Hb (PEG−Hb) species have extremely high COP (50 mmHg) at moderate concentrations (4 g/dL) [37]. This limits the overall O_2 carrying capacity of these solutions. Higher concentrations of PEG−Hb have increased COP which leads to fluid transport from the tissue space into the vascular space which dilutes the blood volume and further decreases blood O_2 carrying capacity.

Cross-linked and polymeric hemoglobin

As discussed previously, modifying the size and increasing the stability of stroma-free Hb can significantly decrease toxicity. One of the simplest methods to increase the size of the HBOC is through reacting the surface amino acid side chains (lysine, valine, etc.) of Hb with cross-linking reagents such as glutaraldehyde, *O*-raffinose, bis(3,5-dibromosalicy)-adipate, and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide. These reagents serve to form covalent bonds between the protein subunits, which increase the overall size of the HBOC. This has traditionally been one of the more popular methods to formulate HBOCs with many materials, including Oxyglobin, Hemopure, Polyheme, Hemolink, and Oxyvita, that have underwent clinical trials in the United States and Europe. Oxyglobin and Hemopure (OPK Biotech, Cambridge, MA) are moderate molecular weight (200−250 kDa) glutaraldehyde polymerized Hbs that had success in Phases I and II clinical trials. PolyHeme is a glutaraldehyde polymerized pyridoxal phosphate cross-linked Hb product developed by Northfield Laboratories (Evanston, IL) [38]. Despite being approved for veterinary use in the United States, Oxyglobin consists of 31% unpolymerized Hb that led to vasoconstriction, hypertension, oxidative stress, and iron deposition in endothelial, neural, and renal tissues [39−41]. Hemopure only has 2% unpolymerized Hb that overall resulted in reduced hypertension [42,43]. However, the low molecular weight of these materials led to negative vascular side effects in patients undergoing aortic and orthopedic surgery [44,45].

Instead of using glutaraldehyde as a cross-linker, Hemosol Inc (Toronto, ON, Canada) used *O*-raffinose to cross-link Hb to form the polymerized Hb product Hemolink. This material showed reduced NO affinity and hypertension in early animal studies in rats. The production process led to a heterogenous distribution of molecular weights which showed significant vasoactivity in Phases II and III clinical trials on coronary artery surgery patients. Hemolink had a low molecular weight (150 kDa), which likely led to organ failure in rats and vasoconstriction in lambs [46,47]. Despite this, production and subsequent clinical trials were abandoned due to ethical concerns during the final clinical trial [48]. One of the reasons these early materials demonstrated poor performance is the overall low molecular weight of the molecules. However, increasing the molecular weight of polymerized Hb significantly decreases hypertension and oxidative tissue injury [25].

To combat vasoconstriction, hypertension, and oxidative stress, OXYVITA Inc. (New Windsor, NY) developed a high molecular weight (17 MDa) HBOC known as OxiVita [49]. This HBOC was instead produced with cross-linking the beta subunit with bis(3,5-dibromosalicy)-adipate combined with tetramer polymerization using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide [50,51].

In addition, other enzymes such as SOD, CAT, and carbonic anhydrase (CAN) can be cross-linked into the polymeric Hb structure to mitigate oxidation and increase CO_2 solubility [52−54]. Cross-linking these antioxidant species into the polymerized Hb structure reduced hypertension. Additional studies have conjugated fibrinogen to the polymerized Hb complex to facilitate coagulation in addition to oxygenation [55]. Because increasing the size of the polymeric Hbs has a significant effect on the side effects induced by cell-free Hb, some researchers have aimed to make Hb nano- and microparticles. One such material is manufactured via the coprecipitation of Hb into a manganese carbonate matrix with glutaraldehyde surface polymerization [56−58]. These particles can have narrow size distributions with negative zeta potentials. Unfortunately, the enormous size of some of these Hb microparticles (>700 nm) can increase phagocytosis and will most likely lead to macrophage activation if the size is not suitably decreased [59]. Despite numerous chemical modifications, many of these cross-linked and polymerized Hb species still had relatively short circulatory half-lives ($\sim$24−48 hours).

Surface conjugated hemoglobin

To increase HBOC circulatory half-life, Hb can be surface conjugated with PEG to cloak the Hb from the immune system. PEG, benzene tetracarboxylate dextran, hydroxyethyl starch, and albumin have all been conjugated to the surface of Hb to increase its circulatory half-life. The PEG conjugated Hb, MP4OX (MP4, Hemospan), has undergone extensive clinical testing. This is a high O_2 affinity Hb species with low cooperativity and Bohr effect that has been generally determined to be safe and

effective [60]. However, these species have been shown to scavenge NO at the same rate as many other HBOCs [18]. Their high COP (50 mmHg at 4 g/dL) limits its concentration in the circulation. Furthermore, its high O_2 affinity and similarity to PEG surfaced conjugated albumin indicate that it acts as a plasma expander [61]. Some studies have shown that steric interactions between the PEG groups conjugated to the Hb tetramer led to $\alpha\beta$ dimerization and high O_2 affinity [26]. More recently, SynZyme Technologies LLC (Irvine, CA) developed a polynitroxylated $\alpha-\alpha$ cross-linked Hb (VitalHeme). This product was designed to take advantage of the O_2 transport of Hb, plasma expansion of PEG, and antioxidant behavior from polynitroxylation [62]. Other studies have attempted to cloak the Hb in a human serum albumin (HSA) core shell structure via covalent bonds [63]. While surface conjugation increased circulatory half-life, it did not always increase the size enough to prevent extravasation into the tissue space and hypertension.

Encapsulated hemoglobin

To both increase HBOC hydrodynamic diameter and vascular retention, researchers can also encapsulate Hb inside vesicles to form artificial cells. Encapsulation of Hb inside vesicles composed of lipids or amphiphilic polymers presents a close analogue to the structure of RBCs. In these HBOCs, Hb is encapsulated inside the aqueous core of vesicles that prevent Hb from directly interacting with the vasculature. Apart from reducing interaction with the vasculature, encapsulation can also reduce facilitated diffusion associated with cell-free Hb. The high Hb concentration inside the vesicle also stabilizes Hb in its tetrameric form. During production of these nanoparticles, it is possible to coencapsulate antioxidants, allosteric coeffectors, and other components to mimic the RBC cytoplasm more closely.

Early iterations of these materials used lipid bilayers to encapsulate Hb inside liposomes. These materials demonstrated low circulatory half-life due to aggregation and liposome fusion during storage [64]. To increase circulatory half-life, reduce plasma component interaction, and increase storage stability, PEG was preferentially incorporated into the outer surface of the vesicles to form PEG conjugated liposome encapsulated Hb (PEG−LEH) [65]. Further studies found that increasing the length of PEG chains increased the circulatory half-life of the PEG−LEH particle [66]. However, over increasing the molecular weight of PEG chains leads to the formation of PEG-lipid micelles [67] and complement activation suppression [68,69]. Like polymerized Hb, increasing the size of the PEG−LEH particle led to a decrease in vasoconstriction and hypertension at similar doses [24]. PEG−LEH particles are primarily cleared through the spleen and liver leading to increased lipid levels 1 week after transfusion [70] and abnormal splenic behavior that persists for several weeks [71]. A primary challenge with the production of LEH species is severe oxidation of the encapsulated Hb (50%−75% metHb) that occurs during encapsulation. Unfortunately, the purification process that isolates Hb from the RBC matrix also removes many of the RBC proteins that are responsible for the reduction of metHb. To combat Hb autoxidation, many LEH products are saturated with carbon monoxide (CO) to stabilize Hb in the Fe^{2+} state. The strong bond between CO and the iron in the heme ligand not only eliminated autoxidation but also the O_2 carrying capacity due to competitive inhibition. Another strategy to reduce autoxidation of Hb consists of coadministering methylene blue and its metabolic byproducts as an electron transfer mediator between LEH and the Embden−Meyerhof−Parnas and pentose phosphate pathways in RBC cytosol [72,73].

Another concern with PEG−LEH species is the low serum-half-life resulting from shear degradation. An actin matrix can be introduced into the core of LEH to increase the mechanical stability of the LEH that further increases half-life [74]. Another alternative is encapsulating Hb within a PEG−polylactic acid membrane nanocapsule with polymerized Hb, SOD, CAT, and CAN. Because of the addition of these components, these materials had reduced phagocytosis and decreased metHb levels [75]. Another alternative is the encapsulation of Hb in nonbiodegradable biocompatible hydrophilic lipogels. These lipogels can be photopolymerized within the lipid bilayer to give hybrid properties of the hydrogels and liposomes [76]. An alternative encapsulation technique uses amphiphilic diblock copolymers (polymersomes) that contain a hydrophilic (PEG) and hydrophobic block to form vesicles [77−79]. These materials allow for control of the membrane thickness and PEG corona [80]. These materials also showed reduced vasoactivity and NO dioxygenation compared to PEG−LEH. Unfortunately, the process of polymersome formation yields extremely low Hb encapsulation efficiency ($\ll 10$ g/dL) which limits the O_2 carrying capacity. Because of the low O_2 carrying capacity, PEG−LEH remains the most attractive type of encapsulated HBOC.

Sources of hemoglobin

The primary source of human-derived Hb is derived from freshly expired human-packed RBC units. Because removing Hb from RBCs eliminates blood group antigens, Hb can be also be derived from nonhuman sources. Many of these nonhuman HBOCs derive their Hb from blood waste from the meat-processing industry. Because of this, HBOCs have incorporated bovine and porcine Hb as potential source materials. Bypassing the need for human

Hb by using bovine Hb for HBOC production can help with patients who refuse allogenic blood transfusions due to religious grounds [81]. However, substantial portions of the global population are unable to receive transfusions originating from bovine, porcine, or other animal sources due to religious or moral beliefs. An alternative to these methods is the production of recombinant Hb using bacterial or yeast cultures to produce Hb.

Recombinant hemoglobin

Development of recombinant Hb began in 1980s with the eventual expression of HbA in transgenic pigs [82], *Escherichia coli* [83], and *Saccharomyces cerevisiae* [84]. Initial yields were modest with 24% HbA in transgenic pigs and 2%−10% expression in *E. coli* and *S. cerevisiae* [85]. Unfortunately, this form of Hb is still prone to the toxicity associated with acellular Hb species. To aid with mitigating the inherent toxicity of recombinant Hb, researchers began to explore genetic engineering to improve its function outside RBCs. The key goals were to decrease NO reactivity, modulate O_2 offloading, decrease autoxidation, and mitigate heme release [85].

The primary method of engineering recombinant Hb is based on rational mutagenesis to decrease toxicity and increase O_2 delivery. One such modification is the use of the di-α gene with a single cysteine link between the C-terminal end of one α subunit and the N-terminal of the second α subunit (rHb0.1) [86]. Because of the di-α link, rHb0.1 does not dissociate into αβ dimers under physiologic conditions. Because of this increase in stability, rHb0.1 serves as a basis for many recombinant HBOCs. The first of these, which underwent preclinical and Phase I clinical trials, was expressed in *E. coli* with glycine-fused α subunits and the Presbyterian mutation (N108K) to decrease O_2 affinity to match that of RBCs (rHb1.1) [85,86]. In a small animal study, rHb1.1 was highly vasoactive because of the small size of the molecule and unmodified NO scavenging potential [87,88].

Following rHb1.1 Baxter Therapeutics and the Olsen group developed an rHb (rHb3011) with glycine fused α subunits, a mutation to reduce capture volume in the distal portion of the heme pocket (αL29W, βV57W) to decrease NO scavenging, and a mutation that weakens that stabilization of bound O_2 to heme (αH58Q) that assists with O_2 dissociation [19,89]. To further reduce extravasation and increase circulatory the half-life, rHb3011 was polymerized and surface conjugated with PEG to form rHb2.0. This material significantly reduced vasoconstriction and hypertension compared to rHb1.1 [87]. Unfortunately, the αL29W mutation that lowered NO reactivity also decreased Hb stability and increased autoxidation and heme loss [85]. Furthermore, compliment activation was observed in clinical trials resulting from autoxidation, heme loss, and subsequent protein degradation [90].

Apart from the mutations used in rHb0.1, rHb1.1, and rHb2.0, other mutations have been considered, including mutations to increase apohemoglobin stability (βG16A, βH116I, αG15A) [91], decrease O_2 affinity by allosterically stabilizing the T-state of the tetramer (αV96W, βK82D) [92,93], and decrease heme dissociation (βS44H) [94]. Other researchers have also proposed replacing tyrosine and methionine residues with phenylalanine to decrease the lifetime of protein radicals to decrease metHb formation and increase Hb stability [95]. Some researchers have proposed that directed evolution and random mutagenesis could be used to screen for Hb with more desirable properties. Despite advancements in directed evolution, screening the resulting large libraries of Hb is limited by protein purification and biophysical analysis [85].

A key concern in recombinant Hb-based O_2 carrier (rHBOC) production is the prohibitive cost of recombinant protein expression combined with low yields. To this end, rHBOC development has recently focused on methods to reduce the cost per gram of rHBOC produced. A major limiting factor is that endogenous heme ligand group production by *E. coli* limits the formation of Hb. This can be solved via addition of the first molecule involved in the porphyrin synthesis pathway and δ-aminolevulinic acid [85]. However, the high cost of δ-aminolevulinic acid can limit production. Instead, excess exogenous hemin is added so that hemin can be introduced via passive diffusion into the cell. Unfortunately, the addition of hemin leads to hematin species that must be removed via compilated purification processes. Researchers have also developed coexpressed heterologous heme transport systems such as plasmids for heme utilization genes (pHUG) [96] and plasmids for hemoprotein expression (pHPEX) [97] to decrease the total amount of heme required. Alternatively, some researchers are using *E. coli* cell lines with higher porosity (BL-21) [98] to reduce the amount of heme required. Because most systems still rely on bacterial expression, additional purification steps to remove lipopolysaccharides and other endotoxins bind to Hb to prevent pyrogenic responses [99]. An alternative may be to use heterologous expression in mammalian systems [100]. As an extension on the molecular engineering of rHBOCs, recombinant albumin has been genetically engineered to conjugate to synthetic tetraphenylporphinatoiron (II) complexes. This complex is capable of reversibly binding O_2 with low O_2 affinity [101,102].

Erythrocruorins

Each of these earlier HBOC design strategies aimed to modify Hb to reduce the toxicity that results from the small molecular diameter of Hb. Thus an alternative

design strategy would be to use an Hb source derived from animals that lack RBCs and have thus evolved Hb-like proteins that can exist outside of the protective environment of RBCs. The earthworm (*Lumbricus terrestris*) is one such animal. *L. terrestris* erythrocruorin (LtEc) is the O_2 carrying protein found in earthworms. This massive 3.6 MDa molecular weight protein contains 144 heme containing globin subunits and 36 nonheme linker proteins held together with disulfide bonds and protein interactions to form a 30 nm diameter nanoparticle [103,104]. LtEc is also less prone to oxidation into the Fe^{3+} and Fe^{4+} states due to the lower solvent exposure of the heme binding pocket and higher redox potential (+112 mV) compared to HbA (−50 mV) [105–107]. Initial applications in small animal models demonstrated that this protein was able to delivery O_2 without causing systemic hypertension [108–110]. In fact, the moderate COP (14 mmHg) and negligible rate of NO scavenging likely led to vasodilation in animal models. Recent work has sought to improve LtEc circulatory half-life and stability via PEGylation, glutaraldehyde cross-linking, and poly(acrylic acid) conjugation [111–113].

The erythrocruorin of the lugworm, *Arenicola marina* erythrocruorin (AmEc) is another annelid Hb that has a much lower rate of autoxidation ($-0.005\ hour^{-1}$) compared to HbA ($0.014\ hour^{-1}$) [106]. In addition, AmEc has a much lower NO scavenging rate compared to HbA [114]. Because of these properties, it is currently being developed as HEMOXYCarrier (Hemarina SA) with positive results in small animal studies. Apart from AmEc the erythrocruorins of several ocean worms including *Oligobrachia mashikoi* and *Glossoscolex paulistus* are strong RBC substitute candidates due to their extreme heat tolerance and hydrogen sulfide transport characteristics [115,116]. However, each of these marine worm species have typically evolved to optimize O_2 transport under subnormothermic conditions (4°C–8°C), thus many of them are not well suited for O_2 delivery under physiologic conditions (37°C) in humans. For both LtEc and AmEc a key concern is their supply. Unlike Hb sourced from humans, cattle, swine, or other mammals, erythrocruorins have limited commercial availability and require extensive purification for use as an RBC substitute [117].

Perfluorocarbons

The second class of RBC substitute is PFCs. PFCs are biologically inert synthetic chemicals composed entirely of carbon and fluorine atoms that are capable of transporting O_2 and other gaseous ligands. These O_2 carriers can exist as either straight or cyclic hydrocarbon chains with the general chemical formula of C_nF_{2n+2}. Common PFCs used in the development of artificial blood include perfluorodecalin, perfluorooctyl bromide, and perfluorotripropylamine. Because of the strong chemical bonds between the fluorine and the carbon atoms, the body is incapable of metabolizing PFCs. These strong bonds also make PFCs highly hydrophobic and lipophobic [118]. Unlike Hb, PFCs do not bind O_2. Instead, the high solubility of O_2 in PFC solutions can increase the total concentration of O_2 in the plasma. For example, the PFC perflubron dissolves 0.697 μL O_2/(mmHg mL PFC) (59.5 μL O_2/mL PFC under atmospheric conditions) [119]. Unfortunately, because of the high insolubility of PFCs, emulsifiers such as albumin and egg yolk phospholipids must be added to solubilize PFCs. These emulsifiers limit the overall concentration of the PFCs that in turn necessitates greater doses to maintain systemic O_2 delivery. The first PFC emulsion approved by the FDA, Fluosol-DA only has an O_2 carrying capacity of 0.07 μL O_2/(mmHg mL PFC) (10.8 μL O_2/mL PFC under atmospheric conditions) which is much less than the O_2 carrying capacity of Hb in RBCs (450 μL O_2/mL blood) [120]. More recently developed PFC emulsions such as Oxygent have increased the O_2 solubility to 0.17 μL O_2/(mmHg mL PFC) (25.5 μL O_2/mL PFC under atmospheric conditions) [121]. Unfortunately, these materials still are not able to offload the same amount of O_2 compared to RBCs. The key difference between HBOCs and PFCs is the linear saturation of PFCs with O_2 as a function of increasing dissolved O_2 concentration. For example, a pure perflubron solution requires an atmospheric O_2 content of ~290 mmHg to match the O_2 delivering capacity of RBCs. In order to match the O_2 delivery capacity of RBCs, most emulsified PFCs require hyperbaric O_2 treatment to maintain the O_2 content in the lungs above 760 mmHg. Another alternative would be to increase the O_2 solubility of the PFC. To match RBC performance an ideal PFC emulsion would have to possess an O_2 solubility of ~1.2 μL O_2/(mmHg mL PFC). Unfortunately, this approximately doubles the solubility of pure PFC solutions and does not come close to approaching the O_2 carrying capacity of RBCs (Fig. 43.6).

Fortunately, PFCs are heat stable in excess of 300°C, which makes them amenable to heat-sterilization techniques. Because PFCs are composed of synthetic chemicals, PFCs can be transfused to individuals that refuse human blood or proteins derived from humans and/or animals. Despite early clinical success, Fluosol-DA was eventually pulled from the market in 1994 due to decreases in platelet count and flu-like symptoms resulting from macrophage activation due to the large size of the PFC particle droplets [122]. Following Fluosol-DA, many strategies were employed to improve emulsified PFC performance while decreasing negative side effects. OxyFluor (HemaGen, Missouri) is a perfluorodichlorooctane emulsion that had an overall higher O_2 carrying capacity compared to Fluosol. Despite its success in clinical trials, flu-like symptoms and thrombocytopenia halted development [123].

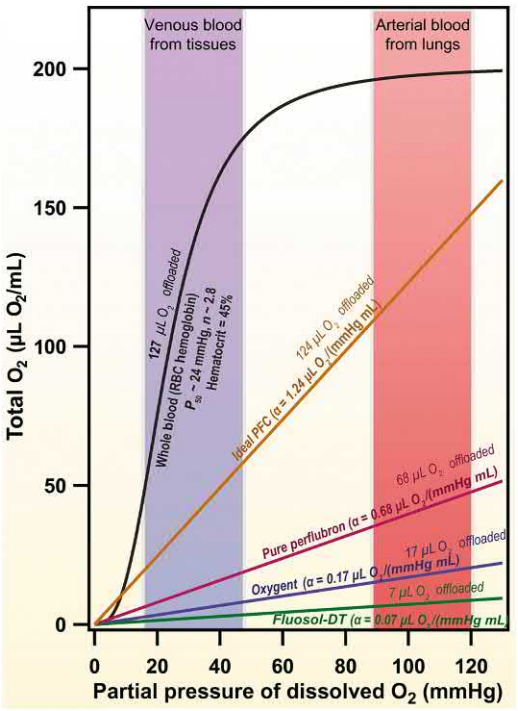

FIGURE 43.6 Total O_2 available from whole blood with a hematocrit of 45%, an ideal oxygen carrying PFC, a pure solution of perflubron, a pure emulsion of Oxygent, and a pure solution of Fluosol as a function of the partial pressure of dissolved O_2. The linear relations were calculated from the solubility of each PFC. O_2 offloading was calculated from the predicted O_2 delivered from the arterial (120 mmHg) to venous (20 mmHg) conditions. *PFC*, Perfluorocarbon.

Another PFC emulsion, Oxycyte (Synthetic Blood International, California), composed of perfluorodecane emulsified in egg-white phospholipid was tested in patients with traumatic brain injury in Phase II clinical trials [124]. However, additional Phase II trials were suspended for this material. Perftoran (Perftoran, Russia) was a perfluorodecalin and perfluoro-*N*-(4-methylcyclohexyl) piperidine emulsified in Proxanol-268 that was used in a variety of applications in Russia and Mexico [125]. Oxygent (Alliance Corp, California) is a perflubron/*F*-decyl bromide PFC emulsified with egg yolk phospholipid developed by Alliance Pharmaceutical Corp. Although Oxygent performed well in a Phase III general surgery trial [126], subsequent trials in cardiopulmonary bypass surgery led to adverse neurological events such as stroke [127]. However, researchers have speculated that these events were likely caused by a failure in the design of the clinical trial rather than from the material properties of the PFC emulsion.

One challenge associated with each of these PFC emulsions is the tendency of the particles to form large droplets. These large droplets elicit the production of cytokines by activated macrophages and impair neutrophil functions [122]. To combat large droplet formation, encapsulation of PFCs can be used to increase the solubility while maintaining a small droplet size. These methods can use synthetic polymers such as poly(lactic-*co*-glycolic acid)−PEG [128], biologic materials such as HSA [129], or RBC membrane fragments [130] to encapsulate the PFC droplets.

Perspectives

Despite decades of work, there is no clinically approved RBC substitute. However, recent work on the effects of HBOC size optimization and advances in reducing the cost of manufacturing and processing has reinvigorated corporate interest in HBOC development. One limiting factor associated with HBOCs is the cost to manufacture the materials. An ideal RBC substitute would ideally be cost-completive with a packed RBC unit. Unfortunately, many HBOCs require either expensive reagents, (PEGylated/encapsulated HBOCs), have low yields (recombinant HBOCs), or extensive purification (polymerized HBOCs/erythrocruorin) which increases the cost of a unit compared to a unit of RBCs. Recently, cost-effective large-scale purification methods such as tangential flow filtration have been used to help reduce manufacturing costs [110,131,132]. Lately, there has also been a tendency to combine several material modifications, such as PEGylation of LtEc [111] and rHb3011 [87], to increase overall performance and decrease side effects. PFCs are typically easy to produce and show no issues with NO scavenging and ROS generation. Furthermore, the introduction of improved emulsification/encapsulation methods in PFC preparation may help mitigate macrophage activation and improve stability. Despite these advantages, PFCs are still limited by the absence of physiologically relevant O_2 offloading that has been implicated with stroke and autoregulatory responses. In addition, despite approval for clinical applications, PFCs have issues associated with the large required doses and increased risk of stroke. Because no RBC substitute is capable of replicating all the functions of RBCs, RBC substitutes have primarily been applied as an "oxygen bridge" until normal blood transfusions can be applied in "extreme, life-threatening situations" [8]. Many companies and researchers are now looking past trauma, hemorrhagic shock, and anemia to other applications including cancer treatment, organ transplant preservation, and tissue-engineered construct oxygenation.

Organ transplant preservation

Due to their increased ability to dissolve O_2 versus aqueous solutions, PFCs have long been used for static cold organ preservation [133]. However, cold static preservation of organs can lead to progressive tissue damage, which directly effects organ function [134]. Machine perfusion of

organs is thought to mitigate the problems associated with cold static organ storage by providing O_2 and nutrients while removing metabolic waste products. Lately HBOCs and PFCs have also been applied to machine perfusion devices to increase O_2 delivery to the tissues. While RBCs may be added to the machine perfusion solution, there are still issues with hemolysis and subnormothermic RBC performance. Instead, both PFCs and HBOCs may be used as an oxygen carrying perfusate in organ perfusion circuits. PFC emulsions have been used to supplement organ perfusion solutions for canine, porcine, and human kidneys [135–137]. Preliminary studies with Hemopure for machine perfusion of porcine livers preserved hepatic function [134,135,138]. Another recent study used AmEc for subnormothermic perfusion of lung tissue that improved graft function [139].

Cancer treatment

Beginning in the early 1990s, researchers attempted to use RBC substitutes to make chemo and radiotherapy more effective in the treatment of cancer. These researchers tried a variety of materials, including polymerized Hb [140–145], PEG–Hb [146,147], and PEG–LEH [148–150]. In general, these studies have shown that HBOCs are effective at increasing O_2 delivery to the tumor tissue if large enough dosages are provided [151]. Supraperfusion was hypothesized to be one of the primary mediators of the increased O_2 delivery [152]. More recently computational models have predicted that the O_2 affinity of HBOCs is a primary determinant of O_2 delivery to hypoxic tissues [153,154]. In addition, some studies have found that PFCs, such as Fluosol-DA and Oxygent, can be used to facilitate increased O_2 delivery to tumors to increase the effect of radiotherapeutic, chemotherapeutic, and photodynamic treatment [155]. A recent article has even used ultrasound paired with PFCs to increase O_2 delivery directly to tumors [156].

Tissue-engineered construct oxygenation

A major barrier in tissue engineering is adequate O_2 supply to tissue scaffolds. Standard tissue-engineering methods rely on diffusive O_2 transport throughout the scaffold, which limits the size of the final construct. Oxygen is a vital for cellular respiration and differentiation [157,158]. Simply increasing the ambient O_2 supply can lead to ROS production and subsequent uncontrolled differentiation and inflammation [159–161]. HBOC supplemented media has been shown to increase aerobic respiration and drug metabolism to hepatocytes cultured within a hollow fiber bioreactor [162,163]. Mixing HBOCs with varying O_2 affinity may also be used to regulate tissue construct oxygenation [28]. In addition to HBOCs, PFC emulsions such as Oxygent and Oxycyte have been used to engineer cardiac muscles on a porous scaffold [164–166]. These PFC emulsions improved cell viability, function, and phenotype of the cultured cells.
