The kidneys are a pair of complex organs that are widely known for their role in urine production and waste elimination, but they also have numerous other responsibilities and are key regulators of normal physiologic processes, including electrolyte homeostasis, acid−base balance, fluid status, blood pressure control, maintenance of bone health, and erythropoiesis. These functions are executed by the collective activity of an array of individual units called nephrons, which are epithelial structures comprising a set of highly specialized segments. Renal failure develops when a significant number of nephrons are injured or lost, which results from a wide variety of acute and chronic etiologies in the clinical setting. Irreversible and progressive diminution of kidney function commonly leads to end-stage kidney disease necessitating renal replacement therapy (e.g., dialysis or transplantation), and this condition is increasing in worldwide prevalence. While dialysis is a reliable method to achieve fluid balance and solute clearance, it is associated with substantial morbidity and mortality, and it can only replace a small fraction of normal kidney functions. Renal transplantation, on the other hand, is significantly limited by donor organ availability and requires lifelong immunosuppression. As a result, there is an obvious need for novel approaches to the prevention and treatment of kidney disease, including tissue engineering and other potential regenerative therapies. One prominent strategy toward this objective is the use of stem cells to generate renal tissues, a field that has progressed considerably in recent years. These efforts have been grounded in an advanced understanding of the basic principles of kidney development, during which stem and progenitor cell types predominate. This chapter will provide a discussion of developmental mechanisms of renal embryology and stem cell biology, and we will review recent advances in regenerative technologies relating to the kidney.

Kidney development

Our current understanding of embryonic kidney development comes from decades of work in a variety of model organisms, including zebrafish, frog, chick, and a remarkable array of mouse genetic studies. The resulting principles have influenced nearly all subsequent efforts toward kidney regenerative medicine. Thus in this section we will review and summarize the relevant literature pertaining to kidney developmental biology, with a particular emphasis on the signaling pathways and tissue interactions that drive organogenesis. We also refer readers to other comprehensive reviews that more thoroughly describe the transcriptional regulators that coordinate nephrogenesis [1−3].

Throughout the course of evolution, the kidney has become increasingly complex and highly specialized. The metanephros is the latest and most sophisticated version of the organ, and it forms the functional adult kidney in amniotic organisms. A significant developmental advancement of the metanephros is an iterative branching process that leads to a compact organ comprising thousands to millions of individual nephrons. The preceding evolutionary structures, the pronephros and mesonephros, do not function in adult amniotes, although they fulfill the excretory needs of lower vertebrates and anamniotes. Importantly, they still form transient structures in mammalian embryos. These vestiges have essential embryologic roles, and their distinctive transcriptional networks and other cellular markers have helped direct developmental programs in vitro

and guide our efforts to generate metanephric kidney tissue from stem cells.

Early embryonic origins of nephrogenic tissues

The kidney derives from a column of tissue, termed the intermediate mesoderm (IM), which is situated between the paraxial and lateral plate mesoderm (LPM). The IM, marked by expression of transcription factors Osr1 and Pax2 [4–6], extends from approximately the sixth somite to the caudal region of the embryo. The presumptive pro-, meso-, and metanephros are arranged in a collinear fashion along the anteroposterior axis. Early in development, a simple epithelial duct (termed the nephric or Wolffian duct) emerges from the anterior IM and begins migrating posteriorly. As it passes the remaining nephrogenic IM, the nephric duct sequentially induces formation of pronephric and mesonephric tubules. Upon reaching the posterior region, it sprouts a branch called the ureteric bud (UB) that invades the metanephric blastema. This process initiates the reciprocal tissue interactions that govern subsequent development of the metanephric kidney. These early events, from gastrulation through early branching morphogenesis, form the basis on which methods for de novo generation of renal tissues have been built.

Gastrulation comprises a complex series of cell movements and fate decisions that segregate the embryo into three germ layers: the ectoderm, mesoderm, and endoderm. Although gastrulae of different species exhibit marked morphologic variation, numerous studies have demonstrated that the molecular circuitry underlying this process is highly conserved. A combination of TGFβ/nodal/activin and WNT/β-catenin signaling are essential for specification of the endodermal and mesodermal lineages, while the fibroblast growth factor (FGF) and bone morphogenetic protein (BMP) pathways also contribute important, albeit less well defined, functions during gastrulation. Together these signals act in concert to direct the organized migration of cells toward their eventual fate and position in the embryo. In amniote embryos, such as birds and mammals, this results in the formation of a visible structure on the posterior half of the embryo—the primitive streak—through which mesendodermal progenitors ingress and differentiate. Recapitulation of the induction of gastrulation, or a primitive streak-like stage, is the foundation of many methods that attempt to differentiate pluripotent cells into renal lineages.

How are the different mesodermal lineages segregated during gastrulation? Initial insights were gathered using lineage-tracing experiments in chick and mouse embryos, which demonstrated that a cell's location within the primitive streak predicts its subsequent fate [7–10]. Specifically, the anteroposterior axis in the streak translates into the mediolateral axis of the embryo: the medially located paraxial mesoderm is derived from anterior streak while the posterior portions form the eventual LPM. The IM comes from an intermediate position, found to be roughly one-third of the streak length posterior to the node [8] (Fig. 44.1A). These findings, as well as similar pregastrula fate mapping data in zebrafish and *Xenopus* embryos [11–13], raise the possibility that cells are committed to the IM fate at a very early stage as they emerge from the primitive streak. However, contrary to

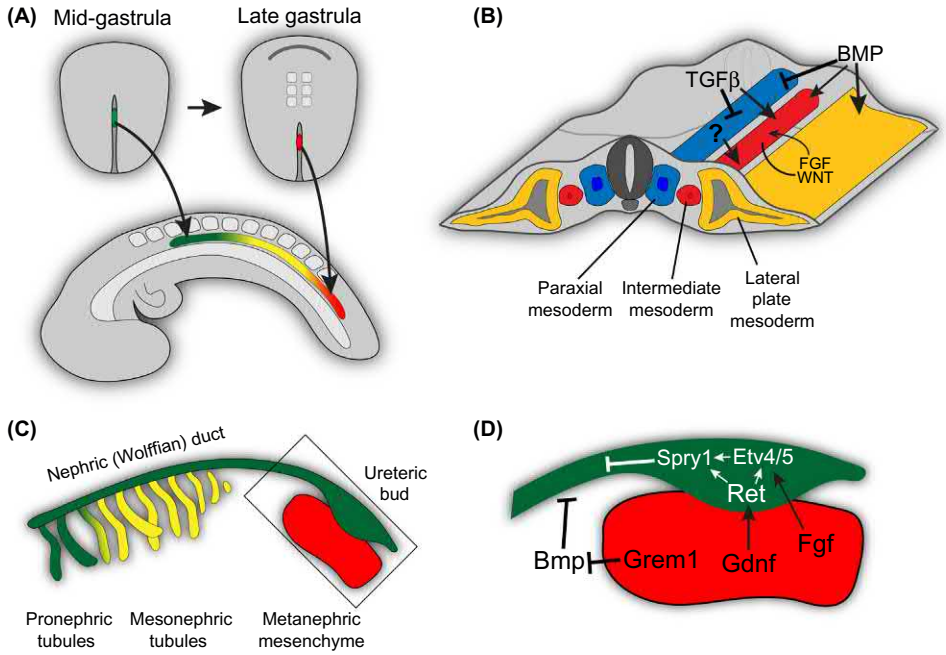

FIGURE 44.1 Early stages of vertebrate kidney development. (A) Presumptive IM cells transit through the mid-primitive streak, with earlier cells contributing to anterior tissues and later cells adopting a posterior fate. (B) Schematic representation of signaling pathways that mediate medial-lateral patterning of early mesodermal tissues. (C) The nephric duct derives from anterior pronephric IM and migrates posteriorly to contact the metanephric mesenchyme. There it develops a thickened UB, which ultimately migrates into the metanephros. (D) Multiple signaling pathways, including Gdnf, Fgf, and BMP, function to coordinate proper location of UB outgrowth. *IM*, Intermediate mesoderm; *UB*, ureteric bud.

this notion, there has been a myriad of experiments across several model organisms demonstrating marked plasticity among the early mesodermal lineages. Thus available data indicate that a cell's fate is instead determined by local signaling cues along the mediolateral axis (summarized in Fig. 44.1B). The BMP pathway has been shown to promote specification of lateral lineages while suppressing the paraxial mesodermal fate [14–16], and *Bmp4* is expressed in both the surface ectoderm and LPM itself at the appropriate developmental time [17]. Explant studies with chick mesoderm suggested a morphogen model in which high BMP promotes LPM, and intermediate signaling activity specifies the IM fate [18]. However, this model is likely oversimplified given that other signals are also involved. TGFβ is required for IM specification in chick mesoderm [19,20], consistent with previous observations that activin can promote pronephric gene expression from *Xenopus* animal caps [21]. Other important pathways include FGF and WNT, as FGF widens the IM field [22], and canonical WNT activity is required for the normal expansion of the IM progenitors [23]. Further, there is an unidentified medial signal, derived from the paraxial mesoderm, that is necessary for IM specification [24,25].

Collectively, the above data suggest that there is a complex milieu of growth factors that act in concert to pattern mesodermal lineages according to their mediolateral positions. Then once the initial blueprint is established, these tissue boundaries are further refined and sharpened by gene regulatory networks controlled by compartment-specific transcriptional regulators [26–28], a commonly observed mechanism throughout development [29]. Despite the tremendous advances in our understanding of these early events, there remains a largely unexplained phenomenon that the IM itself only forms in the caudal half of the embryo. This could be rationalized by one of two possible scenarios: (1) that the particular IM-inducing environment is not found in the rostral mesoderm, or (2) that anterior tissues are somehow refractory to adopting the IM fate. An elegant set of recombination experiments in chick embryos by Barak et al. provided support for the latter possibility [30]. Prospective IM tissue from the primitive streak transplanted into anterior regions adopted renal-specific gene expression (Lim1 and Pax2), while prospective nonnephrogenic tissue from an earlier stage streak was unresponsive to signals in the posterior IM. Hence, these results indicate that appropriate inductive cues are present along the anteroposterior axis in the prerenal mesoderm, but a distinct signaling environment in the primitive streak is required for cells to be competent to adopt the IM fate. One factor that could mediate this effect is retinoic acid (RA), which is both necessary for IM specification [31] and sufficient to cause ectopic anterior expansion of IM gene expression [20]. In chick the RA effect is phenocopied via misexpression of HoxB4, implying that RA is an important regulator of anterior–posterior axis formation.

While we have thus far focused on the specification of the IM as a whole, it is essential to also appreciate the domains along the longitudinal axis within the IM itself. These distinct anteroposterior identities are functionally realized at later stages of development. The anterior region, the site of formation of the pronephros, is unique in its ability to form the nephric duct that extends caudally to induce a wave of induction and tubulogenesis within the nephrogenic cord [32]. The posterior-most IM, where the metanephros forms, develops into the highly branched kidney exclusive to amniotes, while the intervening mesonephric IM forms a simpler pattern of parallel tubules along the trunk of the embryo. The molecular and developmental bases for this patterning are not well understood. Regionalized expression of important regulatory genes is evident soon after IM formation, such as *Gata3* in the rostral IM [33] and *Eya1* in the caudal domain [34]. Other genes, including *Sall1* and *Six1/4*, are broadly expressed but have functions that are specific to the prospective metanephric region [35,36]. To a large extent, though, the foundation of the anteroposterior arrangement within the IM is likely attributable to *Hox* factors, which broadly mediate axial patterning in mesodermal lineages (reviewed in Ref. [37]). Similar to other tissues, *Hox* genes are expressed in the early IM in a collinear order according to their chromosomal positions [20,38]. The posterior *Hox* cluster, particularly the *Hox10/11* paralogs, are crucial for proper development of the metanephric kidney [39–42]. Remarkably, ectopic expression of a *Hoxd11* transgene is sufficient to induce partial metanephric character in the mesonephros [43], consistent with the pattern of posterior dominance described elsewhere [44].

The mechanisms that control axial patterning are poorly understood, likely owing to the dynamic nature of gastrulation and iterative use of signaling pathways that complicate experimentation. It is known that the *Hox* code is established quite early in the embryo [45], even prior to expression of IM-specific genes. Accordingly, Attia et al. used nephric duct-forming capacity as a property specific to pronephric IM to demonstrate in avian embryos that anteroposterior pattern is determined during the primitive streak stage [46]. When prospective pronephros tissue was transplanted from the mid-streak to a comparable position in a later-stage embryo, it migrated and contributed to the posterior IM but still readily formed ectopic nephric duct structures. In the converse experiment, tissue transferred from the later to earlier streak still adopted the IM fate, but its cells did not contribute to the nephric duct. These intriguing results support a model in which the timing of a cell's ingression

through the streak determines its subsequent position along the longitudinal mesodermal axis, with later time points adopting more posterior fates, and its anteroposterior character is fixed at that time. From such a model, one might infer that the signaling environment within the streak is temporally evolving such that it has a more posteriorizing property at later stages, but to our knowledge this has not been demonstrated mechanistically. Candidate pathways that might underlie such a process include TGFβ and FGF, which have anteriorizing and posteriorizing effects, respectively, on the patterning of the nearby paraxial mesoderm [47,48].

Development of the nephric duct and ureteric bud

Following specification of the IM, the pronephric region develops a thin evagination at its dorsolateral boundary that buds to form the nephric duct. This epithelial tube then extends caudally along the length of the embryo, eventually forming the urinary collecting system as well as some components of the male reproductive system. The importance of the nephric duct and its derivatives has been extensively documented; for instance, mechanical impedance to its migration is sufficient to abolish all subsequent renal tubular differentiation in the neighboring IM [32]. The mechanisms underlying induction of the nephric duct, aside from those relevant to the formation of the pronephric IM itself, are poorly understood. Several transcription factors, including Pax2, Pax8, Gata3, Lhx1, and Hnf1β [33,49–51], are essential core components of a gene regulatory network that maintains the nephric duct identity [52]. However, the extrinsic cues that promote segregation of the duct from the remaining nephrogenic IM remain largely unknown.

The nephric duct migrates posteriorly in a stereotypic fashion until it reaches and fuses with the primitive cloaca, suggesting that it is driven by a highly orchestrated set of signaling cues and tissue interactions (reviewed in Ref. [53]). However, comparatively little is known regarding the mechanisms involved in this process. It has recently been shown that the remarkably straight migratory course of the nephric duct is likely guided by a strong attraction to the nearby column of IM [54], although the molecular basis for this observation is not understood. The key signals that drive caudal elongation include FGF ligands, such as Fgf8, which are derived from a posteriorly moving wave of expression that coordinates duct growth with body axis extension [54,55]. Intracellularly, the MEK/ERK pathway is essential for the leading nephric duct cells' response to FGFs, although other downstream signaling components may also play a role. Evidence from axolotl embryos suggests that glial cell-derived neurotrophic factor (GDNF) is another important chemoattractant for the migrating duct [56], but GDNF has been much more extensively studied for its role in morphogenesis of the UB (discussed later). As it grows caudally, the nephric duct also matures structurally from a loose cord of cells into a polarized, simple cuboidal epithelium. It reaches and inserts into the cloaca by embryonic day (E) 9.5 in the mouse embryo, governed by a complex regulatory cascade, at what will ultimately become the vesicoureteral junction [57–60].

Near its distal terminus, in the region of the metanephros, the nephric duct develops an epithelial outgrowth termed the UB. This structure will ultimately form the upper urinary tract, including the ureter, renal pelvis, and intrarenal collecting duct system. Moreover, it plays a fundamental and indispensable role in kidney development. Given that its function is restricted to the metanephric kidney, the UB has principally been studied in the context of mouse embryology, and a wide breadth of genetic studies has uncovered an intricate set of underlying signaling mechanisms (reviewed in Ref. [61]). The first morphologic suggestion of the UB is a club-like thickening of the nephric duct epithelium adjacent to the condensed metanephric mesenchyme (MM) at E10.5 (Fig. 44.1C and D). Within 24 hours, the tall pseudostratified epithelium elongates to form a branch that migrates and invades into the adjacent metanephric blastema. Appropriate positioning of UB outgrowth is crucial; thus it is precisely controlled by a number of positive and negative regulators. Loss of inhibitory signals results in ectopic or malpositioned UBs, which ultimately causes impaired function of the urinary tract. Conversely, failure of the requisite stimulatory molecules to induce proper UB growth leads to severely perturbed kidney development including renal agenesis.

The molecular linchpin of UB induction is GDNF, which is expressed by the MM and signals through the receptor tyrosine kinase (RTK) RET on the adjacent nephric duct cells. Loss-of-function mutations in either *Gdnf* or *Ret*, and even the coreceptor *Gfr1a*, result in failure of UB outgrowth [62–66]. Further, an ectopic source of GDNF is sufficient to induce numerous UBs along the nephric duct [67], indicating that strict regulation of GDNF localization is essential for normal kidney development. Accordingly, *Gdnf* transcription is tightly dependent upon a complex combination of factors that is unique to the MM, including Eya1, Hoxa11/Hoxd11, Six1, Sall1, and Pax2 [68]. In addition, *Gdnf* expression is actively restricted from more anterior regions of the nephrogenic cord by Slit/Robo signaling and FoxC transcription factors [69,70]. Further layers of control over UB outgrowth exist within the nephric duct itself and its cells' ability to respond to induction signals. First, it was shown through chimeric embryo experiments that

RET-dependent competitive cell movements result in convergence of the most signal-receptive cells to a single location in the duct, and this population likely inhibits the neighboring cells from forming additional buds [71]. Second, there are negative feedback regulators, such as Spry1, that antagonize intracellular responses to RTK signaling to locally confine the effect of secreted GDNF [72,73].

Aside from GDNF/RET-driven processes, there are other pathways that further reinforce proper timing and location of UB induction. FGF signaling, including Fgf10 in particular, was found to promote UB development, albeit to a lesser extent than GDNF. In rare cases, *Gdnf* or *Ret* mutant embryos do form primitive buds; strikingly, simultaneous deletion of the antagonist *Spry1* restores fairly normal UB growth in these mutants. In this setting, Fgf10 is indispensable for rescue of UB initiation [74], and it similarly functions through an RTK to activate essential downstream transcription factors *Etv4/5* and *Sox8/9* [75–77]. Conversely, BMP signaling functions to repress UB outgrowth in a pathway parallel to the GDNF/RET axis. Reduction of *Bmp* gene dosage can result in ectopic budding, while addition of exogenous BMP blocks UB growth in ex vivo organ culture [78,79]. Under physiologic conditions, the secreted BMP antagonist Gremlin1 is specifically localized in the MM to mediate derepression of UB formation [80–82].

The UB initially grows as a straight duct into the MM, but by E11.5 the ureteric epithelium initiates an extensive, stereotypic branching program that ultimately produces an elaborate tubular tree. The predominant mechanism driving this process is iterative bifurcation (and less commonly trifurcation) at the tips of the network, which produces >2000 branching events by E16.5 [83]. During branching, the UB is organized into molecularly distinct domains (Fig. 44.2A) with progenitor cells occupying the tip compartments while cells of the "stalk," or "trunk," adopt a more differentiated collecting duct phenotype [84]. The ureteric tip cells are thus essential to normal kidney organogenesis, but isolated ureteric stalks also demonstrate a capacity for regenerating the tip domain and branching program [85]. The maintenance, proliferation, and morphogenesis of the ureteric progenitors are directed by a complex signaling milieu that includes several of the pathways involved in initial UB outgrowth. Again GDNF/Ret and FGF are the dominant pathways that promote proliferation and budding [73,86–90], while BMP signaling antagonizes branching morphogenesis in the stalk domain [91]. The canonical WNT pathway has both cell- and noncell-autonomous roles in ureteric branching; its transcriptional effector Ctnnb1 is required for maintenance of tip identity and morphogenesis [92,93]. Wnt11, whose transcription is specific to tip cells and is RET-dependent, signals to the adjacent mesenchyme to augment *Gdnf* expression as part of a positive feedback mechanism [94]. Disruption of this loop via *Wnt11* knockout results in hypoplastic kidneys. Stromal-derived RA is also required for UB development, in part through direct maintenance of *Ret* expression [95,96]. Finally, Hedgehog pathway activity is actively suppressed in the branching portion of the ureteric tree to prevent precocious loss of progenitor cells [97]. Further work will be necessary to dissect the epistatic relationships among these signaling pathways and to elucidate how they cooperate at the cellular level to coordinate ureteric development.

Maintenance and differentiation of the nephron progenitor cell

By the time of UB outgrowth, the caudal portion of the nephrogenic IM has condensed into a histologically distinct blastema, called the MM, which is a multipotent population of cells. As the UB begins to branch, a large portion of the MM cells organize around the UB tips into domains of cap mesenchyme (CM). The presence of CM persists at the UB tips throughout branching morphogenesis, and it serves several critical functions during kidney development. First, it provides essential signals, such as GDNF, to maintain proliferation and budding of the developing ureteric epithelium. Second, through elegant lineage-tracing experiments using the CM markers *Six2* and *Cited1*, it was demonstrated that CM cells are a self-renewing population of multipotent progenitors that ultimately differentiate into all of the epithelial cells of the nephron from the glomerulus to the connecting tubule [98,99]. Thus in light of this potential, cells of the CM are also referred to as nephron progenitor cells (NPCs). The NPCs and UB tip progenitors are codependent and form intricate reciprocal signaling loops that preserve the nephrogenic niche (Fig. 44.2A). Stromal progenitor cells also contribute to the niche, and they will be discussed in the subsequent section. Here we will focus on the mechanisms that promote maintenance, induction, and differentiation of the NPCs.

Like most stem or progenitor cell populations, balance between NPC self-renewal versus differentiation is regulated by a network of signals within the nephrogenic niche. Perturbation of this equilibrium typically results in hypoplastic and/or dysplastic kidneys. A key transcriptional regulator of the multipotent state is Six2, which is required to prevent precocious differentiation and tubulogenesis in the NPCs [100]. Further, it has more recently been shown that downregulation of Six2 is required for differentiation, as transgenic embryos that maintain Six2 fail to form nephron segments [101]. As is the case with UB progenitors, RTK signaling promotes the survival and

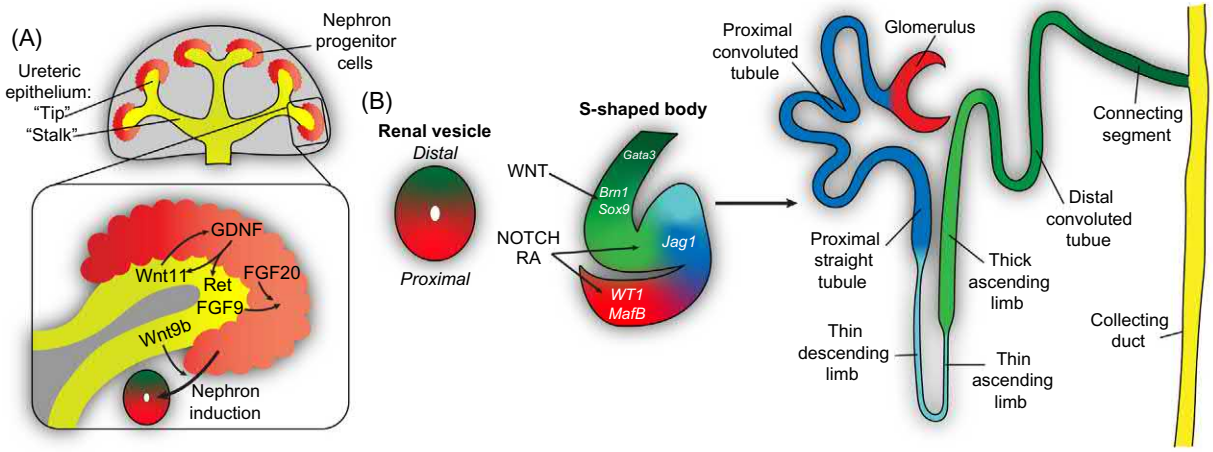

FIGURE 44.2 Overview of metanephric nephrogenesis. (A) Reciprocal interactions between the cap mesenchyme and ureteric epithelium regulate branching events and maintenance of nephron progenitor cells. (B) Following induction, nephron progenitors progress through renal vesicle, comma-shaped body, and S-shaped body stages of differentiation. The S-shaped body is highly organized at the molecular level into distinct domains that will give rise to each of the segments of the mature nephron.

proliferation of NPCs, primarily through the FGF pathway [102,103]. The essential ligands are FGF9 and FGF20, which derive from the UB and CM, respectively [104]. The existence of redundant paracrine and autocrine signals reinforces the importance of NPC maintenance in kidney development, although the genetic circuitry underlying these expression patterns is not well understood. *Bmp7* is broadly expressed in the early kidney, including in both the ureteric epithelium and CM, and it contributes to the renewal of the NPC compartment [105–107]. Interestingly, Bmp7 functions in a Smad-independent manner, instead signaling through MAPK and JNK pathways to maintain the NPCs [108–110]. In somewhat paradoxical fashion, Bmp-mediated SMAD activation actually sensitizes NPCs for induction and causes them to move toward the more differentiated compartment [111,112]. The other major pathway responsible for NPC proliferation is Wnt/β-catenin signaling, which has also been studied for its role in induction/differentiation. Embryos deficient in *Wnt9b*, secreted from the ureteric epithelium, exhibit severe renal hypoplasia [113]. Consistent with a UB-to-CM signaling paradigm, deletion of *Ctnnb1* in the MM phenocopies the *Wnt9b* mutant and results in loss of NPC markers [114,115]. Conversely, genetic activation of the canonical Wnt pathway induces expansion of Six2-expressing NPCs, although nephrogenesis appears somewhat dysplastic [93]. At the molecular level, data from ChIP experiments showed that Ctnnb1 and Six2 can bind an overlapping set of enhancers, suggesting that they may cooperate to regulate a progenitor cell gene regulatory network [116].

At each new branch tip in the developing ureteric tree, a subset of NPCs are induced to condense into a structure called the pretubular aggregate (PTA). Cells in the PTA initiate expression of genes associated with their induced state (*Lhx1*, *Pax8*, *Wnt4*, and *Lef1*) and downregulate NPC genes as they differentiate, although a low level of Six2 expression is still detectable at this stage [117]. PTAs subsequently undergo a mesenchymal-to-epithelial transition (MET) event to form a polarized renal vesicle (RV). Further stereotypic morphogenetic processes transform the RV into an S-shaped body (SSB), named for its appearance in two-dimensional cross section, which already contains the molecular information that will establish the proximal–distal axis of the future nephron (Fig. 44.2B). Recent studies used a combination of time-lapse imaging and genetic lineage labeling to demonstrate that NPCs migrate through the niche and encounter signaling cues in a stochastic manner, and there is also a newly appreciated plasticity at the NPC-PTA differentiation boundary [118,119]. Our current understanding of the inductive events that lead to NPC differentiation is not complete, and it features many of the same pathways implicated in self-renewal. Wnt ligands play a central role, as UB-derived Wnt9b is essential for induction and tubulogenesis [113], as well as its function in the maintenance of progenitor cells. In addition, *Wnt4* is expressed from the PTA itself and is required for MET and differentiation [120–122]. From a mechanistic perspective, *Wnt4* expression is lost in *Wnt9b* mutants, suggestive of an inductive cascade whereby Wnt9b induces initial nephron commitment and transcription of *Wnt4*, which then promotes further differentiation. Interestingly, Wnt4 functions primarily through a noncanonical Wnt/Ca pathway [123,124], consistent with the observation that prolonged stabilization of Ctnnb1 inhibits epithelialization [115].

The finding that Wnt9b can promote both NPC proliferation and differentiation is somewhat perplexing; recent evidence has led to a model in which low-level activation of Ctnnb1 promotes proliferation and high activity drives differentiation [125]. The PTA also expresses *Fgf8*, which is required for the survival and proliferation of the nascent epithelium [126], and this signal appears to function distinctly from the Fgf9/20 that promotes NPC maintenance. How do Wnt and FGF, as well as BMP as described previously, stimulate both self-renewal and induction of progenitors? One possibility is signaling gradients and graded responses, such as that postulated for the Wnt/ß-catenin pathway. An alternative hypothesis is the activity of yet another pathway that can alter the response of a cell to a given signal. Indeed, it has recently been demonstrated that Notch activity is both necessary and sufficient for NPCs to downregulate Six2 and differentiate into epithelial nephron derivatives [101,127,128]. In fact, Notch activation is sufficient to induce MET and tubulogenesis even in the absence of both Wnt9b and Wnt4 [129]. In the native setting, it is unknown which cells are providing Notch ligand to promote differentiation.

Key to the postnatal kidney's remarkable ability to maintain fluid and electrolyte homeostasis is its highly ordered functional segmentation along the proximal−distal axis. This pattern is initially established early during nephron induction, largely through activation of a complex set of transcription factors that will ultimately precisely control the expression of segment-specific channels and transporters [130]. The SSB is organized into morphologically and molecularly discrete proximal, medial, and distal domains (Fig. 44.2 and reviewed in Ref. [131]). Further, single cell transcriptional profiling demonstrated that there is already polarized gene expression within the RV itself, with the proximal portion enriched for genes associated with podocyte fate and distal tubule markers found more selectively in the distal RV [132]. This pattern is not fully refined, however, as a large number of cells express genes associated with multiple lineages. Scrupulous analyses of both mouse and human fetal kidneys have shed further light on this process, revealing that induced nephron progenitors sequentially exit the niche and successively build the presumptive nephron in a distal-to-proximal manner [133]. This suggests that there is a dynamic spatiotemporal signaling microenvironment at the UB tip that coordinates segmentation from the outset of nephrogenesis.

Given the dynamic nature of early tubulogenesis and the iterative use of the same pathways at multiple stages of development, it is challenging to isolate and identify the signaling mechanisms that control nephron segmentation. Despite their dramatically simplified anatomy, the pronephric nephrons of *Xenopus* and Zebrafish larvae exhibit subdivisions analogous to those observed in the metanephric tubule, and these organisms have thus been powerful models to identify the molecular basis of nephron pattern formation. Key signals for determination of proximal fates include Notch and RA. Notch activity promotes formation of proximal structures including podocytes and proximal tubules [134−136], and it functions primarily through the *Notch2* receptor in mammals [137,138]. RA similarly induces proximal and represses distal fates in the zebrafish pronephros [139,140], likely in part through activation of master regulators of tubular differentiation such as *Hnf1β* [141−143]. Assessment of epistatic relationships indicates that RA functions upstream of Notch during segmentation [144], but RA's role in this process has not been tested in mammals. In opposition to these signals is the distalizing Wnt/β-catenin pathway, which forms a morphogen patterning gradient during conversion to the SSB stage [145]. This gradient is also modulated by BMP/PI3K activity that is required for specification of the medial segment and its derivates. Further work is necessary to identify mechanisms of cross talk among these various pathways and how they are integrated to effect cell fate decisions.

Role of stromal lineages in kidney organogenesis

Aside from the NPC-derived epithelial nephron elements and the UB-derived collecting duct system, the other major lineage constituting the kidney is the stroma. This compartment is extensive and includes the glomerular mesangial cells, cortical and medullary interstitial cells, and the highly specialized renal vasculature. Embryologically, these cells largely develop from a population of Foxd1-positive stromal progenitor (SP) cells that surround the CM at the periphery of the kidney. The SP cells are a self-renewing population that, in a manner analogous to NPCs, generate differentiated cell types in a radial, inside-to-outside pattern [146]. The initial origin of the stromal lineage is not entirely resolved. Similar to both the UB and NPCs, the SP cells descend from early Osr1-expressing precursors that are no longer detectable by E11.5 [147]. However, because Osr1 is broadly expressed in both the early IM and LPM, this does not necessarily reflect a shared origin. In fact, clonal analysis via cre/loxp-mediated lineage labeling failed to identify single cells that give rise to both the NPC and SP lineages, suggesting that they arise independently despite their close spatial relationship. On the other hand, several groups have identified occasional instances in which Foxd1 and Six2 are coexpressed, and Foxd1-positive cells sometimes generate renal tubules [132,146]. Further, it was recently found that sustained expression of Pax2 is required in NPCs to actively repress stroma-associated transcriptional programs [148]. These latter experiments lend strong support to a shared lineage model, which may

have previously gone undetected due to technical limitations associated with lineage-tracing experiments. Regardless, new analyses of fetal kidney tissue unexpectedly revealed that there is persistent and considerable overlap between the Six2 and Foxd1 compartments in humans, appreciable at both the transcriptional and protein levels. Thus lineage boundaries are more imprecise or ambiguous in man [149].

While the reciprocal tissue−tissue interactions between the NPCs and UB have been well documented over several decades, we are now gaining more appreciation for the SP cells' contribution to the nephrogenic niche of developing kidneys. Given their juxtaposition to the NPCs in the developing cortex, they occupy a position well suited to impact nephron development. Genetic ablation of the SP lineage results in a striking phenotype in which NPCs accumulate at the ureteric tips and are unable to differentiate [150], suggesting that the stroma may provide permissive signals required for NPC induction. Similar but less extensive phenotypes have been observed in the setting of *Foxd1* deletion, which also results in abnormal ureteric branching and development [57,151]. Candidate prodifferentiation mechanisms downstream of Foxd1 include signaling molecules that impact Wnt, BMP, and Hippo activity within NPCs [150,152], although it is unclear whether the SP cells signal directly to the NPCs or do so indirectly via another cell type. The stroma is also the source of RA, which is required to maintain normal ureteric branching as previously discussed [95].

While the Foxd1 lineage unambiguously gives rise to mesangial and interstitial cells, the origin of the renal vasculature is less clear. The predominance of lineage-tracing data indicate that *Foxd1*-positive cells do not contribute significantly to endothelial cells [146,153], although one group has found it to have substantial contribution to the endothelium [154]. The explanation for the discrepancies between these findings is unclear but could be due to technical differences (i.e., mouse strain, knock-in vs transgenic). Rigorous morphometric analyses revealed that early endothelial progenitors both surround the nascent metanephric blastema and migrate into the developing kidney with a mesenchymal layer surrounding the UB [155,156]. These precursors elaborate organized plexuses around the growing ureteric tips and CM, and they subsequently develop in apparent coordination with early differentiating nephrons. A subset of endothelial cells invades a cleft in the proximal SSB that abuts the presumptive podocyte population. These cells will form the glomerular capillaries, and they also recruit differentiating SP cells to the mesangial compartment in a PDGF-dependent manner [157]. Mesangial cells differentiate under the guidance of Notch signaling, and they are required in turn for further maturation of the glomerular capillary tuft [153].

Nephron endowment

The iterative cycle of UB branching and NPC induction is a powerful mechanism that generates exponential kidney growth and nephron formation [83]. The period of nephrogenesis is finite, however, as the progenitor cells in the niche ultimately are concomitantly depleted in a terminal wave of differentiation [158]. This occurs in the early postnatal period in rodents [159] and sometime around the 36th week of gestation in man [160]. Consequently, individuals are endowed with a fixed number of nephrons that is subject to gradual decline over a lifetime. The supply is highly variable in humans, with up to a 10-fold range reported, and those allotted fewer are at higher risk for complications later in life including hypertension and chronic kidney disease (CKD) [161]. Here we will provide a brief discussion of the genetic and environmental determinants that regulate the timing and extent of nephrogenesis, which overall are not well understood.

The close temporal association between birth and the cessation of nephrogenesis in mice bolsters a model in which some parturition-related signal leads to the en masse differentiation of remaining CM cells. However, because this event normally occurs in utero in humans, there is more likely an intrinsic mechanism that drives terminal differentiation. Although perturbation of any component within the niche could disrupt self-renewal, the NPCs have been the subject of more intense focus given that they are the first observed to lose their progenitor gene expression [158]. One hypothesis is that gradual reduction of NPCs over time alters the signaling environment to ultimately tip the balance in favor of differentiation. Yet when NPC depletion is accelerated through genetic ablation, which results in hypoplastic kidneys with fewer nephrons, nephrogenesis still persists through the same timepoint [162]. Thus the temporal control seems to be more actively regulated. Through a series of heterochronic transplantation experiments in kidney explant cultures, Chen et al. observed that older NPCs exhibit impaired ability to integrate within the nephrogenic niche [163]. These data imply that the progenitor lifespan may be constrained, and NPCs are therefore more analogous to a transient amplifying population than true stem cells. The basis for this progenitor aging is entirely unknown, and it is not readily apparent in transcriptomic comparisons.

While many have described genetic manipulations that disrupt the signaling circuitry in the nephrogenic zone and cause precocious loss and differentiation of NPCs, phenotypes with extended nephrogenesis are very rare. Recently, it was found that forced expression of *Lin28b*, a regulator of miRNA biogenesis with known roles in several stem cell types [164], is sufficient to prolong

nephrogenesis for an additional several weeks [165]. Surprisingly, this phenotype was observed when transgene expression was driven in the *WT1* but not the *Six2* lineage [166]. Further, embryonic kidneys were refractory to the effects of *Lin28b* when induced after E16.5, suggesting that there is an unknown mechanism that impacts plasticity in a temporal-dependent manner. There is also emerging evidence that metabolic pathways might regulate the timing of kidney development. Increased mTOR activity via reduction of *Tsc1* leads to slightly prolonged nephrogenesis and enlarged kidneys [167]. Accordingly, NPCs appear to shift from glycolytic to aerobic metabolism as they transition from self-renewal to differentiation [168], and calorie restriction during pregnancy leads to hypoplastic kidneys [169]. Overall there remains much to uncover regarding the mechanisms driving cessation of nephrogenesis, but it seems likely to involve an interface between environmental factors and the developmental signaling pathways that are known to control renewal and differentiation.

Kidney repair and regeneration

In the clinical setting, the kidney is subject to a number of insults over a lifetime, including ischemic injury, nephrotoxins, and stress associated with chronic and systemic diseases. In response to acute tubular injury, tubular epithelial cells exhibit a significant capacity for repair. However, the recovery process is limited to the regeneration of surviving tubules as it is widely accepted that no new nephrons form beyond the fetal/perinatal period. Further, repair is typically incomplete, and thus renal reserve and kidney function ultimately decline over time with severe or repetitive injury. In the setting of chronic stress, maladaptive mechanisms predominate and lead to fibrosis and CKD [170]. Cumulatively, this leads to a staggering and ever-increasing number of patients that require renal replacement therapy in the form of either dialysis or kidney transplantation. As a result, there are intensive efforts ongoing on several fronts to improve patient outcomes and ease the enormous economic burden associated with CKD. Further elucidation of the normal renal repair mechanisms is essential to help guide development of therapeutic strategies to mitigate injury and augment recovery. Given the significant scarcity of organs available for transplantation relative to the current demand, there is growing interest and enthusiasm for cell- or tissue-based therapies that may over time be able to replace native renal function in individuals with kidney failure. Along these lines, tremendous progress has been made over the past several years in developing methods to generate renal tissues, particularly in the field of stem cell differentiation.

Stem cells in kidney repair

Under normal conditions, the kidney does not exhibit significant turnover or self-renewal like that seen in the skin, GI tract, and blood, and it is therefore thought to be a relatively static organ with respect to its cell populations. Given its ability to initiate proliferation and regenerate tubules subsequent to injury, it has long been speculated that the kidney might contain a small population of quiescent resident stem cells that are activated during the repair process. However, although there are some rare cells in the adult kidney with features similar to tissue stem cells found in other organs [171–173], the predominance of available evidence argues against the existence of a functional renal stem cell. Humphreys et al. in our laboratory first used *Six2*-Cre lineage tracing to demonstrate that regenerated tubules derive from the epithelialized compartment rather than an interstitial cell type [174]. While these experiments do not rule out the possibility of a *Six2*$^{+}$-derived stem cell, it has since been demonstrated through similar techniques that differentiated proximal tubule cells (expressing *Slc34a1*) are the source for the bulk of the regenerated proximal tubular mass [175]. These data therefore support a model in which de-differentiated epithelial cells, instead of stem cells, proliferate and expand in response to injury to restore kidney function. This was further strengthened by single cell labeling studies that showed that regenerative clones are restricted to a single segment fate along the length of the nephron [176,177]. Thus not only do regenerated tubules derive from differentiated epithelia, but there is also no evidence of multipotency or plasticity between cell lineages, which is a defining characteristic of stem cells. With respect to glomerular lineages, several groups have reported populations that exhibit transdifferentiation of *Renin*-expressing cells of the juxtaglomerular apparatus [178–180] and parietal epithelial cells of Bowman's capsule [181,182] into podocytes in the setting of glomerular injury. However, the overall contribution and significance of these lineages in repair and regenerative processes is not fully characterized.

While the aforementioned studies establish differentiated epithelia as the source of regeneration, they do not distinguish whether this property is shared among all tubular cells or limited to a specialized subpopulation. To address this question, proliferating cells in the kidney were sequentially labeled with different thymidine analogs during the acute phase of injury repair. Under these experimental conditions, there was minimal overlap of incorporation of both markers, suggesting that tubular cells divide in a stochastic and limited manner [178]. These data make a compelling argument against the existence of a dedicated progenitor within the epithelium, which would have to undergo numerous rounds of cell

division and thus incorporate multiple labels. At baseline, a small subset of tubular cells expresses the developmental transcription factor *Sox9*, which marks progenitor cells in other organs. This gene is broadly upregulated during the proliferative response to injury, and it is essential for proper tubular regeneration [179]. While these observations raise the possibility that the preexisting Sox9-positive cells are progenitors, they do not preferentially contribute during the repair process, further corroborating the model of stochastic survival and proliferation of tubular cells. With the increasingly widespread use of single cell sequencing technologies, it is likely that heterogeneity within the renal parenchyma will become more and more evident, which will permit further genetic investigation of possible sublineage involvement during injury repair.

The molecular events of tubule regeneration following injury have been intensely studied [180]. One striking feature associated with proliferative epithelial cells is the reexpression of developmental regulatory genes including Pax2, Sall1, and Sox9 [179,181,182]. This phenomenon implies that a dedifferentiation step may be critical for the repair process [183]; however, tubular cells do not reexpress genes, such as Six2, that would indicate full reversion to a NPC-like state [174]. This is consistent with the clonal lineage restriction observed in regenerated tubules [176], which contrasts with the multipotent character of NPCs. In fact, the inability to generate nephrogenic cells with full developmental potential is likely a major underlying reason the kidneys cannot generate new nephrons outside of the fetal period. To determine whether there is ever a time at which the kidney would exhibit de novo nephrogenesis, our laboratory performed cryoablation injury studies in neonatal mice. Surprisingly, even as early as the first postnatal day, at which time NPCs are still proliferative and differentiating, injury does not result in compensatory expansion or prolongation of nephrogenesis [184]. In contrast, the kidneys of other species such as zebrafish contain multipotent nephron progenitors that can regenerate nephrons de novo in response to injury [185–187]. Thus it seems that the mammalian kidney is particularly refractory to neonephrogenesis, and any strategy to replace lost nephrons would have to rely upon mechanisms outside of its usual genetic or physiologic repertoire.

Sources of nephrogenic cells

To overcome the limitations of endogenous kidney regeneration, numerous strategies have been attempted in experimental settings to produce cells capable of de novo nephrogenesis. Drawing on experiences in several fields, including induced pluripotency, Hendry et al. identified a combination of embryonic transcription factors, including Osr1, Six1/2, Eya1, and Hoxa11, that is able to reprogram an adult kidney epithelial cell line into an NPC-like state [188]. Interestingly, the factor Snai2 is also required, highlighting the importance of epithelial-to-mesenchymal transition during this process of reversion to a fetal precursor. Although the resulting cells were able to integrate into the NPC compartment in ex vivo kidney culture, the method is inefficient and the progenitors are unable to differentiate given the continued forced expression of the reprogramming factors. This approach was recently refined to include only three factors (Six1, Eya1, and Snai2) and use of an inducible promoter that allows for silencing of the reprogramming cassette [189]. Under these conditions, induced NPC-like cells indeed incorporate into differentiated tubular structures of the neonatal mouse kidney. The area of direct reprogramming has not been further developed in the kidney, to our knowledge, but it may be a viable strategy in improve repair mechanisms. Fate conversion has been successfully performed in vivo in quiescent epithelial organs such as the pancreas [190], and viral delivery of developmental transcription factors was shown to ameliorate fibrosis and enhance epithelial recovery in liver disease [191].

Given that NPCs exhibit stem cell-like properties in vivo, albeit only over a limited time period, several groups recently explored whether these cells could be cultured and expanded in vitro. Exploiting developmental signaling principles, such as the FGF and WNT pathways, three sets of similar culture conditions were identified that can support serial passaging and propagation of progenitors [111,192,193]. These have been successfully applied to both mouse and human fetal NPCs, although the human cells first require enrichment through FACS based on cell-surface markers [193]. Brown et al. showed that their conditions can select and enrich for NPCs from a heterogenous population of cells from the nephrogenic zone of the fetal kidney, which could alleviate the need for FACS purification. Although the expression of several important factors, such as *Pax2* and *Wt1*, tends to wane over time, the cells retain high expression of other NPC genes and the capacity to differentiate in vitro into nephron elements for many passages. Interestingly, the cells propagated by Brown et al. did not form glomerular derivates when induced in aggregates. While this could reflect altered differentiation capacity, it is more likely due to culture conditions that persistently stimulate the WNT pathway, which is known to antagonize commitment to the podocyte fate [145]. To test in vivo potential, Zhongwei et al. engrafted NPCs into the mouse nephrogenic zone on postnatal day one, and the cells successfully integrated into developing host nephrons. Similar subcapsular injections into the adult kidney in a nephrotoxin AKI model did not yield functional engraftment during tubule regeneration, but it did somewhat improve AKI outcomes

by unknown mechanisms. Intraparenchymal delivery will likely be required to fully assess whether NPCs can assist in the repair process in the setting of acute or CKD.

For many tissues, especially those with well-characterized stem cell populations, the past decade has witnessed an eruption in the development and application of organoid technologies. Much of this work was pioneered in the GI tract by Hans Clevers' group in Utrecht. Typically, strategies for tissue-derived organoids rely on the recreation of the stem cell niche environment to support three-dimensional growth and differentiation of organ-specific progenitor cells, which are most often obtained from patient biopsy samples or sacrificed animals. Until very recently, this methodology had not expanded to include the kidney, likely owing to its lack of stem cells. Schutgens et al. have now described methods to produce kidney "tubuloids," which can be derived from core biopsy specimens or even cells isolated from patients' urine [194]. These three-dimensional structures can be established rapidly, and they expand with genetic stability demonstrated over numerous passages. From any given sample, a heterogenous mixture of tubuloids representing various nephron segments is generated, although the proximal tubule appears to be overrepresented. The epithelia retain the expression of differentiated markers associated with their origin, so it is unclear to what extent, if any, dedifferentiation of the tubular cells is required for their proliferation. Regardless, this system for rapid expansion of tubular cells, which can be done in a minimally invasive and patient-specific manner, represents another possible avenue for replacing cells lost or damaged in disease states. Further, there is more immediate potential for use in disease modeling, diagnostics, and drug testing.

Differentiation of renal tissue from pluripotent stem cells (organoids)

One prospective source of material for regenerative applications in the kidney is human pluripotent stem cells (hPSCs), including both embryonic stem cells (ESCs) and induced PSCs (iPSCs), which have the potential to differentiate into any cell type of the body. These cells could provide a limitless supply of materials for generating renal tissues, and in the case of iPSCs, they offer the ability to generate therapeutic materials that are isogenic to patients. While early work with hPSCs focused on simple, two-dimensional differentiation to generate single desired cell types, more recent advances have highlighted the ability to produce complex three-dimensional structures (usually termed organoids) that comprise numerous cell types and more accurately embody normal organ architecture [195]. Regardless of the culture format, prevailing strategies utilize a stepwise directed differentiation approach designed to recapitulate the natural developmental processes that occur during embryonic organogenesis. In this section, we will summarize how this has been applied to differentiation of hPSCs into the kidney lineage, a field that has seen astonishing growth and progress over just the past few years (reviewed in Ref. [196]).

Early attempts to differentiate renal tissue from hPSCs began with elucidation of mechanisms to specify the IM. In most cases, this appropriately proceeds first through induction of a primitive streak stage that produces an early mesodermal progenitor population, which is typically achieved via activation of a combination of WNT, BMP, and TGFβ pathways to mimic gastrulation [197–201]. Cells are then guided toward the IM fate by various combinations of signals including FGFs, RA, Activin, and BMPs. In some cases, hPSCs are differentiated directly to IM without an obvious mesodermal progenitor intermediate [202,203]. The wide array of methods that have been used to produce progenitors with overlapping molecular features implies that we do not yet fully understand the signaling mechanisms that direct IM specification. It also suggests that hPSC cultures themselves produce a significant complement of endogenous signals that likely support the various approaches to differentiation.

Building upon these previous studies, the laboratory of Melissa Little and our group concurrently developed efficient methods to differentiate hPSCs into MM and NPCs [204,205]. To provide a more physiologic environment, both groups introduced an aggregation step to force the early progenitors to adopt a three-dimensional configuration. A short pulse of induction signal to activate the canonical Wnt pathway, followed by several weeks of culture under permissive conditions, is then sufficient to induce widespread epithelialization and nephron differentiation. The resulting three-dimensional kidney organoids contain multiple nephron lineages, including podocytes, proximal tubule, loop of Henle, and distal tubule (summarized in Fig. 44.3). These structures represent a major advance in the field of kidney differentiation, and the protocols by which they are generated are now being widely applied to a variety of biological questions. Although they most closely resemble early fetal kidneys [206], the organoids have already proven to be tractable models for congenital kidney disease and tubular injury [205,207].

One of the more glaring limitations of the described hPSC-derived kidney organoids is that primarily only one of the major progenitor compartments, the NPCs, is well represented. Although Takasato et al. invoke the presence of putative collecting duct epithelium, several of its molecular markers are also found in other nephron segments [204,208]. Neither protocol leads to efficient production of early ureteric progenitors and organoids do not contain a branching tree that is the cornerstone of metanephric kidney development. This is not altogether

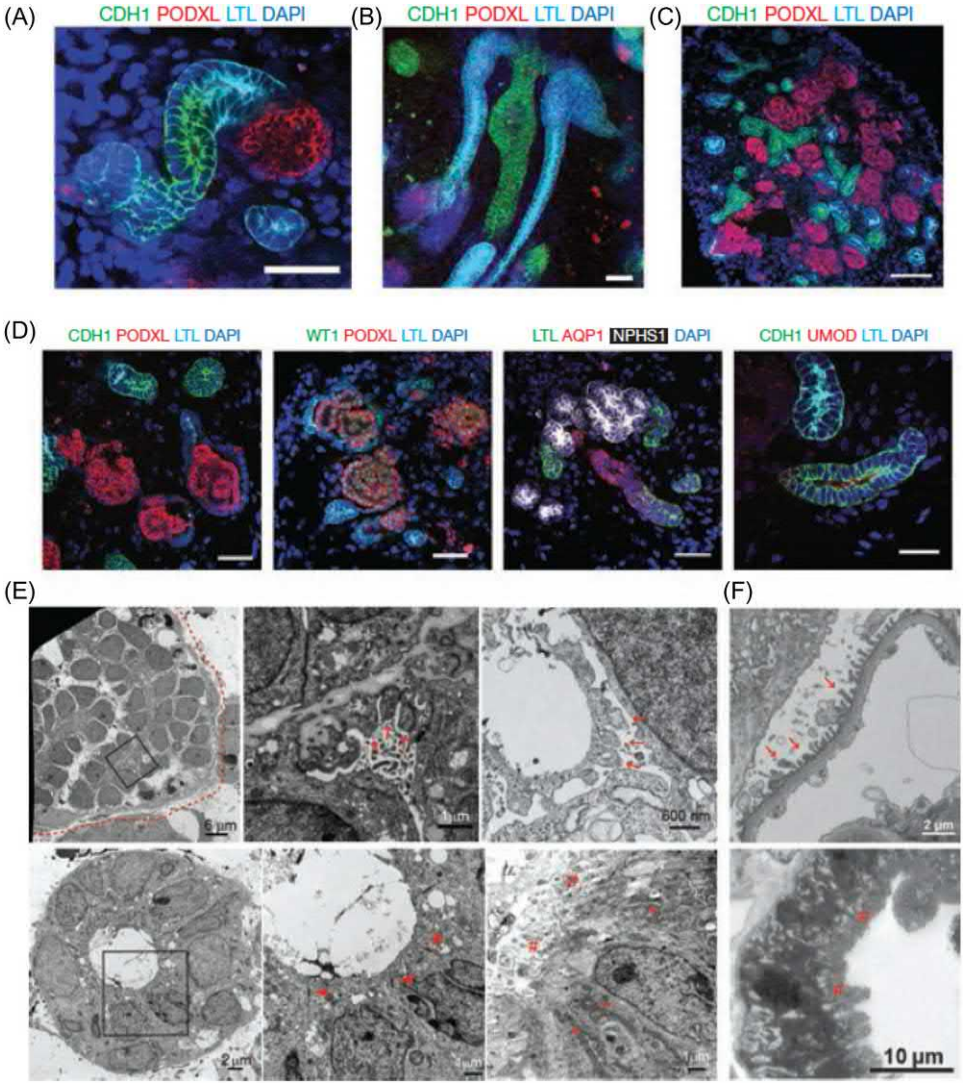

FIGURE 44.3 PSC-derived kidney organoids contain diverse nephron cell types and structures. (A–D) Immunofluorescent staining reveals the presence of glomerular (PODXL, WT1), proximal tubule (LTL, AQP1), and distal tubule (CDH1, UMOD) components within late stage human kidney organoids. Transmission electron micrographs of both human kidney organoids (E) and human kidneys (F) demonstrate similarities at the ultrastructural level, including podocyte foot processes (arrows), epithelial tight junctions (arrowheads), and tubular brush borders (pound sign). Scale bars, 50 µm, in (A–C). *Reproduced with permission from Morizane R, et al. Nephron organoids derived from human pluripotent stem cells model kidney development and injury. Nat Biotechnol 2015;33:1193–200.*

surprising given the distinct embryologic origins of the nephric duct and the NPCs and the approaches taken to serially differentiate stem cells toward MM. To overcome this developmental barrier, the Nishinakamura group developed an ambitious strategy to coculture UB and NPC tissues that were derived in parallel from mouse ESCs [209,210]. This produced remarkable results that not only led to a branching ureteric epithelium, but also a recreation of the progenitor niche and iterative waves of differentiation that built nephron units within the organoids. The drawbacks of this method include the need for cell enrichment due to a less efficient embryoid body–based differentiation system, less impressive results with human PSCs, and probably most importantly, its dependence on SP cells isolated from fetal kidneys. However, these deficiencies are not insurmountable, as others have recently reported the differentiation of hPSCs into UB tissues [211], and a coculture method will likely be required to fully recapitulate the human kidney development in vitro.

Once stimulated for induction, the NPCs within kidney organoids differentiate in a stochastic manner to produce various nephron structures. While this generates cellular diversity and complexity that may be desired for some applications, when using current protocols there is minimal control in determining which cell types form. Further, the indiscriminate three-dimensional culture conditions lead to appreciable variability between experiments [212]. Thus one's ability to explicitly study or utilize a single cell type is limited by multiple challenges, including but not restricted to, the relative scarcity of any particular cell within an organoid. In this regard, it would be advantageous to identify conditions that specifically promote differentiation directed toward individual nephron lineages. To this end, groups have identified methods to efficiently bias differentiation toward the podocyte fate [213,214],

and the resulting cells have been used to model the filtration barrier and drug-induced glomerular injury. Future efforts to refine the podocyte fate and develop other nephron segments will likely depend on further elucidation of the signaling mechanisms underlying patterning in the developing kidney, further attesting to the important role that developmental biology plays in guiding the addition of exogenous factors or 3D context that predict cell fate in organoids.

The technologies for differentiating renal cell types and organoids from hPSCs have been rapidly advancing over the past several years, and the practical utilization of these tissues is in its infancy. One can envision numerous applications, including disease modeling, physiologic studies, and drug testing or screening, which are already underway. These approaches will also likely be supported by evolving bioengineering techniques, such as bioprinting and organs-on-chip. Further, in vitro hPSC differentiation offers an unprecedented opportunity to model and experimentally manipulate human kidney development, which may help resolve species-specific mechanisms of organogenesis. Eventually, it might be possible to generate tissues for clinical application in kidney regeneration or renal replacement therapy. For example, hPSC-derived early renal progenitors were able to engraft and restore kidney function in a mouse model of AKI [215]. However, generation of an autonomously functioning kidney is a much more ambitious goal that is influenced by several important and substantial obstacles. A therapeutically useful renal tissue construct would require a system for urinary excretion, such as a communicating collecting duct network. In addition, a considerable number of nephrons or "nephron equivalents" are necessary to provide adequate clearance. In vivo, exponential growth in nephron number in the embryo is produced by the elaborate and iterative branching mechanism described in previous sections of this review; however, current hPSC kidney organoids do not exhibit this property. Aside from incorporation of an organized ureteric progenitor population to promote branching, these features could potentially be engineered into organoids by using decellularized kidney scaffolds (reviewed in Ref. [216]). Further, tubules within organoids represent a primitive state of differentiation, analogous to a mid-gestation fetus [204], and our current understanding of maturation mechanisms is extremely limited. However, early evidence is encouraging that organoids undergo significant maturation and development, including vascularization, once transplanted to an in vivo environment [217,218]. Furthermore, it is possible to use the current protocols to carry out toxicity assays or phenocopy some key components of diseases such as cyst formation in polycystic kidney disease, suggesting that they may be useful for testing of therapeutic agents using candidate or nonbiased screening approaches. Nonetheless, additional efforts are required to optimize kidney organoids and unlock their full potential.

Conclusion

There has been remarkable progress in the field of kidney stem cells and regeneration, and recent advances have largely been guided by basic principles of renal embryology. Several strategies exist for efficient derivation of NPCs from hPSCs, as well as other sources (Fig. 44.4),

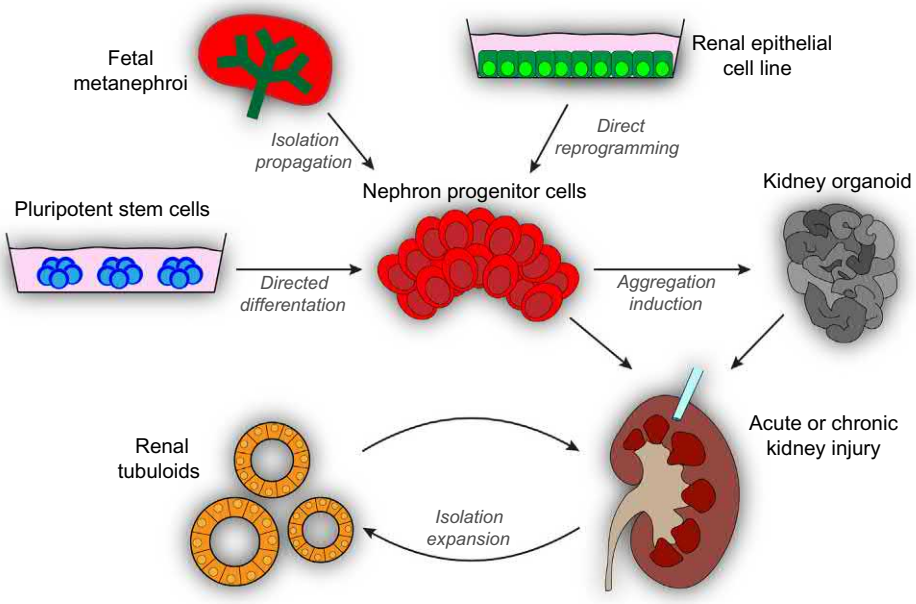

FIGURE 44.4 Putative sources of stem/progenitor cells for potential use in kidney regenerative biology.

which have the capacity to differentiate into numerous nephron cell lineages. Further efforts are now underway to unlock the pathophysiological and therapeutic discovery potential, as well as capacity for clinical renal replacement, of these cells, either through augmentation of endogenous repair processes or via in vitro formation of functional tissues and bioengineered devices. The key obstacles to such endeavors highlight major gaps in our understanding of certain aspects of kidney development, including the growth and maturation of nephron structures and the integration of a sophisticated vascular supply to the organ. The synergistic combination of in vivo and in vitro experimental studies will help further elucidate the developmental and regenerative mechanisms required to promote enhancement of kidney progenitor cells and organoids, ultimately providing strategies for replacement of kidney function.

Chapter 45

Tissue engineering of the kidney

Ji Hyun Kim, Anthony Atala and James J. Yoo
Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

Introduction

Kidney disease, including acute kidney injury (AKI), chronic kidney disease (CKD) and end-stage renal disease (ESRD), is one of the major worldwide health issues [1]. AKI is defined as a rapid decline in renal function, specifically of blood filtration, resulting in an increase in serum creatinine levels and a decrease in urine output [2,3]. Although AKI is a reversible condition, it often progresses to CKD. CKD is a leading cause of mortality and morbidity in western countries with 8%−16% of the adult population suffering from CKD, characterized by a reduced glomerular filtration rate and increased urinary albumin extraction [4,5]. ESRD is the devastating last stage of CKD that can affect multiorgan systems [6]. The current treatment options for kidney disease include lifelong dialysis and kidney transplantation. Although dialysis replaces renal filtration by removing toxins through extracorporeal blood purification, it cannot fulfill other renal functions essential to maintain health [7]. Kidney transplantation is the only definitive treatment for CKD and ESRD patients. Unfortunately, shortages of transplantable donor kidneys (<20% of the demand) and complications such as immune rejection remain problematic [8].

Tissue engineering and regenerative medicine approaches have been identified as promising solutions to address unmet needs in restoring renal functions. Recent progress in stem cell biology and cell culture technologies has led to the identification and development of reliable and efficient cell sources for the treatment of kidney diseases. These therapeutic cells can be administered through systemic injections to patients or through intrarenal implantations with engineered kidney constructs or carriers. One remarkable achievement, for example, is in the use of autologous mesenchymal stem cells (MSCs) in clinics for the kidney transplantation patients [9−11].

Numerous efforts have been made to bioengineer complex three-dimensional (3D) renal constructs. The kidney is a highly complex organ composed of over 30 different cell types. Each cell type is intricately organized and functionally compartmentalized to form thousands of nephrons, the functional units of the kidney [12]. Therefore to replace such complex renal tissues and restore renal functions, several types of 3D renal constructs have been developed using appropriate cell sources and scaffolding systems [13−15]. The application of engineered 3D renal constructs in preclinical renal failure models has shown the formation of renal structures and restoration of renal functions, such as urine production [15]. The results demonstrate the feasibility of bioengineered renal constructs for augmenting renal function. In addition, recent progress in whole organ engineering associated with decellularization/recellularization techniques opens a new era of whole kidney replacements with tissue-engineered whole kidneys [16−18]. While this approach is still in its infancy and several challenges remain, its shows great potential to fabricate functional whole kidney constructs with complex renal structures and functions with intact vasculature.

Another emerging approach in kidney tissue engineering is in situ tissue regeneration. In situ tissue regeneration is the utilization of the body's own regenerative capability by mobilizing and recruiting host stem or progenitor cells to the injury sites to regenerate or repair injured tissue [19−21]. Different from other cell-based tissue engineering approaches, the in situ tissue regeneration approach has several advantages such as elimination of in vitro cell manipulation processes. To enhance kidney regeneration, several target-specific scaffolding systems [19,22−25] and bioactive factors [19,21,26] have been investigated for efficient endogenous stem or progenitor cell recruitment, functional differentiation, and niche formation [19,22−25].

In this chapter, we will review and discuss the current strategies and therapeutic outcomes that show potential

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00047-2

for the treatment of kidney diseases, including cell-based engineering of 3D renal constructs, decellularization/recellularization strategy for whole kidney engineering, and in situ kidney regeneration.

Cell-based tissue engineering of the kidney

Recent advances in the fields of cell/stem cell biology and material sciences allow the development of several types of bioengineered cell-based 3D renal tissue constructs, which show therapeutic potential for the reconstruction or repair of damaged kidneys and restoration of normal kidney function [27–29]. In cell-based bioengineering, cells seeded in scaffolds provide biological and anatomical functions to the engineered tissue constructs. The 3D scaffolding systems fabricated by using biomaterials provide suitable microenvironments to the cells and support cell growth, differentiation, maturation into desirable cell types, and integration with host renal tissues. Bioactive molecules, such as growth factors, cytokines, and small molecules may also be incorporated into bioengineered renal tissue constructs to accelerate tissue formation and improve renal function [30]. In this section, we will introduce current updates and discuss the two major components of bioengineered 3D renal tissue constructs, cell sources and biomaterials-based scaffolding systems, as well as preclinical and clinical outcomes for the treatment of kidney diseases.

Cell sources

The adult kidney is composed of over 30 specialized types of cells, which are distributed to various distinct renal compartments. Each cell type is structurally organized into renal vasculature, interstitia, glomeruli, and tubules with architectural complexity and exerts its own functions [31]. Therefore identification and development of reliable and effective cell sources is a prerequisite for kidney tissue engineering. Recent advances in stem cell biology and cell culture techniques have been made to identify, obtain, and culture a number of cell sources for treating kidney diseases (Table 45.1) [72].

Recently, researchers have developed isolation and culture techniques for primary renal cells isolated from both normal and diseases kidney tissues [32,33]. In addition, renal stem or progenitor cells can be obtained from adult kidneys. Although the existence and identification of kidney-derived stem or progenitor cells has been controversial, several studies have reported that renal stem cells can be identified and isolated from the Bowman's capsule, renal papilla, and renal tubules [73]. These findings indicate that the primary renal cells or stem cells derived from patients' own kidneys can be a promising and practical cell source for the treatment of renal diseases. In addition, various types of adult stem/progenitor cells or pluripotent stem cells (PSCs) derived from nonrenal tissues have been discussed as potential cell sources. PSCs, either embryonic stem cells (ESCs) [74,75] or induced PSCs (iPSCs) [76], have been shown to generate organ-level renal tissues with cellular and architectural complexity. However, due to regulatory and ethical issues, and teratoma formation is a major hurdle for clinical applications. Fetal and adult stem cells such as amniotic fluid stem cells (AFSCs) [77] and MSCs [78] possess self-renewal and differentiation capabilities to develop into renal-specific lineages. Fetal and adult stem cells have lower cell growth and tissue formation capability than PSCs, but they are relatively free from ethical issues and teratoma formation, so a number of clinical studies have been performed using fetal and adult stem cells to treat kidney diseases.

Kidney tissue–derived primary or stem/progenitor cells

Primary renal cells

Primary human renal cells can be isolated from normal and diseased kidney tissues and expanded in culture maintaining their phenotype and function. Proximal tubular cells in the native kidney play a critical role in renal functions such as reabsorption of proteins and ions, hydrolase activity, and erythropoietin (EPO) production [79]. The major cell population of the normal kidney is the proximal tubular cell, comprising about 60% of total cell population, including podocytes, distal tubular cells, descending loop of Henle, and collecting duct cells [80]. Thus primary proximal tubular cells with normal physiology isolated from human kidneys are a powerful renal cell source for autologous cell-based treatments. However, primary renal cells have limited cell proliferation capacities of up to five passages in in vitro culture, highlighting the need for more reliable and reproducible cell culture systems [81,82].

Recently, George et al. focused on the isolation and expansion of primary human renal cells from normal kidneys and from diseased kidneys of CKD patients for the potential use in clinical applications [32,33]. The expanded primary renal cells showed efficient and prolonged proliferation with no differences in growth patterns until passage 9. The majority of the primary renal cells were proximal tubular cells (approximately 70%–80%) with the remaining cells consisting of distal tubular cells, collecting duct cells, podocytes, and other cell types. In 3D culture, primary renal cells formed tubule-like structures with functional properties. Remarkably, primary renal cells from human kidneys of CKD patients had normal phenotypic and functional characteristics similar to the cells from normal kidneys [33]. This study

TABLE 45.1 Cell sources for engineering of the kidney.

Cell type	Origin	Outcome	Refs.
Primary renal cells			
Unpurified human primary renal cells	Human normal and diseased kidneys	High percentage of proximal tubular cells (>80%), high proliferation capability up to passage 9, tubule-like structures with functional properties	[32,33]
EPO-enriched cells	Purified human renal primary cells	Structural and functional improvement in ischemic injury models in rats, amelioration of inflammation and oxidative stress	[34]
Human $CD10^+CD13^+$ cells	Purified proximal tubular epithelial cells	Maintenance of phenotypes and functions over several passages	[35]
Stem/progenitor cells derived from renal tissue			
Human $CD133^+$ cells	Bowman's capsule	Homing and integration with host tubules in a mouse tubulonecrosis model	[36]
Human $C24^+CD133^+$ cells	Bowman's capsule	Regeneration of renal tubules and amelioration of renal function in a mouse acute renal failure model	[37]
Human $CD133^+CD24^+PDX^-$ cells	Bowman's capsule	Regeneration of both tubules and podocytes, reduced proteinuria and glomerular damages in a mouse acute renal failure model	[38]
LRCs	Papilla	Heterogeneity, epithelial, mesenchymal, and neuronal phenotypes; contribution to kidney repair in response to renal ischemic injury	[39,40]
$CD133/1^+$ $nestin^+$ cells	Papilla	Integration and tubule formation	[41]
BrdU retaining and $vimentin^+$ cells	Tubules (S3 segment)	Integration and regeneration of renal tubules in an ischemic injury model	[42]
rKS53	Tubules (S3 segment)	Replacement of injured tubular cells and differentiation into mature tubular epithelial cells in rat AKI models	[43]
$ALDH^{high}$ cells	Proximal tubules	$CD133^+CD24^+$, increased cell proliferation	[44]
Adult stem cells			
BM-MSC	Bone marrow	Functional improvement in mouse and rat models, amelioration of renal transplantation–related complications in human clinical trials	[9–11,45–52]
AD-MSC	Fat tissue	Functional improvement in mouse, rat, and pig models	[53–57]
Fetal stem cells			
AFSC	Amniotic fluids	Functional improvement in mouse renal failure models and pig kidney transplantation models	[58–61]
Pluripotent stem cells			
ESC	Embryo	In vitro differentiation into renal population, ESC-derived cells integration into proximal tubules	[62–65]
iPSC	Genetically modified somatic cells	In vitro differentiation into renal population, functional improvement in a rodent AKI models	[66–71]

AD-MSC, Adipose-derived mesenchymal stem cell; *AFSC*, amniotic fluid stem cells; *AKI*, acute kidney injury; *ALDH*, aldehyde dehydrogenase; *BM-MSC*, bone marrow–derived mesenchymal stem cell; *BrdU*, 6-bromo-2′-deoxyuridine; *EPO*, erythropoietin; *ESC*, embryonic stem cells; *iPSC*, induced pluripotent stem cells; *LRC*, label retaining cells; *PDX*, podocalyxin.

indicates that renal cells isolated from diseased kidneys can be a reliable autologous cell source to treat patients with renal failure.

Thereafter, they purified an EPO-enriched cell population from cultured primary kidney cells and investigated the therapeutic potential of these cells using a rat CKD

model [34]. Intrarenal injection of EPO-enriched cells was capable of functional improvements such as amelioration of inflammation and oxidative stress compared with unpurified cells. These results suggest that EPO-enriched cells within primary kidney cells may be a promising cell source for the treatment of renal failure.

Proximal tubular epithelial cells can be further purified from human renal tissue [35]. $CD10^+CD13^+$ proximal tubular cells exist in very low population densities of 4%. However, once purified, the cells proliferated and maintained phenotypic and functional properties over several passages. In another study, human renal epithelial cells from human thick ascending limbs and early distal tubules were isolated using an immunomagnetic cell isolation technique, showing that these cells can be used as a cell source for an in vitro system and for treating the renal diseases targeting human thick ascending limb of Henle's loop and early distal tubules [83].

Stem/progenitor cells derived from kidneys

Renal stem cells in Bowman's capsule The primary function of the kidney is to remove waste and generate urine by filtrating blood from the glomerulus into the Bowman's capsule [84]. In the filtration process, podocytes, a specialized type of epithelial cell, play a key role; however, podocytes have very limited proliferation in the damaged kidney [85]. Therefore several attempts have been made to identify and obtain a source of renal stem cells capable of replacing podocytes to restore normal kidney filtration functions.

It is believed that $CD133^+$ or $CD133^+CD24^+$ cell, a subset of parietal epithelial cells in the Bowman's capsule, is a possible adult stem cell source. A large population of $CD133^+$ cells were observed in developing embryonic kidneys with self-renewing and multipotent characteristics, and $CD133^+$ cells remained scattered through the tubules and the urinary pole of Bowman's capsule in the adult kidneys [37,38,86]. $CD133^+$ or $CD133^+CD24^+$ renal stem cells can be isolated and expanded from the normal adult kidney cortex and in the kidneys of cancer patients [36,37]. $CD133^+CD24^+$ cells isolated from Bowman's capsule were positive for the stem cell markers CD106, CD105, CD54, and CD44, but negative for podocyte markers, indicating that these cells were not fully differentiated into renal lineages [37,38]. $CD24^+CD133^+$ cells could differentiate into renal lineages, including mature proximal and distal tubules in in vitro culture conditions, showing their possible use as a cell source for kidney regeneration [37].

Due to their multipotency, especially their renal-specific lineage differentiation capabilities, $CD133^+$ cells have been applied to treat renal disease, showing therapeutic potential in in vivo studies. In a study done by Bussolati et al., subcutaneously implanted $CD133^+$ cells in mice formed tubular structures and functional vessels, and intravenously injected $CD133^+$ cells in mice with glycol-induced tubular necrosis successfully homed to and integrated into host tubules [36]. In another study, $CD24^+CD133^+$ cells injected into mice acute renal failure models demonstrated therapeutic potential, evidenced by the regeneration of renal tubules and amelioration of renal function [37]. In addition, injection of $CD24^+CD133^+$ podocalyxin $(PDX)^-$ cells, but not $CD24^+CD133^+PDX^+$ cells, regenerated both tubular cells and podocytes and reduced proteinuria and glomerular damage [38].

Renal stem cells in the papilla The papilla is the apex of the renal pyramids that projects into the lumen of a calyx of the kidney. The papilla contains the epithelial cells of the collecting ducts and the loops of Henle where urine flows into the ureter. Renal stem cells also reside in the papilla. The presence of a stem cell population in the papilla was identified by Oliver et al. [39,40]. Using a nucleotide bromodeoxyuridine (BrdU) labeling technique, they demonstrated that the renal papilla contained BrdU label retaining cells (LRCs) in rodents. The LRCs isolated and cultured in vitro showed a heterogeneous population of ZO-1^+ epithelial, α-smooth muscle $actin^+$ mesenchymal, and β-III $tubulin^+$ neuronal phenotypes. An in vivo study indicated that LRCs contributed to kidney repair in response to renal ischemic injury.

$CD133^+$ cells can be obtained not only from the Bowman's capsule as described earlier [36] but also from the renal papilla [41] in human kidney tissues. Human $CD133^+/1^+$ renal papillary cells were $nestin^+$ and also positive for human ESC (hESC) markers SSEA4, Nanog, SOX2, and OCT4/POU5F1. These cells integrated into developing kidney tubular structures indicating their capability to form renal tubules de novo.

Renal stem cells in tubules The renal tubules play a critical role in the reabsorption of proteins, water, and electrolytes in filtrated fluids. The S3 segment of the proximal tubules has been investigated to identify and isolate renal stem cells in several studies [42,87]. The S3 segment is located near the corticomedullary junction and therefore incurs more severe damage from ischemic injuries than other segments of the nephron. As such, a number of stem cells expressing vimentin and proliferating cell nuclear antigen have been found to reside to repair the damages in the S3 segment [42,87,88]. More recent work reported that renal tubular cells with high aldehyde dehydrogenase (ALDH) activity ($ALDH^{high}$ cells) can be isolated from human tubule tissues [44]. The $ALDH^{high}$ cells showed $CD133^+CD24^+$ phenotypes and had improved cell proliferation capabilities compared to

$ALDH^{low}$ cells. The result indicates that $ALDH^{high}$ cells are renal progenitor cells in adult human tubules.

There were several reports that stem cell populations isolated from renal tubules formed regenerating renal tubules in the ischemia/reperfusion injury model in mice [89–91]. In a study done by Kitamura et al., an epithelial-like cell line, rKS53, was established by purifying cells with a high proliferation rate from the microdissected S3 tubules of rats [43]. This cell line has stem/progenitor cell–like features and expresses the stem cell markers vimentin, c-Met, Sca-1, c-kit, Pax-2, and the neural stem cell marker, Musashi-1, in addition to having the potential to differentiate into different tubule phenotypes. When the rKS53 cells were injected into ischemic kidneys, the cells could replace injured tubular cells and differentiate into mature tubular epithelial cells, demonstrating the regenerative capabilities of rKS53 cells.

Adult and fetal stem cells

Mesenchymal stem cells

MSCs isolated from bone marrow (BM) and fat tissues have been extensively utilized as a promising cell source for the treatment of renal diseases in preclinical and clinical settings [78]. MSCs are easily isolated through minimally invasive techniques such as BM extraction (BM-derived MSCs, BM-MSCs) and liposuction (adipose-derived MSCs, AD-MSCs), expanded with high efficiency in culture, and relatively free from ethical issues compared to the other cell sources. With their self-renewal capabilities and multipotency, BM-MSCs [45–52] and AD-MSCs [53–57] have been applied to regenerate several injured organs, including kidneys [78,92].

Numerous studies demonstrated the therapeutic potential of MSCs to treat renal failure; however, the mechanism of repair and regeneration of the damaged kidney by MSCs treatments is still controversial. Early studies reported that transplanted MSCs differentiate into renal-specific lineages, such as renal tubular cells [90], podocytes [52], glomerular cells [93], and mesangial cells [94], and integrate into host renal tissues to improve renal structure and function in AKI models. On the other hand, recent studies suggest that the predominant mechanism of kidney regeneration by MSCs in AKI models is through their paracrine effects. Trophic factors or secretomes released from transplanted MSCs allow endogenous cells to proliferate and prevent apoptosis to accelerate kidney repair [95,96]. The paracrine effects of MSCs on kidney repair have also been demonstrated in the several studies using MSC-conditioned media [97].

To date, a number of clinical studies have been performed using autologous MSCs for the success and amelioration of kidney transplantation–related complications because of MSCs' low immunomodulatory effects and high regenerative capability [9–11]. For instance, a safety and feasibility study demonstrated that the infusion of autologous MSCs to kidney recipients controls $CD8^+$ T cell function and reduces immune rejections [10]. In another study, autologous BM-MSCs were injected into kidney transplant patients [11]. With 6-month follow-up, the autologous BM-MSC injections improved the resolution of interstitial fibrosis/tubular atrophy. Recently, there are some efforts to initiate Phase I/II clinical trials for restoration of renal function in renal failure patients using autologous MSCs [5]. Despite the promising results of using MSCs for the treatment of renal failure, side effects such as increased interstitial fibrosis have also been reported [98]. Therefore further safety and feasibility studies are necessary for the successful development of MSC-based therapies for kidney repair.

Amniotic fluid stem cells

AFSCs are another potential cell source for the treatment of renal failure. Recently, human AFSCs (hAFSCs) were isolated from amniotic fluid and cultured in vitro [99]. Isolated AFSCs retained high self-renewal potential, high proliferation rats over 250 population doubling, and multidifferentiation ability, with not reported teratoma formation in vivo. Of importance here was the demonstration of the differentiation capability of AFSCs into renal-specific lineages [77].

Recent preclinical studies using AFSCs demonstrated their possible therapeutic effects in treating kidney diseases [58–61]. Hauser et al. reported that intravenous infusion of hAFSCs showed more rapid recovery of kidney function in an acute renal failure model compared to treatment with BM-MSCs [58]. In another study, preconditioning of hAFSCs with neurotrophic factors achieved enhanced renal function outcomes compared to the use of hAFSCs without preconditioning in an AKI model [59]. In addition, injection of AFSCs prevented renal fibrosis and preserved renal function in a mouse CKD model [60] and a porcine model of kidney transplantation [61].

Pluripotent stem cells

Embryonic stem cells

The representative PSCs are ESCs [74,75] and iPSCs [76]. Both ESCs and iPSCs are capable of self-renewal and multidifferentiation into all cell types, cells of mesodermal, endodermal, and ectodermal lineages. Since it has been demonstrated that hESCs can be obtained from the inner cell mass of the embryonic blastocyst, hESCs represented a powerful cell source for developing in vitro models and for treating damaged tissues [75,100,101]. Extensive research has been conducted to establish robust protocols for hESC differentiation to produce functional cells of desired lineages.

Differentiation of ESCs into renal lineages has also been investigated [62–65]. For instance, Kim and Dressler reported that mouse ESCs could be differentiated into renal epithelial cells using nephrogenic growth factors and that these epithelial cells were efficiently integrated into a developing kidney [63]. Vigneau et al. isolated and purified renal proximal tubular progenitor cells from the embryoid bodies using a defined differentiation protocol. When the proximal tubular progenitor cells were injected into a developing newborn mouse kidney, the cells integrated into proximal tubules that had normal morphology and function, without teratoma formation [65].

These previous results strongly support the feasibility of applying ESCs to treat renal failure. However, the widespread use of ESCs is still limited due to legal and ethical issues associated with the use of human embryos in the clinics, uncontrolled growth and differentiation, possibility of teratoma formation in vivo, and immune rejection after transplantation [102,103].

Induced pluripotent stem cells

Another cell source possessing pluripotency is iPSCs. Unlike ESCs, iPSCs can be obtained from somatic donor cells, such as patient's own fibroblasts [76]. iPSCs were first developed by Takahashi and Yamanaka by reprograming human fibroblasts with four genes, Oct3/4, Sox2, c-Myc, and Klf4 [76]. The genetically modified iPSCs have very similar characteristics to ESCs such as self-renewal, ESCs-specific genes expression, embryonic body formation, and teratoma formation. However, iPSCs are relatively free from ethical issues and low immune rejection complications compared with ESCs. Therefore iPSCs can be utilized as an autologous cell source for the treatment of renal diseases in a clinical setting.

Great progress has been made in recent years to establish iPSC culture techniques and differentiation protocols for renal cell lineages in vitro [66–68]. Several preclinical studies have demonstrated the feasibility of iPSC-derived cells to treat kidney diseases [69–71]. For instance, Song et al. reported that the direct differentiation of human iPSCs (hiPSCs) into podocytes was possible and that these hiPSCs-derived podocytes were integrated into metanephric kidney structures [67]. In another study, human kidney organoids containing multiple lineages were generated from hESCs and iPSCs in a 3D culture using a growth factor, FGF9, and a small molecule, CHIR99021 [68]. The kidney organoids contained functional nephrons that were composed of glomeruli with podocytes, distal and proximal tubules, early loops of Henle, collecting ducts, renal interstitium, and endothelial cells. This protocol was modified to a two-dimensional (2D) culture method to generate kidney progenitor cells that were subcutaneously implanted into mice [104]. The implanted kidney progenitor cells formed kidney-like structures composed of glomeruli, tubules, mesangial cells, and capillaries after 3 months. Remarkably, a few following studies demonstrated that the transplantation of renal progenitors differentiated from hiPSCs via intravenous injection [70] or renal subcapsular transplantation [71] has therapeutic effectiveness, attenuating histopathological changes and restoring renal functions.

Despite these promising results, several concerns remain for further clinical use of iPSCs as a cell source. It is difficult to use iPSCs due to multistep differentiation processes that are specifically timed and utilize highly sophisticated bioactive molecules [105,106]. The low efficiency and unpredictability of differentiation in vivo are other challenges to using iPSCs. Poorly differentiated metanephric tissues and islands of cartilage formation have been frequently observed after transplantation [104]. The immunogenicity of the differentiated cells needs to be carefully accessed [107].

Tissue-engineered cellular three-dimensional renal constructs

Engineering three-dimensional kidney constructs using natural and synthetic polymers

Numerous tissue-engineered cellular 3D kidney constructs have been developed using a variety of scaffolding systems, fabricated by natural or synthetic polymers for treating renal diseases (Table 45.2). The basic strategy of engineering renal constructs is to seed cells onto scaffolds with desirable biological, mechanical, or structural properties to support cellular behavior and functions such as proliferation, differentiation, integration, and kidney-like tissue formation. Therefore the ideal scaffolding system is biocompatible: it has porous structures to provide a suitable space with efficient oxygen and nutrients to the cells for survival, provides appropriate biological microenvironments for growth and maturation to desired tissues, possesses the appropriate mechanical properties to support tissue formation and integration of the engineered constructs in vivo, and has appropriate biodegradation rates to allow the cells to produce their own extracellular matrix (ECM) that will eventually replace the scaffolds with newly formed tissues [114].

Natural polymers or synthetic polymers have been widely used as biomaterials to engineer 3D renal constructs. Natural polymers include collagen, hyaluronic acid, fibrin, gelatin, alginate, agarose, and chitosan. Most of the naturally derived polymers are biocompatible and biologically active, and therefore capable of supporting cell adhesion, proliferation, differentiation, and migration.

TABLE 45.2 **Cell-based three-dimensional (3D) renal constructs using biomaterials.**

Biomaterials	Cells	Outcome	Refs.
Natural polymers			
Collagen/ vitrigel	Glomerular epithelial and mesangial cells	Reconstruction of 3D renal glomerular tissue in vitro	[108]
Collagen/ Matrigel	Neonatal rat renal cells	Casting mold system as static stretching device, self-assembly of renal cells tubules and glomeruli-like structures formation with reduced necrosis in vitro	[109]
Collagen	Human primary renal cells	Tubulogenesis and function (albumin adsorption) in vitro cells survival for up to 6 weeks within the kidney in vivo	[32]
Collagen/PCL	Human endothelial cells	Perfusable and endothelialized biomimetic vascular scaffolds for 3D renal tissue constructs	[13]
HA	Fetal kidney tissue	Renal tubules and glomerular structures formation in vitro	[110]
Gelatin/fibrin	Human proximal tubule epithelial cells	Engineering of 3D proximal tubule on a chip using a 3D bioprinting technology, enhanced epithelial morphology and function compared to the cells in 2D culture	[14]
Synthetic polymers			
PGA	Rat renal segments	Nonwoven fibrous scaffolds, glomeruli and tubules formation in a subcutaneous implantation in mice	[111]
PCL	Human kidney primary epithelial cell line	Electrospun scaffold fabrication with high porosity, cell infiltration throughout the scaffold	[112]
PC	Mouse primary renal cells	Tubular-shaped construct formation, yellow urine–like fluid production, glomeruli and highly organized tubule-like structures formation, and vascularization in subcutaneous implantation in mice	[113]
PGA, PC, PE	Renal cells cloned from bovine fibroblasts	Kidney-like unit, urine-like fluid production, unidirectional secretion and concentration of urea nitrogen and creatinine, and formation of organized glomeruli- and tubule-like structures in vivo	[15]

2D, Two-dimensional; *3D*, three-dimensional; *HA*, hyaluronic acid; *PC*, polycarbonate; *PCL*, polycaprolactone; *PE*, polyethylene; *PGA*, polyglycolic acid.

However, natural polymers have poor mechanical properties compared to synthetic polymers. Even so, natural polymer–based scaffolds continue to be widely used for kidney tissue engineering due to their favorable biological properties [115].

Unlike natural polymers, synthetic polymers such as polylactic acid, polyglycolic acid (PGA), and polylactic-*co*-glycolic acid can be synthesized with tailored architecture, so it is easy to control their mechanical properties and degradation characteristics for several weeks to several years. However, synthetic polymers are less biocompatible than natural polymers and their degradation products may stimulate inflammatory responses [116]. Therefore a variety of alternative composite scaffolds combining synthetic polymers with natural polymers have been investigated.

Collagen is a one of the major structural components of the ECM. Collagen as a biomaterial is inherently biocompatible and degradable and has been extensively utilized to fabricate tissue-engineered renal constructs [117]. Numerous reports have demonstrated that collagen is able to provide 3D microenvironments to support cell attachment and growth. For instance, Wang and Takezawa [108] developed a novel technique of renal cell isolation and a long-term 3D culture system using a collagen-based scaffolding system for the reconstruction of renal glomerular tissues in vitro. Glomerular epithelial and mesangial cells were isolated from kidney tissue and cultured on a collagen–vitrigel scaffold. The collagen–vitrigel scaffold provided a suitable environment similar to the glomerular basement membrane for the cells and resulted in the maintenance of cell growth and viability over 1 month, and reconstitution of renal glomerular tissues. In another study, Guimaraes-Souza et al. demonstrated that human primary renal cells could reconstitute the functional renal tissue in vitro using a 3D collagen scaffold [32]. Primary renal cells were differentiated into tubule-like structures composed of proximal tubules, distal tubules, and collecting ducts showing functionality such as albumin uptake. The engineered renal constructs were then implanted into the kidney parenchyma, showing cell survival for up to 6 weeks and integration into glomeruli and interstitium.

These results show that collagen-based tissue-engineered 3D renal constructs utilizing the patients' own cells may be used for restoration of renal function.

While natural polymer–based scaffolds have been widely utilized for tissue regeneration, they have low mechanical properties and sometimes fail to retain shape as described earlier. Natural polymer–based hydrogels contract over time with growth and proliferation of the seeded cells leading to cell death in the center. To prevent scaffold contraction and improve cell viability, Lu et al. utilized a 3D collagen/Matrigel scaffold with casting molds to provide static stretch for neonatal rat renal cell culture. Using this system, neonatal rat renal cells self-assembled into renal tubules and glomeruli-like structures with reduced necrosis [109].

The mechanical properties and degradation rates of synthetic polymers are relatively easy to control and process for the purposes of scaffold fabrication. Therefore synthetic polymers have been more frequently applied to fabricate scaffolds that need more controlled complex architecture than natural polymers. For instance, Burton et al. developed electrospun scaffolds using polycaprolactone (PCL) using a cryogenic electrospinning technique [112]. The resulting scaffolds provided fibrous 3D structures with higher porosity, facilitating cell infiltration throughout scaffolds compared to random or aligned electrospun scaffolds. They also state that the architectural features of the scaffold, including fiber alignment and diameter, affected the attachment, viability, and alignment of renal cells emphasizing the importance of the scaffold architecture on kidney regeneration. Another study by Kim et al. utilized a biodegradable, nonwoven PGA fiber mesh (12 μm in diameters) as a scaffold in order to culture renal segments [111]. They isolated renal segments from rat kidneys, which included nephron epithelial cells, endothelial cells, vascular smooth muscle cells, and stromal cells. An in vivo study of subcutaneous implantation of the renal segment-seeded PGA mesh in mice showed that the 3D renal constructs formed glomeruli and tubules, demonstrating the possibility of reconstituting renal structures using fibrous polymer scaffolds.

Yoo et al. developed a functional artificial renal unit that exhibited urine production [113]. The artificial renal unit was fabricated by seeding mouse renal cells in tubular-shaped polycarbonate scaffolds. This renal unit formed glomeruli and highly organized tubule-like architecture upon subcutaneous implantation in mice. Remarkably, the newly formed renal tissues excreted yellow urine–like fluid. This renal unit was further advanced in a following study by Lonza et al. Their renal unit was composed of cell-seeded unwoven PGA scaffolds and collecting systems constructed by three cylindrical polycarbonate membranes, which were connected to a polyethylene reservoir. The renal unit self-assembled into glomeruli- and tubule-like structures with continuity and showed kidney-like functions such as the production of urine-like fluids and unidirectional secretion of urea, nitrogen, and creatinine in vivo.

With an advanced scaffold fabrication technique, several attempts have made to produce 3D renal scaffolds that mimic native renal structures. For instance, Huling et al. developed a biomimetic vascular scaffold for a 3D renal tissue construct using a novel vascular corrosion cast technique [13]. Vascularization is among the most challenging aspects in fabricating engineered tissues for maintaining viability and function of cells in vitro and in vivo [118]. Also, kidney is a highly vascularized organ, and the very sophisticated renal vasculature plays a critical role in cell viability as well as renal function in blood filtration. In this study, native renal microvasculature was captured using PCL as a sacrificed template followed by embedding into collagen. The resulting collagen scaffolds possessed normal kidney microvasculature and were capable of endothelialization and perfusion, showing potential for application in kidney tissue engineering.

Advances in microfluidics in the last decade and cell culture have made micro-engineered models of the functional units of several human organs, so-called organ-on-a-chip [119,120]. The bioengineered kidney-on-a-chip was fabricated using several types of synthetic and natural polymers where cells were seeded to mimic the functional unit of the kidney. In one study by Homan et al., an engineered 3D proximal tubule-on-a-chip was fabricated by using 3D bioprinting technology [14]. 3D bioprinting is an emerging scaffold fabrication technique that is suitable for creating complex and luminal tissue structures [121]. In the study of Homan et al., 3D printed tubular structures were embedded within ECM and housed in perfusable tissue chips, and then the tubular lumen was seeded with proximal tubule epithelial cells. The resulting engineered 3D proximal tubules-on-a-chip showed enhanced epithelial morphology and function compared to the cells in 2D culture with response to nephrotoxin. Therefore the engineered 3D proximal tubules-on-a-chip can be applicable for in vitro models in studying renal physiology, disease modeling, and toxicity testing.

Decellularization/recellularization strategy

Recently, there have been numerous efforts to bioengineer complex 3D organs and tissues such as the heart, liver, lung, and kidney. Such organs have tissue-specific multicellular architecture and vasculature that is sophisticatedly organized to exert tissue-specific functions. Kidney, as mentioned earlier, is a highly complex organ composed of over 30 different cell types. Each cell type is intricately organized and functionally compartmentalized to form thousands of nephrons, the functional units of the kidney.

Nephrons have different regions: the Bowman's capsule that encloses the glomerulus, the proximal tubule, the loop of Henle, the distal tubule, and the collecting duct. Each region has different anatomical features and physiological roles [12]. This complexity of the kidney makes it difficult to reproduce by traditional scaffold fabrication methodologies.

Recent progress in whole organ engineering, involving the decellularization/recellularization technologies, has provided a promising approach to overcome the limitations of traditional scaffold fabrication techniques and to build complex 3D kidney constructs (Table 45.3) [16–18]. Potentially, this technology may address the unmet medical problem of the shortage of transplantable donor kidneys via an alternative engineered whole kidney. In the decellularization/recellularization approach, acellular tissue is utilized as a scaffolding system. Acellular biologic scaffolds can be produced by removing cells from the tissues or organs through the "decellularization" process, leaving behind a tissue-specific ECM. The decellularized scaffolds can be seeded with cells, in a process called "recellularization" [17,132]. The decellularized tissues maintain the 3D ultrastructure and composition of the ECM, biochemical and biophysical factors, and vascular networks of the native tissues or organs. Over time, the decellularized tissue is degraded and remodeled with new ECM proteins produced by seeded cells. Therefore decellularizing tissues can produce an ideal scaffolding system to provide renal-specific microenvironments for engineering functional whole kidneys.

A variety of decellularization strategies have been developed to generate acellular renal scaffolds using rat [122,123,128–130], pig [124,131], rhesus monkey [126,127], and human [125] kidneys. An efficient decellularization technique is to remove the cellular components to avoid the induction of an immune response while preserving the 3D renal ECM architecture for glomerular and tubular structures and intact vascular networks. The general decellularization protocol for this approach is to perfuse detergents, enzymes, or other cell lysates such as sodium dodecyl sulfate, Triton X-100, and DNase through the inherent vasculature [17,132].

Initial success in kidney decellularization was achieved by Ross et al. in their work on rat whole kidneys [122,123]. Their decellularized rat kidneys preserved the intricate ECM architecture with intact vasculature. They then showed the possibility of using the decellularized kidney as a renal scaffold. They recellularized the acellular kidney scaffold with murine ESCs by manual injection through either the artery or ureter, showing the repopulation and differentiation of ESCs in the acellular kidney scaffolds. Thereafter, several groups have reported efficient decellularization technologies of whole kidneys in pig [131] and monkey [125,127] models to produce acellular renal scaffolds to recreate engineered whole kidney constructs on a clinical scale. Recently, Orlando et al. reported successful decellularization of human kidneys discarded from transplantation with an optimized decellularization protocol [125]. The resulting human whole kidney ECM scaffolds maintained their macro- and micro-3D architecture, biochemical properties, and vascular patency, showing the possibility of utilizing discarded human kidneys for acellular renal scaffolds in whole kidney transplantation.

There have been several attempts to recellularize decellularized whole kidneys to produce functional tissue or organs for transplantation. Early recellularization methods involved manual injection of cells through the renal artery and vein in static culture for several days; however, this approach results in low survival and growth, significant apoptosis, and an uneven distribution of cells [16]. Therefore an efficient recellularization strategy should be established for bioengineering implantable whole kidneys. Recently, a bioreactor system composed of a cell infusion and perfusion culture system such as syringe pump [133], peristaltic pump [130], or pulsatile pump [18,38] has been applied for this process. The bioreactor system allows for constant infusion of cells without apparent damage to the scaffold and supports nutrition, viability, proliferation, and differentiation of the cells within the scaffold [16].

In a recent report by Song et al., a bioengineered rat kidney construct was produced by decellularization/recellularization techniques using a bioreactor system and transplanted into rats [130]. A decellularized rat whole kidney was recellularized using human umbilical vein endothelial cells through the renal artery, and rat neonatal cells through the ureter with negative pressure on the whole kidney chamber, followed by arterial perfusion culture in a bioreactor as previously mentioned. Using this system, they achieved a high recellularization rate, with 70% glomeruli. In another study by Peloso et al., an acellular kidney was repopulated in a customized bioreactor system [129]. In this study, human pancreatic carcinoma cells were manually injected into decellularized rat kidneys through renal arterial vascular networks and cultured in a pulsatile system. In a short-term culture system, the cells were homogenously distributed inside the parenchyma.

Even with the success of these studies, the appropriate source of cells for recellularization is controversial. Current studies use different cell sources, including neonatal kidney cells [130], ESCs [122,123,126–128], primary human renal cells [124], and endothelial cells [130,131], to repopulate acellular kidney scaffolds. ESCs show superior outcomes in terms of differentiation into multiple types of renal cells in bioengineered kidney tissues; however, the use of ESCs in the clinic is still limited due to regulatory and ethical issues. Primary human renal

TABLE 45.3 Decellularization/recellularization strategy for whole kidney tissue engineering.

Species	Decellularization	Recellularization			In vivo	Outcome	Refs.
		Cells	Seeding method	Scaffold culture method			
Rat	3% Triton X-10, DNase, 3% Triton X-100, 4% SDS. Gravity-based perfusion using renal artery and ureter (100 mmHg)	Murine ESCs	Manual injection through either the artery or ureter	Automated perfusion system (120 mmHg/ 80 mmHg)	–	Proliferation and differentiation of ESCs in a complex architecture, production of basement membrane	[122,123]
Pig	0.5% SDS for 36 h and DNase overnight, renal artery perfusion	Human primary renal cells	Static seeding	Static culture for 3–4 days	–	Optimization of decellularization method	[124]
Human	Distilled water at 12 mL/min for 12 h, 0.5% SDS at 12 mL/min for 48 h, and final rinse with PBS at 6 mL/ min for 5 days	–	–	–	–	Optimization of decellularization methodAngiogenic capability	[125]
Rhesus monkey	1% SDS, 7–10 days	hESCs	Static seeding into decellularized kidney sections	Static culture for 8 days	–	Spatial organization cells into tissue-specific structures in vitro	[126,127]
Rat	0.01 M PBS at 2 mL/min for 15 min, 0.5% SDS for 4 h, then PBS for 24 h, renal artery perfusion	Mouse ESCs	Manual seeding through the renal artery and ureter	Perfusion culture	Orthotopic implantation into rat	Reperfusion and urine production with no blood leakage, obstruction of renal artery and vein by a massive thrombi	[128]
Rat	1% Triton X-100 at 70 mL/h for 1 h 25 min, then PBS at 50 mL/h for 1 h	Human pancreatic carcinoma cells	Manual injection through renal arterial vascular network	Perfusion bioreactor at 1 mL/min for 24 h	Orthotopic implantation into rat	Homogeneous cell distribution, obstruction of all vascular structures with thrombi	[129]
Rat	1% SDS 12 h, 1% Triton X-100 30 min, renal artery perfusion (40 mmHg)	Rat neonatal kidney cells and HUVECs	HUVECs: Arterial flow (1 m/min) then static culture overnight, rat neonatal kidney cells: injected through the ureter	Arterial perfusion culture in a bioreactor (1.5 mL/min)	Orthotopic implantation into rat	Graft perfusion by recipient's circulation, urine production through ureteral conduit	[130]
Pig	0.5% SDS	GFP-labeled endothelial cells (MS-1)	Static seeding followed by ramping perfusion, conjugation of CD31 antibodies to the vascular matrix	Perfusion rate at 2 mL/ min and then gradually increased to 5, 10, and 20 mL/min at 10–12 intervals	Orthotopic implantation into pig	Improved endothelial cell retention on the vasculature, enhanced vascular patency of the implanted kidney in vivo	[131]

cells or renal cells derived from hiPSCs, therefore, may be better candidates when considering clinical perspectives.

Although the decellularization/recellularization strategy has shown promising results in vitro and in vivo, several challenges need to be addressed for the successful transplantation of bioengineered whole kidneys. One of the critical challenges is the maintenance of long-term vascular patency of the bioengineered kidneys in vivo [128,129,131]. In a study by Peloso et al., mentioned earlier, it was reported that their implanted whole rat kidney was able to maintain blood perfusion after orthotopic transplantation for 7 days; however, the entire vascular network for the implant was obstructed by a massive thrombosis over time [129]. With this result, they highlighted that the reendothelialization of scaffold vasculature is mandatory for avoiding extensive thrombosis to establish successful transplantation and renal function. To address this issue, Ko et al. developed a novel endothelial seeding method that facilitated effective reendothelialization of a porcine kidney scaffold [131]. Conjugating CD31 antibodies to the vascular lumen increased endothelial cell attachment and retention on the vascular network, and resulted in reduced thrombosis and enhanced vascular patency of the bioengineered whole kidney in vivo.

Cell-free tissue engineering of the kidney

In situ kidney regeneration

Recent progress in tissue engineering and regenerative medicine has adopted the concept of in situ tissue regeneration. Even though cell-based approaches have shown positive effects on tissue regeneration, this approach is challenged by the difficulties in obtaining appropriate cell sources and achieving higher cell survival rates [118,134]. In situ tissue regeneration is the utilization of the body's own regenerative capabilities, without exogenous cell transplantations, to restore organ function. This approach has several advantages compared to cell-based tissue engineering approaches [19,21]. In situ tissue regeneration does not require cell manipulation ex vivo, such as isolation and expansion of cells in large quantities from tissue biopsies. Instead, target-specific scaffolding systems and/or delivery of bioactive molecules can be applied to provide an appropriate niche for enhancing the ability of tissue regeneration [19,22–25]. In addition, considering that current cell-based tissue engineering techniques still struggle to create functional 3D tissues with the structural and cellular complexities of the kidney, in situ tissue regeneration may be more clinically feasible approach.

The simplest and most pharmacologically attractive strategy for in situ tissue regeneration is the delivery of bioactive molecules, such as growth factors, chemokines, or small molecules that support the kidney's own regenerative capability for proliferation, functional differentiation, antiinflammation, and antifibrosis. Although this approach has been extensively applied in kidney regeneration, this approach is not reviewed in this chapter. Instead, the major role of each bioactive molecule used in kidney regeneration is summarized in Table 45.4.

Other in situ approaches include the recruitment of host stem cells from BM or tissue-specific progenitor cells to injury sites for regeneration or repair [19–21]. A key issue in this in situ tissue regeneration approach is how to efficiently recruit desirable cell types into the damaged tissues. For efficient endogenous stem/progenitor cell mobilizing and recruiting into the site of the injury, chemo-attractants such as granulocyte-colony stimulating factor (G-CSF) and stromal cell–derived factor-1 (SDF-1) have been utilized [19,21,26]. Another issue is developing a scaffolding system to provide microenvironments that the recruited stem/progenitor cells can attach to, differentiate into tissue-specific cell types, and form new tissues. Natural ECM and synthetic polymers have been used as a scaffolding system to promote in situ kidney regeneration as described in "Tissue-engineered cellular three-dimensional renal constructs" section, and stem cell mobilizing or recruiting factors and/or other bioactive molecules capable of promoting cellular functions (Table 45.4) can be incorporated within the scaffolding system. In this section, we will review two representative stem cell mobilizing or recruiting factors, G-CSF and SDF-1 for in situ kidney regeneration.

Granulocyte-colony stimulating factor

In early studies, G-CSF was used clinically to treat neutropenia induced by chemotherapy in cancer patients due to its primary role in stimulating the production of granulocytes [180]. Recent findings on G-CSF's effects on stem cell mobilization [e.g., hematopoietic stem cells (HSCs), MSCs] from BM to peripheral blood have opened a new area of research to regenerate damaged organs [181,182]. Numerous clinical studies of G-CSF for organ regeneration have been reported in patients with myocardial infarction [183], ischemic cardiomyopathy [184], myelopathy [185], acute spinal cord injury [186], and muscular dystrophy [187]. With these promising results, several preclinical studies have been conducted using the administration of exogenous G-CSF to regenerate damaged kidneys [135–137,188–190].

For instance, Iwasaki et al. reported that the administration of exogenous G-CSF into AKI-induced mice successfully mobilized BM-derived cells into the peripheral circulation [136]. These BM-derived cells migrated into damaged renal tubules, resulting in increased survival rates and inhibited deterioration of renal functions—promoting reduced serum creatinine and blood urea nitrogen levels.

TABLE 45.4 Bioactive molecules for in situ kidney regeneration.

Bioactive molecules	Major role in kidney regeneration	Refs.
G-CSF	BM-derived stem cells' mobilization, alteration of inflammatory kinetics, antiapoptotic effects of renal tubular epithelial cells, inhibited deterioration of renal function	[135–138]
SDF-1	BM-derived stem cells' recruitment, protection of renal function, antiapoptosis of renal tubular epithelial cells	[24,139–142]
HGF	Antiapoptotic, mitogenic, motogenic, and morphogenic effects on renal tubular cells and angiogenic and angioprotective effects on endothelial cells, antifibrosis	[143–145]
IGF-I	Enhancement of glomerular filtration, renotropic property on renal tubules, improvement of renal function	[146,147]
EGF	Mitogenic effects of renal tubules, improvement of renal function	[148–150]
VEGF	Antiapoptosis and proliferation of endothelial cells, preservation of renal hemodynamics and function, antifibrosis	[151–153]
TGF-β	(Detrimental) Renal fibrosis	[154,155]
BMP-7	Potent inhibitor of TGF-β1 induced epithelial-to-mesenchymal transition of proximal tubular epithelial cells, differentiation and survival factor for podocytes, antifibrosis, diminishing the activation of tubulointerstitial inflammation and fibrosis, preserving renal function	[156–159]
IL-22	Proregeneratory effect on tubular epithelial cells, ameliorates renal ischemia reperfusion injury	[160,161]
Erythropoietin	Antiapoptosis, renoprotective effects, antiinflammation, antifibrosis	[162,163]
Melatonin	Antioxidant and antiapoptotic effects	[164,165]
Galectin-3	Enhancement of nephrogenesis, (detrimental) interstitial fibrosis and progression	[166,167]
Vitamin E	Antioxidant effect	[168]
Activin A	(Detrimental) Inhibition of branching tubulogenesis, profibrotic factor	[169,170]
Follistatin	An antagonist for activin A, antiapoptosis and proliferation of renal tubular cells	[170]
PDGF	(Detrimental) Potent mitogen for mesangial cells, progression of glomerular nephritis, fibrosis	[171,172]
Angiotensin II	(Detrimental) Renal tubular cells apoptosis	[173]
Rapamycin	Reduced inflammation	[174–176]
Anti-HE4 antibody	Antifibrosis	[177]
HDAC inhibitor	Antifibrosis	[178,179]

BM, Bone marrow; *BMP*, bone morphogenetic protein; *EGF*, epidermal growth factor; *G-CSF*, granulocyte-colony stimulating factor; *HDAC*, histone deacetylase; *HE4*, antihuman epididymis protein 4; *HGF*, hepatocyte growth factor; *IGF*, insulin-like growth factor; *PDGF*, platelet-derived growth factor; *SDF*, stromal cell–derived factor; *TGF*, transforming growth factor; *VEGF*, vascular endothelial growth factor.

Fang et al. also reported similar results using G-CSF of boosted migration of BM-derived cell into the ischemic kidneys that could proliferate and differentiate into renal tubular epithelial cells [137]. In another study the antiapoptotic effect of G-CSF to renal tubular epithelial cells was also demonstrated [135].

Despite the favorable results of G-CSF on treatment of renal injuries, the therapeutic effects are still controversial. Tögel et al. and Stokman et al. reported the detrimental role of granulocytes that comigrated into ischemic kidney [139,188]. Indeed, G-CSF stimulates the BM and activates the mobilization of not only BM-derived cells but also neutrophils and macrophages [138]. Alteration of inflammatory kinetics with the use of G-CSF may result in further injury both in experimental animal models and in human patients [188,191]. Therefore careful administration of G-CSF in a controlled manner is necessary for its application to treat renal injuries.

Stromal cell–derived factor-1

Another attractive chemokine that regulates cell migration is SDF-1. It is well known that the retention and mobilization of stem/progenitor cells is controlled by SDF-1/C-X-C chemokine receptor 4 (CXCR4) axis [192]. CXCR4 is one of the major receptors that regulate trafficking of BM-derived stem cells such as MSCs, HSCs, and endothelial progenitor cells (EPCs). Under normal conditions the SDF-1 concentration in BM remains higher than that in the periphery. Stem/progenitor cells reside in BM. However, when tissues get injured, hypoxia-induced factor 1–induced SDF-1 expression increases in damaged tissues. The reversed SDF-1/CXCR4 axis allows stem/progenitor cells to mobilize from the BM to the peripheral blood and then be recruited to the site of injury [193]. Therefore it is possible that local administration of exogenous SDF-1 within injured tissue can generate a higher concentration gradient than that in the natural healing process, thereby recruiting more stem/progenitor cells to the injured sites than in the normal regeneration process, accelerating the regeneration process [22].

Recent reports have demonstrated the feasibility of local delivery of SDF-1 using an engineered scaffolding system for tissue regeneration. Ko et al. developed a SDF-1-loaded poly(L-lactide)/gelatin scaffolding system for local release of SDF-1 in a controlled manner [24]. Subcutaneously implanted scaffolds efficiently recruited host stem/progenitor cells into the implants and the recruited stem cells were capable of multilineage differentiation. The results implicated that local delivery and implantation of SDF-1-loaded scaffolds can be applied for tissue regeneration by mobilizing and recruiting host endogenous stem/progenitor cells into injured sites.

Using similar methods, the therapeutic potential of the controlled delivery of SDF-1 in an ischemia/reperfusion injury of skeletal muscle was demonstrated [194]. SDF-1-conjugated polyethylene glycol-fibrin scaffolds implanted into damaged muscles enhanced cell recruitment and revascularization of regenerating muscle. In another study, implantation of SDF-1-conjugated scaffolds into muscles also efficiently promoted tissue-specific host cell recruitment [23]. Recently, Sun et al. developed a collagen-binding SDF-1 system for sustained and local release of SDF-1 [195]. Implantation of collagen-binding SDF-1 scaffolds successfully recruited endogenous stem cells to the ischemic hearts and improved cardiac function. Koudy Williams et al. reported interesting results that the local delivery of the SDF-1 showed comparable regeneration capability to cell therapy for treating urinary incontinence [196]. In addition, ADM3100, a CXCR4 antagonist, has been widely investigated in preclinical and clinical studies [197,198]. Several clinical studies have demonstrated that the AMD3100 is an effective agent for HSC mobilization, and AMD3100 in combination with G-CSF mobilized higher numbers of HSCs than G-CSF alone [197]. Preclinical studies have showed that the AMD3100 mobilized EPCs and increased the number of circulating angiogenic cells. Those mobilized EPCs were able to home to the sites of vascular injury and enhanced angiogenesis [199,200]. Therefore it is expected that SDF-1-based in situ tissue regeneration strategies can be alternatives to current cell-based therapy models.

These studies suggest that an SDF-1-based approach may play a protective and regenerative role in regenerating damaged kidneys. There is evidence that the SDF-1/CXCR4 axis is one of the key mediators in the migration and homing of stem/progenitor cells for renal regeneration. Previous studies demonstrated that increased SDF-1 or AMD3100 concentration and CXCR4 expression in cells in an ischemia–reperfusion-induced kidney injury model provided pathological and functional protection and prevented renal tubular epithelial cell apoptosis [139–141]. AMD3100 treatments mobilized HSCs and EPCs and reduced levels of blood urea nitrogen and serum creatinine in following kidney ischemia/reperfusion injury in a rat, implying the therapeutic potential for protection after renal failure [142].

Our group has also investigated the renoprotective and regenerative effects of SDF-1 in a rat acute renal failure model. We previously demonstrated that the intrarenal injection of collagen hydrogel can efficiently recruit host renal stem/progenitor cells and MSCs to facilitate the regeneration of glomeruli and tubules and promote functional recovery in ischemia/reperfusion injury–induced kidneys [25]. With this encouraging result, we developed a controlled local SDF-1 delivery system in collagen hydrogel. The implantation of this collagen-based SDF-1 delivery system into kidneys could achieve successful recruitment of renal progenitor cells and MSCs, and restoration of renal function, showing the potential use of this system for future treatment.

Conclusion and future perspectives

Recent progress in tissue engineering and regenerative medicine has demonstrated great potential for regenerating and restoring normal kidney functions in preclinical renal failure models as well as in a number of clinical trials using autologous cells. Recent tissue engineering approaches of cell therapy, engineered 3D renal tissue constructs, decellularization/recellularization strategy, and in situ renal regeneration have achieved successful outcomes in terms of structural and functional improvements following renal damage. However, several challenges still need to be addressed. Development of reliable cell sources, defined culture methods, and expansion techniques is prerequisite.

Advanced 3D renal construct fabrication strategies is needed to mimic structural and functional complexity of the native kidney. There are still uncertain complicated mechanisms of the renal regeneration process. More sophisticated approaches for engineering renal construct implantations are required to address immunological issues, vascularization, innervation, and renal physiology. The only definitive treatment option for renal failure in AKI, CKD, and ESRD is kidney transplantation. However, the shortage of donor kidneys and complications of immune rejections leading to transplant failure present remaining challenges. Whole kidney engineering using the decellularization/recellularization strategy can be an attractive alternative even though long-term patency of the implants has not been demonstrated in vivo. Even though the kidney tissue engineering faces many challenges to be addressed for clinical translation, multidisciplinary research and close collaboration will be able to accelerate generating functional and transplantable kidney for the treatment of kidney diseases.

Chapter 46

Tissue engineering: bladder and urethra

Yuanyuan Zhang, James J. Yoo and Anthony Atala
Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

Introduction

The entire urinary tract is divided into two parts: the upper (kidney and ureter) and lower urinary tract (bladder and urethra). The function of the urinary system is to remove waste products accumulated from the body, regulate water, and salt balance, and to store and transport urine out of the body. Histologically, the urinary tract consists of urothelium lined lumen surrounded by a collagen-rich connective tissue and smooth muscle layers. In the lower urinary tract, the main source of force that allows for the release of urine is the detrusor muscle, which is a layer of the urinary bladder wall consisting of smooth muscle fibers that are arranged in a spiral, longitudinal, and circular bundles. The smooth muscle tissues can be extended to allow for the storage of urine and contracted to empty the bladder. The urothelium serves as a passive barrier to prevent the absorption of urine and does not generate mucus. This internal lining of the bladder and part of urethral lumen, composed of urothelial tissue and lamina propria, is believed to regulate some aspects of overall bladder physiology in response to stimuli, such as distension during filling [1].

The urinary bladder is one of the most elastic organs in the body and can increase its volume significantly to accommodate up to 800 mL of urine at maximum capacity in adults. Transitional epithelium, elastic fibers, and visceral muscle tissue in the wall of the urinary bladder contribute to its distensibility and elasticity, allowing it to easily extend and return to its original size several times each day. The bladder is connected with the male urethra, which is a narrow fibromuscular tube that passes urine and semen from the bladder and ejaculatory ducts, respectively, to the exterior of the body.

Congenital disorders, cancer, trauma, inflammation, or other conditions of the bladder and urethra can damage the anatomical tissue structure or cause complete loss of function. Both situations usually necessitate eventual reconstruction or replacement of the damaged tissue. Although patients suffering from diseased or injured organs can be treated with transplanted organs, there is a severe shortage of donor organs, which is worsening yearly as the population ages and new cases of organ failure increase. Lower urinary tract reconstruction has been performed with autogenic nonurologic tissues such as gastrointestinal segments, mucosa from multiple body sites, homologous tissues from a donor (cadaver or living donor kidney), or heterologous tissues or substances (e.g., bovine collagen) [2]. All these materials often cause a series of complications after surgery due to the implanted tissue rejection or because of the inherently different functional parameters that cause a mismatch in the system. For example, the replacement of bladder tissue with gastrointestinal segments can be problematic because the normal urothelium excretes proteins [3], whereas gastrointestinal tissue generally absorbs them. This mismatched state can lead to severe metabolic complications in addition to infection and other issues [4]. Therefore replacement of lost or deficient urologic tissues with functionally equivalent ones would certainly improve the outcome of reconstructive surgery in the genitourinary system. This goal may soon be achievable with the use of tissue engineering techniques.

Tissue regeneration uses the principles of cell biology, biomaterials science, bioactive factors, and biomedical engineering to develop biologic substitutes that can restore and maintain the normal function of damaged or lost tissues and organs. Tissue engineering involves the use of natural or synthetic matrices, often termed scaffolds, which encourage the body's natural ability to repair itself and assist in determining the orientation and direction of new tissue growth. Often, tissue engineering uses a combination of these techniques. For example, matrices seeded with cells can be implanted into the body to encourage the growth or regeneration of functional tissue.

In the last two decades, scientists have attempted to cultivate native and stem cells, engineer tissues and

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00048-4

develop treatment modalities using regenerative medicine techniques for the urinary tract system. This article reviews the progress of the bladder reconstruction efforts with tissue engineering technology.

Cell sources

Bladder and ureter cells

Although implanted tissue can be heterologous, allogeneic, or autologous in experimental animal models, only the autologous cells are considered as a viable source for clinical use currently [5] to avoid graft rejection and long-term use of immunosuppressive medications after allogeneic transplantation. Autologous somatic cells obtained from the bladder or ureters [6] are often used for tissue-engineered bladders. The donor tissue is dissociated into individual urothelial cell (UC) and smooth muscle cell (SMC), which are expanded in culture, attached to a support matrix, and then implanted back into the host. Ideally, this approach allows for the augmentation of the bladder tissue function [7–10]. However, suitable bladder cells from the patient for this purpose are sometimes limited or unobtainable because of the disease conditions, such as malignancy.

Stem cell sources

Adult stem cells could be a suitable alternative to the bladder cells. They are an appealing cell source for tissue regeneration due, in part, to their self-renewal, long-term expansion in vitro, and differentiation potential. Three types of cell sources have been used for bladder regeneration in experiment models that are autologous cells: UCs and SMCs, urothelial progenitor cells [11,12], bone marrow stromal cells (BMSCs) [13,14], adipose stem cells [15,16], urine-derived stem cells (USCs) [17–20], and hair follicle stem cells [21,22]; allogeneic cells: UC + SMC [23] and mesenchymal stem cells (MSCs); and xenogenous cells: amniotic fluid–derived cells [24], dental pulp stem cells [25], hBMSCs + HSPCs (hematopoietic stem/progenitor cell) [14], and genetically modified hBMSCs [26]. Different types of stem cells used for bladder reconstruction are listed in Table 46.1.

Adult stem cells avoid some ethical issues associated with embryonic stem cells (ESCs) or induced pluripotent stem cells (iPSCs). They do not transdifferentiate into a malignant phenotype; thus there is a diminished risk for teratoma formation or immunogenicity after the cells are implanted in vivo. In addition, these cells possess paracrine effects, immunomodulatory properties, are immune privileged (i.e., tolerate the introduction of antigens without eliciting an inflammatory immune response), and have a low immunogenic potential [28]. Adult stem cells, especially MSC and hematopoietic stem cell, are well-investigated cell types in stem cell biology [29]. Adult stem cell research remains an area of intense study, as their potential for therapy may be applicable to various degenerative disorders. Many other types of adult stem cells have been identified in organs throughout the body and are thought to serve as the primary repair entities for their corresponding organs. The discovery of such tissue-specific progenitors has opened up new avenues for research. Within the past decade, adult stem cell populations have been found in many adult tissues other than the bone marrow, skin [30], and adipose tissue [31], including those traditionally considered a postmitotic organ, such as brain [32], heart [33,34], and urine [35].

ESCs or iPSCs exhibit two remarkable properties: the ability to proliferate in an undifferentiated but still pluripotent state (self-renewal) and the ability to differentiate into different specialized cell types [36]. These cells have been maintained in the undifferentiated state for at least 80 passages and 200 population doublings (PDs) in vitro when grown using currently published protocols [37,38]. In addition, human ESCs differentiate into cells from all three embryonic germ layers in vitro. However, these cells are not currently used for many clinical applications because of the risks for immunogenicity and teratoma formation, in addition to the ethical dilemmas associated with the manipulation of embryos in culture.

Although the entire urinary tract system is responsible for excreting ions, metabolic products, and toxic wastes from the body, it is a closed system with a germ-free environment—unlike the digestive system, which is open and does not have sterile conditions. There are some living cells in urine that can survive for a few hours within the sterile urinary system. Stem cells exist in human voided urine and urine drained from the upper urinary tract. These cells, termed USCs [35], possess stem cell characteristics with clonogenicity, cell growth pattern, robust proliferative potential, and multipotential differentiation. These cells can be obtained using simple, safe, noninvasive, and low-cost procedures, thus avoiding the adverse events associated with obtaining cells from tissue sources. A single USC can expand to a large population with 60–70 PDs [39,40]. When seeded onto a scaffold and subcutaneously implanted into nude mice, multilayered tissue-like structures are formed consisting of urothelium and smooth muscle. In addition, USCs differentiated into endothelial, osteogenic, chondrogenic, adipogenic, skeletal myogenic, and neurogenic lineages. However, implantation of these cells in vivo, observed for up to 3 months, did not form teratomas despite the telomerase activity (TA). USCs have been used in cell-based therapies and urogenital tissue engineering applications, including urethral tissue repair [40,41], bladder reconstruction [42], kidney and urethral sphincter [43,44], vesicoureteral reflux [43], and erectile dysfunction [45,46].

TABLE 46.1 Stem cell properties for bladder regeneration.

	MSCs	Primitive stem cells	USCs	ESCs/iPSCs	Somatic cells
Cell types	• BMSCs [13,14] and ASCs [15,16] • Urothelial progenitor cells [11,12] • Hair follicle stem cells [21,22] • Dental pulp stem cells [25] and hBMSCs + HSPCs [14] • Genetically modified hBMSCs [26]	AFCs [24,27] or placenta-derived stem cells	USCs [17–20]		UC + SMC [23]
Self-renewal and expand capability	Limited, PD ~ 30	High, PD	High, PD 60–70	Very high, PD > 200	Limited, PD < 30
Multilineage differentiation capability	Multipotent, but mainly limited within mesodermal cell lineages	Yes	Multipotent differentiation potential	Pluripotent (can form all lineages)	Non
Urothelial, endothelial, or myogenic differentiation capability	Very low	High	High	Low	Non
TA/telomere length	Cannot be detected	Yes	Up to 75% USC clones possess TA and relative long telomere	Possess TA and long telomere	Non
Harvest approach	Invasive, relatively hard to harvest bone marrow stromal cells at the senior	Aspirate from amniotic fluid	Noninvasive, simple, cost-low, safe	Invasive for iPSCs	Invasive
Pure stem cell isolation	Hard isolate pure stem cell	Easy	Very easy	Easy	Non
Number of stem cells harvested	1 MSC/10^4 bone marrow stromal cells at new bore baby, 1 MSC/10^6		100–140 USC clones/24 h urine in adult		Non
Rejection after implanted in vivo	Autogenous or allogeneic	Allogeneic	No rejection	Likely to be rejected if donor is unmatched	No rejection if autogenous cells are used
Oncogenic potential	No reported	No reported	No reported	Yes, harbors disease-causing genes of donor	No reported

AFCs, Amniotic fluid–derived cells; *ASCs*, adipose stem cells; *ESCs*, embryonic stem cells; *iPSCs*, induced pluripotent stem cells; *MSCs*, mesenchymal stem cells; *PD*, population doubling; *SMC*, smooth muscle cell; *TA*, telomerase activity; *USCs*, urine-derived stem cells; *UCs*, urothelial cells.

In chronic bladder diseases, USCs might be a suitable cell source for bladder tissue regeneration because cells from the upper urinary tract are normal. In the treatment of end-stage bladder diseases or muscle-invasive bladder cancer, using engineered bladder tissue with USCs would be superior to bladder reconstruction using intestinal segments. Intestinal segments used for bladder reconstruction appear to be at an increased risk for malignancy, particularly adenocarcinoma, because of histologic changes in the intestinal mucosa after long-term exposure to urine. Recent studies showed that all children with neurogenic

bladder disease are at increased risk of bladder cancer regardless of exposure to intestine [47]. Bowel tissue also increases the risk of complications such as stone formation and excess mucous secretion [48]. Harvesting USCs from patients who already have a nephrostomy tube in place would be a simple, noninvasive, and low-cost approach to obtaining cells for engineering bladder tissue.

Other sources of stem cells include the amniotic fluid and placenta. These contain multiple partially differentiated cell types derived from the developing fetus [27,49]. Stem cell populations have been isolated from these sources and express ESC and adult stem cell markers, but they do not form teratomas. The cells are multipotent and can differentiate into cells from all three germ layers. In addition, such cells have high replicative potential and could be stored for future self-use, without the risks for rejection and ethical concerns.

Mechanism of cell therapy

Cell expansion

Fetal stem cells, such as amniotic fluid and primitive stem cells (such as placenta-derived stem cells), showed promise for future clinical applications [27,49]. These cells can give rise to cells from the endoderm, mesoderm, and ectoderm and can be maintained for over 250 PD. Long telomeres are retained and a normal karyotype without tumorigenicity is observed in vivo [50]. Adult stem cells have been successfully isolated from various types of tissues. These cells usually reach a PD rate of 20−40 in 10 passages [19].

USCs can generate large numbers of cells in a single clone [20,40]. Around 100−140 USC clones can be formed from 24-hour urine collection from one individual [51]. Up to 75% of these cells are highly proliferative due to their relatively higher TA (USC-TA$^+$) and longer telomeres compared to bone marrow stem cells (BMSCs) [20]. USCs are reported to have a PD rate of 60−70 for up to 20 passages, whereas other USCs without TA can be maintained for 8−10 passages with 34 PDs. Based on this ratio of cells and urine volume, two urine samples containing 20−30 USC clones could potentially yield at least 1.5×10^9 USCs at the end of passage 4 within 4−5 weeks [5,39].

Isolation of USCs is a separation- and digestion-free procedure. Urine samples are simply centrifuged, and cells are seeded in a mixed media composed of keratinocyte serum-free medium and embryonic fibroblast medium in a 1:1 ratio [35]. Expanded USCs are a relatively homogenous population and only require 2%−5% serum to be maintained in vitro; by contrast, most MSCs require 10%−20% serum [20]. When cells collected from voided urine are cultured in USC culture media, only USCs tend to attach to the culture container and continuously expand in culture [20]. This quick, easy, and economical process for USC isolation may also facilitate their large-scale expansion for potential clinical trials.

Multipotentiality

During tissue repair, stem cells accelerate tissue repair and regeneration in various ways (Table 46.2). Although ESCs and iPSCs are pluripotent and can differentiate into multiple specialized cell types [36], their differentiation capability into urologic-specific cell types is relatively low [19]. Under appropriate conditions, BMSCs can be successfully induced into cells with bladder SMC characteristics, both in vitro and in multiple animal models [57−59]. Induced BMSCs proliferate at a similar rate as bladder SMCs and possess a similar histologic appearance and contractile phenotype. However, only 5%−10% of cells in BMSCs can be induced into urothelial-like cells

TABLE 46.2 Multiple modes of action assigned to adult stem cells.

Multiple functions of stem cells	Outcomes and potential applications	References
Multipotent differentiation	Osteocytes, chondrocytes, adipocytes, myocytes, epithelial, and endothelial cells for cell replacement	[20,39]
Secretion of trophic factors	Recruitment resident cells to tissue repair	Liu et al. [52]
Secretion of extracellular matrix	Prompt cell proliferation, rejuvenation, and differentiation of bone marrow-derived stem cells	[53]
Immunomodulatory and antiinflammatory	Inhibited T- and B-cell proliferation to decrease fibrosis	[54]
Gene delivery via angiogenic growth factor gene transfection	Soluble factor gene therapy to accelerate tissue regeneration at the site of chronic injury with extensive scarring	[45,55,56]

with specific lineage marker expression [60–65]. One reason for this could be their relative scarcity; only an estimated 1 in 1 to 1.5×10^4 cells in the bone marrow is BMSC [66].

Although the effects of aging on MSCs remain controversial, some studies show an age-related decline in stromal vascular fraction number, proliferation rate, longevity, differentiation potential, and MSC immunophenotype expression in BMSCs from older compared to younger donors [67–71]. This question becomes of great importance, given that the aging population is increasing, and thus the prevalence of urologic diseases also is increasing. Considering the large quantity of MSCs (up to 10^9) required for clinical applications, especially for bladder reconstruction, it is critical to find a stable cell source with potent MSCs [5].

Importantly, unlike many other cell lineages, USCs can efficiently differentiate into urologic tissue-specific cell lineages, including UCs, SMCs, and Endothelial cells (ECs). They have higher differentiation frequency in UCs than BMSCs. Under the same induction conditions for 7 days, up to 60%–70% USCs are induced into a uroepithelial lineage, compared to only 5% for BMSCs [20,58]. If induction extended to 14 days, up to 90% of USCs are differentiated. Cells develop a cobblestone-like morphology and express both urothelial-specific cell markers (uroplakin-III and uroplakin-Ia) and generic epithelial cell markers (CK7 and AE1/AE3). Differentiated USCs also present tight junction markers (ZO-1, E-cadherin, and cingulin) in a dose-dependent and time-dependent manner [20]. Those cells display enhanced barrier function with at least a 60% decrease in leakage than noninduced cells [20].

USCs-derived UCs were seeded on a porcine small intestinal submucosal scaffold and cultured in vitro for 14 days before implantation into nude mice. Constructs generated stratified layers in vivo, and neo-tissue expressed urothelial-specific cell markers (uroplakin-III and uroplakin-Ia). USCs have comparable differentiation potency into SMCs as BMSCs [60]. Up to 80% of induced USCs express early smooth muscle differentiation markers (α-smooth muscle actin and calponin), contractile SMC markers (desmin and myosin), and smooth muscle-specific marker (smoothelin) after 14 days induction with smooth muscle differentiation media in vitro [20]. Cells exhibit rapid lattice contraction as mature SMCs. When implanted in vivo on a porcine small intestine submucosal scaffold, those cells formed multiple layers of SMCs beneath the UC layers and presented SMC markers (desmin, myosin, α-smooth muscle actin). USCs are also capable of endothelial differentiation with a barrier function. EC-induced USCs display vessel-like structures on a solidified Matrigel surface after in vitro induction. Those cells express EC-specific genes (vWF and CD31), proteins (CD31, vWF, KDR, FLT1, and eNOS), and tight endothelial junction marker (VE-cadherin). When implanted subcutaneously into athymic mice, EC-induced USCs effectively form neo-vessel structures [72].

Paracrine effects and immunomodulatory properties

Stem cells have two important roles in tissue regeneration. First, they can replace diseased cells by engrafting, cell fusion, and differentiating into the required host cell type (e.g., bone marrow transplant and cell therapy for myocardial ischemia). Second, grafted cells stimulate the host's cells to repair the injured tissue, without the donor cells contributing directly to form the new tissue. This occurs because the grafted cells secrete factors that signal the host's cells to change their biological behavior and the microenvironment. The signaling from one cell to another is referred to as paracrine effect.

Adult stem cells can invoke a paracrine response [73]. The implanted stem cells secrete factors that promote angiogenesis and protect against apoptosis, fibrosis, and inflammation [13,74,75], which prompt the host's cells to repair the tissue themselves. Humans and most mammals have a wound repair mechanism that, on its own, can only be able to repair small wounds, but not for large wounds. Large wound is often remodeled by scar tissue. However, human tissue still possesses regenerative potential once it receives the appropriate signals to initiate internal tissue regeneration and repair provided by paracrine effects of the grafted stem cells.

Although stem cells are known to have a short life span (1–3 weeks) after implantation, they have long-term effects on tissue repair. For example, they appear essential for initiating tissue regeneration but are expendable once the patient's cells are activated. Paracrine effects are amplified once the grafted cells are attracted to injured tissues. Cells within the damaged tissues often secrete cytokines, regulatory factors that act as mediators to generate an immune response that attracts grafted cells. Sequentially, the grafted cells secrete their own cocktail of proteins that stimulate the host's stem cells and inhibit inflammation and oxidative stress, protect against fibrosis, promote resident cell proliferation, and increase vascularization and blood flow into the injured areas.

In addition, the paracrine effects of adult stem cells can reduce immune response and possess immunoregulatory properties. For example, regulatory T cells play an important role in the induction of peripheral tolerance, inhibition of proinflammatory immune responses, and decreased immune reactions. To test the immunomodulatory effects of USCs, our studies demonstrated that USCs can inhibit proliferation of peripheral blood mononuclear cells (PBMNCs) (T and B cells), and secreting interleukin

(IL)-6 and IL-8 [76]. In the specific experiment the mononuclear cells usually proliferate when mixed with other somatic cells due to immune stimulation. In contrast, PBMNC concentrations in USC wells are much lower than in somatic cells, even BMSC culture wells [76]. Colorimetric enzyme-linked immunosorbent assay (ELISA) showed less BrdU labeled in the USC−PBMNC mixed culture wells and more in BMSC culture wells. As costimulatory molecules, CD80 and CD86 initiate and modulate the T-cell immune response. Both CD80 and CD86 expressed on the surface of antigen-presenting cells interact with cytotoxic T-lymphocyte antigen-4 expressed on activated T cells and mediate critical T-cell inhibitory signals. About 3% of the BMSCs were positive for CD80 (vs 1.05% of USCs), and 1.3% of the BMSCs were positive for CD86 (vs 0.55% of USCs). Human cytokine release arrays showed that IL-6 and IL-8 concentrations were elevated after stimulation by PBMNCs in USC supernatant, higher than BMSC supernatant. Thus it indicates that IL-6 and IL-8 might be the main immunomodulatory cytokines to target in future studies aimed at preventing and treating bladder abnormalities that accompany diabetes, other immune system disorders, or rejection of transplanted organs.

Biodegradable biomaterials

A biological scaffold tailored to stem cells is central to mimic the function of the extracellular matrix (ECM) in tissue engineering. The ECM provides structural support and a physical environment so that cells can attach, proliferate, migrate, differentiate, and function [77]. It confers mechanical properties to tissues and delivers bioactive cues for regulating activities of residing cells and provides a dynamic environment for vascularization and new tissue formation. Scaffolds can be designed to stimulate and direct tissue formation to replace portions of tissues or whole tissue structures. The material would possess appropriate porosity and interconnectivity between the pores to facilitate cell attachment, migration, penetration, differentiation, tissue growth, and integration. The ideal type of cell replacement should be composed of materials with similar physical and mechanical properties as the native tissue and should degrade at the same rate as the new tissue is generated. Porosity should allow nutrient transfer and cell adhesion without compromising mechanical strength. Two categories of scaffolds designed to carry cells include synthetic scaffolds and natural collagen matrix for the bladder regeneration (Table 46.3).

Synthetic scaffolds

Various porous structures composed of natural or synthetic biodegradable and biocompatible materials have been used as scaffold carriers. Some biomaterials have been approved by the US Food and Drug Administration (FDA) for the use in medical devices in humans. These include polyesters of naturally occurring a-hydroxy acids such as polyglycolic acid (PGA), polylactic acid, poly (lactic-*co*-glycolic acid), and polycaprolactone. Metabolites formed after degradation of these materials have been confirmed as nontoxic and are eventually eliminated from the body as carbon dioxide and water [91]. Because these polymers are thermoplastic, they can easily be fabricated into a three-dimensional (3D) scaffold with the desired microstructure, gross shape, and dimensions by various techniques, including molding, extrusion [92], solvent casting [93], phase separation, and gas foaming techniques [94]. In addition, synthetic polymers can be manufactured on a large scale using various techniques, including electrospinning [95], phase separation, gas foaming, particulate leaching, inkjet printing, and chemical cross-linking. The strength, degradation rate, and microstructure may be adjusted during manufacturing. Scaffolds can be made in different shapes and porosity to facilitate cell engraftment, or further modified by incorporation, surface adsorption, or chemical attachment of bioactive factors. However, one drawback of synthetic polymers is the lack of biologic recognition. To incorporate cell recognition domains into these materials, copolymers with amino acids have been synthesized [96]. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(ortho esters), can also be used to fabricate scaffolds with controlled properties [97].

Biodegradable properties

Biodegradable biomaterials in tissues of the urinary tract system function as an artificial ECM to replace the biologic and mechanical functions of native ECM. These biomaterials facilitate localization and delivery of cells or bioactive factors (e.g., cell-adhesion peptides and growth factors) to desired sites in the body and define a 3D space for the formation of new tissues with appropriate structures. They also serve as a guide for the development of new tissues with the appropriate function. Direct injection of cell suspensions without such matrices has been used in some cases [98]. However, without this scaffold function, the localization of transplanted cells is difficult to control.

For cell-based tissue engineering, expanded cells are seeded onto a scaffold synthesized with the appropriate material. Since most mammalian cell types are anchorage dependent and will die if no cell-adhesion substrate is available, biomaterials provide such a substrate capable of delivering cells to specific sites with high loading efficiency. Biomaterials can also provide mechanical support against in vivo forces, maintaining the predefined 3D

TABLE 46.3 Summary of advantages and limitations of biodegradable materials for bladder regeneration.

	Advantages	Limitations
Synthetic scaffolds		
• PGA/PLGA • PLLA • Collagen–fibrin hybrid scaffold with IGF1 [78] • Acellular collagen-heparin scaffolds with growth factors [79] • VEGF-loaded nanoparticle-modified BAMAs [80] • PGA with PGA/chitosan "sandwich" graft [81]	• Renewable, sustainable, and biodegradable • Safe for use, nontoxic, free-immunogenic, free-carcinogenic, and free-thrombogenic • Ease of manufacturability • Reasonable cost • Durable and storage stability • Process ability: fine complex architectures such as porosity rate, pore size can be generated; highly controllable • Consistent products	• Take time to be degraded • Poor biocompatibility • Potential toxic degradation of by-products • Lacks specific integrin-binding site
Biological scaffolds		
SF [23,82,83] or BAMG–SF matrix [83]	• Unlimited source biomaterials • Easy to produce • Most allogenic or xenogeneic antigen contents can be removed after decellularization • Native architecture is preserved • Growth factors and cytokines bound with matrix remain • Integrin-binding sites are retained • Easy to suture to bladder tissue	• Variability depending on the source of biomaterial • Antigenicity • Weak biomechanical properties • Not suitable for subtotal cytoplasty • Take time to produce in the lab
SIS [84–86] and BSM		
BAMG [15,24,87] or UBM [88]		
Decellularized colon matrix [89]		
Matrix with hydrogel (such as HA–PLGA-modified SIS [90])		

BSM, Bladder submucosa matrix; *BAMA–SF*, bladder acellular matrix graft–silk fibroin; *BAMG*, bladder acellular matrix grafts; *HA*, hydroxyapatite; *IGF1*, insulin-like growth factor 1; *PGA/PLGA*, polyglycolic acid/polylactic-*co*-glycolic acid; *PLLA*, poly-L-lactic acid; *SIS*, small intestine submucosa; *UBM*, urinary bladder matrix; *VEGF*, vascular endothelial growth factor.

structure during tissue development. Furthermore, bioactive signals, such as cell-adhesion peptides and growth factors, can be loaded to help regulate cellular function. Generally, two classes of biomaterials are used for engineering of genitourinary tissues: synthetic polymers and tissue-derived matrices. Although synthetic polymers can be produced on a large scale with controlled properties of strength, degradation rate, and microstructure, naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition, which can lessen host-versus-graft reactions.

Limitations of nutrient and gas exchange currently restrict tissue-engineered implants to a volume of approximately 3 mm^3. Therefore vascularization of the regenerating tissue is essential in order to engineer large complex tissues and organs. Three approaches have been used to encourage the vascularization of bioengineered tissue. First, incorporating angiogenic factors into bioengineered tissue can attract host capillaries and enhance neovascularization. Second, some studies have investigated the effects of seeding endothelial cells with other cell types in the bioengineered tissue [75]. Finally, vascularizing the matrix before cell seeding has been attempted. There are many obstacles to overcome before large tissue-engineered solid organs are produced; however, recent developments may provide important knowledge and essential materials to accomplish this goal.

Porosity

Recellularization of biological materials (scaffold) with cell-seeded technology provides a promising option in tissue regeneration. The scaffold needs to have a 3D structure with high porosity but also maintains a normal tensile strength. A 3D scaffold with higher porosity and relatively larger pore size (50–200 μm) promotes cell proliferation, migration, and infiltration into the matrix and appears to allow abundant cell loading onto the scaffold, thereby promoting in vivo tissue regeneration [99–101]. Treatment with 5% peracetic acid solution (PAA) led to high porosity on the surface of the matrix with less cellular material retained, and about 75% of normal tensile strength remained. Cells penetrated deeper into the lamina propria of the matrix compared to untreated matrix [102].

Natural collagen matrix

Naturally occurring matrix materials may also function as 3D scaffolds in tissue engineering and regenerative

medicine, including both decellularized natural matrix and matrix produced from naturally extracted polymers. Natural materials are widely used in tissue regeneration such as bladder submucosa matrix (BSM) and small intestinal submucosa (SIS); and naturally derived materials, such as collagen, alginate, and silk [23,82,103]. As the most abundant structural protein in the body, collagen is an FDA-approved biocompatible material for various medical uses. Natural decellularized ECM retains tissue-specific architecture and provides various biological and physical material properties specified by the nature of the original tissue. Such matrix materials also share highly conserved matrix proteins among species, such as collagen, laminin, and fibronectins, suggesting they could be nonimmunogenic and attractive for recellularization and tissue integration.

Under certain circumstances, UCs and SMCs differentiated from adult stem cells can form multiple uniform layers on porcine decellularized SIS scaffold in vitro and in vivo, showing the potential of this 3D cell/matrix to develop into a multilayer mucosal structure similar to native urinary tract tissue [41]. When seeded with USCs, bacterial cellulose scaffolds represent a promising material for urinary conduits with a multilayered urothelium and cell/matrix infiltration in vitro and in vivo [40]. However, in the context of future clinical applications, the decellularized matrix could be contaminated by xenogeneic factors. There is also a risk of incomplete decellularization and residual cell bodies, and altered tissue properties due to complete decellularization and deproteinization [104,105].

Acellular tissue matrices

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues, often by mechanical and chemical manipulation of a segment of bladder tissue and small intestine [41,106]. Matrices slowly degrade after implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrowing cells. Acellular tissue matrices support cell ingrowth and regeneration of genitourinary tissues, including urethra and bladder, with no evidence of immunogenic rejection [106]. Because protein structures (e.g., collagen and elastin) in acellular matrices are well conserved and normally arranged, the mechanical properties of acellular matrices are not significantly different than those of native bladder submucosa [107].

Collagen

Collagen is the most abundant and ubiquitous structural protein in the body and is readily purified from both animal and human tissues through enzyme treatment and salt/acid extraction. Collagen exhibits minimal inflammatory and antigenic responses and is approved by the FDA for many types of medical applications, including wound dressings and artificial skin [108]. This material can be processed into various structures such as sponges, fibers, and films [109].

Silk

Silk fibroin (SF) is a protein obtained from *Bombyx mori* cocoons and may have potential uses in low urinary tract reconstruction. SF contains up to 90% of the amino acids glycine, alanine, and serine, compared to other natural biomaterials. SF has excellent biocompatibility and low inflammatory properties and can be fully degraded by naturally occurring proteolytic enzymes [110]. SF has used as an effective biomaterial for bones [111], cartilages [112], blood vessels [113], peripheral nerves [114], cornea [115], bladder [116], and urethra [117], among other tissues. Silk processing methods allow construction of films [118], foams [119], hydrogels [120], gel−spun matrices [116], and woven or nonwoven meshes [121]. Electrospinning may also be an appropriate technique for urethral reconstruction with SF, because it can create a 3D and highly porous scaffold in a conformation that mimics ECM structure in vivo [95].

Matrix binding with growth factors

Tissue engineering approaches should mimic the in vivo setting by providing a biocompatible scaffold, a cell source of appropriate progeny or type, nutrients and other environmental conditions, and appropriate bioactive factors. Localized delivery of bioactive factors is considered to be effective and necessary in mimicking the natural microenvironment of cells within specific tissues. Delivering biomolecular cues, especially growth factors in solution, is difficult because of their rapid diffusion to extracellular fluids, and growth factors always have a limited half-life in vivo. However, sustained delivery of growth factors is important for clinical applications of tissue engineering.

Vascular endothelial growth factor (VEGF) is an important active protein for inducing angiogenesis in tissue engineering, but it requires a delivery system targeted to a given site. There are several ways that the matrix could bind with growth factors. Native human VEGF fused with a collagen-binding domain (CBD-VEGF) can bind to collagen specifically to exert angiogenesis effects that promote regeneration. CBD-VEGF was constructed by linking a sequence that encodes the CBD (TKKTLRT) with VEGF complementary DNA. CBD-VEGF was inserted into one plasmid (pET-28a). The plasmid was transformed into the BL21 strain of *Escherichia coli*. CBD-VEGF could be purified from the protein made from *E. coli*. When collagen was used as a scaffold in

TABLE 46.4 **Experimental animal models for the lower urinary tract reconstruction.**

Surgical procedures	Advantages	Challenges
For the bladder		
Hemicystoplasty	• Evaluation of cell-seeded or nonseeded tissue-engineered technology for the bladder augmentation • The neobladder often retain contractile function because of original bladder + regenerated bladder • histologically, fully regenerated urethelium; partial muscle regeneration and innervation	Stone formation, graft shrinkage
Subtotal cystoplasty	• Assessment of cell-seeded tissue engineering technology for the bladder replacement • Acts as the urinary reservoir • Regenerated urothelium • Bladder capacity increases at the early stages	• High risk of graft collapse or shrinkage and bladder stone formation • Limited innervation, myogenesis, and blood supply at center of the graft • Bladder volume may decrease over time
For the urethra		
Full circumferential repair	• Replacing urethra with severe urethra scarring • Commonly used in preclinical studies • Cell-seeded scaffold is required	Successful rate urethroplasty of relatively low due to heavy scar tissue, poor blood supply, chronic information in the wounded urethra tissue
Inlay or onlay repair	• Used for most cases with urethra restructures • Commonly used in clinic for the patients • Cell-free scaffold could achieve good outcome if the urethral segment is <3 cm in human	Potential infection risk in the local urethral tissue
Animal models		
Large animals		
Canine [24,87,90,123]; porcine, i.e. juvenile Yorkshire swine [28,82]; rabbit [23]; sheep [79]; nonhuman primates [13]	• Physiology, anatomy, and histology similar to humans • Autograft models • Easy development of subtotal cystoplasty model • Test both synthetic or thicker nature-based collagen scaffold with cells • Easy to perform urodynamic studies • Enough tissue regenerated to do contractility studies of muscle strips in organ bath	• High cost to purchase and maintain large animals • Not easy to fix a urethral catheter after surgery in pigs and nonhuman primates

(*Continued*)

TABLE 46.4 (Continued)

Surgical procedures	Advantages	Challenges
Small animals		
Athymic rodent [26] and rat [15,78,83,89]	• Easy to maintain • Well-known histology • Allogeneic and xenogeneic-grafted stem cells not rejected by the host • Economical • Commonly used for hemicystoplasty • Dynamically observe bladder regenerative processes at the different time points • Allogeneic or even xenograft models	• Subtotal cystoplasty model not possible • Require thinner scaffold • High risk of stone formation • Requires special fine devices for urodynamic study and images • Cannot observe immune reaction within graft in immunodeficient rodents

tissue engineering that CBD-VEGF can bind to in vitro and in vivo, VEGF could maintain activity [122].

Preclinical models

Tissue regeneration models

Two in vivo experimental models have been frequently used for bladder regeneration, including hemicystoplasty (in which 40%−50% bladder tissue is removed) and subtotal cystoplasty (in which >75% bladder tissue is removed or trigone-sparing cystectomy) (Table 46.4). Cell seeded or cell free−seeded scaffolds are capable of increasing bladder volume in small animals after hemicystectomy, while cell-seeded scaffolds are often designed for the replacement of diseased bladder in a larger animal model after subtotal cystectomy. A rodent model such as rat is often used to test new cell sources or new biomaterials and study histologic changes in the regenerative bladder. Larger animal models are used to evaluate the effectiveness of bladder function and volume, and anatomical and histological structure changes (Table 46.5). Beagles and minipigs have been used widely used as larger animal models for preclinical studies.

For urethra applications, two surgical approaches have been frequently used for urethral reconstruction: full circumferential and inlay procedures (Table 46.4). The full circumferential technique is used in the cases with significant urethral scarring or lichen sclerosis, while the onlay or inlay procedures have been applied for partial replacements. Depending on the patient and local factors, procedures can be performed as a one-stage procedure or as a planned multistage procedure. More challenges exist in the full circumferential repair for urethra reconstruction due to the large size of graft used, limited blood supply, and free-infected wound in the urethra. For urethra reconstruction studies, the most commonly used animal models are medium or large animals such as rabbit [124] and dog [125]. In either the full circumferential or inlay repair, the cells-seeded scaffolds significantly reduced the probability of side effects in the experimental animals, compared to biomaterial alone used [126]. The majority of preclinical studies involve full circumferential repair, where clinicians generally perform inlay repair [127]. The most likely reason is that preclinical investigators endeavoring to demonstrate the efficiency of the experimental therapy for the most challenging in circumferential techniques, supposing that it could also be effective in less difficult in inlay methods [126].

Fibrotic bladder model

Most in vivo experimental models of tissue-engineered bladders are performed in the normal bladder following cystectomy. However, in clinical situations, patients have diseased bladders with fibrosis, chronic inflammation, or lack of good blood supply. Thus a disease model that mimics the target disease conditions is needed to test the efficacy of tissue engineering technology. Several approaches have been used to create a neurogenic bladder dysfunction model [128] or fibrotic bladder model induced by bladder atrophy due to urinary diversion [129], bladder ischemia [130], or chemical agents [131].

To generate a bladder atrophy model, urinary diversion is performed to achieve a rapid decrease in contractile function in adult or fetal animal bladders. In one study, Liu

TABLE 46.5 Criteria for tissue engineering techniques for lower urinary tract regeneration.

Preimplantation	
Cells	• Characterize cell proliferation capacity, phenotypes, paracrine effects of stem cells, urothelially and myogenically differentiated stem cells or cultured urothelial and smooth muscle cells with immunocytochemical staining; label to monitor the fate of grafted cells if needed
Scaffold	• Determine biocompatible, biodegradable and mechanical properties, porosity, pore size, and bioactive proteins within scaffold (for natural collagen-based extracellular matrix biomaterials)
Cell-biomaterial interaction	• Demonstrate interactions for cell adhesion and infiltration into the scaffold using histologic techniques
Postimplantation	
Gross examination	• Graft size and hardness, tissue adhesion around organs • Signs of graft contraction, stoned, or calcification on the bladder lumen side
X-ray examination	The anatomy of low urinary tract can be visualized with the use of X-ray contrast media. A cystogram is used for the bladder and a urethrogram for the urethra. A urethrogram can be done in conjunction with a cystogram or as a separate procedure
Bladder function tests	• Bladder volume, pressure, and contraction style with urodynamic • Contractility of regenerated bladder strips assessed with organ bath
Histologic structure	• Cell survival rate • Distribution and life span of the labeled graft cells • Entirety of urothelial layers and thickness of muscle layers • Ratio of collagen and muscle in regenerated bladder tissue • Angiogenesis or revascularization and innervation

et al. [129] developed a urinary diversion model in the rat. Female Sprague Dawley rats were distributed into age-matched control, sham urinary diversion, and urinary diversion groups. Each group was subsequently evaluated 1 or 8 weeks after urinary diversion or sham operation. The diversion was made by the surgical disconnection of the ureters from the bladder and implantation to the uterine cervix. The results demonstrated that bladder weight decreased in the diversion group. The urinary diversion group had decreased intercontractile intervals and voided volumes compared to the control and sham-operated groups. Compliance was decreased in bladders of rats with urinary diversion. Smooth muscle and urothelium were decreased as a proportion of the total bladder cross-sectional area. Collagen increased in rats with either 1 or 8 weeks of urinary diversion versus controls. Urinary diversion caused decreased expression of muscarinic 3 and ligand-gated purinergic 1 receptor, but no change in muscarinic 2 or ligand-gated purinergic 2 receptors. In summary, urinary diversion causes dysfunctional and abnormal morphometric alterations in the bladder in this model.

In a study by Matsumoto et al. [132], urinary diversion was performed in fetal sheep after 90 days of gestation (term 147 days), and bladder tissue was obtained 2 weeks later. Bladders from fetal sheep subjected to urinary diversion weighed significantly less than control fetal bladders. Marked reorganization of smooth muscle elements was observed in those with diversion. Carbachol stimulated a tonic contraction, while field stimulation administered during the tonic contraction elicited a phasic relaxation or a biphasic response, consisting of an initial relaxation and then a phasic contraction in control and diverted bladders. Contractile responses of defunctionalized strips to carbachol were significantly less than those of control bladder strips. In brief, urinary diversion in normal fetal sheep resulted in marked bladder atrophy, reduced muscle mass, and decreased bladder contractility.

Both indwelling urethral catheterization and suprapubic catheterization are types of urinary diversion. The former is associated with a risk of urolithiasis, urethral trauma, urethral erosions and/or strictures, bladder fibrosis, epididymitis, orchitis, and bladder cancer. Therefore in most clinical cases, indwelling urethral catheters are inappropriate for long-term treatment, and suprapubic catheters are a better option. But recent clinical data [133] showed that long-term indwelling urinary catheterization has similar rates of upper tract damage, vesicoureteral reflux, renal or bladder calculi, and symptomatic urinary tract infections compared to suprapubic catheters. The catheter was changed every 2 weeks, which can prevent the complications of indwelling urethral catheterization. Although a bladder dystrophy model is closer to diseased conditions, it is time-consuming to create such a model. A novel bladder fibrosis model is needed for bladder tissue regeneration studies.

Clinical trials

Clinical translation

Human UC and muscle cell can be expanded in vitro, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells for the lower urinary tract reconstruction. The cell-polymer scaffold can then be implanted in vivo. Histologic analysis indicated that viable cells were able to self-assemble back into their respective tissue types and would retain their native phenotype [134]. These experiments demonstrated, for the first time, that composite layered tissue-engineered structures could be created de novo. Before this study, only nonlayered structures had been created in the field of regenerative medicine.

In order to determine the effects of implanting engineered tissues in continuity with the lower urinary tract, animal models of bladder augmentation were used [135]. Partial cystectomies were performed in dogs. The animals were divided into two experimental groups. One group had their bladder augmented with a nonseeded bladder-derived collagen matrix, and the second group had their bladder augmented with a cell-seeded construct. The bladders augmented with matrices seeded with cells showed a 100% increase in capacity compared with bladders augmented with cell-free matrices, which showed only a 30% increase in capacity.

Most of the free grafts (without cells) used for bladder replacement in the past showed adequate histology, in terms of a well-developed urothelial layer, but they were associated with an abnormal muscular layer with varying tissue development. It has been well established for decades that the bladder is able to regenerate generously as urothelium is associated with a high reparative capacity. Bladder muscle tissue is less likely to regenerate in a normal fashion. Both urothelial and muscle ingrowth are believed to be initiated from the edges of the normal bladder moving toward the region of the free graft [136]. However, contracture or resorption of the graft has been evident in most cases. The inflammatory response toward the matrix may contribute to the resorption of the free graft. It was hypothesized that building 3D structure constructs in vitro, before implantation, would facilitate the eventual terminal differentiation of the cells after implantation in vivo and would minimize the inflammatory response toward the matrix, thus avoiding graft contracture and shrinkage. A dog study demonstrated a major difference between matrices used with autologous cells (tissue-engineered matrices) and those used without cells [135]. Matrices implanted with cells for bladder augmentation retained most of their implanted diameter, as opposed to matrices implanted without cells for bladder augmentation, in which graft contraction and shrinkage occurred. The histomorphology demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in the matrices implanted without cells. Epithelial−mesenchymal signaling is important for the differentiation of bladder smooth muscle [137]. The results of initial studies showed that the creation of artificial bladders might be achieved in vivo; however, it could not be determined whether the functional parameters noted were caused by the augmented segment or by the intact native bladder tissue. To better address the functional parameters of tissue-engineered bladders, an animal model was developed that required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ [138].

The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder capacity (22%-46% of pre-operative values) and compliance (10% and 42% total compliance). Average bladder capacity was increased in the cell seeded tissue engineered bladder replacements (95% of the original pre-cystectomy volume). The compliance of the cell-seeded tissue-engineered bladders showed almost no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal UCs with a thickened submucosal fibrotic and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle. Immunocytochemical analyses confirmed the muscle and urothelial phenotype. S-100 staining indicated the presence of neural structures [138]. These studies, performed with PGA-based scaffolds, have been repeated by other investigators, showing similar results in large numbers of animals long term [139]. The strategy of using biodegradable scaffolds with cells can be pursued without concerns for local or systemic toxicity [140]. However, not all scaffolds perform well if a large portion of the bladder needs replacement. In a study using SIS for subtotal bladder replacement in dogs, both the unseeded and cell-seeded experimental groups showed graft shrinkage and poor results [141]. The type of scaffold used is critical for the success of these technologies. The use of bioreactors, wherein mechanical stimulation is started at the time of organ production, has also been proposed as an important parameter for success [142,143].

To evaluate the effect of cell-seeded tissue engineering technology in the bladder regeneration compared to scaffold alone, a group of experimental dogs underwent a trigone-sparing cystectomy and were randomly assigned to one of three groups. One group underwent closure of the trigone without a reconstructive procedure, another group underwent reconstruction with a nonseeded bladder-shaped biodegradable scaffold, and the last group underwent reconstruction using a bladder-shaped biodegradable scaffold that was seeded with autologous UC and SMC

[138]. The cystectomy-only and nonseeded controls maintained average capacities of 22% and 46% of preoperative values, respectively. Average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements; however, the subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% of total compliance, respectively). The compliance of the cell-seeded tissue-engineered bladders was almost no different from preoperative values (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal UCs with a thickened submucosal fibrotic and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle [138], indicating the benefit of cell-seeded tissue engineering technology in the bladder reconstruction, compared to nonseeded tissue-engineered bladder.

For urethral reconstruction, many surgical procedures, such as autografting to replace damaged areas of the male urethra, may eventually fail. Various strategies have been proposed over the years for the regeneration of urethral tissue in several animal models, including woven meshes of synthetic polymers such as PGA without cells [144,145] and with cells [7], naturally derived collagen-based materials such as decellularized bladder submucosa [106], acellular urethral submucosa [146], and small intestine submucosa [124].

Clinical studies

A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was conducted starting in 1998. A small pilot study of seven patients was reported [5], using a collagen scaffold seeded with cells with or without omental coverage or a combined PGA−collagen scaffold seeded with cells and omental coverage. The patients reconstructed with the engineered bladder tissue created with the PGA−collagen cell-seeded scaffolds showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods over time [5]. It is clear from this experience that the engineered bladders continued their improvement with time, mirroring their continued development. Although this report was promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional

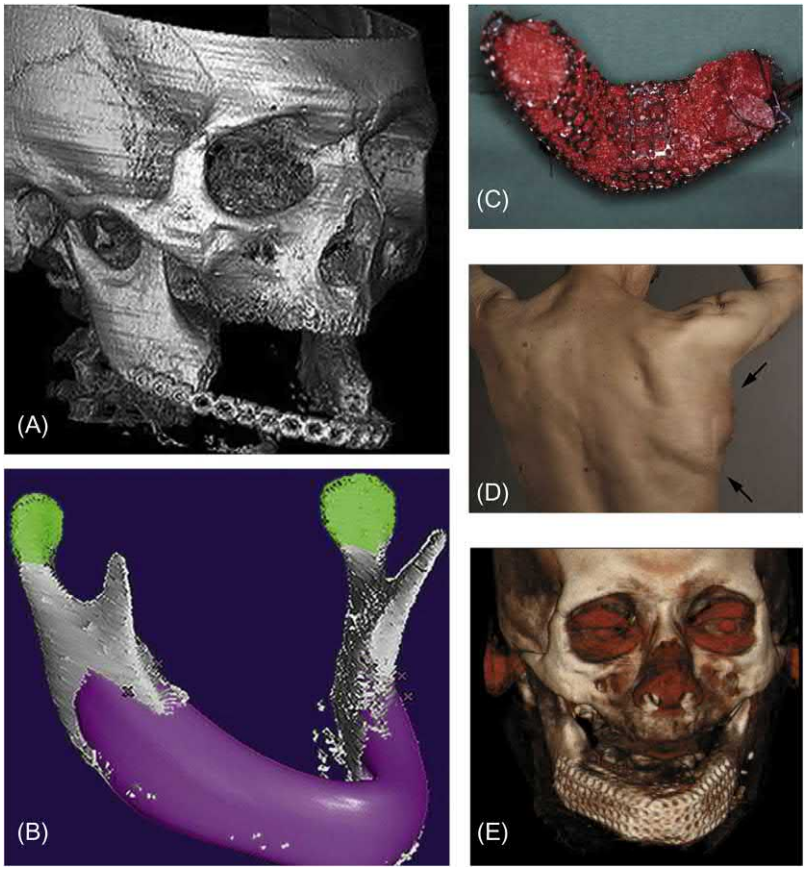

FIGURE 46.1 Image-guided tissue-engineered reconstruction of a massive mandibular defect. (A) The region of interest (jaw) is imaged using 3D CT. (B) The CT data are then fed to CAD software to generate an idealized virtual replacement of the missing parts of the mandible. (C) A titanium mesh is then formed in the shape of the missing bone model and augmented with BioOss hydroxyapatite blocks, OP-1 collagen implant, rhBMP-7, and autologous bone marrow aspirate. (D) The engineered mandibular graft is implanted in a heterotopic muscular pouch in the patient to establish vascularization and initial osteogenesis. (E) The graft was finally implanted orthotopically to reconstruct the mandibular defect. The patient had functional mastication and satisfactory esthetic outcome. *3D*, Three-dimensional; *CAD*, computer-aided design; *CT*, computed tomography. *Reproduced with permission from Warnke et al. (2004).*

bladders. This was a limited clinical experience, and the technology is not yet ready for wide dissemination, because further experimental and clinical studies are required. FDA Phase II studies have now been completed.

The effectiveness of using collagen-based inert matrix was confirmed clinically in a series of four patients with a history of failed hypospadias reconstruction. Twenty-two-month follow-up showed successful repair of urethral defects with human bladder acellular collagen matrix in three out of four patients [147]. In another study of 30 patients with recurrent stricture disease, human demineralized bone matrix obtained from cadaveric donors was processed and prepared for use as an off-the-shelf material [148]. Up to 36-month follow-up showed that a healthy urethra bed (two or fewer prior urethral surgeries) was needed for successful urethral reconstruction using the acellular collagen-based grafts. In an advanced study, with more than 10-year follow-up [149], a human clinical trial with a collagen-coated PGA tubularized scaffold seeded with autologous cells was conducted in a pilot series of five patients. The scaffolds were seeded with autologous cells derived from bladder biopsies taken from each patient. The cell-seeded scaffolds were then matured in an incubator and used to repair the urethral defects present due to trauma. Long-term follow-up evaluation showed normal range urinary flow rates, and voiding cystourethrograms indicated that these patients maintained wide urethral calibers. Yearly biopsies showed that the grafts had a histological architecture consistent with normal urethral tissue (Fig. 46.1).

Conclusion

We reviewed experimental and clinical data related to bladder and urethra regeneration, highlighting the use of different stem cell types and various biomaterials. Recent progress suggests that engineered urologic tissues may have wide use for clinical applicability. Assessments of the histologic structure and physiologic function of the lower urinary tract can help better elucidate mechanisms responsible for functional tissue-engineered bladders and urethra. Well-established in vitro and in vivo models are available for experimental evaluations of the regenerated bladder and urethra, providing invaluable data to predict clinical efficacy.

Standard cell culture studies can define the biological and molecular cues of UC, SMC, and endothelial cell or differentiated stem cells. Novel and noninvasive cell sources are needed to further improve the regenerative efficacy of the lower urinary tract. In addition, 3D construction remains critical to recapitulate the epithelial−stromal microenvironment in bladder and urethra regeneration studies. The development and optimization of reliable and reproducible scaffolds with the necessary porosity, biodegradability, flexibility, and firmness are vital for assessing in vitro and in vivo efficacy of tissue-engineered bladders and urethra. Biomaterials with coated with growth factors are promising tools for bladder and urethra regeneration. Therapeutic investigations should be continued, with the development of new biomaterials and optimized cell source to improve treatment outcomes for the lower urinary tract diseases through the tissue engineering technology.

Chapter 47

Tissue engineering for female reproductive organs

Renata S. Magalhaes, James K. Williams and Anthony Atala
Wake Forest Institute for Regenerative Medicine, Wake Forest University, Winston-Salem, NC, United States

Introduction

Fertility is a key element of reproductive health. The World Health Organization recognizes infertility as a global public health issue, affecting between 8% and 12% of reproductive-aged couples [1]. By definition a couple is considered infertile when they fail to conceive after 1 year or longer of timely unprotected intercourse [2,3]. For most women the experience of infertility negatively affects multiple aspects of their quality of life, causing substantial sociopsychological burdens [4].

Female infertility may arise from genetic abnormalities, infectious or environmental agents, endocrine imbalances, aging, and specific acquired diseases [5]. The prevalence of infertility, secondary to genetic abnormalities, ranges from 0.1% to 5% of the general female population [6–9]. These developmental issues can be associated with Müllerian duct malformations such as the Mayer–Rokitansky–Küster–Hauser syndrome (MRKHS). It is characterized by an absent uterus, cervix, and upperpart of the vagina and occurs in approximately 1 of 4000 newborn girls [10–12]. Acquired diseases associated with female infertility may result from fallopian tubes dysfunction/obstruction, endometriosis, leiomyomas (fibroids) distorting the uterine cavity, severe intrauterine adhesions, and hysterectomy [13,14]. The most prevalent etiologies underlying female infertility include ovulatory disorders, fallopian tube occlusion, and endometriosis.

Reproductive medicine has experienced significant advances over the past decades with the development of assisted reproductive technologies, such as in vitro fertilization, and molecular and genetic approaches to female infertility [15]. However, there is an increased demand for therapies that will restore function and/or compensate for the anatomical absence of organs. Tissue engineering approaches have emerged as an attractive alternative to address these problems by integrating biomaterials, cells, and growth factors to promote functional tissue repair. This chapter highlights progresses in tissue engineering applications for female reproductive organs.

Uterus

The uterus is the largest organ of the female reproductive system. It has an inverted pear shape and is anatomically divided into the uterine body or fundus connected on each side to the fallopian tubes; and the lower segment where the cervix opens into the vaginal cavity. Its histological elements include the endometrium (inner epithelial layer surrounded by stroma); the myometrium, consisting of oriented layers of smooth muscle cells; and outer serosa (perimetrium) that envelop the organ.

Uterine factor infertility affects 2%–8% of reproductive-aged women and arises from congenital (MRKHS, uterine hypoplasia, uterine malformation) or acquired causes including hysterectomy due to benign diseases (leiomyoma, adenomyosis), postpartum hemorrhage, intrauterine adhesions (Asherman's Syndrome), or malignant tumor [16,17]. Currently, these patients can achieve motherhood through gestational surrogacy and/or adoption; however, both options are associated with complex legal and ethical issues [18–20].

Allogenic uterus transplantation has been investigated preclinically and clinically as a potential curative therapy for uterine infertility [21,22]. The first live birth from a transplanted uterus was reported in 2014 by Brännström et al. [23]. While considered a promising approach, it is still experimental and associated with significant limitations, including organ donor shortage and a need for long-term immunosuppression therapy [24].

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00049-6

Acellular tissue engineering approaches for uterine tissue repair

Current tissue engineering approaches involve the use of constructs for partial uterine tissue repair. One of the first attempts in uterine tissue regeneration investigated the use of synthetic graft materials, including polytetrafluoroethylene (PTFE) and polyetherurethane/poly-L-lactide (PU/PLLA), in a rat model [25]. Initial experiments using these synthetic polymers showed that 6 weeks after engraftment, nonabsorbable PTFE grafts elicited an intense local inflammatory response, leading to poor tissue ingrowth and severe adhesions. While endometrium-like tissue ingrowth was observed within biodegradable PU/PLLA grafts, they failed to provide luminal patency.

Naturally derived biomaterials, including collagen and extracellular matrices (ECMs), have been investigated as candidate scaffold material for uterine tissue engineering due to their biodegradability and biocompatibility properties. Collagen scaffolds, loaded with basic fibroblast growth factor (bFGF), were developed by fusing a collagen-binding domain (CBD) to the N-terminal of native bFGF (NAT) and tested in a rat model of severe uterine injury [26]. A section of the uterine horn was removed and replaced by a 15 mm × 5 mm collagen-based bFGF delivery system membrane. At 90 days after surgical implantation, there was enhanced vascularization, improved endometrium ingrowth, and partial development of smooth muscle bundles where there had once been collagen-based implants. In addition, postoperative pregnancy rate in the collagen/CBD−bFGF implant group was comparable to the sham-operated group [26].

Using a similar approach, vascular endothelial growth factor (CBD−VEGF)-bound collagen was injected in a full-thickness rat uterine injury model [27]. The results showed that the collagen targeting VEGF delivery system promoted tissue ingrowth, neovascularization, and endometrial gland development in the injection sites [27].

ECMs are thought to be advantageous over synthetic scaffolds due to their distinct native tissue microstructure and composition (collagen and glycosaminoglycans). They also include the presence of several growth factors, which could potentially render an adequate cell differentiation and growth, as well as constructive host tissue remodeling response in vivo [28]. The specific three-dimensional (3D) features, composition, and distribution of the ECM elements may vary depending on the tissue source and processing methods [29]. Initial studies applying ECM-derived scaffolds for uterine tissue regeneration involved the use of porcine small intestinal submucosa (SIS) in rabbits [30]. The results indicated tissue ingrowth within engrafted membranes, but functionality was limited due to poor mechanical strength.

ECM-based scaffolds for uterine tissue reconstruction can be obtained through the process of decellularization (DC) of tissues and organs. The commonly used DC processes involve physical, chemical, and enzymatic methods [31]. As an initial step, Santoso et al. [32] investigated the effectiveness of three different DC protocols using Sprague Dawley rat uterine segments. Protocols involved the use of sodium dodecyl sulfate (SDS), high hydrostatic pressure (HHP), or Triton-X at optimized conditions and examined their effects on in vivo uterine tissue regeneration. Histological results indicated efficiency upon cell removal and minimal changes in the overall matrix structure using SDS and HHP protocols, whereas Triton-X severely reduced collagen and elastin content within the matrix. Thirty days after decellularized grafts (15 × 5 mm) were implanted into rat uteri, there was greater cell migration and tissue integration in the HHP group versus the other groups; however, it was restricted to the native tissue-graft transition area due to the absence of a connected microvascular network to support nutrition [32]. To address the lack of vascular supply and nutrient delivery to cells, whole uterus perfusion-based DC techniques have been developed in murine [33] and porcine models [34]. In vitro and in vivo studies have been conducted to optimize the applicability of whole uterus ECM-based scaffolds for partial uterine tissue repair.

Cell-seeded scaffolds for partial uterine repair

In an effort to enhance the regenerative capacity of tissue-engineered scaffolds, different cell sources combined with biomaterials have been explored. Atala et al. investigated the possibility of engineering autologous uterine tissue using a biodegradable polymer-based scaffold seeded with primary uterine cells [35,36]. Endometrium and myometrium cells were isolated and expanded ex vivo from rabbit uterine horns and seeded in a stepwise fashion onto the lumen and outer surface, respectively, of preconfigured semicircular scaffolds composed of polyglycolic acid (PGA)—coated poly-DL-lactide-*co*-glycolide (PLGA). The uterine construct was used to replace a subtotal excised horn in animals from which the cells derived. Six months after cell-seeded construct implantation, the neouterine tissue showed organized cellular and anatomical structures as well as expression of specific markers for epithelial, stroma, and smooth muscle cells. Functional studies are being conducted to assess the reproductive outcomes from the autologous bioengineered uteri.

Collagen scaffolds seeded with donor rat bone marrow−derived mesenchymal stem cells (BM-MSCs) have been studied in a murine model of severe uterine

injury [37]. A suspension of labeled BM-MSCs (5×10^5 cells/cm^2 scaffold) was seeded into collagen membranes (15×5 mm) and incubated for 1−3 hours before being engrafted in a partially removed uterine horn. Four weeks after surgery, BM-MSCs migrated to the basal layer of the graft, and the perigraft tissue had greater expression of bFGF, insulin-like growth factor 1, VEGF, and transforming growth factor-β1 than that in the collagen membrane-only group. Reproductive studies conducted 90 days after engraftment confirmed viable offspring in the BM-MSC/scaffold group suggesting that BM-MSCs may contribute to functional uterine tissue regeneration [37].

In another study, collagen scaffolds were loaded with endometrium-like cells derived from human embryonic stem cells (ESCs) and used as an implant in a rat uterine full-thickness injury model [38]. The results from in vivo studies indicated that although the cellularized collagen scaffold enhances uterine tissue regeneration, few human ESCs-derived cells were detected in the engrafted sites.

Other DC/recellularization techniques have been applied to create implantable grafts for uterine tissue regeneration. Miyazaki et al. [39] attempted to repopulate a whole rat decellularized uterine matrix injecting 5.1×10^7 neonatal uterine cells, 2.7×10^7 adult uterine cells, and 1.0×10^6 rat BM-MSCs in the uterine wall. After 3 days of incubation in a perfusion system, an endometrium-like tissue formation was observed, although cells were not evenly distributed within the matrix. When recellularized grafts (15×5 mm) were implanted in a partially excised rat uterine horn, uterine tissue ingrowth was noticed within the grafts, and pregnancy outcomes were reported to be nearly comparable to animals with an intact uterus. In another study, Hellström et al. [40] recellularized whole rat uterus matrices with donor primary heterogeneous uterine cells mixed with rat green fluorescent protein (GFP)-labeled MSCs. Grafts (20×5 mm) received multiple injections of a cell mix (one primary uterine cell per 150 GFP-MSCs) and were incubated for 72 hours. In vitro analysis of recellularized scaffolds revealed cell distribution limited to the matrices' external surface. Recellularized matrices (5×10 mm) were implanted in full-thickness excised rat uterine horns; and tissue ingrowth within the grafts was described at 6 weeks, mainly from host cells. Pregnancies in the remodeled uterine horn were reported, although embryo implantation did not occur directly in the grafts [40].

Scaffold-free approaches for partial uterine repair

Scaffold-free approaches have been evaluated in uterine tissue engineering to produce tissues by mimicking developmental processes. These methods often follow a pattern of cell condensation, cell proliferation, cell differentiation, ECM production, and tissue maturation. Campbell et al. [41] implanted tubular boiled blood clot templates (25×5 mm) in the peritoneal cavity of rats to produce autologous grafts. After 2 weeks an encapsulated myofibroblasts-rich tissue was formed and used to partially replace one uterine horn of the host animal. At 12 weeks the grafted tissue developed organized morphology with luminal and glandular epithelium, and two distinct layers of smooth muscle bundles interspersed with collagen, resembling native tissue; moreover, engrafted horns supported late-stage pregnancies.

Cell sheet engineering technology has also been explored for endometrium reconstruction. This technique involves cells self-organization and requires external manipulation to form a desired structure. Primary endometrial cells were isolated from immature mice, and rats were cultured using a temperature-responsive culture system [42]. Murine endometrial cell sheets harvested by lowering the culture temperature were transplanted onto exteriorized muscle and formed endometrium-like tissue structures.

Uterine cervix tissue engineering

The cervix has important mechanical and protective roles during pregnancy and undergoes significant remodeling during parturition. A dysfunctional cervix may result in preterm birth, which is associated with significant perinatal complications. House et al. [43] developed 3D cervical−like tissue constructs to investigate cervical remodeling in vitro. Human stromal cervical cells were seeded on a collagen-coated porous silk protein scaffold and cultured under static or dynamic conditions. At 8 weeks, cervical cells proliferated and synthetized an ECM with biochemical and structural properties that resembled native tissue. The dynamic culture condition led to increased collagen deposition, glycosaminoglycan synthesis, and mechanical stiffness of the 3D cervical construct.

Ovary

The hypothalamic−pituitary−ovarian axis controls mechanisms involved in the development and regulation of female reproductive function. The fundamental role of the ovary is to produce oocytes capable of fertilization as well as secrets sex steroids hormones. The ovarian follicle is the functional unit of the ovary, and it comprises an oocyte (germ cell) surrounded by layers of somatic follicular cells (granulosa and theca cells) and a basement membrane. Ovarian hormones play a major role in breast development, uterine receptivity for embryo implantation, bone homeostasis, as well as sexual function [44].

Pathological ovarian dysfunction may occur due to surgical resection, premature ovarian failure, or cancer chemotherapy treatment, compromising reproductive function and leading to an increased risk for cardiovascular diseases and osteoporosis. Current ovary tissue engineering approaches aim to restore its gonadal and endocrine physiological roles.

Tissue engineering ovarian follicles

In vitro culture systems to promote ovarian follicle growth and maturation have been proposed as a promising strategy to restore female fertility. Maintenance of the complex 3D architecture and granulosa–oocyte interaction is critical for successful in vitro follicle maturation. In conventional two-dimensional (2D) tissue culture systems, early-stage follicles tend to flatten, and granulosa cells migrate away from the oocyte, impairing the maturation process [45–48]. To address 2D-related limitations, tissue engineering technologies have been applied to develop in vitro maturation systems to recapitulate the architecture of ovarian follicles and provide a supportive environment for cell–cell interaction and paracrine signaling to direct follicular growth [49,50]. To enhance ovarian graft survival, Shikanov et al. [51] developed a delivery system combining hydrogels (fibrin and alginate) and angiogenic factors in a murine model. A cryopreserved/thawed ovarian cortical tissue was encapsulated in fibrin hydrogel modified with heparin-binding peptide loaded with VEGF and transplanted into the ovarian bursal cavity. The results indicated that the delivery strategy enhanced neovascularization and improved survival of primordial follicles in the graft. In another study, Krotz et al. [52] developed a self-assembled artificial human ovary as a tool to mature early antral oocytes in vitro. In this study, theca cells were isolated from reproductive-aged women and cultured into agarose molds to form a honeycomb structure. Granulosa cell spheroids or cumulus–oophorus complexes (COCs) were then placed in the honeycomb openings. After 72 hours, theca cells surrounded the COCs, resulting in self-assembled complex microtissues that supported oocyte maturation, confirmed by visualization of the polar body extrusion.

Hydrogel-based systems for in vitro maturation of isolated oocytes have also been explored. Pangas et al. [53] pioneered the use of an alginate-based system to grow individual immature mouse granulosa cell–oocyte complexes. Alginate is a naturally occurring polysaccharide, typically extracted from brown algae, and one of the most commonly used biomaterials for encapsulation owing to its biocompatibility, low toxicity, low cost, biomechanical properties, and its ability to form gel in the presence of calcium ions [54,55]. Studies using 3D alginate culture systems reported oocytes in vitro maturation [56,57]; moreover, embryos derived from in vitro fertilized cultured oocytes [58] produced viable offspring [59].

Cell encapsulation techniques have also been investigated as a potential cell-based hormone replacement therapy. The advantage of this approach over current pharmacological therapies is to potentially provide a more physiological activation of the hypothalamic–pituitary–ovarian axis in patients with ovarian failure. Ideally, the microcapsules should be biocompatible, provide a barrier between the allogeneic ovarian cells and the recipient to prevent immune rejection, and promote long-term cell survival. Sittadjody et al. [60] developed an engineered multilayer ovarian tissue model using alginate-based encapsulated ovarian cells from immature rats that secretes ovarian hormones in response to follicle-stimulating hormone and luteinizing hormone in vitro. Moreover, these 3D-engineered multilayered ovarian constructs achieved stable hormone secretion for up to 90 days following in vivo implantation in ovariectomized rats [61]. Similarly, studies using ovarian cell microcapsule delivery systems have reported increased levels of endogenous female hormones following transplantation in rodent models [62,63]. Ovarian cell encapsulation techniques have also been applied in microfluidic devices to create a biomimetic ovarian microtissue [64]. These systems have the potential to recapitulate human ovarian folliculogenesis [65] and therefore further improve in vitro maturation systems for fertility restoration in young cancer survival patients.

Vagina

Vaginal agenesis and other congenital or acquired disorders compromise a woman's sexual and reproductive life, often resulting in psychological issues [66,67]. A variety of vaginoplasty techniques have been described to create a neovaginal canal between the bladder and rectum. However, current approaches using nonvaginal autologous and allogenic grafts to line the surgically created cavity have been associated with complications such as graft rejection, chronic stenosis, and poor mechanical strength [68].

Tissue engineering approaches for neovagina reconstruction

The lack of optimal biomaterials that adequately mimic the vaginal tissue structure has led researchers to develop alternative vaginal tissue substitutes for neovaginal reconstruction procedures. Proof-of-concept studies evaluated the applicability of synthetic scaffolds for vaginal reconstruction in animal models [69–71]. Biodegradable PGA/PLGA scaffolds seeded with in vitro expanded autologous vaginal epithelial and smooth muscle cells were

subcutaneously implanted in nude mice [70]. After 4 weeks, retrieved grafts were neovascularized and had multilayered vaginal tissue−like organization.

Biologic scaffolds such as acellular vagina matrix (AVM) have been proposed as a potential source of organ-specific biomaterial [72]. Porcine vagina tissues were decellularized using a multistep method, and the resulting matrices displayed biomechanical properties and growth factor content comparable to that of the SIS. In vivo AVM biocompatibility was tested in a rat model of vaginal reconstruction. Three months after implantation, the neovaginal tissue formed epithelial and muscle layers.

Stem cell sources have also been investigated for autologous vaginal tissue engineering. BM-MSCs cocultured with vaginal epithelial cells were seeded onto SIS matrix for rat vagina reconstruction [73]. In vivo results indicated epithelial differentiation of seeded cells and significant matrix infiltration in the graft.

The potential of autologous adult cells sources has also been evaluated in clinical studies. Autologous vaginal vestibule cells were isolated and used to fabricate grafts in patients with MRKHS [74,75]. Cells were in vitro expanded and mounted on hyaluronic acid-embedded gauze to cover the surface of a surgically created vaginal canal. After a 12-month follow-up, neovaginal tissue biopsies revealed vaginal-like tissue formation, and patients reported a satisfactory sexual quality of life [75].

A variety of scaffold materials for vaginal reconstruction have been investigated in clinical studies, including acellular dermal matrix [76], SIS [77−80], allogenic amniotic membrane [81,82], and oxidase cellulose [83,84]. Raya-Rivera et al. [85] reported that tubular-shaped SIS scaffolds seeded with autologous primary vulvar cells are a feasible method for neovaginal reconstruction in patients with MRKHS. SIS membranes initially measuring 7×10 cm were customized for each patient based on their pelvic morphometric analyses and seeded with ex vivo cultured epithelial and smooth muscle cells. SIS-engineered grafts were then surgically implanted and serial tissue biopsies, imaging, and clinical exams confirmed a stable lining with native-like three-layered structures and patent neovaginal cavity for up to 8 years. Moreover, patients were sexually active, and a validated self-administered Female Sexual Function Index questionnaire indicated had functional variables were within the normal range.

Conclusion and future perspectives

Tissue engineering approaches have demonstrated great potential for treating disorders in the female reproductive system. Experimental studies provide encouraging results for uterine tissue engineering strategies for partial uterine repair. Several cell sources and promising scaffold materials and designs have been established, but there is no consensus or standardized methods to effectively produce engineered uterine constructs. In vivo studies suggest that cell migration and positioning within ECM-based scaffolds are primarily dependent on microstructural and microenvironment factors [86]. Additional studies are needed to produce adequately vascularized grafts that mimic the complex microarchitecture and plasticity of the human uterus and reproduce the complex nature of uterine function.

Progress in 3D culture systems for the follicle-enclosed oocyte maturation represents a major achievement in reproductive biology. Challenges still remain regarding the optimization of these in vitro culture systems for growing follicles with greater diametric sizes such those present in human ovaries.

The first-in-human study of autologous-engineered vaginas provides compelling evidence of safety and feasibility of this technology. Nonetheless, clinical trials comparing the long-term postoperative performance of various scaffold materials for vaginal tissue reconstruction are paramount to providing strong evidence of successful outcomes before introducing new technologies into the clinical setting.

Lastly, the future of tissue engineering approaches for the human female reproductive organs will rely on identifying optimal scaffold materials, viable cell sources, and comprehension of the underlying mechanisms of organogenesis to achieve engineer reproductive tissues that are functional and safe for recipients and their offspring.

Introduction

The science of male reproductive function and dysfunction has experienced significant progress in recent years. Especially clinical applications of molecular medicine to male infertility and hypogonadism [1], the "invention" of intracytoplasmic sperm injection (ICSI) as a treatment of male infertility [2] and the introduction of effective oral medication for erectile dysfunction (ED) [3,4] can be considered major breakthroughs. Infertility affects around 15% of couples who wish to have children, and half of these cases are associated with male-related factors [5]. ED is defined as the consistent or transient disorder, and inadequate erection affects at least half of men between the ages of 40 and 70, while chronic ED affects about 5% of men in their 40s and up to 25% of men by the age of 65 [6,7]. Hormonal and surgical approaches have been used to treat patients suffering from reproductive system disorders. Currently, regenerative medicine has become a promising concept in the development of new therapies for all fields of medicine, including reproduction [8]. The field of tissue engineering and regenerative medicine covers different areas of biomedical technology, including biomaterials, tissue engineering, and stem cell therapy. Three main strategies have been used: (1) utilizing extracellular matrices (ECMs) without cells, allowing the natural ability of the body to generate new tissue; (2) utilizing ECM seeded with cells for implantation; and (3) direct injection of cells either with or without carriers such as hydrogels. The ECMs used for tissue engineering may either be synthetic or derived from natural sources [9,10]. Different cell types may also be used, including (1) tissue-specific stem cells; (2) mesenchymal stem cells (MSCs); and (3) pluripotent stem cells such as embryonic stem cells, induce pluripotent stem cells, or amniotic and placental-derived stem cells. These cells can be either autologous or allogeneic. Autologous cells derived from a small biopsy are the preferred source because of immune compatibility. The biopsy is obtained from the patient, and the cells isolated from this biopsy tissue are expanded in vitro. However, for some patients, this is not an option as there is not enough functional tissue to obtain a biopsy. Therefore other sources of cells, such as stem cells (either autologous or allogeneic), might be used for these patients [9,10]. The ultimate goal of regenerative medicine strategies for the treatment of reproductive system disorders is to restore normal sexual function and preserve fertility.

Testes

The hypothalamus, the pituitary, and the testes form an integrated system responsible for an adequate secretion of male hormones and for normal spermatogenesis. The general anatomy of the testis consists of the seminiferous tubules and, among them, the interstitial space [11]. The seminiferous tubules contain germ cells in different maturation levels. The pool of germ cells is supported by spermatogonial stem cells (SSCs) that are covered by a layer of Sertoli cells embedded in lamina propria [12]. The lamina propria consists of the basal membrane covered by peritubular cells. Differentiated germ cells including spermatocytes and spermatids are located across the tubule toward its center. The main component of the interstitial space is the Leydig cell population that produces testosterone, but the interstitial space also contains macrophages, lymphocytes, loose connective tissue, and neurovascular bundles [13].

Spermatogonial stem cell technology

Etiologies of nonobstructive azoospermia include endocrinopathy, testicular failure, genetic anomaly, and idiopathic factors. In the United States on average, about five

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00050-2

men become azoospermic everyday due to the adverse effect of cancer treatments [14]. In sexually mature boys and men suffering from cancer and who are at risk of infertility, sperm cryopreservation is the simplest and most effective method to preserve their fertility [15]. However, less than 25% of these patients apply for sperm banking [16]. Lack of knowledge about semen cryopreservation is one of the major reasons of low percentage of sperm storage [16]. However, since the production of sperm has not yet started in prepubescent boys [17], sperm banking is not an option for prepubertal cancer patients. On average, more than 14 boys younger than 15 years of age are diagnosed with cancer every day and more than 80% of them will be cured [18]. Therefore long-term infertility will be a critical issue for many of these childhood cancer survivors that have no option for sperm banking. SSCs are present in the testis of most mammalian species, including nonhuman primates and human [19]. Spermatogonia are the cells located in the basement membrane of seminiferous tubules in the testis, and a small subpopulation of them are SSCs that play a primary role in spermatogenesis [19]. Normally, SSCs are able to divide and differentiate to haploid germ cells (sperm) and maintain fertility in men during their life [19].

In 1994 the feasibility of isolating and transplanting SSCs to restore fertility in mice testes was established [20]. Since that time, several groups have tried successfully to transplant SSCs in other species including nonhuman primates [21]. This has given great hope in finding an effective alternative to preserve fertility in adult males, which may also represent a solution for restoring fertility in prepubescent boys following cancer treatment (Fig. 48.1). In addition to cancer survivors, other patients including but not limited to cryptorchidism (at risk of infertility because of undescended testes at birth) and Klinefelter syndrome (47XXY; at risk of testis fibrosis) may benefit from SSC implantation [19].

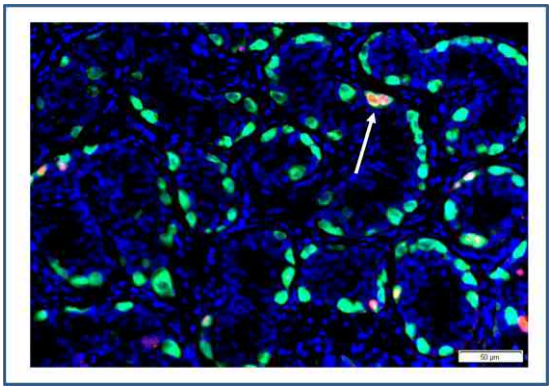

FIGURE 48.1 Spermatogonial cells (green fluorescent) in the base membrane of seminiferous tubules of a 5-year old boy. The cells were stained by MAGE-A4 antibody as a spermatogonia marker. Some of the spermatogonial cells have already started proliferation (*white arrow*; stained by Ki67 antibody). 4′,6-diamidino-2-phenylindole (DAPI) (blue) identified the nuclei of the cells. Scale bar 50 μm.

Nagano et al. [22] isolated human SSCs from six infertile men, which were transplanted to busulfan-treated nude mice. It was shown that human SSCs migrated into the base membrane of mouse seminiferous tubules of testis, but their numbers decreased significantly 1 month after transplantation. However, some SSCs remained in the mouse testis for up to 6 months without any evidence of differentiation [22]. Recently, a xenotransplantation study of prepubescent human SSCs showed similar results to the previous study on adult human SSCs [23]. The feasibility of SSC transplantation in a nonhuman primate model was demonstrated by Hermann et al. [21]. In this study, ejaculatory lentiviral positive sperm was found in the testes of more than 75% of adult (9 out of 12) and 60% of matured prepubescent (2 out of 5) recipient macaques monkeys for up to 63 weeks (average of 40.1 ± 4.9 weeks) after lentivirus-marked SSC transplantation. Autologous transplantation was twice as successful (70.5%; 12 out of 17) than allotransplantation (33.3%; 2 out of 6) in terms of presence of sperm in the ejaculate [21]. The ability of these sperms to fertilize eggs and develop preimplantation embryos was confirmed by performing ICSI. However, full pregnancies and live births were not observed in this study [21]. These results suggest that this technique could be translated to a clinical application in humans. In the previous study, an average of 88 ± 17.1 and 45.8 ± 14.5 million viable cells were used for transplantation to adult and juvenile testes, respectively [21]. It is well known that increasing the number of cells corresponds linearly with SSC transplantation success rate [24]. The number of SSCs in testis is very low (0.03% of germ cells and 1.25% of spermatogonial cells in mice; unknown in human) [25,26], and the size of testicular biopsy from premature boys undergoing cancer treatment is also very small (around 100 mm^3; containing 30,000 spermatogonia/mm^3) [19,27]. Although human SSC autotransplantation has not been tried yet, it is expected that successful human SSC autotransplantation requires in vitro expansion of these cells prior to transplantation. This culture method had been developed in animal models [26,28–30]. Recently, in a study involving the isolation and culture of human testicular cells from six different adult men who underwent orchiectomy as part of their prostate cancer treatment, we were able to maintain and propagate human SSCs in vitro for longer than 20 weeks [31]. The number of SSC increased more than 18,000-fold over 64 days of in vitro culture. In a follow-up study using testicular tissue from two boys aged 6.5 and 8 years, who were diagnosed with Hodgkin's lymphoma, isolated SSCs were able to propagate in vitro for at least 15.5–20 weeks [32]. Other groups have been successful in culturing human SSCs

[33–36]; however, this culture system should be optimized under good manufacturing practice regulations.

Before the first clinical trial of SSC autotransplantation in human, several safety issues must be addressed. First, especially in nonsolid cancer survivors such as hematopoietic malignancies, the transplanted cells should be free of any malignant cell contamination that may reintroduce the cancer to the recipient. In a study on culturing acute lymphoblastic leukemia (ALL) cells in combination with testicular cells from three different patients, ALL cells were undetectable beyond 26 days of culture even at extremely high initial concentration (40% ALL cells) [37]. However, it will be beneficial to test more cell lines from different types of leukemia to ensure complete purging of malignant cells. Second, the genetic integrity of stored, isolated, and propagated SSCs is very important, as it can influence the next generation of offspring. It has been shown that in vitro expanded mouse SSCs showed normal karyotype and stable androgenetic imprinting over 24 months [38]. Our work confirmed the genetic stability of in vitro propagated human SSCs; however, we found some changes in the epigenetic status of human SSCs during culture [39] .

Although trying for natural conception after SSC autotransplantation is ideal, testis tissue grafting or in vitro spermatogenesis followed by ICSI are other potential options to preserve fertility in many patients. Testicular tissue grafting and xenografting are extensively tested technologies that have been replicated in numerous mammalian species [40]. Immature testicular tissues from mice, pigs, goats, rabbits, hamsters, dogs, cats, horses, cattle, and monkeys have been grafted under the back skin of immune-deficient nude mice and matured to enable spermatogenesis, produce fertilization-competent sperm (pigs, goats, and monkeys) [41–43], and generate live offspring (mice, pigs, and monkeys) [43–46]. Therefore it is theoretically possible to graft immature testicular tissue from a childhood cancer survivor into an animal host to produce sperm that can be used in the in vitro fertilization (IVF) clinic to achieve pregnancy. However, the possibility that viruses or other xenobiotics could be transmitted from the animal host to humans needs to be carefully considered [47,48]. Recently, a model of prepubertal cancer survivor in rhesus macaques was introduced and reported that autologously grafted, frozen, and thawed prepubertal rhesus testicular tissues were matured to produce sperm that were competent to fertilize rhesus oocytes, establish a pregnancy, and produce a healthy graft-derived baby [49]. Complete spermatogenesis from grafted human tissues has not yet been achieved. Human tissue studies are needed to understand the scope, safety, and feasibility of testicular tissue grafting in patients. During the last three decades, in vitro spermatogenesis models have moved forward from initially conserving anatomical structure of the testis in culture to complete meiosis from testicular mouse germ cells [50]. Recently, we developed a three-dimensional (3D) testis organoid system from adult human testicular cells [47]. These human testis organoids (HTO) consist of SSCs, Sertoli, Leydig, and peritubular cells (Fig. 48.2A). Each organoid is approximately 300 μm in diameter and remain viable for at least 3 weeks (Fig. 48.2B and C) in an enriched medium with testicular ECM. This organoid system mimics in vivo spermatogenesis by supporting the differentiation of SSC to postmeiotic germ cells, albeit at a low frequency of approximately 0.2% [51]. The feasibility of using this system should be tested on prepubertal human testicular cells, and then the fertilization potential of the differentiated haploid cells should be analyzed as well.

Androgen-replacement therapy

Testosterone is the primary male sex hormone that plays multiple roles in the body. It has key roles in the development of male reproductive tissues such as testes and prostate, as well as promoting secondary sexual characteristics such as increased muscle and bone mass, and the growth of body hair [52]. Patients with testicular dysfunction and hypogonadal disorders may need androgen-replacement therapy to restore and maintain physiological levels of serum testosterone and its metabolites. Therefore testosterone therapy can increase muscle strength, stabilize bone density, improve osteoporosis, and restore secondary sexual characteristics, including libido and erectile function [53]. However, long-term exogenous testosterone therapy is not optimal and can cause multiple problems, including excessive erythropoiesis, bone density changes, and even infertility [54]. To address these problems, researchers are looking for an effective method to provide sufficient endogenous testosterone. In an animal model, isolated Leydig cells from rats that were cultured and stimulated with human chorionic gonadotropin (hCG) showed a high level of testosterone production [55]. In this study, engineered alginate-poly-L-lysine-encapsulated Leydig cell microspheres (with an average diameter of 0.7 ± 0.06 mm) were injected into castrated rats. Approximately 10% of a normal adult rat Leydig cell population was injected into each castrated animal. The serum testosterone levels increased and were maintained up to 40% of normal for a maximum period of 43 days, without any HCG stimulation [55]. Bilateral testicular agenesis or atrophy often requires the placement of testicular prostheses and androgen supplementation [56]. In this regard the possibility of creating hormone releasing testicular prostheses has been investigated [57]. To form testicular prosthesis, isolated chondrocytes from bovine articular cartilage were seeded on testicular shaped

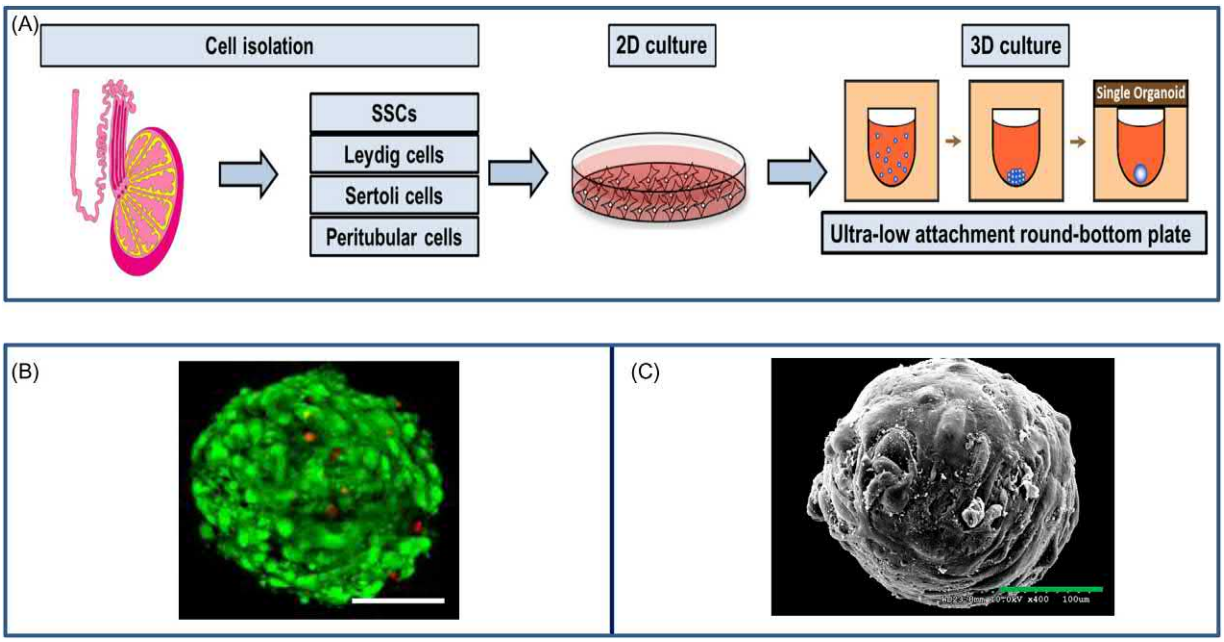

FIGURE 48.2 Human 3D Testis organoid system (HTO). (A) Testicular cells, including SSCs, Leydig cells, Sertoli cells, and peritubular cells, are isolated and propagated in 2D culture, then seeded into ultralow attachment round-bottom plates for 3D formation of organoids. The HTO formation takes 48–72 h. (B) Live/dead staining of organoid revealed maintenance of viability throughout the culture period. Green and red fluorescents represent alive and dead cells, respectively. (C) Ultrastructural analysis of multicellular human testicular organoids using SEM to show exterior morphology. Scale bars are 100 μm. *3D*, Three-dimensional; *SEM*, scanning electron microscopy; *SSCs*, spermatogonial stem cells.

polymer scaffolds. Implanted engineered testis prostheses loaded with 100 μg testosterone enanthate were able to maintain the physiologic levels of testosterone in vivo for at least 16 weeks in recipient mice [57]. For a better outcome, combinations of Leydig cell technology and engineered testicular prosthesis need to be further explored.

As mentioned earlier, we have recently developed a 3D testis organoid system from adult human testicular cells (HTOs) [51]. This HTO system consists of SSCs, Sertoli, Leydig, and peritubular cells. The Leydig cells in this multicellular structure could produce androgen with and without hCG stimulation [51] (Fig. 48.3).

Future work should focus on the feasibility of implanting adequate numbers of these HTO to castrated animal models as a potential, novel androgen-replacement therapy.

Ejaculatory system

Ejaculation is the process of transporting sperm through the urethra and expelling semen from the urethral meatus. The organs involved in the ejaculatory process are the epididymis, vas deferens, prostate, seminal vesicles, bladder neck, external urethral sphincter, and bulbourethral glands. In normal ejaculation, anatomic structures are precisely coordinated via neural centers to allow normal ejaculation to take place [58,59].

Engineering vas deferens

Congenital bilateral absence of the vas deferens (CBAVD) causes obstructive azoospermia which is common in about 1% of infertile men [60]. As CBAVD men have normal spermatogenesis, they are able to achieve biological fatherhood with the help of assisted reproduction techniques, that is, surgical sperm extraction, and IVF [61]. In addition, conception also requires the female partner of CBAVD men to undergo ovarian stimulation for IVF/ICSI procedure. A solution to this problem would be replacing the vas deferens. A novel approach for the tissue engineering of vas deferens has been tried in a rabbit model [62]. Polyethylene tubes (with 0.86 mm diameter and 6 cm length) were implanted into the peritoneal cavities (as an in vivo bioreactor) of 16 rabbits [62]. After 2–3 weeks the tubes were removed and the encapsulating myofibroblast-rich tissue that resulted from the foreign body response to the biomaterial was harvested for grafting as vas deferens in the rabbits [62]. At 2, 4, 6, and 8 months postimplantation, morphological and immunohistochemical evaluations showed that the structure of engineered vas deferens was similar to native vas deferens tissue [62]. In addition, the presence of sperm in the ejaculate indicated normal function of the engineered vas deferens. However, more research on large animal models is required before this approach can be used in humans.

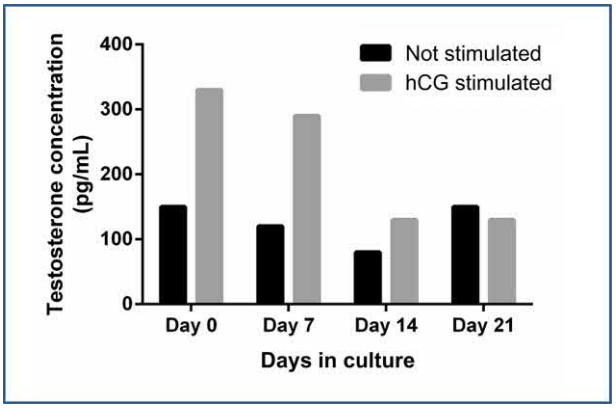

FIGURE 48.3 Androgen production by Human 3D Testis organoid system (HTO). Testosterone concentration in organoid culture media was measured over 3 weeks. Organoids were treated with hCG to stimulate testosterone production. Media from organoids treated with hCG was compared to control media from organoids with no hCG treatment. On day 0, 7, and 14, organoids produced more testosterone when stimulated with hCG. However, on day 21, organoids did not produce more testosterone when stimulated with hCG. The lack of increase in testosterone production on day 21 in response to hCG stimulation could be due to organoids becoming desensitized to hCG (in each time point the secreted hormone from a group of 16 organoids were pooled; $n = 16$). *3D*, Three-dimensional; *hCG*, human chorionic gonadotropin.

Spinal ejaculation generator

The incidence of anejaculation in the population is small, but when present, it represents a formidable challenge to the infertile couple and their treating physician [63]. Spinal cord injury (SCI) is the most common cause of anejaculation encountered in clinical practice [64]. The incidence of traumatic SCI is estimated at 16 individuals per million per year in Western Europe and 39 individuals per million per year in North America with a prevalence of 300 and 853 individuals per million, respectively [65]. In the United States the mean age at occurrence of SCI is 37.1 years, and 77.1% of SCI patients are male [66]. Ejaculation can be physiologically defined as the rhythmic, forceful expulsion of semen at the urethral meatus. Ejaculation comprises two successive phases, emission and expulsion, each involving different pelvic–perineal anatomical structures [67]. Emission is controlled by autonomic (sympathetic and parasympathetic) spinal centers, and expulsion is controlled by somatic spinal centers. These centers act in synchrony for antegrade ejaculation to occur. Such synchronization has been reported to be led, in rats, by a group of lumbar spinothalamic neurons forming the spinal generator of ejaculation (SGE). The critical role of the SGE and its organization have been described during the last decade in functional and neuroanatomical studies [67–71]. Penile vibratory stimulation (PVS) is a procedure that uses external vibration to stimulate the sensory nerves on the penis, with resultant reflex ejaculation (Fig. 48.4A). Electro ejaculation is an option for SCI men with lower motor neuron lesions and for those who have failed PVS, but it is somewhat more invasive. This technique uses electricity delivered via a rectal probe to recruit the ejaculatory reflex. The Seager Electroejaculator (Dalzell Medical Systems, The Plains, VA) remains the only FDA-approved device for this procedure (Fig. 48.4B).

In the past two decades numerous studies have focused on therapeutic approaches of SCI in animal models. Significant progress on functional remyelination [72], direct injection of biological agents [73], formation of neuronal relays [74], biomaterial approaches to enhancing neurorestoration [75], and neural stem cells transplantation [76,77] have been made. These studies promise translation to more clinical trials on SCI and neuronal regeneration. Although the main aim of these studies is correcting motor and sensory deficits, it will be interesting to evaluate the improvement on ejaculation function of these patients too.

Penis

Penile reconstruction

Congenital and acquired genitourinary tract anomalies of the penis require surgical reconstruction. Lack of sufficient normal autologous tissue is the major limitation in many surgical procedures for different conditions such as ambiguous genitalia, epispadias, hypospadias, micropenis, aphallia, severe chordee, impotence, female-to-male genital reassignment, and traumatic or iatrogenic penile defects [78–80]. The possibility of developing tissue composed of corporal cells in vivo has also been investigated [81]. Human corporal smooth muscle cells (SMC) and endothelial cells (EC) were seeded on biodegradable polymer scaffolds at concentrations of 20×10^6 and 10×10^6 cells/cm^3, respectively. These constructs were then implanted in the subcutaneous space of nude mice [81]. Histological evaluation showed the formation of vascularized corpus cavernosum comprising these two cell types 28 and 42 days postimplantation [81]. To achieve a 3D corporal structure, naturally derived polymer scaffold from rabbit corporal tissue was used in combination with primary human cavernosal SMC and EC [82]. Engineered corporal tissues were maintained in culture for up to 4 weeks and then implanted into nude mice [82]. The matrices showed a stable collagen concentration 8 weeks postimplantation [82]. Immunocytochemical studies using α-actin and factor VIII antibodies confirmed the presence of corporal SMC and EC in vivo [82]. Organ bath studies also showed that the cell-seeded corporal tissue matrices responded to electrical field stimulation [82]. In a follow-up study, structural parameters were evaluated up to 6 months postimplantation in a rabbit penile defect model

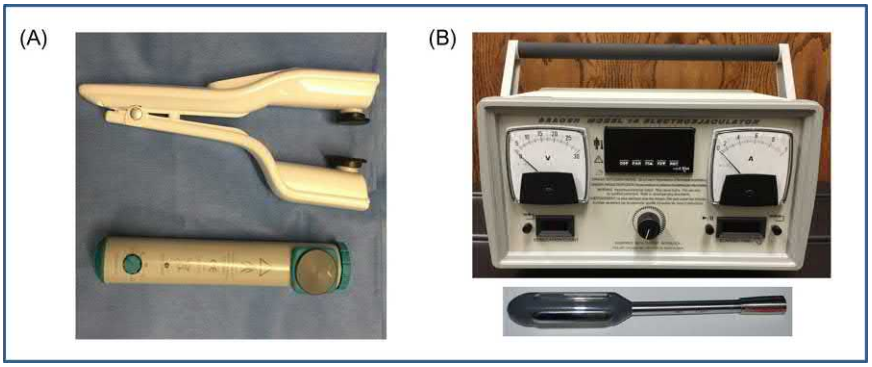

FIGURE 48.4 Currently available instruments to collect semen from spinal cord injury patients. (A) PVS including FertiCare (bottom device) and Viberect X3 (top device). These devices can be placed on either the dorsum or the frenulum of the penis (or both). (B) Seager EEJ and its transrectal probe. The probe is used to deliver electrical current directly to the prostate and seminal vesicles, resulting in ejaculation. The harvested sperm can be used for either IUI or IVF. *EEJ*, Electro ejaculation; *IUI*, intrauterine insemination; *IVF*, in vitro fertilization; *PVS*, penile vibratory stimulators.

[83], where the engineered corporal bodies showed structural integrity on cavernosography. The presence of sperm after copulation was confirmed in rabbits with the engineered corpora [83]. In all of these studies, it was shown that a short segment of the penile corporal body (approximately one-third of the penile corpora) can be replaced using naturally derived collagen matrices with autologous cells [81–83]. To improve the results of previous studies, engineering of the entire length of both penile corpora was attempted [84]. In another study the matrices were seeded with the autologous corporal SMC and EC, using a novel multistep cell seeding protocol [85], and the cell-seeded matrices were used to replace the entire pendular penile corpora in 12 male rabbits [84]. At 1, 3, and 6 months following the implantation of the engineered corpora, the rate of sperm presentation on vaginal swabs and pregnancy rates of mated female rabbits were found to be 83% and 30%, respectively. Untreated rabbits showed no evidence of intravaginal sperm and no pregnancies happened [84]. These studies demonstrate that penile corpora cavernosa tissue can be engineered and transplanted to restore function.

Penile transplantation

As an option for penile reconstruction, penile transplantation has been considered, especially after near-complete penile loss. So far, three allogenic penile transplantations have been performed worldwide. The first one was performed in 2006 in China successfully; however, it was removed after 2 weeks because of severe psychological problems of the recipient and his wife [86,87]. The second case was described in 2014 and performed in South Africa. The surgery was complicated by a reintervention after 4 days to remove a thrombus from the anastomosis and another reintervention for hematoma drainage. The patient, however, reported normal sexual and urinary function 3.5 months after transplantation [88]. The third case was the first US-based penile transplantation and performed in a patient suffering from penile cancer [89]. The requirement of lifelong, multidrug immunosuppression bearing the risk of serious side effects still remains a limiting factor for widespread clinical application of penile transplantation [90].

Stem cell therapy for erectile dysfunction

ED is defined as the consistent or recurrent inability to achieve or maintain an erection sufficient for sexual activity [91]. The interest on recruiting either endogenous or exogenous stem cells to treat ED is increasing [92]. It is generally believed that tissue-specific stem cells exist in most postnatal tissues. So far, two types of foreskin stem cells have been isolated to date, including skin-derived progenitors [93] and MSCs [94]. In a rat study using EDU labeling the presence of stem/progenitor cells has been shown. These cells, mainly distributed within the subtunic and perisinusoidal space of penis, are defined as subtunic penile progenitor cells and perisinusoidal penile progenitor cells. These cells expressed c-kit, A2B5, and PCNA [95]. It is expected that reactivation of endogenous stem cell potential might help the rejuvenation of damaged erectile function [96]. Human MSCs have been isolated from a large number of adult tissues (bone marrow, adipose tissue, skeletal muscle, etc.). Adipose tissue, being a rich and easily obtainable source of MSC, has been of particular interest in the treatment of ED [97]. MSCs express low levels of MHC class I and do not express MHC class II molecules; thus they are minimally immunogenic. Therefore they can be used from either autologous or allogenic sources [98]. Isolated MSCs from rat paratesticular fat tissues were injected in a bilateral cavernous nerve injury model. One month after injection, measurement of intracavernous pressure revealed significant improvement on ED [99]. Effect and mechanisms of low-energy shock wave (LESW) therapy has been tested in a rat ED model induced by pelvic neurovascular injuries. After 4 weeks of LESW treatment and 2 week of wash out, all rats underwent erectile function measurement. LESW treatment improves erectile function by

leading to angiogenesis, tissue restoration, and nerve generation with more endogenous EdU + progenitor cells recruited to the damaged area and activation of Schwann cells. LESW facilitates more complete reinnervation of penile tissue with regeneration of neuronal nitric oxide synthase−positive nerves from the major pelvic ganglion to the penis. In vitro treatment of Schwann cells with ESWL demonstrated its direct effect on cell proliferation. Western blot analyses showed that Schwann cell activation−related markers including p-Erk1/2 and p75 were upregulated after LESW treatment [100]. In another rat injury model, long-term therapeutic effect amongst three different types of human cell on ED has been tested. Two and half million cells of umbilical vein EC (UVEC), adipose-derived stem cells (ADSC), or amniotic fluid−derived stem cells (AFSCs) were injected intracavernously into the penile tissue. Saline injection was served as a control group. Erectile function and histomorphological analyses of penile tissues were assessed 12 weeks after defect creation and cell or saline injection. The ratio of intracavernous pressure to mean arterial pressure (functional indicator) was significantly higher in the cell therapy groups compared to the saline-injected control group ($P < .05$). Immunofluorescence staining showed more cells expressing biomarkers of endothelial, smooth muscle, and nerve cells within the penile tissue in the cell therapy groups when compared to the control group. This study demonstrated the beneficial effects of AFSC, UVEC, and ADSC on the penile corporal sinusoids showing a recovery of about 80%, 70%, and 60% of normal erectile function, respectively [101]. All of these observations demonstrate how stem cell treatment is a promising tool to restore normal erectile function, but these applications need further development for future clinical trials.

Conclusion

Regenerative medicine is a branch of translational research in tissue engineering and molecular biology, which deals with the process of replacing, engineering, or regenerating human cells, tissues, or organs to restore or establish normal function of tissues and organs. In the past two decades, most of the effort toward engineering of male reproductive tissues has occurred in animal models. Safety of engineered reproductive tissues is usually more critical than other organs because, in many cases, more than just recipients are involved. The health of offspring as well as the patient's partner should be considered carefully in any clinical trials in the future. Regenerative medicine has opened new avenues to treat disorders of male reproductive system affecting fertility and sexual life.

Introduction

A half century ago, Friedenstein et al. [1] described a population of nonhematopoietic cells isolated from human bone marrow with the in vitro ability to adhere, proliferate, and differentiate into chondrocytes, osteoblasts, and adipocytes. Such cells were identified in small amounts in multiple tissues throughout the body. Because of their differentiation properties and the ease of their isolation and in vitro expansion, these mesenchymal stem cells (MSCs) were considered an attractive candidate progenitor cell type for tissue engineering and regenerative medicine applications. Extensive investigation has yielded knowledge about their biology, particularly tools for controlling their activity and cell fate that are critical to their clinical use. Beyond their original identification in bone marrow–derived cells, MSC-like cells have been shown to have more tissues of origin, as well as differentiation capabilities that include various cells of mesenchymal lineages, including cellular phenotypes representative of the musculoskeletal tissues, such as cartilage, bone, muscle, ligament, and tendon. A plethora of factors control the extensive proliferative and multipotent differentiation capacity of MSCs, including cytokines, hormones, various soluble and insoluble signaling molecules, and transcription factors. The development and maturation of musculoskeletal tissues demand specific form and mechanical strength, and the success of a tissue-engineered outcome depends on the dynamic interactions between scaffolds, cells, and various physical and chemical environmental cues. By exploiting the current knowledge of MSC, promising and exciting results have been generated toward engineering tissue replacements for cartilage, bone, osteochondral, and other musculoskeletal tissues. Future clinical successes will rely on significant knowledge-based improvements. The current understanding, recent advances, and remaining challenges for the deployment of MSCs for musculoskeletal tissue-engineering applications constitute the subject of this chapter.

Mesenchymal stem cell biology relevant to musculoskeletal tissue engineering

An ideal cell source for tissue engineering should exhibit the following characteristics: easy access and high availability of the source cells, capacity for extensive self-renewal or expansion to generate sufficient quantity, the capacity to differentiate readily into cell lineages of interest upon instructive differentiation cues, and/or the ability to modulate the native environment to promote appropriate tissue repair and integration, including minimal immunogenic or tumorigenic ability. We will discuss below the intrinsic properties of MSC that determine their behavior, as well as external factors that affect the growth, differentiation, and the developmental outcomes of MSCs.

Mesenchymal stem cell identification

Since their initial description in the 1960s [1], MSCs have been shown to possess the capacity to differentiate into cells characteristic of several mesenchyme-derived tissues, including cartilage, bone, fat, muscle, tendon, and hematopoietic-supporting marrow stroma (reviewed in Ref. [2–7]). In addition to these mesenchymal lineages, MSCs were shown to differentiate into other cell/tissue types, including hepatocyte-like cells [8] and neural-like tissues [9,10]. However, the functionality of these nonmesodermal MSC-derived cells remains debatable.

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00051-4

Experimentally, MSCs are identified and isolated first by their ability to adhere to plastic. Next, proliferative and differentiable MSCs are identified, at a minimum, by the expression of a combination of surface markers [11]. These include STRO-1, SB-10, 5′-nucleotidase (CD73), and SH4 antigens as well as Thy-1 (CD90), TGF-β receptor type III endoglin (CD105), hyaluronic acid receptor CD44, integrin subunits α1 (CD49a), α2 (CD49b), α5 (CD49e), αV (CD51), β1 (CD29), activated leukocyte-cell adhesion molecules (CD166), melanoma cell adhesion molecule (CD146) [12,13], cell surface peptidase CD13 [14], and possibly others [2,15]. MSCs are negative for the hematopoietic markers, CD19/CD79a, CD34, CD45, CD11b/CD14, and HLA-DR [2]. CD73, SH4, and STRO-1 antibodies recognize antigens that are present on MSCs and other cells but not hematopoietic cells (for review, see Refs. [16–18]). The presence of CD75, CD90, and CD105 and absence of hematopoietic markers, while not sufficient to fully identify an MSC, has been suggested by the International Society of Cell Therapy as the minimum positive criteria necessary to consider a potential cell an MSC [19]. It therefore remains a challenge to isolate MSCs specifically from a mixed cell population. Frequently, a combination of antibodies is used to retrospectively characterize the MSC phenotype. Inconsistency in the literature on the growth characteristics and differentiation potential of MSCs underscores the need for a clear functional definition of MSCs [20]; at present the sole characteristic uniting disparate MSC sources is their ability to

1. adhere to tissue culture plastic under standard culture conditions;
2. form colonies, that is, a single cell giving rise to a colony of undifferentiated cells;
3. proliferate, that is, to self-renew and remain in an undifferentiated state until provided the signal to differentiate; and
4. differentiate along specific mesenchymal lineages when induced (Fig. 49.1).

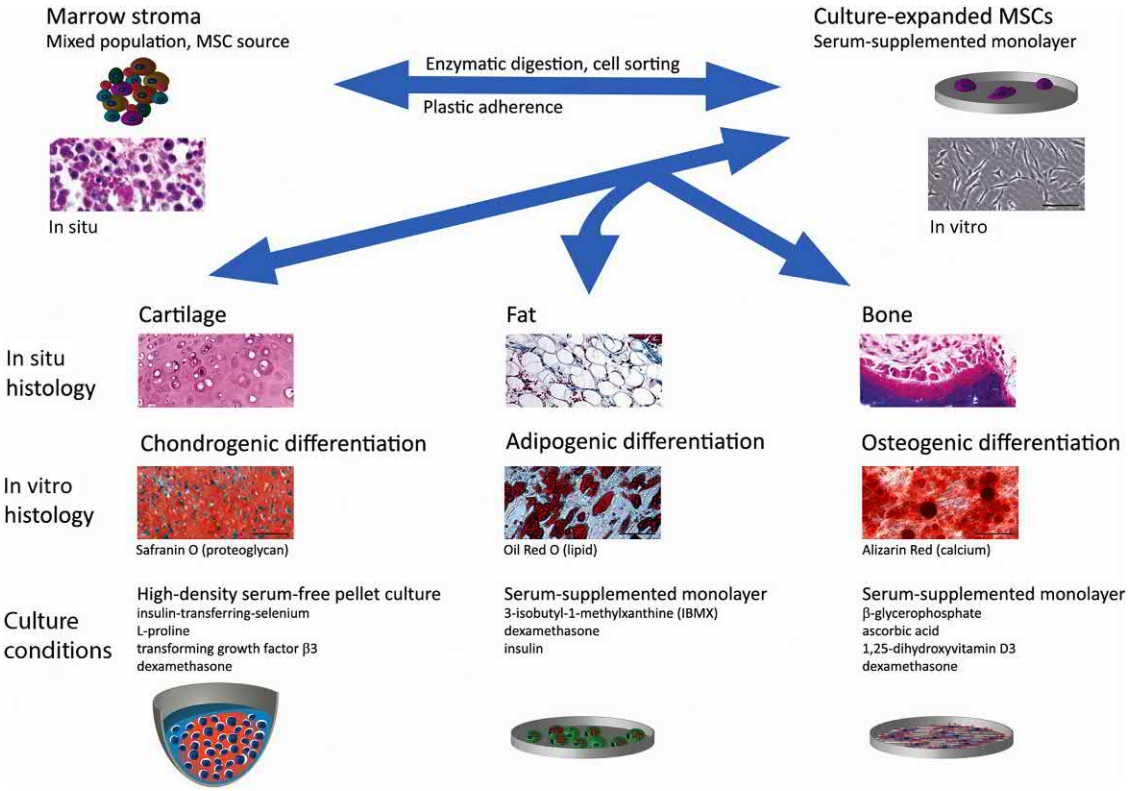

FIGURE 49.1 Minimum multilineage differentiation potential of mesenchymal stem cells. MSCs are able to differentiate into cell types of multiple lineages under appropriate conditions (adapted from [21]). Classically, these lineages include but are not limited to bone, cartilage, and fat. Bone marrow–derived MSCs, specifically, can repopulate the bone marrow stroma under certain conditions. Strong evidence exists that MSCs, once differentiated in vitro, can be dedifferentiated and subsequently used without harm to their multipotency. In addition to the standard lineages shown previously, additional work suggests that this transdifferentiation ability also applies to in vitro tenogenesis and musculogenesis (adapted from [22]). In situ and in vitro histology is shown for phenotype comparison (scale bar = 100 μm). *MSCs*, Mesenchymal stem cells. *Adapted with permission from Tuan RS, Boland G, Tuli R. Adult mesenchymal stem cells and cell-based tissue engineering. Arthritis Res Ther 2003;5(1):32–45.*

Tissue sources of mesenchymal stem cells

While bone marrow remains the best studied tissue source for MSCs, MSC-like cells have been identified in a number of other tissues. That MSCs or MSC-like cells can be found in almost all organs that harbor connective tissues implies that these cells may have a fundamental functional role in the body. The endogenous function(s) and exact location of these stem cells in the various tissues are under investigation, and they are generally thought to participate in local tissue repair and regeneration. Bone marrow MSCs can give rise to stromal cells that support hematopoiesis in vitro and in vivo, possibly providing extracellular components as well as various growth factors and cytokines [23]. Besides the bone marrow, other tissues of origin of MSCs have been investigated and their relevance to MSC biology debated. In 2008 Crisan et al. demonstrated that, independent of tissue sources, pericytes, which are mural cells located in direct contact with endothelial cells, while embedded within the basement membrane of small blood vessels, are indeed MSCs [12]. From this and other following studies, it was concluded that the perivascular niche serves as a universal source of MSCs, which are generally thought to participate in local tissue repair and regeneration [24]. Nevertheless, MSC-like cells could also be isolated from avascular (or less vascular) tissues such as human adult articular cartilage [13] and tendon [25,26].

Due to their early identification, MSCs from bone marrow have been widely investigated for regenerative therapies. Bone marrow is relatively easy to access, but isolation of bone marrow is an invasive procedure accompanied by potential donor site morbidity, pain, and infection. In addition, the low cell incidence of 0.001%–0.01% of the overall cell population and a relatively long cell doubling time (approximately 60 hours) [5,27] have prompted researchers to find alternative cell sources for MSC isolation [16–18,28,29] (Table 49.1). Adipose tissue was found to be an abundant source of MSCs, which yields 500 times more MSCs than an equal amount (volume) of bone marrow [67]; in addition, adipose-derived cells exhibit a high proliferation potential with a doubling time of approximately 20 hours [68,69] (Table 49.2). Other easily accessible sources of MSCs include a number of perinatal tissues, such as placenta, umbilical cord and umbilical cord blood [70], amnion [71], as well as urine [72,73] and the more recently emerging endometrial MSCs [74], which can be derived from menstrual blood [75,76].

TABLE 49.1 Tissue sources of human mesenchymal stem cells.

Tissue source	Representative references
Bone marrow	[1,5,6]
Trabecular bone	[30,31]
Muscle	[32–34]
Adipose	[35,36]

However, it is noteworthy that the multilineage differentiation and regeneration potencies of MSCs or progenitor cells derived from different tissues are still under investigation and debate. MSC yield, proliferation rate, multipotency, differentiation potential, and the previously mentioned accessibility determine the usefulness of MSCs from different tissue origins. Although MSCs derived from different tissues share a number of phenotypic characteristics, they clearly are not identical, as they show different propensities in proliferation and differentiation. For example, a study comparing human MSCs derived from bone marrow, umbilical cord blood, and adipose tissue showed that adipose tissue contained the highest number of MSCs, while umbilical cord blood contained the lowest; however, umbilical cord blood–derived MSC could be cultured for the longest period of time and showed the highest proliferation capacity, whereas bone marrow–derived MSC showed the lowest proliferation capacity [68]. Sakaguchi et al. compared the properties of MSCs isolated from bone marrow, synovium, periosteum, skeletal muscle and adipose tissue, and found significant differences in their multilineage differentiation potential [85]. MSCs from bone marrow, synovium, and periosteum showed greater chondrogenic activities, with synovium-derived MSCs exhibiting the highest capacity. Adipose-derived MSCs exhibit enhanced chondrogenesis if expanded in the presence of excess fibroblast growth factor (FGF)-2, then chondrogenically induced with bone morphogenetic protein (BMP)-6 (BMP6) [86,87]. With regard to osteogenesis the rate of matrix mineralization was highest in bone marrow, synovium, and periosteum-derived MSCs. Therefore the optimal source of MSCs for therapeutic use for the musculoskeletal system remains to be determined.

In addition to tissue source, donor age, life style, and disease stage may also directly affect MSC yield, rate of proliferation, multipotency, and regenerative potential. Decreasing MSC number and proliferation rate as well as differentiation potential were observed with increasing donor age [88]. MSCs from obese donors had a significantly impaired proliferation and differentiation potential [89]. When isolated from osteoporotic women, MSCs showed significantly reduced proliferative response and osteogenic differentiation [90]. With bone marrow MSCs, advanced osteoarthritis condition, regardless of age, had a significantly deleterious impact on proliferative capacity and chondrogenic and adipogenic activities when compared to healthy donors [91]. Decreases in MSC quantity and quality due to age and disease may limit the use of autologous MSCs in clinical settings, warranting further study of allogeneic MSCs for tissue repair. In addition to disease transmission, these nonautologous tissues might carry the risk of immune rejection and allogeneic reaction by the host and will be discussed in detail later.

Mesenchymal stem cell isolation and in vitro culture

Some adult tissues, such as adipose tissue, contain stem/progenitor cells with similar characteristics of MSCs and have higher occurrence rate (1%–5% in lipoaspirates) than in bone marrow, and the exact number depends on the isolation and characterization methods used [92]. Various protocols of MSC isolation are available, and some are species specific.

It is important to note that the isolation method of MSCs also impacts the number as well as quality of isolated cells. Depending on the tissue source, a number of enzymatic, mechanical, explant culture, and density-gradient centrifugation methods are employed (reviewed in Ref. [93]). To extract MSCs from solid tissues, proteolytic enzymes, for example, collagenase, dispase or trypsin, are used. These are sometimes coupled with mechanical dissociation methods, such as shear force and centrifugal force, especially for the isolation of MSCs from adipose tissue. A less frequently used approach is explant culture, where cells are allowed to grow out from small tissue pieces, for example, in the isolation of trabecular bone-derived MSCs [30,94].

Human bone marrow MSCs can be isolated by simple direct plating after isolation from native tissue, sometimes involving enzymatic digestion [95]. Frequently, this is performed after density-gradient centrifugation over Ficoll or Percoll, where a layer of mononuclear cells containing MSCs is obtained. With culture time and medium changes, nonadherent hematopoietic cells are washed away, and MSCs appear as small, adherent, spindle-shaped fibroblast-like cells.

As none of these methods allow immediate distinction between stem and nonstem cell populations, surface marker–based selection is often utilized to enrich MSCs in the isolated cells. These methods include positive or negative selection using either magnetic-activated cell sorting or fluorescence-activated cell sorting to further purify the MSC population. Positive selections have been based on the detection of markers that are expressed, albeit not exclusively, by MSCs; negative selection is based on the exclusion of markers that are expressed by hematopoietic cells, using antibodies against CD34, CD45, and CD11b, as mentioned previously.

Because of their low abundance in adult tissues, the number of MSCs in the primary isolate is often insufficient for clinical applications, necessitating the expansion of MSCs in vitro. Growth medium cocktails, designed to maintain the multipotent and proliferative capacities of MSCs, vary widely and typically involve culture in serum-supplemented Dulbecco's Modified Eagles Medium (DMEM) or α-Minimum Essential Medium (Table 49.1). Similar procedures are applicable for MSCs and progenitors derived from other tissues.

After initial expansion, cultures are maintained at densities of 50–100,000 cells/cm^2 [4,96,97]. The extensive expansion capacity of MSCs depends on the harvesting techniques, culture conditions, and the health condition and age of the donor. Culture conditions, such as initial seeding density and glucose levels in the medium, also influence the expansion capacity of MSCs. For example, higher proliferation profiles of MSCs was seen when plated at low initial plating density (1.5–3 cells/cm^2) but not at high density (12 cells/cm^2), resulting in a dramatic increase in the fold expansion of total cells (2000-fold vs 60-fold increase, respectively) [83]. Another example is the observation that tissue-specific progenitor cells grow faster in low glucose (5.5 mM), DMEM-based growth medium compared to high glucose (25 mM) culture medium, as the former condition better supports stem cell maintenance and prevention of cell aging [13,83,98].

Since the use of animal-derived serum increases the risk of transmission of zoonotic agents and the presence of xenogenic components in MSC products may elicit potential immunogenicity, the use of human-derived serum and platelet lysate has been explored [99,100]. Ideally, serum-free, chemically defined media are preferred and are being developed for isolation and expansion of MSCs under good manufacturing practice compliance [101]; in this manner, MSC expansion strategy may be readily customized for different applications [102].

Mesenchymal stem cell self-renewal and proliferation capacity

In vivo, MSCs likely remain in a mitotically quiescent state (G0 stage of the cell cycle) as demonstrated by the analysis of fresh bone marrow cell harvests continuously exposed to tritiated thymidine labeling [103]. BrdU labeling of cells in a human trabecular bone explant culture also revealed that cell proliferation, including that of STRO-1 positive mesenchymal stem/progenitor cells, was inhibited completely within the explant tissue milieu [104]. Since most of the tissues/organs from which MSCs are derived exhibit a relatively slow turnover rate in the adult organism, it is not unreasonable to speculate that self-renewal or proliferation of MSCs is normally suppressed in vivo in the course of tissue homeostasis, possibly regulated by intrinsic factors present in the tissue microenvironment and/or through direct or indirect interaction with neighboring cells. Once homeostasis is altered by injury or disease, the tissue progenitor cells or MSCs are activated, and cell behaviors, including proliferation and migration, can be observed, such as in the case of cartilage-derived stem/progenitor cells in an osteoarthritic articular cartilage (Fig. 49.2) [105,106].

In vitro cell cycle studies revealed that the majority of MSCs (between 78.7% and 96.45%) are in the G0/G1 phase of the cell cycle while a very small fraction of MSCs are engaged in active proliferation. During the exponential phase of cell growth, human MSCs isolated from bone marrow and fetal pancreas exhibited a similar population doubling time, ranging from 10 to 30 hours [107].

Unlike embryonic stem cells, MSCs do not expand indefinitely in vitro when cultured in the presence of serum, which could be a reflection of their intrinsic properties as adult stem cells or their exposure to a suboptimal culture environment. After extensive propagation, MSCs change their phenotype from a fibroblastic shape to a

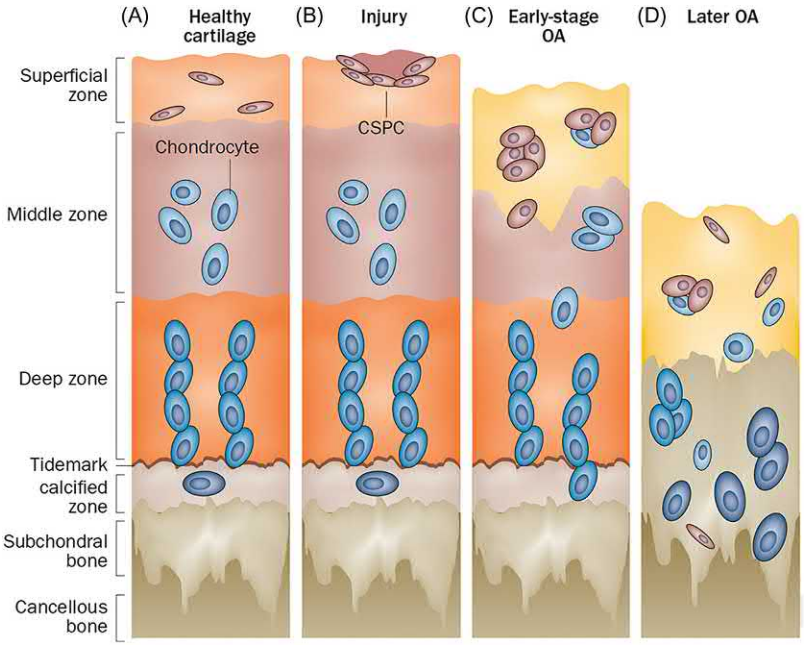

FIGURE 49.2 Human articular cartilage and schematic of CSPCs distribution during osteoarthritis pathogenesis. Zonal architecture and chondrocyte distribution in healthy adult articular cartilage, showing the superficial zone, middle zone, deep zone, tidemark, calcified zone, subchondral bone, and cancellous bone. (A) CSPCs (red) in normal adult cartilage—probably at superficial layer, and Notch-1 positive. (B) CSPC (red) response to injury—spindle shaped cells appear and migrate to the injury site. CSPCs in early OA (red)—with loss of superficial layer and changes in the internal structure of articular cartilage—stem cell markers are expressed and cell clusters emerge, containing cells positive for stem cell markers. (D) CSPCs in late stage OA (red)—with continuing matrix loss and chondrocyte hypertrophy, CSPCs appear to migrate throughout the articular cartilage. *CSPCs*, Cartilage-derived stem/progenitor cells. *Adapted with permission from Jiang Y, Tuan RS. Origin and function of cartilage stem/progenitor cells in osteoarthritis. Nat Rev Rheumatol 2015;11 (4):206–12.*

more flattened morphology with extensive pseudopodia and actin stress fiber formation, a phenomenon usually referred to as "replicative senescence." Consistent with their limited expansion capacity, human MSCs do not have high telomerase activity as compared to immortalized cells, and their telomere length is reduced as the cells grow older [108]. However, the telomerase activity appears to play a crucial role in maintaining the self-renewal and multidifferentiation potential of MSCs. Thus murine MSCs derived from telomerase knockout mice failed to differentiate into adipocytes and chondrocytes and lost telomere at late passage [109]. On the other hand, when transduced with telomerase, hMSCs stably expressing telomerase reverse transcriptase could undergo 80 [110,111] or 260 [112] population doublings without growth arrest.

Presence of growth factors and specific culture conditions also play a role in the expansion capacity of MSCs. Thus basic FGF (bFGF) can prolong the replicative capacity of hMSCs and increase the total cell numbers several-fold when included in the basal culture medium [113]. Other growth factors and cytokines, including canonical Wnts, for example, Wnt 3A [114], and interleukin-6 (IL-6) [115], have also been found to enhance the proliferative activity of adult human MSCs. Growth factor pretreatment may also help define the differentiation potential of the cultured MSCs [116], and this type of primed-MSCs are more ready to reenter the differentiation state of primed-lineages compared to unprimed MSCs [117,118]. Detailed study of MSC biology and proliferation, as well as variations due to culture conditions, may further extend the number and potential efficacy of MSCs.

Skeletogenic differentiation of mesenchymal stem cells

MSC differentiation can be controlled by a number of factors, including growth factors, hormones, and extracellular matrix (ECM) molecules, working through various signaling pathways and mechanisms. For instance, of relevance to cartilage tissue engineering, in vitro chondrogenesis of MSCs, or cartilage formation, is accomplished by culturing the cells in a three-dimensional (3D) culture condition, either as pellet culture, high-density micromass cultures, or within biomaterial scaffolds in the presence of a member of the transforming growth factor-β family (TGF-β1, TGF-β2, TGF-β3, or BMPs), insulin growth factor (IGF), Indian hedgehog (Ihh), parathyroid hormone–related protein (PTHrP), FGF, and Wnt/β-catenin [113,119,120]. Supplementation with dexamethasone also promotes the expression of chondrocyte phenotype [121]. Other nontraditional chondrogenic induction approaches, such as biomechancial conditioning, electrostimulation, and oxygen tension, have also been shown as alternatives to chemical agents to promote MSC chondrogenesis [122–124]. Chondrogenesis is demonstrated histologically as well as on the basis of the expression of genes encoding cartilage matrix components, including aggrecan, collagen types II and IX, and cartilage oligomeric matrix protein (COMP) [125]. Control of MSC chondrogenesis will be discussed in more detail in the "Cartilage tissue engineering" section.

Osteogenesis, that is, bone formation, can be induced in vitro by treating MSCs with the synthetic glucocorticoid dexamethasone, β-glycerophosphate, ascorbic acid, and 1,25-dihydroxyvitamin D_3. Alkaline phosphatase (ALP) activity and calcification of the ECM are typical markers used for detecting osteogenesis and mineralization, respectively. As in chondrogenesis induction, dexamethasone is similarly introduced during osteogenic induction of MSCs, and it has been reported to stimulate MSC proliferation and increase ALP activity [126]. Matrix mineralization only occurs in the presence of β-glycerophosphate, ascorbate, and dexamethasone and is further enhanced by 1,25-dihydroxyvitamin D_3 [127]. Although used less uniformly, a number of growth factors, including IGF-1, epidermal growth factors, and vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF), have also been reported to contribute to MSC osteoinduction to varying extents [128]. In addition to treatment with growth factors, osteogenesis can be stimulated in vitro by other biophysical and biochemical stimuli, including mechanical stimulation, pulsed electromagnetic field [129], hydrostatic pressure, oxidative stress, or immunomodulators [130–136]. Such models, in addition to offering insight into bone-forming processes, can also be used to analyze various injury mechanisms and to develop potential therapies.

Plasticity of mesenchymal stem cells

Plasticity/transdifferentiation refers to the ability of a cell type committed to and progressing along a specific developmental lineage to switch into another cell type of a different lineage through epigenetic reprogramming. As demonstrated by several studies, terminally differentiated cells can switch their phenotype under appropriate stimulations. For example, chondrocytes can become osteocytes [137,138], and adipocytes can convert to osteoblasts [139–141]. Since all of these cells are the mature progenies of MSCs, the conversion between each other might reflect the plastic property of MSCs. By using an in vitro differentiation strategy, we have demonstrated that human MSCs precommitted to a given mesenchyme cell lineage can transdifferentiate into other cell types in response to inductive extracellular cues [22]. Understanding the

molecular mechanisms that control the transdifferentiation potential of MSCs will facilitate the identification of regulatory factors, thus providing tools to manipulate adult stem cells for cell-based tissue engineering applications. Recent evidence suggest that mesenchymal cell populations contain a subpopulation of multilineage-differentiating stress enduring (MUSE) cells that possess pluripotency and may account for some of the plasticity observed [142]. Moreover, variations in the nanotopographical structure of materials supporting seeding cells can also lead to different cell fates [143].

In addition, plasticity also refers to the multiple differentiation lineages associated with MSC cell fate commitment during tissue morphogenesis that takes place as a function of development and disease pathogenesis in vivo. MSCs participate in the remodeling and repair of many tissues and commit to different cellular lineages dependent on the action of genetic, molecular, and microenvironmental mediators. For example, during aging, MSCs are more inclined to undergo differentiation into adipocytes rather than osteoblasts [144]. Besides the well-characterized TGF-β/BMP/WNT signaling pathways, other factors that regulate the plasticity of MSCs in the bone marrow include noncoding RNAs, such as miR-188 and lncRNA-Bmncr [145,146].

Mesenchymal stem cell heterogeneity

A high degree of variability was observed in MSCs, dependent on donors and tissue sources, including microanatomical locations within a given tissue [147]. Such cellular heterogeneity is reflected as differences in cell morphology, rate of proliferation, onset of senescence, differentiation potential, and functionality [148].

Individual colonies derived from single MSC precursors exhibit a heterogeneous nature in terms of cell proliferation and multilineage differentiation potential. For instance, only a minor proportion of colonies (17%) derived from adult human bone marrow continued to grow beyond 20 population doublings, while the majority of the colonies exhibited early senescence [80]. There is also a marked difference in the differentiation capacity of MSC colonies. For example, Pittenger et al. [5] reported that only one-third of the initial adherent bone marrow–derived MSC clones are multipotent to differentiate along the chondro-, osteo-, and adipogenic pathways (osteo/chondro/adipo). Furthermore, nonimmortalized cell clones examined by Muraglia et al. [78] demonstrated that 30% of the in vitro-derived MSC clones exhibited a tri-lineage (osteo/chondro/adipo) differentiation potential, while the remainder displayed a bilineage (osteo/chondro) or unilineage potential (osteo). These observations are consistent with other in vitro studies using conditionally immortalized clones. Even within a clonal colony, cellular phenotype can be highly heterogeneous [149]. Kuznetsov et al. demonstrated that only 58.8% of the single colony–derived clones had the ability to form bone within hydroxyapatite (HAP)–tricalcium phosphate (TCP) ceramic scaffolds after implantation in immunodeficient mice [150]. Similar results were reported by using purer populations of MSCs maintained in vitro [80] as well as human trabecular bone–derived MSCs [31]. Taken together, these results suggest that MSCs are heterogeneous with respect to their developmental potential and place a significant challenge on selecting the most potent cells for clinical application in tissue regeneration.

There exist a number of inconsistencies and discrepancies among currently published results on MSCs, perhaps reflecting the heterogeneity of the cell population, different isolation, and culture methods, as well as the different stimuli used for the differentiation procedures [20]. There has not been a single MSC-specific marker to unequivocally identify MSCs, and there is heterogeneity in MSC populations. The emerging tools of single-cell isolation and analysis [151] should yield better profile information about cellular heterogeneity and characteristics of different subpopulations, to improve the selection of the proper MSC candidates in clinical applications [152].

Mesenchymal stem cell effect on host immunobiology

Ideally, autologous MSCs would have advantages over allogeneic MSCs for regenerative medicine as autologous MSCs pose few immunological complications. Due to the low abundance of MSCs and the possible decrease in quantity as well as quality of the MSCs with age and disease, the use of allogeneic MSCs for replacing or repairing damaged tissues needs to be taken into consideration. Before this is deemed acceptable or feasible, it is important to understand how allogeneic cells elicit host immunological reactions. Allogeneic cells are normally detected and deleted by the host immune systems. However, MSCs have been surprisingly different in this aspect and offer several advantages, including possible immunomodulatory, including immunosuppressive, effects on the host response.

The first immunological advantage of MSCs is that they are hypoimmunogenic and can evade host immune system, as shown by several in vitro experiments [153]. This makes MSCs attractive for allogeneic transplantation whose major limitation is host immune rejection. MSCs express low (fetal) to intermediate (adult) major histocompatibility complex (MHC) class I molecules and do not express MHC class II molecules on their cell surface [154,155]. The lower expression of MHC class I molecules helps to protect MSCs from deletion by natural

killer (NK) cells. The lack of surface MHC class II expression gives the MSCs the potential to escape recognition by alloreactive CD4 + T cells. MSCs contain an intracellular pool of MHC class II molecules that can be mobilized onto cell surface when treated with interferon-γ (IFN-γ). However, induced surface expression of MHC class II still does not render the MSCs immunogenic [155]. After differentiation, MSCs continue to express MHC class I but not class II molecules on their cell surface and continue to be nonimmunogenic [154,155]. Nevertheless, it has been shown that although allogeneic MSCs are less immunogenic than other cell types, they do not completely evade immunological recognition [156]. Indeed, the survival period of allogeneic MSCs is significantly shorter than autologous MSCs [157].

MSC-mediated immune modulation is induced via both paracrine and direct cellular interactions with monocytes/macrophages, dendritic cells, T cells, B cells, and NK cells. Experimental evidence suggests that MSCs can interact directly with immune cells and modulate and suppress alloreactivity. MSCs inhibit T cell proliferation in vitro [158–160], do not seem to express costimulatory molecules, CD40, CD40 ligand, CD80, and CD86 (formerly B7–1 and B7–2, respectively), and probably do not activate alloreactive T cells [160]. In fact, MSCs suppress T cell activation and proliferation. For example, MSCs have been shown to suppress CD4 + and CD8 + T cells in mixed lymphocyte cultures [159,160]. Even though T cell proliferation can be induced by exogenous costimulation, when they are cocultured with MSCs in the presence of a stimulant, T cell proliferation is not observed [160]. MSCs can also induce apoptosis of activated T cells but not resting T cells [161]. MSCs also facilitate the formation of regulatory T cells (Tregs) in vitro and in vivo. Tregs are involved in immune homeostasis and are implicated to be a major effector cell type responsible for MSC-mediated immune modulation [162,163]. Supporting these observations, Bartholomew [158] showed that allogeneic baboon MSCs inhibited the proliferation of lymphocytes in vitro and prolonged skin graft survival in vivo. In addition to their effects on T cells, MSCs can also affect dendritic cell differentiation and maturation and interfere with their function [164,165]. MSCs have also been shown to inhibit polarization of macrophages and monocytes toward a proinflammatory phenotype (M1) and facilitate their polarization toward an immunomodulatory (M2) phenotype [166,167]. They also alter the phenotype of NK cells and can suppress the proliferation, cytokine secretion, and cytotoxicity of these cells against MHC class I targets [168]. By directly interacting with B cells, MSCs are also capable of reducing plasmablast formation and induce a regulatory phenotype in B cells [169].

In addition to cell–cell interaction mediated inhibition, MSCs are capable of secreting soluble factors to create a local immunosuppressive environment. These factors have been shown to include hepatocyte growth factor (HGF), TGF-β1, IL-10, and prostaglandin E2 [159,162]. When anti-HGF and anti-TGF-β1 antibodies are included, MSC inhibition on T cell proliferation is lifted [159]. IL-10 is a cytokine for Tregs and can suppress inflammatory immune response. Similarly, MSCs are shown to produce IL-10 either constitutively, or in coculture, and MSCs can mediate the suppressive activities partially through secretion of IL-10 [162,164,170]. Taken together, these in vitro findings suggest that MSCs can interact with the various subsets of cells of the immune system, alter the response of the immune cells, and shift the response from a proinflammatory response to an antiinflammatory response, possibly through the inhibition of the proinflammatory cytokines, such as IFN-γ and tumor necrosis factor-α (TNF-α), and stimulation of the immunosuppressive cytokines, including IL-10 and prostaglandin E2 [162]. Other identified crucial antiinflammatory factors secreted by MSCs include TNF stimulated gene 6 (TSG6) and indoleamine 2,3-dioxygenase (IDO). The latter was implicated to be partially responsible for NK cell suppression [162] and T cell activation [171]. MSC-derived TSG6 was demonstrated to attenuate inflammatory response and promote tissue repair in acute lung injury [172], peritonitis [173], and arthritis [174]. Another emerging field of research concerns extracellular vesicles (including exosomes), which carry microRNA, mRNAs, and other proteins and have been shown to be at least partially responsible for the immunomodulatory properties and therapeutic effects of MSCs [175–179].

The role of secreted factors in the immunoregulatory action of MSCs remains an actively investigated area [180,181]. Contradictory results exist as to which factors are important for this function. For example, although a role for IL-10, TGF-β, and prostaglandin E2 has been suggested, in other studies, none of these factors was found to be responsible for the immunosuppressive action of MSCs [160].

Recent studies have further reported that apoptotic, heat inactivated (dead), or even fragmented MSCs have immunomodulatory properties [182]. These were implicated to be mediated via monocytes and macrophages, which phagocytose dead MSCs and their fragments, leading to their polarization toward an antiinflammatory M2 phenotype [183]. A potential mechanism implicates that IDO is released within phagocytes, which in turn leads to the inhibition of T cells [184–186]. Irrespective of the exact mechanism of action, these findings suggest the feasibility of transplantation of MSCs between MHC incompatible individuals.

The in vitro studies showing that MSCs possess immunomodulatory and immunosuppressive activities suggest that MSCs can be potentially used in vivo for enhancing the engraftment of other cells and tissues (e.g., hematopoietic stem cells) or for the prophylactic prevention and even possibly as a treatment of graft-versus-host-disease, to prevent rejection, and promote transplant and patient survival. Other potential applications include inflammatory bowel disease, multiple sclerosis, liver and kidney injury, just to name a few. Indeed, a search of clinicatrials.gov (August 19, 2019) returned 194 studies using the terms "mesenchymal stem cell" and "immune" [187]. However, before MSC treatment can be used as standard therapy on humans, more in vivo animal studies need to be performed, and the biology and mechanism of MSC immunomodulation effect need to be better elucidated.

Safety of using mesenchymal stem cells for transplantation

MSC transplantation for therapeutic purpose has been under intensive investigation, and many studies have advanced from bench to bedside [188]. There is an abundance of clinical trials and studies using autologous or allogeneic MSCs for tissue regeneration and disease conditions. Most of the autologously derived MSCs, progenitors, and derivatives [189] have been proven to be safe [190], and many applications also show some favorable clinical results, including osteochondral repair [13], rotator cuff repair [191], and knee osteoarthritis [192,193]. For allogeneic cells the survival rate of the transplanted cells decreases dramatically after a short period of time, usually 1−2 weeks, indicating a treatment time window, and the need for multiple administrations during treatment. The allogeneic MSCs have proven to be safe in recurrent uterine adhesion [194], multiple sclerosis [195], and other application scenarios. Currently, the major safety concerns of using MSCs focus on how to reduce the residual animal-derived products present during cell expansion cultures, suppress potential immune reaction and related side effects, and increase cell survival rate after transplantation.

Indeed, the ability of MSCs to undergo extensive self-renewal via proliferation raises some concern as to whether MSCs, after prolonged in vitro culture, can become tumorigenic. For now, there is no strong evidence of the tumorigenic transformation of MSCs; however, it should be noted that endogenous MSCs are usually recruited by tumor cells during tumor growth and progression [196−199]. The immunosuppressive properties, especially the potential systemic immunosuppressive ability of MSCs, bring caution to the use of MSCs under certain clinical conditions, such as cancer. There are distinct effects of MSCs in the initial and progressive stage of tumorigenesis [198], and there are ongoing debates on the use of MSCs for cancer therapy. It has been shown that cotransplantation of an MSC cell line (C3H10T1/2) favors tumor growth of subcutaneously injected B16 melanoma cells in a murine melanoma tumor model [200]. However, this tumor-promoting effect was not observed in another study of coculture of a rat MSC line, MPC1cE, with rat colon carcinoma cells in a gelatin matrix. In the latter case, inhibitory effect of MSCs on the outgrowth of the tumor cells was observed [201]. The effect of MSCs on tumor growth thus requires further investigation in order to minimize or eliminate the potential side effect of therapeutic use of MSCs [202].

Mesenchymal stem cells in musculoskeletal tissue engineering

The musculoskeletal system of the human body is designed to sustain and maintain its form and function in the face of strenuous load bearing demands throughout a normally active life. Form and mechanical strength are vital for the function of this system. The mechanical and biochemical properties of the musculoskeletal system that define its structure and function also define the functional requirements of a tissue-engineered substitute. Successful tissue engineering−based replacement of native tissues will likely require constructs that possess functional properties similar to those of the native tissues to minimize premature failure. There are two basic approaches in tissue engineering. The first one is ex vivo tissue engineering, in which the construct is cultivated in vitro to achieve appropriate functionality before implantation. The second approach is in vivo tissue engineering, in which the construct is allowed to mature in vivo for tissue repair and regeneration. For both approaches, three components govern the eventual outcome of tissue-engineered constructs: *appropriate scaffold, instructive environment, and responsive cells*.

Cartilage tissue engineering

The need for engineered cartilage arises from the fact that while the tissue often functions well through a lifetime of use, over 30% of adults in the United States over 30 years of age have radiographic evidence of cartilage degeneration, with 9%−10% of the US population aged 30 and over suffering symptoms of osteoarthritis of the hip or knee [203,204]. The total cost of osteoarthritis is estimated at $36 billion dollars per year in the United States alone [205], with >200,000 knee replacements performed each year. The intrinsic healing capacity of the native tissue is limited, and given the increasing incidence of osteoarthritis and increasing life expectancy of the population,

there is a growing demand for novel repair strategies. Effective treatment of cartilage injuries may eliminate or forestall the need for joint replacement, thus enhancing the quality of life.

General properties of articular cartilage

Articular cartilage is the dense white tissue that lines the surfaces of joints and functions to transmit the high stresses associated with joint motion. The tissue consists of both a solid ECM component as well as a fluid phase [206,207]. The solid ECM is composed of a dense network of specialized molecules that engender the unique mechanical properties of the tissue. Collagen content (predominantly collagen type II) of the tissue ranges from 5% to 30% by wet weight while proteoglycan content ranges from 2% to 10%. In addition to these major elements the ECM also includes numerous minor collagens (e.g., types VI, IX, and XI), and linking molecules (COMP, hyaluronan, link protein, and fibronectin). The highly charged ECM and the proteoglycans, in particular, trap a large amount of water within the cartilage matrix, which comprises the fluid component of cartilage matrix. Together, these elements make up the fluid-filled fibrous network with larger collagen fibers interwoven throughout an array of large proteoglycan aggregates (aggrecan core protein with its covalently linked keratin and chondroitin sulfate moieties) attached to long hyaluronan chains.

The exact composition of cartilage changes slightly but sequentially as one progresses from the surface zone of the articular cartilage to the calcified zone that interacts with the subchondral bone. The surface zone, which is well adapted to tensile forces, comprises relatively little matrix with finer fibrillar structure rich in the proteoglycan lubricin arranged parallel to the articular surface as revealed by polarized microscopy and the squamal morphology of the cells in this region. The deep zone, well adapted to compressive forces, comprises larger collagen fibrils with greater cross-linking arranged perpendicular to the articular surface. These core constituents change with age, resulting in the emergence of adult functional properties, and deteriorate with disease processes, such as osteoarthritis [208–210].

The cellular component of cartilage, the chondrocytes, comprises less than 10% of the tissue volume [211]. The sparse distribution of chondrocytes belies their critical importance in maintaining the balance between anabolic synthesis of ECM constituents and continual remodeling and degradation over time [212]. Chondrocytes display a rich transcriptional profile in situ [213], reflective of their specialized cartilaginous phenotype, which is lost when these cells dedifferentiate with expansion in monolayer culture [214]. This process may be substantially reversed, with chondrocytes redifferentiating toward their mature phenotype when returned to 3D culture [215]. However, injury and diseased conditions may lead to the cells undergoing "irreversible" phenotypic changes such as the expression of collagen type I that leads to fibrosis, and the expression of matrix metalloproteinases (MMPs) [216], thus reducing the mechanical properties of the matrix comprising repair tissue or engineered cartilage, and harkening matrix and tissue degeneration.

The mechanical properties of articular cartilage are complex and underlie its ability to act as a low friction, weight-bearing surface over a lifetime of use. These properties are a result of both the solid (matrix) and fluid phases of the tissue. Regarding the solid, matrix phase, the dense, negatively charged, proteoglycan-rich ECM results in an equilibrium compression modulus of 0.2–1.4 MPa [217,218]. Meanwhile, the collagen content engenders a tensile modulus that is higher, ranging from 1 to 30 MPa [219,220]. Other structural elements of cartilage, including collagen type IX [221] and COMP [222], participate in the cross-linking of the collagen type II ECM, increasing matrix connectivity.

The highly charged ECM and the proteoglycans, in particular, trap a large amount of water within the cartilage matrix [223]. These electrostatic forces and the physiological cyclic loading (0.1–2 Hz) of the tissue maintain elevated interstitial fluid pressure. Fluid pressurization increases with contact and supports >90% of applied stress, shielding the matrix from excess deformation [224]. This fluid pressurization also results in a higher dynamic modulus than equilibrium modulus, stiffening the tissue with higher frequency and/or higher rate of loading. Finally, this fluid pressurization, coupled with molecules that participate in boundary lubrication, maintains the frictional coefficient of cartilage at extremely low values (lower than ice on ice), further protecting the tissue from excess wear with physiologic use [225,226].

Cells for cartilage tissue engineering

In the quest to repair or replace damaged articular cartilage, any replacement material, tissue, or their composite must be fabricated to retain the complex mechanical properties described previously. The development of such a material begins with the consideration and combination of appropriate and responsive cells, biocompatible and mechanically conductive scaffolds, and inductive environment for the optimal differentiation and proliferation of the cell type of interest. As discussed in this and other chapters, MSCs derived from various adult tissues have emerged as promising cell sources because of the ease with which they can be isolated and expanded and their multilineage differentiation capabilities.

When tissue engineering was originally proposed as a strategy for repairing diseased or damaged tissues [227],

it was believed that articular cartilage would be one of the first successes in this new field, owing to its relatively simple composition (possessing a single cell type) and lack of neural and vascular supply. First approaches focused on the chondrocyte itself, postulating that as these cells make and maintain matrix in vivo, exogenous cells should be able to reconstitute the tissue when implanted [228]. The first-in-patient successes demonstrated enhanced repair when high density chondrocyte solutions were transplanted to focal defects beneath a periosteal flap [229], a procedure now commonly referred to as autologous chondrocyte implantation (ACI) [230]. It stands as the first clinically available tissue-engineering strategy to enhance cartilage repair, and later was commercialized as the Carticel method by Genzyme Biosurgery and other brands and companies [231]. While questions remain regarding the cost-effectiveness of this approach, as compared to the simple bone marrow stimulation approach [232], the treatable defect size and quality of repaired tissue [233], and the over 20 years of good and satisfied follow-up results [234] make it a reliable and indispensable method for cartilage repair [231]. With subsequent technology development, scaffold or matrix has been incorporated into the original cell-based approach for better cell retention and as a substitute for the periosteal flap (referred to as matrix-assisted ACI or MACI) [235].

Although significant progress has been made in the production of engineered cartilage constructs with chondrocytes, several significant impediments exist that limit their clinical application. For instance, autologous chondrocytes are present in limited supply and are often of an aged and/or diseased state in patients presenting with osteoarthritis [236,237]. One opportunity for overcoming such concerns is the use of chondroprogenitor cells, such as tissue-specific progenitors [13] or progenitors derived from adult MSCs [231]. As described previously, these cells may be readily obtained from the adult bone marrow and other tissues and retain self-renewal ability and multipotency. These cells are expandable in culture [82] and can be grown in sufficient numbers to populate tissue-engineered cartilage. Recently, Jiang et al. reported the successful application of human autologous cartilage–derived stem/progenitors to treat large-sized osteochondral defects (6–13 cm^2) in patients [13].

The use of MSCs for cartilage regeneration and tissue engineering has shown enormous potential and initial success. MSCs have been used as cellular therapeutics directly, via injection into the joint space (with and without a carrier matrix) in an undifferentiated state [238–240] and after differentiation down a cartilage differentiation factors that drive their own chondrogenesis after implantation [241]. Of note, one current surgical strategy for enhancing the repair of cartilage defects is via microfracturing of the subchondral bone. This technique, also referred to as bone marrow stimulation [231], provides entrance for marrow elements, including MSCs, to the wound site and has been shown to generate an enhanced, albeit fibrous, repair response [242].

Mesenchymal stem cell chondrogenesis

Mesenchymal stem cell chondrogenic potential

Control of chondrogenesis in MSCs is a complex and developing research area, with much of our understanding of the relevant molecules and processes stemming from a continuing elucidation of the events that control healthy cartilage homeostasis as well as cartilage formation in the developing limb. Elements including soluble factors such as growth factors, cytokines, hormones; various intracellular signaling pathways and transcription factors; environmental factors such as mechanical loading and oxygen levels; and seeding density all affect chondrogenic differentiation of MSCs.

The standard in vitro system of MSC chondrogenesis involves a 3D culture of MSCs under the stimulation of a suitable chondrogenic stimulus. High density cultures of pellet or micromass are frequently employed, modeling early chondrogenesis in development where condensation of the early progenitor cells initiates the cascade of events leading to cartilage formation [243]. These MSCs can then effectively differentiate under standard chondrogenic conditions (serum-free medium supplemented with insulin–transferrin–selenium, ascorbate, proline, dexamethasone, and TGF-βs). In addition, MSCs may also be seeded on various 3D scaffolds to induce chondrogenesis. While the maintenance of a spherical shape in these scaffolds may be enough to shape a chondrogenic phenotype by MSCs, a chondroinductive growth medium is still required to realize the terminal differentiation and cartilage matrix accumulation of these cells. The hallmarks of an articular chondrocyte are initially high levels of Sox9 expression followed by ultimately high levels of collagen types II, IX, and XI and concomitant expression of aggrecan, COMP, and link protein, among others. Together these extracellular components produce a cross-linked and highly hydrated matrix surrounding the cells and their pericellular and intercellular matrix. This phenotype represents the prehypertrophic state of cartilage in the parlance of developmental biology describing the growth plate, the cartilage anlage of the endochondral skeleton [243].

MSCs that have undergone chondrogenic differentiation assume a chondrocyte-like phenotype characterized by increases in proteoglycan deposition and expression of aggrecan, COMP, and collagen type II [244] as described previously, and microarray analysis has shown increased gene expression of a large number of other cartilage ECM

elements as well [22,245,246]. A major challenge to articular cartilage engineering is to prevent the apparently natural progression of the cells down the path of chondrocyte hypertrophy, matrix mineralization, and apoptosis that promotes the ossification of the tissue to mature bone, as observed during the endochondral ossification process of embryonic skeletogenesis [243]. In this latter process, cells express Runt-related transcription factor 2 (Runx2), collagen types I and X, and matrix degradative enzymes such as MMPs (e.g., MMP13). Interestingly, these markers are also characteristic of chondrocytes in osteoarthritic cartilage [247] and, if expressed in engineered cartilage, are presumed to result in matrix degradation, and scaffold and construct failure.

Signaling in mesenchymal stem cell chondrogenesis

Growth factors that have regulatory effects on MSCs include members of the TGF-β superfamily, the IGFs, the FGFs, and the PDGFs. Among these growth factors, members of the TGF-β family, including TGF-β1, TGF-β2, and TGF-β3, as well as BMPs are the most potent inducers to promote chondrogenesis of MSCs. For human bone marrow–derived MSCs, TGF-β2 and TGF-β3 were shown to be more active than TGF-β1 in promoting chondrogenesis [244]. BMPs, known for their involvement in cartilage (as well as in bone) formation, act alone or in concert with other growth factors to induce or enhance MSC chondrogenic differentiation. For example, BMP2, BMP4, or BMP6, combined with TGF-β3, induced the chondrogenic phenotype in cultured human bone marrow–derived MSC pellets, with BMP2 seemingly the most effective [248]. Other growth factors, such as IGF, FGF, and PDGF, are important signaling molecules that mediate chondrocyte physiology rather than promoting chondrogenesis of MSCs and therefore commonly work with TGF-βs to promote chondrogenesis and enhance chondrocytic activities of differentiated MSCs. The promitotic activity of the FGFs has also been exploited for cell expansion purposes [249]. Interestingly, FGF-2-supplemented human MSCs proliferated more rapidly and exhibited greater chondrogenic potential than untreated controls [250]. Canonical Wnt signaling has been shown to enhance MSC differentiation [251], and Wnt signaling in chondrogenesis has been shown to crosstalk with TGFβ signaling [252–254]. The current challenge in finding the most efficient growth factor(s) for MSC chondrogenesis is that the regulatory effects of signaling molecules are dependent on property, dose, and timing of the molecules administered to the cells. This may explain some of the contradictory results regarding the effects of specific growth factors on chondrogenesis. Furthermore, the exact mechanisms of articular cartilage development in vivo remain incompletely understood; however, we may surmise that it occurs in a very complex biochemical environment, and that some level of this complexity must be replicated in vitro in order to produce functional articular cartilage. Replication of this complexity begins in part with the application of growth factor cocktails, applied combinatorially or sequentially, and as the effects of growth factors are changed in the presence of other growth factors and environmental cues, the exact repertoire of prochondrogenic formulations is likely to remain unsettled before the field achieves clarification.

Growth factors act on cells and induce various intracellular signaling pathways to coordinate transcription factors and change cellular phenotype. The most important molecule intrinsic to the assumption of the cartilaginous phenotype is the transcription factor, Sox9. The role of Sox9 in cartilage formation was first observed in the process of cellular condensation in the developing mouse limb, and its presence is thought to be required for cartilage formation [255]. The expression of Sox9 is considered a master regulatory step of chondrogenesis, defining the commitment of a mesenchymal cell, such as the MSC, down the chondrogenic lineage. The action of Sox9 is enhanced by the related molecules, Sox5 and Sox6 [256], with recent evidence suggesting that the exogenous introduction of the combination of the three is sufficient to induce chondrogenesis in a variety of cell types [257]. In human bone marrow–derived MSCs, exogenous expression of Sox9 led to increased proteoglycan deposition and expression of link protein [258,259]. It has been shown that the addition of BMP2 resulted in dose-dependent increase in Sox9 expression in C3H10T1/2 cells, a mesenchymal progenitor cell line [260].

In terms of clinical applications, BMP2 and BMP7 (also known as OP-1) have been approved by the US Food and Drug Administration (FDA) for clinical use [261], thus rendering them good candidates for preclinical studies of cartilage tissue engineering. Recent studies have shown that the nature of the effective chondrogenic growth factors and their combinations are slightly different for MSCs-derived from different tissue sources, for example, bone marrow, adipose, induced pluripotent stem cell (iPSC)-derived progenitors, and tissue-specific progenitors. For example, bone marrow–derived MSCs are primarily responsive to TGF-β1 and TGF-β3 [244,262,263], whereas adipose-derived MSCs require BMP6 in addition to TGF-βs to achieve adequate chondrogenesis [264,265]. Adding BMP4 to TGF-β supplemented chondro-inductive medium can boost chondrogenic differentiation of bone marrow or cartilage-derived cells [13,266]. These differential requirements likely reflect the inherent differences in tissue origin [152], and proper combination and strategy of applying growth factors thus depends on the source of MSCs and the delivery method used for cartilage tissue engineering.

In addition to growth factors a number of "physical" environmental factors also influence MSC chondrogenesis. These include oxygen tension, mechanical loading, and hydrostatic pressure. Articular cartilage is an avascular tissue, therefore nutrients and metabolites are provided via diffusion from the synovial fluid and the subchondral bone, aided by the movement and resulting fluid flow in the joint. Oxygen tension in the deep zones of articular cartilage has been reported to be between 1% and 2% with an increasing oxygen gradient toward the articular surface [267,268]. Hypoxia is a positive regulator of the chondrocytic phenotype and MSC chondrogenic differentiation [269–271]. Regular, cyclic loading of cartilage is vital to its homeostasis in vivo, and cyclic loading has been shown to be chondroinductive in vitro [272–274] and even prevent the induction of hypertrophic markers in vitro [275]. Hydrostatic pressure itself, a component of the increased interstitial pressure experienced by cartilage under load, is chondro-stimulatory [276], although not in isolation, and its effects are quite variable between individuals [277]. One interesting way to regulate chondrogenesis of MSC is to use biophysical signals, such as short-term high voltage electric signals. Application of nanosecond pulsed electric fields to precondition MSCs can enhance the differentiation ability in subsequent in vitro cultures [278,279]. These examples illustrate the importance of understanding normal cartilage homeostasis in order to engineer better articular cartilage.

Scaffolds for cartilage tissue engineering

The 3D substrate upon which the cells are grown can have profound effects upon MSC differentiation. Considerations include the material composition, its structure and topography, and its biodegradability. In general, scaffolds may be made of natural or synthetic biomaterials and may be in the form of hydrogels, sponges, fibrous meshes, and nanofibers. Only some of the many available scaffolds are appropriate for cartilage tissue engineering. Among artificial materials, poly-glycolic acid (PGA), poly-L-lactic acid (PLA), poly-ε-caprolactone (PCL) polyethylene oxide, and polyethylene glycol (PEG), among others, have shown potential in cartilage tissue engineering [280–286]. These polymers may be employed as either sponges formed through phase separation and salt leaching or as micro- or nanofibers formed by electrospinning. The small diameters of nanofibers closely match the geometry of collagen fibrils comprising a natural cartilage matrix, making these structures a potentially useful biomimetic scaffold (Fig. 49.3) [287,288]. The high porosity, high surface-to-volume ratio and their unique mechanical properties account for the popularity of these structures in cartilage engineering as well. In recent studies, natural materials such as chitin [289], collagens [290], hyaluronan [291], silk [292,293] among others, have been processed into nanofibrous scaffolds. These biomaterials have the added value of providing natural epitopes for cell attachment as well as sites for covalent attachment of osteogenic molecules. Cospinning different materials together can be useful in creating complex surface topographies, greater porosity, increasing biological activities, and adjusting mechanical properties of the resulting scaffold [294]. Finally, fibers may be spun directionally to yield the proper matrix alignment as well as potentially transmit or absorb mechanical forces necessary to the protection and function of the tissue.

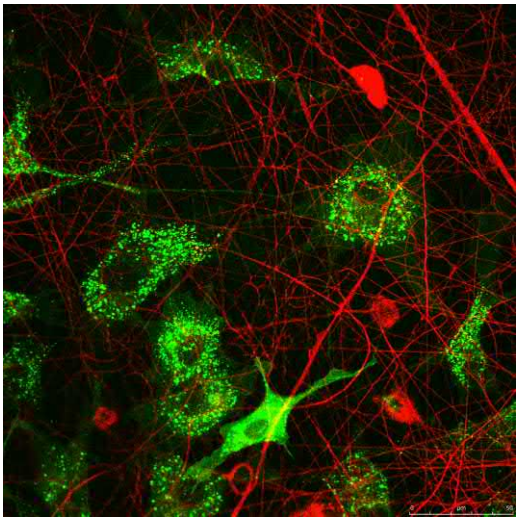

FIGURE 49.3 Confocal laser scanning fluorescence microscopy of adult human MSCs (green) seeded on to an electrospun nanofibrous scaffold (red). MSCs appear to be well integrated within the nanofibrous matrix, interacting with individual fibers via cellular processes, as well as filling the "pores" within the scaffold. Scale bar = 50 μm. *MSCs*, Mesenchymal stem cells.

In addition to fibrous scaffolds, various biocompatible hydrogels have also been applied for the in vitro and in vivo growth of cartilage constructs. Hydrogels are 3D, hydrophilic, polymeric networks capable of retaining large amounts of water or biological fluids and commonly used to mimic the chondrogenic environment. Frequently used hydrogels include synthetic materials such as PEG, self-assembling peptides, and natural materials, including agarose [207,295,296], alginates [297–299], the cartilage matrix components collagen type I [300–302], collagen type II [303], hyaluronan-based gels [304,305], and fibrin gels [306,307]. The exploration of each of these scaffolds has contributed to our understanding of MSC chondrogenesis for tissue engineering.

Agarose gels have been employed extensively in cartilage tissue engineering and are unique in that they offer cells no epitopes for adhesion. The agarose maintains the cell in a spherical shape, which alone has been shown to maintain and even promote chondrogenesis.

The otherwise inert agarose has been useful in elucidating the effects of mechanical loading, TGF-β exposure, and differences between chondrocytes and MSCs.

Synthetic PEG hydrogels, although relatively inert, have been shown to support cartilage tissue formation by both chondrocytes and MSCs [308,309]. Unlike many other synthetic polymers, PEG may be modified to include arginine−glycine−aspartic acid (RGD) and other bioactive peptides [310,311] to enhance viability [312] and chondrogenic differentiation of encapsulated cells [313], and to control the mechanical [314] and degradation [315] properties of the hydrogel itself. These features have made it a staple of tissue engineering. The inclusion of cartilage matrix molecules or peptide derivatives greatly enhances the PEG scaffold support of chondrogenesis and may be tuned to create multilayered constructs [316−318]. The addition of hyaluronan is particularly potent in inducing MSC chondrogenesis [319]. A natural component of cartilage, hyaluronan is also functionally involved in biological processes, including cell proliferation, morphogenesis, inflammation, and wound healing. Hyaluronan hydrogels also support chondrogenic differentiation of MSCs, making it a promising scaffold for cartilage regeneration [320].

Recent work in our laboratory has led to the development of photocrosslinkable, gelatin-based hydrogel materials that incorporate biocompatibility, mechanical stiffness, high cell viability, and adaptability to clinical imaging guided 3D bioprinting, with the ability of live cell encapsulation during scaffold fabrication [123,321−323]. These materials have allowed efficient MSC-based cartilage tissue engineering and have been applied for the repair of cartilage defect in an in vitro model [324], as well as the construction of an osteochondral chip that functions as an in vitro microphysiological system to simulate the osteochondral junction of an articular joint [325,326].

Factors influencing outcomes of tissue-engineered cartilage

Since the quality of the ECM and the mechanical properties of engineered constructs generally fall short of the characteristics of native cartilage, many studies have focused upon the combination of chondrogenic stimuli. The evolution of a tissue-engineered construct is a time-dependent process, controlled by numerous (and sometimes unanticipated) factors. These factors include an evolving cell phenotype, changing biochemical and biophysical environments, and continuous remodeling of the matrix from the engineered scaffold to native ECM. Two philosophies govern the engineering of each component. On the one hand, tissue engineers may strive to build and control each component throughout the development of the construct. On the other hand, components and processes may be permitted to proceed as naturally as possible in situ. In both cases a perfect scenario involves the development of all construct components in unison to ultimately form a functional tissue. The fact that no tissue-engineered construct based upon MSCs has successfully repaired articular surfaces over the long term shows that such a coordinated development has not been achieved. Thus it is imperative that we seek to understand each process better, particularly as they relate to each other.

In recent years, there has been rapid growth in the number of studies analyzing the synergistic effects of various chondrogenic stimuli, covering

1. different growth factor combinations;
2. scaffolds comprising complex materials with different mechanical, biological, and biodegradation properties;
3. the inclusion of mechanical stimulation and/or hypoxia to the differentiation equation; and
4. the inclusion of various biological matrices, including devitalized tissue matrices and blood fractions including platelet-rich plasma.

While clearly all components of the tissue-engineered construct are under continuous study and improvement, the development of biomaterial scaffold in particular is undergoing rapid evolution. Investigators have focused on how to recapitulate the multiple roles of native ECM, including its roles in structural integrity, mechanotransduction, and repository and coreceptor for various signaling molecules. Toward this end, scaffolds have been decorated with peptide sequences derived from the bioactive motifs of collagen, fibronectin, and laminin (among others) through adsorption or covalent bonding. These peptides have also been modified to include substrate sequences for specific proteolytic enzymes to allow targeted release, a property which is particularly useful when nondegradable scaffolds, such as agarose, are used.

Most bioresorbable scaffolds undergo a degree of degradation that is essentially incomplete during tissue regeneration. Growth factors may be incorporated in the scaffolds using microparticles of select composition, micelles, and composite structures with specific time-release profiles to deliver changing combinations of stimulatory factors to enhance the chondrogenic phenotype of the MSCs. A major advance in the use of hydrogels has been the development of photo-polymerizable monomers that make hydrogels amenable to photo-stereolithography. This technique allows the design and fabrication of detailed internal and surface microarchitecture of large scaffolds such as those required for joint resurfacing. With precise spatial control, scaffolds can be loaded with micro- or nanoparticles of varying composition, tuned to release encapsulated growth factors at specified times. Our recent work showed that the incorporation of

graphene oxide in the photocrosslinked gelatin hydrogen promotes chondro-inductive factor-free chondrogenic differentiation of MSCs, presumably due to the highly efficient adsorption of endogenously produced growth factors by the MSCs, resulting from the high surface area and adsorptive characteristics of the graphene oxide nanoparticles [327]. Thus spatiotemporally specific differentiation of the seeded MSCs can be controlled to approximate and recreate the zonal organization of articular cartilage, osteochondral plug, or musculoskeletal entheses.

Despite such excellent design and fabrication strategies, many challenges remain in using such large complex scaffolds, including enhancement of cell survival as well as efficient and spatially targeted cell seeding. The latter may be largely overcome by centrifugation or vacuum aspiration, traditionally used to seed fibrous scaffolds, or direct incorporation of cells within the scaffold during fabrication, a technique commonly used with hydrogels. In the bottom-up approach to tissue engineering using photo-stereolithography, another challenge is the cytotoxic conditions generated by the UV-activation of photoinitiators during the polymerization of the monomer solution. A solution has recently been reported by the development of a visible light-activatable photoinitator-based method of projection stereolithography [321].

Bone tissue engineering

Bone has a vigorous potential to regenerate itself after damage; however, the efficacious repair of large bone defects resulting from resection, trauma, or nonunion fractures still requires the implantation of bone grafts. Five hundred thousand surgical cases of bone grafting procedures are performed annually [328], and the demand for bone grafts is expected to be even greater over the next decade as the population ages. Natural bone grafts have been used extensively in clinical settings. Autografts are considered the gold standard for bone implantation due to their robust performance in osteoinductivity, osteoconductivity, and osteogenesis, as well as their advantage of immunocompatibility over allografts and xenografts. However, complicating issues, such as donor site morbidity, risk of infection, and the availability of bone tissue of the correct size and shape, limit the use of autografts in orthopedic applications. One possible remedy for the shortage of bone grafts is a functional tissue-engineered bone graft possessing one if not all of the following properties—an osteoconductive matrix, osteoinductive factors, and osteogenic cells [328]. Within this context, MSCs represent an attractive cell type for bone tissue engineering due to their easy accessibility, self-renewal and avid bone forming ability, acceptable genomic stability, and minimal ethical complications for clinical application. In bone tissue engineering, MSCs can either be used together with scaffold carriers or through scaffold-free approaches, such as systemic/local injection or cell sheet-based therapy, in the presence or absence of various osteoinductive factors [329,330].

Traditionally, MSCs are induced to undergo osteogenesis in vitro by the use of chemical supplements as described earlier (see the "Skeletogenic differentiation of mesenchymal stem cells" section) before in vivo application. Growth factors, such as Wnt family members, are noteworthy as they are well-established signals that can regulate multiple bone−related biology processes [114]. Interestingly, different Wnt family members can exert different roles in MSC osteogenesis. For example, in vitro exposure of MSCs to Wnt3a-conditioned medium or overexpression of ectopic Wnt3a inhibits osteogenesis. This was evidenced by dramatically reduced expression of several osteogenic genes, for example, ALP, bone sialoprotein, and osteocalcin, while Cbfa1/Runx2 expression, an early osteo-inductive transcription factor remained unchanged. These results implied that the Wnt3a-mediated canonical signaling pathway could inhibit but was not sufficient in complete blockage of MSC osteogenesis. On the other hand, Wnt5a, a typical noncanonical Wnt member, has been shown to promote MSC osteogenesis. Since Wnt3a promotes MSC proliferation during early osteogenesis, it is very likely that canonical Wnt signaling functions in the initiation of early osteogenic commitment by increasing the osteoprogenitor reservoir, while noncanonical Wnt drives the progression of osteoprogenitor to mature functional osteoblasts. The exact identity and actions of intracellular mediators of Wnt signaling in regulating MSC osteogenesis remain to be elucidated.

In addition to Wnt family members, their pathway modulators, such as Dickkopf-related protein 1 (DKK1) and Sclerostin (SOST), and other growth factors or osteogenesis molecules, for example, TGF-β, BMP, FGF, IGF, PDGF, Ihh, NEL-like protein 1 (NELL-1), slit guidance ligand 3 (SLIT-3) [331,332], Notch, PTH, and PTHrP, have all been shown to regulate MSCs osteogenesis and may be considered for application in bone tissue engineering.

In order for MSCs to generate a successful bone graft, the cells require 3D biomaterial scaffolds to secure them at the implantation site, provide physical protection, and maintain and direct tissue shape. In MSC-based bone tissue engineering, various biomaterial scaffolds have been evaluated for their potential as cell carriers. These scaffolds may be made from natural or synthetic materials that have been fashioned into structures with different shapes and sizes. In general, natural polymers, such as collagens, contain bioactive domains favorable for biological activities involved in tissue regeneration, whereas synthetic polymers, such as poly(α-hydroxyesters),

feature controllable material properties that can approximate the physical properties of native tissue. Among the materials that have been used in bone tissue engineering, HAP and their derivatives, such as β-TCP, are the most common scaffold materials for osteogenic induction of MSCs. Bioresorbable β-TCP–based scaffolds, compared to HAP-based ones, showed comparable results on ectopic bone formation [333] and, moreover, both synthetic ceramics support osteogenic differentiation more efficaciously than demineralized bone matrix [334]. To improve the affinity of osteoconductive ceramics for cells, HAP has been coated with bioactive peptides [335] or proteins [336], to enhance MSC attachment and osteogenic differentiation. In addition, surface modifications of bone-inductive scaffolds have been developed, such as using cerium oxide nanoparticle [337,338] or miRNA [339] to bioactivate the scaffold interface, to promote bone formation by MSCs and enhance angiogenesis.

Composite scaffolds, composed of multiple materials, are expected to be physically and biologically superior to single material–based scaffolds, as the properties of a composite may be programmatically varied by mixing different materials in various ratios. Both the composition and the relative ratio of the constituent materials can affect bone formation. HA has been used as a primary material combined with other materials such as TCP [340], poly-lactic-*co*-glycolic acid (PLGA) [341], and chitin [342] to produce various composite scaffolds. It was reported that scaffolds with different ratios of HA/TCP loaded with MSCs showed different extents of bone formation in vivo. Composites in which the HA/TCP ratio was designed to coordinate scaffold degradation with tissue deposition seemed optimal in promoting the greatest ectopic bone formation [343].

Finally, growth factors, cytokines, and other nonproteinaceous chemical factors are critical for osteogenic differentiation of MSCs. To successfully augment bone formation, it is necessary to continuously introduce osteoinductive molecules, most of which have a short half-life, in a spatially and temporarily controlled manner into the cell culture or the defect site. One strategy for enhancing bone formation is to use biomaterial scaffolds both as a cell carrier and a reservoir for the release of growth factors in a controllable manner. BMP2 is the most efficacious growth factor among the BMP family members and has been incorporated in various forms of biomaterial scaffolds to induce osteogenesis in ex vivo cultures [344], or to stimulate bone formation in vivo [345], as well as in clinical applications (e.g., INFUSE Bone Graft/LT-CAGE Lumbar Tapered Fusion Device, Medtronic). For example, Zhao et al. employed microfluidic technology to encapsulate bone marrow–derived MSCs and growth factors within injectable, photocrosslinkable gelatin methacrylate (GelMA) microspheres, producing a combination of MSCs, BMP2, and scaffold as a unit construct, resulting in increased bone mineralization and osteogenesis [346]. Another approach recently developed in our laboratory is to combine MSCs and BMP2 gene-based therapy approaches, delivered in a photocrosslinkable hydrogel scaffold, to enhance bone formation in vivo [347–349].

More importantly, in view of the considerable self-healing ability of bone, namely, that bone defects have an inherent regenerative capability, the more challenging current clinical need is to enhance bone remodeling and regeneration under various chronic disease conditions, such as osteoporosis or osteonecrosis. The mechanisms and feasibility of tissue regeneration for these bone diseases are under intensive investigation. For example, the microenvironment of inflammation and related reactive oxygen species production have been shown as essential for the biological activities of tissue-engineered grafts, which can be regulated by chemical compounds [350–352]. Proinflammatory cytokines produced by host cells can affect the results of musculoskeletal tissue engineering, especially under specific pathological conditions such as tumor [353]. In MSC-based bone tissue engineering, osteoclasts from the myeloid lineage are also active participants, in processes mediated by small RNAs and hormones [354,355]. Recent work by Lai et al. showed a promising way to use a 3D printed PLGA/TCP scaffold in combination with the bioactive molecule, Icariin, that can increase bone regeneration under the challenging condition of osteonecrosis [356].

Osteochondral tissue engineering

Severe joint defects often extend to damage or destruction of subchondral bone, leading to associated pain and mechanical instability of the joint. Clinical results show that, even for a partial thickness cartilage defect, there are beneficial effects in exposing subchondral bone by drilling, as well as the incorporation of a bone layer as an anchor to securely integrate grafts with host tissue. Osteochondral grafts or plugs are used clinically in the treatment of both chondral and osteochondral defects. However, poor integration of allograft with host tissue leads to eventual graft failure. Although a variety of methods, such as pulse lavage, have been proposed to remove allogenic bone marrow to decrease immunogenicity and facilitate host–graft integration; the results have been less than promising and better techniques for processing osteochondral allograft plugs are required [357].

Tissue engineering offers a promising alternative to autologous osteochondral grafts through the combination of biocompatible materials possessing widely varying physical properties with the multilineage differentiation potential of MSCs. Chondrogenesis and osteogenesis of

MSCs require different biophysical and biochemical cues from matrices and soluble growth factors/cytokines, respectively. A commonly used approach is to fabricate cartilage and bone independently before integrating those using sutures or glues. MSCs loaded into a hyaluronan or a TCP ceramic scaffold were separately induced to undergo chondrogenic or osteogenic differentiation, respectively. Subsequently, these two components were integrated together with fibrin sealant, becoming a single unit of an osteochondral construct [358,359]. One drawback with this method is the less-than-optimal integration between the chondral and bone constructs; poor integration leads to uneven cell distribution at the interface and/or the possibility of eventual separation of the two components.

Several groups have reported different alternatives to improve interface integration. In one approach, MSCs after in vitro chondrogenic or osteogenic differentiation were loaded into two separate PEG hydrogel layers before the cell-loaded PEG gels were photopolymerized together. Since the two components polymerized together, the osteochondral construct exhibited a less defined gap-line [360]. Another approach was to apply a press-coating process [361] to fabricate osteochondral constructs. Specifically, a PLA scaffold was pressed into a high-density pellet of chondrogenically induced MSCs then seeded at the opposite end with osteogenically differentiated MSCs. Macroscopically, the osteochondral composite consisted of a cartilage-like layer adherent to, and overlying, a dense bone-like component [362]. Since both cartilage and bone were produced in a single unit, no gap developed between the two tissues; instead, an interface resembling the native osteochondral junction was observed. Recent attempts have included the combination of MSCs encapsulated in microbeads of collagen type I, separately induced into osteogenic and chondrogenic lineages, with an interface consisting of undifferentiated MSCs, which resulted in a trilaminar osteochondral construct with an interzonal "tidemark"-like structure reminiscent of native interfacial tissue [363].

The ideal scenario for the fabrication of biphasic osteochondral constructs would be to differentiate MSCs cultured in a single unit scaffold into chondrocytes on the top and osteoblasts on the bottom. To this end the biomaterial scaffold should chemically and structurally support both chondrogenesis and osteogenesis. Nanofibrous scaffolds morphologically resembling natural ECMs have been shown to successfully support both chondro- and osteo-genesis of MSCs in vitro [364,365]. In addition, for in vivo applications, growth factors such as SDF-1 may be incorporated into the scaffolds to facilitate local stem cell homing and tissue regeneration [366].

Another need for achieving this goal is a culture system in which an MSC-laden construct can differentiate into cartilage and bone simultaneously. A double-chamber bioreactor with a unique two-compartment design allowing the storage and delivery of different media was used to culture osteochondral constructs [326,367,368]. With this double-chamber bioreactor, it would be feasible to engineer an autologous osteochondral graft using MSC-embedded biomaterial scaffolds. In addition to producing an integrated, biphasic graft with osteochondral-like composition and architecture, an additional requirement is to achieve adequate load-bearing properties to restore joint function and movement.

Subchondral bone reconstruction is critical in providing supportive structure for the repair of osteochondral defects [369]. Given the native mechanically demanding requirements, there are few if any grafts that exhibit adequate tensile and compressive properties capable of withstanding the high loads in the articular joint. Recent advances in biomaterials have shown potential in addressing this issue with the advent of a 3D-printable, biohybrid scaffold comprising supramolecular hydrogen bonding strengthened hydrogel comprising methacrylated gelatin and poly(*N*-acryloyl 2-glycine) [370]. Recently, other photocrosslinkable, biocompatible polymeric scaffolds have also been used to fabricate constructs with excellent mechanical properties that are comparable to those of native cartilage, including poly-D,L-lactic acid/PEG/poly-D,L-lactic acid [123], which may be bioactivated with the incorporation of hyaluronic acid to enhance chondrogenesis [323]. Applications of such scaffolds that possess biomimetic and adequate mechanical properties are expected to achieve better clinical outcomes.

Engineering other skeletal tissues with mesenchymal stem cells

MSCs may also be applied for the repair of a number of other musculoskeletal tissues besides bone and cartilage. There have been studies on the use of MSCs and tissue specific stem/progenitor cells in tendon/ligament, meniscus, muscle, and nerve repair. MSCs derived from different tissues display generally similar phenotypes but also different phenotypic and differentiation capabilities, partly attributable to their shared developmental origins [371] as well as the natural presence of multipotent MSC variants within these target tissues [25,372] or from neighboring tissues [373].

Tendon/ligament

In tendon/ligament repair (see Fig. 49.4, overview of tendon structure), early studies showed that rabbit MSCs contract collagen type I carrier gels and that the delivery of these constructs to patellar and Achilles tendon defects improved the biomechanical properties of the repair tissue

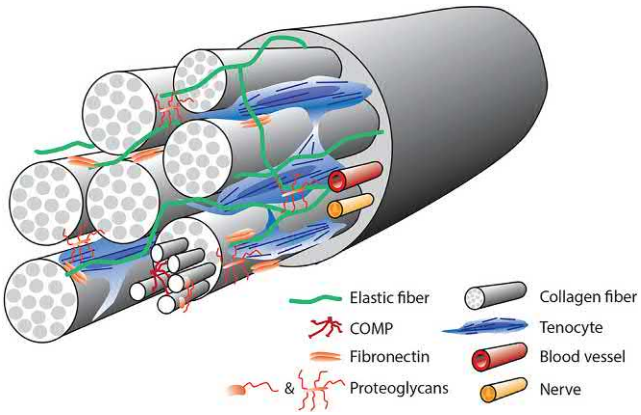

FIGURE 49.4 Overview of tendon tissue architecture. Tenocytes reside between collagen fibers and deposit extracellular matrix proteins into the microenvironment. The proteoglycans, decorin, biglycan, fibromodulin, and lumican, are involved in collagen fibrillogenesis and stem cell niche maintenance. Besides proteoglycans, other types of glycoproteins are also important constituents of tendon for cell adhesion and structural integrity, such as fibronectin, COMP, and lubricin. The collagen fibers are wrapped by a layer of connective tissue known as endotenon that contains blood vessels, lymphatics, and nerves. *COMP*, Cartilage oligomeric matrix protein. *Adapted with permission from [374] Rothrauff BB, Yang G, Tuan RS. Tendon resident cells—functions and features. In: Gomes ME, Reis RL, Rodrigues MT, editors. Tendon regeneration: Understanding tissue physiology and development to engineer functional substitutes. Academic Press (Elsevier), 2015. Chapter 2, pp. 41–76.*

as compared to acellular controls [375]. Newly emerging silk scaffolds that have been modified with RGD moieties and/or formed into nanofibrous scaffolds may also prove useful for tendon/ligament tissue engineering with MSCs [376]. Hybrid scaffolds consisting of silk and bFGF-releasing PLGA stimulated MSC proliferation and increased expression of tendon specific markers [377]. Using SDF-1 releasing collagen–silk scaffold, in combination with intra-articular injection of ligament-derived stem/progenitor cells, can enhance both anterior cruciate ligament (ACL) regeneration and bone–ligament–bone healing in rabbit models [378]. Studies applying tensional and torsional mechanical stimulations to MSC-seeded collagen gels in vitro have shown enhanced tenogenesis [379]. Adipose-derived MSCs have also recently been used for enthesis healing after the repair of acute and chronic massive rotator cuff tears in rats [380]. These studies suggest a potential role for MSCs in regenerative applications for tendon and ligament defects, particularly with the modulation of the mechanical loading environment. MSCs have also been applied to replicate the hierarchical, multitissue transition features in injured tendon/ligament tissues [381]. As tendon/ligament injuries are typically localized to the bone-tendon/ligament interface, there have been multiple reports on the fabrication of fibrous scaffolds with a mineral gradient to mimic features found in native entheseal tissue [382,383]. In such applications, MSCs have demonstrated promise for tendon/ligament repair, where fibrous scaffolds and mineral composition are found to induce adipose-derived MSC alignment and matrix mineralization, respectively, via topographical and biochemical cues [383]. Finally, an urea-solubilized extract of bovine Achilles tendon has recently been shown to exhibit strong protenogenic effect on human MSCs [384,385] and has been incorporated into a composite gelatin and electrospun-aligned PCL nanofibrous scaffold for tendon/ligament tissue engineering [386,387]. More details regarding cellular therapy in enthesis tissue repair can be found in a recent review article [381].

Meniscus

The meniscus is the most commonly injured structure in the human knee. To date, meniscus repair approaches has revolved around surgical techniques and development of meniscus tissue engineering. However, until recently, there have been limited options for partial replacement of meniscus. This is due in part to the fact that, for functional restoration of meniscus, the biomaterial scaffolds need to be mechanically robust to sustain weight bearing and movement, as well as having strong regenerative potential, given that the central portion of meniscus has a poor blood supply that impedes successful graft remodeling and healing [388]. Accordingly, exogenous MSC application has been used to the augment repair of the fibrocartilaginous knee meniscus. Multipotent MSC-like cells have been identified in the meniscus, with some zonal specificity [389]. It has been reported that intra-articular injection of MSCs derived from synovium [390] and meniscus-derived tissue specific stem/progenitor cells [391] (absent a tissue engineering delivery vehicle) can have an ameliorating effect on meniscus defect–induced joint degeneration. Recent studies combining MSCs with cartilage-promoting agents, such as growth factors and tissue-derived ECMs, have shown promising healing outcomes in meniscus repair [392–397]. It is noteworthy that, compared to classic growth factor-based approach, the use of tissue-derived ECM takes advantage of their natural, tissue- and region-specific bioactivity on progenitor cells [394,397]. Given that knee meniscus exhibit region-specific compositional and healing differences, an ECM-based approach is likely to bring more precise, efficacious treatment for meniscus repair. In addition to combining with various cartilage-promoting agents, MSCs are seeded on various types of scaffolds and implanted into meniscal defects. These scaffolds included devitalized meniscal allografts [398] fibrin glue [399], hyaluronan/gelatin [400] hyaluronan/collagen [401] composite matrices, and kartogenin with platelet-rich plasma gel [392].

A collagen-based meniscus implant (also known as Menaflex) has shown promising results in Europe and is available in the United States as the only approved collagen scaffold for segmental augmentation for the medial meniscus after overcoming regulatory hurdles [402]. Recent studies combining MSCs with cartilage-promoting agents, such as growth factors and tissue-derived ECMs, in combination with appropriate biomaterial scaffolds, have shown promising healing outcomes in meniscal repair [392–397]. Clearly, MSCs can play a role in the reparative process of the meniscus, although the mode of their administration and the nature of the carrier materials require further optimization.

Gene therapy in musculoskeletal tissue engineering

Gene therapy is a promising technique for disease treatment, in which genetically modified cells are transferred into or generated within individuals for therapeutic purpose. The cells with modified genes can be induced to differentiate into desired cell types or produce proteins needed for tissue repair. Although safety issues still remain, a likely future scenario is the combination of gene therapy, cell therapy, and tissue engineering for the treatment of musculoskeletal diseases.

There are two strategies that are currently used in gene therapy, viral transduction and nonviral transfection, and both strategies can be conducted in vivo and ex vivo [403]. In vivo gene therapy is simple but often lacks controlled tracking of the gene-modified cells and target site specificity. An attractive alternative is to combine gene therapy with tissue-engineering approaches to transduce or transfect cells of interest ex vivo and then use a carrier or scaffold to deliver these genetically modified cells to the target site. This approach offers the advantages of flexibility of target cell type and retainment of gene-modified cells at the site of interest. Gene transduction using viral vectors, such as retrovirus, adenovirus, and lentivirus, effectively modifies the host chromosome but raises concerns about mutagenesis and possible immune reactions. In contrast a nonviral approach is safer but the efficiency of transduction is lower. More research efforts are needed to overcome the limitations associated with each approach. The ultimate goal is to develop a simple, safe, and effective means to transfer genes into cells of interest.

Currently, the most frequently applied example of gene therapy in bone and cartilage tissue engineering is the transduction/transfection of MSCs with BMP genes. BMPs play important roles in the regulation of osteogenic differentiation of MSCs and the production of bone matrix during bone formation. To overcome the short half-life of growth factors, MSCs are transduced or transfected with BMP genes for continuous protein expression in vitro and in vivo. BMP2-transduced MSCs were induced to differentiate into osteoblasts producing bone matrix and synthesize BMP2, thus attracting host cells to migrate and differentiate. Compared to control MSCs, the BMP2-producing MSCs effectively enhance bone formation, even at large defect sites such as segmental femoral defects [404]. Similar results have also been reported when BMP2 or BMP4-transduced MSCs were delivered to bone defects using different biomaterial scaffolds, such as demineralized bone matrix [404], gelatin [405], β-TCP [406], and calcium phosphate cement [407]. Currently, several research groups are testing the effects of overexpressing a combination of factors such as BMP with VEGF, a potent inducer of angiogenesis [408]. The potential benefits of cartilage repair using gene therapy are also gaining recognition. For example, BMP7-transduced MSCs delivered by PGA scaffolds successfully regenerated cartilage, whereas the control nontransduced group did poorly [409], and BMP4 transduction induced chondrogenesis and enhanced cartilage repair [410]. In our recent work, we have successfully demonstrated the utility of activating an MSC-embedded PLLA scaffold with AAV-BMP2 gene construct, resulting in gene transduction of cells in situ and concomitant BMP2 production, to achieve enhanced osteogenesis in vitro and bone formation in vivo, which represents a new delivery strategy for combined gene and cell-based therapy [347–349].

Conclusion and future perspectives

Due to their ease of isolation, their capacity for undergoing in vitro proliferation to achieve a large number of cells for cell therapy, their ability to undergo lineage specific differentiation into musculoskeletal cells, and their potential immunomodulatory advantages, MSCs present significant potential in musculoskeletal skeletal tissue engineering, which promises to bring hope to patients and surgeons alike for the generation of functional tissue substitutes. As discussed in this chapter, MSCs have been used in tissue engineering of a number of musculoskeletal tissues, including cartilage, bone, osteochondral constructs, ligament, and tendon. Currently, tissue-engineered constructs and biologics have not been readily accepted for clinical use to treat musculoskeletal tissue defects [411,412]. There clearly is a need for further research that combines concerted efforts of biologists, engineers, and clinicians. Critical to the success of these approaches is a better understanding of MSC biology. So far, there has not been a marker that can be used to unequivocally identify and prospectively select MSCs from diverse tissues. The various growth factors, signaling pathways, and transcription factors that regulate phenotype transition, that is,

uncommitted versus differentiated phenotype, remain to be identified and studied. The ultimate fate of the implanted cells also needs to be ascertained. In addition, the microenvironmental conditions that optimally allow MSCs to differentiate completely and stably into a desirable lineage require further elucidation. Despite our incomplete understanding of MSC biology, their use in musculoskeletal tissue engineering is of high potential. Current and future efforts in this area should focus on the fabrication of optimized scaffolds, systematic studies of the interplay of MSCs, scaffold and environmental factors, and the development of quantitative outcome measurements, both in vitro and in vivo, for tissue-engineered constructs. Ultimately, in vivo, functional testing serves as the gold standard to assess the long-term utility of the engineered constructs and warrants much greater attention [412]. The immunosuppressive and antiinflammatory effects of MSCs present a potentially powerful biological target for their use in allogeneic transplantation in the inflammatory environment of an injury site. With further research and development the use of MSCs in tissue engineering is expected to bring to fruition the generation of functional tissue substitutes, either in situ or suitable for implantation to improve the quality of life of patients with debilitating musculoskeletal injuries.

Acknowledgments

We acknowledge Drs. Faye H. Chen, Lin Song, Robert L. Mauck, Peter G. Alexander, and Heidi R. Zupanc, and Ms. Karen L. Clark for their contribution to the previous version of this chapter. This work is supported in part by grants from The Chinese University of Hong Kong.

Introduction

Medical advances have led to a welcome increase in life expectancy. Indeed, by 2020, 20% of the population will be over 65. However, this progress presents its own new challenges: increases in age-related diseases, associated reductions in quality of life, and attendant substantial socioeconomic cost [1]. Fractures alone cost the European economy €17 billion and the US economy $20 billion annually. In the United States, there are some 8 million bone fractures per year, of which approximately 5%–10% are associated with delayed healing or nonunion. Furthermore, it is predicted that the number of hip fractures worldwide will increase from 1.7 million in 1990 to 6.3 million in 2050 emphasizing the importance of enhanced knowledge around skeletal reparative approaches for bone. Thus there is now an urgent unmet need to develop robust regenerative strategies to enhance bone loss and improve quality of life. Recent advances in the isolation of the human skeletal stem cell confirm the skeletal stem cell confer to bone its innate capacity for regeneration, repair, and remodeling in response to mechanical stimuli and regeneration upon damage providing, alongside skeletal development, a natural paradigm informing tissue engineering strategies. Bone regeneration strategies seek to harness and enhance this reparative capacity for skeletal tissue replacement lost as a consequence of aging, disease, or trauma. Critical in the development of approaches to repair skeletal tissue is an understanding of the skeletal cell, skeletal cell function, growth factor interaction, and the appropriate development of biomimetic scaffolds that incorporate/deliver growth factors/biological cues together with mechanical cues to aid formation (Fig. 50.1).

Bone tissue engineering could potentially offer an effective, personalized therapeutic option with a reduced risk of disease transmission, infection and immunogenicity, and limitless availability. Although the complex processes that drive and regulate the reparative capacity of bone have yet to be fully elucidated, current approaches seek to facilitate bone reparation by providing a suitably conducive microenvironment that does not interfere with, while synergistically accelerates, native regenerative processes. While this rationale may appear simple, it has proven to be extremely difficult to execute, evidenced by limited clinical translation. This review details current development in skeletal cells, scaffold development, and preclinical models for bone tissue formation. Finally, we review current regenerative strategies to augment bone formation in a range of orthopedic applications and the challenges and opportunities that present.

Skeletal stem cells

Adult bone marrow (BM) contains a small population of nonhematopoietic stroma–derived stem cells, which exhibit extensive proliferation and multilineage differentiation potential. These multipotent progenitor cells referred to as skeletal stem cells, or more commonly mesenchymal stem cells (MSCs), are capable of differentiating into osteoblasts, chondrocytes, and adipocytes (reviewed in Ref. [1,2]). Regenerative strategies for skeletal tissue seek to harness and enhance the reparative capacity of the skeletal stem cell for skeletal tissue replacement damaged or lost through congenital defects, trauma, and as a consequence of aging. The multipotent, self-renewing stem, and progenitor stem cell of BM stroma are widely

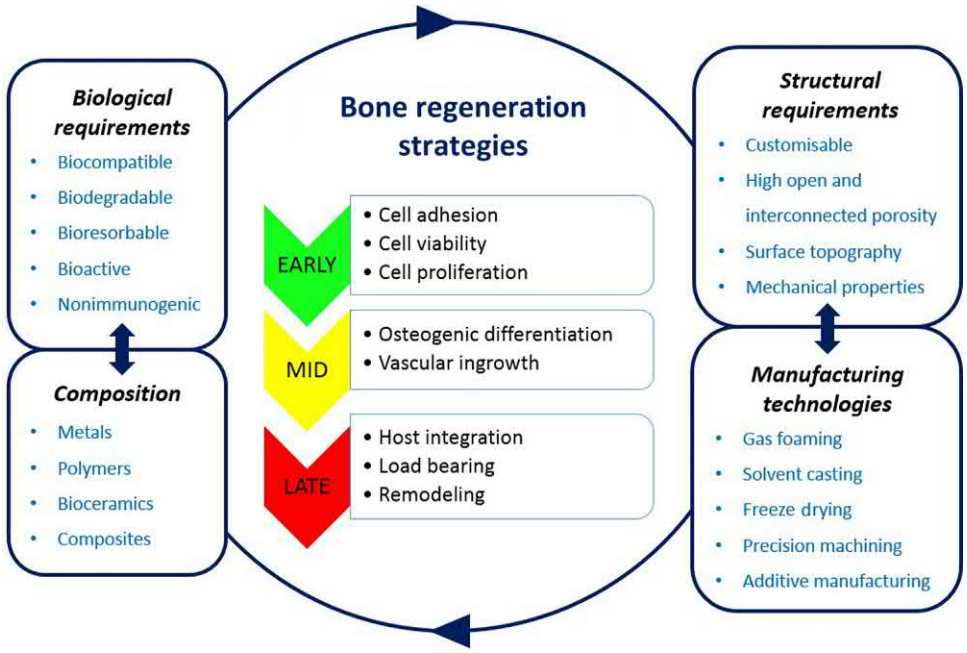

FIGURE 50.1 Interlinked factors in contemporary bone regeneration.

referred to as MSCs (a term originally coined by Caplan in 1991 and extensively used in the literature), mesenchymal stromal cell, as well as medicinal signaling cell, indicating the degree of uncertainty over the in vivo identity, phenotype, function, and clinical utility of cells typically designated as MSCs. Critically, "skeletal stem cells" was introduced by Bianco and Robey to denote, specifically, MSCs from BM stromal tissue that confers to bone its innate capacity for regeneration, repair, and remodeling (reviewed in Refs. [1–3]). The International Society for Cell Therapy proposed a minimal definition for multipotent "mesenchymal stromal cells" as (1) CD73, CD90, and CD150 positive; (2) CD11b, CD14, CD19, CD34, CD45, and HLA-DR negative; and (3) possess the capacity to differentiate into osteoblasts, chondrocytes, and adipocytes under in vitro stimulation [4]. However, in vitro assays of differentiation potential are themselves poorly predictive of in vivo function, either following transplantation or, more critically, in native tissues during turnover, and following injury. Seminal work by Alexander Friedenstein confirmed the presence of a bone-forming stem cell (1–10 per 100,000 nucleated cells), in the form of fibroblast-like clonogenic cells [colony-forming unit-fibroblastic (CFU-F)] tissue culture plastic adherent, non-hematopoietic fraction in BM. The progeny from the CFU-F generated bone and cartilage tissue following transplantation in diffusion chambers and, critically, a full ectopic BM organ when implanted on an open calcium phosphate scaffold [5,6] (reviewed in Ref. [1]). More recently, lineage tracing studies in mice have informed our knowledge on the role and potential of the skeletal stem cell for bone regeneration, with indication of a hierarchy of skeletal progenitors with defined surface phenotypes important in bone turnover and repair [7,8]. Thus Chan et al. demonstrated using ectopic transplantation assays, a defined lineage profile of skeletal stem and progenitor cells with osteo-, chondral-, and stromal-potentialities characterized by variation in expression of CD200, CD105, Thy, and 5C3 surface markers. Importantly, a similar developmental hierarchy of skeletal progenitors was also confirmed by the same authors to be present in humans [9]. Single-cell transcriptome analysis of the growth plate and diaphysis of human fetal femurs indicated that differential expression of a number of markers (PDPN, CD146, CD73, and CD164) on tissue formation evaluation form clonal populations revealed a developmental hierarchy of skeletal stem and skeletal progenitors. Chan et al. demonstrated that SSCs (Skeletal Stem Cells) ($PDPN^+$ $CD146^-$ $CD73^+$ $CD164^+$) gave rise to an early bone, cartilage, and stromal progenitor ($PDPN^+$ $CD146^+$), which in turn transitioned into osteo/stromal progenitors ($PDPN^-$ $CD146^+$) or chondroprogenitors ($PDPN^+$ $CD146^-$ $CD73/CD164^-$) prior to any tissue-specific terminal differentiation although these cells do not differentiate into adipocytes [9].

These rigorous in vivo studies have important implications for bone regeneration and bone fracture repair, providing evidence for the existence of spatially and temporally discrete pools of skeletal stem/progenitor populations within bone, involved in development and holding distinct physiological roles. Indeed, the recent identification of a $CD200^+$ $CD105^-$ periosteal stem cell

present in the long bones and calvarium of mice [10,11] distinct from the endosteal skeletal stem cell provides further insight into the repertoire of discrete skeletal progenitor pools. The authors observed periosteal stem cells displayed self-renewal and the ability to give rise to a hierarchy of progeny—including cartilage following injury and the potential to form bone ossicles following subrenal transplantation via direct intramembranous bone formation in the absence of cartilage formation or hematopoietic cell recruitment. Harnessing discrete appropriate skeletal cohorts has important implications for not only our understanding of bone function but the harnessing of appropriate skeletal fractions for intramembranous and endochondral bone repair.

The complexity that resides in dissecting out and understanding the requisite skeletal cohorts to employ in reparative bone strategies is perhaps reflected in the ongoing challenge of identifying a therapeutic effect following translational MSC transplantation studies with MSC grafting and a focus on paracrine or immunomodulatory mechanisms (independent of stem cell or tissue progenitor function). A wealth of data has emerged on the pleotropic effects of SSCs on cells of the immune system [12]. The phenotype of SSCs has been widely described as Major Histocompatibility Complex (MHC) Class I+, MHC Class II−, CD40−, CD80−, and CD86−. Although MHC Class I molecules have the potential to activate alloreactive T cells, the absence of CD80 and CD86, responsible for providing costimulatory signals necessary for T-cell activation and survival, would leave the T cells anergic. Macrophages are key players of the innate immune system in initiating and controlling inflammation, and SSCs can influence macrophage function depending upon the inflammatory context. Monocytes arriving at an inflammatory environment can develop into activated macrophages, which produce proinflammatory cytokines such as tumor necrosis factor alpha (TNF-α) and interferon gamma (IFN-γ). The resulting proinflammatory microenvironment activates SSCs to adopt an immunesuppressive phenotype and release mediators, which skew the differentiation of monocytes toward antiinflammatory macrophages that secrete high levels of interleukin (IL)-10, transforming growth factor-β1, and low levels of cytokines (TNF-α, IFN-γ, IL-1, IL-6), and aid tissue regeneration following inflammation. The regulatory effects of SSCs on immune and inflammatory cells will necessitate defined rigorous in vivo systems on the immunogenicity and immunomodulatory capacity of SSCs in specific pathophysiologic models. This will inform the full therapeutic potential of these cells.

Given osteoblasts are needed to make bone, the cell source employed in the cell reparative paradigm is as crucial as the choice of biomaterial (see Table 50.2). Incorporation of skeletal populations into bone tissue engineering has been a key advancement. BM-derived stem cells are the most frequently utilized stem cell source, given the wealth of information available and their ease of acquisition [1,3]. Adipose tissue-derived stem cells have been proposed as a viable alternative, given their reported osteogenic ability in vitro, ease of acquisition, abundance, and ability to survive low oxygen or glucose environments [13]. Such resilience is advantageous, particularly when the blood supply is limited. Recently, there has been an interest in using oral cavity MSCs and induced human pluripotent stem cells in bone tissue engineering [13,14] (Table 50.1).

Fracture repair—the (limited) self-reparative capacity of bone

Under optimal conditions, bone can heal completely without the formation of a fibrous scar, such that the regenerated tissue is indistinguishable from its state prior to injury [16]. Impairment in this remodeling process occurs in osteoporosis, which, in turn, results in increased fracture risk, particularly amongst the elderly. Fracture healing is a complex biological process that is intertwined with the innate immune system. Following trauma or damage, bone heals either by the direct intramembranous or indirect pathway. The latter is the most common and comprises of intramembranous and endochondral ossification. Primary fracture healing requires anatomical reduction and rigidly stable conditions, achieved by surgical intervention via open reduction and internal fixation methods, which minimizes the fracture gap and interfragmentary motion. In such conditions, bone is able to heal by direct regeneration of anatomical lamellar bone followed by Haversian systems, without the need for remodeling to occur. When a slightly larger gap exists between bone fragments, gap healing occurs, whereby the voids are filled with direct deposition of intramembranous woven bone. Haversian systems are reestablished through osteoclast-mediated remodeling [17,18]. However, complete rigidity is not possible in most fractures treated by splinting, intramedullary nailing, or external fixation methods. In these scenarios, secondary fracture healing, which involves intramembranous and endochondral ossification, occurs. In fracture repair the fibrin network provides the initial matrix for inflammatory cell influx triggered by platelet-derived factors, local tissue macrophages, complement fragments, as well as signals released from necrotic tissue. Neutrophils arrive within the first 24 hours and recruit macrophages and monocytes to the fracture site which, in turn, work together with macrophages resident in the peri- and endosteum to regulate the inflammatory response, a critical stage of secondary fracture healing [18]. Macrophages phagocytose necrotic cells

TABLE 50.1 Cell types used in bone tissue engineering.

Cell type	Multipotent or differentiated	Potential for bone tissue engineering	Advantages	Disadvantages
Bone marrow–derived stem cells	Multipotent	Osteogenic Potential for neovascularization	Relatively easy acquisition Extensively characterized	Donor morbidity Limited proliferative potential Fewer cells compared to other sources Dependent on age and health of donor
Umbilical vein stem cells	Multipotent	Osteogenic	High proliferation Minimal donor morbidity	Not extensively characterized
Oral cavity MSCs (dental pulp, gingival stem cells)	Multipotent	Osteogenic	Abundant Easy acquisition	Not extensively characterized
Adipose-derived stem cells	Multipotent	Osteogenic Potential for neovascularization	Easy acquisition Extensively characterized Able to grow in nonideal conditions	Donor morbidity (due to anesthesia)
EPCs, specifically ECFC	Lineage directed	Potential for neovascularization Supports osteogenic differentiation	Easy acquisition (peripheral blood, umbilical cord blood) Abundant Minimal donor morbidity Can be coseeded with bone marrow–derived stem cells	Not multipotent Limited proliferating potential of early EPCs Differences in isolation and cultivation procedures make comparison studies on EPC functionality difficult Requires coseeded cells for stabilization for neovascularization
Human umbilical vein endothelial cells	Differentiated	Potential for neovascularization	Easy acquisition Can be coseeded with bone marrow–derived stem cells	Not multipotent
Induced human pluripotent stem cells	Multipotent Differentiated	Osteogenic Chondrogenic	Easy acquisition Minimal donor morbidity Patient specific Unlimited self-renewal and higher proliferative capacity than MSCs Relatively established cell reprograming protocols produce lineage-specific cell types from any cell source	Variable cell reprograming efficiency. Protocol optimization still needed Necessary induction into high-quality progenitor cells posttransplantation Risk of tumor formation

and the initial fibrin mesh and secrete chemotactic and inflammatory mediators such as TNF-α, IL-1β, IL-6, and C–C motif chemokine ligand 2, which trigger MSC, local osteoprogenitor cell, and fibroblast recruitment. Stromal cell–derived factor 1 mediates the local and systemic recruitment of MSC, while platelet- and macrophage-derived signals guide the proliferation, differentiation, and extracellular matrix (ECM) synthesis of recruited MSC and osteoprogenitor cells. This enables the removal of the hematoma and cessation of the acute inflammatory response within a week after the initial damage, allowing for the generation of granulation tissue rich in

TABLE 50.2 Comparison of contemporary bioengineered bone scaffold types.

Scaffold type	Advantages	Limitations
Metals (or metal alloys), e.g., titanium, cobalt, nickel, tantalum, stainless steel	Biocompatible Superior mechanical properties which could be useful in situations of slow bone (in)growth Bioactivity can be enhanced by surface modification techniques Established fabrication techniques and already in clinical use	Expensive Stress-shielding Poor biodegradability Potential ion release may cause local and distal toxicities Manufacturing processes unsuitable for biofabrication use
Hydrogels, e.g., collagen, gelatin, alginate, hyaluronic acid, fibrin, poly(ethylene oxide), poly(ethylene glycol)	Generally biocompatible High water content allows for cell encapsulation and growth Controllable mechanical properties and biodegradability Tunable biomolecule release 3D patterning to mimic tissue microarchitecture(s) Multimaterial compositions	Limited physical manipulation Limited mechanical strength. Increasing gel mechanical properties can reduce cell survival and functionality Random cell distribution Time-consuming optimizations required, particularly for bioprinting applications Bioactivity dependent on gel composition and properties
Polymers • Natural, e.g., alginate, gelatin, chitosan, silk • Synthetic, e.g., polycaprolactone, poly-L-(lactic acid), poly(lactic-*co*-glycolic acid)	Low cost Biocompatible Tunable biodegradability Mechanical properties and bioactivity can be controlled by adjusting compositions	Limited mechanical properties Can lack bioactivity Performance and purity affected by manufacturing quality Time-consuming optimizations required, particularly for bioprinting applications, and composites
Bioceramics, e.g., tricalcium phosphate, (nano)hydroxyapatite, biphasic calcium phosphate	Osteoinductive and osteoconductive properties enhance osseointegration Biocompatible, similar to native bone mineral content Ease of manufacturing and delivery, e.g., paste, injectable, bioprintable Low cost	Inherent brittleness limits its mechanical property when used in isolation Uncontrolled degradation and resorption in vivo Unsuitable for cell encapsulation when used in isolation
Bioactive glass, e.g., Bioglass 45S5	Osteoconductive properties enhance osseointegration Biocompatible Tunable bioactivity Already in clinical use	Inherent brittleness limits its mechanical property when used in isolation Limited physical manipulation Poor control of resorption Potential release of toxic ions

proliferating mesenchymal cells and neovasculature embedded within a collagen matrix [17,18].

Disruption to local vasculature with subsequent reactive arteriolar contraction results in a hypoxic environment, particularly in the area adjacent to the fracture gap. This low oxygen tension, together with a degree of micromotion and microenvironmental signals, guide MSC differentiation along the chondrogenic pathway. Chondrocytes produce cartilage, which extends throughout the gap, connecting the ends of the fracture. In conjunction with fibrotic tissues the soft callus provides initial mechanical stability and becomes the scaffold for endochondral bone formation. While this occurs, in areas with improved blood supply and greater stability, new woven bone forms via intramembranous ossification. This begins in the inner layer of the periosteum and advances toward the gap. The woven bone covers the external surface of the soft callus. Chondrocytes in the soft callus hypertrophy and undergo apoptosis, secreting calcium and factors that stimulate vascular ingrowth into the cartilage scaffold-stabilized gap. Increased blood flow is accompanied by osteoprogenitor cell differentiation into osteoblasts and deposition of woven bone onto the cartilage scaffold, creating a hard callus. As the cartilage mineralizes, the mechanical stability of the fracture site increases until the new bone formed is able to support mechanical loads independently. Osteoclasts remove immature woven bone and cartilage matrix, initiating remodeling, which

regenerates the Haversian system. However, the establishment of the normal integrity of bone can take several months to complete [18].

Around 5%−10% of all bone fractures are prone to delayed bone union or progress to a nonunion or pseudoarthrosis [19]. Successful fracture healing is thus dependent on interlinking factors, which affect the mechanical stability of the fracture, the influx of osteogenic and inflammatory cells, growth factors and chemotactic mediators, and adequate vasculature. Underlying pathological conditions and factors such as aging, smoking, diabetes mellitus, and obesity can adversely affect bone healing as well as aging [18,19]. Current therapeutic approaches involve artificial implants that last 15−20 years. Revision surgery in patients who are less medically fit can be fatal. Postoperatively, patients may face the prospect of losing their independence or living with a disability, through loss of function or mobility. These patients might additionally have to endure chronic pain caused by a malfunctioning implant, which could worsen any underlying comorbidities or result in anxiety and/or depression. Given bone is the second most transplanted tissue [20], and increasing aging demographic, there has never been a greater need for new bone reparation approaches (Fig. 50.2).

A framework for bone repair: biomaterial-driven strategies for bone regeneration

Bone tissue engineering scaffolds typically consist of a solid support structure possessing an open and interconnected pore network, while matrices are often hydrogel based. Both forms must possess appropriate biophysicochemical properties (such as mechanical strength, stiffness, biodegradability, and surface chemistry) for tissue formation, as well as having the capability to withstand and respond to mechanical stresses (Fig. 50.1) [22]. In silico and multimodal imaging and tracking approaches are being developed to help identify optimal scaffold design parameters for bone [23−25]. Conventional methods used to fabricate bone tissue engineering scaffolds have (typically) variable abilities in controlling pore size,

geometry and interconnectivity, and upscalability (Fig. 50.1) [26]. Therefore scaffold design and manufacturing techniques are crucial factors that determine the biomechanical efficacy of the scaffold in vivo. These factors are in turn dependent on the properties of the biomaterial(s) to be used. Scaffolds typically consist of a biomaterial made of bioceramics, metal, self-assembly peptides, synthetic, or natural polymers [27,28]. Composite scaffolds are increasingly used to overcome the specific advantages and disadvantages of each type of biomaterial. Several combinations of biomaterials, with and without cells, have been investigated using in vitro and/or in vivo methods for their potential use in bone [20,29].

Different surface modification techniques, such as surface coating, electrochemical deposition, oxidization, or anodization via cathodic pretreatment, can be employed to further enhance the biocompatibility and osteoinductive capability of biomaterials [30]. These postmanufacturing processes alter surface roughness (and thereby, topography) and/or the wettability of the biomaterial(s). However, despite in vitro successes, the number of in vivo studies showing enhanced osseointegration is limited [30]. This is reflected by the paucity of biomaterials that have achieved clinical translation, and with limited efficacy [27]. There remains no clear consensus as to which biomaterial, or combination thereof, scaffold design or manufacturing approach, are optimal for bone regeneration (Table 50.3).

Growth factors: biomimetic-driven strategies for bone regeneration

In vivo, biochemical signals in the form of growth factors, hormones, and/or cytokines are secreted at local injury sites or in areas undergoing bone remodeling, triggering the migration of progenitors and inflammatory cells (as in the case of bony injury) or the activation of osteoblasts and osteoclasts (as with bone remodeling) [31,32]. This allows for the generation of new bone tissue as part of the healing or remodeling process respectively. Inadequate in vivo osseointegration of cell-free scaffolds has seen an increasing trend in the past decade toward the integration of cells and bioactive molecules into bone tissue engineering approaches, through harnessing their innate regenerative properties by the induction of physiological processes These integrated, biomimetic scaffolds have been termed as "smart scaffolds." Recent studies have begun to investigate the efficacy of synthetic peptides rather than growth factors (Table 50.4) [33], as well as the paracrine effect of the secretome of MSC or stromal cells (shuttled

TABLE 50.3 Growth factors currently investigated for bone tissue engineering.

Growth factor	Tissues studied	Observed function
BMP (-2, -7)	Bone, cartilage	Differentiation and migration of osteoblasts, with accelerated bone healing observed
FGF (-1, -2, -18)	Bone, muscle, blood vessel	Migration, proliferation and survival of endothelial cells Increased osteogenic differentiation of MSCs
IGF-1	Bone, cartilage, muscle	Proliferation and differentiation of osteoprogenitor cells
PDGF (-AA, -BB)	Bone, cartilage, blood vessel, muscle	Proliferation, migration, growth of endothelial cells Osteoblast replication in vitro Type 1 collagen synthesis
PTH	Bone	Increased bone formation through osteoblast stimulation with intermittent dosage. Bone resorption if administered continuously
TGF-β3	Bone, cartilage	Proliferation and differentiation of bone-forming cells Enhances hyaline cartilage formation in vivo Antiproliferative to epithelial cells
VEGF	Bone, blood vessel	Enhanced vasculogenesis and angiogenesis but functionality of vasculature dependent on concentration used Reduction or increment in bone formation dependent on concentration when used in combinational delivery with BMP-2

through extracellular vesicles or embedded within ECM molecules) to target osteoinduction, as well as the inflammatory and immunity processes involved in regeneration [34,35].

Different types of biomolecules need different delivery systems to achieve optimal therapeutic effects (Table 50.5 [34]). However, clinical studies typically employ growth factors at supraphysiological doses (mg/mL rather than ng/mL), resulting in adverse effects that include ectopic bone formation, antibody development, and possibly, carcinogenesis [28]. As such, only a few synthetic grafts containing bioactive molecules are commercially available for surgical use in certain countries [27]. There is no consensus as to the appropriate doses of growth factors or biomolecule combinations for bone tissue repair, with a wide range in use [36]. Furthermore, the actual dose of growth factors delivered by constructs in vivo when used in defects remains uncertain [37].

Bone biofabrication

In the past decade, additive manufacturing (AM) techniques have been used to manufacture 3D artificial implants using existing biomaterials in a precise and reproducible manner that is capable of meeting stringent performance criteria for clinical use [30,38]. The utilization of AM in the fabrication of bone tissue engineering constructs has also driven advancements in AM itself [24]. The incorporation of cells into the AM process to create integrated cell–biomaterial–biomolecule constructs is a recent development termed as biofabrication. Such an approach is typically divided into two categories based on the workflow pattern: top-down or bottom-up approach. Table 50.6 summarizes the three most commonly investigated 3D printing methods used for bone biofabrication. As bone tissue requires its composite cells to be at different stages of proliferation, differentiation, and maturation within a multilayered hierarchical structure, the ability to seed cells and biomolecules in 3D space, with a high degree of precision, in a user-controlled manner affords biofabrication an advantage over conventional techniques [24]. AM has been used for the concomitant spatial printing of different cell types on 3D scaffolds to generate complex tissues [39,40]. Another advantage of AM is the ability to incorporate biomolecules within a cellular matrix or within the scaffold itself during the printing process, providing another method for controlled drug delivery and gradient release [41,42]. Central to this approach remains the ability of printed cells to retain their functionality, as well as permitting bone remodeling by external and internal stimuli [43].

Biofabrication enables the generation of a customized 3D construct that is a closer fit to the defect (in comparison to traditional bone grafts), reducing the risk of engraftment or repair failure. Biofabricated bone will, ultimately, eliminate the need for donor bone grafts, allowing patients to have their operations earlier (thereby reducing wait times for surgery while regaining functionality sooner), and with lower physical and psychological morbidity. The risk of rejection of the biofabricated bone tissue is lower with the use of autologous cells compared to allogenic cells or graft. Thus biofabricated bone represents a potentially cost-effective way to treat patients with musculoskeletal defects, in addition to providing a new therapy for patients unable to be treated by conventional means. However, biofabrication is not without its limitations. The choice of biomaterial for biofabrication is currently limited by the AM method employed. AM

TABLE 50.5 Current delivery strategies for biomolecules in bone tissue engineering.

Biomolecule type	Delivery strategy
Nucleic acids, e.g., miRNA, siRNA	Intracellular and intranuclear preprograming
Small molecules, e.g., bisphosphonates	Surface adsorption, sustained release
Growth factor, e.g., BMP-2, VEGF	Surface presentation, controlled release
Endocrine, e.g., PTH, vitamin D_3, estradiol	Time-controlled release
Inorganic biomaterials, e.g., bioceramics, bioglass	Surface adsorption, surface deposition

TABLE 50.6 Advantages and limitations of common 3D printing methods used in bone biofabrication.

3D printing method	Advantages	Limitations
Microextrusion deposition	Good precision and microscale resolution Wide variety of biomaterials Capable of printing physical or compositional gradients, cell and bioactive factor bioprinting Potential for upscalable construct fabrication	Cell survival postbioprinting dependent on bioink properties, printing temperature, and build time Often requires use of support materials to fabricate porous constructs, increasing build time Low-to-moderate cost
Laser-assisted bioprinting	Nanoscale precision and prints at ambient conditions Capable of printing multiple physical or compositional gradients, and simultaneous cell and bioactive factor bioprinting	Remains extremely cost-prohibitive Limited upscalability
Inkjet-based cell printing	Low cost Capable of printing gradients and simultaneous cell and bioactive factor bioprinting, with high cell viability postbioprinting Relatively rapid fabrication	Limited biomaterial choice due to bioink printing requirements Poor resolution Limited upscalability

methods, such as stereolithography, require postprocessing procedures that are cytotoxic, while laser sintering can cause thermodegradation of the biomaterial, resulting in a loss of precise microstructure, which in turn affects material porosity and cell viability [38,44]. This limits the type of AM that can be employed for bone biofabrication purposes. No single biofabrication approach has yet been found to be ideal for bone tissue engineering purposes, with varying process protocols, limited upscalability, and questionable cell viability postbioprinting thus far limiting progress in the field [24].

Development of vascular bone

Bone is a metabolically active tissue supplied by an intraosseous vasculature with osteocytes located no greater than 100 μm from an intact capillary [45]. Thus a key issue to be addressed is the generation of a vascularized construct. Critically, complex engineered 3D constructs of clinically relevant size cannot be sustained by diffusion alone, and the development of a functional vascular network is necessary for ensuring a nutrient supply and equally important, waste removal, throughout the construct [46]. The integrated blood vessels within the bone matrix act as a regulator of bone integrity with the provision of stem cells, growth factors, and spatiotemporal cues [47]. This is the mainstay of the developing femur, particularly in endochondral bone formation, whereby incursion of blood vessels modulate and control the bone tissue to develop in a coordinated and systematic manner. Recapitulating these series of events will provide skeletal engineers with the tools to address the clinical problems of replacing and regenerating large bone defects. At the molecular and cellular level, the cross communication between vascular cells and skeletal cells (whether they be stem or differentiated osteoblasts) is

significantly effective in directing the cells toward skeletal patterning. Factors that regulate angiogenesis also play a role in bone development and repair. In fracture repair vascular endothelial growth factor (VEGF) activity is fundamental to angiogenesis, stem cell recruitment, callus formation, and endochondral ossification [47]. This tight coupling of osteogenesis and angiogenesis has moderated the direction of tissue engineers to develop models, materials that can mimic both in vitro and in vivo these interactions to develop better strategies to improve nonunion fracture repair.

Functionalization of biomimetic materials whether they be ceramics, polymers, or hydrogels to release angiogenic inducing factors such as VEGF has shown improved bone repair and regeneration [48]. Composite scaffolds designed to release VEGF and bone morphogenetic protein (BMP) 2 via different dynamic release profiles improved bone healing and vascularization when implanted in critical-sized skeletal defects [49,50]. Difficulties in controlling the in vivo release and maintenance of therapeutic activity and the high cost of these growth factors make such strategies less attractive for clinical translation. Alternative strategies that have been investigated include a nanocomposite coating of graphene oxide−copper which was applied to scaffolds of porous calcium phosphate cement. This composite was able to induce bone repair and vascularization when implanted in the rat calvarial defect model [51]. Oliveira et al. [52] were able to improve bone repair and vascularization in a rat condyle defect by the controlled release of Ca^{2+} through the application of an injectable composite comprising of calcium phosphate glass−ceramic with a (hydroxypropyl)methyl cellulose matrix [52].

The use of vascular endothelial progenitor cells (EPCs) has had a significant effect on the neovascularization at bone defect sites [53,54] and when combined with MSCs has significantly improved the osteogenic potential of regenerating bone [55]. Pericytes (which play a role in angiogenesis) and perivascular stromal cells have been implicated as a source of cells capable of bone regeneration [56]. Indeed, Tawonsawatruk et al. [57] showed pericytes derived from adipose tissue improved bone formation when implanted into the site of nonunion bone fracture. The problems associated with the seeding of vascular cells on synthetic composite bone biomaterials are the lack of anastomosis, leakage of primitively formed blood vessels, and cell death due to the slow angiogenic integration of the scaffold. The use of decellularized matrices has tried to circumvent these issues for improving vascularized skeletal repair [58] and was able to demonstrate vascularized bone regeneration by the combination of scaffolds derived from decellularized tendons seeded with human adipose derived stem cells (hADSC)-derived osteogenic cells and human cord blood-derived EPCs [58].

The periosteum is an overlooked but critical part of bone functionality. It has been demonstrated that engineered periosteal tissue can significantly improve bone fracture repair [59,60]. Moreover in an organotypic culture model, placental-derived decellularized blood vessels were employed as a pseudo periosteal sheath improving the repair of bone defects [61]. Lack of specific porosity and tight integration of tissue-engineered scaffolds at the defect site, or in the case of hydrogels, the leakage of gels into the surrounding tissue has been a problem for vascular bone repair strategies. With the development of better technologies such as 3D bioprinting and material design, production has significantly improved to create tailored complex vascular material structures for the engineering of bone tissue [62]. Cui et al. [63] demonstrated an example of this, whereby complex structures can be printed with functionalized porous scaffolds incorporating VEGF and BMP-2 perfused with human umbilical vein endothelial cells (HUVECS) and MSCs [63]. In addition, to provide better integration and minimize cell death in large bone defect/scaffold implants, the engineering of prevascularized scaffold composites can potentially overcome these quandaries. Bioprinting techniques have been used to create complex porous structures with integrated channels and MSCs [64]. These scaffolds could be actively perfused for longer than 6 weeks with osteogenic growth factors. In addition, Klotz was able to develop a multifaceted composite in which endothelial colony-forming cells and MSCs were seeded to a central channel of 600 μm and hydrogel respectively. The self-assembling capillary networks that developed in the osteogenic construct demonstrated the potential prevascularization of large bone scaffold tissues [65]. The potential of these strategies on a large scale was demonstrated by the use of a sheep arteriovenous-loop model to regenerate bone by combining MSCs, BMP-2, and β-tricalcium phosphate-hydroxyapatite [66].

Ongoing developments in bone regenerative strategies, coupled with a better understanding of the interactions between vasculature and bone processes, are necessary toward achieving the clinical translation of engineered bone for the repair of large bone defects, as well as the screening of new biomolecules for use in bone reparation.

Preclinical development—ex vivo/in vivo small and large animal preclinical models

Progressive bone tissue regenerative technology such as 3D bioprinting and material functionalization requires robust successful testing to understand the potential of these complex composites and the interaction of skeletal regenerative cells before translation into the clinical environment. Autologous bone grafting sets the gold standard

for bone defect repair both in preclinical and clinical models. However, there are limitations to the use of autologous and allogenic bone grafting. Alternative bone regenerative strategies have included the direct application of stem cells or skeletal progenitors into bone defect sites, usually in combination with functionalized osteogenic inducing bioscaffolds such as demineralized bone matrix, polymethylmethacrylate, hydrogels, polymers, and ceramic scaffolds [67,68]. In vitro models inform essential ex vivo and in vivo studies into bone regenerative therapies [69,70]. Whereas preclinical models provide the 3D environment, vascularization and immunology gain insights into the potential outcomes of regenerative strategies in repairing and regenerating bone defects. Indeed, bone pathology that arises from many disease processes, for example, nonhealing fractures, osteoporosis, neoplasia, dental tissues, have been replicated in animal models [71−73].

Successful regenerative outcomes of skeletal defects using stem cell therapies in combination with biomimetic scaffolds or hydrogels rely on the material being biocompatible, bioactive, and biodegradable without adverse tissue or toxicity interactions [74]. Hence, the principles of bone regeneration via osteoconduction, osteoinduction, and osteointegration are key. Examples of these biomaterials in preclinical bone repair models include the use of chondroitin-sulfate glycosaminoglycan scaffolds as a delivery vehicle for BMP-2 [75] and a biomaterial-based scaffold (macroporous gelatin−calcium sulfate−hydroxyapatite) with osteoinductive rhBMP-2 and zoledronate to repair a rat tibial defect [76]. Careful examination of biomimetic scaffolds in vivo should be carried out early in the study material development pathway to avoid wasting time and resources pursuing materials that are not viable. For example, collagen-1-based scaffolds have been demonstrated to negatively impact fracture healing by inhibiting mineralization during osteogenic differentiation [77].

Factors to be considered when selecting the animal type for a bioengineering bone defect repair in vivo study include ease of handling and intensity of care, uniformity of breeds, similar biology to humans, lifespan, and speed of healing. Rodent models have many advantages; however, they differ from human bone by the lack of Haversian systems [78]. Depending on the study objective, preclinical rabbit models are used and sheep have become more popular as the large animal model of choice for clinical translation. Mills & Simpson [79] describes the variance in these models for normal healing fracture repair, delayed union, nonunion, segmental defects, and fractures at risk of impaired healing.

"Implantation models" provide the first indications of the biocompatibility and osteogenic induction of materials and stem cells, an essential step in the pathway to clinical translation. The organotypic (avian, rodent) bone culture ex vivo system and the avian chorioallantoic membrane vascular implantation model provide an initial, rapid assessment of the function and biocompatibility of materials and cell constructs for bone regeneration [80]. Implantation models involve siting scaffolds or ECM-like materials with or without adjunctive agents and/or cells into an ectopic site, for example, subcutaneously or into a muscle pouch [81]. Fig. 50.3 depicts the osteogenic development of various manufactured (casted or 3D−printed) scaffolds [Laponite−alginate−methylcellulose (3−3−3)] by microcomputed tomography scanning over an 8-week period when subcutaneously implanted into immunocompromised mice.

Another implantation model includes a calvarial defect model, a nonloading bone defect model that has been employed successfully to assess the osteogenic capacity of biomaterials for bone regeneration. Improved rates of repair in a critical-sized calvarial defect were achieved by the combined implantation of bone marrow stromal cells (BMSCs) and vascular cells [82]. Furthermore, in a rabbit critical-sized calvarial defect model, repair was achieved by a composite hybrid scaffold composed of MSC sheets, hydroxyapatite, and platelet-rich fibrin granules [83]. Lee et al. [84] described a 3D printed kagome-structure scaffold using a rabbit calvarial defect model which enhanced osteoconductivity and was robust when mechanically tested. In a comparative study the tibia and parietal bones were compared showing greater "neobone" formation in the tibia due to a higher vascular input and mechanical load compared to the parietal defects which derive vascularization and osteogenic cells from the dura mater [85].

In vivo spinal fusion models have been employed to develop clinical treatments primarily to augment spinal fusion to increase the success rate of fusion and decrease the need for secondary interventions. Rat models have been successfully used in posterolateral lumbar spinal fusion studies to assess pharmacological agents, gene therapy, and growth factors including BMPs. Studies have found that 10 μg rhBMP-7 added to collagen bone matrix resulted in a clinically solid fusion as early as 3 weeks postoperatively, compared to 3 μg rhBMP-7, which showed new bone formation but no solid fusion mass [86]. Recently, successful bone formation in a rat posterolateral fusion model was achieved with platelet-rich plasma combined in a collagen-mineral scaffold compared to that of platelet-poor plasma or scaffold only groups [87]. Anterior lumbar spinal fusion was modeled in sheep using an rhBMP-2 collagen composite. The rhBMP-2 group was found to be 20% more stiffer and had three times higher histologic fusion rates compared to autograft [88].

Load bearing bone defects in rodents have been the driving force in ascertaining the potential therapeutic

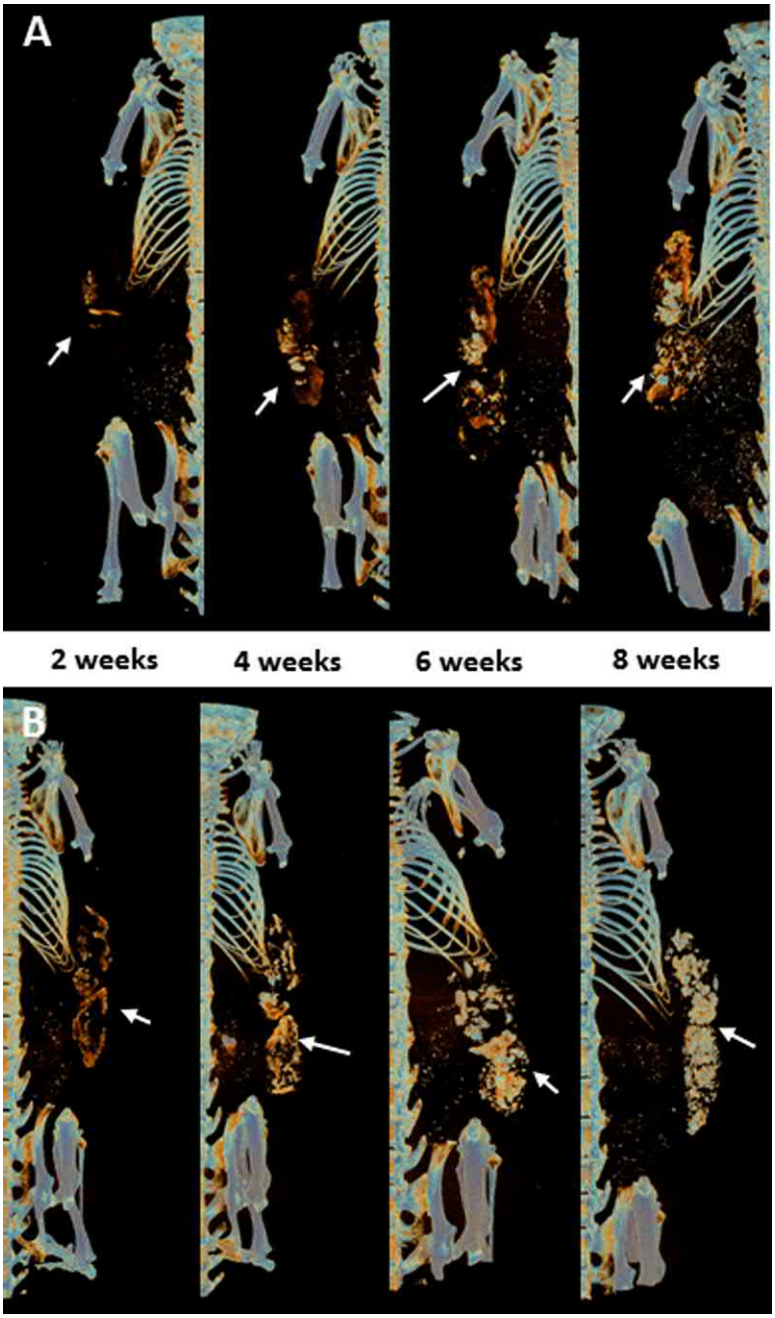

FIGURE 50.3 Sequential micro CT scanned images (2−8 weeks) of subcutaneous implanted scaffolds into an immunocompromised mouse. activity of various composite biomaterials for bone repair. In a unicortical femoral defect model in the rat, significant levels of osteogenesis were achieved by the injection of a hyaluronan hydrogel with encapsulated BMP-2 [89]. In critical-sized bone defects, combinations of vascular cells and skeletal stem cells with functionalized scaffolds have been shown to significantly improve bone repair and vascularization [50,90]. Of relevance, infection of bone defect sites is a critical problem, particularly when implanting artificial prosthesis or biomaterials. Nanosilver−PLGA (poly(lactic-co-glycolic acid) composite BMP-2 scaffolds were found to induce bone formation with significant antibacterial (antimicrobial) properties when implanted into a rat femur defect [91]. However, if

incorporated, antibiotic release from a scaffold should continue until the material is degraded to ensure it does not act as a nidus for infection [92].

Rabbits are often used prior to progressing to larger animals as rabbit bone contains Haversian systems and so replicates large animal models of bone structure. However, they have a higher capacity for increased bone turnover making it difficult to assess healing rates compared to humans [93]. Anand et al. [94] investigated mesoporous bioactive glasses with surfactants in rabbits and found them to be nontoxic, biodegradable, and biocompatible with hexadecyltrimethylammonium bromide and were the most effective material investigated in regenerating new bone. A 3D printed polylactide-*co*-glycolide/tricalcium phosphate composite scaffold incorporating magnesium powder was employed in a rabbit radii segmental defect study and was biocompatible and enhanced bone regeneration [95]. Mini-pig bone (tibial) defects have been successfully regenerated via a two-step therapy by implanting MSCs seeded collagen sponge and injecting microbubbles with BMP-6 plasmid DNA at later time points and activating these molecules by ultrasound [96]. Moreover, microvesicles derived from stem cells containing mediators of paracrine effects can be used to communicate with cells to enhance bone regeneration. Hence, scaffolds with the capability of microvesicle delivery are potential therapies for bone defect repair [97].

For successful clinical translation of bone tissue engineering therapeutic constructs, preclinical models need to replicate the surgical procedure and biomechanical forces that the implanted biomaterials will endure [98]. Sheep are a similar bodyweight to humans with bone dimensions amenable to fixation and biomaterial studies. However, ovine bone slightly differs from human bone with seasonal and age variation [93]. The osteochondral and tibial defect sites in large animals have provided the optimal model to investigate critical sized defect repair [99]. However, in most cases these large models are far from standardized making it difficult to compare differing bone tissue engineering reparative strategies. Autograft, rhBMP-7, and scaffolds (medical-grade polycaprolactone and tricalcium phosphate) with BMSC have been successfully tested in an ovine critical-sized defect model [100]. Moreover, at the site of an iliac crest bone defect, the application of encapsulated MSCs in a composite RGD (Arg-Gly-Asp)-hydrogel of alginate and hyaluronate containing biomineralized polymeric microspheres significantly increased vascularization of the defect site with increased osteoid and bone formation occurring compared to the controls [101]. Many other studies, not included in this section, that have a skeletal pathophysiology are relevant models for investigating regeneration of fractures. For example, there are osteoporotic models whereby MSCs strontium hydroxyapatite engineered scaffolds have induced osteogenesis in a bone defect site [102]. When choosing these models it is worth noting that metaphyseal bone fracture healing differs from diaphyseal bone healing.

In vivo studies are key in translating potential bioengineering treatments to ensure the skeletal regenerative materials are safe, robust, and efficacious for clinical use. It is vital to include positive and negative controls for each experiment such as a novel agent compared to bone graft and a nontreatment control [81]. Pilot studies to determine variation within the model, assess control treatments and allow surgical planning and technique are crucial for in vivo experimental design and statistical power calculations [81]. These steps will help standardize the multitude of bone tissue engineering preclinical models, providing robust comparable data sets between research models and the new bone biomaterials being developed for potential translation to the clinic.

Clinical translation

The current gold standard for stimulation of fracture union or arthrodesis is autograft, while autograft or allograft is commonly used in clinical practice to replace lost bone stock. Autograft is osteoconductive, osteoinductive, and does not provoke an immunogenic reaction, although associated donor site morbidity limits its use. For larger procedures, allograft is the material of choice, but holds significant biological, economical, and practical disadvantages to its application. Thus tissue engineering and regenerative medicine have come to the fore in recent years in an attempt to address the unmet need for skeletal repair and bone augmentation. Tissue engineering approaches were categorized as (1) use of cells, (2) use of tissue inducing substances, and (3) delivery of cells within a matrix [103]. Significant innovation has taken place in the decades since these seminal articles, including the application of nanotopography to modulate in situ cell responses [74]. It is intuitive that different clinical problems such as a fracture nonunion and an osteochondral defect represent distinct biological problems requiring distinct tissue engineering strategies. However, less obvious, but of critical importance is that within a single clinical problem, for example, fracture nonunion, a variety of problems may prevent healing. Thus patient selection is critical to enable successful application of a tissue engineering strategy. For example, atrophic nonunion, exemplified radiographically by poor callus formation represents a failure of bone biology. In contrast, hypertrophic nonunion in which copious callus is observed radiographically represents a failure of mechanical stability. A trophic nonunion would be an appropriate target for a tissue engineering strategy designed to stimulate bone cells, in contrast this would be ineffective in cases of

biologically active hypertropic nonunion. Indeed, the phrase "right patient, right operation, right time" may be adapted in the context of tissue engineering "Right tissue engineering strategy for the right biomechanical problem." In this section, clinical translation of tissue engineering strategies in metabolic bone disease, stimulation of union (post fracture and arthrodesis), bone defects, and osteochondral defects are discussed.

Modulation of in situ cellular activity by denosumab, a monoclonal antibody has been used for the treatment of osteoporosis for many years [104]. More recently an additional monoclonal therapy, burosumab has been approved for the treatment of X-linked hypophosphatemia [105]. Denosumab inhibits resident osteoclasts, while Burosumab increases renal absorption of phosphate via an inhibitory effect on fibroblast growth factor 23. While these treatments are efficacious and novel, they represent isolated manipulation of an in vivo pathway rather than cell selection or application of a cell-laden scaffold. In contrast, BMP, a potent osteoblast stimulator, has been applied within a bovine-derived collagen sponge and used to stimulate fracture healing for many years [106]. However, this treatment has not been widely adopted and subsequent meta-analysis has suggested there is limited evidence to suggest that BMP may be more effective than controls for acute tibial fracture healing. While the evidence for the use of BMP in treating nonunion remains unclear, limited evidence suggests that BMP use may be appropriate in treatment of acute high energy tibial fractures at high risk of nonunion with standard treatment [107]. BMP-2 delivered in a collagen sponge combined within a titanium cage (INFUSE) has been approved since 2002 by the FDA to mediate intervertebral fusion. INFUSE has shown efficacy in randomized controlled trials when compared with iliac crest autograft in mediating spinal fusion. However, a number of significant side effects, including heterotopic ossification, possibly related to the use of supraphysiological doses [108] appear to have precluded more widespread use.

A plethora of synthetic bone graft materials have been produced over the decades to treat both bone loss and stimulate union or arthrodesis. Synthetic bone has been produced using acid-mediated demineralization of bone matrix—resulting in demineralized bone matrix, hydroxyapatite $Ca_5(PO_4)_3OH$, calcium phosphate $Ca_3(PO_4)_2$, calcium sulfate, coral, bioactive glass—and from polymers such as poly(methyl methacrylate) and polylactic acid. In clinical practice, bone graft may be required to fulfill distinct objectives such as regeneration of bone stock, for example, during arthroplasty revision for aseptic loosening; stimulation of healing in nonunion; and provision of mechanical stability in tibial plateau fractures. As such, the optimal characteristics of a bone graft will depend upon the clinical requirements of a particular patient and their fracture or disease. At present, synthetic products lack osteogenicity associated with autograft, and attempts are being made to overcome this problem by combining synthetic graft with autologous BM aspirate.

The pathogenesis of atraumatic osteonecrosis of the femoral head, resulting in bone loss and bone collapse, remains poorly understood and has been associated with a variety of conditions including steroids, alcohol, sickle cell disease, and Caisson disease (diver's disease). Combination of standard therapy (core decompression of the femoral head) with delivery of autologous BM stromal cells failed to show efficacy in a randomized controlled trial [109]. However, it is conceivable that such an approach may show efficacy in a subgroup of patients due to the variation of pathogenesis of osteonecrosis.

Success of arthroplasty in providing pain relief for millions of patients has resulted in ever greater numbers of patients requiring revision arthroplasty procedures. A recent novel approach has been the use of nanotopography on the implant service to modulate the behavior of resident osteoblasts and promote osteointegration of the implant [74], thereby attempting to reduce revision.

Osteochondral defects, commonly seen in the knee and talus, represent a spectrum of disease ranging from localized areas of cartilage loss to more widespread tissue damage. Cartilage loss may result from a known single episode of trauma or from repetitive microtrauma in which joint stability and mechanical alignment may be causative factors. Osteochondral defects can also result from osteochondritis dissecans, the etiology of which remains unknown. Osteochondral defects may result in pain, swelling, and mechanical symptoms such as "catching" or "locking". Treatment of osteochondral defects is extremely challenging as the cartilage is avascular and subject to significant mechanical loading. A current treatment strategy is microfracture or marrow stimulation in which holes are drilled during arthroscopy in the damaged cartilage to induce bleeding from the underlying subchondral bone. However, this procedure if successful results in the generation of fibrous tissue over the defect rather than biomechanically superior native hyaline cartilage. There is a consensus that this approach is not effective in defects larger than 2 cm^2 [110]. In an attempt to improve tissue regeneration, autologous chondrocyte implantation (ACI) was developed. Initially, this was a two-stage process involving isolation of chondrocytes from nonarticular "donor" region, in vitro culture and subsequent implantation. ACI has demonstrated efficacy in the treatment of osteochondral defects, although the long-term effects remain unknown [110]. Requirement for two surgical procedures, harvesting of "donor" cartilage and in vitro culture, represent major limitations of ACI. To overcome these limitations an approach utilizing synthetic hyaluronic acid scaffolds seeded with autologous BM cells

harvested intraoperatively from the iliac crest has been developed (ABICUS). Efficacy of ABICUS compared to microfracture in the treatment of osteochondral defects has been evaluated in a randomized controlled trial the full results of which are eagerly anticipated [111]. Thus while significant progress has been made in translation of bone tissue engineering strategies in the field, major challenges include evaluation of treatments applied to treat injuries classified under broad clinical diagnostic criteria often as a consequence of an absence of the ability to distinguish variations in underlying biological and mechanical pathophysiology and the unresolved need for simple, efficacious strategies to generate, at scale, vascularized constructs.

Summary and future perspectives

Bone regeneration strategies offer new and alternative therapies for orthopedic applications, including nonunion fracture, healing of critical-sized segmental defects, and regeneration of articular cartilage in osteochondral defects. The ready accessibility of skeletal progenitor and stem populations from BM and the ability of these cells to differentiate into bone-forming osteoblasts when implanted in vivo augers well for translational bone tissue engineering. Key challenges remain the need for facile isolation protocols in the absence of specific markers coupled with safe and efficacious delivery systems to ensure skeletal cell phenotype and function. Despite a multitude of biomaterial scaffold products to aid this process, key challenges remain (1) reduced osteogenicity of synthetic graft materials compared to autograft and (2) development of vascularity within the graft material [112]. While synthetic bone graft materials have been produced with porosity optimized for vascular ingrowth and prepared with BM aspirate to optimize osteogenicity, for example, nanOss [113], evaluation of the efficacy of such products is challenging due to the interpatient variation in quality and quantity of BM aspirate and autograft with which the synthetic product is mixed [113]. Interestingly, the use of synthetic engineered bone products in a number of clinical applications, including (1) filling of voids, (2) fracture stabilization, (3) impaction grafting during arthroplasty surgery, and (4) spinal repair, is supported by randomized controlled trials and various proof of concept studies. However, a significant unmet challenge remains the development of cell-loaded, vascularized constructs for application in large segmental bone defects and in cases requiring large scale bone reconstruction. At present the utility of bone tissue engineering strategies is in part limited by our diagnostic capabilities. Advances in imaging and use of biomarkers may permit early identification of fractures which are likely to fail to unite and potentially indicate a particular biological limiting factor. Such information would allow more specific tissue engineering strategies to be deployed, improving safety, efficacy, and affordability in a financially austere environment.

Future developments of tissue engineering will undoubtedly involve lessons from developmental paradigms of musculoskeletal tissue formation, specifically for understanding developmental biology of bone formation, particularly in the adult context of injury and disease.

To provide a step change in the field will necessitate interdisciplinary and multidisciplinary working with the cross fertilization between clinicians and life scientists paramount to aid our understanding of the continuum of skeletal cell development, skeletal niche, skeletal cell plasticity, and skeletal reparation. These are exciting times, bone tissue engineering promises to deliver specifiable replacement tissues, with significant orthopedic application. Although, there remains for many a significant gap in translation to the clinic, the judicious selection of skeletal populations, biomaterial scaffolds, and generation of vascularized skeletal constructs at scale is a goal worth pursuing, not least given the opportunities to improve the quality of life for an aging population demographic.

Acknowledgments

The work in the authors' laboratories was supported by the grants from the BBSRC (BB/G010579 and BB/G006970/1) and MRC (G1000842 and G0802397) and a grant from the UK Regenerative Medicine Platform (MR/R015651/1). We thank Dr. J McEwan for clinical input and Dr. Gianluca Cidonio for the images in Fig. 50.3. The work presented here is based on many useful discussions with past and current members of the Bone and Joint Research Group in Southampton.

Introduction

The intervertebral disk (IVD) is the fibrocartilaginous part of a "three-joint complex" that governs motion, flexibility, and weight-bearing in the spine (Fig. 51.1). As a part of this complex the disk undergoes a lifetime of "wear and tear" that contributes to multiple IVD disorders of enormous consequence for human disability and suffering. These IVD disorders are poorly understood musculoskeletal pathologies characterized by multiple anatomic features, including internal disk disruption, loss of IVD height, IVD tears, IVD dehydration, and the generation of herniated disk fragments [1–3]. These anatomic features may associate with nerve root compression or irritation, spinal canal narrowing (stenosis or spondylolisthesis), or facet joint impingement that contribute to symptoms of low back pain, neurological deficits, and disability that affect between 4% and 33% of the US population annually and have a mean global lifetime prevalence of 38.9% [4–6]. Like most cartilaginous tissues, the IVD is an avascular and a lymphatic structure that exhibits little to no capacity for repair following injury and experiences aging-related cell density losses that may further limit biologically mediated repair [7]. The extreme mechanical demands on the IVD also contribute to tissue failure and degeneration, due to the high magnitudes of compressive, tensile, and shear stresses and strains that result from joint loading, muscle activation, and spinal flexibility. As a result, strategies to intervene in the progression of IVD disorders are met with significant biological and mechanical challenges that frustrate success.

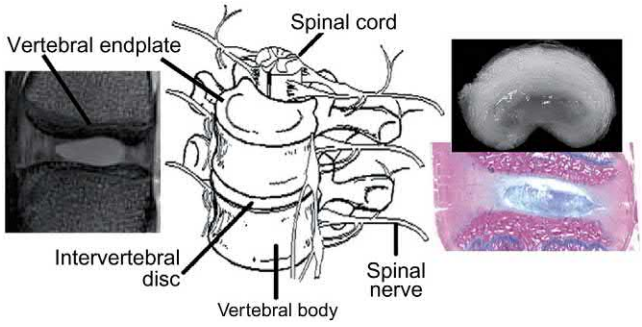

FIGURE 51.1 Schema of spinal motion segment illustrating location of intervertebral disk between superior and inferior vertebral bodies. Image at left MRI appearance of immature lumbar disk with characteristic intense nucleus pulposus region. Images at right illustrate (top) gross appearance of nondegenerate lumbar disk and (bottom) histological appearance of immature disk in a stained section. *MRI*, Magnetic resonance imaging. *Modified schema reprinted with permission from Columbia-Presbyterian Neurosurgery.*

Numerous surgical procedures have been developed to treat IVD disorders, which rely almost completely upon reducing motions across the disk space to restore stability during weight-bearing. A large number of devices have been developed that promote bony fusion processes across the disk space, with less attention being given to mobile-bearing artificial disk replacements and dynamic stabilization devices that allow but limit motions [8]. In cases where the pathology permits, removal of extruded IVD fragments may be performed in a procedure termed as discectomy. Together, these procedures comprise more than 300,000 inpatient hospitalizations annually in the United States alone [9]. The clinical practitioner would not typically entertain the idea of fusing or plating most pathological joints in the body, such as the hip, knee, or shoulder, although this is our 21st century standard of

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00053-8

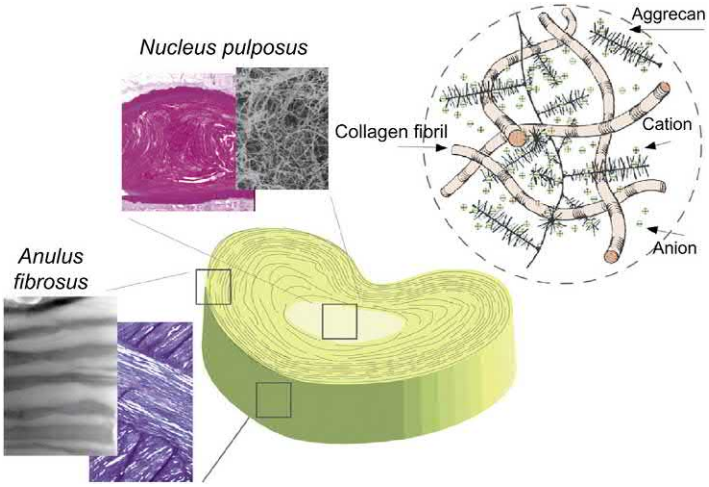

FIGURE 51.2 Schema of different zones and microstructures comprising the intervertebral disk.
Annulus fibrosus insets of macroscopic appearance and stained section illustrate the lamellar structure of the tissue. The lamella comprises aligned collagen fiber bundles that are oriented with alternating angles of ±60 degrees. Nucleus pulposus insets of a stained section and scanning electron micrograph illustrate the randomly organized network of fine collagen fibers and gelatinous nature of the tissue. Circular inset contains a schema of building blocks for these cartilaginous tissues that include banded type I and type II collagen fibrils, aggrecan and smaller proteoglycans, water and multiple ionic species.

care for the pathological IVD. There exists an obvious need to develop alternative strategies to not only treat the consequences of IVD disorders but also to detect and limit the progression of symptomatic IVD pathology.

Success with cellular therapies for articular cartilage regeneration, gene therapy, and in vitro regeneration of cartilaginous tissue has raised hope for tissue-engineered treatments for IVD disorders. Tissue-engineered approaches to IVD regeneration have been focused around implantation of cell-supplemented or acellular biomaterials that may partially or fully replace the IVD structure, as well as delivery of cells or bioactive factors designed to promote the natural repair process. In this chapter a review of these tissue-engineering strategies will be provided along with evaluations of their adaptation and implementation for treatment of IVD disorders.

Intervertebral disk structure and function

In all structures of the IVD the extracellular matrix (ECM) provides physical and biochemical cues that regulate cell-mediated repair or breakdown in mature or aging tissues [10]. The native matrix organization and interaction with the local IVD cell population will be important considerations in the design of any tissue-engineered regeneration strategy. The IVD comprises a centrally situated and gelatinous tissue, the nucleus pulposus (NP), that differs substantially from the more fibrocartilaginous annulus fibrosus (AF), on the radial periphery (Fig. 51.2). On both superior and inferior faces are cartilaginous endplates that provide an intimate mechanical and biophysical connection between the vascularized vertebral bone and the avascular IVD. Both the AF, with a vascularized periphery, and the cartilaginous endplates are believed to be important routes of nutrient transport to all cells of the IVD [11,12]. Given the low cell density of the IVD, maintenance of both cellularity and a generous nutrient supply is often held to be critical to a successful biologically based regenerative strategy.

The immature NP is highly hydrated (>80% water) with ECM components that include randomly organized type II collagen fibers and multiple forms of negatively charged proteoglycans (Table 51.1 [13]). A population of large and highly vacuolated cells is present in the NP during development and growth, with a shift toward a more chondrocyte-like cell population by age 7 [14,15]. Like all IVD regions, the NP contains multiple collagenous and noncollagenous proteins, including types III, V, VI, and IX collagens; elastin, fibronectin; and laminin [16–18]. The NP is largely loaded in compression (Fig. 51.3) and experiences high interstitial swelling and fluid pressures, which arise from joint loading and a high density of osmotically active, proteoglycan-associated negative charges [19,20]. Nachemson showed, as early as the 1960s, that this interstitial fluid pressure is greater than 0.5 MPa (or ~5 times atmospheric pressure) in the NP region [21]. An early loss of hydration or tearing in the NP [3], often detected as a loss of MR signal [22], is believed to contribute to a loss of fluid pressurization in the IVD that may lead to herniation or stenosis with aging [23–25]. With the loss of fluid pressurization the load distribution to the AF will shift from a characteristic outward "bulging" of the annulus to one of inward displacement [26–28]. Partial or complete removal of the NP, occurring in some discectomy procedures, may lead to a loss of disk pressurization and disk height that will transfer loads to facet joints of the spine, increase segmental range of motion, and impact overall spinal stability. Restoration of this interstitial swelling pressure in the NP, or restoration of MR signal intensity, is an oft-cited criterion for the restoration of a healthy functioning disk.

The AF is a lamellar, fibrocartilaginous structure that is highly organized into distinct lamellae of highly oriented and largely type I collagen–containing fiber

TABLE 51.1 **Intervertebral disk (IVD) composition and mechanical properties.**

	Water (wt.%)	Collagen (% dry wt.)	Proteoglycan (% dry wt.)	Other proteins (% dry wt.)	Compressive modulus (MPa)	Shear modulus (MPa)	Tensile modulus (MPa)	Interstitial pressure (MPa)[a]

Ranges reported for compositional features and mechanical properties for nucleus pulposus and annulus fibrosus tissue regions of the nondegenerate IVD. Both composition and mechanical properties of the disk vary substantially with region and with degeneration. Additional mechanical features important to tissue function, such as failure strength, are not shown here.
[a]*Reported also as peak hydrostatic pressures, or swelling pressures.*

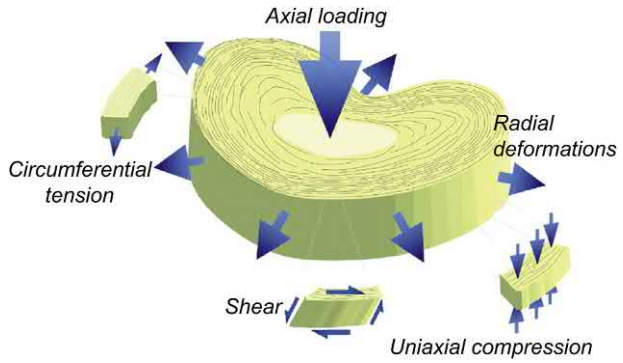

FIGURE 51.3 Axial compressive loading of the intervertebral disk gives rise to a radial deformation, or "outward bulge", as the disk deforms in response to the compressive load.
The high tensile stiffness of the healthy annulus fibrosus in the circumferential direction acts to restrict this outwardly directed deformation. Tissues of the disk will be variably loaded and experience a combination of compression, tension and shear, as shown. Pressurization of the central and gelatinous nucleus pulposus is an important mechanism for load support and load transfer to the annulus fibrosus and contributes to maintenance of disk height.

bundles [29,30]. Type II collagen concentration increases toward the innermost region of the AF, as the concentration of type I collagen is diminished. As with the NP, the AF contains proteoglycans within the collagenous ECM, although at lesser concentrations that vary from outer to inner regions of the tissue. The collagen reinforcement within the AF resists the tensile loads, which arise during physiological joint motions, and the swelling effects, which give rise to significant annular bulging and deformation. Consequently, the AF has a very high stiffness in tension, with moduli that vary with the angle of orientation along the principal collagen fiber direction (Table 56.1 [31–36]). Cells of the AF originate from the mesenchyme and exhibit many characteristics of fibroblasts and chondrocytes [10,37–39]. These cells are sparsely distributed in the mature IVD and exhibit very little intrinsic ability for self-repair. Disorders of the IVD that involve displacement or herniation of an IVD fragment are believed to arise from tears in the AF region, and discectomy procedures frequently involve removing a portion of this annulus tissue. Some tissue-engineering strategies are being developed around the restoration of healthy AF function or composition in part motivated by a need to repair damage subsequent to intradiscal cell or biologics delivery.

The hyaline cartilage endplates of the IVD are important structures that transmit and distribute loads of the spinal column to the disks. Because of their direct contact with both the AF and the NP, the endplates are believed to be an important route of nutrient transport, particularly to cells of the NP [12,40–42]. With aging the cartilage endplate will thin, as it undergoes mineralization and eventual replacement by bone. This mineralization of the endplate is thought to impede diffusion and nutrient flow to the disk, principally the NP that is lacking in an alternate short diffusion pathway. Endplate changes, such as sclerosis, fracture, or modified vascularity, may be detected by magnetic resonance imaging (MRI) changes [43] and are believed to contribute to symptomatic IVD degeneration [44,45]. Thus tissue-engineering strategies that preserve the health of the endplate without inducing additional damage are believed to be critical to restoring IVD function.

Cell-biomaterial constructs for intervertebral disk regeneration

A persistent limitation of acellular, synthetic replacements of the IVD is their biologically mediated or mechanically induced failure due to the harsh loading conditions and bioactivities of cells within the disk space. These challenges are rooted in the fact that the materials used for such applications have no capacity for self-renewal nor self-repair. This has led to increasing interest in tissue-engineering methods to regenerate new IVD in situ or to transplant IVD tissue that has been generated ex vivo. Such strategies have been employed to augment repair of other types of cartilage, most notably articular cartilage and meniscus, which share some features of the harsh biologic and mechanical loading environment within the IVD.

Nucleus pulposus cell-biomaterial implants

As in other cartilage tissue-engineering applications, a main strategy for IVD regeneration has been the inclusion of cells with biomaterials to enable production and long-term maintenance of newly generated tissue. Biomaterials that enable appropriate cellular phenotypes and matrix biosynthesis, and that sometimes enable polymeric degradation or resorption, have been proposed as alternative implantable biomaterials and have been studied largely in vitro. The goals for use of these scaffolds are similar to that for other biomaterial implants, with the additional goals to support native and exogenous cell survival, promote ECM synthesis and remodeling, reduce pathogenic fibrosis, reduce inflammation, and improve spinal stability [46]. Studies of cell-biomaterial constructs cultured in vitro have demonstrated potential for many materials (Table 51.2), including thermosensitive gels such as chitosan, modified chitosans, and elastin-like polypeptides (ELPs) [47–50]; self-associating gels composed of agarose, collagen, and fibrin [51–53]; or modified forms of these same materials, native tissue constructs such as intestinal submucosa [54], crosslinkable alginates, polyethylene glycol, poly(glycolic acids) (PGAs), and more

TABLE 51.2 Representative intervertebral disk (IVD) tissue-engineering studies.

Material	Target tissue	Cell type	Cell density	In vitro/ in vivo	Assessment

[46,55–59]. More recently, decellularized NP tissue and NP cell–derived matrices have been investigated due to their mimicry of the native tissue [60–62]. In vitro studies with the above materials are based on evaluating new matrix formation, cell proliferation, differentiation potential, and sometimes degradation characteristics. Hydrogels, such as alginate and gelatin, have been used most commonly for engineering NP tissue, likely due to the fact that such materials reasonably approximate the gel-like properties of the native tissue. Cells of different origins, including native IVD cells, stem cells, and chondrocytes, are capable of synthesizing and depositing collagen and glycosaminoglycans (GAGs) within these hydrogels, although there is little agreement upon the targeted composition necessary to achieve a satisfactory tissue construct. This is a particularly challenging determination for the IVD as the matrix contains varying amounts of both types I and II collagen, so that the exclusive presence of type II collagen does not serve as a phenotypic matrix marker as is the case for articular cartilage.

Annulus fibrosus repair and regeneration

Sealing AF defects is critical after discectomy for disk herniation or implantation of NP replacements, as annular injury has been shown to lead to further IVD degeneration, and integrity of the AF is necessary to retain implanted NP materials [63,64]. While mechanical devices and suturing techniques to seal AF defects are effective for preventing herniation, they do not promote tissue healing and ultimately cannot prevent IVD degeneration [65,66]. Efforts to regenerate the AF have focused on materials, cells, and biomolecules that are able to both restore integrity to the AF to prevent herniation and promote long-term healing of the tissue. Natural and synthetic biomaterials have been investigated for AF repair and regeneration, including hydrogels composed of alginate, agarose, gelatin, hyaluronic acid, and collagen [64,67–70], as well as materials that mimic the native fiber and porous architecture of the AF, including decellularized AF, PGA, polylactic acid (PLA), poly(ε-caprolactone), poly(vinylidene difluoride), collagen, silk, hyaluronic acid, and/or GAGs [71–77]. Recent investigations have documented that this fibrocartilage is heterogeneous, with a distinct microstructure containing proteoglycan-rich microdomains dispersed between fibrous, collagen-rich tissue [78]. Han et al. developed a tissue-engineered construct that mimicked the heterogeneity of fibrocartilage, which appears to be critical to achieving similar mechanical and mechanobiological properties of native tissue (Fig. 51.4). Oftentimes, the same scaffolds evaluated for NP cells are also studied with cells of the AF, with findings that generally illustrate the importance of cell origin in determining the resultant ECM synthesis. A common observation, however, is that cells of either origin that are maintained in a rounded morphology tend to generate more type II collagen, characteristic of hyaline cartilage, whereas those that are cultured in an elongated morphology generate more type I collagen. Moriguchi et al. implanted a collagen/alginate whole IVD in the canine cervical spine and found that

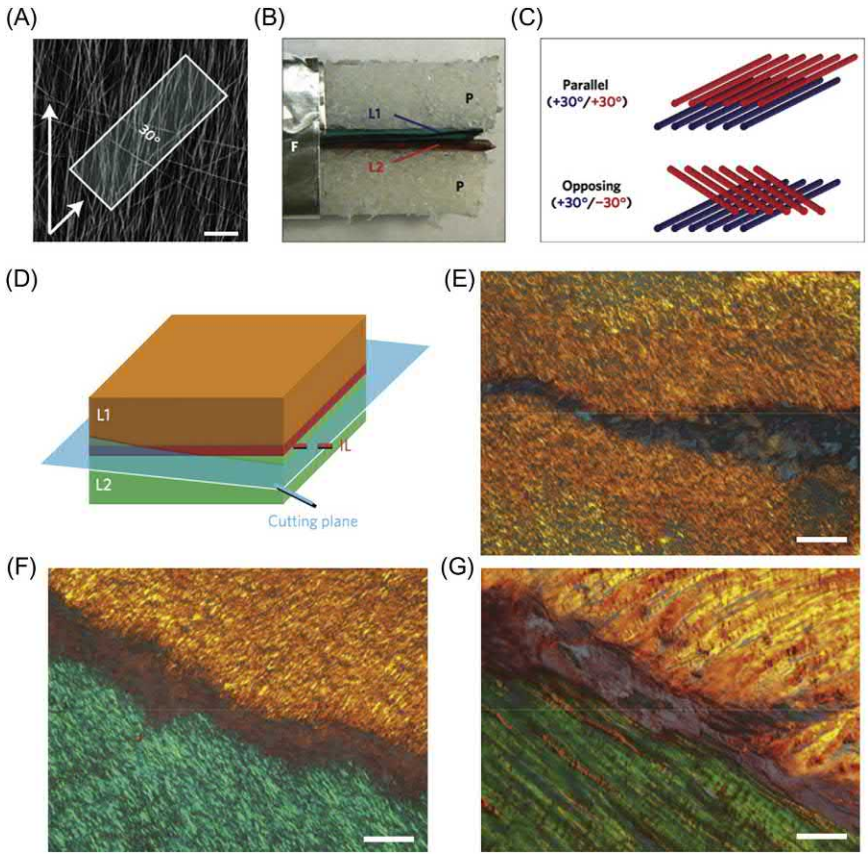

FIGURE 51.5 Fabrication of fiber oriented AF tissue constructs.
(A) Scaffolds were excised 30 degrees from the prevailing fiber direction of electrospun nanofibrous mats to replicate the oblique collagen orientation within a single lamella of the annulus fibrosus. Scale bar: 25 μm. (B) At 0 week, MSC-seeded scaffolds were formed into bilayers between pieces of porous polypropylene and wrapped with a foil sleeve. *F*, Foil; *L1/2*, lamella 1/2; *P*, porous polypropylene. (C) Bilayers were oriented with either parallel (+30/ + 30 degrees) or opposing (+30/ − 30 degrees) fiber alignment relative to the long axis of the scaffold. (D) Sections were collected obliquely across lamellae, stained with Picrosirius Red, and viewed under polarized light microscopy to visualize collagen organization. When viewed under crossed polarizers, birefringent intensity indicates the degree of alignment of the specimen, and the hue of birefringence indicates the direction of alignment. *IL*, Interlamellar space; *L1/2*, lamella 1/2. (E) After 10 weeks of in vitro culture, parallel bilayers contained coaligned intralamellar collagen within each lamella. (F and G) Opposing bilayers contained intralamellar collagen aligned along two opposing directions (F), successfully replicating the gross fiber orientation of native bovine annulus fibrosus. (G) In engineered bilayers, as well as the native annulus fibrosus, a thin layer of disorganized (nonbirefringent) collagen was observed at the lamellar interface. The distribution of collagen fiber orientations was determined by quantitative polarized light analysis [45]. Scale bars: 200 μm (B and C), 100 μm (D). *AF*, Annulus fibrosus; *MSC*, mesenchymal stem cell. *Figure modified with permission from Nerurkar et al. Nat Mater, 2009.*

cells in the collagen region were elongated like fibrochondrocytes found in the AF, while cells in the alginate region were rounded and appeared similar to NP chondrocyte-like cells [79] (Fig. 51.4).

A main challenge has been reproducing the intricate lamellar arrangement of collagen fibers that give the AF its unique mechanical properties and the cells their unique morphology. For this reason, AF tissue-engineered materials have moved toward scaffolds that mimic the apparent collagen architecture. Some investigators have developed synthetic and natural polymeric scaffolds with anisotropic features such as an oriented honeycomb structure [80], aligned collagen gel fibers [81,82], oriented electrospun fibers [83−86], and oriented silk fibers [87]. One approach is based on engineering AF to contain oriented and lamellar electrospun polycaprolactone (PCL) fibers with tensile mechanical properties on the order of native AF [71] (Fig. 51.5). These results are indeed suggestive of the potential to engineer anisotropic collagenous tissues.

While tissue-engineered AF repair strategies have not reached the clinic, there are numerous preclinical in vivo studies in both small and large animal models to repair AF defects. A large percentage of these studies have taken place in the sheep lumbar spine, where tissue-engineered repair strategies are applied after mechanical injury to the AF that simulates human IVD herniation and degeneration [64,88−91]. One such study demonstrated the usefulness of using a tissue-based strategy to repair an AF defect by patching AF defects with small intestinal

submucosa (SIS) anchored by titanium bone screws [92]. The SIS patch produced new integrated tissue at the defect site and increased the capacity of the IVD to pressurize post anulotomy and increased disk hydration compared to anulotomy-only levels after 24 weeks in an ovine model. Other studies have demonstrated closure of AF defects and prevention of degeneration after discectomy in rat tail and sheep lumbar spine models using cross-linked high-density collagen [68,69,88,93,94]. This method involves injection of a collagen hydrogel into AF defects, followed by photo-crosslinking to form the hydrogel to the shape of the defect and increase the strength of the seal. In another study, genipin cross-linked fibrin hydrogels were developed that demonstrated mechanical properties on the order of AF, maintained cell viability, and maintained adhesion to native AF tissue under physiological load [95–98]. While these studies and others with different materials have shown excellent repair of the outer AF, it remains a challenge to effectively repair the inner AF. A potential solution may be the combination of cells, biomolecules, and biomaterials to orchestrate more effective healing of the entire AF [88,91,99,100]. Biomolecules such as bone morphogenetic protein (BMP) 13 have been shown to locally regenerate tissue when applied to AF defects [101]. Further in vivo characterization of these strategies is necessary prior to implementation in the clinic.

Composite cell-biomaterial intervertebral disk implants

Tissue-engineered strategies targeting the NP and AF are primarily aimed toward early-stage IVD degeneration, with the goal of halting degeneration and regenerating the native tissue. Composite tissue-engineered IVD strategies are typically seen as treatments for end-stage degeneration and an alternative to spinal fusion, where there is little salvageable tissue and an entirely new IVD is necessary. Similar synthetic and natural materials are used for the NP and AF regions as discussed previously, often seeded with primary NP and AF cells. Tissue-engineering whole composite IVDs are a complicated endeavor due to the necessity to recapitulate both the gelatinous nature of the NP and the circumferentially fibrous architecture of the AF. In addition, the composite construct must integrate with the surrounding tissue and mimic the mechanical response of native IVDs under varied and complex loads. As such, in vivo testing is necessary to fully characterize how the composite structure integrates with native tissue.

Recent studies have explored the development of composite IVDs using a variety of materials and techniques. Composite IVDs have been produced with AF composed of PGA/PLA, electrospun poly-L-lactic acid, contracted collagen gel, silk, electrospun PCL, and demineralized bone matrix gelatin and NP composed of alginate, hyaluronic acid, hyaluronic acid/fibrin, agarose, silk hydrogel, and collagen II/hyaluronate/chondroitin-6-sulfate [82,87,102–106]. In one of the earliest examples of an integrative tissue-engineering approach, investigators generated NP tissue in vitro by culturing primary bovine NP cells at high density upon a calcium polyphosphate substrate, in order to mimic the natural integration of the NP against the vertebral endplate (Fig. 51.6 [107]). The NP cells formed tissue with a proteoglycan, but not collagen content matched to that of the native NP. Importantly, functional properties in some testing configurations approached that of the native tissue. Gullbrand et al. recently demonstrated effective IVD replacement in the rat caudal spine and goat cervical spine in vivo using agarose/nanofibrous PCL/porous PCL composites [108]. These constructs mimicked the NP, AF, and cartilage endplates and were shown to mature and match native IVD mechanical properties over a period of 20 weeks. While the goat model required external fixation, this is a significant translational step toward bringing tissue-engineered total IVD replacement to the clinic. Additional work will be required in adapting composite tissue-engineering approaches to ensure that mechanical integration with adjacent tissues is adequate.

In studies conducted by Bonassar et al., IVD regeneration was attempted in the native disk space of an athymic rat with a fully integrated scaffold combining contracted collagen gels as a scaffold for AF, and a cross-linked alginate hydrogel as a scaffold for NP tissue [81,82] (Fig. 51.7). Primary cells for culture within each scaffold region were derived from the corresponding native IVD tissues, and the resultant cell-laden scaffolds were implanted in place of the native disk in athymic rats for a period of 6 months. The results illustrate spatially directed matrix regeneration with ECM that exhibited distinct morphologies, contained native levels of collagen and GAGs, and was functionally integrated with native tissue. In biomechanical tests the motion segments containing the composite tissue-engineered disks were found to have a compressive modulus and permeability to flow similar to the native motion segments. Thus this approach illustrated an ability for cell-laden scaffolds to regenerate integrated functional ECM with some of the functional and compositional features of the native tissue in the native disk space. More recent studies in the beagle cervical spine showed similarly promising results; however, this study demonstrated the importance of animal model anatomy [79]. Extreme curvature at certain levels in the beagle cervical spine led to the displacement of the implanted tissue-engineered IVDs, while no displacement and excellent integration were observed in levels without excessive curvature.

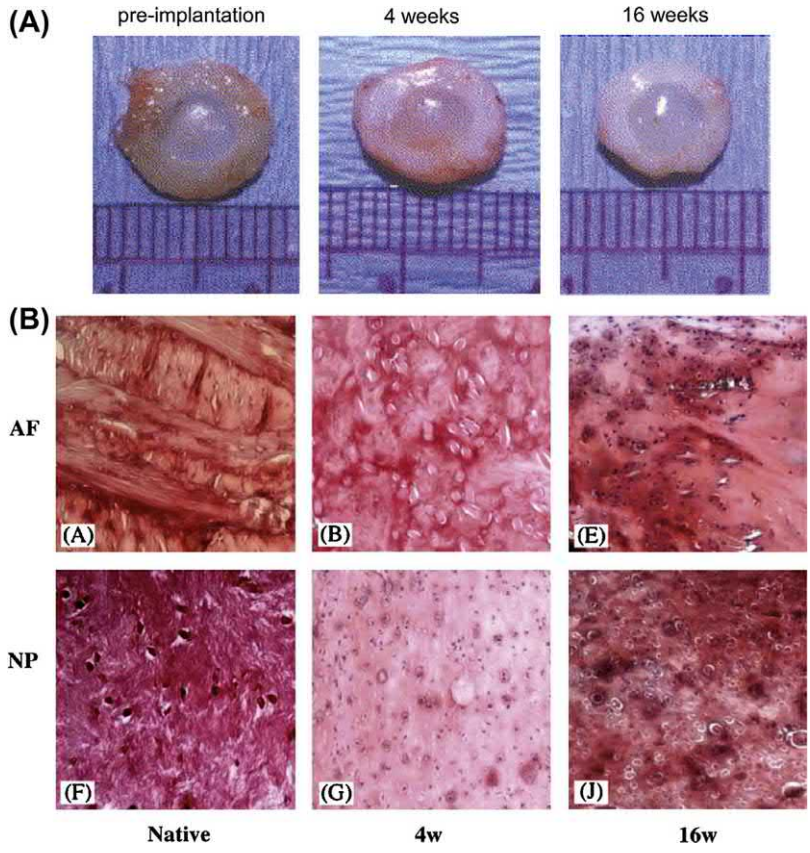

FIGURE 51.6 Histological appearance of in vitro–formed tissues showing newly generated NP tissue. Histological appearance of (A) in vitro–formed cartilage at 2 weeks (time at which the NP cells would be seeded); (B) in vitro–formed NP–cartilage–calcium pyrophosphate composite (triphasic construct) at 8 weeks following seeding of chondrocytes; and (C) in vitro–formed cartilage tissue alone (biphasic construct) at 8 weeks. Biomaterials 2006;V27:397–405.*

Assessment of the success of IVD tissue-engineering efforts is critical to moving these technologies toward clinical application. To date, the most common tool for the assessment of newly generated IVD tissue has been histology, although analysis of mechanical properties, gene expression, and ECM composition has been frequently employed to confirm the appropriate phenotypic behavior in engineered IVD. In vitro studies have laid the foundation for necessary and/or sufficient characteristics of a successful scaffold for AF and NP replacement. From these studies, for example, it is evident that a high starting cell density and a high degree of initial matrix stability are essential for promoting long-term construct stability and matrix accumulation to eventually restore mechanical function and swelling pressure [109]. Mechanical analysis of engineered IVD tissue is essential in assessing the formation of functional IVD tissue, however both for NP implants—that must restore spinal stability—and annular repair strategies—that must withstand repeated cycles of nucleus pressure. In vivo studies may also evaluate an ability to restore disk height as a common outcome variable, as well as clinical MRI imaging to access in vivo tissue hydration. In vivo, largely preclinical work has begun to verify that engineered IVD tissues may eventually be capable of restoring disk height, maintaining spinal stability and flexibility and retarding disk degeneration in pathological tissues.

Cellular engineering for intervertebral disk regeneration

Given the relatively small numbers of studies in the area of IVD tissue engineering, there is a surprising amount of breadth to not only the biomaterials but also the cell sources utilized for regeneration. The question of cell source is of particular note for IVD tissue engineering, given that the availability of autologous disk cells is extremely low in the adult and that the phenotype of cells varies so substantially with both spatial position and with age. In animals studied for IVD tissue engineering ex vivo the origin of cells in the NP may be partly notochordal or mesenchymal, depending on the age of the animal in question. As such, the choice of species used as a source of cells may be quite important. Due to the ease of availability, porcine and bovine cells are the most commonly used, with other efforts reporting the use of cells of canine, lapine, and ovine origin as well as human. However, cells derived from bovine or ovine tissues may be exclusively mesenchymal in origin, while those

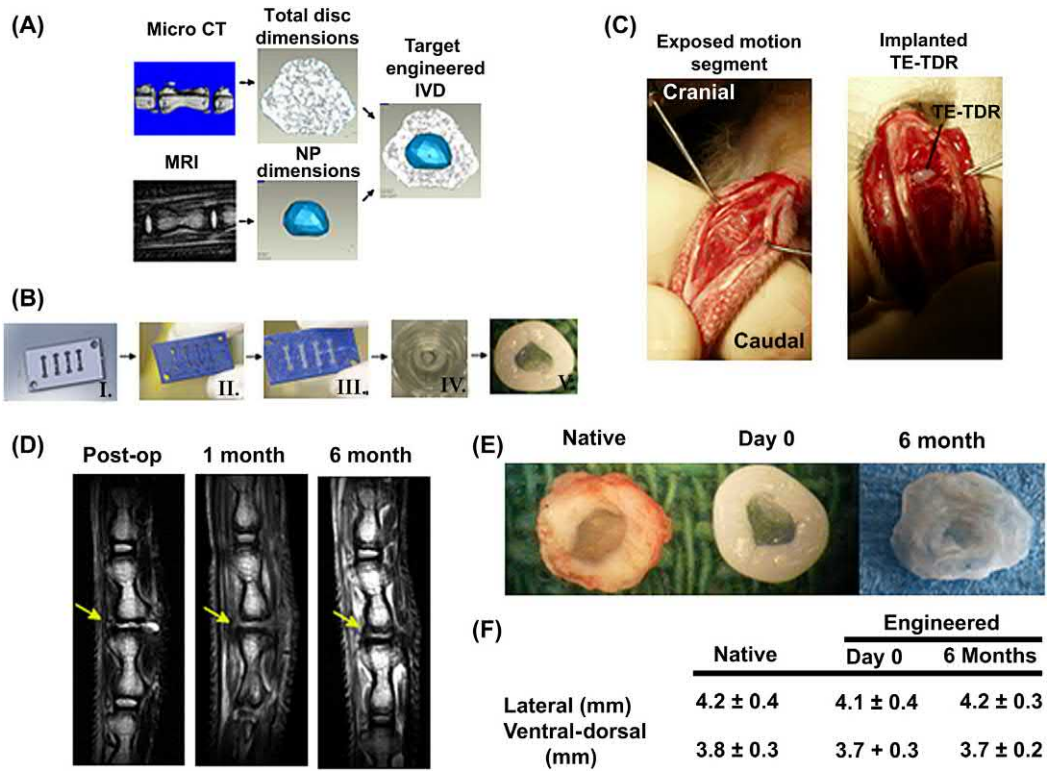

FIGURE 51.7 Anatomical composite TE-IVD, designed from MRI and CT, survives in disk space for 6 months.

(II) Injection mold 3-D printed out of acrylonitrile butadiene styrene plastic. (III) Cell-seeded alginate was injected into mold, removed, (IV) placed in center of 24 well plate, and cell-seeded collagen was poured around alginate NP. (V) After 2 weeks of culture, cell-seeded collagen contracts around the NP to form composite TE-IVD. (C) Intraoperative images showing exposed caudal 3/4 disk space and implanted TE-IVD. (D) T2-weighted MRI of implanted disk space (marked by *yellow arrows*) and adjacent native levels immediately postoperative, at 1 month, and 6 months after implantation. (E) History of TE-IVD in native disk space. Intraoperative photo showing explanted native IVD next to the TE-IVD (day 0) that was implanted in its place and TE-IVD after being implanted into native disk space for 6 months. (F) Size of engineered IVD compared to native IVD. Measurements were taken along the lateral and ventral−dorsal planes of the engineered and native IVD. Engineered IVD measurements were taken at day 0 prior to implantation ($n = 12$) and compared to explanted native disks ($n = 12$). Engineered IVD measurements were also taken after 6 months of implantation ($n = 12$). *IVD*, Intervertebral disk; *MRI*, magnetic resonance imaging; *NP*, nucleus pulposus; *TE*, tissue-engineered. *Reprinted with permission from Bowles, et al. PNAS 2011.*

derived from porcine, lapine, or rodent tissues may be largely notochordal. Further, the notochordal or mesenchymal original of cells from canine sources is known to vary by breed. These phenotypic differences add an additional and unique complicating factor for investigators studying preclinical models for IVD tissue regeneration.

Given the very limited availability of native IVD cells that can be effectively harvested for tissue engineering, there has been an interest in using other cells as sources for these efforts. The primary target for other sources has been stem cells derived from sources such as bone marrow [110], embryonic cell lines [111], and adipose tissue [112]. A major challenge in this approach has been the development of methods to guide the development of stem cells toward phenotypes found in the IVD (see the next section). This has been attempted through manipulation of the culture medium and gas conditions [113], as well as coculture with primary cells from the IVD [114,115]. The more recent development of induced pluripotent stem cells has also provided the possibility for an additional cell source for cell delivery to treat musculoskeletal disorders [116]. In comparison to the use of adult primary disk cells derived from often pathological or degenerated IVDs, the use of autologous mesenchymal stem cells (MSCs) or progenitor cells may be most promising to the future of ex vivo tissue-engineering strategies that rely upon cell supplementation.

Cell therapy preclinical studies

If the local environment within the IVD is conducive to the survival of cells, direct cell supplementation without biomaterial scaffolds may hold promise for IVD repair. This strategy has been pursued by several groups preclinically and clinically, using either IVD cells, chondrocyte-like cells, or progenitor cells.

In the first reported work of disk cell supplementation, NP tissues from the rat were inserted following removal of nucleus tissue and showed some beneficial effects in inhibiting the degenerative IVD changes of nucleotomy [117]. Since then, several preclinical studies have reported the benefits of cell supplementation in delaying disk degeneration. These studies include mouse, rat, rabbit, canine, pig, goat, and sheep animal models [118].

In studies of cell therapy, three primary types of cells have been utilized: disk cells, chondrocytes, and stem cells [118]. Ideally, cells derived from native or native-like tissue (i.e., cartilage) would be used as they are better suited to disk environments they are implanted into, but there are limitations in using these cells, as it is relatively difficult to obtain sufficient cell numbers and cell activity may be impaired in cells derived from degenerated tissue. To mitigate issues of cell number, some studies have focused on delivery of cells through delivery of allograft tissues based on the concept that less cells are lost in processing and that preservation of ECM is an equally important criteria for regeneration [80,107]. To mitigate issues of impaired cell activity, some studies have focused on using techniques for cell reactivation [119]. These approaches were shown to be effective in delaying some degenerative features such as the loss of disk architecture following reinsertion of the "activated" cells in a rabbit model. Overall studies with disk cells and chondrocytes have shown positive effects and safety, which has allowed them to move forward into clinical trials as discussed in the next subsection [120].

With challenges associated with obtaining disk or disk-like cells, there has also been a focus on developing stem cell therapies for disk regeneration [121,122]. There have been several in vivo studies that have demonstrated efficacy; therefore these therapies have also moved forward to clinical trials as described in the next subsection. Still, there are concerns regarding stem cell survival in the harsh disk environment which questions the longevity of these stem cell therapies [123]. Therefore current preclinical work is focused on enhancing survival and regenerative capability of stem cells in these environments. This has been investigated through preconditioning, genetic engineering, and biomaterials. An example regarding preconditioning shown by Peck et al. demonstrated hypoxic expansion of stem cells that enhance their survival in low oxygen and low nutrient environments, like that of the disk [124]. Biomaterials in general have been considered a necessity for cell delivery to prevent osteophyte formation, but many have also been utilizing them to improve therapeutic outcomes of cell therapy [73]. For example, Tsaryk et al. demonstrated that a collagen-hyaluronic acid interpenetrating network with transforming growth factor (TGF) β3 loaded gelatin microspheres could perform successful cell delivery and induce differentiation of MSCs in vivo in mice [125]. Gene therapies have investigated enhancing cell inflammatory resistance and/or differentiation of stem cells ex vivo [126,127]. Enhancing resistance to inflammation is also applicable to nonstem cell therapies and has been applied to disk cells in vitro [128]. These studies hope to provide methods to overall further improve all cell therapies and increase their longevity and rate of success.

Cell therapy clinical studies

The first study clinically investigating implantation of disk cells began in 2002 with a prospective, controlled, multicenter study undertaken to compare autologous disk cell transplantation plus discectomy against discectomy alone [129]. Since then, a total of 14 clinical trials of cell therapies have been published and the results of these trials are reviewed in further detail elsewhere [120]. In addition, several cell therapy clinical trials are currently underway and the results of these studies are pending. Overall the results of clinical trials of cell therapies, utilizing cells derived from multiple tissue sources, including disk cells, chondrocytes, platelet-rich plasma (PRP), and stem cells, have shown promising therapeutic potential in initial studies.

One approach for IVD cell therapy has been the implantation of autologous IVD chondrocytes [129,130]. In these clinical trials, patients receiving cell transplantation reported improved pain and reduced disability. In addition, the IVDs of patients receiving cell implantation showed significant improvement in disk hydration when compared to the IVDs of patients in the discectomy group. However, disk height was found to be similar in patients receiving cell transplantation and those in the discectomy group. This clinical study led to the development of at least one product termed ADCT, or autologous disk chondrocyte transplantation with or without a hydrogel carrier (NOVOCART), which has been widely used and approved in Germany since 2008. Utilizing a similar approach, clinical trials have demonstrated that patients receiving intradiscal implantation of allogenic chondrocytes reported reduced pain, improved disability scores, and improved flexibility when compared to patients undergoing discectomy [131].

In addition to chondrocytes, clinical trials have tested the implantation of IVD cells as cell-therapy treatment strategy. Mochida et al. demonstrated that patients receiving autologous NP cell implantation reported improved pain and disability scores. In addition, disk height and disk hydration were maintained, and Pfirrmann's classification of disk degeneration was improved in patients receiving intradiscal IVD cell implantation [132]. Overall, these clinical trials have established the safety of intradiscal chondrocyte and IVD cell implantation and the initial findings of these clinical trials reported improvements in

several important patient outcomes, including pain and disability scores. Further clinical trials are required to determine the efficacy of these cell implantation strategies for the treatment of painful disk degeneration.

Due to the inherent properties of MSCs, the implantation of MSCs harvested from a patient's own bone marrow [133–138] or adipose tissue [139] for the treatment of disk degeneration and/or disk herniation has been tested in recent clinical trials. In clinical trials utilizing MSCs harvested from autologous bone marrow, patients receiving intradiscal transplantation of autologous MSC reported decreased pain and improved disability scores at up to 6 years following procedures [133–138]. In addition, the IVDs of patients receiving cell transplantation demonstrated reduced disk bulge size, maintained disk height, and maintained or improved the level of disk degeneration (Pfirrmann's classification).

In addition to bone marrow MSCs the ability of intradiscal transplantation of adipose-derived MSCs to regulate disk degeneration has been tested in recent clinical trials [139]. In these studies, patients receiving autologous adipose derived MSC implantation reported improved pain and disability scores. In addition, the disks of patients receiving cell transplantation exhibited maintained disk height and maintained levels of degeneration. Together, these clinical studies have demonstrated the safety of MSC cell transplantation to the pathological disk, and the ability of MSC implantation to regulate several key outcomes for patients with disk degeneration and/or herniation.

Growth factors and other biologics for intervertebral disk regeneration

In vitro studies

Disk cells modulate their activity by a variety of substances, including cytokines, growth factors, enzymes, and enzyme inhibitors in a paracrine and/or autocrine fashion [140]. Tissue-engineering approaches to disk regeneration have been based on attempts to upregulate important matrix proteins (e.g., aggrecan) or to downregulate proinflammatory cytokines [e.g., interleukin-1 (IL-1); tumor necrosis factor-α (TNF-α)] [141–147] and matrix-degrading enzymes [e.g., matrix metalloproteinases (MMPs); aggrecanases] [148–151]. The delivery of these modulating biologic agents, with and without scaffolds and/or through cell transplantation, has been the subject of many years of efforts in tissue engineering. In vitro studies have shown that the rate of matrix synthesis or gene expression for matrix proteins, principally proteoglycan or collagen, can be increased several-fold in IVD cells in the presence of one or a combination of these growth factors: supplemental TGF-β [152–157] and its subtype TGF-β3 [158–160], osteogenic protein-1 (OP-1; otherwise known as BMP-7) [58,161–163], BMP-2 [164–166], BMP-12 [166], growth and differentiation factor-5 (GDF-5) [167–169], epidermal growth factor (EGF) [170], connective tissue growth factor (CTGF) [171], or insulin-like growth factor-1 (IGF-1) [172,173]. Other studies have demonstrated the potential of these growth factors, as well as platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF), to reduce cell apoptosis [174] and to promote cell proliferation [175,176]. Several recent studies examined the effects of the in vitro costimulation of IVD disk cells by two or more growth factors. In micromass cultures of fetal outer annulus cells, TGF-β1 and IGF-1, both alone and in combination, stimulated the synthesis of sulfated GAGs, and collagen types I and II. While TGF-β1 and BMP-2 each had strong anabolic effects on NP cells cultured in an atelocollagen scaffold, there were no additive or synergistic effects on cell proliferation and matrix synthesis. Autologous PRP, which contains a variable mixture of growth factors, including TGF-β1, PDGF, and IGF-1, has also been shown to be an effective stimulator of cell proliferation, proteoglycan, and collagen synthesis, as well as proteoglycan accumulation, when added to porcine IVD cell cultures in vitro. Other studies examined the effect of PRP on bovine AF cells and found that it increased aggrecan and type-II collagen production and also decreased the catabolic protein MMP-1 [177,178]. In human NP cells, PRP containing 1 ng/mL TGF-β1 induced cell proliferation and differentiation and promoted the in vitro formation of tissue-engineered NP as indicated by cell morphology, mRNA expression profile, and GAG accumulation [179] (Table 51.3).

In a different approach, supplementation of IVD cell cultures with a naturally occurring antiinflammatory molecule, IL-1 receptor antagonist (rhIL-1Ra), has been shown to inhibit the downregulation of biosynthesis induced by the proinflammatory cytokine, IL-1 [176]. Pretreatment of NP cells with both IL-1Ra and a fusion protein between IL-1Ra and an ELP reduced the expression of MMP-3 and the aggrecanase, a disintegrin and metalloproteinase with thrombospondin motifs 4 (ADAMTS-4), when the cells were subsequently treated with IL-1 [203]. The in vitro application of rhIL-1Ra to degenerated human disk tissues reduced levels of enzymes, MMP-3, -7, and -13, implicated in the degradation of the IVD [204]. The incubation of herniated human disk tissues with IL-1Ra or an antibody inhibitor of TNF both decreased levels of active MMP-3, indicating that these inhibitors may have an effect on the resorption of herniated disks [205]. The inhibition of p38 mitogen-activated protein kinase in IL-1-activated NP cells reduced the production of factors associated with the catabolic effects of IL-1 and TNF-α [206]. An extension of that study revealed that the IL-1 upregulation of gene

TABLE 51.3 Representative gene, growth factor, and cell therapy studies.

Factor (s)	Cell type and source	Delivery	Results	Year	Reference
bFGF	Bovine IVD cells	rhFGF (5 ng/mL) for 24 h	Induced cell proliferation of quiescent cells	2007	[173]
BMP-2	Rat NP cells	rhBMP-2 (100, 1000 ng/mL)	Increased collagen and sGAGs, as well as expression of type-II collagen, aggrecan, and Sox9 mRNA	2003	[165]
	Human IVD cells	rhBMP-2 (2.5–2000 ng/mL) for 3 weeks	Upregulation of aggrecan and type-I/type-II collagen mRNA. Increased proteoglycan synthesis	2003	[164]
	Human IVD cells	rhBMP-2 (25–300 ng/mL) for 2 days	Increased collagen and proteoglycans in NP cells only	2008	[166]
BMP-12	Human IVD cells	rhBMP-12 (25–100 ng/mL) for 2 days	Increased collagen and proteoglycans in NP cells only	2008	[166]
	Human NP and AF cells	Adenovirus	Increased cell proliferation and matrix protein synthesis in NP and AF cells	2008	[166]
CTGF	Rhesus monkey IVD cells	Adeno-associated virus	Increased proteoglycan and type-II collagen synthesis	2010	[171]
EGF	Canine IVD cells	EGF (1 ng/mL) for 48 h	Increased cell proliferation and stimulation of matrix synthesis	1991	[170]
GDF-5	Bovine IVD cells	rhGDF-5 (100, 200 ng/mL) for 21 days	Increased cell proliferation, proteoglycans, and collagen in both NP and AF cells	2006	[167]
	Mouse IVD cells	Mouse GDF-5 (1–100 ng/mL) for 9 days	Upregulation of aggrecan and type-II collagen mRNA	2004	[168]
	Mouse IVD cells	Gene therapy	Increased type-II collagen and aggrecan mRNA expression	2007	[169]
IGF-I	Bovine IVD cells	rhIGF-I (100 ng/mL) for 24 h	Induced cell proliferation of quiescent cells	2007	[173]
	Bovine NP cells	IGF-I (0.1–1000 ng/mL)	Increased proteoglycan synthesis	1996	[172]
OP-1	Human IVD cells	rhOP-1 (100, 200 ng/mL) for 21 days	Prevention of decreased cell number Increased proteoglycan synthesis and accumulation	2007	[163]
	Rabbit IVD cells	rhOP-1 (100, 200 ng/mL) for 72 h	Increased cell proliferation, total proteoglycan, and collagen	2006	[60]
	Rabbit IVD cells	OP-1 (200 ng/mL) for 21 days	Rapid recovery of proteoglycans and collagens which were lost as a result of IL-1α treatment	2002	[61]
	Rabbit IVD cells	OP-1 (200 ng/mL) for 21 days	More rapid recovery of proteoglycans and stimulated matrix repair following chemonucleolysis with chondroitinase ABC	2005	[62]
PDGF	Bovine IVD cells	rhPDGF-BB (10 ng/mL) for 24 h	Induced cell proliferation of quiescent cells	2007	[73]
TGF-β	Human NP cells	TGF-β1 (10 ng/mL) for 6 days	Increased aggrecan, type-I and type-II collagen, and Sox9 mRNA expression	2013	[53]
	Rat AF cells	TGF-β1 (5 ng/mL) for 5 days	Increased GAG output and type-I/type-II collagen	2011	[56]

TABLE 51.3 (Continued)

Factor (s)	Cell type and source	Delivery	Results	Year	Reference
	Human AF cells	TGF-β1 (5 ng/mL) for 7 days	Stimulated ECM production. Increased production of sulfated proteoglycans	2010	[51]
	Human IVD cells	TGF-β1 (0.25–5.0 ng/mL) for 10 days	Enhanced cell proliferation. Increased biglycan production	1997	[52]
	Rat IVD	TGF-β3 (10 ng/mL) for 1 week	Preservation of disk morphology and architecture. Prevention of cell death. Increased expression of ECM genes and sulfated proteoglycans	2006	[57]
	Human NP cells	TGF-β3 (10 ng/mL) for 28 days	Increased collagen and aggrecan gene expression. Production of proteoglycan- and type-II collagen-rich matrix	2009	[58]
	Human NP cells	TGF-β3 (10 ng/mL) for 7 days	Increased cell proliferation. Exhibition of an anticatabolic gene expression profile	2012	[59]
TGF-β, BMP-2	Rabbit NP cells	rTGF-β (10 ng/mL)rBMP-2 (100 ng/mL)	Increased cell proliferation and proteoglycan synthesis Upregulation of aggrecan, type-I/type-II collagen mRNA	2012	[75]
PRP, TGF-β	Human NP cells	PRP containing TGF-β (1 ng/mL) for 7 days	Upregulated Sox9, type-II collagen, and aggrecan mRNA Increased GAG accumulation	2006	[79]
IGF-1, βMP-2, TGF-β	Human IVD cells	Adenovirus	Increased proteoglycan synthesis	2008	[54]
PRP	Bovine AF cells	25%–50% PRP for 4 days	Increased GAG synthesis and cell number	2014	[77]
	Bovine AF cells	PRP for 24 h	Increased type-II collagen and aggrecan. Decreased MMP-1	2016	[78]
	Porcine IVD cells	PRP for 72 h	Upregulated proteoglycan, collagen synthesis, and cell proliferation	2006	[76]
Factor	**Animal model/ clinical trial**	**Delivery**	**Results**	**Year**	**Reference**
BMP-2	Rabbit (annular tear)	rhBMP-2 (100 μg in 100 μL)	More frequent and severe degeneration. Increased vascularity and fibroblast proliferation	2007	[180]
GDF-5	Rat (compression)	GDF-5 (8 ng in 8 μL)	Expansion of inner annular fibrochondrocytes into nucleus. Cells expressed aggrecan and type-II collagen mRNA. Increased disk height	2004	[181]
	Rabbit (puncture)	rhGDF-5 (0.01–100 μg)	Restoration of disk height. Improved MRI and histologic grading scores	2006	[167]
	Mouse (puncture)	Adenovirus	Increased disk height. Improved GAG retention	2010	[182]
	Phase I/II clinical trial ($n = 32$)	rhGDF-5 (0.25, 1.0 mg)	Improved patient-reported pain scores and a decrease in pain-related disability	2016	[183]
	Phase II clinical trial ($n = 24$)	rhGDF-5 (1.0, 2.0 mg)	Failed to show significant improvements over placebo for Oswestry Disability Index, Pain Visual Analog Scale, and quality of life	2016	[184]
GDF-6	Sheep (annular puncture)	GDF-6 (300 μg in 70 μL)	Greater disk hydration retention. Reversed or arrested loss of ECM proteins	2009	[101]
	Rabbit (annular puncture)	GDF-6 (100 μg in 10 μL)	Partial restoration of disk height	2018	[185]
HGF	Rat (annular pucture)	rhHGF (10 ng in 2 μL)	Increased type-II collagen in the NP. Retardation of disk degeneration as observed by MRI	2013	[186]

(*Continued*)

TABLE 51.3 (Continued)

Factor	Animal model/ clinical trial	Delivery	Results	Year	Reference
IGF-1	Rat (compression)	IGF-1 (8 ng in 8 μL)	Early, transient increase in cell density and cell proliferation	2004	[181]
OP-1	Rabbit (normal)	rhOP-1 (2 μg in 10 μL)	Increased disk height and proteoglycan content	2005	[187]
	Rat (chronic compression)	OP-1 (200 ng in 1 μL)	Prevention of mechanical hyperalgesia. Increased ECM	2005	[188]
	Rabbit (puncture)	rhOP-1 (100 μg in 10 μL)	Increased water content in NP. Increased proteoglycan content in NP and AF. Lower degeneration grades	2006	[189]
	Rabbit (annular puncture)	OP-1 (100 μg in 10 μL)	Restored biomechanical properties of degenerated IVDs. Higher IVD elastic and viscous moduli. Increased proteoglycan and collagen content	2006	[190]
	Rabbit (chemonucleolysis)	rhOP-1 (100 μg in 10 μL)	Increased disk height; higher proteoglycan content	2007	[191]
	Rat (chronic compression)	OP-1 (200 ng in 1 μL)	Restoration of normal disk morphology. Increased Safranin O staining in NP. Extended ECM. Reduced presence of catabolic proteins	2007	[192]
PDGF	Rabbit (annular puncture)	PDGF-BB (1 ng/μL/disk)	Prevention of apoptosis and collagen-3 matrix deposition. Decreased degeneration. Increased compressive strength	2016	[193]
TGF-β	Rabbit	Adenovirus	Increased proteoglycan synthesis	1999	[194]
	Rat (compression)	TGF-β1 (1.6 ng in 8 μL)	Increased population of annular fibrochondrocytes. Increased matrix synthesis	2004	[181]
	Phase I/IIa clinical trial ($n = 50$)	YH14618 (1–6 mg/disk)	Improvements in Oswestry Disability Index and Pain Visual Analog Scale. No significant changes in disk height or MRI scores	2015	[195]
	Phase IIb clinical trial	YH14618	Trial halted as YH14618 failed to show anticipated benefits compared to placebo. Another phase-II clinical trial is anticipated	2016	[184]
PRP	Rabbit (nucleotomy)	PRP in gelatin hydrogel microspheres	Decrease in degeneration, increased proteoglycan in NP and inner AF	2007	[196]
	Rabbit (annular puncture)	PRP in gelatin hydrogel microspheres	Greater disk height. Preservation of water content. Higher mRNA expression of proteoglycan core protein and type-II collagen. Fewer apoptotic cells in NP	2009	[197]
	Rabbit (annular puncture)	PRP releasate (20 μL)	Restoration of disk height. Higher number of chondrocyte-like cells	2012	[198]
	Human; prospective trial ($n = 22$)	PRP (1.5 mL)	Improved patient-reported pain scores and a decrease in pain-related disability	2015	[199]
	Human; preliminary assessment ($n = 6$)	PRP (2 mL)	Improved patient-reported pain scores and increased patient function	2015	[200]
	Human (clinical study; $n = 29$)	PRP (1–2 mL)	Improvements in pain and function through 2 years of follow-up	2016	[201,202]

AF, annulus fibrosus; *bFGF*, basic fibroblast growth factor; *BMP*, bone morphogenetic protein; *CTGF*, connective tissue growth factor; *ECM*, extracellular matrix; *EGF*, epidermal growth factor; *GAG*, glycosaminoglycan; *GDF*, growth and differentiation factor; *IGF*, insulin-like growth factor; *IL*, interleukin; *IVD*, intervertebral disk; *MMP*, matrix metalloproteinase; *MRI*, magnetic resonance imaging; *NP*, nucleus pulposus; *OP*, osteogenic protein; *PDGF*, platelet-derived growth factor; *PRP*, platelet-rich plasma; *TGF*, transforming growth factor; *HGF*, Hepatocyte Growth Factor.

expression of MMP-3, IL-1, and IL-6 was reduced, while the IL-1 downregulation of matrix protein gene expression and proteoglycan synthesis was reversed in NP cells [206].

These above in vitro studies illustrate that both stimulatory factors, as well as antiinflammatory or anticatabolic factors, may be considered for therapeutic purposes in IVD regeneration. Overall, the potential for biologics to assist in matrix regeneration through controlling both cell metabolism and cell number has been established and paved the way for more recent studies evaluating these biologics in vivo.

In vivo studies: growth factors

Protein injection into the disk space is relatively simple and practical and has been the most widely studied of all approaches for delivery of growth factors and biologics for IVD regeneration. Walsh et al. reported the in vivo effect of single or multiple injections of several growth factors, including bFGF, GDF-5, IGF-1, or TGF-β, in mouse caudal disks with degeneration induced by static compression [181]. Fibrochondrocyte aggregates were observed at 4 weeks in the nucleus of disks that received a single injection of GDF-5 and multiple injections of TGF-β, while a single injection of IGF-1 may have elicited an early, transient response at 1 week and bFGF treatment had little effect. A statistically significant increase in disk height 4 weeks after GDF-5 treatment was also reported and the authors suggested that GDF-5 and TGF-β are mitogens for annular chondrocytes.

A single intradiscal administration of recombinant human OP-1 (rhOP-1) into normal rabbit disks in vivo resulted in increased disk height and proteoglycan content in the NP regions in comparison to a saline injection control group [187]. Other studies used a rabbit model of disk degeneration caused by needle puncture of the AF and showed that an injection of rhOP-1 (100 μg/disk) restored disk height, structural change, and mechanical properties [189,190]. In another rabbit model of disk degeneration a single injection of rhOP-1 (100 μg/disk) significantly reversed the decrease in disk height following chondroitinase ABC chemonucleolysis; the reversal was sustained for up to 16 weeks and resulted in a significantly higher proteoglycan content compared to the vehicle control group [191]. The in vivo efficacy of rhOP-1 has been confirmed in a rat model of chronic compression of tail IVDs; under continuous compression load the injection of rhOP-1 resulted in an increase of the ECM, as observed by histology, in the degenerated disks [188]. An extension of that study confirmed that a direct injection of OP-1 into the chronically compressed rat tail IVDs induced anabolic and anticatabolic activities, as documented by reduced immunostaining for aggrecanase, MMP-13, TNF-α, and IL-1β [192].

The effectiveness of direct protein delivery was also confirmed in experiments using rhGDF-5, where a single injection of rhGDF-5 resulted in the restoration of disk height, and improvements in MRI and histological grading scores in the rabbit annular puncture model of disk degeneration [167]. In this model a single injection of rhGDF-5 significantly suppressed the mRNA expression of cytokines (IL-1β, IL-6, TNF-α), catabolic enzymes (ADAMTS4, cyclooxygenase-2), and pain-related molecules [nerve growth factor (NGF), vascular EGF] by punctured disks. The benefits of increased levels of GDF-5 on IVD regeneration have also been explored by a more indirect mechanism. In a mouse annular puncture model, GDF-5 overexpression vectors delivered via adenovirus increased disk height and improved GAG retention [182]. However, despite the apparent success of intradiscal injection of rhGDF-5 in animal models, the results have not been able to be replicated in clinical trials. An initial combined phase I/II clinical trial with 32 participants showed promising results as patients reported improved pain scores and a decrease in pain-related disability [183], but a double-blind placebo-controlled phase II clinical trial revealed no significant improvements over placebo in pain, disability, or quality of life [184].

In a rabbit annular stab model of disk degeneration, an intradiscal injection of BMP-2 resulted in degenerative changes that were more frequent and severe than with the saline control, and promoted hypervascularity, and fibroblast proliferation but had no effect on new bone formation or fusion of the IVD after 12 weeks; the authors suggest that rhBMP-2 may be involved with a response to injury after an annular tear [180]. In an annular stab ovine large animal model of disk degeneration the simultaneous injection of recombinant human GDF-6 (rhGDF-6; also known as BMP-13), which plays a role in spinal column development and promotes the expression of chondrogenic marker genes in a variety of cell types, was protective against loss of disk height and cells from the disk, and resulted in increased levels of disk ECM proteins compared to annular stab alone [101]. In a rabbit annular puncture model, intradiscal injection of GDF-6 (10 or 100 μg/disk in PBS) 4 weeks after degeneration was initiated resulted in a partial restoration of disk height and an improvement of MRI degeneration grades 12 weeks later [185].

Intradiscal injections of rhPDGF-BB in a thiol-modified hyaluronic acid hydrogel in a rabbit annular puncture model showed that PDGF prevented cell apoptosis and the deposition of matrix containing type-III collagen 4 weeks after treatment [193]. When examined 8 weeks after treatment, PDGF-treated degenerated IVDs had significantly higher MRI indices, reduced degeneration, and an increase in compressive strength to failure.

The in vivo application of PRP-impregnated gelation hydrogel microspheres (PRP-GHMs) has been evaluated

in a nucleotomy rabbit model of disk degeneration. Histological and immunohistochemical studies revealed that the structure of the IVD and the accumulation of proteoglycans were preserved by the injection of PRP-GHMs, but not in PRP alone and saline controls [196]. An extension of these studies in this model reported that

1. disk height and water content were preserved in PRP-GHMs-treated IVDs in MR images,
2. the mRNA expression of proteoglycan core protein and type II collagen was significantly higher, and
3. the number of apoptotic cells in the NP was lower after PRP-GHM treatment compared with other treatment groups (PRP-saline, saline-GHM, puncture only) [197].

PRP treatments continue to show promise in human trials for treating degenerative disk disease. In preliminary human assessments and clinical trials, patients receiving PRP injections have reported modest improvements in pain and function as measured by the pain visual analog scale (VAS) and the Oswestry Disability Index (ODI) even up to 2 years after receiving the treatment [199–202].

Aberrant TGF-β signaling has been implicated in matrix degradation and subsequent IVD degeneration [195,207,208]. Increasing the presence of TGF-β by its overexpression or by delivering recombinant protein directly to the disk has shown promise in multiple animal models by exhibiting increased matrix synthesis and an increase in annular fibrochondrocytes [181,194]. However, TGF-β is highly expressed in patients with DDD and has also been shown to increase the presence of catabolic proteins such as aggrecanase and MMP through a secondary signaling pathway via the ALK1 receptor that results in the phosphorylation of Smad 1/5/8 [207,208]. This concept gave rise to another unique approach to modulating TGF-β signaling that employs a peptide known as YH14618. This peptide binds to TGF-β1, thus causing its preferential binding to specific receptor heterodimers and resulting in a reduction in downstream Smad 1/5/8 phosphorylation [184,195,209]. The outcome of these processes is an increase in the synthesis of ECM components and a reduction in TGF-β-induced NGF expression [195]. In 2015 YH14618 completed a combined Phase I/II clinical trial with 50 participants that showed improvements in both VAS and ODI, but no significant changes in disk height or MRI scores. The following year, a Phase IIb trial was halted as YH14618 failed to show the anticipated benefits as compared to the placebo group [184]. Despite the setback of the failed clinical trial, YH14618 was recently licensed to a separate company and another clinical trial is expected to begin soon.

In vivo studies: other biologics

LinkN is an in vivo proteolytic degradation byproduct of proteoglycan aggregate stabilizing link protein. The effect of the intradiscal administration of the synthetic peptide of LinkN, which stimulates proteoglycan and collagen synthesis of IVD cells in vitro, was evaluated in the rabbit anular puncture model of disk degeneration and was shown to partially restore disk height, increase anabolic ECM gene expression, and reduce catabolic gene expression [156]. In a recent study in a large animal model of disk degeneration, the disk architecture and mechanical properties of surgically denucleated porcine (minipig) IVDs injected with a fibrin sealant, which promotes IVD cell proliferation and matrix synthesis, were preserved [210]. In addition, fibrin also inhibited fibrosis of the NP, increased proteoglycan synthesis, reduced secretion of proinflammatory cytokines, and increased the synthesis of the proresolution factors, TGF-β, and IL-4. Nasto et al. have recently demonstrated that inhibition of NFκB activity via intraperitoneal injection of Nemo Binding Domain peptide reduced proteoglycan loss in disk degeneration observed in a mouse model of accelerated aging [211].

The therapeutic use of PRP treatments for the management of chronic low back pain has recently been tested in multiple preclinical [196–198,212–217] and clinical trials [199,201,218,219]. The results of these studies have been reviewed in detail elsewhere [220]. PRP is a concentrated, autologous blood product containing platelets, as well as natural concentrations of cytokines and growth factors [221,222]. The recent success of PRP therapies in the treatment of tendinopathies [223] and osteoarthritis [224] have led to increased interest in PRP treatment for low back pain and disk degeneration. In small animal models of disk degeneration, disks receiving intradiscal PRP injection have demonstrated decreased disk degeneration [196,216], increased disk height, increased disk hydration [197], and improved of disk appearance and signal in MRI imaging [216]. In clinical trials, patients receiving intradiscal PRP injection for the treatment of painful disk generation reported reduced pain [199,201,218] and improved disability scores when compared to patients in discectomy group. While findings from these clinical trials are promising, further clinical trials will be required to establish a standardized PRP treatment for painful disk degeneration.

Gene therapy for intervertebral disk regeneration

While the studies described above illustrate a range of proteins considered as possible therapies for IVD regeneration, it is important to consider the unavoidable limitations of protein delivery to the disk space. Issues such as protein half-life or solubility, the need for a proper carrier, need to preserve mechanical environment or cell numbers, and/or the presence of inhibitors are all factors that can be

expected to affect the therapeutic efficacy of protein delivery in vivo. A consideration for the use of recombinant protein therapies is also cost, as some disk pathologies and the need to inhibit disk degeneration may be chronic in nature or require multiple treatments. Gene therapy has been advocated as a therapeutic alternative for the delivery of biologics in disk regeneration [225]. DNAs that encode specific proteins may be delivered into the cells by viral or nonviral transfection, with the result that these cells produce proteins to, theoretically, prolong the duration of action. In this section, we discuss multiple methods of gene therapy that have been performed for regeneration and inhibition of degeneration of the IVD.

Gene transfer studies: viral

Adenoviral vectors often possess high titers and infectivity and are able to infect nondividing cells such as IVD cells. Adenoviral-mediated gene transfer to human IVD cells has been shown to be efficient and to produce transcripts across nondegenerative to degenerative cell types [226,227]. Studies have demonstrated an ability to increase expression of anabolic proteins such as Sox9, GDF-5, and LMP-1 in disk cells and have anabolic effects including increased proteoglycan synthesis [227–229]. The feasibility of using direct in vivo adenoviral-mediated gene transfer to disk cells has also been demonstrated for anabolic proteins such as GDF-5, TGF-β1, and LMP-1 and shown to exert a biological effect on biosynthesis, often for several weeks [182,194,228].

In addition to upregulation of anabolic factors, inhibition of catabolic processes has also been studied using gene therapy for IVD regeneration. Wallach et al. reported that gene transfer of the tissue inhibitor of metalloproteinase-1 (TIMP-1), an inhibitor of catabolic enzymes, can increase proteoglycan accumulation within pellet cultures of human IVD cells [230]. Le Maitre reported that human disk cells infected with Ad-IL-1 receptor antagonist (Ad/IL-1Ra) were resistant to IL-1 [231]. When in vitro–infected cells were injected into disk explants in vitro, IL-1 receptor antagonist protein expression was also increased and maintained for the 2-week time period investigated.

There are significant concerns about adenoviral vector use clinically, however, that may include significant toxicity when used in spinal applications [232,233]. These concerns have led investigators to begin consideration of adeno-associated viral vectors (AAVs) which are known to be less immunogenic [234]. Studies have been performed with AAV to deliver genes previously delivered with adenovirus, including the delivery of Sox9, TIMP1, TGF-β1 in vivo [235–237]. All of these studies demonstrated measurements that indicated delayed disk degeneration. Therefore even though AAV systems have a disadvantage in that they induce lower levels of protein expression and the expression of transferred genes is more delayed, they can still mediate gene transfer with desired effects in the IVD [238].

Adenoviral vectors and AAV are a form of transient gene transfer as genes do not integrate into the genome. Therefore to have more long-term effects lentivirus has also been considered for IVD gene therapy [239]. Lentivirus has successfully been used to deliver anabolic genes, and inhibitors of catabolic processes in vivo. In a study by Yue et al., it was demonstrated that delivery of Survivin, an antiapoptotic gene, by lentivirus in vivo into a rabbit animal model reduces disk cell apoptosis [240]. Yue et al. also performed an additional study where they multiplexed lentivirus-based Survivin overexpression with TGFβ3 and TIMP1 overexpression. In this study, they demonstrated improved matrix composition in addition to decreased apoptosis [241]. The other in vivo lentiviral gene delivery study done to date investigated the delivery of TGFβ3 and TIMP1 along with CTGF [242]. This study by Liu et al. demonstrated that degeneration characterized by MRI was ameliorated, and type II collagen and aggrecan expression levels were significantly higher than puncture control for up to 20 weeks after treatment. Overall positive effects of lentivirus-mediated gene delivery have been demonstrated by these studies and some assessment of safety has been performed [239], but more extensive studies of longevity and safety are needed. The main safety concerns associated with lentivirus are insertional mutagenesis which can have a carcinogenic effect if the insertion affects a gene associated with cell division. This has become less of a concern with new generations of lentivirus which are much safer [243]. In addition, recent clinical trials have utilized lentivirus for in vivo gene delivery for the treatment of Parkinson's and macular degeneration and have not observed adverse effects related to the lentivirus [244,245].

Gene transfer studies: nonviral

To avoid safety concerns found with viral gene transfer, several nonviral methods for direct gene transfer to cells have been proposed. Reports using microbubble-enhanced ultrasound gene therapy [246] and a "gene gun" method [247,248] have shown that the introduction of a marker or growth factor gene could be accomplished and provides sustained gene expression without the need for viral vectors. These methods still demonstrated a low efficiency for the transfection of plasmids (~8%–14%). With a need to improve nonviral gene transfer efficiency, more recent research has focused on making this gene transfer more efficient. For example, in a study by Feng et al., nanofibrous spongy microspheres, which are a complex of hyperbranched polymers and DNA, demonstrated a

transfection efficiency of 32.4% into rat NP cells, and an ability to deliver NR4A1 (a fibrosis inhibitor) and have a therapeutic effect [249]. Another study by Feng et al. developed a cationic block copolymer gene delivery system that demonstrated an efficiency of 32.5% in vitro and therapeutic effects when used to deliver heme oxygenase-1 in vivo [250].

Endogenous gene regulation

Aside overexpressing therapeutic genes via exogenous gene delivery, there has also been an investigation of endogenous gene regulation. This regulation of endogenous genes in disks and disk cells has been performed through both viral and nonviral methods.

Nonviral methods have successfully been used to deliver and overexpress small transcripts for regulating gene expression, such as microRNAs and siRNAs. Regarding siRNA, both in vitro and in vivo have been performed and shown positive results [225]. Seki et al. have demonstrated a single injection of naked ADAMTS5 siRNA oligonucleotide demonstrated improved MRI scores and histological grade in a rabbit annular puncture model [251]. Banala et al. simultaneously delivered siRNA against caspase-3 and ADAMTS5 via lipoplexes in vivo and saw regenerative effects in histological analysis [252]. MicroRNA is a regulatory RNA that has more recently been discovered to play roles in disk degeneration by regulating genes associated with disk degeneration or disk tissue maintenance [253]. Delivery of microRNA mimics or microRNA inhibitors can be achieved nonvirally, with significant positive effects. For example, in a study by Sun et al., overexpression of miR-155 by lipofectamine-based transfection into rat NP cells significantly inhibited matrix degradation [254]. In a study by Zhang et al., overexpressing miR-140-5p using lipofectamine transfection inhibited liposaccharide-mediated inflammation in human NP cells [255]. An in vivo study by Ji et al. demonstrated that delivery of an oligo inhibiting miR-141, a microRNA, which mediates progression of disk degeneration using a commercial lipid−based delivery system, reduced histological scores and decreases in disk height in a mouse model of disk degeneration [256]. The microRNA field is still relatively new in IVD research, and there is still work to be done to evaluate if this nonviral microRNA delivery is feasible in vivo, but it holds promise in providing a gene therapy with a regenerative effect.

Viral methods have been utilized to deliver CRISPR/dCas9 systems to disk cells for endogenous gene regulation. To date, only two studies have utilized disk cells, both performing gene downregulation with the CRISPR/dCas9 system [128,257], and several have been performed in stem cells with the purpose of enhancing their regenerative effects [258]. Farhang et al. successfully downregulated TNFR1 expression via lentiviral delivery to human NP cells and demonstrated inhibition of apoptosis and catabolic gene expression under inflammatory stimulation [128]. Although it has not been performed in disk cells yet, these systems can also be used to upregulate endogenous genes [259]. This may be useful in future work for regulating genes mediating ECM expression (i.e., aggrecan) in a multiplex manner, which have been difficult to overexpress, especially simultaneously, due to size. In fact, this concept has already been demonstrated in adipose-derived stem cells [260]. Overall, these CRISPR/Cas9 systems hold promise in regulating the expression of specific genes to enhance the regenerative effects of either endogenous disk cells or exogenously delivered cells.

Gene therapy in summary

Overall, there are advantages and disadvantages to each gene therapy method discussed. With safety concerns associated with viral delivery, nonviral methods are preferred if possible. Though nonviral methods are still not as efficient as viral methods, but with a rise of ex vivo engineered cells being used for therapies, as seen by a number of in clinical trials in this area [261], this issue may not be as problematic. In addition, ex vivo gene transfer may be more desirable even if we eventually do achieve high efficiency with nonviral methods. This is due to the proximity of the disk target to the spinal cord. Significant harm can occur when there is due to failure to control delivery, as seen with paralysis in rabbits due to accidental gene delivery in the intradural space [233]. Overall, there is a lot of ongoing gene therapy research for IVD regeneration, and there is still more work to be done in determining the best approach to use clinically.

In vivo preclinical models for intervertebral disk regeneration and replacement

In order for tissue-engineered IVD regeneration and replacement strategies to reach the clinic, there are critical translational steps that must occur to bring technologies from bench to bedside. Most tissue-engineered concepts are first developed and tested through ex vivo and in vitro models, with promising technologies moving onto small then large in vivo animal models. There are many well-defined ex vivo and in vitro models used to develop and analyze regenerative strategies; however, less is known about effective in vivo animal models for studying IVD regeneration. A vast array of animals have been used for in vivo study of IVD degeneration and

regeneration ranging from sand rats to primates [64,99,262–268]. Some models are chosen because they naturally degenerate and simulate aging in humans, while others are induced to a degenerative state by using methods ranging from mechanical injuries to chemical digestion to long-term smoking. The ideal animal model will depend on the tissue-engineered strategy being used, where regeneration strategies typically are applied on degenerated IVDs, while whole IVD replacement studies may not require degeneration prior to implantation. Knowing how to use these models to advance the translational potential of tissue-engineered regeneration schemes is equally as important as the repair technology itself. This section will briefly describe current animal models used to study IVD degeneration and regeneration, but for additional reading material Singh et al. provide an excellent review.

When selecting an animal model for in vivo study, there are a variety of factors to consider depending on the type of regenerative strategy and the purpose of the study. Small animal models have been proven to be valuable tools for initially screening a variety of therapeutics for therapeutic efficacy and immune response but do not mimic the geometry or mechanical loads seen in humans IVDs [268]. Rat tail and lumbar spine models are popular choices for initial screening of novel tissue-engineered strategies for their ease of surgical access and well-defined degeneration progression. Degeneration is not a natural phenomenon in either rat tail or lumbar IVDs; however, it may be induced through mechanical injury, tail bending, axial compression, or tail suspension. Another commonly used small animal model for in vivo study is New Zealand white rabbits, whose lumbar IVDs have slightly larger geometry than rats and have been induced to degenerate through the above methods and chemical digestion, torsional injury, resection of bony processes, and fusion of adjacent IVDs.

Once a tissue-engineered therapy has been shown effective with minimal host response in a small animal model in vivo, large animal models are almost always necessary prior to translation to humans. Commonly used large animal models are sheep lumbar spines, goat lumbar spines, dog cervical and lumbar spines, pig lumbar spines, and primate lumbar and cervical spines [64,268]. Large animal models are useful to analyze the safety and efficacy of regenerative therapies under conditions more similar to the human spine with respect to IVD geometry, mechanical loading, and nutritional requirements. Care must be taken, however, to avoid solely choosing a model based on the above characteristics without considering the fibrosity of the NP, curvature of the spine, and presence of notochordal cells. Excessive spinal curvature can create large discrepancies in mechanical loading between the human spine. In one study the beagle cervical spine was chosen to investigate whole tissue-engineered replacement IVDs in vivo; however, the curvature and angle of cervical IVDs led to instability and migration of the implanted constructs [79]. Notochordal cells are the developmental progenitors of NP cells and disappear before skeletal maturity in humans; however, they are persistent in some species throughout adulthood [268]. The presence of notochordal cells will actively regenerate NP cells and other cell populations, which tends to keep the NP more fluid-like as seen in young human IVDs rather than fibrous as is common in aging human adults.

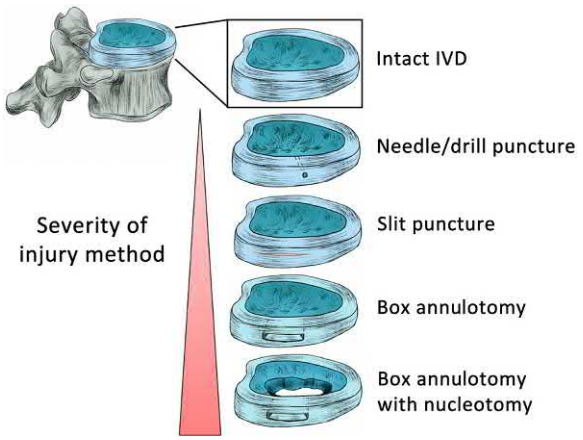

FIGURE 51.8 Representative injury methods to precipitate IVD degeneration for in vivo animal models.
A wide variety of injury methods have been used to initiate IVD degeneration in preclinical animal models. Needle and slit puncture are the most simple and consistent; however, they may not be aggressive enough to initiate degeneration. More aggressive injuries such as annulotomy and nucleotomy have a greater chance of precipitating degenerative changes to the IVD but are more difficult to employ and the amount of tissue removed is variable. *IVD*, Intervertebral disk. *Adapted from Sloan, et al. Tissue Eng, B 2018.*

As with the small animal models, there are a variety of methods to precipitate IVD degeneration if the selected animal model does not degenerate spontaneously. In large animal models, mechanical injury is the commonly used method, where injury/removal of the AF and NP leads to degeneration over time in vivo [63]. Groups have demonstrated successful IVD degeneration in vivo using slit/stab injuries, needle punctures, box annulotomies, and box annulotomies with nucleotomy [64]. The aggressiveness of the injury method dictates the progression of IVD degeneration, where small injuries lead to low levels of degeneration if any, while larger injuries can lead to herniation and collapse of the disk space (Fig. 51.8). Elliott et al. found that degeneration is proportional to the size of the injury relative to disk height and that on average injuries over 40% of the disk height have a high probability to initiate degeneration [63]. Besides mechanical injury, injection of chemolytic agents into the IVD such as chondroitinase ABC and chymopapain have been shown to

induce degeneration over time [265,269]. Varying degrees of degeneration can be achieved by tuning the concentration of the injected substances.

Concluding remarks

Efforts to regenerate and replace the tissues of the IVD have virtually exploded over the last two decades, although the field remains in its infancy. The complexity of the diverse degenerative and pathological processes that affect the IVD, as well as the intrinsic complexity of the heterogeneous disk structures, require that multiple strategies be developed for the treatment of the IVD. Development of strategies using cells, biologics, or gene therapy is often focused upon restoration of a single tissue source, such as NP or AF, and with or without biomaterial scaffolds. However, a growing number of tissue-engineering solutions have been proposed to integrate multiple tissues in the repair process, and additional work to promote integration amongst native, neo-generated, and implanted tissues will be critical to restoring IVD function. Many of the identified strategies derive largely from knowledge gained in cartilage tissue engineering, although the differing cellular, functional, and structural requirements of the IVD suggest that custom approaches are needed. Advances in IVD cell biology are needed to enable the identification of novel therapeutic targets, to select for classes of biomaterials, and to suggest appropriate drug delivery strategies, as disk cell phenotype, cell-biomaterial interactions, and the biology of aging for these cells, are still poorly understood. While a diverse array of molecules, cell sources, and materials are suggested as appropriate for IVD regeneration, additional work is needed to reveal some common and unique themes in human IVD cell responses that focus research on IVD specific strategies. Currently, underway clinical trials of autologous cell therapies or autologous protein products will pave the way for later generations of cellular and biologic-based therapies, as they are expected to illustrate the unique challenges of treating the pathologic and aged human IVD. The next decade promises great advances in the translation of basic and applied sciences to the clinical treatment of IVD regeneration and replacement.

Chapter 52

Articular cartilage injury

J.A. Martin, M. Coleman and J.A. Buckwalter

Department of Orthopedics and Rehabilitation, Iowa City Veterans Administration Medical Center, University of Iowa College of Medicine, Iowa City, IA, United States

Introduction

In an effort to decrease the risk of posttraumatic osteoarthritis (OA), surgeons and scientists have been seeking ways to prevent progressive joint degeneration following injury. Surgeons have used operative treatments, including penetrating subchondral bone, soft-tissue grafts, and cell transplants, to stimulate restoration of damaged articular surfaces, with variable results. This chapter covers recent advances in efforts to prevent posttraumatic OA and in the use of artificial matrices, growth factors, and immature chondrocytes, or stem cells to promote cartilage repair as well as work suggesting that several biologic agents, including caspase inhibitors, antioxidants, and anti-inflammatory drugs, may minimize the effects of mechanical damage to chondrocytes.

Mechanical loading of articular surfaces in excess of the tolerances of those surfaces damages chondrocytes and their matrix; this damage can cause joint degeneration leading to the clinical syndrome of posttraumatic OA. The risk of posttraumatic OA depends on the type and severity of the injury and also on the repair and remodeling of the damaged articular surfaces. Three classes of joint injuries can be identified, based on the type of articular surface damage:

1. chondral damage and, in some cases, subchondral bone damage that does not cause visible disruption of the articular cartilage;
2. mechanical disruption of the joint surface limited to articular cartilage (chondral ruptures or tears); and
3. mechanical disruption of articular cartilage and subchondral bone (articular surface fractures).

In most instances, chondrocytes can repair damage that does not disrupt the articular surface if they are protected from further injury. Mechanical disruption of articular cartilage stimulates chondrocyte synthetic activity, but this response, with few if any exceptions, fails to repair the tissue damage. Disruption of articular cartilage and subchondral bone stimulates chondral and bone repair. The osteochondral repair response usually heals the bony injury, but the chondral repair tissue does not duplicate the properties of normal articular cartilage.

Normal pain-free movement depends on the unique properties of the articular cartilage that forms the bearing surfaces of synovial joints [1]. Degeneration of this remarkable tissue causes OA: joint pain and dysfunction that limit mobility [2,3]. The mechanisms, frequency, and natural history of articular surface injuries are poorly understood, but it is clear that these injuries can lead to posttraumatic OA [1,4–6]. Limited awareness of chondral and osteochondral injuries and difficulty in diagnosing many of these injuries makes it impossible to determine accurately their incidence, or their relationship to the development of joint degeneration [1,7,8]. However, arthroscopic examinations of injured knee joints suggest that closed articular surface injuries occur frequently [9,10]. One group of surgeons arthroscopically examined 85 knees with traumatic hemarthrosis but absent or negligible ligamentous instability [9]. Twenty percent of these knees had articular surface defects. In many patients cartilage injuries occur in association with injuries to other joint tissues, including menisci, ligaments, joint capsule, and synovium. In these people the cartilage injury may be overlooked; even when it is identified, it is difficult to distinguish the effects of the cartilage injury from the effects of the injuries to the other tissues. Damage to articular surfaces that does not result in visible disruption of articular cartilage or subchondral bone is not easily detected, although it probably occurs far more frequently than chondral and osteochondral fractures [4,6].

Recent advances in methods of diagnosing articular surface injuries, including arthroscopy and magnetic resonance imaging [11–13], combined with reports of new

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00054-X

methods of stimulating cartilage repair or regeneration and osteochondral transplantation have increased interest in these injuries. Clinical evaluation of patients with articular surface damage and determination of the appropriate role of new treatments or the need for any treatment requires an understanding of the mechanisms of these injuries and their natural history. This chapter discusses the relationship between articular surface injury and joint degeneration, mechanisms of articular surface injuries, the responses of articular surfaces to injury and approaches to preventing joint degeneration following joint injury.

Articular cartilage injury and joint degeneration

The end stage of posttraumatic OA, the OA that follows joint injury, is identical to that of primary OA. In contrast to primary OA, which primarily affects older individuals and does not have a known inciting event, patients with posttraumatic OA are often young or middle-aged adults and have a well-defined precipitating insult [14,15]. Clinical experience and epidemiologic studies show that meniscal, ligament, and joint-capsule tears, joint dislocations, and intraarticular fractures increase the risk of the progressive joint degeneration and posttraumatic OA [14,16,17]. Participation in sports that expose joints to high levels of impact or torsional loading also increases the risk of joint degeneration [8,15].

The risk of OA following joint injury varies with the type of injury: meniscal and ligamentous injuries have a lower risk than intraarticular fractures. Gelber et al. [14] found that 13.9% of those who had a knee injury (including meniscal, ligamentous, or bone injuries) during adolescence or young adulthood developed knee OA, as compared with 6.0% of those who did not have a knee injury. A study of patients who suffered ligamentous and meniscal injuries of the knee reported that they had a tenfold increased risk of OA compared with patients who do not have joint injuries [18]. Intraarticular fractures have the greatest risk of OA. Depending on the severity of the injury and on the joint, the risk ranges from about 25% to more than 50% of patients [15,19].

The time interval between joint injury and the development of OA varies from less than a year in patients with severe intraarticular fractures to a decade or more in some patients with ligamentous or meniscal injuries [15,19]. Because many joint injuries occur in young adults, the population of patients with posttraumatic OA includes many individuals under 50 years of age. But older individuals may have an increased risk of OA after joint injuries. Studies of patients with intraarticular fractures of the knee show that patients older than 50 years of age have a two- to fourfold greater risk of developing OA than younger patients; patients over 40 years who have acetabular fractures and patients over 50 years who have displaced ankle fractures may also have a greater risk of OA than younger patients who have similar injuries; and age increases the risk of knee joint degeneration after anterior cruciate ligament (ACL) injury [15,20].

Mechanisms of articular cartilage injuries

Understanding the mechanisms of articular surface injuries requires appreciation of how loads and rate of loading affect articular cartilage [6,21]. Slowly applied loads and suddenly applied loads differ considerably in their effects. The articular cartilage extracellular matrix (ECM) consists of water and a macromolecular framework formed primarily by collagens and large aggregating proteoglycans [1]. The collagens give the tissue its form and tensile strength, and the interaction of aggregating proteoglycans with water gives the tissue its stiffness to compression, resilience, and probably its durability. Loading of articular surfaces causes movement of fluid within the articular cartilage matrix that dampens and distributes loads within the cartilage and to the subchondral bone [22]. When this occurs slowly, the fluid movement allows the cartilage to deform and decreases the force applied to the matrix macromolecular framework. When loading is too rapid for normal tissue deformation and fluid flow to occur through, as with sudden impact or torsional loading of the joint surface, the matrix macromolecular framework sustains a greater share of the force. If this force is great enough, it ruptures the matrix macromolecular framework, damages cells, and exceeds the ability of articular cartilage to prevent subchondral bone damage by dampening and distributing loads.

In vivo, expected and unexpected, slow and sudden articular surface loading may differ in the amount of force transmitted to joint surfaces. Muscle contractions absorb much of the energy and stabilize joints during slow, expected movements or impacts. Sudden or unexpected movements or impacts may occur too rapidly for muscle contractions to stabilize joints and decrease the forces on the articular surfaces. For this reason, sudden and unexpected movements or impacts can transmit greater contact stresses to joint surfaces.

Acute or repetitive blunt joint trauma can damage articular cartilage and the calcified cartilage zone—subchondral bone region while leaving the articular surface intact [4,23–26]. The intensity and type of joint loading that can cause chondral and subchondral damage without visible tissue disruption has not been well defined. Physiologic levels of joint loading do not appear to cause joint injury and are necessary to maintain articular cartilage, but impact loading above that associated with normal activities but less than that necessary to produce cartilage disruption can

cause alterations of the cartilage matrix and damage chondrocytes [4,23,24,26–28]. Experimental evidence shows that loss of proteoglycans or alteration of their organization (in particular, a decrease in proteoglycan aggregation) occurs before other signs of cartilage injury following impact loading. The loss of proteoglycans may be due either to increased degradation of the molecules or to decreased synthesis. Significant loss of matrix proteoglycans decreases cartilage stiffness and increases its permeability. These alterations may cause greater loading of the remaining macromolecular framework, including the collagen fibrils, increasing the vulnerability of the tissue to further damage from loading. These injuries may cause other matrix abnormalities besides loss of proteoglycans, such as distortions of the collagen fibril meshwork and disruptions of the collagen fibril proteoglycan relationships and swelling of the matrix, and they may injure chondrocytes [4,26].

Currently, there is no clinically applicable method of detecting alterations in articular cartilage that predictably lead to OA; however, new imaging techniques may provide methods of assessing articular cartilage composition and changes in cartilage thickness that inevitably lead to OA, including advances in magnetic resonance imaging, contrast enhanced μCT, and standing CT [29]. When probing the articular surface, surgeons sometimes find regions of apparent softening that may result from alterations in the matrix, and devices are being developed that will allow in vivo measurement of articular surface stiffness. Combined with information about cartilage composition, these measurements may make it possible to better define injuries to the articular surface that do not result in visible tissue disruption.

Disrupting a normal articular surface with a single impact requires substantial force, presumably because of the ability of articular cartilage and subchondral bone to dampen and distribute loads. A transarticular load of 2170 N applied to canine patellofemoral joints caused fractures in the zone of calcified cartilage visible by light microscopy and articular cartilage fissures that extended from the articular surface to the transitional or superficial radial zone of the articular cartilage [24]. A study of the response of human articular cartilage to blunt trauma showed that articular cartilage could withstand impact loads of up to 25 N/mm^2 (25 MPa) without apparent damage. Impact loads exceeding this level caused chondrocyte death and cartilage fissures [30]. The authors suggested that reaching a stress level that could cause cartilage damage required a force greater than that necessary to fracture the femur. Another study [31] measured the pressure on human patellofemoral articular cartilage during impact loading and found that impact loads less than the level necessary to fracture bone caused stresses greater than 25 MPa in some regions of the articular surface. With the knee flexed 90 degrees, 50% of the load necessary to cause a bone fracture produced joint pressures greater than 25 MPa for nearly 20% of the patellofemoral joint. At 70% of the bone fracture load, nearly 35% of the contact area of the patellofemoral joint pressures exceeded 25 MPa, and at 100% of the bone fracture load 60% of the patellofemoral joint pressures exceeded 25 MPa. These latter results show that impact loads can disrupt cartilage without fracturing bone.

Other experimental investigations show that repetitive impact loads can split articular cartilage matrix and initiate progressive cartilage degeneration [32–34]. Cyclic loading of human cartilage samples in vitro caused surface fibrillation [33]. Periodic impact loading of bovine metacarpal phalangeal joints in vitro combined with joint motion caused degeneration of articular cartilage [35]. Repeated overuse of rabbit joints in vivo combined with peak overloading caused articular cartilage damage including formation of chondrocyte clusters, fibrillation of the matrix, thickening of subchondral bone, and penetration of subchondral capillaries into the calcified zone of articular cartilage [34]. The extent of cartilage damage appeared to increase with longer periods of repetitive overloading, and deterioration of the cartilage continued following cessation of excessive loading. This latter finding suggests that some cartilage damage is not immediately visible.

An investigation of cartilage plugs also showed that repetitive loading disrupted the tissue and that the severity of the damage increased with increasing load and increasing number of loading cycles [36]. Two-hundred-and-fifty cycles of 1000 $lb/in.^2$ compression caused surface abrasions. Five-hundred cycles produced primary fissures penetrating calcified cartilage, and 1000 cycles produced secondary fissures extending from the primary fissures. After 8000 cycles, the fissures coalesced and undermined cartilage fragments. Higher loads caused similar changes with fewer cycles. The experiments suggested that repetitive loading can propagate vertical cartilage fissures from the joint surface to calcified cartilage and cause extension of oblique fissures into areas of intact cartilage.

Clinical studies have identified articular cartilage fissures, flaps, and free fragments and changes in subchondral bone similar to those produced experimentally by single and repetitive impact loads [4,37]. In at least some patients, acute impact loading of the articular surface or twisting movements of the joint apparently caused these injuries. In other patients, the cartilage damage may have resulted from repetitive loading. Magnetic resonance imaging of joints soon after an acute impact or torsional load occasionally shows changes in subchondral bone consistent with damage to the zone of calcified cartilage and subchondral bone, even when the articular surface is intact [11–13,38].

Clinical experience suggests that chondral ruptures or tears and osteochondral fractures result from similar impact and twisting-joint injuries, but they tend to occur in different age groups, and some individuals may have a greater risk of chondral tears. Chondral tears generally occur in skeletally mature people, while osteochondral fractures typically occur in skeletally immature people or young adults. This difference may result from age-related changes in the mechanical properties of the articular surface, including the uncalcified cartilage, the calcified cartilage zone, and the subchondral bone, that is, age-related alterations in the articular cartilage matrix decrease the tensile stiffness and strength of the superficial zone, and the calcified cartilage zone–subchondral bone region mineralizes fully following the completion of skeletal growth, presumably creating a marked difference in mechanical properties between the uncalcified cartilage and the calcified cartilage subchondral bone region. Taken together, these changes probably increase the risk of ruptures of the superficial-cartilage matrix and of these ruptures extending to the calcified cartilage subchondral bone region. Genetically determined abnormalities of the articular cartilage may also increase the risk of chondral ruptures from a given impact or torsional load, but the relationships between known genetic abnormalities of articular cartilage and cartilage properties have not been well defined.

Response of articular cartilage to injury

Articular surface injuries can be classified based on the type of tissue damage and the repair response:

1. cartilage matrix and cell injuries, that is, damage to the cartilage that does not cause visible mechanical disruption of the articular surface;
2. chondral fissures; flap tears, or chondral defects, that is, visible mechanical disruption of articular cartilage limited to articular cartilage; and
3. osteochondral injuries, that is, visible mechanical disruption of articular cartilage and bone (Table 52.1).

Matrix and cell injuries

Acute or repetitive blunt trauma, including excessive impact loading, can cause alterations in the articular cartilage matrix, including a decrease in proteoglycan concentration and possibly disruptions of the collagen fibril framework. Injuries that do not cause an apparent articular cartilage injury, including joint dislocations or ligament and joint capsule tears, may have associated damage to the articular cartilage cells and matrix [39]. The ability of chondrocytes to sense changes in matrix composition and to synthesize new molecules makes it possible for them to repair damage to the macromolecular framework [40]. It is not clear at what point this type of injury becomes irreversible and leads to progressive loss of

TABLE 52.1 Chondral and osteochondral injuries.

Injury	Clinical presentation	Repair response	Potential for healing
Damage to chondral matrix and/or cells and/or subchondral bone without visible disruption of the articular surface	No known symptoms, although subchondral-bone injury may cause painInspection of the articular surface and current clinical imaging methods for articular cartilage lesion may cause injuryImaging of subchondral bone may show abnormalities	Synthesis of new matrix macromolecules and cell proliferation	If the basic matrix structure remains intact and enough viable cells remain, the cells can restore the normal tissue compositionIf the matrix and/or cell population sustains significant damage or if the tissue sustains further cannot detect this type of damage, the lesion may progress to cartilage degeneration
Cartilage disruption (chondral fractures or ruptures)	May cause mechanical symptoms, synovitis, pain, and joint effusions	No fibrin clot formation or inflammation and synthesis of new matrix macromolecules and cell proliferation, but new tissue does not fill the cartilage defect	Depending on the location and size of the lesion and the structural integrity, stability, and alignment of the joint, the lesion may or may not progress to cartilage degeneration
Cartilage and bone disruption (osteochondral fractures)	May cause mechanical symptoms, synovitis, pain, and joint effusions	Formation of a fibrin clot, inflammation, invasion of new cells, and production of new chondral and osseous tissue	Depending on the location and size of the lesion and the structural integrity, stability, and alignment of the joint, the lesion may or may not progress

articular cartilage. Presumably, the chondrocytes can restore the matrix as long as the loss of matrix proteoglycan does not exceed what the cells can rapidly produce, if the fibrillar collagen meshwork remains intact, and if enough chondrocytes remain viable. When these conditions are not met, the cells cannot restore the matrix, the chondrocytes will be exposed to excessive loads, and the tissue will degenerate. Recent analyses of cartilage anabolic/catabolic turnover suggest that the collagen fibrils are largely not turned over during adulthood, whereas proteoglycan and other key structural molecules are continuously, sometimes rapidly turned over [41]. This description of the crucial role for production of macromolecules by chondrocytes during disease has led to increased focus on cell metabolic machinery. Recently investigators have found compelling evidence that chondrocyte mitochondrial dysfunction has a central role in the development of OA following joint injury and that preventing mitochondrial dysfunction can prevent or decrease the severity of post-joint injury OA [42].

Chondral injuries

Acute or repetitive trauma can cause focal mechanical disruption of articular cartilage, including fissures, chondral flaps or tears, and loss of a segment of articular cartilage [4]. The lack of blood vessels and lack of cells that can repair significant tissue defects limit the response of cartilage to injury [43,44]. Chondrocytes respond to tissue injury by proliferating and increasing the synthesis of matrix macromolecules near the injury. But the newly synthesized matrix and proliferating cells do not fill the tissue defect, and soon after injury the increased proliferative and synthetic activity ceases.

Osteochondral injuries

Unlike injuries limited to cartilage, injuries that fracture subchondral bone cause hemorrhage and fibrin clot formation and activate the inflammatory response [43–45]. Soon after injury, blood escaping from the damaged-bone blood vessels forms a hematoma that temporarily fills the injury site. Fibrin forms within the hematoma and platelets bind to fibrillar collagen. A continuous fibrin clot fills the bone defect and extends for a variable distance into the cartilage defect. Platelets within the clot release vasoactive mediators and growth factors or cytokines (small proteins that influence multiple cell functions, including migration, proliferation, differentiation, and matrix synthesis). These cytokines include transforming growth factor beta and platelet-derived growth factor. Bone matrix also contains growth factors, including transforming growth factor beta, bone morphogenic protein, platelet-derived growth factor, insulin-like growth factor I, insulin-like growth factor II, and others. Release of these growth factors may have an important role in the repair of osteochondral defects. In particular, they stimulate vascular invasion and migration of undifferentiated cells into the clot and influence the proliferative and synthetic activities of the cells. Shortly after entering the tissue defect, the undifferentiated mesenchymal cells proliferate and can begin to synthesize a new matrix. Within 2 weeks of injury, some mesenchymal cells assume the rounded form of chondrocytes and begin to synthesize a matrix that contains type II collagen and a relatively high concentration of proteoglycans. These cells produce regions of hyaline-like cartilage in the chondral and bone portions of the defect. Six to eight weeks after injury, the repair tissue within the chondral region of osteochondral defects contains many chondrocyte-like cells in a matrix consisting of type II collagen, proteoglycans, some type I collagen, and noncollagenous proteins. Unlike the cells in the chondral portion of the defect, the cells in the bony portion of the defect produce immature bone, fibrous tissue, and hyaline-like cartilage. Over time, this tissue remodels form normal bone.

The chondral repair tissue typically has a composition and structure intermediate between that of hyaline cartilage and fibrocartilage, and it rarely, if ever, replicates the elaborate structure of normal articular cartilage [1,46–48]. Occasionally, the cartilage repair tissue persists unchanged or progressively remodels to form a functional joint surface. But in most large osteochondral injuries, the chondral repair tissue begins to show evidence of depletion of matrix proteoglycans, fragmentation and fibrillation, increasing collagen content, and loss of cells with the appearance of chondrocytes within a year or less. The remaining cells often assume the appearance of fibroblasts as the surrounding matrix comes to consist primarily of densely packed collagen fibrils. This fibrous tissue usually fragments and often disintegrates, leaving areas of exposed bone. The inferior mechanical properties of chondral repair tissue may be responsible for its frequent deterioration [1,44]. Even repair tissue that successfully fills osteochondral defects is less stiff and more permeable than normal articular cartilage, and the orientation and organization of the collagen fibrils in even the most hyaline-like cartilage repair tissue do not follow the pattern seen in normal articular cartilage. In addition, the repair tissue cells may fail to establish the normal relationships between matrix macromolecules, in particular, the relationship between cartilage proteoglycans and the collagen fibril network. The decreased stiffness and increased permeability of repair cartilage matrix may increase loading of the macromolecular framework during joint use, resulting in progressive structural damage to the matrix collagen and proteoglycans, thereby exposing the repair chondrocytes to excessive loads and further compromising their ability to restore the matrix.

Clinical experience and experimental studies suggest that the success of chondral repair in osteochondral injuries may depend to some extent on the severity of the injury, as measured by the volume of tissue or surface area of cartilage injured and the age of the individual [49]. Smaller osteochondral defects that do not alter joint function heal more predictably than larger defects that may change the loading of the articular surface. Potential age-related differences in healing of chondral and osteochondral injuries have not been thoroughly investigated, but bone heals more rapidly in children than in adults, and the articular cartilage chondrocytes in skeletally immature animals show a better proliferative response to injury and synthesize larger proteoglycan molecules than those from mature animals [40,50–54]. Furthermore, a growing synovial joint has the potential to remodel the articular surface to decrease the mechanical abnormalities created by a chondral or osteochondral defect.

Preventing joint degeneration following injury

Orthopedic surgeons routinely perform extensive surgical procedures, some having substantial complication rates, in an effort to restore the alignment and congruity of articular surfaces following intraarticular fractures [19]. The purpose of these procedures is to decrease residual joint incongruity and thereby to decrease focal elevations of contact stress, presumed to be responsible for posttraumatic OA. These widely accepted practices are based largely on the assumption that joints are less likely to develop OA if the peak stresses on focal areas of the articular surface are reduced. However, there is little evidence to guide surgeons in determining how much stress the articular surface can tolerate, in the form of either acute impact or chronically increased stress, and the potential for human joints to repair and remodel the articular surface after injury is poorly understood.

The importance of mechanical forces in the pathogenesis of OA has led to the inception of new minimally invasive, nonsurgical manipulations of the biological responses to joint injuries with a high risk of posttraumatic OA aimed at preventing or delaying the disease. For example, the work of D'Lima et al. [55–57] shows that caspase inhibition can decrease mechanically induced chondrocyte apoptosis. Haut et al. have reported that P188 surfactant can limit chondrocyte necrosis following impact loading [58,59].

Other investigations indicate that antioxidants can prevent mechanically induced chondrocyte damage [42,57,58]. These studies showed that chondrocytes are subject to oxidative stress and damage induced by various mechanical insults to cartilage, including single impacts and chronic overloading [42]. Chondrocyte mitochondria respond to overloading by overproducing superoxide ($O_2^{\bullet -}$) from complex I of the electron transport chain in a tissue strain–dependent manner [42]. $O_2^{\bullet -}$ is a free radical that damages cellular proteins, lipids, and nucleic acids. It is rapidly dismuted to hydrogen peroxide (H_2O_2), which also causes oxidative damage to the cell. Excessive oxidant production can therefore lead to cell death, or irreversible disruption of mitochondrial mass or activity as well as permanent deficits in glycolysis in surviving cells, each of which undermines protein synthesis and ECM stability [42]. Recent reports indicate that interventions limiting $O_2^{\bullet -}$ production (amobarbital) or that aid in the detoxification of H_2O_2 by cellular reductases (*n*-acetylcysteine) block these harmful effects and delay the development of posttraumatic OA in a porcine intraarticular fracture model, underscoring the centrality of oxidative stress to cartilage injury [42].

Promoting articular surface repair

Better understanding of articular cartilage injuries and recognition of the limitations of the natural repair responses have contributed to the widespread interest in cartilage repair and regeneration [4,43,44,60–62]. In the last four decades, clinical and basic scientific investigations have shown that implantation of artificial matrices, growth factors, perichondrium, periosteum, and transplanted chondrocytes and mesenchymal stem cells can stimulate formation of cartilaginous tissue in synovial joint osteochondral or chondral defects [1,16,60,62–66]. In addition, chondrogenic progenitor cells residing in articular cartilage are chemotactically drawn to sites of cartilage injury and in the presence of chondrogenic growth factors regenerate mechanically competent hyaline cartilage. Use of these cells offers an exciting approach to research directed toward regeneration of articular cartilage using autologous cells.

Penetration of subchondral bone

Experimental and clinical investigations show that penetration of subchondral bone leads to formation of fibrocartilaginous repair tissue on the articular surfaces of synovial joints [16,44,59,64–66]. In regions with full-thickness loss or advanced degeneration of articular cartilage, penetration of the exposed subchondral bone disrupts subchondral blood vessels, leading to formation of a fibrin clot that fills the bone defect and usually covers the exposed bone surface [49,60]. If the surface is protected from excessive loading, undifferentiated mesenchymal cells migrate into the clot, proliferate, and differentiate into cells with the morphologic features of chondrocytes [67]. In most instances, over a period of six to eight weeks they form

bone in the osseous portion of the defect and fibrocartilaginous tissue in the chondral portion [43,68,69]. Initially, the chondral repair tissue can closely resemble articular cartilage in gross and light-microscopic appearance, but it fails to duplicate fully the composition, structure, and mechanical properties of normal articular cartilage, especially the types and concentrations of collagens and proteoglycans, and in many instances it will deteriorate with time [1,43,44,46].

Surgeons currently use a variety of methods of penetrating subchondral bone to stimulate formation of a new cartilaginous surface, including arthroscopic drilling and abrasion of the articular surface and making multiple small-diameter defects or fractures with an awl or a similar instrument, a method referred to as the microfracture technique [16,37,60,66,68,69]. Multiple authors report that these procedures can decrease the symptoms from isolated articular cartilage defects of the knee in a majority of patients [37,66,68–73].

Periosteal and perichondrial grafts

The potential benefits of periosteal and perichondrial grafts include introduction of a new cell population along with an organic matrix and some protection of the graft or host cells from excessive loading. Animal experiments and clinical experience show that perichondrial and periosteal grafts placed in articular cartilage defects can produce new cartilage [73,74]. O'Driscoll has described the use of periosteal grafts for the treatment of isolated chondral and osteochondral defects and demonstrated that these grafts can produce a new articular surface [16,64,75,76]. Other investigators have reported encouraging results with perichondrial grafts [77,78]. However, one study suggests that increasing patient age adversely affects the results of soft-tissue grafts. Seradge et al. [79] studied the results of rib perichondrial arthroplasties in 16 metacarpophalangeal joints and 20 proximal interphalangeal joints at a minimum of 3 years following surgery. Patient age was directly related to the results. One-hundred percent of the patients in their 20s and 75% of the patients in their 30s had good results following metacarpophalangeal joint arthroplasties. Seventy-five percent of the patients in their teens and 66% of the patients in their 20s had good results following proximal interphalangeal joint arthroplasties. None of the patients older than 40 years had a good result with either type of arthroplasty. The clinical observation that perichondrial grafts produced the best results in younger patients [79] agrees with the concept that age may adversely affect the ability of undifferentiated cells or chondrocytes to form an articular surface or that with age the population of cells that can form an articular surface declines [47,50,54].

Cell transplantation

Transplantation of chondrocytic cells grown in culture provides another method of introducing a new cell population into chondral and osteochondral defects. Experimental work has shown that both chondrocytes and undifferentiated mesenchymal cells placed in articular cartilage defects survive and produce a new cartilage matrix [1,80–84]. In addition to these animal experiments, orthopedic surgeons have used autologous chondrocyte transplants for treatment of localized cartilage defects [65,81–83,85,86]. Proponents of this procedure report that it produces satisfactory results, including the ability to return to demanding physical activities, in as many as 90% of patients [87,88].

Artificial matrices

Treatment of chondral defects with growth factors or cell transplants requires a method of delivering and in most instances at least temporarily stabilizing the growth factors or cells in the defect. For these reasons, the success of these approaches often depends on an artificial matrix. In addition, artificial matrices may allow, and in some instances stimulate, ingrowth of host cells, matrix formation, and binding of new cells and matrix to host tissue [89,90]. Investigators have found that implants formed from a variety of biological and nonbiological materials, including treated cartilage and bone matrices, collagens, hyaluronan, chitosan, fibrin, carbon fiber, hydroxyapatite, porous polylactic acid, polytetrafluoroethylene, polyester, and other synthetic polymers, facilitate restoration of an articular surface [1,74,90–92]. Lack of studies that directly compare different types of artificial matrices makes it difficult to evaluate their relative merits, but the available reports show that this approach may contribute to restoration of an articular surface.

Growth factors

Growth factors influence a variety of cell activities, including proliferation, migration, matrix synthesis, and differentiation. Many of these factors, including the fibroblast growth factors, insulin-like growth factors, and transforming growth factor betas, have been shown to affect chondrocyte metabolism and chondrogenesis [49,74,93,94]. Bone matrix contains a variety of these molecules, including transforming growth factor betas, insulin-like growth factors, bone morphogenic proteins, platelet-derived growth factors, and others [49,95]. In addition, mesenchymal cells, endothelial cells, and platelets produce many of these factors. Thus osteochondral injuries and exposure of bone due to loss of articular cartilage may release these agents, which affect the formation of cartilage repair tissue and have an important role

in the formation of new articular surfaces after currently used surgical procedures, including penetration of subchondral bone.

Local treatment of chondral or osteochondral defects with growth factors has the potential to stimulate restoration of an articular surface [94,96–98]. Despite the promise of this approach, the wide variety of growth factors, their multiple effects, the interactions among them, and the possibility that the responsiveness of cells to growth factors may decline with age [50,52–54] have made it difficult to develop a simple strategy for using these agents to treat articular surface injuries. However, development of growth factor–based treatments for isolated chondral and osteochondral injuries in combination with other approaches, including use of artificial matrices and cell transplants, appears promising [62,99].

Antiinflammatories

Posttraumatic synovitis is associated with joint injuries that cause OA [98]. Joint injury results in increases in proinflammatory cytokines in synovial fluids, which may promote cartilage degeneration. A clinical study indicated that anticytokine therapy relieved acute knee pain in patients with ACL tear [100], a result suggesting that such treatments could protect the joint from inflammatory damage. Why damage to joint tissues results in cytokine elevation and inflammation is unclear. However, results from studies of other organ systems show that inflammation is triggered by cell death resulting from tissue injury [99]. These observations strongly suggest that antioxidants, or drugs that downregulate immune responses to cell death, could block joint inflammation following a wide variety of joint injuries. Indeed, it was found that blocking innate immune responses to alarmins mitigated the development of posttraumatic synovitis in a mouse model of intraarticular fracture.

Conclusion

Articular surface injuries are a significant unsolved problem. They are common, the value of many current treatments is uncertain, and many of these injuries initiate progressive joint degeneration, a condition recognized as posttraumatic OA. Surgeons attempt to decrease the risk of posttraumatic OA by restoring joint stability, congruity, and alignment following injury. In addition, to promote repair and remodeling of damaged articular surfaces, they penetrate subchondral bone and insert periosteal and perichondral grafts and autologous chondrocytes. The results of these procedures vary considerably among patients, and there is limited information concerning the long-term outcomes. However, the available studies of people who have suffered joint injuries indicate that even with optimal current treatment the risk of posttraumatic OA is high following chondral tears and articular surface fractures. For this reason there is a clear need to improve the treatment of joint injuries. Clinical and experimental studies show that chondrocyte and mesenchymal stem cell transplantation, synthetic matrices, growth factors, and combinations of these treatments have the potential to restore articular surfaces. Other investigations suggest that biologic interventions may minimize chondrocyte damage due to mechanical forces. The most dramatic improvements in the treatment of articular surface injuries are likely to come from approaches that help maintain chondrocyte viability and function following joint injury, restore joint stability and congruity, and promote articular surface repair or regeneration and remodeling following joint injury.

Chapter 53

Engineering cartilage and other structural tissues: principals of bone and cartilage reconstruction

Batzaya Byambaa[1] and Joseph P. Vacanti[2]

[1]3D BioLabs, LLC, Cambridge, MA, United States, [2]Harvard Medical School, Center for Regenerative Medicine, Massachusetts General Hospital, Cambridge, MA, United States

Introduction

Cartilage is a fiber-reinforced composite material composed of chondrocytes surrounded by specialized extracellular matrix (ECM) in unique architectures. There are three types of cartilage, namely, hyaline, elastic, and fibrocartilage. Hyaline cartilage is the most prevalent type of cartilage and can be found in synovial joints [1]. It is a translucent stratified tissue composed mainly of type II collagen that consists of several distinct microscale cellular niches [2]. Hyaline cartilage enables joints to articulate with low frictional forces by providing smooth and lubricated surface. One unique characteristic of hyaline cartilage is the lack of blood vessels, nerves, or lymphatics. It also has a limited capacity for intrinsic repair and healing. This type of cartilage is composed of a dense ECM with chondrocytes and the nutrients usually reach chondrocytes through diffusion. Hyaline cartilage chondrocyte homeostasis is achieved through cyclic compression, which facilitates the exchange of nutrients and waste products [3]. Elastic cartilage is similar to hyaline cartilage in architecture, and it contains yellow elastic fiber networks and type II collagen. The matrix is dominated by elastin fiber networks, and chondrocytes lie between the fibers [4]. Elastic cartilage is found in the ear, epiglottis, and pinnae. Fibrocartilage is composed of a mixture of types I and II collagen and is whitish in color. This type of cartilage is found mainly in soft tissue-to-bone attachments, symphysis pubis, annulus fibrosus, and menisci. Cartilage is largely populated by chondrocytes, which are specialized cells that can secrete proteins that form the ECM of cartilage. Collagen is the main constituent of cartilage and is made from amino acids wrapped together to form elongated triple-helix fibrils. Fibrils are structural materials that are usually in the scale of 10−100 nm [5]. Aggrecan, bone sialoproteins, and proteoglycans are also found in the ECM of cartilage.

Cartilage tissue has limited self-repair potential due to its avascular nature, and current surgical interventions are associated with mixed results. The concept of tissue-engineering (TE) approach to cartilage repair was first demonstrated in 1977 by a transplantation of chondrocytes into damaged cartilage [6]. Nowadays, autologous chondrocyte implantation (ACI) and matrix-induced ACI presented promising results [7,8]. However, these techniques are associated with complications such as graft failure, periosteal hypertrophy, and delamination. The most important factors to consider in regeneration of cartilage tissue are the underlying biology. The structure and composition of cartilage tissues are depth dependent, which are divided into superficial, middle, deep, and transitional zones depending on the alignment of collagen fibers and composition of proteoglycan. Despite their single cell type, chondrocytes present significant differences in morphology, organization, and density across the depth of cartilage. These topographical differences over the range of a few micrometers in relation to cartilage thickness and matrix contents exist [9−11].

Biomaterials for cartilage tissue engineering

The selection of biomaterial is critical to the success of TE approaches in cartilage repair. Biomaterials for cartilage

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00055-1

repair can be selected from either natural or synthetic materials. Natural materials include various types of collagen-based materials, chitosan, hyaluronic acid (HA), gelatin, keratin, and fibrin hydrogels [12−15]. As for synthetic materials, mostly biodegradable polymers such as poly-glycolic acid (PGA), poly-L-lactic acid, or their composite copolymers poly lactic-*co*-glycolic acid (PLGA), also nonbiodegradable polymers such as polytetrafluoroethylene and polyethylmethacrylate have been studied [16,17]. Among them, collagen has been used widely to construct cartilage scaffolds because it is the most abundant protein in mammals. For instance, Funayama et al. developed chondrocyte-laden type II collagen scaffold and injected the scaffold into damaged rabbit cartilage without a periosteal graft [18]. After 8 weeks of the injection a favorable regeneration of hyaline cartilage was observed. Furthermore, a significant difference on cartilage regeneration was observed between transplanted and control groups at 24 weeks after the injection [18].

Besides chemical composition, material topography and architecture are critical for engineering cartilage tissue. For engineering cartilage scaffolds, various fabrication methods have been reported. It includes solid free fabrication, which allows the production of an anatomical meniscal scaffold using a fiber-deposited method with an XYZ robotic arm. The scaffolds are prepared from poly(ethylene oxide-terephthalate)-*co*-poly(butylene terephthalate) and analyzed using computerized tomography (CT) and magnetic resonance imaging (MRI) dataset [19]. Electrospinning technology has used to create aligned collagen fibers across the depth of cartilage [20]. A five-layer scaffold consisted of type I and II collagen fibers was fabricated with random and aligned orientations using electrospinning technology. After 7 days of static culture under growth factor, seeded MSCs within the electrospun fibers produced higher aggrecan and collagen II, which demonstrates chondrogenic differentiation of MSCs within the aligned scaffold [20]. As far as hyaline cartilage is concerned, few groups have tried to reconstruct the zonal organization mimicking the structure of native cartilage [9,10,21,22]. One approach would include seeding chondrocytes from specific zones in particular layers to reconstruct the multizonal topography of native cartilage [21,22]. This is supported by the finding that chondrocytes from different zones respond differently in terms of gene expression and matrix production. On the other hand, layering- or gradient-customized hydrogel could allow construct with zonal properties [10,22].

Cell sources for cartilage tissue engineering

There are multiple cell sources for the development of regenerative therapies for cartilage constructs. Adult chondrocytes or chondrocyte progenitor cells sourced from human tissues are an ideal logical way [23]. Mature differentiated chondrocyte isolation from adult tissues is possible, and at present, the technology is commercially available (e.g., Carticel and ChondroCelect). However, there are still drawbacks such as donor site morbidity, isolated cells present phenotypic instability in culture, and comparatively low yield of cells isolated from autologous tissue [24]. To overcome these drawbacks, research has focused on cells with potential to differentiate to a chondrogenic phenotype. Wang et al. used genetically modified cells such as dermal fibroblasts that were programed to differentiate into osteochondrogenic cells [25]. Some more attractive approaches have developed such as direct differentiation of human embryonic stem cells into chondrocytes [26] as well as chondrogenically differentiated induced pluripotent stem cells for cartilage defect repair [27]. However, safety concerns and differentiation protocols still need to be addressed.

MSCs for cartilage regeneration have been isolated from bone marrow, cartilage, periosteum, adipose tissue, synovial lining of large joints, muscle, and from embryonic tissues [23,28,29]. MSCs harvested from various tissues have been shown to have different potentials for chondrogenic differentiation. Among them, MSCs isolated from adipose tissues demonstrated an excellent potential as adipose tissue is in abundance in the human body, although some studies reported that adipose tissue-derived stem cells have poor chondrogenic potential [30]. Other challenges include seeding density, number of passages, biomaterials, and the use of growth factors to induce the chondrogenic phenotype. Chondrogenesis can be influenced by the concentration of chondrocytes in the construct. Li et al. showed that a concentration of 5.0×10^6 cells/mL can induce a higher chondrogenic output in comparison to lower and higher concentrations [31]. The passage number of the cells is another factor that can diminish the MSC to chondrocyte transition with studies suggesting that MSCs after passage 10 lose their chondrogenic differentiation [32]. No consensus in regard to the ideal scaffold for cartilage regeneration exists with the most common biomaterials to include PLGA, fibrin glue, hydrogel, collagen, tissue membrane, PGA, and alginate. Additives to the carrier have been used, including HA, culture media, plasma, and collagen [33−35]. Finally, growth factors to induce chondrogenic phenotype are required with transforming growth factor (TGF)-β1 or TGF-β3 and CDMP-1 and fibroblastic growth factor (FGF)-2 been the most commonly used [36]. It must be emphasized that, to date, there is no single generally accepted method, and the aforementioned techniques are still controversial.

Biofabrication of cartilage tissue

Magnetic resonance imaging and computerized tomography scans

Biofabrication of cartilage tissue requires a detailed knowledge of underlying anatomy. Three-dimensional (3D) graphics of cartilage can be generated through anatomical specimens by MRI scans, which later can be used in 3D printing of the scaffolds. Fig. 53.1 shows 3D graphics of cartilage generated from laser-scanning technology. High-resolution MRI is an emerging technology that is gradually being introduced into the clinical practice, and it enhances the resolution and sensitivity rate considerably [39,40]. X-ray and CT scans produce low value information as they do not capture cartilage, although they can show bone anatomy. It is essential to quantify both the thickness and the volume of the cartilage as it varies between anatomical areas. Substantial progress has been recently achieved in enhancing the imaging of cartilage physiology and detecting changes in proteoglycan content and collagen ultrastructure [37]. Another way to obtain a 3D model of the cartilage is by producing a 3D coordinate frame. Coordinate measuring machines can be used where a probe meets the sample, and the 3D coordinates are recorded. This technology has the capacity to capture the surface anatomy with a resolution of 1 μm. However, it cannot distinguish between tissues or provide information of the composition of multilayered tissues.

Scaffolds for cartilage tissue engineering

Scaffold-free fabrication of cartilage allows cartilage tissues to be grown in the lab and subsequently implanted to the area that needs to be treated [41]. Here, silicone molds are used to form petri dish, upon which the chondrocytes could grow. The agarose solution is poured on the silicone molds, which results in the micro-molded nonadhesive agarose hydrogel. The cell suspension is carefully implanted into spherical chambers at the bottom. After 18 hours, the cell suspensions coalesce and turn into spheroids that are then implanted into the body.

Hybrid scaffolds can be printed using digital light processing (DLP), a new water-based 3D printing method using photosensitive hybrid polymers such as polyurethane with HA [42]. The hybrid materials have high printing resolution and have shown nontoxic properties toward attached cells. In addition, 3D printed constructs promote good cell adhesion and could be customized for cartilage tissue reconstruction. Fig. 53.2 explains the fabrication of the cartilage tissue and its clinical application for cartilage repair. The key factor in 3D printing by using a DLP printer is the viscosity of the material, which affects the printing resolution and accuracy. The mixture of the resin is stirred at high speed while the material is heated to remove water. Photo-initiators and poly(2-hydroxyethylmethacrylate) are added to aid in the light curing, which results in a customizable print where the shape has an error of only 4% varying from the original design (Fig. 53.2A). Moreover, this customized hybrid scaffold shows high cytocompatibility with excellent

chondrogenic differentiation capacity and closely mimics the mechanical properties of articular cartilages [42].

Bioprinting techniques for fabrication of cartilage constructs

A number of studies have investigated the application of inkjet and micro-extrusion printing techniques using hydrogels for cartilage tissue engineering (TE). Micro-extrusion is a commonly used technique where bioinks are expelled while carrying a payload of feasible cells, genetic materials, or factors of growth [43]. Fig. 53.3 shows a schematic drawing for micro-engineered GelMA hydrogels production using several techniques at microscale.

In an early study, chondrocytes were extruded into basic geometries utilizing dextran-based hydrogel and HA [45]. Researchers observed high cell feasibility for up to 3 days in vitro showing the guarantee of such methods. In another study, chondrocytes were encapsulated in GelMA, and they were then extruded into simple porous structures for engineering grids [46]. Cells were alive for about 4 months in vitro and the researchers have shown collagen type II and sGAG generation inside the constructs. Another method for 3D bioprinting has additionally been investigated for engineering cartilage by employing droplet-producing bioprinting. Here, a discrete volume of bioink is deposited in a translating pattern rather than continuous strands as in micro-extrusion. These droplets can be produced by using either inkjet [47], acoustic droplet [48], or micro-valve [49] based technologies.

Bioinks for cartilage tissue printing

Hydrogels have been selected as attractive candidates for bioinks due to their highly tunable properties, cytocompatibility, and high water-content property. Table 53.1 provides a summary of different bioinks that are used for keeping cartilage fabrication up-to-date. Several types of bioinks were manifested to be theoretically sufficient for inkjet- and micro-extrusion-based bioprinting. These bioinks include GelMA [50], fibrin [51], collagen [52], various PEG-derivative hydrogels [53], agarose [54], and HA-based hydrogels [55]. These hydrogels represent excellent rheological properties, so it can be controlled easily during the micro-extrusion process. In addition, they provide structural similarity to ECM due to their high water-content property, which supports cellular viability and proliferation postprinting. Important parameters that must be considered during the design of bioinks are viscosity, shear thinning behavior, and yield stress. For instance, high cross-linking densities of hydrogel polymers are preferable because it possess high viscosity and yield stress, which enhances mechanical stability for extrusion process. In contrast, encapsulated cells take advantage of lower cross-linking densities of hydrogels

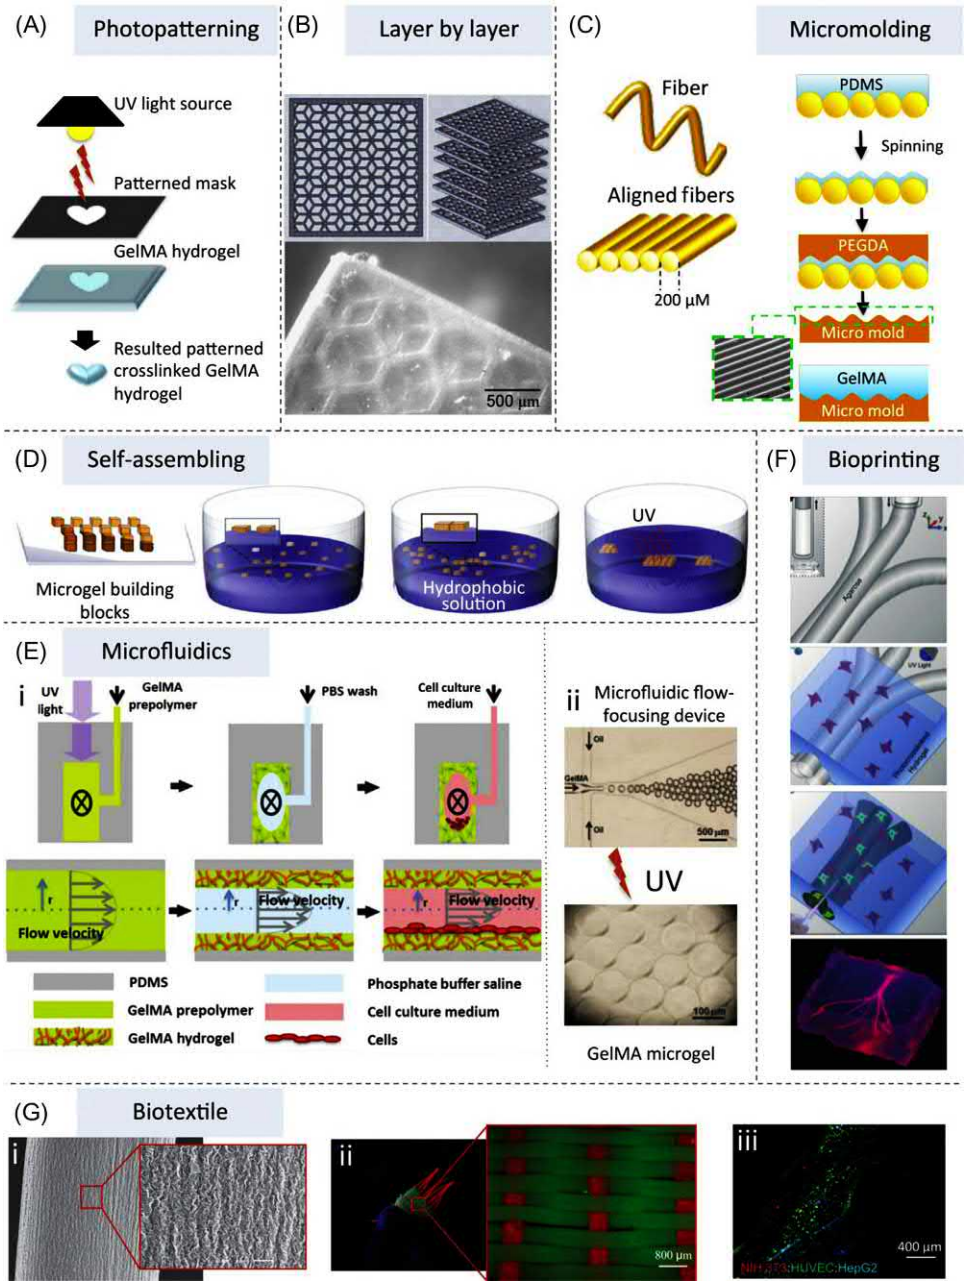

FIGURE 53.3 Microfabrication techniques used to produce GelMA hydrogels constructs: (A) photopatterning of GelMA using a prepatterned photomask; (B) stacked layers of patterned GelMA hydrogels fabricated using a micromirror projection stereolithography system; (C) fiber-assisted micromolding technique for the production of parallel microgrooved surfaces that serve as a template for micropatterning GelMA; (D) self-assembly of microgels fabricated by photo patterning; (E) examples of the microfluidics of GelMA hydrogels microfabrication: (i) coating microchannels with GelMA hydrogel and (ii) fabrication of spherical GelMA microhydrogels using a microfluidic flow-focusing device; (F) schematic representation of the bioprinting method for fabricating microchannels inside a GelMA hydrogel using an agarose template; (G) biotextile techniques as applied to the microfabrication of hybrid alginate and GelMA fibers and their assembly: (i) SEM image of fabricated fiber, (ii) typical woven fabric, and (iii) a braided construct from NIH 3T3 fibroblasts, HUVECs, and HepG2 as a liver model. *Adapted from Yue K, et al. Synthesis, properties, and biomedical applications of gelatin methacryloyl (GelMA) hydrogels. Biomaterials 2015;73:254–71 [44].*

for their proliferation and differentiation into targeted tissue [56]. The contradiction between these two parameters is determined as bioprinting window [56]. It is worth mentioning that small-sized nozzles with high extrusion pressure could lead high cell death rate postprinting due to the increased shear forces imposed on the cells. It was reported that less than 35% of cell viability was observed after extrusion at the shear stress of 60 kPa or higher [57]. Controlling the needle geometry can decrease shear forces encountered by the cells during the extrusion process. For example, cell viability could be increased at lower inlet pressure by using conical needles rather than cylindrical ones [58].

An early study demonstrated printing of layer-by-layer construct for cartilage repair using human articular chondrocytes encapsulated in a poly(ethylene glycol) dimethacrylate bioink. This study demonstrated the capability to fabricate cartilage matrix components using continuous inkjet printing of chondrocytes while maintaining cell viability and biological functionality within 3D printed scaffold. In another study, the same authors tested the way it was viable to leverage the method to an immediate print

TABLE 53.1 Bioinks for bioprinting of cartilage tissue.

Bioink	Chondrogenic capacity	Inherent printability	Resolution (μm)
Agarose	1	1 (Difficult to print high aspect ratios discarding the need for supporting structures)	30–100 [27]
Alginate	1	2 (Needs smart cross-linking methodologies/thickening agents to print constructs with higher fidelity)	1000 [27]
Sulfated Alginate	2 (Can bind growth factors, e.g., TGF and FGF and uses encapsulated bovine chondrocytes to induce for collagen II deposition and potent proliferation)	2 (Needs smart cross-linking methodologies/thickening agents to print constructs with higher fidelity)	650 [27]
Alginate/ nanocellulose	1 (The effect of the adding nanocellulose is still not studied)	3 (Nanocellulose imparts and a behavior of shear thinning)	400–600 [27]
GelMA	1	2 (Needs smart cross-linking methodologies/thickening agents to print constructs with higher fidelity)	50 [2]
HA	2	2	10–100 [28]
GelMA + (HA)	2 (Adding of HA improves chondrogenesis)	2 (Adding HA enhances rheological properties)	
GelMA/ gellan gum	1 (The addition of gellan gum does not improve chondrogenesis in comparison to GelMA alone)	3 (Adding gellan gum imparts a shear thinning behavior)	
PEGDMA	1	2 (Needs smart cross-linking methodologies/thickening agents to print constructs with higher fidelity)	
Collagen	1	2 (Needs high collagen with high densities for a controlled extrusion ~15 mg/mL)	100 [27]
Fibrin	1	1 (Needs smart cross-linking methodologies/thickening agents to print constructs with higher fidelity)	Can be improved to 1 with DLP printing [29]

Chondrogenic capacity = 1, indicates for a material that has unknown inherent chondro-inductive factors. Chondrogenic capacity = 2, indicates for a material that can support chondrogenesis of MSCs, excluding the need for the addition of growth factors such as TGF-β3. Inherent printability = 1, indicates for a material that cannot be easily for more than one layer reliably. Inherent printability = 2, indicates for a material where extrusion can relatively form simple shapes. Inherent printability = 3, indicates for a material where extrusion can relatively form complex shapes. *DLP*, Digital light processing; *FGF*, fibroblast growth factor; *HA*, hyaluronic acid; *PEGDMA*, poly(ethylene glycol) dimethacrylate; *TGF*, transforming growth factor.

right into a cartilage defect [59]. Matrix formation was assessed after 6 weeks regardless of a visible interface between the local and repaired cartilages, and the interface failure stress had significantly increased demonstrating the potential of this approach [60].

Combining alginate with cartilage matrix components such as chondroitin sulfate and HA can produce hydrogels with more biomimetic capabilities that support neocartilage formation [61]. In another study, it was found that it is possible to support cartilage tissue construction by using chondrocytes along with hMSCs [46]. In general, GeIMA has been used to support the development of fibrocartilage with a mixture of higher amount of type I collagen [62]. An addition of chondroitin sulfate and HA into GeIMA/collagen cartilage matrix enhanced the chondrogenesis. Moreover, the addition of these two cartilage matrix components resulted in a higher bioink viscosity, which improved printability significantly [45]. Similarly, a synthetic hydrogel having thermosensitive characteristics and constituted from a base triblock methacrylated polyHPMA-lac-PEG copolymer has been chemically combined with either methacrylated HA or methacrylated chondroitin sulfate for cartilage bioprinting. Another type of bioink comprising nanofibrillated cellulose and alginate was developed for cartilage engineering as a novel shear thinning bioink [63]. This type of shear thinning property has both high printability and high cell proliferation rate. The chondrogenic capabilities of these bioinks can be further improved by sulfated alginate components. Sulfated alginate can activate FGF

signaling that assists in maintaining chondrogenic phenotype. However, nanocellulose component in bioinks also performs as a thickening agent that induces shear stress through extrusion printing nozzles due to its high viscosity, which decreases chondrocyte proliferation and capability to synthesize ECM components [64].

Osteochondral tissue engineering

Osteochondral injury can happen at any joint; however, it is most common in the knee and ankle joints [65]. Such injuries can be well localized or can be the outcome of a complex injury associated with a fracture. Cartilage becomes torn or damaged and the progression of cartilage damage is closely associated with the extent of injury and the condition of the subchondral bone [32]. A genetic predisposition in terms of progression has been also hypothesized [66]. Osteochondral defects in the knee may occur in either femoral or tibial side [67]. In the ankle, such defects are frequently seen in the talus. Osteochondral defects cause pain and disability especially following prolonged use of the affected limb. Such injuries can be devastating for young people who are prone to these injuries through participation in athletic activities and contact sports.

The clinical management of osteochondral defects is challenging. Debridement of the loose and unstable osteochondral fragments might improve patient's symptoms. Microfracture is a procedure performed allowing the coverage of the defect by fibrocartilage. Alternatively, the osteochondral autograft transplantation surgery can be performed by harvesting and inserting osteochondral materials from nonweight-bearing areas to treat osteochondral defects [68]. Alternatively, ACI is designed to regenerate cartilage tissues with structural and functional features [69]. However, these techniques still have some drawbacks related to the donor site morbidity and graft failure due to peripheral chondrocyte death. Furthermore, there are several challenges that face the success of treatment of osteochondral defects. These include issues related to grafting, implant availability and biomechanical integrity, short cell viability, and risk of disease transmission for allografts. In addition, cell leaking in the articular space and loss of chondrogenic phenotype in the case of the ACI first-generation technique utilizing expanded chondrocytes has been voted as well as the need for two interventions delaying times and increasing costs for scaffold-based ACI [69,70].

3D bioprinted osteochondral constructs may provide a promising solution for treating arthritis associated with bony defects. Even in cases of isolated cartilage damage, treating the defect might not be sufficient as there is evidence to suggest that osteoarthritis is a disease affecting not only the cartilage but also the subchondral bone [32]. Hence, a holistic approach to treat arthritis is needed. In order to use this technology in a clinical trial, major steps have to be taken. The International Cartilage Repair Society is serving a leading role in analyzing the current state of scientific developments for the treatment of osteochondral lesions in order to provide recommendations for the execution of preclinical and clinical studies [71].

So far, there are several attempts to treat osteochondral defects. A number of researchers focused on the production of osteochondral constructs rather than cartilage patches [72–76]. Bone constructs loaded with chondrocytes showed the integration of cartilage on bone [73]. The authors concluded that such constructs with designed mechanical properties might offer alternative reconstruction procedures for the treatment of articular surfaces [73]. In one study, hyaline cartilage was created in a rabbit proximal humeral joint following bioprinting of Hydroxyapatite (HAp) powder and Polycaprolactone (PCL) [74]. The scaffold was infused with TGF-β3. By using this technique, promising results were also reported in cases of reconstruction of femoral head [76] and temporomandibular defect repair [75]. In summary, much progress has been made in the area of bone and cartilage TE. New technologies are being investigated to improve the quality and outcomes in this important area.

Introduction

Tendons and ligaments are collagenous soft tissues within the musculoskeletal system that serve important mechanical roles in providing joint stability and enabling mobility. The primary distinguishing feature between these connective tissues is what they connect: tendons transfer muscle forces to bones while ligaments form links between distinct bones. Due to the high mechanical demands placed upon these tissues, tendon and ligament are frequently injured, causing pain and disability to patients, while also representing a significant clinical burden [1]. Minor to moderate tendon and ligament injuries commonly occur in the form of subfailure strains, sprains, or repetitive use aggravation [2]. In addition, injuries that fully compromise the mechanical integrity of tendon and ligament are also common in the form of acute traumatic tears [e.g., anterior cruciate ligament (ACL), Achilles tendon], acute lacerations (e.g., flexor and extensor tendons), and/or chronic overuse damage (e.g., rotator cuff tendons, ulnar collateral ligament). Tendon and ligament injuries afflict people of all ages, with some tissues more commonly injured in young adults (e.g., ACL tear) and other injuries more often appearing in elderly (e.g., rotator cuff degeneration and tear) [3]. Some injuries track more closely based on patient occupation and/or hobbies, such as manual labor (e.g., flexor tendon laceration) or baseball pitching (e.g., elbow ligament fatigue damage). Although significant differences separate these various conditions, common features for most tendon and ligament injuries include pain, reduced activity, and disability from limited use of affected joints [4].

In general, the inherent healing response and regenerative capacity of tendon and ligament are quite low, such that recapitulation of functional tissue integrity typically requires clinical intervention [1]. Even then, successful treatment of many tendon and ligament injuries remains elusive. Nonsurgical treatments can sometimes provide pain relief and may improve motion, but such approaches are not useful in restoring proper function of torn tissues [5]. In that case, surgical repair can be performed by directly reapproximating torn tissue ends [6], reinforcing/augmenting a tissue repair using biomaterials [7], or fully replacing the damaged tendon and ligament with a biologic or synthetic graft [8]. In certain conditions, surgical reconstruction of damaged tissues can yield relatively successful clinical outcomes, but many procedures suffer from serious challenges and limitations. For example, while reconstructions performed using auto- and allografts may offer the best match for tissue properties, these procedures are impacted by donor site morbidity and limited supply of graft tissues, respectively [9]. Synthetic materials overcome these challenges but are not generally able to match the complex mechanical properties of tendon and ligament (e.g., anisotropic, inhomogeneous, nonlinear, viscoelastic), thereby limiting their utility, and are not capable of adapting to varying functional demands since they are not biologically active [8]. In addition, these graft-based repairs struggle to recapitulate proper interfaces between dissimilar tissue types (e.g., muscle−tendon, ligament−bone), which can lead to additional postsurgical complications [10]. Tissue engineering offers a very appealing solution for tendon and

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00056-3

ligament repair and reconstruction due to the potential for such an approach to overcome many of the weaknesses and limitations of current strategies. For example, tissue engineering offers the potential for available supply, bioadaptability, interfacial ingrowth, and even patient-specific customization. This chapter will highlight some of the important considerations and ongoing challenges for tissue engineering of tendon and ligament.

Tendon and ligament composition, structure, and function

Composition

In general terms, tendon and ligament are composed of similar constituents that include collagen, proteoglycans, elastic fibers, glycoproteins, other minor proteins, and water [1]. While water makes up a large overall percentage of these highly hydrated tissues (~65%–75% wet weight), type I collagen comprises ~70%–80% of the dry weight and represents the primary structural component of tendon and ligament, providing significant mechanical strength when these tissues are subjected to tensile forces [11,12]. At different points in space and time, enzymatic and nonenzymatic cross-links are known to form between collagen molecules, the quantity and distribution of which affect the overall mechanical properties of the collagen network [13]. Various proteoglycans—with their corresponding negatively charged, water-binding glycosaminoglycan side-chains—are found within the tendon and ligament, including small leucine-rich proteoglycans such as decorin and biglycan, as well as larger proteoglycans such as aggrecan and versican. The amount and location of these various proteoglycans is believed to be predominantly due to differences in functional demands, where tissue regions subjected to compression typically exhibit higher quantities of proteoglycans to support these nontensile loads [14]. Other constituents such as glycoproteins and minor collagens may also be distributed differentially depending on requirements inherent to specific physiological loading environments [15]. Recent work has begun to describe a potentially important mechanical role for elastic fibers in tendon and ligament, which may contribute to the low-force response to load and/or energy-return for certain tendon and ligament with high demands (e.g., Achilles tendon); more work will be required to fully elucidate the role of elastic fibers and other minor tissue constituents of the extracellular matrix (ECM) [16]. In addition to these ECM components, tendon and ligament contain cells, most commonly fibroblasts but also progenitor cells, chondrocyte-like cells in some regions, and inflammatory cells in tendinopathic conditions [1]. While cells provide the bioresponsiveness and adaptability of tendon and ligament, the relatively low density of cells may contribute to the limited regenerative capacity of these tissues.

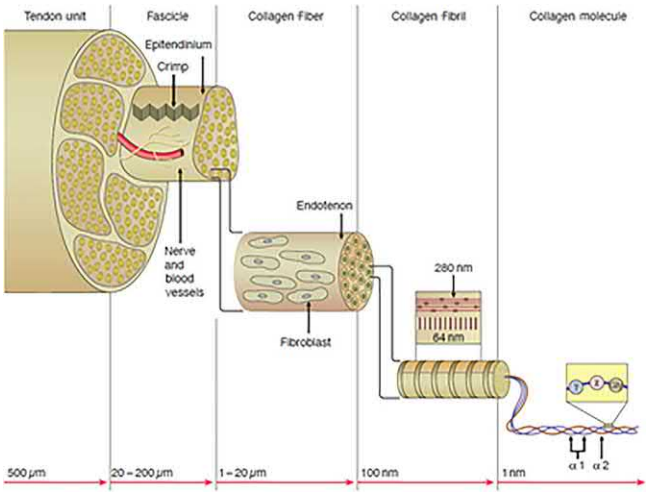

FIGURE 54.1 Hierarchical structure of tendons, where the organizational structure of collagen aggregates with increasing length scales. Ligaments exhibit a similar structural hierarchy. *Reprinted with permission from Zeugolis DI, Chan JCY, Pandit A. Tendons: engineering of functional tissues. In: Pallua N, Suscheck CV, editors. Tissue engineering: from lab to clinic. Berlin, Heidelberg: Springer Berlin Heidelberg; 2011. p. 537–72 [17].*

Structure

Tendon and ligament are hierarchical structures with an organization that builds from the nanoscale to the centimeter scale, based primarily on the built-up form of type I collagen (Fig. 54.1). Starting with procollagen that weaves together to form collagen molecules, which are then packaged into fibrils, and subsequently fibers, fascicles, and whole tendon, the hierarchical structure of tendon and ligament is key to providing mechanical support necessary for proper function. For example, the degree to which collagen fibers are organized (e.g., uniformly aligned vs partially dispersed) in the direction of loading correlates with mechanical properties [18,19]. Other structural features are believed to contribute to important aspects of tendon and ligament function (e.g., collagen crimp at the fibril level likely contributes to the nonlinear stress–strain response). Also, various noncollagenous compositional constituents, such as proteoglycans and elastic fibers, may have roles at specific levels of the hierarchical structure of tendon and ligament. Taken together, the structural organization of tendon and ligament is fundamental to the primary purpose of supporting and transferring mechanical load.

Function

Although nearly all tendon and ligament share a common function that is primarily mechanical, there is significant

variability in the nature of the physiologic demands imposed upon each specific tissue throughout the body [2]. Specifically, the magnitude, frequency, duration, and direction of forces that connective tissues experience can vary dramatically in different anatomical locations. For example, while some tendon and ligament are subjected to low-magnitude, low-frequency, short-duration, and uniaxial loads, other tissues may experience high-force, repetitive, long-term, and/or multiaxial loading. Such variability of in vivo mechanical demands leads to tendon and ligament throughout the body that exhibit unique compositional and structural properties. In addition, obvious differences in composition/structure exist between mid-substance tendon and ligament tissue compared to enthesis tissue, where soft tendon or ligament transitions to unmineralized fibrocartilage and then mineralized fibrocartilage before transitioning into bone [10] (Fig. 54.2A). Each of the zones of the tendon and ligament–bone insertions contains specific compositional/structural features that enable force transmission across this complicated interface between dissimilar materials (Fig. 54.2B). While such adaptations to physiological loading is vital to proper tissue function, such variation also further complicates the already challenging endeavor of treating tendon and ligament injury and degeneration since there are unlikely to be any universal or one-size-fits-all solutions for repairing or reconstructing damaged connective tissues [10,21–23]. Since proper mechanical function is the key to success, tissue engineering strategies must seek to recapitulate the compositional, structural, and mechanical properties of tendon and ligament, including properties unique to specific anatomical locations and distinct loading conditions.

Requirements for a tissue-engineered tendon/ligament

A tissue-engineered tendon or ligament must be compatible with the physiologic environment where it will reside, macroscopically meet the anatomic demands of the tissue it replaces, and provide a hospitable microenvironment for a cell population to regenerate [24] (Fig. 54.3A). For these reasons, the selection of scaffold material for a tissue-engineered construct typically consists of (1) natural materials that exist in the native tendon and ligament ECM, (2) synthetic materials that are biodegradable and can eventually be replaced by ECM deposited by a native or new cell population, or (3) some combination of natural and synthetic materials that can impart advantages of

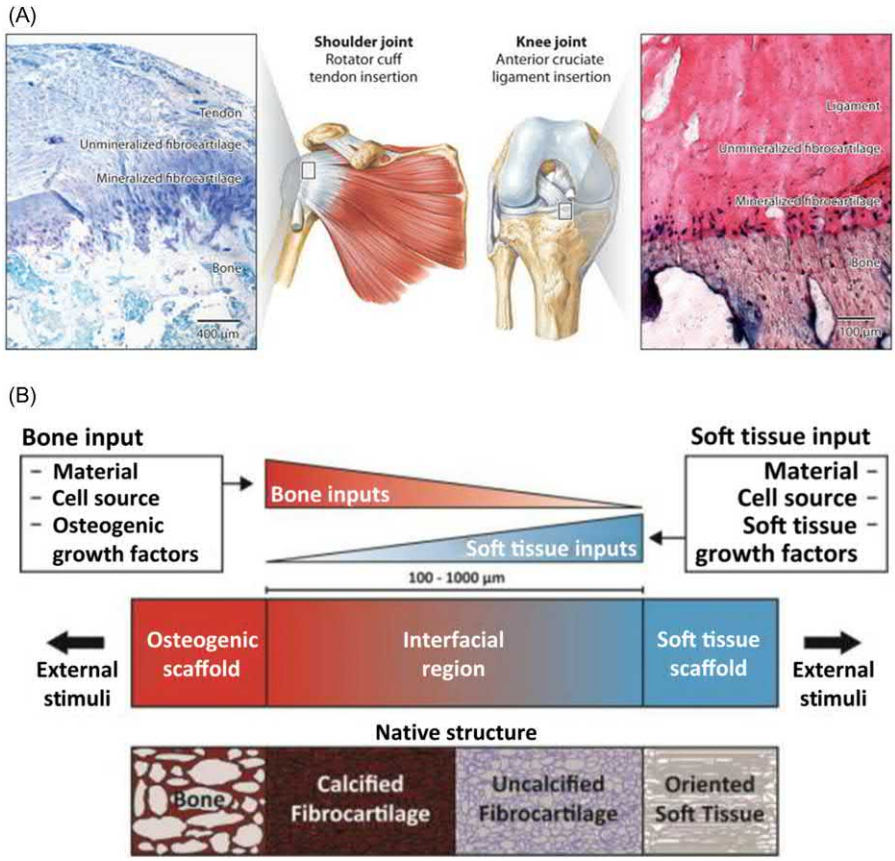

FIGURE 54.2 Considerations for engineering tissue entheses. (A) Histological images of soft tissue-to-bone insertions. Tendon (left) and ligament (right) entheses are characterized by transition from tendon or ligament, respectively, to unmineralized fibrocartilage and mineralized fibrocartilage before inserting into underlying bone. both types of scaffold [27–29]. As the fundamental structural feature of tendon and ligament are a highly aligned type I collagen fiber matrix, the chosen scaffold must be able to recapitulate the high tensile strength that the native microstructure imparts. In addition to providing mechanical strength directly, the scaffold will also influence the cellular behavior as the cell population within a tissue-engineered construct will respond to the structure of the scaffold (alignment, organization, fiber size, pore size, etc.). Thus scaffold properties should be inspired by the native organization of the tendon and ligament in order to elicit a proper cellular response [30,31]. The cell population itself must be biocompatible, capable of ECM interaction, and able to exhibit propensity to remodel the scaffold in a manner similar to native tissue. Often, the natural choice is to utilize the native tendon and ligament cell type (ligamentous fibroblast and tenocyte), but a plastic stem cell source (embryonic, adult, or induced pluripotent) can also be utilized and stimulated appropriately to differentiate into a desired cell phenotype. In addition, paracrine signaling between these cell types can be exploited in coculture approaches, as stem cells have been shown to secrete cryoprotective factors that can positively influence regenerative capacity of native cell types [32,33]. Tendon and ligament construct design must provide support for cellular remodeling after seeding to ensure tissue maturation, mechanical development, and eventual adaptation to the in vivo environment. Maturation is essential for the proper mechanical functioning of a tendon and ligament-engineered construct, as its primary role is to attenuate load. Stimulus resulting in matrix remodeling can be provided preimplantation via mechanical stimulation during culture using a bioreactor that can match the desired loading environment [34]. Construct maturation can also occur through application of appropriate growth factors (GFs) and other biochemical signals provided in vitro [28]. Construct design should also allow for postimplantation maturation, as the in vivo environment equilibrates with the scaffold through processes such as tissue ingrowth. Finally, a proper soft tissue-to-bone interface (i.e., enthesis) should also be established in a complete tendon and ligament tissue–engineered construct to promote proper integration with the host site [10,22,35,36]. Although difficult to engineer due to gradations in composition, structure, mineralization, and cell type, entheses provide a direct means of fixation and mechanical support as a tendon or ligament inserts into bone.

Scaffold

The choice of scaffold for tissue engineering applications is crucial to the success of a potential implant. As most cells in human tissues are anchorage-dependent and responsive to their local environments, scaffold composition, architecture, and bioactivity will directly influence cell adherence, behavior, and matrix deposition [31]. The scaffold also provides the initial mechanical properties of a construct; if a scaffold cannot survive the loading environment of the implantation site, proper maturation (mechanical or chemical) of the graft cannot take place [10,28]. The selected scaffold material can also, through modification or functionalization, act as a vehicle for

delivery of biochemical or GFs. As the scaffold effectively provides the backbone for the engineered construct, care should be taken to select and tune the properties of the scaffold to provide the best possible match to those of the tendon or ligament that will be replaced.

Composition/material selection: The primary constituent of tendon and ligament ECM is type I collagen, and as such, is often the protein of choice for scaffold material [27]. Collagen is simple to isolate through techniques such as acid extraction or pepsin digestion, and is intrinsically biocompatible [37]. Collagen-based scaffolds can be created as sponges through freeze-drying [38], as a hydrogel [39], electrospun into nanofibers [40], as well as numerous other forms. When fabricating collagen-based materials, properties such as shape, pore size, fiber alignment, density, and mechanical robustness can be tuned through a variety of fabrication procedures [37]. Cells seeded onto a collagen scaffold will actively adhere due to presence of integrin-binding domains [41], which can then actively remodel the matrix based on prescribed stimuli [42]. However, collagen scaffolds—particularly as a hydrogel—often fail to achieve sufficiently strong mechanical properties necessary to survive the load-bearing environment of a tendon or ligament after implantation [28].

Many other naturally occurring (noncollagenous) materials have been used as scaffolds for tendon and ligament tissue engineering. Silk fibroin was one of the first materials used for ligament tissue engineering [26,43] and shares many of the same benefits as type I collagen (Fig. 54.3B). Silk fibroin has mechanical properties comparable to that of native tendon and ligament (e.g., ultimate tensile strength, linear stiffness, and yield point [26]) when fabricated into structures such as cords, nets, and sponges [26,44]. Importantly, silk fibroin can also be formed in a manner that recapitulates some aspects of the hierarchical structure seen in the native collagen ECM in tendon and ligament [26], which may be important for structural support and mechanobiological signaling across length scales.

Tissue-engineered scaffolds can also be created for tendon and ligament applications from a number of natural hydrophilic polymeric biomaterials such as chitosan [45], gelatin [46], fibrin [47], alginate [48], and hyaluronan [49,50]. These types of biomaterials are often formed into hydrogel scaffolds, consisting of a small portion of polymer with a very high percentage of water. A highly hydrated structure can be advantageous for tendon and ligament tissue engineering by providing a suitable microenvironment for cell suspension as well as flexibility in construct design [50]. However, hydrogels on their own typically lack mechanical strength compared to other scaffolding options, but can be reinforced with fibrous materials via a composite scaffolding approach [51].

Another popular method of scaffold fabrication is decellularization of native tendon or ligament tissue [52]. Elimination of the native cell population produces a scaffold with preserved biomechanical properties, matrix organization, and mature cross-links, yielding a scaffold that is well suited to perform in vivo [53]. Decellularization can also preserve native tendon or ligament entheses [10,53], which helps make implantation more effective, improve mechanical performance, and eliminate the technically challenging requirement of engineering a new soft tissue-to-bone transition [21,36,54]. Cells are able to repopulate decellularized grafts to provide bioactivity, but can be limited by the degree to which they can infiltrate into the decellularized scaffold [55]. In addition, lack of complete decellularization of a tissue can result in an inflammatory response upon implantation [56], which may limit overall success.

The necessity of selecting a scaffold material that is both biodegradable and mechanically robust has led tissue engineers to fabricate tendon and ligament constructs out of synthetic materials. The motivation for using synthetic materials is to provide a more stable initial structure than natural materials can allow, permit cellular infiltration, then subsequently degrade at a rate similar to that at which the cell population can produce and deposit new ECM [28,29]. As these materials are fabricated, their biophysical, biochemical and structural properties are inherently tunable and can be manipulated to direct cellular function and behavior [57]. Some common materials used for tendon and ligament tissue engineering include polyglycolic acid, polylactic acid (PLA), polycaprolactone (PCL), and polyethylene glycol (PEG) diacrylate [28,58–61]. One primary concern with using these synthetic materials is the possibility of a negative reaction of the cell population. Modification of the scaffold (e.g., addition of integrin-binding motifs) is often needed to ensure cell attachment and proliferation; such effects may be due to high hydrophilicity of some polymers [62]; however, this is not consistent for all synthetics [59]. As selected polymers are typically biodegradable, care must also be taken to ensure that the degradation rate is not too rapid to outpace corresponding adequate tissue ingrowth after implantation or that the degradation process does not produce acidic byproducts [59].

Structure/architecture: Fabrication of scaffolds can be performed with a variety of techniques that allow for morphological aspects to be tuned as well [63,64]. Processes such as electrospinning allow for directed fiber alignment of a scaffold, which has been shown to influence cellular responses such as motility and ECM deposition [65]. Gradients in scaffold fiber alignment have also been shown to aid in recapitulation of characteristics of soft tissue-to-bone interfaces [10,66,67]. Other microstructural features (e.g., pore size) can be controlled using

techniques such as salt leaching [66,68], freeze-drying [69–71], electrospinning [72], and weaving or braiding [59,73]. In addition, scaffold materials can be functionalized or conjugated with GFs to further direct construct maturation [57]. Finally, although synthetic or natural materials have been historically used separately for replacing damaged tendon and ligament, recent work has created composite scaffolds that are able to encapsulate the advantages of each type of material [28]. Composites can also be used in engineering scaffolds for the soft tissue-to-bone interface, as they can help provide appropriate regionally dependent compositional and structural stimulus to a cell population when recapitulating a multitissue environment [74]. Furthermore, proper selection of scaffold material and design of architectural components are critical in both providing biomechanical support and development of a tendon and ligament construct microenvironment capable of regeneration.

Cell

Cell-based strategies have been widely explored in tendon/ligament tissue engineering and have great potential for developing novel translatable therapeutic approaches. Two categories of cells have been the main candidates for tendon/ligament tissue engineering, namely differentiated cells (such as tenocytes and fibroblasts) and mesenchymal stem cells (MSCs). MSCs are capable of differentiating into distinct cell types, secreting trophic factors, and eliciting minor immune responses, thus making them a potentially better source for clinical application compared with differentiated cells. MSCs are commonly delivered to the injury site by isolated cell injections; however, this method is associated with significant cell loss and low cell-adhesion efficiency. Cell sheet technology, an alternative approach of delivering cells, that overcomes disadvantages of cell injections and allows readily cell-host tissue integration, has been recently developed (Fig. 54.4) [75]. Human rotator cuff–derived cell sheets have been shown to improve enthesis healing after infraspinatus tendon repair in a rat model [76]. Similarly, the utilization of human ACL-derived cell sheet in a rat ACL reconstruction model promoted tendon-to-bone healing in terms of graft maturation, proprioceptive recovery, and mechanical strength [77]. In addition, recent research using a large preclinical canine model demonstrated superior enthesis healing after rotator cuff repair augmented with a multiphasic scaffold and bone marrow–derived mesenchymal stem cell (BMSC) sheet [78]. Given these encouraging results, cell sheet technology may serve as a new strategy for improving tendon/ligament repair and regeneration on patients.

Increasing evidence has revealed that ECM microenvironment cues play a pivotal role in determining stem cell fate [79–82]. Decellularized scaffolds or bioimprinted materials that possess or replicate the natural tendon ECM microenvironment can support MSCs distribution, direct MSCs alignment, and induce MSCs tenogenesis [80,82]. Furthermore, the combination of mechanical stimulation and inherent ECM cues is able to provide sufficient signals for guiding stem cell differentiation toward a tenogenic/fibroblastic pathway without exogenous chemical stimuli [81,83]. Therefore seeding cells on materials that recapitulate native tendon/ligament ECM cues together with optimized mechanical stimuli would yield biomimetic functional substitutes for promoting tendon/ligament tissue regeneration and reconstruction.

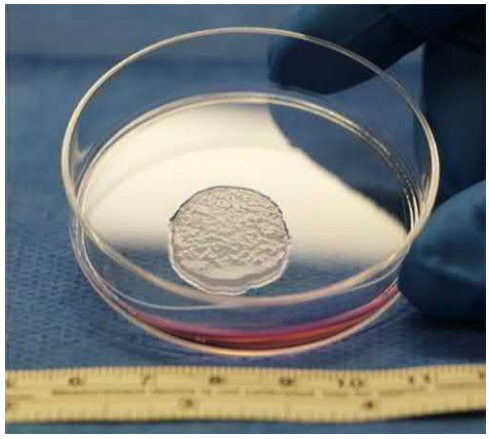

FIGURE 54.4 An intact BMSC sheet was detached from the dish and ready for implantation.

Various sources of MSCs, including bone marrow, adipose tissue, muscle, tendon, and bursa, have been investigated for tendon/ligament tissue engineering with overall promising results in preclinical studies [84,85]. Among different tissue-derived MSCs, BMSCs are currently the preferred cell source in clinical settings. In a clinical study with up to a 10-year follow-up, patients that received autologous BMSCs injection during single-row arthroscopic rotator cuff repair had better healing rate by 6 months and higher tendon integrity rates at the final follow-up [86]. In addition, recent studies have shown the beneficial effects of bone marrow stimulation on reducing retear rates among patients undergoing surgical repair of large to massive rotator cuff tears [87,88]. Through bone marrow stimulation that is performed by creating multiple holes at the footprint, the endogenous BMSCs are recruited and released from the proximal humerus and subsequently infiltrate the repaired tendon and contribute to postoperative enthesis healing. These results emphasize that autologous BMSCs, either by implantation or stimulation, play a positive role in rotator cuff surgical treatment. Conversely, a clinical study using stem cells in ACL reconstruction suggested that intraoperative autologous BMSC application to the femoral tunnel did not

accelerate graft osteointegration at 3 months based on magnetic resonance imaging (MRI) assessment [89]. In the future, more clinical studies evaluating other tissue-derived MSCs are needed to identify the best cell source for tendon/ligament regeneration in humans.

Bioactive factors

The past decade has witnessed an upsurge of interest in using GFs and platelet-rich plasma (PRP) to improve tendon/ligament healing or as adjuvants for surgical intervention. A variety of GFs, including transforming GF, bone morphogenetic proteins (BMPs), fibroblast GF, platelet-derived GF, granulocyte-colony stimulating factor, vascular endothelial GF, matrix metalloproteinase inhibitors, have been reported to exert positive effects on tendon/ligament healing in numerous laboratory and animal studies [84,85,90]. In contrast to individual GFs, PRP contains various types of GFs and has been extensively studied in the field of tendon/ligament tissue engineering. PRP can be administered intraoperatively or postoperatively, directly or indirectly to the injury site. Using small animal models, it has been shown that autologous PRP administration resulted in improved tendon-to-bone healing histologically and mechanically in surgical repair of either acute or chronic rotator cuff tears [91,92]. Similarly, PRP in combination with BMSCs or bone substitute enhanced graft-bone healing after ACL reconstruction as determined by imaging, histology, and biomechanical testing [93,94]. With respect to large animals, researchers found that multiple intra-articular injections of PRP could promote ACL healing, improve limb function, and reduce pain in a canine ACL deficiency model [95]. In addition, repair of large and retracted cuff tendons using PRP hydrated bone matrix led to increased mechanical strength, improved histology and MRI scores in a canine shoulder model [96].

Interestingly, while the laboratory and animal studies have shown overall favorable effects of PRP application, the clinical results on PRP remain controversial regardless of rotator cuff repair or ACL reconstruction. In a comparative cohort study assessing arthroscopic repair of large or massive cuff tears with or without leukocyte−platelet-rich plasma injection, no appreciable difference was found between groups in terms of tendon healing and functional outcomes at a minimum 2-year follow-up [97]. In a randomized clinical trial (RCT), the use of PRP perioperatively in patients undergoing ACL reconstruction failed to prevent tunnel widening based on CT scanning although similar clinical outcomes were observed at 3 months post-surgery [98]. Furthermore, several RCTs have suggested that there was no significant improvement in structural integrity and functional outcomes in patients receiving PRP as adjuvants for rotator cuff repair [99−102]. A recent systematic review also revealed that PRP might show promise in accelerating graft maturation after ACL reconstruction, but its beneficial effects on clinical outcomes has not been proven yet [103]. The discrepancies between experimental and clinical studies could be attributed to the native differences between animals and humans; the timing, concentration, and formulation of PRP; and the relative short follow-up time in clinical trials. The true clinical efficacy of PRP in tendon/ligament healing could be answered by future high quality RCTs with a long-term follow-up.

Over the past few years, the secretome of MSCs has gained increasing attention and has emerged as a potential cell-free strategy in regenerative medicine. It has been revealed that MSCs-derived secretome promoted human tendon cell viability in vitro and improved enthesis healing when combined with an electrospun keratin scaffold in surgical repair of massive rotator cuff tears in rats [104]. Among the numerous contents of MSCs-derived secretome, exosomes are believed to be the primary agent mediating the therapeutic effects on tissue repair or regeneration. Exosomes are nanosized vesicles containing RNAs and proteins which critically involved in cell−cell communication (Fig. 54.5). A recent study has shown the

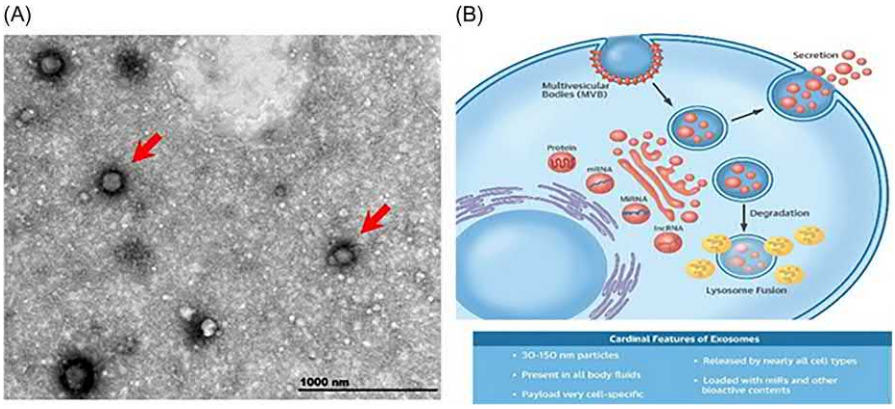

FIGURE 54.5 (A) The morphology of human plasma-derived exosomes under TEM. (B) The basic features of exosomes. *TEM*, Transmission electron microscopy. *Reprinted with permission from Journal of the American College of Cardiology 71(2), 2018.*

efficacy of human MSCs–derived exosomes in enhancing periodontal ligament cell proliferation and migration, as well as improving periodontal tissue regeneration in a rat model [105]. Despite the fact that benefits of MSCs-derived exosomes have been evaluated in vascular, muscle, and bone regeneration [106–108], its role in tendon/ligament tissue engineering has not yet been explored. With the growing interest in exosome-based therapy, future studies are warranted to elaborate its function on tendon/ligament healing and to develop novel cell-free treatment for clinical translation.

Three-dimensional bioprinting and bioink

In general, an engineered tissue or organ can be constructed with two strategies: bottom-up and top-down [109–112]. For bottom-up strategy, a tissue is built from materials at molecular or nanolevel to micro or macroscopic level. For top-down strategy, cells and bioactive molecules are seeded into a macroobject to make a tissue construct. Three-dimensional (3D) printing is a technology that can construct a tissue either from microscale in cellular level (bottom-up) or volume porous scaffold (top-down) [113].

3D printing is a kind of additive manufacturing. The driving idea was borrowed from "machine" operation, where a lathe can be numerically controlled to move in *X*, *Y*, and *Z* direction by a computer. The computer can "talk" to the lathe using "G-code" for communication. For a 3D volume or block process (manufacturing) in printing, an STL, an abbreviation of "stereolithography," with 3D point-line-surface information is a commonly adopted format and created by computer-aided design software. Thus a slicing program is needed to "cut" the 3D block into paper-like pieces where their dimensional (location) information is stored in G-code in each plane. Thus a 2D "paper" can then be stacked into a 3D volume (block). The sliced "paper" can be tuned in its thickness from a few microns to hundreds, which depends on the printing's resolution. The materials used for bioprinting are named "bioink [113]."

In general, there are four types of bioprinting methods, including extrusion-based, inkjet, stereolithography (SLA)-based, and laser-assisted. For extrusion, one of the most popular bioprinting technologies, bioink is loaded in a container, commonly, a syringe tube. Air pressure or screw-driven plate pushes the bioink to go through an orifice, which can be tuned in size for the considerations of bioink viscosity, deposition rate, and the printed objects size and accuracy (Fig. 54.6). The temperature effects could also be added in the printer for thermal sensitive polymers and melting plastics. Once bioink for extrusion printer gets through a small orifice, the ink experiences shear-thinning phenomena (Fig. 54.7). Under a high

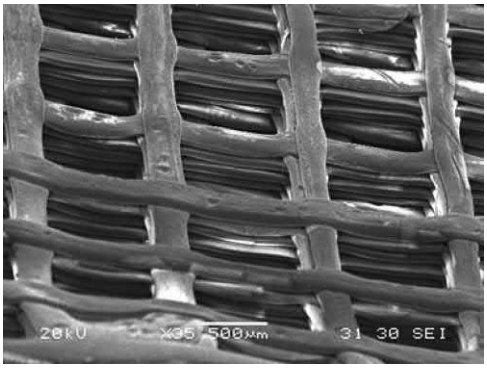

FIGURE 54.6 A printed hydrogel scaffold with controlled pattern size, pitch width, line width, and the number of layer.

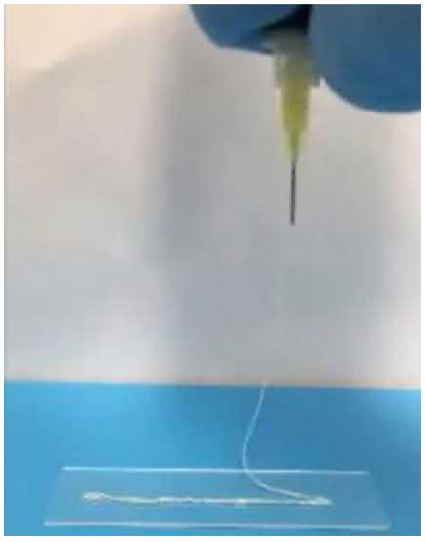

FIGURE 54.7 Bioink's shear thinning and viscosity are critical for a successful extrusion and deposition to form 3D pattern. *3D*, Three-dimensional.

pressure and shear stress, its viscosity will decrease in the orifice but will go back to the original after the ink is printed out. The procedures perfectly simulate the bioink passing through small orifice with high pressure and shear ratio. Viscosity is also critical for bioink's deposition onto the printing substrate. Inks with a low viscosity are not favorable for layer-by-layer constructs, while high viscosity inks perform well since under a stroke of extrusion the ink should be cleared away from printing head for next G-code input. Thus a rheological test can be conducted to characterize the viscosity mechanics of various bioinks under different shear rates and temperatures.

The inkjet approach to bioprinting (Fig. 54.8) is like an "office-use" printer with bioink in their cartridge classified with continuous-inkjet bioprinting, electrohydrodynamic jet bioprinting, and drop-on-demand inkjet bioprinting from driving mechanisms of thermal, piezoelectric, and electrostatic. From the perspective of

FIGURE 54.8 SLA printed high-resolution microneedles.

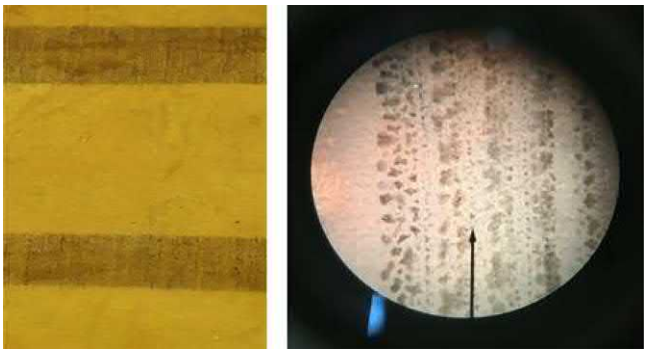

FIGURE 54.9 Inkjet printed graphene oxide–gelatin pattern with high-resolution finer line inside (right:under microscopy).

efficiency and convenience, inkjet printing has limited popularity compared with extrusion-based printers. In addition, the viscosity of available bioinks is not as diverse as in extrusion printers. Inkjet-based printing is a noncontact printing technique in which droplets of dilute solutions are dispensed, driven by thermal, piezoelectric, or microvalve processes.

SLA is a technology to use light with a specific wavelength to polymerize molecular chains and/or to make crosslinks to form polymer networks (Fig. 54.9). After polymerization and cross-linking the formed bulk system will not be dissolvable in water. Noncross-linked portions will be sacrificial layers that can be washed away in water or other solvents, while the remaining material will be printed in desired patterns. In general, bioink precursors have double bonds (e.g., vinyl), which can be activated for free-radical polymerization by light (e.g., wavelength of 365 nm). One majorly used and verified safe initiator is Irgacure2959 (Ciba), while some commonly used bioinks are acrylate-carried biomaterials (e.g., PEG, gelatin, chitosan, F127, acrylic acid, and acrylic amide) and methacrylate (MA) derivatives, etc.

Developed decades ago, laser-induced forward transfer (LIFT) can be used in 3D printing with high-resolution deposition of bioink. Pulsed-laser evaporation for direct writing has been used for cell printing. The mechanism is based on high powerful pulse laser and two glass slides, with one as energy absorption and the other containing cells. LIFT has high resolution but is also with high cost.

Bioink inspired from ligament and tendon structures

A tendon is composed of toughly packing self-assembled and paralleled multiscaled collagen fibers. This connective tissue bridges muscle to bone to sustain cyclic mechanical loadings of tension, compression, torsion, and shear. Similar to tendons in mechanics, ligament connects bone to bone. 3D bioprinting tissue could be used as a model to study musculoskeletal related disease and to screen drug molecules. Gelatin-MA was printed on a microplate for musculoskeletal tendon–like tissues on postholder cell culture inserts in 24-well plates. Human primary skeletal muscle cells and rat tenocytes were cocultured around the posts. Different printing patterns were used to demonstrate related gene and protein expressions, which could be used as a screening platform [114]. ACL is commonly reconstructed with tendon grafts following injury. Tissue-engineered implants can be printed in a thin-walled cylindrical mesh (Fig. 54.10), which can be used to enhance the strength for ACL reconstruction as an internal brace. The printing ink was composed of PCL, poly(lactic-*co*-glycolic acid) (PLGA), and β-TCP (tricalcium phosphate) under a pneumatic pressure of 500 kPa for deposition [115]. However, the integration between implant and bone had potential complication due to insufficient bone filling. Thus in a subsequent study, 3D printed cylindrical mesh was coated with recombinant human BMP 2 (rhBMP-2) with poly(propylene fumarate) as bioink; results demonstrated significantly increased pullout strength [116].

Until now, for 3D printed functional ligament and tendon, the research mostly focused on using thermal plastic polymers (such as PCL, PLA, and PLGA), natural hydrogels (such as gelatin, chitosan, alginate, and fibrin) and some ceramic materials (such as hydroxyapatite and β-TCP). In general, plastics and ceramics contribute to stiff phase and hydrogels contribute to soft phase. Meanwhile, cells and therapeutic agents can be added inside. However, a tough but flexible structure is able to mick ligament and tendon is still a challenge. For 3D printing ligament and tendon, the key is about how to deposit bioink with toughness, mimetic structures, and

FIGURE 54.10 3D printed cylindrical tough mesh coated with hydrogel. *3D*, Three-dimensional.

cell-compatible environments. Toughness means how much energy the material can absorb before failure. In order to enhance mechanical strength and fatigue resistance, multiple methods have been considered. Physical bonds can be introduced [e.g., polyacrylic acid, polyacrylamide (PAM), cellulose, and mussel-inspired dopamine]. On the other hand, a chemical double-network hydrogel can be designed with an elastic phase on chemical cross-linking and a dissipative phase on physical cross-linking. For instance, PAM gel with appropriate concentrations of monomer acrylamide and methylenebisacrylamide cross-linker is a superelastic gel, and alginate cross-linked with a cationic chelator Ca^{2+} is a physical gel. Upon mechanical impact, the PAM phase experiences fast deformation, and the stored elastic energy can be consumed by sacrificing physical cross-linking, which is reversible [117]. Liu et al. demonstrated gelatin-MA, a chemical and biocompatible gel reacted with tannic acid, can lead to a strong, tough, compressible, and stretchable gel with self-healing even underwater [118–122]. Electrospun short nanofibers of PCL, PLA, polyurethane, and natural polymers such as chitosan, alginate, collagen (type I), and gelatin can be mixed with ink–gel for printing. Nanofibers are pushed through printer's orifice (normally a long needle with regular round shape). The pressure and shear stress will promote these short nanofibers arranged to follow the flow direction. As a result, the nanofibers can have an orientation with alignment tendency. Upon light cross-linking, a tough scaffold with aligned fibers can be produced, for example, electrohydrodynamic jet printed out multilayered microfibrous films with longitudinal orientation fibers [123]. The film can be rolled up into a sleeve-like structure with high mechanical strength, which also enables migration of human tenocytes into the film with enhanced cellular activity.

In addition, some inorganic micro- to nanostructures can be used for mechanical enhancement of 3D printing. Cellulose nanofibers (or nanocrystal) are natural polymers with high aspect ratio and high stiffness, which can be included for tough and aligned scaffolds. Besides, hydroxyl and/or carboxylate functional groups provide multiple opportunities for modification (e.g., cellulose can be oxidized to produce aldehyde groups). It offers a convenient approach to working with the amine groups of gelatin for a bioink due to the Schiff base formation. Similar to cellulose nanocrystal, carbon nanotube and graphene oxide (Fig. 54.11) can also be used in bioinks as mechanical enhancers.

Tissue engineering tendon and ligament in clinical application

A typical tissue-engineered tendon and ligament should include scaffold, cells, and bioactive factors. However, this ideal engineered tendon combined with all three components has not been tested in clinical trials due to the barriers of the biological complexity for clinical applications. As the tendon and ligament is acting as a biological cable to move and stabilize the joints, engineered tendon and ligament scaffolds alone have been widely used in the clinic to treat tendon and ligament injuries. There are mainly three clinically used types of scaffolds, including native tendon tissue, other connective tissues [small intestine submucosa (SIS), fascia lata, etc.], and synthetic material tendon/ligaments. Native tendon scaffolds are the most common form for clinical applications, which include autograft, allograft, and xenograft. The tendon autograft to replace either damaged tendon or ligament is the gold standard to treat tendon and ligament defect in clinical practice. However, due to limited resources and

donor morbidity of the autograft tendons, allograft and xenograft tendons, or other tissues, have been utilized increasingly in recent decades. In order to reduce immunogenicity of the allografts, a lot of biologic scaffolds have been derived using the decellularization technique. Currently, the clinically approved connective tissue scaffolds include allograft (acellular human dermis) and xenograft (bovine pericardium, porcine SIS, porcine dermis) [124–127]. In general, the allograft or hybrid graft could provide satisfactory clinical outcomes [125,126,128–135]. When compared to the repairs without grafts, the use of grafts provided superior tendon healing [125–127]. However, the autograft still showed better results compared to allograft [136]. It is important to pay close attention to the processing procedure of the allograft because this could affect clinical outcomes. Many studies found that the use of nonirradiated or nonchemically treated allografts could achieve comparable outcomes to those repairs with autografts [128,129]. As for the xenograft, many studies have reported the high risk of inflammatory reaction, which refrain their utilization in clinic [125,127]. Iannotti et al. demonstrated the use of SIS resulted in an inferior healing rate compared with repair without augmentation [137]. Inflammatory reactions were observed in the patients using SIS augmentation [137]. Phipatanakul and Petersen reported complications of SIS, which included one infection and two localized skin reactions [138]. Walton et al. also confirmed a severe inflammatory response to SIS [139]. Lots of synthetic grafts have been proposed since the beginning of the 20th century. The materials for synthetic grafts include polypropylene terephthalate, poly-L-lactide acid, and polycarbonate. The synthetic patches show initial promising biomechanical properties [126]. However, the high failure rates have been confirmed among most of the artificial grafts used for ACL reconstruction. The failure rate after an ACL reconstruction, using Darcon, ranged from 20% at 2 years postoperatively up to 44% at 9 years [140,141]. The main concern about using synthetic grafts is the risk of infection and adverse host reaction [142]. More randomized controlled trials are needed to confirm their long-term clinical outcomes.

Bioactive factors, including GFs and small molecules, play an important role in tendon/ligament tissue engineering. With many preclinical models, the bioactive factors have been well proved to enhance tendon/ligament healing [143–146]. However, these results could not be directly translated to clinic practice. The main challenges have to be overcome such as the selection of optimal GF(s) or combination, identification of the most efficient stage and duration of delivery, and the design considerations for the delivery device [143]. Many researchers endeavor to figure out the dose concentration and feasibility of bioactive factors when applied to repair tendon/ligament in clinic [147,148]. Ide et al. showed local rhBMP-12 on an absorbable collagen sponge could be an adjuvant therapy for rotator cuff repair [147]. Oh et al. investigated the effect of recombinant human growth hormones on the outcomes after arthroscopic rotator cuff repair [148]. There was no statistically significant improvement in healing or outcomes related to the treatment of human hormone after repair. Therefore further, larger, and multicenter clinical studies should be conducted. Platelet-rip plasma (PRP) products have been well investigated in the recent decades. Wang et al. found that the PRP injection after rotator cuff repair did not enhance the early tendon healing and functional recovery [101]. Many other studies also confirmed that the use of PRP would not improve the rotator cuff healing [149–151]. However, for treatment of patellar tendinopathy using PRP, the clinical outcomes are controversial. Based on a systemic review of 15 clinical trials, Jeong et al. showed promising potential of PRP to restore patients to their daily work, living, and sports [152]. Nonetheless, it is hard to draw a clear conclusion for the effectiveness of PRP treatment on patellar tendinopathy [152]. With regards to ACL reconstruction, there was no proof that the use of PRP could enhance the ACL surgery clinical outcomes [103].

The MSC-based tissue engineering approach has emerged as a new therapy for tendon/ligament repair. The autologous stem cells utilized in the clinic are mainly bone marrow stem cells (BMSCs) or adipose-derived mesenchymal stem cells (ADSCs). Both BMSCs and ADSCs showed promising clinical results in rotator cuff injury [86,153,154]. Hernigou et al. demonstrated that the healing outcome of rotator cuff repair was significantly augmented with BMSCs [86]. Kim et al. revealed that the injection of ADSCs loaded in fibrin glue could significantly decrease the retear rate [154]. There were, however, no clinical outcome differences after a 28-month follow-up [154]. Although lots of preclinical studies showed benefits of MSC in the repair of ACL in animal models, only one clinical study, conducted by Silva et al., reported that adult noncultivated BMSCs did not seem to accelerate graft-to-bone healing [89].

In conclusion, tissue-engineered tendon and ligament have a high potential for clinical application due to a large amount of clinical demand. However, there is limited consensus in terms of scaffolds, bioactive factors, and stem cells in clinical trials. Further, basic science research for revealing mechanism and large animal models for translational research are critical for the successful clinical trials.

Summary

Tendons and ligaments are dense soft connective tissues that connect either muscle to bone (tendon) or bone to bone (ligament) to mobilize or stabilize the joints. Almost

all skeletal muscles need tendons to attach to bones, and all joints rely on ligaments for their stabilization and function. Loss of tendon or ligament integrity impairs muscle, bone, and joint function. Therefore tendon ligament functional restoration after injury is crucial. Due to anatomic and functional characteristics, tendon and ligament are the most vulnerable tissues suffering from injury in the musculoskeletal system, including acute and chronic injures. Furthermore, tendon and ligament have less vascularity and cellularity compared to other musculoskeletal connective tissues, such as bone, that lead to a slow and incomplete tissue healing with fibrotic scar formation. Treatment of tendon and ligament injuries remains a significant clinical challenge. Complications during the healing process are also high, such as retear of the rotator cuff repair, which has been reported as high as up to 90% [155–157]. Tissue engineering in the tendon and ligament field has been increasingly investigated recently in both experimental and clinical studies. As the tendon or ligament is a connective tissue, the mechanical strength, especially tensile properties, is the most important parameter when the engineered tendon or ligament is constructed. Thus the scaffold of the engineered tendon or ligament becomes crucial. Although many scaffolds, including native tissues or synthetic materials, have been used for tendons and ligament tissue engineering, the native tendon seems a good biomaterial for the tendon and ligament scaffold. However, as the tendon is a dense connective tissue, the revitalization or recellularization is challenging. Some technologies to increase the cell infiltration, such as multislicing or multislide, have been recently studied in animal models with promising results [158–160]. However, preclinical long-term studies would be necessary before clinical trials could be pursued. Cellular therapy and bioactive factors, especially PRP, have been used for tendon and ligament repair and regeneration clinically. However, there are no clear conclusions that can be determined from the limited number of clinical trials to date. More extensive, well-executed randomized control trials are needed in the future. Therefore in the next decade, tissue engineering in tendon and ligament area will remain a hot topic in both clinical trials and experimental studies. We hope there will be a breakthrough in the development of tissue-engineered tendon and ligament that could be translated successfully in clinical practice and commonly accepted by the clinical practitioners.

Chapter 55

Skeletal tissue engineering

Matthew P. Murphy, Mimi R. Borrelli, Daniel T. Montoro, Michael T. Longaker and Derrick C. Wan

Hagey Laboratory for Pediatric Regenerative Medicine, Division of Plastic and Reconstructive Surgery, Department of Surgery, Stanford University School of Medicine, Stanford, CA, United States

Introduction

With an aging global population, the socioeconomic and biomedical burden from musculoskeletal disease remains high. Compared to the period from 1990 to 2007 the percentage change of years lived with disease over the past decade have continued to increase [1], and musculoskeletal health issues have substantially contributed to nonfatal health loss and lower quality of life. With an increasingly elderly population, the number of high risk osteoporotic fractures has also been estimated to double by 2040 [2]. In light of this, developments in materials science and bioengineering, stem cell biology, and molecular biology have begun to converge on strategies to accelerate bone formation through tissue regenerative approaches and this offers an exciting new option to address the reconstruction of osseous defects.

The clinician is confronted with an array of large nonhealing bone defects resulting from trauma, resection of malignancies, nonunion of fractures, and congenital malformations. Autografts remain the best option for reconstructing bony defects because they provide osteogenic cells, osteoinductive factors, and a lattice needed for bone regeneration. They can be obtained from a patient's calvarium, ribs, iliac crest, distal femur, greater trochanter, or proximal tibia. Autografts, however, subject the patient to inherent risks of surgery during harvest, with recent large studies following iliac crest bone graft harvesting, for example, reporting acute gait abnormalities in 45.7% and persistent donor site pain in over 3% [3]. Furthermore, autografts are a relatively scarce resource and are limited by the amount of bone that can be removed. In situations where autografts are not sufficient or possible, allogeneic bone from donors or cadavers may be used. Allografts, however, may be accompanied by the risk for disease transmission, immunologic rejection, and graft-versus-host disease. To minimize the risk of disease transmission and contamination, there are strict guidelines in place for allogenic bone providers; however, there are few guidelines outlining donor eligibility [4].

As an alternative, synthetic materials such as hydroxyapatite (HA), polyetheretherketone, polymethylmethacrylate, and titanium have been used as bone substitutes to repair skeletal defects. Each, however, has its own associated problems [5], and the choice of biomaterial frequently relies on surgeon preference. However, when choosing, it is important to weigh considerations, including biocompatibility, osteointegration, mechanical resistance, aesthetic results, cost, availability, and infection risk of each material type. Unfortunately, comparing outcomes of each material has been complicated by variables such as their use in different defect sizes, the quality of surrounding bone, preexisting infection, radiation history, and age of patient. The wide range of options available for osseous reconstruction is indicative of the many advances made in biomaterials, and recent developments in biotechnology utilizing computer 3D analysis has allowed for patient-specific synthesis of biomaterials and optimization of surgical planning resulting in reduced operating time and complication rates [6]. Importantly, the plethora of options also reflects the inadequacies of any single method. As such, tissue engineering holds great promise to adequately address the issue of repairing bone defects. The delivery of osteogenic cytokines is already employed clinically, specifically bone morphogenetic proteins (BMPs), for the induction of bone regeneration. The ultimate translational goal, however, is to deliver both osteogenic cells and cytokines via a biologically active scaffold, in order to heal a bony defect in an accelerated fashion.

This chapter will begin with an overview of distraction osteogenesis, a modality that translates directed mechanical force into endogenous bone formation, to emphasize

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00057-5

the important role of the mechanical environment in bone formation and to highlight some of the growth factors that play a role in inducing bone formation. Emerging data in this field have also highlighted the significance of recapitulating developmental programs in bone formation leading to an evolution in regenerative paradigms. This chapter will now discuss recent advances in our understanding of skeletogenesis and the implications these discoveries have on cell-based strategies for bone tissue engineering. Finally, use of osteogenic cytokines and scaffolds to promote bone reconstruction will be examined, with an emphasis placed on recent discoveries.

Distraction osteogenesis

Distraction osteogenesis provides a model for the study of endogenous bone formation in large skeletal defects. First described by Alexander Codivilla in 1905 for limb lengthening and later codified by Gavril Ilizarov in the 1950s, distraction osteogenesis represents an endogenous form of bone tissue engineering [7,8]. New bone is formed during the process of separating osteogenic fronts with gradual but constant mechanical force. As a first step, an osteotomy is usually performed on the bone of interest, followed by application of rigid fixation. This is followed by a variable latency period of several days, during which a soft callus forms between the two osteogenic fronts. Gradual distraction is then applied, followed by stable fixation/consolidation, until a robust osseous regenerate is formed. It is thought that the mechanical forces applied by distraction can contribute to bone formation by induction of cytokines that guide mesenchymal cells in the bony gap to differentiate along an osteogenic lineage. Distraction osteogenesis not only triggers bone formation but also stimulates local angiogenesis as part of the process [9].

Research has been devoted toward characterizing the association between stress and strain patterns with bone formation. Correlating tensile force measurements with histology, Loboa et al. demonstrated that the greatest amount of bone formation occurs during active distraction, the period of greatest strain [10]. Loboa went on to further characterize the forces of distraction, using finite element analysis models created from three-dimensional computed tomography image data of rat mandibles at different phases of distraction osteogenesis [11]. The models described patterns of moderate hydrostatic stress within the gap, predictive of intramembranous ossification, and patterns of mild compressive stress in the periphery, consistent with endochondral ossification. These data derived from finite element analysis were consistent with previous histological findings.

Great interest surrounds research characterizing how mechanical forces may be translated into molecular signals that promote bone regeneration. Tong et al. described the role of focal adhesion kinase (FAK), a regulator of the integrin-mediated signal transduction cascade, in distraction osteogenesis [12]. In a rat model of mandibular distraction osteogenesis, immunolocalization of FAK in regions of new bone formation secondary to distraction was observed but was absent in the control groups where new bone formation occurred without distraction [12]. Similarly, investigations have also colocalized c-SRC, a kinase involved with activation of the mechanical transduction complex (p130), in regions of bone regeneration secondary to distraction osteogenesis [13]. In addition, microarray data from a rat model of distraction osteogenesis showed that FAK expression increases in response to mechanical stimulus [14]. While signaling molecules involved with transduction of mechanical forces are being identified, further work elucidating the mechanisms of these messenger molecules is required to clarify the influence of the mechanical environment on skeletal tissue engineering.

More recently, Ransom et al. have developed a mouse model for mandibular distraction, allowing for more detailed interrogation of the cellular and molecular events during guided bone regeneration [15]. Importantly, a localized clonal expansion of skeletal progenitor cells was identified leading to robust bone formation across the distraction gap. Furthermore, utilizing new techniques to investigate changes to the transcriptome and chromatin landscape, FAK-dependent mechanotransduction was found to activate a distinct regenerative program within a skeletal stem cell (SSC) population indicative of reversion to a more primitive neural crest genetic profile and different from transcriptional pathways activated by normal fracture healing. Inhibition of FAK abolished new bone formation, highlighting the importance of this mechanotransduction pathway in the activation of a gene-regulatory program and long interspersed nuclear element retrotransposons normally active in primitive neural crest cells. This reversion to a developmental neural-crest-like state by SSCs has been thought to underlie the robust bone tissue growth that facilitates stem-cell-based regeneration of the adult mandible with distraction (Fig. 55.1). These findings have thus expanded our understanding of how localized stem cell populations interact with their niche and have revolutionized our ability to potentially govern and regulate tissue healing and postnatal bone regeneration.

Distraction osteogenesis has also emphasized the multitude of growth factors that participate in bone regeneration. Elucidation of their roles and mechanisms will be a key element in successful tissue engineering. Transforming growth factor β-1 (TGF-β1), a potent growth factor known to stimulate osteoblast proliferation, has been demonstrated to have increased expression after osteotomy [16]. Immunohistochemistry revealed that TGF-β1 is localized to osteoblasts, primitive mesenchymal cells, and the extracellular matrix during the active distraction phase.

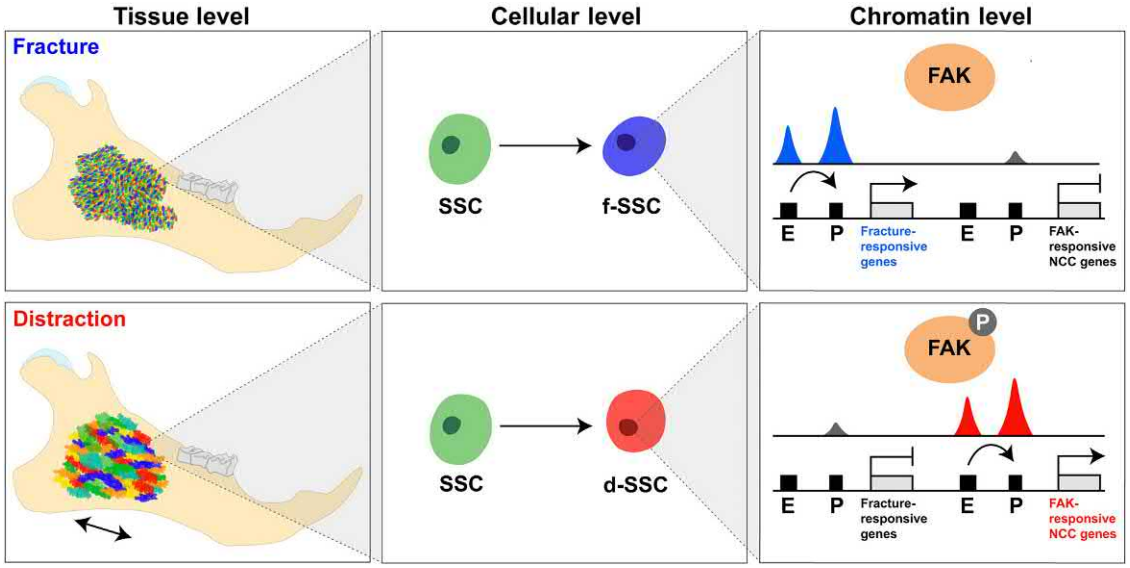

FIGURE 55.1 A comparison of the regenerative repair following fracture and MDO. At the tissue level: fracture results in a disorganized and nondirectional clonal proliferation that is diminished in magnitude (*left, top*). Bone lengthening following MDO, in contrast, results in expansion of large clones in a highly linear and directional manner (*left, bottom*). At the cellular level: the SSCs activated by fracture (f-SSC) (*middle, top*) retain postnatal SSC characteristics, whereas those activated by MDO (d-SSC) (*middle, bottom*) demonstrate plasticity and take on a NCC-derived signature. At the chromatin level: fracture promotes transcription of fracture-responsive genes in f-SSCs (*right, top*). In contrast, FAK-P in d-SSCs, there is a gain of accessibility at promoters (p) of FAK-responsive NCC-specific craniofacial and enhancers (E) (*right, bottom*). *FAK*, Focal adhesion kinase; *FAK-P*, phosphorylated FAK; *MDO*, mandibular distraction osteogenesis; *NCC*, neural crest cell; *SSC*, skeletal stem cell. *Adapted from Ransom RC, et al. Mechanoresponsive stem cells acquire neural crest fate in jaw regeneration. Nature 2018;563:514–21. doi:10.1038/s41586-018-0650-9.*

BMPs, another member of the TGF-β superfamily and known mediators in bone formation, have also been localized to regions of successful distraction osteogenesis. In examining femoral lengthening in rats, gene expression levels of BMP-2 and -4 were found to be elevated during the period of distraction [17]. Likewise, in distraction osteogenesis of rabbit tibia, immunohistochemical staining revealed intense BMP-2, -4, and -7 staining in fibroblast-like cells and chondrocytes during the distraction phase [18]. This was confirmed in membranous bone, where analysis of the bone regenerated from mandibular lengthening in rabbits revealed BMP-2 and -4 to be highly expressed in osteoblasts during distraction and in chondrocytes during consolidation [19]. Repeated local application of BMP-2 during distraction osteogenesis in a sheep model has been shown to significantly enhance the rigidity and architecture of the callus, indicating that enhancement of endogenous mechanisms may improve outcomes with this procedure [20]. Finally, transgenic mice have been used to show that the supporting vascular tissue, in particular smooth muscle and vascular endothelial cells, may be a significant source of BMP-2 during distraction osteogenesis [20]. Conversely, mesenchymal cells have been found to express proangiogenic growth factors within the distraction gap, suggesting that both bone and vascular tissue formation may be coordinated via a mutually supporting set of paracrine loops [21].

Insulin-like growth factor-1 (IGF-1) has also been implicated to play a role in the early stage of distraction osteogenesis. IGF-1 has been shown both in vitro and in vivo to stimulate osteoprogenitor cell mitosis and differentiation. In a canine tibia lengthening model, serum levels of IGF-1 increased initially during the early distraction period, followed by elevations in local IGF-1 at the region of distraction [22]. Schumacher et al. also presented evidence supporting the role of IGF-1 in early distraction, where periosteal IGF-1 levels in the rat tibia were increased only during active lengthening [23]. Exogenous addition of IGF-1 in a rabbit model of mandible distraction osteogenesis resulted in increased bone formation compared to control groups [24].

Lastly, studies have shown fibroblast growth factor (FGF) to be involved in promoting bone formation in distraction osteogenesis. Immunohistochemical analysis of sheep mandibles revealed FGF-2 staining in the region of distraction, with greater staining in animals found during high-rate distraction [25]. Exogenous administration of recombinant human FGF-2 (rhFGF-2) to a rabbit model of callus distraction following submetaphyseal corticotomy was also shown to increase the mineral content of the callus [26]. Further supporting the role of FGFs in bone formation, recent work utilizing a transgenic mouse with a gain-of-function FGF-receptor 3 mutation has shown accelerated ossification with distraction osteogenesis [27].

Distraction osteogenesis is thus a useful modality for translating discrete applications of mechanical force into molecular signals that induce skeletal regeneration. This process is not without its own morbidities however, such as soft-tissue infection, osteomyelitis, pin-tract infection or loosening, and patient discomfort [28]. Distraction osteogenesis is also limited by the need for complex hardware to accomplish distraction, and by the length of time required for large defects. Given these considerations, work continues on the development of alternative cell-based bone tissue engineering strategies to address large osseous defects.

Critical-sized defects

In the search for optimal elements of successful skeletal tissue engineering, the critical-sized defect has proven to be an indispensable tool for evaluating the performance of various constructs in the in vivo context. Critical-sized defects are bone defects that fail to heal without intervention, whereas noncritical defects may heal without planned reconstruction [29]. Critical-sized defects provide an easily accessible and quantifiable platform to evaluate the performance, dosages, and combinations of various cellular sources, osteogenic cytokines, and scaffolds.

Well-described bone defect assays include calvarial intramembranous bone, endochondral long bone, and segmental mandible defects [30]. The calvarial model is particularly useful in evaluating constructs for craniofacial defects given the relative ease in handling of the calvarial plate and support provided by the surrounding intact bone, absolving the need for fixation [31]. As it bears minimal mechanical load, the influence of exogenous forces on the investigation of specific cellular elements is reduced. Long bone segmental defects can also be created in the radius, where the ulna provides endogenous stability of that limb. Alternatively, in situations where load bearing of the construct is desired, femur defects can be used.

All these models are accessible to serial radiographic examination of the amount and density of mineralization using modalities such as plain films and micro-computed tomography. Histomorphometric analysis, however, allows cellular-level resolution and evaluation of bone resorption, changes in endogenous structure, and quality of the bone regenerate [30]. Serving as functional in vivo bone regeneration assays, critical-sized defects allow researchers to assess the rate and degree of bone healing for individual components of a bone construct and the combined effects of multi-modality treatments.

Cellular therapy

Over the past two decades, significant progress has been made in the identification of suitable cellular building blocks in regenerative strategies for bone engineering. Much of this has been due to an improved understanding in postnatal progenitor cells and fundamental bone biology. Resident progenitor cells can be found in many adult tissues and are active in endogenous mechanisms of repair and regeneration. Isolation, characterization, and utilization of these cells have provided many new promising treatment options. From a more developmental standpoint, studies have also begun to elucidate mechanisms involved in osteogenic lineage commitment of embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) and a growing body of work has shown progress toward harnessing their differentiation potential for regenerative therapies [32,33].

Early studies on postnatal stem cells have identified resident progenitor cells in a wide range of tissues, including bone marrow, periosteum, muscle, fat, brain, skin, and umbilical cord blood [30], though bone marrow represents the most well-studied source. Over the years, substantial work has been performed to characterize the ability for bone marrow mesenchymal stromal cells (BMSCs) to be guided along multiple mesenchymal lineages [34] and BMSCs have been successfully applied across multiple animal models for skeletal tissue engineering. Both Ohgushi et al. and Bruder et al. documented the ability for implanted rat and human BMSCs, respectively, loaded onto calcium phosphate ceramics to accelerate healing and promote union across rat femoral defects [35,36]. Furthermore, in a rabbit calvarial model, BMSCs delivered on a fibrin scaffold demonstrated osseous regeneration similar to control implants seeded with osteoblasts [37]. Finally, multiple mouse models have revealed that both human and murine BMSCs may effectively contribute to bone formation in vivo [38–43].

An alternative mesenchymal cell population composed of adipose-derived stromal cells (ASCs) has similarly been isolated from postnatal fat and studies have likewise demonstrated the ability of these cells to form various mesenchymal components [44]. A frequently cited advantage for these cells is their ability to be procured in large numbers from individuals with minimal morbidity and used in an autologous fashion for tissue regeneration or reconstruction [45]. Lee et al. first demonstrated the in vivo ability of ASCs to generate bone by implanting polylactic-co-glycolic acid (PLGA) scaffolds seeded with predifferentiated rat ASCs subcutaneously [46]. ASCs have also been shown to be capable of healing osseous defects, as reported by Cowan et al. who used these cells to repair critical-sized calvarial defects in mice [39]. Significant bone formation could be appreciated at 2 weeks, with complete bony bridging by 12 weeks, and comparison of defects implanted with ASCs or BMSCs demonstrated similar rates of bone formation. These experiments established an important proof of principle

that ASCs could contribute to bone formation in a critically sized, skeletal defect in mice. Subsequent studies have since documented human ASCs to also be capable of stimulating bone regeneration in critical-sized defects in both rat and mouse models [47,48].

A third, well-studied source of adult tissue-resident progenitor cells for bone regeneration is skeletal muscle, from which muscle-derived stem cells (MDSCs) may be obtained [49]. Alone or in combination with BMP, MDSCs have been shown to improve bone regeneration of critical-sized calvarial defects in mice [50,51]. Recently, using the same mouse model, MDSCs were also described to have the ability to regenerate vascularized corticocancellous bone with a diploic space [52]. However, given the potential for MDSCs to form both osteogenic tissue and hematopoietic supportive stroma, it is possible that they possess distinct subpopulations of lineage-restricted progenitors. Furthermore, the in vivo osteogenic capacity of MDSCs may be dependent on BMP signaling [51], and MDSCs may have the same issues as BMSCs when it comes to donor site morbidity and a lower potential yield [53], limiting their utility in cellular-based regenerative strategies.

Despite the promise for application of these mesenchymal progenitor cells in regenerative medicine, however, there remains a lack of common standards and precise definition of cell populations that represents a major obstacle for research and utilization in skeletal tissue engineering strategies. The known heterogeneity of starting populations has made interpretation of results between different reports difficult, and extensive work has thus been devoted to evaluation of phenotypic surface antigen markers which, when used alone or in combination, may be employed to prospectively isolate more homogeneous fractions for bone regenerative applications [54]. Among BMSCs, studies have described use of Leptin Receptor that identifies a postnatal population of cells that proliferate after skeletal injury and possess the ability to differentiate into bone and adipose tissue [55]. Nestin expression may also be used to isolate a population of self-renewing mesenchymal cells within bone marrow with enhanced osteogenic differentiation capabilities [56] and Gremlin has been reported to identify a population of osteochondrorecticular cells located within the metaphysis with the capability to differentiate into bone, cartilage, and reticular marrow stromal cells [57]. Finally, studies have shown use of platelet-derived growth factor (PDGF) receptor α and Sca-1 to be capable of isolating a perivascular population of progenitor cells from bone marrow with the capacity to differentiate into hematopoietic, osteogenic, and adipogenic tissues [58].

In similar fashion, many studies have been published describing use of various surface antigens in ASCs to prospectively identify subpopulations with increased osteogenic capacity. An enriched fraction low in CD105 (endoglin) expression has been shown to possess enhanced in vitro osteogenic differentiation and the ability to promote faster healing of critical-sized calvarial defects in mice compared to an unenriched population [59]. This has been likewise demonstrated with CD90 (Thy1), where positive selection for cells with this surface maker has been found to identify a subpopulation more capable of both in vitro and in vivo bone formation [60]. And as BMPs have been shown to accelerate osteogenic differentiation, prospectively isolating ASCs with increased BMP receptor-IB expression has been reported to delineate a highly osteogenic fraction of cells for potential use in bone regenerative strategies [61].

However, despite our expanding knowledge with the use of specific cell-surface proteins to improve the enrichment of mesenchymal progenitor cells for skeletogenic activity, cells prospectively isolated with these markers are still nonetheless incredibly heterogeneous. And what has been previously described as "mesenchymal stem cells" based on their adherence to plastic culture plates likely represents a population comprising multiple distinct lineage-committed progenitors rather than a uniformly purified bone forming stem cell. Only recently has a more precise functional hierarchy of skeletal tissue-forming cells been defined. The existence of a true multipotent SSC was first demonstrated by Chan et al. who, with the use of rainbow-reporter mice, identified clonal expansion of bone at growth plates encompassing only bone, cartilage, and stromal tissue [62]. This suggested that these tissues arise from lineage-restricted stem and progenitor cells that do not also give rise to hematopoietic, adipose, or muscle tissue. Subsequent work has defined a lineage tree of skeletal stem/progenitor cells with the mouse SSC giving rise to a bone, cartilage, stromal progenitor (BCSP) and other downstream committed progenitors with the capacity to specifically form cartilage, bone, or stromal tissue (Fig. 55.2). Interestingly, subpopulations within the skeletogenic tree have been found to encompass mesenchymal subtypes previously identified by prospective isolation strategies. Both Leptin receptor and Nestin-expressing cells have been shown to overlap with the mouse SSC population [63].

Importantly, identification of the mouse SSC has substantially deepened our understanding of bone and cartilage repair and regeneration. Growth factors such as BMPs have been extensively used to successfully promote bone formation, though overactive signaling has also been linked to pathologic heterotopic ossification. Studies in mice have revealed that BMP-2 can induce skeletal reprograming through de novo formation of SSCs, even within extraskeletal sites such as adipose tissue [62]. Emerging evidence also suggests that blocking vascular endothelial growth factor (VEGF)-dependent ossification can drive chondrogenic differentiation of SSCs. Following skeletal

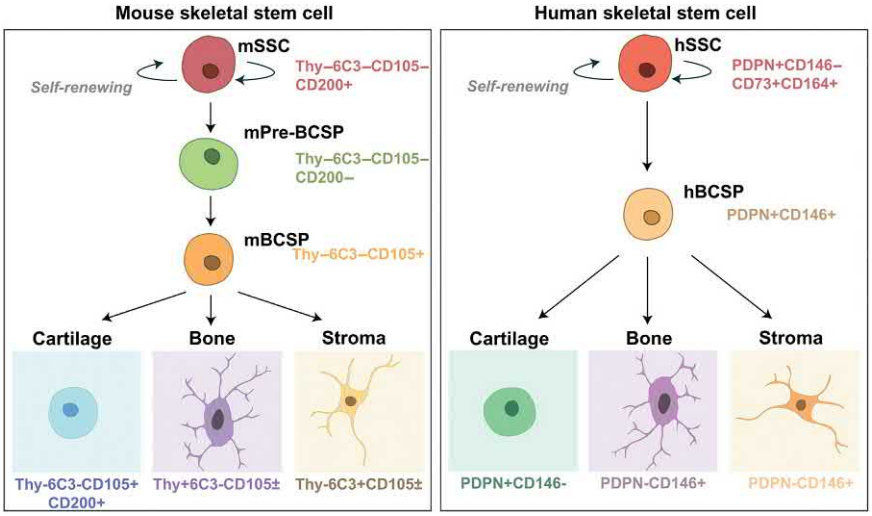

FIGURE 55.2 Schematic representation of the mouse (left) and human (right) SSC lineage trees. The surface markers used to isolate the distinct cell types by flow cytometry are shown. All cells in the mouse SSC tree are negative for the mouse lineage markers (CD45, TER119, Tie2) and positive for AlphaV. All cells in the human SSC tree are negative for the human lineage markers (CD45, CD235a, CD31, Tie2). *BCSP*, Bone cartilage stromal progenitor; *SSC*, skeletal stem cell. *Adapted from Chan CKF, et al. Identification of the human skeletal stem cell. Cell 2018;175:43–56.e21. doi:10.1016/j.cell.2018.07.029.*

injury, expansion of a specific fracture-induced BCSP (f-BCSP) downstream of the SSC has also been identified with enhanced skeletogenic potential secondary to gene expression patterns recapitulating perinatal skeletogenesis [64]. In the setting of diabetes, where fracture repair may be impaired due to suppression of SSC expansion, pharmacologic strategies to restore SSC proliferation and osteogenic potential has been shown to rescue bone healing in a diabetic mouse model [65]. These reports point to the future development of molecular strategies aimed toward the modification of specific progenitor cell microenvironments to address skeletal deficiencies, underscoring the impact of the SSC discovery in mice.

Recent studies have now extended findings to the human skeleton, where a similar SSC and hierarchical tree have been described [66]. By using a mouse SSC/BCSP-specific human ortholog gene set, human SSCs have been identified in the prehypertrophic and hypertrophic zones of fetal femoral growth plates. However, with divergence in surface protein expression between mouse and human cells, flow-cytometric analysis has revealed a distinct panel of surface markers characterizing the human SSC (Fig. 55.2). Nonetheless, these cells are still capable of lineal generation of chondrogenic and osteogenic subsets and reside at the top of the skeletogenic differentiation tree like their mouse counterpart. Studies with human fetal phalanges engrafted into the flank of immunodeficient mice have similarly shown fracture-induced amplification of human SSCs in response to skeletal injury, and BMP-2 has likewise been found to induce SSC expansion at extraskeletal sites, including freshly isolated human adipose tissue. Understanding how these cells can be controlled to regenerate bone may thus allow for alleviation of some of the burden of chronic musculoskeletal disorders associated with aging and disease. Perhaps the greatest implication of this work, however, relates to our comprehension of convergent and divergent skeletal regulatory programs between mouse and human bone progenitors. Assays characterizing differences in transcriptomic and genomic landscape between mouse and human SSCs have defined distinct features in accessibility regions reflective of species-specific gene expression patterns that may be the result of divergent evolution in epigenetic regulation. These discoveries may have direct significance in our design of bone regenerative strategies and interpretation of translational results.

In contrast to the more skeletal lineage-restricted potential of postnatal progenitor cells, work has also been done with pluripotent stem cells for bone tissue engineering. Despite the broad differentiation potential of ESCs, ethical and political controversies have fueled pluripotent cell research toward adult-derived iPSCs for tissue engineering [67]. In vitro studies have demonstrated osteogenic gene expression and bone forming capabilities of mouse ESCs and iPSCs to be similar, making iPSCs a preferred source of osteogenic cells [68]. While iPSCs have the capacity to spontaneously differentiate across all three primary germ layers, researchers have developed methods to drive differentiation of iPSCs into more pure populations of a single lineage for developmental research, drug screening, disease modeling, and for cell and tissue replacement. However, barriers to the use of iPSC technology for clinical applications include availability of a large autologous cell source, efficiency and safety of reprograming, defined optimal culture conditions, efficiency of directed differentiation, tumorigenicity risk, and stability and immunogenicity of transplanted cells. Nonetheless, significant progress has been made in addressing some of these clinical hurdles for use of iPSCs in bone regenerative strategies.

A number of adult tissues, from skeletal muscle satellite cells to circulating T cells, can serve as a source of

patient-specific cells for iPSC reprograming [69,70]. Notable for reconstructive surgeons, fibroblasts from skin biopsies and ASCs from liposuction aspirate provide readily available, large quantity cell sources that can readily yield iPSCs [71]. Initial reprograming experiments used lentiviruses expressing cancer-related genes c-Myc and Klf4, and transcription factors Oct4 and Sox2, introducing risk of insertional mutagenesis at the sites of viral integration and downstream tumorigenic risk from continued oncogene expression [72]. A variety of reprograming methods have subsequently improved on lentiviral technology using nonintegrating minicircle plasmids [73], microRNA [74], stabilized mRNA [75], and nucleotide-free recombinant protein [76]. Though these methods result in lower efficiency of reprograming than the lentivirus, they carry a reduced risk of mutagenesis and have better safety profiles.

Important to engineering of skeletal bone, iPSCs have been demonstrated to respond robustly to osteogenic inductive media containing β-glyerophosphate and ascorbic acid to form osteoblasts in vitro [77]. Following induction of differentiation with embryoid body formation, addition of these components has been shown to drive in vitro osteogenic differentiation of mouse iPSCs, as demonstrated by upregulated *RUNX2* and *Col1a1* gene expression and histologic staining for extracellular matrix mineralization. Furthermore, addition of TGF-β1 increases bone nodule formation after treatment of iPSCs with osteogenic media [78]. For use of iPSCs in vivo, cells must be differentiated sufficiently to avoid uncontrolled and undesired proliferation leading to teratoma formation. For this reason, many studies have first derived mesenchymal cells from mouse iPSCs prior to successful use in the reconstruction of mouse critical-sized calvarial defects [79]. Alternatively, transgenic mouse iPSCs expressing SATB2, a gene critical in normal bone development, transplanted directly into the same defect site has been reported to promote calvarial bone regeneration without teratoma formation [80]. Human iPSCs have also been used to generate mesenchymal cells that have then been shown to successfully repair critical-sized rat calvarial defects [81]. Finally, the calvarial niche is naturally composed of high concentrations of cytokines and bone progenitors and manipulation of this microenvironment may be potentially used to drive in situ osteogenic lineage commitment by transplanted iPSCs. In support of this, Levi et al. found that delivery of undifferentiated human iPSCs on a biomimetic scaffold, in conjunction with osteogenic factors such as BMP-2, was sufficient to both strongly drive osteogenic differentiation and dramatically reduce the incidence of teratoma formation [82].

Research granting agencies, both private and public, have dedicated significant funds to advancing the translation of stem cell applications toward clinical trials and therapeutic development. Continued work to advance transplantation of tissue-specific progenitors such as BMSCs, ASCs, MDSCs, and SSCs, or pluripotent cells such as ESCs and iPSCs toward the actualization of novel therapies will need to address challenges of immune privilege and rejection, the establishment of standard operating protocols for defined culture and storage conditions, tailoring cell/scaffold combinations for specialized craniofacial regions, and defined predictability of graft retention and integration into host. As these are active areas of research undergoing continuous rapid advancements, the field continues to hold promise for future skeletal reconstructive applications.

Cytokines

Studies from developmental biology and distraction osteogenesis have revealed a host of growth factors involved in cell proliferation, differentiation, adhesion, and migration during bone formation. An understanding of these interactions will undoubtedly allow for their use in bone tissue engineering. Successful skeletal tissue engineering will likely involve the incorporation of or stimulation by appropriate cytokines combined with the delivery or recruitment of a bone forming progenitor population. Some examples of the most well-studied cytokines include BMPs, IGFs, FGFs, PDGFs, and VEGFs [83].

Already in use clinically, BMPs hold the most promise as a growth factor for use in skeletal tissue engineering. BMPs were originally isolated by Urist from bovine bone extracts and were found to induce ectopic bone formation subcutaneously in rats [84]. This large group of proteins, comprising nearly one-third of the TGF-β proteins, has also been found to be involved in mesoderm induction, skeletal patterning, and limb development. BMPs are known to control both intramembranous as well as endochondral ossification through chemotaxis and mitosis of mesenchymal progenitor cells, induce lineage commitment to osteogenic or chondrogenic pathways, and regulate programed cell death [85]. BMPs transmit their signals via ligand binding to the heteromeric complex of type I and II serine/threonine kinase receptors on the cell surface. The ligand signal is then transduced intracellularly via activation of SMAD (signaling mothers against decapentaplegic) proteins, which subsequently migrate to the nucleus to effect gene expression. Noncanonical BMP signaling has also been shown to occur through the MAP-kinase (mitogen-activated protein) pathway [86].

BMP-2, -4, -6, -7, and -9 have been well studied most as osteoinductive agents. It is thought that BMPs regulate osteoblast differentiation via increased transcription of core-binding factor-1/Runt related family 2 (Cbfa1/Runx2), a molecule known to be necessary for commitment along an osteoblastic lineage [87]. These osteoinductive BMPs

have been demonstrated to promote osteogenic differentiation in multiple cell types, including fibroblasts, chondrocytes, BMSCs, and ASCs, and as previously discussed, BMPs have also been shown to induce formation of SSCs [62]. The effect of BMPs has also been noted to be concentration dependent; at low concentrations, they foster chemotaxis and cellular proliferation, but at high concentrations, BMPs induce bone formation [88]. Interestingly, in culture and in vivo, BMP-2/6, -2/7, and -4/7 heterodimers have been shown to more effectively enhance osteogenesis than homodimer combinations [89,90]. Recent work has now focused on delivery of BMP-2 in sustained fashion to more effectively stimulate bone formation. Keeney et al. found that integration of minicircle DNA incorporating a BMP-2 transgene into PLGA scaffolds could effectively sustain BMP-2 release by transfected cells and enhance calvarial reconstruction in a mouse model [91]. And as previously discussed, BMP-2, in concert with VEGF inhibition, may be capable of promoting cartilage formation [62]. Importantly, BMP-2 has been approved for use by the FDA for surgical reconstruction of various bone defects, and though some controversy exists over clinical outcomes and concerns have been raised over ectopic bone formation and inflammation, most studies show that treatment with BMP-2 has promising clinical efficacy.

IGF-1 and IGF-2 are 7.6 kD polypeptides that have been demonstrated to stimulate bone collagen synthesis, as well as osteogenesis and chondrogenesis. A transgenic mouse with upregulated IGF expression in osteoblasts was found to have increased bone formation of the distal femur as compared to control mice [92]. Of interest, however, histology did not reveal an increase in the number of osteoblasts, suggesting that IGF-1 increased the activity of existing bone progenitor cells. Conversely, in an IGF-1-null transgenic mouse model, the size and bone formation rates of the knockout mice were significantly reduced as compared to their wild-type littermates [93]. From a skeletal tissue engineering perspective, studies have suggested age-related reduction in IGF-1 production to be associated with impaired bone forming capacity of human mesenchymal progenitor cells derived from elderly patients, and overexpression of IGF-1 can enhance biomineralization of these cells in culture [94]. IGF-1 was also shown to enhance the ability of bone marrow-derived mesenchymal progenitor cells to restore osteochondral defects in rabbit knee joints [95].

FGFs consist of a highly conserved family of 24 known peptides that transmit their signals via a family of four transmembrane tyrosine kinases. FGF-2, the most abundant ligand of the family, is known to increase osteoblast proliferation and enhance bone formation in vitro and in vivo [96]. In FGF-2 haplo-insufficient and null mice, decreased bone mineral density has been observed, and impaired bone formation has also been correlated with decreased expression of FGF receptor-2 [97]. Application of exogenous FGF-2 has been shown to rescue bone nodule formation in osteoblast cultures from these FGF-2 mutant mice. More recently, utilizing a beagle dog periodontal defect model, exogenous FGF-2 with a hydroxypropyl cellulose vehicle was shown to increase angiogenesis and osteogenesis in vivo by increasing local expression of BMP-2 and other osteoblast differentiation markers within the regenerate [98].

Platelet-derived growth factor, a 30 kD polypeptide, has also been demonstrated to be a potent stimulus for osteoblast proliferation, chemotaxis, as well as collagen activity. In particular, PDGF-BB has been shown to upregulate osteogenic gene expression and extracellular matrix mineralization by ASCs [99]. The utility of PDGF in vivo has been shown with enhanced bone formation after local application to tibial osteotomies in rabbits and canine mandibles after periodontal surgery. PDGF, also studied for chronic wounds, is now being evaluated clinically for periodontic indications. A recent multicenter trial demonstrated that the application of recombinant human PDGF in a tricalcium phosphate matrix resulted in significantly increased periodontal bone formation [100].

Finally, the recruitment of blood vessels has long been known to be vital to support newly formed tissue. In support of this, application of VEGF to both intramembranous and endochondral bone defects resulted in increased blood vessel formation, ossification, and new bone in various mouse and rabbit models [101]. Not only does VEGF have a role in angiogenesis, but it may also stimulate osteoblast differentiation and osteoclast activation for bone formation and remodeling. Inhibition of VEGF by application of a receptor neutralizing agent has also been shown to diminish blood vessel formation and osteogenesis [102].

Interestingly, a direct comparison of the ability of VEGF-A, BMP-2, and FGF-2 to enhance intramembranous bone healing in a critical calvarial defect has revealed that application of each of these cytokines increases proliferation of osteoblasts and progenitors in the defect region [103]. While all three cytokines significantly enhanced healing of the defect, VEGF-A and BMP-2 increased angiogenic support, while the effects of FGF-2 were independent of new blood vessel formation. Supporting the hypothesis that angiogenesis is critical to calvarial bone healing, VEGF-A and BMP-2 applications also resulted in the most bone formation, with nearly complete healing in a mouse critical-sized defect at 3 weeks [103].

Scaffolds

The challenges of incorporating cytokines in skeletal tissue engineering involve identifying cell populations and molecules that stimulate and participate in bone formation, but

the effectiveness of these treatments is largely based on the mode of delivery, effective dosages, and compatible carrier mechanisms. Fortunately, advances in materials science have provided an abundance of innovations for developing an appropriate carrier for these cells and molecules. In the selection of a biomimetic scaffold for engineering bone, the material should be osteoconductive, osteoinductive, biocompatible, and biodegradable without eliciting an immune response. Osteoconductivity refers to the ability of the graft to support the attachment of cells and allow for new cell migration and vessel formation. The osteoinductive quality of scaffolds describes their ability to guide progenitor cells along an osteogenic lineage. Some of the challenges in designing the structure of scaffolds lie in the need to maximize the porosity of the scaffold to promote cellular and neovascular ingrowth while maintaining the structural integrity of the lattice [30]. Potential matrices can be generalized into three categories: natural, mineral-based, and synthetic polymers.

Natural scaffolds are typically biodegradable and include the use of collagen, hyaluronic acids, calcium alginate, and chitosan. In many instances, they exhibit osteoinductive properties, exclusive of cells or cytokines. Implantation of collagen type I alone into critical-sized defects of rat mandibles resulted in partial bone healing [104]. However, one disadvantage of natural scaffolds is their lack of mechanical stability, hence, their limited utility for use in load-bearing regions of the skeleton. Clinical application of natural scaffolds in patients is also limited by the biochemical changes often induced by sterilization procedures. Some of these limitations, in particular structural integrity, can be offset by using composites that combine the best properties natural scaffolds with other materials discussed below [105].

Mineral-based scaffolds include calcium phosphate ceramics and bioactive glass. Calcium phosphate ceramics are available as HA or β-tricalcium phosphate, with HA most closely mimicking the structural and chemical characteristics of the mineral component of bone. Tricalcium phosphate is marked by a high-dissolution rate that accelerates material resorption and elicits an immune response, while HA has high chemical stability. Mineral-based scaffolds provide an osteoinductive signal to encourage differentiation of progenitor cells along an osteogenic lineage. There is, however, great variability in the quality of calcium phosphate ceramics to support osteogenesis due to the difficulty in reproducibly creating these scaffolds [106], and many formulations have been found to be too brittle alone for use in skeletal reconstruction of load-bearing regions.

Synthetic polymer scaffolds, including polylactic acid (PLA), polyglycolic acid, polydoxanonone, and polycaprolactone (PCL), have been engineered to provide a greater ability to withstand mechanical forces. These lattices are marked by their incredible strength while also being designed to be biodegradable via hydrolysis. Polymer scaffolds allow ingrowth of bony tissue but lack osteoinductive properties. To overcome this deficiency, polymer scaffolds, such as PLGA, have been combined with mineral coating to create an osteoconductive niche with enhanced architectural strength. HA-coated PLGA scaffolds have been extensively used in various animal models to promote bone reconstruction [39,107,108].

Hydrogels represent another class of polymer scaffolds that are formed by polymerization and cross-linking of molecules such as collagen, acrylic acid, and *N*-isopropylacrylamide [109]. Hydrogels are an attractive option because of their temperature-dependent physical properties. Synthetic formulations can be designed to be gelatinous at room temperature but take on more rigid qualities at body temperatures. This property allows for the administration of tissue-engineering constructs via injection. Hydrogels also allow for relatively easy chemical manipulation of individual peptides, making them bioavailable as free molecules in the matrix or tethered for sustained release. Incorporation of arginine−glycine−asparagine (RGD) peptide motifs on these polymers has been demonstrated to enhance osteoblast adhesion and proliferation [110]. By combining collagen hydrogels with PLGA microparticles to deliver osteogenic mesenchymal progenitor cells, researchers have described a cell delivery mechanism that is elastic enough to adapt to the shape of a defect but will mineralize and acquire structural rigidity in the presence of differentiating cells [111]. Other groups have used a hybrid scaffold by combining an osteoconductive load-bearing polymer matrix with a peptide hydrogel providing controlled release of recombinant human BMP (rhBMP)-2 [112]. Cells seeded on this scaffold demonstrated increased expression of in vitro bone differentiation markers. However, progress over the last several years with nanoengineering has now shown promise for incorporation of two-dimensional nanosilicates in nanoengineered hydrogels to eliminate this need for BMP-2 [113]. Hybrid hydrogels may thus provide for multiple reconstructive goals, including structural integrity, sustained release of cytokines, and support of cell differentiation, and are one of the more promising scaffold candidates for actualizing large defect reconstruction.

Lastly, electrospinning has emerged in recent years as a novel method to construct scaffolds that closely mimic natural extracellular matrix. Nanowoven fibers are generated by shooting a jet of polymer solution through a high electric field [114]. Adjusting the polymer solution and the electric field allows the fiber diameter and porosity to be controlled with high precision. By blending various materials using this technique, structural properties of the resultant scaffold can be tightly controlled. For example, electrospun PCL/PLA nanofibrous scaffolds have been

found to improve human mesenchymal progenitor cell osteogenesis and lead to robust bone formation in vivo [115]. Silk fibroin has also been incorporated into three-dimensional electrospun structures for bone tissue engineering purposes [116].

Of note, many different osteogenic materials or cytokines can also be incorporated into electrospun scaffolds, accurately reproducing natural bone matrix with embedded osteoinductive factors. Along these lines, silk fibroin fiber scaffolds incorporating BMP-2 and nanoparticles of HA have been shown to enhance mineralization of human bone marrow mesenchymal cells cultured on these scaffolds in vitro [114]. Electrospun biodegradable fibers seeded with amniotic-derived mesenchymal progenitor cells were likewise used to generate allogeneic fetal bone grafts, which were superior for in vivo reconstruction of craniofacial defects compared to prosthetic materials in a rabbit model [117].

Tissue engineering in practice

Clinical applications for tissue engineering have long focused on the delivery of BMP cytokines and use of cytokine-scaffold devices. More recently, however, alternative strategies have been reported with use of other cytokines or cell-based approaches. Nonetheless, with many of these applications, criticism has still been voiced over the need for high doses of cytokines necessary to obtain clinical relevance and the resulting costs associated with manufacturing growth factors for patient use. Concern also exists about rare but reported incidences of high blood pressure and even myocardial infarctions in animal models, which may be secondary to an immunologic response to implanted constructs [118].

The Infuse Bone Graft/LT Cage fusion device has been used in over one million procedures worldwide and is currently approved by the FDA for use in spinal fusion, tibia fractures, and oral–maxillofacial reconstruction of bone defects associated with teeth extraction (Medtronic Sofamor Danek, Minneapolis, MN). This product involves an absorbable, bovine collagen implant soaked with rhBMP-2. Importantly, humans require supraphysiologic doses ranging from 0.4 to 1.5 mg/mL of rhBMP-2 to form new bone, and because of these high doses, there have been some concerns raised about excess bone growth around the growth factor implantation site. Interestingly, a clinical study of Infuse in 74 consecutive patients revealed radiographic lumbar fusion in 100% at 12 and 24 months without any abnormal bone overgrowth. However, this study was significantly weakened by the lack of a control group [119]. Off-label use for other procedures in spine have been reported to cause complications including tissue swelling, seroma, ectopic bone formation, paralysis, and death [120,121]. This has led many surgeons to reconsider the broad use of Infuse for off-label applications. And given reports describing a link between osteosarcoma and BMP activity [122], clinicians have also been hesitant to use Infuse in the pediatric population. Of note, several recent animal studies have actually found BMP-2 to inhibit tumor expansion and development of lung metastases through induction of bone formation in heterogeneous osteosarcoma cells [123,124].

rhBMP-2 has also been used in patients requiring maxillary sinus floor augmentation, in preparation for endosseous dental implants. In one study, rhBMP-2 was applied to the maxillary sinus floor on an absorbable collagen sponge at 0.75 and 1.5 mg/mL [125]. Radiographic evaluation for bone mass in the maxillary sinus floor revealed that rhBMP-2 with collagen sponge alone was able to induce bone formation, but this was found to be less effective than autogenous bone grafting in fostering new bone formation. Notably, however, rates of successful placement of dental implants were similar between the bone graft treatment arm and patients receiving rhBMP-2 [125].

Similar to BMP-2, rhBMP-7, originally marketed under the brand name OP1, has been studied to aid in the fusion of vertebral bodies and to treat critical-sized bone fractures. It is also delivered via a bovine collagen matrix and has been used in limited situations to treat nonunion in the tibia of at least nine months, secondary to trauma, in skeletally mature patients. However, in a small case series report, the use of rhBMP-7 in five patients who had failed allografts did not result in any significant healing [126]. Compared to rhBMP-2, rhBMP-7 may also be less effective at promoting bone formation following spinal procedures and has thus struggled to obtain FDA approval [127].

In addition to BMPs, other cytokines have now emerged for use in human clinical trials to promote bone formation. In particular, a recent randomized double-blinded multicenter trial investigating the use of rhFGF-2 in combination with a β-tricalcium phosphate scaffold showed that there was significant improvement in linear bone growth and percentage of bone fill at vertical periodontal defects with use of this construct [128]. Akin to these findings, Kitamura et al. also observed the ability for rhFGF-2 within a 3% hydroxypropylcellulose delivery vehicle to stimulate regeneration of periodontal bone in patients without any serious adverse events noted throughout the clinical trial period [129].

Aside from clinical use of growth factors for skeletal tissue engineering, studies have also begun to evaluate cell-based strategies for bone regeneration in patients. For example, several reports have looked at the use of BMSCs for skeletal reconstruction. A wide range of studies in the literature have shown some promise for use of these cells in applications ranging from nonunion and fracture healing, to segmental bone defects and spinal

fusion, to distraction osteogenesis [130]. Of particular interest, a recent randomized, controlled clinical trial investigating the effect of bone regeneration in the maxillary sinus using autologous mesenchymal progenitors derived from bone marrow on a β-tricalcium phosphate scaffold revealed higher density of engineered bone compared to patients receiving scaffold alone [131]. Furthermore, the greatest benefit was observed in patients with the most severe alveolar deficiencies, with superior bone quality noted compared to control patients who did not receive autologous cells. These results were also correlated with degree of CD90 + progenitor cell enrichment, and the higher the CD90 composition of transplanted cells, the greater the regenerated bone. Not surprisingly, this parallels the previously discussed work by Chung et al. highlighting enhanced osteogenic potential of this same mesenchymal cell subpopulation [60].

Promising results are nonetheless tempered by other studies that have questioned the long-term stability of clinically reconstructed skeletal defects using mesenchymal cells. Thesleff et al. recently reviewed five patients who had undergone prior calvarial defect repair with ASCs, β-tricalcium phosphate granules, and titanium or resorbable mesh. While initial results were found to be promising and no serious complications were noted, long-term follow-up at 6 years revealed many patients with marked resorption bone and only two of the five showing stable, successfully ossified grafts [132]. However, substantial heterogeneity among the harvested cells used may have contributed to these suboptimal results, and continued efforts to refine our understanding of functionally distinct mesenchymal cell subpopulations, along with the recent discovery of the mouse and human SSC, lend confidence to the development of future successful cell-based strategies for skeletal tissue engineering.

Conclusion

The intersection of advances in stem cell biology, molecular biology, biochemistry, bioengineering, and materials science has brought to the forefront the ability of regenerative medicine to address problems of skeletal defects. Efforts are furthered by continued research on identification of postnatal osteoprogenitor cells, the functions and interactions of osteogenic cytokines, and scaffold design. In particular, the influence of nanotechnology on scaffold development and the advancements of growth factor releasing scaffolds and hydrogels are promising advancements that may help one to promote bone formation by progenitor cells without the need for supraphysiologic doses of cytokines such as BMP-2. Nonetheless, efforts are still needed to develop methods for creating vascular support of large osseous constructs, and this may potentially be achieved through the use of proangiogenic agents. Further investigation into identifying and enriching available osteoprogenitor populations now that the SSC and hierarchical tree have been described along with continued advancements in pluripotent cell research may lead to future human clinical trials and more available tools for reconstructive surgeons. Given the immense biomedical burden of skeletal defects and the significant developments in skeletal tissue engineering, osseous regeneration provides a promising and attainable goal that will be achieved through interdisciplinary collaboration.

Part Fifteen

Nervous system

Chapter 56

Brain implants

Lars U. Wahlberg
Gloriana Therapeutics, Inc., Providence, RI, United States

Introduction

Even though regulatory-approved cellular brain implant therapies are not yet available, experimental data strongly support the use of cellular brain implants and tissue engineering concepts in the treatment of brain disorders and promise new disease-modifying medical products for patients. Various cellular implants have already been applied in the clinic in proof-of-concept studies in Parkinson's disease (PD) [1−3], Huntington's disease (HD) [4−6], Alzheimer's disease (AD) [7−9], epilepsy [10], and stroke [11−13]. Due to its defined anatomy and relatively well-established disease mechanisms, PD is a major therapeutic target for cellular brain implants and is highlighted in this chapter as a disease example to illustrate the tissue engineering concepts applied to date.

Despite the long-standing success of many drugs for PD, such as L-dihydroxyphenylalanine (L-DOPA) therapy, the current treatments of PD do not stop the progressive dopamine neuron dysfunction and cell death. Over time, patients on chronic L-DOPA therapy develop both progressive symptoms and drug-induced side effects and require additional treatment options. For these patients so-called deep brain stimulation (DBS), which utilizes implantable neural stimulators that inhibit neuronal transmission in local areas of the brain, often the subthalamic nucleus, can yield good therapeutic results without inducing permanent lesions in the brain [14,15]. These devices are Food and Drug Administration approved and are commercialized by several companies, with Medtronic, Inc. being the most well-known. Despite successful applications of DBS for the treatment of PD, this therapy is based on the inhibition of normal neurons to compensate for the disease damage. DBS does not address the biology of the underlying disease itself and, albeit successfully applied in many patients, the compensatory destruction or inhibition of normal tissue is not an optimal treatment for neurological disorders. There is therefore a need for new treatment strategies that can address the pathology more directly and offer disease-modifying effects. Fortunately, the accumulated knowledge of the pathological processes, molecular and cell biology, biomaterials, imaging, and successful implementation of DBS and its associated stereotactic neurosurgical procedures make it now possible to implement disease-modifying brain implants based on tissue engineering concepts to the treatment of PD and other neurological diseases.

In many untreatable neurological disorders, the progressive loss of neurons and their associated function is the primary underlying cause for the symptoms of the disease. Therefore various cell implant strategies have been designed to either *replace* the neurons or their function or to *protect and/or regenerate* the function and health of the diseased neurons, or a combination of both (Fig. 56.1).

Clinical applications to replace the dopaminergic function in patients with PD have so far mainly utilized primary tissues or cells but more recently early clinical trials with stem cells are underway [2,16]. Dopaminergic neurons derived from stem cells and more sophisticated tissue-engineered implants may thus be developed to replace diseased and lost dopaminergic neurons and have a potential to cure PD [17]. This chapter reviews some of the cell replacement and regenerative brain implants applied in the clinic and touches on what may be developed in the future.

Cell replacement implants

Primary tissue implants

As mentioned earlier, oral L-DOPA therapy remains the main treatment for PD. L-DOPA is a precursor to dopamine that passes the blood−brain barrier and is mainly taken up by the residual dopaminergic neurons that convert L-DOPA to dopamine and increase their dopamine

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00058-7

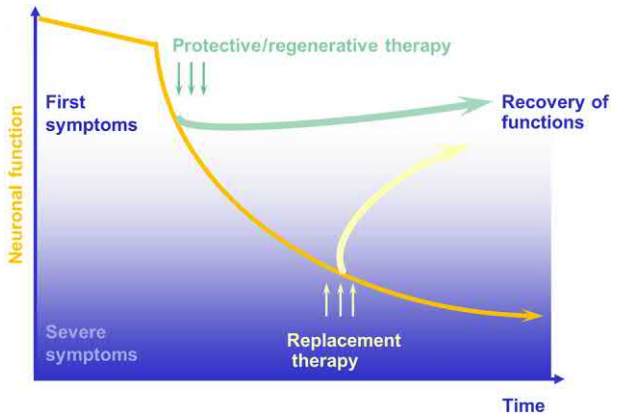

FIGURE 56.1 The concepts of cell replacement and protection/regeneration are depicted. A loss of neurons or their function (*orange line*) occurs with aging but in a disease, such as PD, neuronal loss is accelerated and after a while, the loss is significant enough to cause symptoms of the disease. At this stage, further deterioration could be prevented by protecting the neurons and the system could even be improved by applying regenerative factors to the diseased host cells. After significant loss of neurons, regeneration of the host system is not possible. However, the implantation of cells capable of replacing the function of host cells could be possible. Both approaches have been applied in PD and a combined treatment of neuroprotection/regeneration with replacement may be achieved in future brain implants. *PD*, Parkinson's disease.

production and storage. However, with the progressive loss of dopaminergic neurons, the L-DOPA therapy eventually becomes ineffective and severe fluctuations in the ability to initiate movements occur. Because L-DOPA can increase the production of dopamine and alleviate the symptoms of PD, a reasonable therapeutic approach may be to implant dopamine- or L-DOPA-secreting cells in the relevant areas of the brain (striatum).

Considering this idea, the first clinical transplantation for PD using a cellular brain implant was performed at the Karolinska Hospital in Stockholm, Sweden in the early 1980s [18]. Autologous dopamine–secreting adrenal chromaffin cells were harvested from one of the patient's adrenal glands and successfully transplanted to the striatum. The procedure was adopted very quickly by the medical community and initial reports indicated good clinical results. With time though, other studies showed poor survival of the cells and minimal positive clinical effects, resulting in the cessation of the treatment [19]. However, the concept of cellular brain implants had made its definite entry into the clinic and paved the way for cell therapies of the brain.

At about the same time as the first clinical chromaffin cell transplants were made at the Karolinska Institute/Hospital in Stockholm, preclinical research at the same institution demonstrated the concept of using fetal tissue dopamine grafts capable of replacing the loss of function of lesioned endogenous dopaminergic neurons [20]. This promising cell transplantation strategy for PD was developed further by Björklund and Lindvall at Lund University in southern Sweden [1]. After several years of extensive validation of the concept in animal models, cells were transplanted to the striatum of two PD patients [21]. The first results were safe but relatively unimpressive from a cell survival perspective, prompting modifications to various parts of the experimental procedure, and a second pair of patients transplanted about 1 year later fared much better [22]. These patients showed positive clinical recovery starting about 4 months after the procedure. Positron emission tomography (PET) data indicated that the grafts survived and took up and secreted dopamine. More than 10 years after the procedure, one of the patients showed persistent graft viability on PET scanning and required only minimal L-DOPA therapy [23,24]. To date, more than 300 patients have been transplanted with fetal ventral mesencephalic tissue at different centers around the world with mixed but encouraging results. However, ethical considerations, the lack of suitable donor material, the heterogeneity of the tissues and preparations, and the inability to industrialize the process, have all made it difficult to make standardized medical trials and therapy geared for a large number of patients. Two National Institutes of Health–sponsored controlled trials with fetal transplantation showed only minimal efficacy and some patients developed movement side effects (dyskinesias) that were related to the grafting procedure [25,26]. It has also been observed that grafted fetal neurons may be able to survive for many years after surgery, but these same grafted neurons are subject to the same pathological processes that underlie the loss of endogenous dopaminergic neurons in PD [27]. Therefore fetal transplantation as a therapy for PD is no longer actively pursued as a therapeutic option except on an experimental level and 11 patients were recently transplanted in a highly controlled trial aims to minimize variables identified in previous trials and establish protocols for future stem cell transplantations [16]. New stem cell replacement strategies for PD will therefore replace primary tissues and cells. However, the translational studies with chromaffin and fetal–derived primary tissues have generated important data that continue to facilitate the development of tissue-engineered implants for the treatment of PD and other neurological disorders.

1. Allogeneic cells can survive over many years in the brain with initial immunosuppression therapy (6–18 months) [22] but xenogeneic (porcine) implants do not [28].
2. Grafted neurons can integrate, function, and interact with the host brain in a physiological and reciprocal manner.
3. The mechanisms of graft-induced dyskinesias have been elucidated and may be eliminated.

4. Animal models have been developed to translate and scale up experimental brain implants for the clinic.
5. Surgical techniques have been developed that allow for the safe injection and implantation of cells and tissue-engineered products in the brain.
6. Trial designs and outcome measures have been developed that facilitate safety and efficacy measures in the clinic.
7. Imaging techniques have been developed to evaluate the implantation and function of the brain implants.

Cell line implants

Aside from ethical considerations, important drawbacks using primary tissues are its limited supply, its heterogeneity, and the difficulty and prohibitive costs to implement the necessary good manufacturing principles for harvesting, manipulation, storage, and later use. For example, fetal transplantation experiments for PD required fresh tissue from 4 to 8 donors resulting in procedural difficulties and poor quality control and may help explain the poor and variable efficacy outcomes in controlled trials. Therefore the ability to expand and store cells in cell banks is paramount to creating allogeneic cell alternatives to primary tissue grafts. Primary cell lines normally retain a limited number of cell cycles but allow for the proliferation of enough cells to transplant hundreds of patients from a single donor. Cultured primary cells can be expanded while retaining normal genotypes and phenotypes with normal contact inhibition and differentiation behaviors. These cells are therefore relatively safe to use, and the formation of tumors or other abnormal behaviors are relatively unlikely.

A few years ago, primary cell lines of retinal pigmented epithelial (RPE) cells derived from the retinas of organ donors were made with limited expansion capacity and were evaluated in clinical trials for PD. The RPE cells were thought to secrete L-DOPA and function by increasing the intrastriatal L-DOPA concentration and subsequent conversion to dopamine by residual dopaminergic nerve endings and glia. These cells were grown and transplanted on gelatin microcarriers to improve survival and prevent immune rejection. A report on a clinical pilot trial showed that these implants were well tolerated and safe [29]. However, a Phase II trial failed to reveal any evidence of efficacy [30] and earlier published autopsy results demonstrated poor cell survival at 6 months [31]. This approach has since been abandoned but was the first translational trial of primary cell lines grown on an artificial scaffolding for brain implantation.

In my laboratory, we were able to make the first long-term human expandable primary cell lines that contained neural progenitor/stem cell cultures capable of making various neurons or glia. These were mitogen responsive and could be isolated from various regions of aborted and adult human central nervous system (CNS) tissues and expanded for more than 1 year in vitro [32]. These cells could form the three major phenotypes of the nervous system (neurons, astrocytes, and oligodendrocytes) in vitro and in vivo and showed excellent survival without the formation of tumors in vivo. These stem cell–containing cultures were transplanted to various regions in animals and survived, integrated, migrated, differentiated, extended neurites, and arborized [33]. Even though the cells tended to retain the markers consistent with the anatomical region from which they were isolated [34], the cells could be manipulated with epigenetic and genetic factors to make specific cellular subtypes potentially useful for cell replacement implants. These studies were important in showing that neural progenitors could be expanded and manipulated, but sourcing still required tissue samples from adult or fetal brains and the cultures displayed senescence and limited life span. These types of cells were eventually implanted in clinical trials [35] of spinal cord injury, Batten's disease, and Pelizaeus–Merzbacher disease, but all three trials failed to meet the efficacy endpoints set up to support further development.

In general, all primary cell lines derived from tissue stem cells have a large but limited expansion potential and show senescence [36,37]. This may be due to the successive loss of immortal stem cells through the asymmetric division into progenitors (as seen in neurospheres) or alternatively, the stem cells themselves have a limit to their proliferation.

More recently, pluripotent stem (PS) cells consisting of either embryonic stem (ES) cells or derived from the induction of somatic cells into induced PS (iPS) cells have created sources of human cell lines that can provide an unlimited source of therapeutic cells from single donors. Especially iPS cells are currently being exploited as they do not involve the collection of cells from a human embryo and have therefore less ethical implications and could potentially also provide autologous cell lines where immune reactions can be avoided. Both cell types defy the normal senescence of primary cells and can be expanded from a single clone indefinitely without losing pluripotentiality [38,39]. From an industrial and tissue engineering perspective, this feature is extremely attractive as a single donation could give rise to a cell line source with the capacity to make all organs of the body in unlimited numbers. One major drawback of PS cell–derived products, however, is that the cell itself cannot be implanted but needs to undergo the relevant development in vitro to make suitable organ-specific cells for transplantation, for example, dopaminergic neurons for PD or islet cells for diabetes mellitus. As it is difficult to make pure cultures without retaining one or more

undifferentiated pluripotent cell, the risks of heterogeneous cell preparations and potential tumorigenesis have had to be overcome to develop pluripotent cell–derived brain implants [39,40].

The generation of functioning human dopaminergic neurons in vivo akin to those derived from primary ventral mesencephalic (VM) tissues was initially difficult to achieve. Although neurons with the dopaminergic machinery could be made from growth factor–expanded human neurospheres, genetically immortalized committed dopaminergic neuroblasts, and PS cells, it became increasingly clear that dopaminergic neurons in different areas of the brain were not the same and specific gene expressions consistent with dopaminergic neurons of the substantia nigra were necessary in order to survive and function in a similar manner to the dopaminergic neurons lost in PD. Interestingly, even though PS cells would have hypothetically needed more steps to be differentiated into dopaminergic neurons for a PD application, relatively short-step protocols that use developmental signals involved in the rostrocaudal and ventrodorsal specification of the midbrain can push PS cells into functional dopaminergic neurons as first demonstrated in a rat model of PD [41,42]. The nigral dopaminergic differentiation protocols of PS cells have now been relatively well established and clinical translation has started [17]. Studies have also identified important transcription signals involving the Lmx1a and MSX homeobox genes that when overexpressed in ES cells under the nestin promoter can yield dopaminergic neurons with markers consistent with substantia nigra neurons [43]. Transplantation of these dopaminergic neurons in a rat model of PD yields excellent survival, neurite extension, and function consistent with results from primary VM tissues. However, similar to the human ES cells [40], these cells also form tumors in vivo. Cell sorting techniques has therefore been applied and are used to purify the transplantable populations with promising results [44]. These findings may not only pave the way forward to make relevant "nigral" dopaminergic neurons from human PS cells and neural stem cell cultures in the not-too-distant future but also show the need for adult- and fetal-derived neural stem cell sources that do not form tumors.

Cell protection and regeneration implants

The use of primary tissues or cell lines in cell replacement approaches are aimed at making transplantable mimics of the cells lost in the disease process. In PD the use of chromaffin cells, dissected developing ventral mesencephalon, RPE cells, or PS cells have all been aimed at replacing or augmenting the dopaminergic function. However, primary tissues, cell lines, and genetically modified cells also produce secreted factors that can influence the nearby host cells or transplanted cells in potentially beneficial ways. Several growth factors are endogenously made by cells, including fibroblast growth factors, transforming growth factors, and interleukins that can have neuroprotective, regenerative, and antiinflammatory effects on nearby nerve cells. Custom therapeutic cell lines can also be made by genetic engineering to secrete specific growth factors such as nerve growth factor (NGF), glial cell line–derived neurotrophic factor (GDNF), and ciliary neurotrophic factor that when implanted in relevant anatomical areas can affect specific neuronal populations in neuroprotective and regenerative ways (ex vivo gene therapy). To protect the transplanted cells from immune rejection and to allow for the retrieval of the therapeutic cell implants, an encapsulated device can be used.

Cell implants secreting endogenous factors

Before expandable stem cells were available, an immortal carcinoma cell line derived from a human testicular teratocarcinoma isolated from a metastasis in a patient was used in clinical applications to treat the neurological sequelae of stroke [45]. This immortal cell line was pluripotent and could be induced to stop dividing and to differentiate into a neuronal phenotype using retinoic acid. A preparation of this cell line was investigated in the clinic for the treatment of ischemic stroke based on animal data suggesting that the postinjury transplantation of this cell line into an infarcted area could improve recovery. The mechanisms surrounding this effect were unclear but likely related to beneficial factors released from the cells. In a study in patients with lacunar stroke in a randomized controlled Phase II trials at the University of Pittsburgh, United States, the therapy with this cell line failed to meet the efficacy endpoints [46]. The transplantation of a cell line derived from a human cancer has obvious risks associated with it. Importantly, the approval of this trial demonstrated that cell transplantation for severe neurological disorders is seen as a reasonable strategy by the regulatory agency, as long as strong safety and some efficacy can be demonstrated in animal models.

Other groups are investigating the transplantation of immortal cell lines but are using genetic engineering to immortalize cells. Advances in genetic engineering have made it possible to extend the number of doublings a primary cell line can go through by inserting various oncogenes and cell cycle regulators. This allows for the selection, clonal expansion, and banking of a large number of cells. Besides the genetic modification, these cells retain otherwise normal genotypic characteristics. ReNeuron, a British biotechnology company, made immortal human neural stem cells that showed regenerative effects in stroke models [47] and a Phase I trial was

completed demonstrating safety and positive effects in stroke patients [48]. A Phase II trial is currently ongoing and results are expected in mid-2020 [11]. Similarly, StemCells Inc., used growth factor–expanded human neurosphere cell lines in a strategy to treat Batten's disease, a rare neurometabolic disorder, with the idea that the endogenous enzymes and factors made by the stem cells would have a therapeutic effect [35,48,49]. Unfortunately, this trial also failed to show efficacy. Neural stem cells derived from ES cells and fetal tissues have also been tested for spinal cord injury and are in current trials for amyotrophic lateral sclerosis, multiple sclerosis, and PD; but so far an efficacious treatment has not been demonstrated (see clinicaltrials.gov). Lastly, implanted autologous mesenchymal stem cells are being studied in clinical trials for stroke with mixed results [50] and in neurodegenerative disorders [51] with the idea that they produce endogenous growth factors and/or antiinflammatory molecules beneficial to injured tissue. The use of these cells appears safe but clinical efficacy has been hard to demonstrate.

The use of nonspecific neuroprotective and regenerative strategies based on the implantation of cells with unclear mechanisms may pose regulatory problems as the risk–benefit analyses become difficult to make. For example, even though positive results were inferred from the published trial with the human teratocarcinoma–derived cell line in stroke, the clinical data were not convincing enough to continue clinical development [46]. In this trial, no significant adverse events or tumors were reported but, if it they had occurred, a major setback for tissue-engineered brain implants could have been the result. The risk–benefit analysis is often difficult, and the predictive value and scale-up issues through animal models are not straightforward as demonstrated by several clinical trial failures despite efficacy demonstrated in animals. The regulatory agencies have therefore a real dilemma and, similar to the initial setbacks experienced in the field of gene therapy, a push to do clinical trials with poorly characterized cell preparations and mechanisms in patients desperate for a treatment may cause significant adverse events that can create setbacks for the whole field of tissue engineering. On the other hand, a too restrictive regulatory body may make the hurdle of bringing potentially beneficial but complex tissue-engineered products into the clinic too costly and difficult. These regulatory issues are hard to resolve, but as experience with cell containing implants build, it is likely that the decision-making and risk–benefit analyses will improve. Some of the clinical trials using primary autologous cells such as hematopoietic or mesenchymal stem cells derived from the bone marrow can also bypass regulatory scrutiny and only need approval by a local ethics committee. Unfortunately, this has led to the initiation of clinical trials based on very little evidence of preclinical beneficial effects causing potentially false hopes, high personal expenses, and potentially harmful side effects to patients desperate for therapy.

Cell implants secreting engineered factors (ex vivo gene therapy)

As PD involves a slow and progressive degeneration of dopaminergic neurons, a protective and/or regenerative strategy could be applied in the earlier stages of disease. Many protein factors have been shown to protect fetal dopaminergic neurons both in vitro and in vivo and one of the most powerful factors is GDNF [52]. This factor promotes the survival (neuroprotective effect) and neurite extension (regenerative effect) of dopaminergic neurons both in vitro and in vivo. Based on strong positive animal data, GDNF has been tried in humans in several clinical trials using infusion of the protein factor itself or via adeno-associated viral vectors coding for GDNF [53,54]. All trials have so far failed to meet the efficacy endpoints of the clinical cohorts, but individual patients have shown strong improvements supported by imaging and postmortem evidence that GDNF has affected the dopaminergic fibers and signaling in a positive manner. Therefore there remains strong interest to apply GDNF to patients earlier in their disease and in a manner that can increase the local striatal dose of the factor. Our approach to accomplish this goal is to use an encapsulated cell device capable of de novo synthesis of GDNF in the striatal target, which is described in more detail in the following section.

Encapsulated cell brain implants

The implantation of naked cells has the advantage of allowing for migration, integration, and the formation of neurites and synapses in replacement strategies. The migration and homing mechanisms that neural stem cells display in models of stroke and glioma tumors may also be utilized to deliver regenerative or tumoricidal agents respectively in genetically modified cells. However, naked cells cannot readily be removed and if a potent protein factor is being delivered to the brain, the inability to stop the treatment may pose a problem if untoward effects are noted or if the regenerative treatment is only needed for a limited amount of time. A device containing encapsulated cells that secrete the factor combines the advantages of cell and gene therapy with that of the safety of a retrievable device. One type of brain implant is depicted in Fig. 56.2 and consists of a recombinant cellular core attached to a polymer scaffolding and enclosed by a custom-made hollow fiber membrane that in turn is attached to a tether allowing for its placement and replacement/removal as necessary.

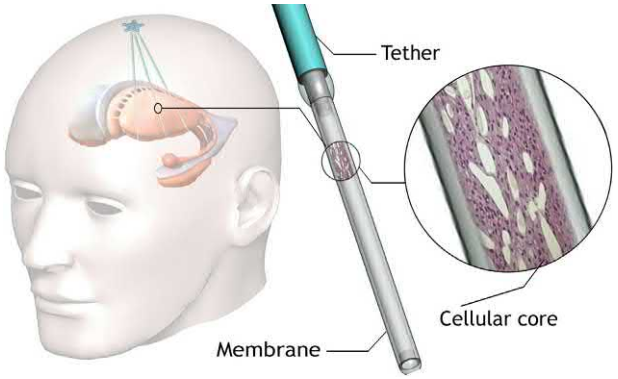

FIGURE 56.2 A schematic of the implantation for the treatment of PD is depicted and shows three separate encapsulated cell implants targeting the human putamen. The 20 mm long tips of the implants house a human immortal human cell line engineered to secrete GDNF. The cell line is grown on a three-dimensional synthetic scaffolding and this *cellular core* receives nutrients and oxygen from the surrounding brain interstitial fluid via the semipermeable *membrane* allowing for long-term function (>1 year). In turn, the factor can diffuse along the membrane in several mm wide perpendicular radii and the combination of 3–4 implants per putamen allows for therapeutic levels to reach the diseased dopaminergic nerve endings. The membrane protects the engineered cells from immune rejection. The entire device can be removed or replaced through the use of the *tether* anchored with a titanium holder beneath the skin at the skull burr hole level. The implants measure approximately 1 mm in diameter, which is similar in size to DBS electrodes currently used in the clinic. *DBS*, Deep brain stimulation; *GDNF*, glial cell line-derived neurotrophic factor; *PD*, Parkinson's disease.

These encapsulated cell implants are true tissue-engineered devices that combine genetically modified cell lines with artificial scaffolding enclosed behind an immunoprotective membrane. The polymeric membrane excludes larger molecules and cells but allows for the bidirectional passage of nutrients and transgene products. The encapsulated cells can thus be protected from immune rejection, making allogeneic or even xenogenic transplantation possible without immunosuppressive therapy. The host is also protected from the implanted genetically modified cells and the risks of gene transfer or tumor formation are greatly diminished. The tether allows for handling, implantation, and removal/replacement. These devices can be implanted intraparenchymally, intracerebroventricularly, or intrathecally depending on the application. Cellular survival and continuous production of factors have been demonstrated for at least 12 months in the brain allowing for long-term delivery of therapeutic factors [55,56]. Encapsulated devices secreting GDNF have been studied in rodent models for PD and have shown both neuroprotective and neuroregenerative effects on dopaminergic cells [57,58]. A Phase Ib trial in Alzheimer's patients was completed demonstrating safe and targeted delivery of NGF to the brain using encapsulated, genetically modified ARPE-19 cells. The cells survived for up to12 months with no evidence of surrounding brain inflammation or device displacement [56,59–61].

Other investigators have published data on using encapsulated porcine choroid plexus cells for the potential treatment of HD [62] and PD [63]. These cells are reportedly therapeutic by secreting various endogenous factors that have neuroprotective and regenerative effects. The application of the choroid plexus cells in these studies were made with an injectable microencapsulated cell configuration. In this setting the encapsulation provided immunoprotection for the porcine-derived primary choroids plexus cells. Unlike the macro-encapsulation brain implants described earlier, these injectable micro-implants would not be retrievable and may be less suited for applications in which the treatment may need to be stopped or modified. A recently completed Phase II trial for the treatment of PD with these encapsulated porcine choroid plexus cells failed to meet the efficacy endpoints [3] and it is unclear if other clinical applications are contemplated.

Controlled-release implants

Acellular synthetic polymeric brain implants that are able to deliver protein factors or other drugs to the CNS have also been developed [64–66]. These systems normally release drugs by degradation- or diffusion-based mechanisms over an extended time (weeks) but cannot sustain release over a long time (months), which is possible with cellular-based systems.

Appropriately designed, polymeric controlled-release devices have several possible applications and could for example support the survival and integration of transplanted cells. Furthermore, a polymeric system can support the sequential release of growth factors that may be necessary to fully support the stepwise differentiation of immature cells. This concept could become applicable to transplanted neural stem cells that may lack important embryonic developmental signals in the adult brain.

Combined replacement and regeneration implants

From a tissue engineering point of view, the future goal is to make replacement organs for the body that can take over the function of a failed organ or structure in an anatomically and physiologically correct manner. And even though it would be difficult if not impossible to make entirely new brains, it should become possible to not only replace cells but also to make new axonal pathways and restore the correct connections.

The transplantation of fetal dopaminergic cells to the striatum is called heterotopic transplantation. This means that the dopaminergic cells are transplanted into an anatomical region different from their normal location, which is the substantia nigra. The heterotopic implantation of dopaminergic neurons may result in the loss of important

normal innervation and feedback loops. Many transplants for PD may thus only work as simple cellular pumps that increase the striatal dopamine levels. Although simplicity is desired, an ultimate strategy to treat PD could be to transplant the dopaminergic neurons to their anatomically correct position (homotopic), regenerate the nigrostriatal axonal pathway, and induce terminal sprouting and innervation of the striatal target neurons. This would regenerate the appropriate connections and represent a more physiologic strategy.

An initial approach may be to provide survival factors to the implanted cells. Even in the most optimal VM grafts applied heterotopically in PD, the total fraction of surviving dopaminergic neurons was only about 10%–20% [67]. This required a large number of donors [4–8] to assure enough surviving cells for a clinical effect. Also with dopaminergic grafts derived from PS cells, the survival and integration may require supportive signals. The combination of dopaminergic grafts with a neuroprotective and regenerative effect of GDNF or other factors is therefore a logical idea. Experimental data indeed show that the application of GDNF delivered by encapsulated cells in combination with either rat or human VM grafts increase the survival, neurite extension, and innervation of the striatum in a rat model of PD [68,69]. Similarly, it would be expected that GDNF would have survival and regenerative effects on dopaminergic cells derived from stem cells when placed in vivo. A combined approach with dopaminergic grafts and encapsulated cell implants secreting GDNF may therefore be contemplated in future transplantation studies in PD.

A large challenge for tissue engineering approaches in the treatment of neurological disorders is the regeneration of axonal pathways. Axons between the cell bodies and their targets often extend for several centimeters in the brain and close to one meter between the brain and the lumbar spinal cord neurons in an adult. Compared to the relatively short distances that the axons had to grow during development to make the appropriate connections, the regeneration in the adult may pose a particular challenge. Fortunately, science has made progress in this area and what was though impossible only a few years ago now seems more feasible. Several molecules are now known to both promote and guide axonal outgrowth. As mentioned, GDNF is a strong promoter of axonal outgrowth of dopaminergic neurons. In addition, certain extracellular matrix proteins, such as laminin, can guide axonal outgrowth and extensive nigrostriatal reconstruction has been accomplished using bridges of striatal tissues in combination with fetal mesencephalic grafts placed in the substantia nigra [70]. The finding that the central myelin and glial scars are inhibitory to axonal outgrowth has led to the identification of various inhibitory molecules that can be manipulated in various ways with inhibitors and enzymes [71]. From a tissue engineering point of view, the combination of replacement cells with regeneration channels or scaffoldings capable of releasing survival and neurite-promoting factors and coated with molecules that facilitate axonal outgrowth may thus become a future reality. In combination with nanotechnology, synthetic bridges or living cell channels can be made that promote extensive fiber regeneration and functional restoration [72,73].

Even though there mounting data show that axonal bridges can improve axonal growth in animal models, these methods have not been applied to humans. As the cellular building blocks become better refined, it is likely that more “true” tissue-engineered brain implants will enter the clinic. These types of implants could have great potential use for regeneration in many areas of the CNS, particularly the spinal cord.

Disease targets for brain implants

As mentioned, PD has been a major target for cellular brain implants. However, many other neurological disorders should become amenable to tissue-engineered implants.

In HD, several neuronal populations slowly degenerate and cause the clinical signs of choreiform movements and progressive dementia. HD is inherited as an autosomal-dominant disease and the responsible mutation has been located to chromosome 4. Carriers of the disease can therefore be screened for and identified before the onset of symptoms. This makes a neuroprotective strategy for HD an attractive possibility, where the delivery of neurotrophic factors could prolong the symptom-free interval [74].

Cell replacement strategies have also been tried in HD [75]. Primary fetal striatal tissue transplantation for HD has been performed at a handful of centers in the world. Long-term follow up has described mild improvements in some of the implanted patients but effects have not been consistent [4,5,76]. One theoretical advantage over PD is that the transplantation for HD involves homotopic implantation, which should allow for the differentiation of the transplanted cells using normal environmental cues. However, in HD, multiple sets of neuronal populations degenerate, including both cortical and striatal neurons. The homotopic transplantation for HD may thus require more extensive regeneration of axonal pathways than in PD.

Other diseases that could be amenable to the implantation of cells within the brain are the myelin disorders. Animal experiments have shown the ability of neural tissue, purified oligodendrocytes, oligodendrocyte precursors, immortalized glial cells, and neural stem cells to remyelinate areas of demyelination [77,78].

One of the most common neurological disorders is epilepsy that affects about 1%–2% of the population.

Epilepsy is characterized by recurrent abnormal electrical discharges in the brain affecting subparts of the brain or generalizing to deeper parts in the brain resulting in unconsciousness. A subgroup of these patients has temporal lobe epilepsy that is generated by a loss of neurons and an imbalance of inhibitory and excitatory neurotransmitters in the hippocampal formation. In medically intractable cases, this disease can sometimes be treated surgically with the removal of the medial hippocampus and the abnormal area. This procedure eliminates or reduces the frequency of seizures in selected patients but involves a major surgical procedure and the ablation of normal tissue. A less invasive procedure may be to implant inhibitory cells in the seizure focus that would raise the seizure threshold [79]. This idea is supported by animal experimentation data that indicate that locus coeruleus grafts and the local delivery of inhibitory substances such as GABA can increase the seizure threshold. Preclinical studies have suggested that interneuron precursor cells derived from the medial ganglionic eminence may be a source of inhibitory GABAergic neurons perhaps providing a useful source of transplantable cells for epilepsy [80]. More recently, stem cell–derived GABAergic cells have been generated with antiepileptic effects when transplanted to animal models [81]. Furthermore, the encapsulated cell devices secreting GDNF have been shown to have strong antiepileptic effects in two different models of epilepsy warranting translation toward the clinic [82,83].

Other disease indications that may benefit from brain implant strategies include stroke, brain injury from trauma, AD, and rare disorders such as cerebellar degeneration and inherited metabolic disorders. Besides the brain, the spinal cord and retina are potential targets for similar approaches.

Surgical considerations

The surgical implantation of most brain implants involves the use of stereotactic techniques. The stereotactic method (stereotaxis) in brain surgery was established in the beginning of this century and is now well established in neurosurgical practice [84]. It involves attaching a rigid frame (stereotactic frame) to the skull followed by imaging such as MRI. Attached markers (fiducials) create a three-dimensional coordinate system in which any point in the brain can be defined and related to the frame with high precision. In the operating room the markers used during imaging are replaced with holders that guide the instruments. It is a relatively simple neurosurgical procedure often done under local anesthesia and mild sedation. The procedure is therefore safe and relatively painless. The patients are usually discharged from the hospital after an overnight observation.

Conclusion

In this chapter, various brain implants have been described that may have potential to treat PD and other neurological disorders using tissue engineering strategies. Most of the current literature describes the transplantation of various primary cells such as fetal tissue. Tissue engineering principles and cell lines have only more recently been introduced. Applications using growth factor support, genetic engineering, scaffolds, extracellular matrices, and encapsulation have all been able to improve the survival and function of the brain implant. The ultimate implants are yet to be developed and may combine stem cells, genetically modified cells, controlled delivery devices, axonal bridges, scaffolds, and encapsulated cells.

Introduction

The use of brain signals for interaction as well as for controlling robots and prosthetic devices has gained increasing attention over the last two decades. This is a rapidly emerging field of multidisciplinary research called *brain–machine interfaces* (BMIs), or *brain–computer interfaces* (BCIs), which has seen impressive achievements over the past few years—prototypes for writing messages with a virtual keyboard [1–6], playing brain games [2,7–10], and even controlling robots or wheelchairs [11–21]. A BMI monitors the user's brain activity, extracts specific features from the brain signals that reflect the intent of the subject, and translates their intentions into actions—such as closing the prosthetic hand or selecting a letter from a virtual keyboard—without using the activity of any muscle or peripheral nerve [22]. The central tenet of a BMI is the capability to distinguish between different patterns of brain activity, each being associated to a particular intention or mental task. Hence, adaptation is a key component of a BMI, because, on one side, users must learn to modulate their brainwaves so as to generate distinct brain patterns, while, on the other, machine-learning techniques ought to discover the individual brain patterns characterizing the mental tasks executed by the user. This chapter introduces the field of BMI, with a particular focus on principles for reliable and long-term operation of neuroprostheses. For a more detailed coverage of BMI, interested reader can refer to [22–24].

BMI technology offers a natural way to restore, replace, or augment human capabilities by providing a new interaction link with the outside world. In this respect, it is particularly relevant as an aid for patients with severe neuromuscular disabilities, although it also opens up new possibilities in human–machine interaction for able-bodied people [25]. Fig. 57.1 shows the general architecture of a brain-actuated device such as neuroprostheses for motor restoration and recovery. Brain activity, electroencephalogram (EEG) signals in this example, is recorded with a portable device. These raw signals are first processed in order to extract some relevant features that are then passed on to a mathematical model (e.g., statistical classifiers/regression or neural networks). This model computes, after some training process where it finds the prototypical patterns of brain activity associated to each mental command, the user's intention that is transformed into an appropriate action to control the device. Finally, visual feedback, and maybe other kinds such as haptic stimulation [26,27], peripheral stimulation [28], or intracortical microstimulation [29–31], informs the subject about the performance of the neuroprosthesis so that they can learn appropriate mental control strategies and make rapid changes to achieve the task.

This chapter is organized as follows: first, we will review the different kinds of brain signals that can be recorded as input for a BMI. Then we will discuss a series of principles to build efficient BMIs that are independent of the particular signal of choice. These principles concern the nature of electrical brain correlates more suitable to control neuroprosthetic devices and to promote motor rehabilitation, the use of machine-learning techniques, and the design of context-aware BMIs. We will conclude discussing some future research directions in the field of BMI.

Brain–machine interface signals

A BMI may monitor a variety of brain signals, such as electrical, magnetic, and metabolic. Magnetic fields can be recorded with magnetoencephalography (MEG), while

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00059-9

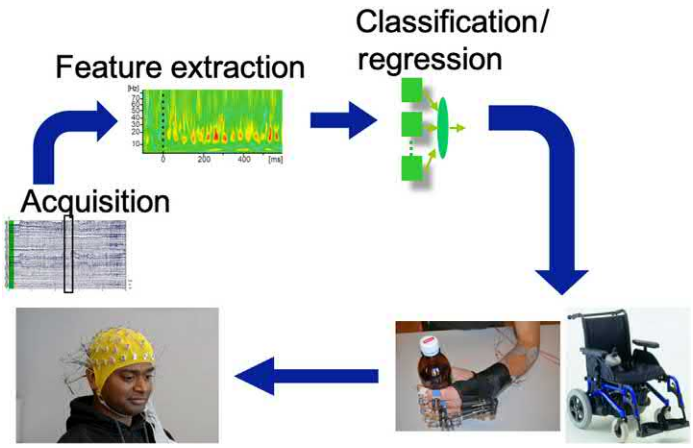

FIGURE 57.1 General architecture of a BMI for controlling devices such as a hand orthosis or a motorized wheelchair. In this case the BMI measures EEG signals recorded from electrodes placed on the subject's scalp. *BMI*, Brain–machine interface. *EEG*, electroencephalogram.

brain metabolic activity—reflected in changes in blood flow—can be observed with positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and near-infrared spectroscopy. Unfortunately, MEG, PET, and fMRI require sophisticated devices that can be operated only in special facilities. Moreover, metabolic signals have long latencies and thus are less appropriate for ecological interaction. Brain electrical activity, on the other hand, can be recorded with portable devices and has an excellent time resolution—we can detect changes in brain activity at the millisecond range—that makes it the natural candidate for a BMI. We can record the electrical brain activity invasively or noninvasively. The former technique employs microelectrode arrays implanted in the brain that record the activity of single neurons (single unit activity, SUA) or of small neuronal populations (local field potentials, LFP). The overall concerted activity of neuronal populations can also be recorded (semi-) invasively with electrodes placed on the surface of the brain (electrocorticography, ECoG). Noninvasive EEG activity is recorded from electrodes placed on the scalp. It measures the synchronous activity of thousands of cortical neurons. LFP, ECoG, and EEG signals are similar in nature, although derived at different levels—microscopic, mesoscopic, and macroscopic, respectively.

Invasive approaches (LFP and SUA) carry a detailed information that may allow decoding of complex movement intentions [4,16,18,20,21,29,32–35]. However, we need to record from many electrodes and different areas to capture the global set of motor parameters, which are encoded in a rather distributed brain network. Also, implanted microelectrode arrays damage brain tissue, and so signals may not last long. Consequently, one area of active research is the design of safe biophysical interfaces that, in addition, should be ultralow power and wireless [36]. On the other hand, being recorded on the scalp, noninvasive EEG signals suffer from a reduced spatial resolution and increased noise. In particular, EEG can be contaminated with muscular—such as subtle facial movements—and ocular artifacts that, ideally, must be filtered out. Alternatively, we must ensure that the selected control features are proper brain signals and not generated partially, or completely, by non-brain sources.

Regarding the spatial resolution of EEG, it can be greatly improved by spatial filters that estimate the electrical activity originated in radial sources immediately below each recording electrode. Another way to increase the spatial resolution of raw EEG is to estimate the cortical activity from the scalp EEG, thus unraveling the contributions of different small cortical areas that are picked up and mixed by a single scalp electrode [37,38].

Analysis of human ECoG is attracting significant interest as, being semi-invasive, it blends the advantages of both approaches: high spatial resolution and simple surgery with minimal health risks. Although not largely used because of limited access to patients—who undergo neurosurgery for epilepsy or brain tumor—during short periods of time, initial results show high potential [39–43]. Long-term stability of ECoG has been demonstrated in daily use communication by humans [5].

Voluntary activity versus evoked potentials

A BMI can exploit signals associated to external sensory stimulation—such as visual flashes or auditory tones—or to endogenous voluntary decision processes—such as the onset of a movement. In the former case the brain reacts with the so-called evoked potentials. Three different evoked potentials have been mainly explored in the field of EEG-based BMI, namely, P300 [6,22,44–47], steady-state visual evoked potential (VEP) (SSVEP) [48,49], and

error-related potentials (ErrPs) [50–52]. P300 is a potential evoked by an awaited infrequent event that appears at centro-parietal locations along the midline of the scalp, independently of the sensory stimulation modality. As indicated by its name, it is a positive wave peaking at around 300 ms after task-relevant stimuli. The amplitude of the P300 depends on the frequency of stimulus occurrence—less frequent stimuli produce larger responses—and task relevance. VEPs reflect electrophysiological mechanisms underlying the processing of visual information in the brain and vary in response to changes in visual stimuli. SSVEPs are VEPs induced by a stimulus repeated at a rate higher than 6 Hz. SSVEP is composed of a series of components over the visual cortex whose frequencies are the harmonics of the stimulus frequency. Another interesting case of evoked potential is the ErrP, elicited by the neural processing of an erroneous event [53]. ErrPs are known to originate at the anterior cingulate cortex creating EEG waveforms typically composed by a first characteristic negative deflection in fronto-central regions followed by a positive peak also centrally localized. ErrPs could be used for endogenous, seamless error-correction in BCI [54–56] or even as the main BCI control modality [57,58].

Evoked potentials are, in principle, easy to pick up. The necessity of external stimulation does, however, restrict the applicability of evoked potentials to a limited range of tasks. This is particularly the case when controlling robotic devices and for motor rehabilitation. In both cases, BMI has to rely upon brain correlates of voluntary mental activity, which users can modulate at different frequency ranges—or rhythms. Populations of neurons can form complex networks with feedback loops, which give rise to oscillatory activity. In general, the frequency of such oscillations becomes slower with the increasing size of the synchronized neuronal assemblies. A particularly relevant rhythm can be recorded from the central region of the scalp overlying the sensorimotor cortex during the imagination of body movements. Correlates of imaginary movements can be recorded at any scale—microspopic, SUA and LFP; mesoscopic, ECoG; and macroscopic, EEG. Apart from their different degrees of spatial resolution, microscopic and mesoscopic signals also have a broader bandwidth (up to 300–500 Hz) than macroscopic signals (normally, less than 100 Hz).

In the case of frequencies below 2–4 Hz, we can observe slow cortical potentials (SCP). The analysis of SCP is usually done in the temporal domain. Notably, SCP measured with scalp electrodes was the basis of the first demonstration of a BMI for lock-in patients (1), who learned to modulate the SCP amplitude to control a BCI speller. The negative amplitude of SCP is related to the overall preparatory excitation level of a given cortical network—the more negative the more active. Another example of SCP that can be observed in the EEG is the so-called Bereitschaftspotential, or readiness potential—a slow negative shift over the controlateral motor cortical area starting around 400–500 ms before the onset of a movement. This makes the readiness potential particularly relevant for motor rehabilitation. However, being close to 0 Hz, its presence in single trials seems to be elusive. Nevertheless, it has been recently shown that it allows detection of self-paced reaching movement intention in single trials with humans, including stroke patients [59]. Readiness potentials are also present in intracranial LFP [60] as well as in ECoG [61]. In the former case, intracranial LFP recorded from the supplementary motor area (SMA) in an epileptic patient yielded high-recognition rates in the detection of self-paced reaching movements well before the onset. The intention to execute a self-paced movement has also been decoded from SUA in humans [62], where progressive neuronal recruitment in the SMA over 1500 ms before subjects made the decision to move could be observed. As a last observation, recent experiments have shown that scalp SCP also carries enough information to decode 3D arm trajectories [63,64].

Most spontaneous BMI rely on variations of brain rhythms in higher frequencies than SCP. In the case of EEG and ECoG, imagination of limb movements gives rise to amplitude suppression—event-related desynchronization, ERD—of Rolandic μ (8–12 Hz) and β (13–28 Hz) rhythms over the controlateral limb motor cortical area [65]. This imagination-related ERD shows different time courses in the two bands. In the μ band the ERD recovers to baseline level within a few seconds. On the other hand, the central β activity displays a short-lasting ERD followed by an amplitude increase—event-related synchronization, ERS. In particular, ERD has been largely exploited to build BMIs where subjects imagine movements of their left versus right hand or arm, or upper limbs versus feet. References are too numerous to cite them all, but see [2,3,7,9,11,12,14,15,19,26–28,40,55,66,67]. Apart from these "classical" imagined movements of hands, arms, and feet, recently researchers have also shown the feasibility of recognizing different wrist movements [68,69]. Also, as mentioned before, recent results show how it is possible to decode 3D arm trajectories from EEG [63,66] as well as basic grasping patterns such as hand closing/opening [15,70,71]. Other mental tasks such as visual attention [72,73] or even direct speech decoding [42,43,74] hold promise of a wide variety of ecological BCI designs.

Finally, because of its higher spatial resolution and broader frequency range, ECoG seems also to carry information about different motor parameters such as movement kinematics [41,61,75,76] that could provide finer

FIGURE 57.2 Example of a BMI for the restoration of grasping. The BMI is combined with functional electrical stimulation that activates the subject's peripheral nerves under the electrodes and contracts the corresponding muscles for hand closing and opening. This operation is further facilitated by the use of a light passive hand orthosis that synchronizes finger movements so as to generate natural grasping patterns. *BMI*, Brain–machine interface.

control of neuroprostheses and could greatly help in motor rehabilitation. As mentioned before, decoding of complex movement intentions has been largely demonstrated with the use of intracranial recordings (LFP and SUA) [16,18,20,21,34,35].

Although more work remains to be done in developing BCIs that decode motor intentions, their combination with functional electrical stimulation [12,15,20,21] and light exoskeletons [77,78] (see Fig. 57.2) is quite relevant for motor restoration and even rehabilitation in spinal cord injury and stroke patients (see section "Future directions").

Mutual learning

A critical issue for the development of a BMI is training—that is, how users learn to operate the BMI. Some groups have demonstrated that some subjects can learn to control their brain activity through appropriate, but lengthy, training in order to generate fixed EEG patterns that the BMI transforms into external actions [1,66,79]. In this case the subject may be trained over several months to modify the amplitude of a prespecified parameter of their brain signals, from EEG to fMRI. An alternative approach is to attempt to relieve the user from any training by using machine-learning techniques to rapidly find individual patterns of brain activity associated to the mental commands the user wants to convey [80]. The drawbacks of this approach are that the BMI usually needs to be recalibrated at the beginning of every session, or even continuously [81,82], and that many users are unable to spontaneously produce distinct brain activity decodable by pattern-recognition techniques. Most BMI systems lie in between these two extreme approaches as they need to adopt a mutual learning principle, where the user and the BMI are coupled together and adapt to each other [9].

Mutual learning facilitates and accelerates users' training process thanks to the use of statistical machine-learning techniques that both select relevant, stable features and build optimal models to decode the user's intention. Feature selection yields user-specific brain components—normally spatio-frequency features for rhythmic activity or spatiotemporal for evoked potentials—that maximize the separability between mental commands [83,84]. In addition, because of the nonstationary nature of brain signals, selected features must also be stable over time. These initial features represent those brain components that the user can naturally modulate and, via feedback received during online BMI training, learn to control quickly and voluntarily [9]. Selection of stable features can be enhanced by removing nonstationary brain sources [85].

Although there are reports of users who keep a stable level of performance over months and even years, BMIs suffer from the natural variability of brain signals due to changes in background activity and learning. This calls for the use of online adaptation techniques to keep the BMI tuned to drifts in the signals [54,81,82,86–91]. Care should be taken to coordinate the two learning agents in the BCI loop—the subject and the machine—and assure that the adapting BCI does not harm the user's learning process [9].

Context-aware brain–machine interface

Independent of the kind of BMI signal (SUA, LFP, ECoG, or EEG), paradigm (voluntary activity or evoked potential) and learning approach, users cannot sustain high levels of performance over long periods of time. This is mainly due to the natural variability of brain signals. Furthermore, EEG-based approaches yield low throughput. As a consequence, it seems that the current state-of-the-art BMI technology is insufficient for full dexterous control of complex applications such as neuroprostheses. Nevertheless, we can cope with these limitations and achieve reliable mental control by designing context-aware BMIs [92]. Such a BMI collects information about the state of the device (e.g., position and velocity of the cursor or neuroprosthesis), as well as its environment (e.g., icons in the screen or potential targets and obstacles perceived by the prosthesis' sensors), and combines it with the user's mental commands. In this approach the smart brain-controlled device interprets and executes the mental commands with respect to the context, thus enabling the performance of complex tasks even with a reduced scattered number of commands. Furthermore, any eventual decrease in mental control is compensated, up to a certain degree, by the smart device.

Examples of context-aware BMIs are neuroprostheses such as robots and wheelchairs [11,17,19,93–95], games [10], as well as smart virtual keyboards [96,97] and other assistive technology (AT) software with predictive capabilities [3]. Remarkably, in the case of control of complex devices such as a telepresence robot, this approach yields similar performance to manual control despite the fact a BMI is not a perfect control channel. This was the case not only for expert BMI users, but also for novel BMI subjects [94] and users with physical disabilities [19]. Fig. 57.3 shows our brain-controlled wheelchair.

A common form of context awareness is shared control, a technique widely used in robotics, where the user and the smart device share responsibilities in choosing the final action to be executed that best matches the user's intent. For example, it requires quite precise control to drive a wheelchair in a home environment (scattered with chairs, tables, doors, etc.). Also, it can take a long time to navigate between rooms. In a shared-control BMI the user delivers high-level mental commands such as left, right, and forward, which the wheelchair interprets based on the contextual information from its sensors to compute the actual motor commands (speed of the motors) to travel smooth trajectories and avoid obstacles. In such a way, shared control can facilitate the operation of the device by inferring goals, reducing the cognitive workload (the user does not need to care about all low-level details), inhibiting pointless mental commands (e.g., driving zigzag), preventing critical situations (e.g., collisions), and determining meaningful motion sequences (e.g., for an arm neuroprosthesis).

Future directions

Current BMI technology, in particular EEG-based, enables the operation of simple brain-actuated devices over short periods of time. Increasingly complex prototypes are being developed and demonstrated. No doubt, this will represent an important achievement for motor-disabled people. Yet, robust and natural brain interaction with more complex devices, such as neuroprostheses, over long periods of time is a major challenge.

A related issue is to develop practical BMI technologies that can be brought out of the lab and into real-world applications in order to improve the lives of countless disabled individuals. For this we need to confirm the benefit of BMI for disabled people outside laboratory conditions and, ideally, in a longitudinal manner. Only a few longitudinal studies have been conducted up to now [5,6,9,10,47,79]. In this respect, BMI technology is emerging as a promising tool for motor rehabilitation, especially after stroke [98–102]. Recent randomized clinical trials have shown the benefits of BMI-based interventions for stroke patients when combined with rehabilitation robots [98,99], virtual reality [100], and functional electrical stimulation [101]. In the latter study

FIGURE 57.3 Brain-controlled wheelchair. Users can drive it reliably and safely over long periods of time thanks to the incorporation of shared control (or context awareness) techniques. This wheelchair illustrates the future of intelligent neuroprostheses that, as our spinal cord and musculoskeletal system, works in tandem with motor commands decoded from the user's brain cortex. This relieves users from the need to deliver continuously all the necessary low-level control parameters and, so, reduces their cognitive workload.

[101], BMI patients exhibited a significant functional recovery after the intervention, which remains 6–12 months after the end of therapy and was associated with quantitative signatures of functional neuroplasticity. These results illustrate how a BMI-FES therapy can drive significant functional recovery and purposeful plasticity thanks to contingent activation of body natural efferent (motor-related brain activity) and afferent (somatosensory and proprioceptive feedback) pathways.

One of the main barriers towards wide use of BMI technology is the limitation of today's electrodes, both invasive and noninvasive. In the former case, they damage brain tissue and do not last long before they lose signal. Consequently, one area of active research is the design of safe biophysical interfaces that, in addition, should be ultralow power and wireless. In the latter case, EEG signals suffer from a reduced spatial resolution and increased noise when measurements are taken on the scalp. Significant research is taking place worldwide on algorithms to improve EEG analysis and decoding. Another of the shortcomings of today's EEG technology, which is essentially the same as 30–50 years ago, is the need for conductive gel to reduce impedance. Success of BMI, especially with recent breakthroughs, is creating a market for new sensors that will make the use of EEG-based systems much easier and robust over long periods of time. Examples of this new technology are dry electrodes that do not require any gel and can be integrated into aesthetic helmets [103], as well as skin sensors that can remain operational for months, if not years [104]. An associated challenge, however, is to develop new techniques to analyze the signals they will measure, which will probably differ from conventional electrodes.

Apart from addressing new sensors and its associated signal processing techniques, we should also develop new principles to make BMI work effectively for disabled people. In this respect, it seems natural to combine BMI with existing AT [105]. This is called a hybrid BMI—a combination of different signals including at least one BMI channel [105–107]. Thus it could not only be a combination of two BMI channels but, more importantly, also of BMI and other residual biosignals (such as electromyographic, EMG) or special AT input devices (e.g., joysticks and switches). A general architecture and a common software framework for hybrid BMIs has been already introduced [108]. Importantly, shared control (context-aware techniques) is a key component of the hybrid BMI, as it will shape the closed-loop dynamics between the user and the brain-actuated device so that tasks can be performed as easily and effectively as possible. Last but not least, novel-training paradigms and carefully designed mutual learning models could play a crucial role toward universal access to BMI technology [9,10,109,110].

Chapter 58

Spinal cord injury

Nicolas N. Madigan and Anthony J. Windebank
Department of Neurology, Regenerative Neurobiology Laboratory, Mayo Clinic, Rochester, MN, United States

Introduction

The spinal cord has a limited potential to regenerate after traumatic injury, due to extensive tissue destruction and a natural healing process which creates physical, cellular and molecular barriers in an attempt to preserve residual function. In this chapter, we focus on tissue-engineering approaches that use biomaterials as combinatorial therapies for spinal cord injury (SCI) repair. SCI is first described as the disruption of anatomic organization, along with its clinical and epidemiological consequences. Key tissue-engineering principles to facilitate spinal cord regeneration using biomaterial platforms in multimodal approaches are discussed. Bioengineering considerations for material fabrication in macro- and microarchitectures, and for integrated biocompatibility in animal models of SCI, are addressed. The applications of natural and synthetic polymer scaffolds with cellular and molecular functionalization, and their outcomes in regenerating spinal cord tissue after injury, are presented in detail. The chapter concludes with perspectives on the clinical translation of these technologies to improve neurologic function in patients with SCI.

Epidemiology

SCI affects more than 290,000 people currently living in the United States, with over 17,700 new cases occurring each year, primarily in men (78%), and in the prime of their lives (average age 43) [1]. While the global incidence rate is estimated to be 23 cases per million population [2], the incidence rate in the United States is more than twice than that, at 54 cases per million population [3]. A bimodal distribution of injuries by age and mechanism has been increasingly recognized. Young patients between the ages of 16 and 24 are most commonly injured in motor vehicle accidents, by acts of violence including knife and gunshot wounds, and in sporting or recreational accidents. Patients older than 65, who frequently have predisposing spinal stenosis or other structural spine disease, are injured from falls. The estimated lifetime costs attributable to the injury in individual patients varies by patient education, preinjury employment, and the extent of neurologic impairment, but range from approximately $5 million in a young, severely injured patient, to $1.2 million in an older, less affected patient [1]. The emotional, social, and psychological cost to each patient and their family is immeasurable.

Spinal cord organization

The human spinal cord is approximately 45 cm (1.5 ft) in length and is organized into 30 neuronal segments, 8 cervical, 12 thoracic, 5 lumbar, and 5 sacral segments, which span 20 bony vertebral segments from the foramen magnum to L1. The transverse diameter of the healthy human spinal cord [4] ranges between a maximum of 1.33 ± 0.22 cm ($\sim$0.5 in.) at the C5 level, to a minimum of 0.83 ± 0.21 cm ($\sim$1/3 in.) at T8. Anteroposterior measures are more uniform, ranging between 0.74 ± 0.16 cm at C5 and 0.63 ± 0.2 cm at T8. The lumbar spinal cord segments are slightly larger again than the thoracic cord, giving the length of the cord a subtle hour-glass contour. The spinal cord terminates as the conus at approximately the L1 vertebral level, immediately below the posterior rib cage, fanning out into the individual rootlets of the cauda equina.

More than 100 billion neurons are organized within this compact volume. Neurons and their supporting cells form discrete tracts and fascicle arcades to convey integrated motor commands for muscle movement from the brain to the limbs and torso (descending spinal cord tracts). Separate tracts and fascicles in the spinal cord also convey sensory information for touch, vibration, joint position, pain, and temperature from the peripheries to the brain (ascending spinal cord tracts) (Fig. 58.1). Discrete

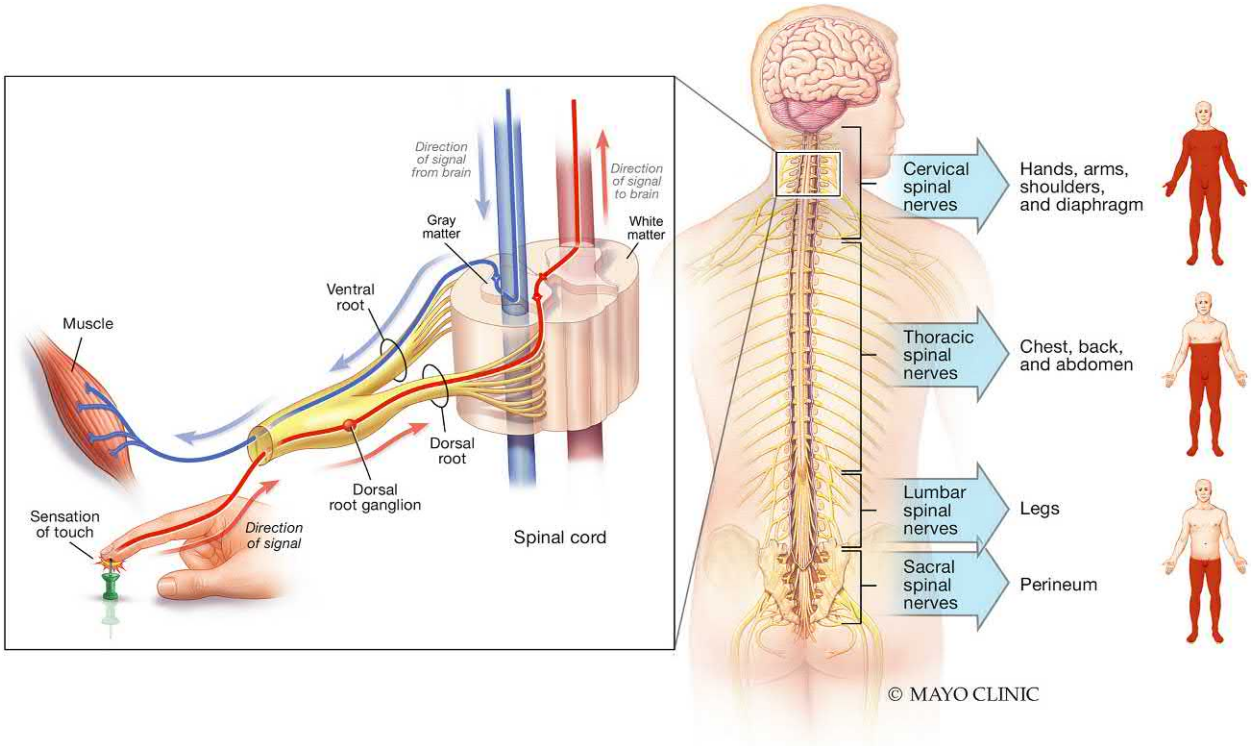

FIGURE 58.1 Organization of the spinal cord and injury sequelae. The centralized gray matter of the spinal cord contains neuronal cell bodies/nuclei, projecting interneuron axons, and glial cells. The gray matter is surrounded by white matter, containing myelinated axons which ascend and descend in sensory and motor tracts, respectively. Outgoing (efferent) messages for muscle movement exit the cord through ventral roots, while incoming messages conveying sensation (pain, temperature, vibration, limb, and joint position) enter the spinal cord via dorsal roots. The cell bodies for motor neurons are within the anterior horns of the gray matter. Bipolar neuron cell bodies for sensory neurons are outside of the spinal cord in an adjacent dorsal root ganglion, projecting a short axon into the posterior horn, which synapses to cross to the opposite side of the cord and into the ascending tract. The other axon projects distally to acquire sensory signals. The spinal cord is very densely vascularized. Clinical sequelae of an injury depend on the spinal level (cervical, thoracic, lumbar, and sacral levels), with the broad distribution of sensory and motor deficits indicated in red.

tracts are intricately interconnected within and between nearby segments by spinal interneurons. Many motor and sensory networks are organized by interneuron processing into central pattern generator systems within the spinal cord that locally integrate movements such as walking, breathing, postural control, and learned repetitive or reflexive movements [5]. These pattern generator networks can be initiated and fine-tuned by volitional control from the brain. They may also operate independently with external stimulation, including electrical spinal cord stimulation or passive limb kinetic movements, after a spinal injury that does not directly damage them [6]. Motor signals exit the spinal cord segmentally from ventral roots (efferent pathways), while sensory inputs (afferent pathways) enter the spinal cord from dorsal roots. These roots pass through the spinal bones via narrow neural foramina to converge as individual peripheral nerves.

Spinal cord injury

Any injury to the spinal cord will have dire and wide-ranging consequences in such condensed, high-priced neurologic real estate. Primary injuries typically occur due to traumatic compression of the spinal cord by vertebral column bone or disc elements that are mechanically displaced into the cord substance by violent force (Fig. 58.2) [7]. A number of injury mechanism classifications have been proposed, depending on whether there has been a spinal flexion injury (wedge fractures, vertebral body subluxation, and oblique facet dislocation), spinal extension injury (posterior column fractures), or axial load injuries (vertebral burst fractures) [8]. Less commonly, in about 25% of patients, the spinal cord is superficially lacerated or deeply transected by penetrating injuries. A minority of injuries are nontraumatic, including primary inflammatory disorders of the spinal cord (multiple sclerosis and transverse myelitis), viral infection, and neoplastic or neurodegenerative pathologies.

The spectrum of clinical phenotypes depends upon the injury mechanism, its severity, acuity, time to decompression, and the spinal level involved. Injuries affect both sensory and muscle control function and can be complete, resulting in total loss of sensation and muscle movement below the injury level, or incomplete, where limited

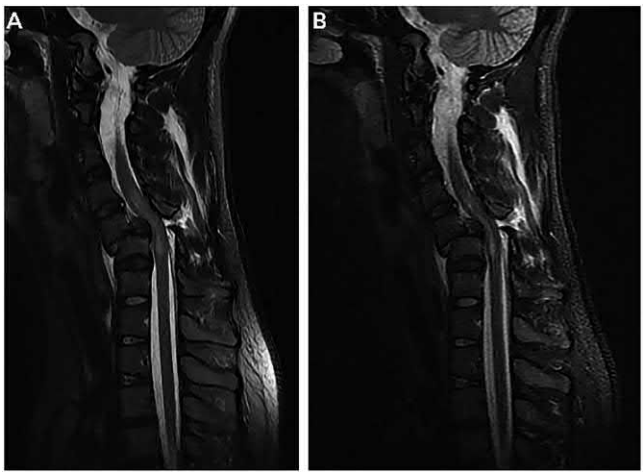

FIGURE 58.2 Traumatic cervical spinal cord injury. T2-weighted sagittal MRI of a young patient with a C5–C6 dislocated fracture and traumatic disc herniation causing severe spinal cord compression. (A) Fat-saturated imaging and (B) STIR imaging show spinal cord swelling and intermedullary signal changes consistent with acute spinal cord edema and hemorrhage. *MRI*, Magnetic resonance imaging; *STIR*, short tau inversion recovery. *Adapted from Rabinstein AA. Traumatic spinal cord injury. Continuum (Minneapolis, MN) 2018;24(2, Spinal Cord Disorders):551–66, with permission.*

function is preserved below the injury level. One-third of the patients have a complete SCI resulting in total lower limb or combined upper and lower limb paralysis, and will never recover any neurologic function. Injury in the cervical region, the most common site of injury, will produce paralysis of the arms and legs (quadriplegia or tetraplegia) (12% complete and 48% incomplete) [1]. Severe respiratory compromise occurs with higher levels of cervical injury due to damage to the innervation of diaphragm muscles, via phrenic motor nuclei located in C3–C5 spinal cord segments. These control centers may extend to the C7 level in some patients [9]. Injuries at any level, however, can affect respiratory function, through the destruction of descending motor tracts innervating thoracic, intercostal, and abdominal accessory muscles. Ascending sensory signals for coughing, vomiting, and secretion clearance reflexes are also disrupted [10,11]. Injury at the lower thoracic or lumbar level results in paralysis of the legs (paraplegia) (20% complete and 20% incomplete). SCIs at most levels will affect the autonomic nervous system, impacting upon bowel, bladder, and sexual function, as well as the vital control of blood pressure and heart rate [12]. The most common causes of death in spinal cord injured patients are related to cardiac and respiratory dysfunction, pulmonary embolus, and complications of pneumonia and septicemia [13]. Mortality rates are highest within the first 12 months after injury. Medical and surgical treatments dramatically improved life expectancy of injured patients after World War II through the 1960s. However, life expectancy has not further improved over the last 50 years despite advances in medical care and management.

Available clinical interventions

In the acute phase of injury, clinical management focuses on spine immobilization, the support of vital respiratory and cardiac/hemodynamic function, and the needs for surgical decompression and spine reconstruction. Surgical decompression within the first 24 hours of injury has been shown to improve functional outcomes in a subset of patients [12]. Pharmacologic strategies for neuroprotection, including high dose methylprednisolone [14–16], unless potentially administered within 8 hours of injury (per one post hoc analysis) [17], and the induction of epidural or systemic hypothermia [18], have not shown definitive outcome benefits in patient trials. The use of minocycline and rapamycin in clinical trials, among other experimental agents, is currently under investigation for anti-inflammatory properties and the reduction of neural excitotoxicity, respectively [19,20].

The continuum of physical, cellular, and molecular barriers to spinal cord regeneration

The spinal cord has limited potential to regenerate after damage occurs to neurons and nerve pathways. Over the first week, the acute, primary injury includes bleeding, swelling, and inflammation, through which cells of the spinal cord die as a direct consequence of local hypoxia, ischemia, and compression. Secondary acute insults may include mechanisms of necrosis via primary adenosine triphosphate (ATP) energy depletion through mitochondrial damage, calcium-induced glutamate excitotoxity, and action potential ion-pump failure. Cells may enter into programed cell death pathways including apoptosis and autophagy, or succumb to free-radical production and membrane compartment lysis via lipid peroxidation. A wound healing response is then initiated as a secondary chronic phase that aims to contain the extent of damage, rather than to recover function [20]. Regeneration requires that disrupted nerve axons regrow to traverse the site of injury and reestablish functional connections. Any neuron that suffers irreparable injury to the cell body will be permanently lost and will never be replaced. In principle, any spinal cord neuron that retains a functional cell body soma has a capacity to reextend their axons through regeneration. Viable axons remaining within the injury area (tissue-sparing) may also locally extend growth cones through sprouting, as distinguished from longer distance axonal regeneration. Functional improvement after injury then is fundamentally a balance between the

neuronal cells' ability to extend axons, sprout, and remodel synapses (neural plasticity), in the face of a hostile injury environment that is evolutionarily primed to deter regeneration.

Over the ensuing weeks to months after injury, immune-mediated tissue destruction, large cysts, extensive gliosis, and spinal cord atrophy combine to form dense physical barriers to axonal regeneration [21,22] (Fig. 58.3). Gliosis represents a process of physical scarring that is unique to the nervous system and that is coordinated by astrocytes, microglial cells, invading systemic immune cells and fibroblasts. The area of cysts and glial scarring does not contain cells or tissue that could contribute to regeneration and is consequently both a gap and a barrier to regeneration. Such areas tend to form at the injury epicenter. Adjacent to these core areas of large

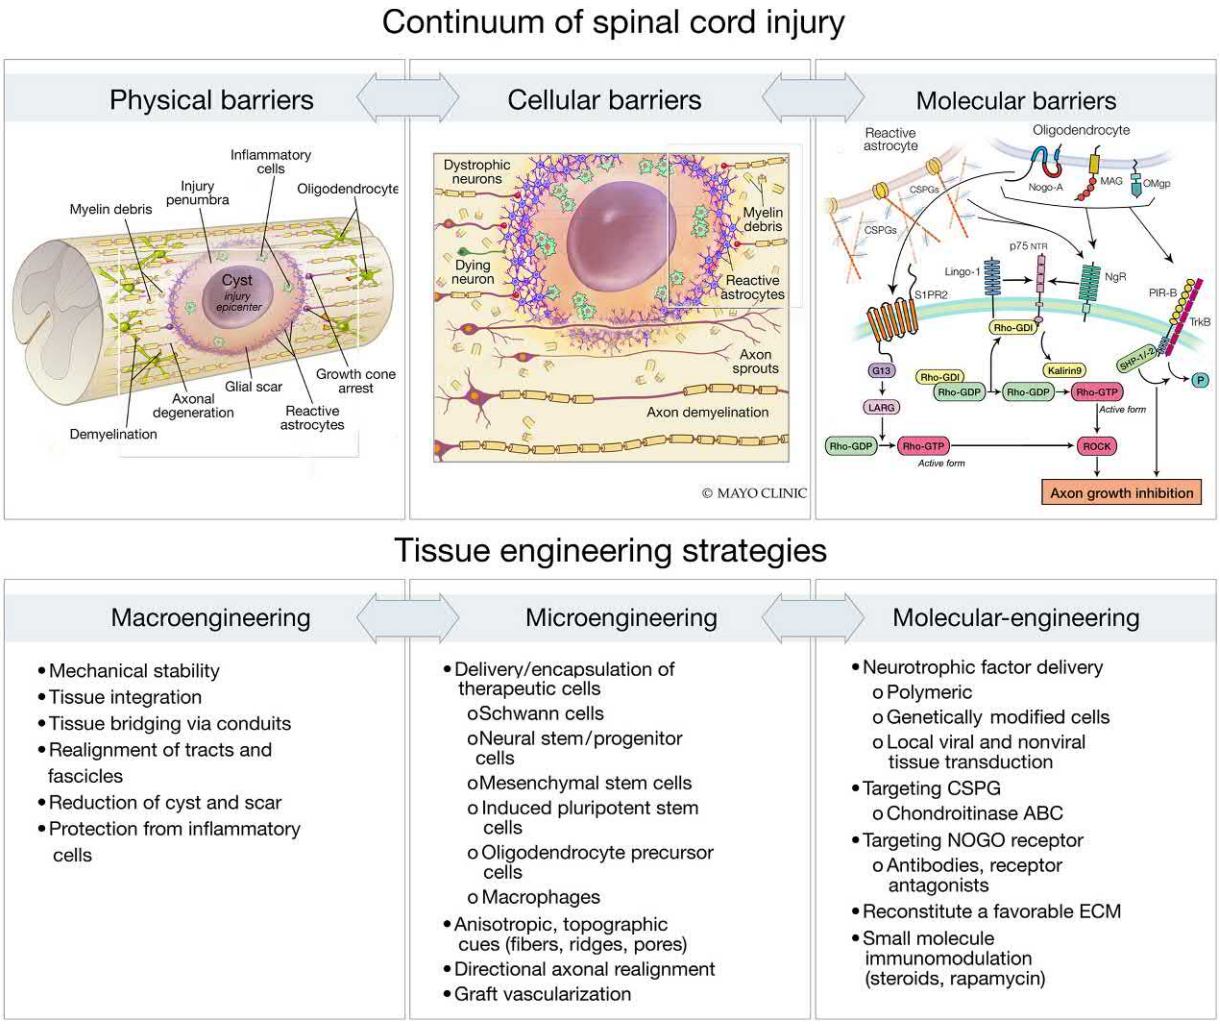

FIGURE 58.3 The continuum of spinal cord injury and corresponding tissue-engineering strategies. Physical barriers after spinal cord injury include large cysts, dense glial scarring, and spinal cord atrophy. Tissue injury occurs in a gradient of severity moving outward from a centralized epicenter of complete destruction that is walled off by the glial scar, and extending into areas of relative tissue sparing (injury penumbra). Reactive astrocytes align along the injury border to seal the area off and limit further extension through the deposition of glial scar. Damage to axons may be from the primary insult or from secondary degeneration due to oligodendrocyte injury and loss of myelination. An influx of fibroblasts and immune cells contributes to the formation of collagenous, fibrotic scarring (granulation tissue). Molecular cues that directly inhibit axonal regrowth into the injury are derived from the cellular responses. Fragments of myelin debris contain inhibitory epitopes including NOGO-A, MAG, and OMgp, which will bind to axon surface receptors and initiate protein signaling cascades that lead to growth cone collapse. Similarly, contact with CSPG molecules in the glial scar signals toward axonal growth arrest or directional changes and results in the formation of dystrophic nerve terminals. CSPGs have several molecular growth cone targets including inhibiting integrin receptor interaction with laminins, as well as binding NOGO receptors. Tissue-engineering strategies for spinal cord regeneration must address the physical, cellular and molecular barriers in parallel, through macro-, micro-, and molecular engineering. Biomaterial scaffolds are powerful platforms for such combinations of therapies and as a means for hypothesis testing and experimental observation. *CSPG*, Chondroitin sulfate proteoglycan; *MAG*, myelin-associated glycoprotein; *NOGO-A*, neurite outgrowth inhibitor A; *OMgp*, oligodendrocyte-myelin glycoprotein.

physical gaps, resident cells of spinal cord are damaged in a gradient of severity that tends to lessen with distance from the injury epicenter. Neural axons undergo degeneration, leaving behind fragments of their myelin. Damaged oligodendrocytes are unable to effectively remyelinate axons. Those axons that are at a critical threshold for survival may further be lost; those barely surviving will have poor signal conduction across the injury with incomplete remyelination and may undergo further secondary axonal degeneration [23]. Astrocytes in the injury area shift their phenotype to become hypertrophic and "reactive," adjusting in their role from neuronal health maintenance toward glial scar production and damage limitation. Fibroblasts are normally excluded from the spinal cord, except in perivascular areas. After injury, they may migrate from the peripheral nervous system and fibrotic linings of the spinal cord through disrupted tissue planes to produce additional collagen-dense scarring. Inflammatory cells, including B- and T-lymphocytes and microglial cells, coordinate to both produce tissue debris through cytotoxic responses and to clear tissue debris through phagocytosis [24].

These cellular responses themselves involve the elaboration of molecular cues that actively impair regeneration (Fig. 58.3). Myelin debris contains several protein epitopes, including oligodendrocyte-myelin glycoprotein (OMgp), myelin-associated glycoprotein (MAG), and neurite outgrowth inhibitor A (NOGO-A) [25], which will initiate signal transduction cascades within advancing axons and lead to growth cone collapse [26]. Reactive astrocytes manufacture and construct a dense network of chondroitin sulfate proteoglycans (CSPGs) [27] that become the principle components of the glial scar [28]. Contact with a CSPG network by regenerating axons leads to growth arrest, or at best, an abrupt change in the direction of axonal outgrowth. Fibroblasts produce an abundance of collagen, deposited in a dense network of fibrils that is impenetrable to axonal extension. The loss of an intact vasculature at the capillary level produces an environment that is hypoxic, acidotic, and favors the accumulation of metabolic wastes over their clearance.

These cellular responses create an environment that is devoid of natural molecular cues which axons need to survive and regrow. A number of protein factors, which are essential in the normal spinal cord as trophic and survival cues for specific neuronal populations, are lost as a consequence of cellular injury [29]. For example, nerve growth factor (NGF) is involved in the growth of nociceptive cells, brain-derived neurotrophic factor (BDNF) primarily modifies the activity of motor neurons, neurotrophin (NT) -3 supports the corticospinal tracts and dorsal sensory axons, NT-4 and -5 the proprioceptive and motor inputs, and glial cell-derived neurotrophic factor (GDNF) broadly supports the proprioceptive, dorsal sensory, ascending motor, and nociceptive neurons [30]. Each of these signals plays a critical role in the development of the spinal cord during embryogenesis; several of these factors also may also be important to mobilize new glial and neuronal cells from the stem cell niche [31]. In adulthood, insufficient concentrations of these factors after SCI profoundly influence neuronal and glial cell tolerance for the injury and their ability to survive and recover function.

During normal tissue development, cells of the central nervous system also use the extracellular matrix (ECM) as a guide for cell migration and morphogenesis [32,33]. The native ECM is a naturally occurring, three-dimensional (3D) fibrillary protein network that provides key structural support, cell adhesion sites, molecular guidance cues, and biologic signals for cell survival [30]. In injured spinal cord tissue, the native ECM is damaged or destroyed and is replaced by a provisional matrix that is devoid of laminin proteins and that is derived primarily from blood plasma to include an abundance of fibronectin [34]. Such matrices again serve primarily to limit the extension of the SCI lesion but may allow time for surviving cells, including fibroblasts and glial cells, to begin to reassemble a neuronal-specific fibrillary matrix enriched with innate ECM proteins including collagen, tenascin-C, hyaluronan, and proteoglycans [35] in perineural nets. This innate matrix may also induce the proliferation of progenitor cells in the CNS for neural tissue replacement [36] and provide binding sites for soluble factors which enhance neuronal outgrowth and survival [37].

The role of tissue engineering in spinal cord injury repair

A key principle of tissue engineering in the spinal cord may therefore be to facilitate a process of "redevelopment." It may be critical to use the introduction of biomaterials, transplanted cells, and the delivery of bioactive molecules after injury as a means to guide the spinal cord tissue back through specific developmental stages, rather than to provide more mature tissues by engraftment. The mechanisms of SCI are complex, chaotic, and occur on a continuum at gross anatomical, cellular, and molecular levels. Multiple, concurrently applied strategies aiming to address each aspect of the injury continuum are necessary to facilitate repair of the injured spinal cord (Fig. 58.3). Strategies for neuroprotection and immunomodulation may maximize the capacity for surviving tissue to contribute to repair by local plasticity and are needed in conjunction with longer distance axonal regeneration [38]. Facilitating axons to regenerate across the physical injury needs further refinement in order to impact upon neurologic function, including strategies to improve the efficiency of signal conduction through remyelination, and to

enhance the accuracy of synapse formation [39]. A new microvasculature must be regenerated in parallel [40] to support regenerating axons and glial cells and to recapitulate the primary developmental phenotype of the neurovascular bundle [41].

Viable strategies may include a functional bypass, by nerve autografts [42,43] or electronic interfaces to conduct messages to and from the brain and limbs [6]. The tissue-engineering approach is to replace the cyst/scar with tissue that promotes the development of neural tissue bridges through polymeric scaffolds to carry regenerating ascending and descending axons and facilitate functional reconnection [44]. Biomaterial scaffold technologies may be particularly useful in multimodal approaches for the investigation and treatment of SCI. Surgically implanted biomaterials can bridge the physical gaps, form approximations of viable tissue with structured order, and serve as a replacement matrix to guide axonal growth through the area of injury [45,46]. Scaffolds can also be architectural systems for the delivery of cellular and molecular therapies [47]. Moreover, scaffold technologies allow for finely tuned control of the microenvironment of the injured cord and for a powerful means to make direct experimental observations in animal models [48]. Identifying and reproducing an environment that facilitates axonal extension, that provides positive trophic and survival cues, and that reduces the influence of negative cues would significantly advance biomaterial design for SCI repair and could contribute to recovery of neurologic function in patients. Tissue-engineered replacement of discrete tracts within short segments of the cord may be feasible for those patients with complete injuries and without evidence of residual functional tissue after injury. The optimal timing of surgical placement of scaffolds in an acute, subacute, or chronic phase of injury has not been determined but should ensure that no additional disruption to function occurs as a direct consequence of the surgery.

Bioengineering for integrated spinal cord biocompatibility

Tissue engineering in the spinal cord, as in other organ systems, poses bioengineering challenges that are unique to the specific tissue environment. Biomaterials, cells, matrices, and therapeutic molecules need to have properties that are compatible within that environment in order to successfully influence spinal cord tissue regeneration. In general, bioengineering attributes that most closely recapitulate the intrinsic mechanical characteristics of the original tissue may improve regeneration. For example, the elastic modulus of the human cervical cord without pia mater was measured to be on the order of 0.04 ± 0.006 MPa, and the maximum stress to failure was recorded to be 0.062 ± 0.005 MPa in one study [49]. The authors' results also implied that the spinal cord may be softer under tensile (stretch) loading than compressive loads. In another study, the moduli of intact human spinal cord with pia intact mater and without pia mater were 1.40 ± 0.088 and 0.089 ± 0.021 MPa, respectively. Despite reinforcement from the pia mater, the modulus values for spinal cord tissue are in the range of a soft gelatin, that is, a "viscoelastic" material that has nonlinear stress−strain curves and anisotropic properties [50]. This reflects the need to develop materials and biologics that have corresponding biomechanical properties: soft materials that integrate but do not damage the adjacent tissue in the dynamic environment of a moving spinal column. Biomaterial permeability, degradation kinetics and the nature of the biproducts, and physical properties of the material including swelling, stiffness, porosity, and tensile strength are key characteristics that are specific to the polymer used and its modifications (Table 58.1). These parameters determine how the biomaterial will interact with host tissue to direct a regenerative tissue response for axonal extension and remyelination. Critical regenerative responses include provision of an ECM, engraftment of exogenous transplanted or endogenous migrating cells, vascularization, and the controlled release of molecules of therapeutic interest. To provide for biocompatibility of an engineered construct, transplanted cells ideally would be autologous, or at a minimum, derived from an inbred allogenic strain to avoid host immune rejection. The experimental design should establish the viability of implanted cells over time according to the specific delivery method employed. Protein based biologics such as neurotrophic factors should be produced from the genetic sequences of the host animal to avoid eliciting immune responses. The immunogenicity and toxicity of other nonmammalian proteins (green fluorescent protein) and chemical drugs must similarly be established.

Animal models of spinal cord injury

Animal models of complete spinal cord transection, dorsal or unilateral cord hemisection, clip or balloon compression, and computer-controlled impact contusion injuries are commonly used to develop tissue-engineering methodologies and to test experimental hypotheses for regeneration [51]. These animal models approximate the human pathology of spinal cord transection or laceration, and closed compression or contusion injuries. Each injury model requires a surgical laminectomy to access and injure the spinal cord, with the exception of balloon-catheter compression. The use of a particular injury model is largely influenced by the specific experimental aims, laboratory expertise with the technique, the intensity of animal care after injury, the animal species and size, the capacity to quantitatively assess the outcome, and the

TABLE 58.1 Tissue- engineering for spinal cord biocompatibility.

Bioengineering attribute	Influence on biocompatibility within the spinal cord
Permeability	• Is a measure of a material's capacity to transmit fluid or dissolved molecules of variable size • Cerebrospinal fluid is low in cellular nutrients in relation to blood • Permeability to a wide range of molecular sizes is crucial for engineered tissue oxygenation, nutrient supply, removal of metabolic wastes, and potential for vascularization
Swelling ratio	• Defined as the ratio of hydrated to dehydrated polymer weight • The spinal cord environment is highly aqueous • Swelling influences the maintenance of implant alignment and the potential to compress adjacent tissue or occlude a scaffold lumen space
Degradation kinetics	• The rate of material degradation influences the lifespan and structural integrity of the implant in vivo • The scaffold structure should be maintained long enough to allow for tissue in-growth in the desired conformation • Degradation may be accelerated by tissue ingrowth, deposition of ECM or metalloproteinases, and the cell type coimplanted • Slowly degrading materials are likely to become encapsulated by fibrosis through foreign body reaction • Rapidly degraded materials risk outpacing tissue ingrowth • Can be employed for controlled-release of encapsulated molecules
Degradation biproducts	• Must be nontoxic to local and systemic tissues • Should not elicit an immunogenic response • Preferably can be processed by innate catabolic pathways
Compression or elastic modulus	• Defined as the ratio of stress (force per cross-sectional area) to strain (displacement per unit length) of a material • Ideally should match or approximate that of the spinal cord • Materials should be elastic enough not to damage the adjacent spinal cord with movement
Flexural modulus	• Defined as the ratio of stress to strain in flexural deformation • Assessed by three-point bending measurements • Informs the risk of structural deformation or collapse as proportional to the length of the scaffold
Tensile strength	• Defined as the maximum stress a material can withstand before failure • Surface tensile strength influences cell adhesion, migration, and may determine cell phenotype • Will influence the ability to hold a suture on implantation if required
Porosity	• Pores of varying size will influence permeability, degradation, stiffness, tensile strength, and swelling • Influences cell adhesion and vascularization of the implant • Can improve interlocking between innate tissue and the implant • May be employed to create microreservoirs for controlled release
Surface charge	• Influences cell surface adhesion • May be employed for controlled release of oppositely charged molecules

ECM, Extracellular matrix.

need to implant a device. Each model requires rigorous training to ensure reproducibility of the extent and severity of the injury, and carries distinct advantages and disadvantages in the context of a particular application (Table 58.2).

Contusion injuries are the most commonly used, in about half of all experimental SCI publications, followed by (hemi)transection and less commonly compression injuries. The most frequently used species is rat, followed by mouse, and the primary level of injury for experimental injury is within the thoracic cord (80% of publications) [52]. While the cervical cord is the most commonly injured location in humans, experimental models of cervical injury in animals are more rarely used due to high animal mortality. Each model can provide for a wide diversity of locomotor and sensory behavioral testing, autonomic assessments, neurophysiologic recordings, and histopathologic outcome measures to determine the extent of an injury and the biologic response to the intervention. Chronic contusion or compression with spinal cord cavitation, and complete or incomplete transection injuries are the most suitable for tissue-engineering

TABLE 58.2 Animal models of spinal cord injury.

Spinal cord injury model	Advantages	Disadvantages
Impact contusion		
Weight drop Computer assisted: Infinite Horizon Impactor New York University Impactor Ohio State University Impactor Frequency of use: 44% of publications [52]	• Close physiologic correlation to common human contusion and injuries • Accurately recapitulates the progression from acute primary/secondary and chronic secondary injury phenotypes • Fine control over injury severity based upon computer settings for impactor speed and delivered energy • Reproducibility of injury within and between cohorts • Less intensive animal aftercare • Most extensively published experience	• Variability of incomplete injury • Complex injury environment for measurement of outcomes • Difficulty discriminating between spared and regenerating tissue histologically • Cannot accommodate devices • Rate of animal recovery • Cost
Transection		
Complete transection Dorsal or lateral hemisection Frequency of use: 35% of publications, in roughly equal proportion [52]	• Most amenable for biomaterial device implantation and tissue-engineering applications • Allows for the creation of confined microenvironments within scaffold compartments for measurement and observation • A reproducibly complete injury • Restoration of function is primarily modulated by regenerative responses rather than by axon sprouting from spared tissue	• Represents a rare injury type in humans • Intensive animal aftercare
Compression		
Aneurysm clip Calibrated forceps Balloon Physical spacer Frequency of use: 21% of publications [52]	• Close physiologic correlation to complex bony compression injuries in humans • Clip tension, balloon pressure, and duration may be finely controlled • Reproducibility • Percutaneous (balloon) • Injury can be calibrated over time to mimic human chronic progressive SCI as in cervical spinal stenosis	• May involve an implanted device (balloon or spacers) that introduces an additional variable

SCI, Spinal cord injury.

applications, due to practical space requirements for biomaterial implantation. Bioengineered materials may be delivered as gels to fill small cavities and tears, as gels or sponges for larger defects, or as tubular or multichanneled conduits to bridge longer gaps [53]. Feline, canine, porcine [54], and primate models [55,56] of SCI typically represent advanced preclinical studies in preparation for the translation of scaffold technologies into humans. Their advantages include similar anatomic caliber of the cord and physiologic injury responses to humans. The use of these large animal models however is often cost-prohibitive, carries ethical concerns, and requires specialized facilities and veterinary expertise. It is also important to note that all of the animal types used, other than primates, are quadrupedal. Gait coordination is significantly different between bipeds and quadrupeds.

Principles of biomaterial fabrication for spinal cord injury repair

The vast majority of biomaterials used in animal models of spinal cord regeneration are polymers [57]. One classification broadly is whether the polymer is naturally derived, or whether the polymer is chemically synthetic. Scaffold biomaterials are fabricated by dissolving the monomer units in aqueous or organic solvent. The liquid state is then polymerized through the addition of a cross-linking reagent, and chemical initiators and/or accelerators. The cross-linking reaction may be initiated chemically, thermally, or by exposure to visible or ultraviolet light, depending on the specific initiator used. The biomechanical properties of the material are primarily established during fabrication, through the choice of monomer,

the fine-tuning of monomer concentrations, the stoichiometric ratios of the initiators or accelerators, and the time allowed for polymerization. Most scaffolds are produced by some form of mold-injection, confining the monomer reaction within a preformed cast, while it is still in a pre- or early polymerized state, followed by the maturation of the polymer within the mold [46]. Scaffold channels are formed by casting the polymer over multiple linear structures, such as thin wires, polystyrene cylinders, or ice crystals. Porogens of various sizes may be added to the aqueous polymer, including salt crystals, bubbles of gas or foaming (peroxide) reactions, or with composite polymers materials. The principle for pore formation is that the polymer forms around the porogen which itself is then subsequently removed, for example by dissolving the salt crystal or composite away from the solid polymer, leaving open spaces [58]. Additive manufacturing or 3D printing is just being introduced into tissue-engineering applications for SCI, and there are few published reports in this area.

Macroengineering for spinal cord scaffolds refers to the architectural features of polymerized scaffold structures that are on the order of 100−1000 μm, matching the size of nerve tracts in the human spinal cord, and typically taking the form of longitudinal conduits. Macroengineering designs address the problem of regenerating of spinal cord tissue across physical barriers and gaps for reapproximation and realignment of the disrupted fascicular anatomy. Continuous porous structures may improve regeneration and functional recovery by mimicking the intrinsic mechanical characteristics of the original tissue [59], enabling cell-responsive attachments and allowing for greater distances to be bridged [60,61]. Porosity also allows for vascularization of the scaffold implant and may improve implant stability at the cord-scaffold interface through tissue interlocking [62] (Fig. 58.4). Open conduits provide central spaces as well as walled surfaces for host axonal extension, cell migration into the construct, and for therapeutic cell delivery. The design overall may aim to align specific spinal cord fascicles or tracts (Fig. 58.5) or to provide a multitude of channels in a less specific manner for broader coverage. Early studies established the need to optimize the size and number of channels [64] provided in the scaffold design. For example, channel sizes in poly(lactic-*co*-glycolic acid) (PLGA) scaffolds of 660 μm in diameter resulted in the formation of wider areas of fibrous scarring along the inner circumferential surface of the channel walls, and smaller areas of centralized regenerated glial and axonal tissue, than open channel sizes of 450 μm [65]. This phenomenon likely relates to differential rates of cell migration into the scaffold, and cell proliferation once within the scaffold, for fibroblast and inflammatory cells over rates of axonal extension or glial cell migration into channels. The provision of more space favors the establishment of cells that migrate and proliferate quickly, even when another cell type, such as Schwann cells (SCs), are exogenously seeded within the scaffold [41]. The scaffold channel lumen over time may then become occluded with fibrotic tissue which forms a further barrier to regeneration [66].

The ratio of open space to solid polymer must also be considered in the scaffold design. It is inefficient to provide for low open space−to-polymer ratios, such that axonal regeneration is physically blocked with excessive areas of solid polymer. If the polymer itself is rigid, the adjacent spinal cord may be damaged, and the injury extended, by wider areas of spinal cord to polymer apposition [64]. On the other hand, a high open space−to-polymer ratio has implications for the mechanical integrity of the scaffold and the risk that the conduits will collapse or buckle. Finally, increasing the number of open spaces of smaller diameters (200 μm) provides for proportionally more surface area upon which cells may attach or along which axons may extend, in the form of the inner circumferential surfaces of the channel walls [67]. This

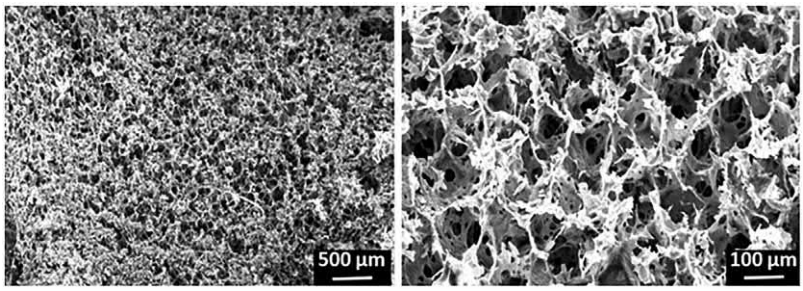

FIGURE 58.4 Scaffold porosity. A composite hydrogel fabricated from chitosan and β-glycerophosphate disodium salt as a gelling agent has a highly porous macro- and microarchitecture upon freeze drying. Porosity as a biomaterial property is critical for scaffold integration into the injury site, encapsulation of transplanted cells, and graft vascularization. *From Boido M, Ghibaudi M, Gentile P, Favaro E, Fusaro R, Tonda-Turo C. Chitosan-based hydrogel to support the paracrine activity of mesenchymal stem cells in spinal cord injury treatment. Sci Rep 2019;9(1):6402, with permission.*

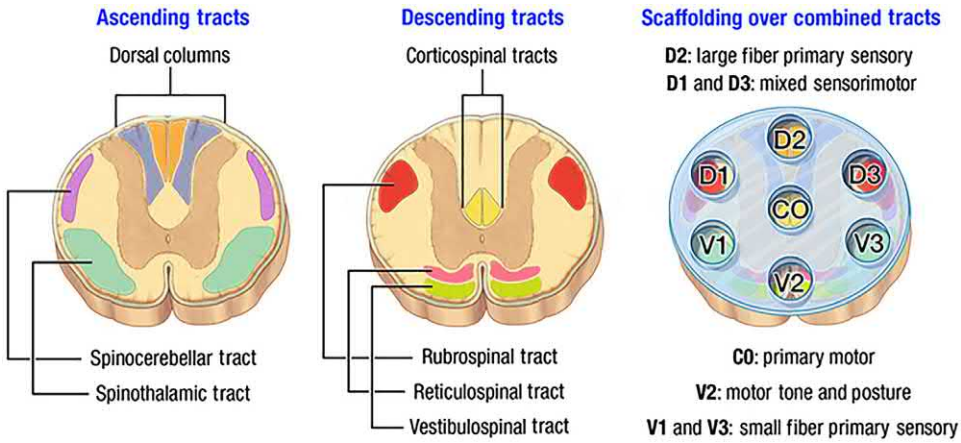

FIGURE 58.5 Macroengineering for the realignment of spinal cord tracts and fascicles. Biomaterial scaffold channels may be designed to overlap anatomically with ascending and descending tracts in the human or rat spinal cord. Individual channels therefore could support histologically and modality-specific neural regeneration. The most significant difference between the human and rat spinal cord is in the location of the descending corticospinal tracts. The rat corticospinal tracts have a centralized location in the dorsal white matter (shown here in the middle panel). A central channel (C0) (panel right) would be continuous with the descending rat corticospinal tracts and periaqueductal gray matter. A dorsal midline channel (D2) would convey axons from the dorsal columns, while dorsolateral (D1 and D3) channels overlap with ascending spinocerebellar and descending rubrospinal tracts. A ventral midline channel (V2) would associate with vestibulospinal and reticulospinal descending tracts. Bilateral ventrolateral channels (V1 and V3) are primarily ascending sensory spinothalamic tracts.

principle becomes particularly important in combinational strategies to enhance the ECM for improved cell engraftment and axonal extension.

The use of computer-assisted design, including laser etching [68] and more recent advances in additive manufacturing [69], have enabled rapid fabrication of scaffolds that precisely match the geometry of an individual spinal cord, or are biomimetic (Fig. 58.6). Matching the fit of gray–white matter interfaces, the diameter of specific neuronal tracts, and major blood vessel distribution, in addition to more general parameters such as spinal cord size overall, may help to produce scaffolds that are individualized to a specific patient's anatomy. Laser etching technologies remove areas of polymer in layers from a solid block. Inkjet or extrusion bioprinters build a scaffold structure in additive layers, which may introduce small defects consequent to the layering and droplines as the fine polymer stream is initiated. Technological advances in continuous projection printing methods have been developed for seamless scaffold production without artificial interfaces [69]. The incorporation of cells within the polymer stream for encapsulation has been achieved in applications outside of spinal cord regeneration and will likely soon be adapted for spinal cord repair [71].

Microengineering for the spinal cord refers to architectural designs of a few microns in at least one dimension [72], matching the diameters of individual or groups of cells and axons. Microengineering therefore addresses the problem of regenerating and realigning spinal cord tissue at a cellular level. Large myelinated axons in the spinal cord have diameters between 15 and 20 μm, while small myelinated and unmyelinated axons are on the order of 0.15–10 μm [73]. These design principles aim to support the anisotropic properties of the spinal cord through the linearization of the engineered tissue, recapitulating the natural anatomic tendency of 3D axons, myelinating cells and blood vessels to extend longitudinally in the planes of two primary dimensions [74]. Axonal extension is precisely guided by anisotropic polymer surfaces with etched microgrooves, embossed ridges, or aligned microfibers in addition to larger scale conduits [75]. Precision of axonal extension is necessary to optimize the likelihood that a disrupted fascicle could be rejoined together and to improve the accuracy of the intended synaptic targets. Axons and their growth cones preferentially extend along the surface interface angles that are created by ridges and grooves [68].

These topographic guidance cues have been produced on polymer surfaces by precision laser etching and by photolithography techniques (Fig. 58.7A and B). Early work demonstrated that a surface groove depth of at least 2 mm was required to linearize axonal growth over more shallow grooves or untreated surfaces [77]. Subsequently, groove widths of 30 μm, depths of 50 μm, and ridge or plateau widths of 200 μm resulted in the highest densities of bridging neurites and focal adhesion contacts over grooves of other dimensions [78]. Grooved surfaces that are coated with collagen, or laminin to provide ECM contact [79], including concentration gradients of laminin [80–82], further improve the ability to refine topographic guidance. Axons are directed to migrate from lower to higher concentrations of laminins or neurotrophic factors by molecular signaling at the growth cone through surface receptors (integrins and neurotrophic factor receptors) that adjust the axons' internal microtubule structure and

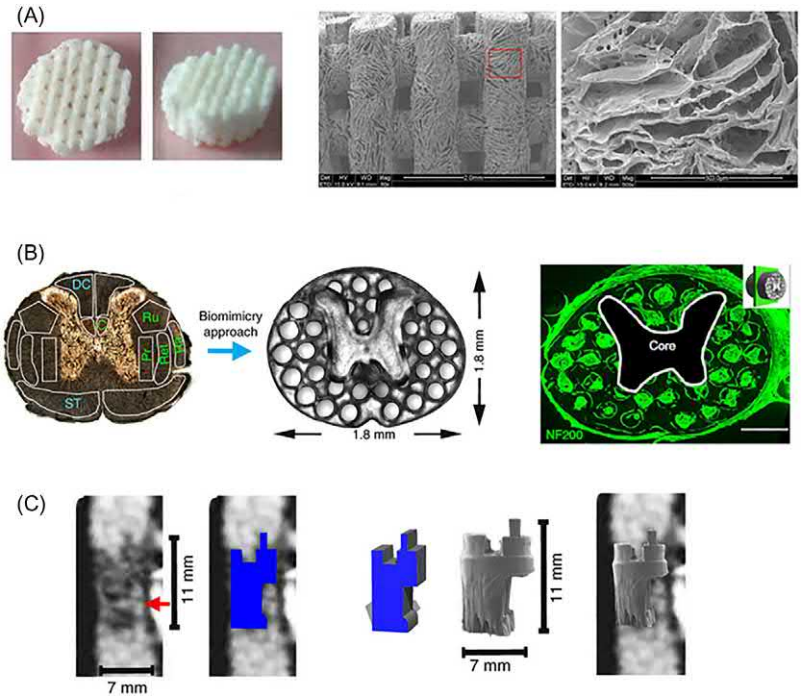

FIGURE 58.6 **Computer-assisted 3D printing.** Recent advances in additive manufacturing, building polymer scaffolds in layers with 3D printers, have enabled rapid fabrication of precision geometries for spinal cord injury repair. (A) A collagen heparin sulfate composite is printed in an open lattice design, creating larger pores between polymer columns, as well as a uniform microporous architecture within the column structure. (B) 200 μm channels are printed precisely in 3D space using a microscale continuous projection printing method and a polyethylene glycol−gelatin methacrylate copolymer, to provide conduits for specific motor (shown in green) and sensory systems (shown in blue). Since gray matter does not typically project axons following an injury, that corresponding volume was printed with solid polymer to provide for structural stability in the scaffold core. Axonal regeneration into the graft is demonstrated using neurofilament antibody labeling (NF200) after 4 weeks in vivo. (C) Computer-aided design 3D modeling of a complete mid-cervical injury cavity outlines the lesion volume, including areas of spared tissue, from a patient's T1 weighted MRI image and produces a precise scaffold shape to be printed for that individual patient. *3D*, Three-dimensional; *C*, corticospinal tract; *DC*, dorsal column sensory axons; *MRI*, magnetic resonance imaging; *Pr*, propriospinal tract; *Ra*, raphespinal tract; *Ret*, reticulospinal tract; *Ru*, rubrospinal tract; *ST*, spinothalamic tract. *Adapted from (A) Chen C, Zhao ML, Zhang RK, Lu G, Zhao CY, Fu F, et al. orientation along the gradient [83,84]. The addition of glial cells to patterned substrates, either to form cellular channels [85] or to be decellularized for creating a patterned native ECM [86], represent biomimetic approaches to axonal guidance.

The remyelination of axons fundamentally relies on axonal extension, as several molecular cues for SC and oligodendrocyte differentiation and maturation into fully myelinating cell phenotypes are on the axonal membrane surface. Myelinating SCs are naturally elongated and may measure between 2 and 5 μm in maximal diameter around an axon but extend between 220 and 400 μm along an axon [87]. The longitudinal extension of small blood vessels has been shown to have a directly proportional relationship to the number of adjacent axons [41], and the stereologic relationship between axon number and distance from blood vessels tends toward a Gaussian distribution.

Axons preferentially grow along the length of polymer fibers (Fig. 58.7C and D). Such fibers may be created from monomer units as the natural molecular assembly of the polymer into helices, by chemical techniques such as phase separation, freeze drying, or by electrospinning [88,89]. In vitro optimization experiments that varied poly(acrylonitrile-*co*-vinyl chloride) hollow fiber diameter from greater than 100 to 5 μm identified that filament bundles in the cellular to subcellular range (5−30 μm) improved alignment and neurite outgrowth densities [90]. The addition of laminin coating to these filaments produced longer neurite outgrowth distances. Electrospinning utilizes electrical charge to elongate threads of liquid polymer from a syringe pump source. The polymer solvent evaporates upon contact with the air, and the filament threads may be deposited in random orientations onto a flat plate or may be aligned onto rotating spindles. The diameter of the fiber is a function of the polymer concentration, the strength of the electric field, the rate of polymer draw, and the nozzle tip diameter. Aligned axonal outgrowth and glial cell alignment on electrospun fiber scaffolds have been demonstrated in animal models of SCI repair [91−93]. Polymer fibers in random orientations that are assembled into mats and sponges create a meshwork of niche environments for exogenously transplanted or migrating endogenous cells to successfully engraft into the spinal cord construct. Meshes enable a greater number of surfaces, spaces, and projections to support axonal sprouting and synaptic contacts in 3D space rather than imposing specific directionality [94].

Biomaterials for spinal cord tissue engineering: natural polymers

Biomaterials used in spinal cord tissue-engineering applications may be broadly classified into naturally derived or synthetic materials. Naturally derived polymers may be subclassified as being components of the native ECM [collagen, hyaluronic acid (HA), cell-assembled, and decellularized matrix]; components of blood (fibrin, fibrinogen); or components from marine life, insects, spiders, or other sources (agarose, alginate, chitosan, silk). Naturally derived polymers are fibrillary proteins, or complex carbohydrates such as polysaccharides or glycosaminoglycans (GAG). They form hydrogels. The use of natural hydrogels takes advantage of the intrinsic role of the polymer, as it would function as an ECM or in structural support, as well as favorable degradation characteristics. Hydrogels are particularly attractive for use in spinal cord tissue engineering, as they are typically soft materials that conform well to the injury site placement, they are porous to allow for cell engraftment and alignment [58], and they are readily permeable for aqueous exchange of cellular waste and nutrients.

Extracellular matrix polymers

Natural polymers derived from ECM proteins are intended to replace the critical role of spinal cord ECM that is lost following injury. The most commonly used ECM polymer in spinal cord scaffolds is type I collagen. Solutions of liquid monomer are easily polymerized into collagen fibrils by adjusting the solution pH or with the addition of ionic salts. Several advantages of collagen include that it is a soft material with low autologous antigenicity, and that it offers natural molecular sites for cell adhesion, migration, cell-signaling via integrin contacts, and may direct stem cell differentiation [95,96]. The collagen material by itself, however, was shown early on to have a limited capacity to support axonal extension [97,98]. Indeed collagen accumulation in scaffold channels, as deposited by the scaffold material, by migrating fibroblasts and as a foreign body response to scaffold placement over time (particularly type IV collagen deposition), is a primary barrier to axonal regeneration [66,99]. As a naturally fibrillar protein, collagen fibers scaffolds were developed to have parallel longitudinal orientations along which axons extend (Fig. 58.8). Collagen scaffolds may be more effective therefore as functionalized matrices to deliver cells or to elute molecules of therapeutic interest in single polymer or copolymer, composite systems [71,101]. For example, the covalent modification of collagen with the addition of laminin gradients provided for improved, directional axonal extension along collagen fibers in vivo [102]. Collagen is also a thermoresponsive matrix, in that it may be delivered to the spinal cord as an injectable solution which then gels or polymerizes at physiologic temperatures within the injury site [102]. Controlled release of neurotrophic factors that are in solution with the collagen

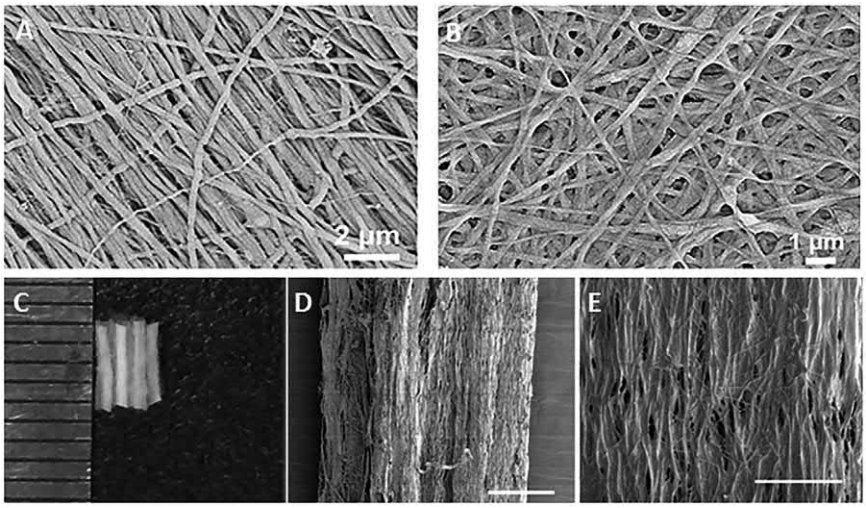

FIGURE 58.8 Collagen scaffolds. As a natural fibular protein, collagen has been a versatile material for spinal cord tissue engineering. (A) Collagen may electrospun into aligned or (B) randomly oriented fibrous mats which are then formed into tubes for surgical placement. (C–E) Linear ordered collagen scaffolds which incorporate collagen binding domains as linkers have been used extensively for the controlled release of neurotrophic factors, neutralizing antibodies and small drug molecules. *(A and B) Reproduced with permission from Liu T, Houle JD, Xu J, Chan BP, Chew SY. (C–E) from Fan C, Li X, Xiao Z, Zhao Y, Liang H, Wang B, et al. A modified collagen scaffold facilitates endogenous neurogenesis for acute spinal cord injury repair. Acta Biomater 2017;51:304–16, with permission.*

has improved axonal counts and locomotor function after injury, with the rates of elution dependent upon the degradation of the collagen [103]. Collagen-binding domains have been extensively employed to covalently tether a number of small molecules and growth factors for sustained elution from linearly ordered collagen scaffolds [104,105] (Fig. 58.7) (Table 58.3).

HA is a primary GAG component of the native ECM of the spinal cord and brain [227] and, as such, was initially considered to be a good candidate to support axonal regeneration after SCI. Performance of HA as a physical substrate for axonal extension in vivo has been modest [228]. The principle uses of HA have evolved as injectable copolymer systems for drug delivery and for the encapsulation of cells [133]. The advantages of using HA in both applications include its low immunogenicity and the ability to fluidly conform to the injury defect and fill the lesion cavity with the therapeutic intervention. In addition, HA may modify astrocyte reactivity around the injury site, reduce the local extent of CSPG deposition at the injury–polymer interface [229], and limit the evolution of secondary injury mechanisms through neuroprotective effects [230] including reduced microglial cell activation [231] and subarachnoid inflammation [232].

Acetate-modified HA and methylcellulose (HAMC) copolymers have been developed with the distinctive quality of gelling at ambient and physiologic temperatures and then liquefying when subjected to sheer forces, such as within a needle and syringe, for in situ delivery [134,233]. Early applications included the sustained release of collagen embedded epidermal growth factor [135] and erythropoietin [136], enhancing neuroprotection, reducing cavity size, increasing neuron numbers, and improving tissue penetration of the therapeutic by prolonging the bioavailability following spinal cord clip compression (Fig. 58.9). The intrathecal HAMC system has been shown to have remarkable versatility for fine tuning of release and elimination kinetics of therapeutic molecules [138], through small molecule encapsulation (anti-NOGO-A) [139], PEGylation of fibroblast growth factor-2 (FGF-2) [137], NT-3, and small molecule delivery from slowing-eluting nanoparticles [140–142]. The system has subsequently been adapted and characterized for the delivery of therapeutic cells to the injured spinal cord [234], including neural stem cells (NSCs) [143], induced pluripotent stem cell (iPSC)–derived oligodendrocytes [144] (Fig. 58.9), and embryonic stem cell–derived astrocyte ECM [145].

A variety of other HA-derivative composites have been shown to support SCI repair. Strategies for the replacement of growth factors, ECM, and remyelinating cells have included using sodium hyaluronate microparticles encapsulating ciliary neurotrophic factor [235], hyaluronan tetrasaccharide [236], HA incorporating poly-L-lysine and mesenchymal stem cells (MSCs) [237,238], hydroxyphenyl HA modified with RGD peptide and fibrinogen [146], and thiol-modified HA for oligodendrocyte precursor cell (OPC) delivery [147]. Composite chitosan and HA nanoparticles have been shown to be capable of nonviral poly(ethylene imine)

DNA transfection [239], lentiviral transduction [240], and small-inhibitory RNA delivery [241] (Table 58.3).

Cell-assembled ECM is produce by whole tissues or by confluent cell cultures that are subsequently subjected to a decellularization procedure with gentle detergents. While the cells themselves are removed, the native ECM remains intact on the polymer surface, with advantages of being a complex 3D matrices with multiple protein and trophic components that may better recapitulate the original tissue [242]. Whether decellularized ECM is truly inert with respect to residual antigen has appropriately been the subject of debate [243]. Early applications of decellularized ECM for spinal cord tissue engineering have focused on using injectable hydrogel systems with ECM solubilized from porcine spinal cord, brain or optic nerve [244,245]. Porcine spinal cord ECM has been shown to be a favorable substrate for axonal ingrowth into a spinal cord hemisection lesion in vivo [148] but had disadvantages of rapid degradation rates. Acellular, solubilized ECM derived from peripheral nerve tissues (Fig. 58.10) supported transplanted cell survival and axonal growth when engrafted with SCs following a thoracic contusion injury [149]. Recent in vitro studies have shown that substrates with ECM from decelluarized protoplasmic astrocytes, in turn derived from mouse embryonic stem cells [150], as well as micropatterned fibroblast-derived ECM [86], are effective topographic surfaces for neurite outgrowth (Table 58.3).

Polymers from marine or insect life

Agarose is a naturally linear polysaccharide derived from seaweed, which is cross-linked through melting or temperature gradient change through hydrogen bonding. Agarose scaffolds have been used extensively in spinal cord repair strategies. They have the advantages of low antigenicity, a similar gelatin-like consistency to the spinal cord, and slow biodegradation rates. The ability for agarose as a material to innately support axonal extension along its surface is limited [151–153]. Agarose is also

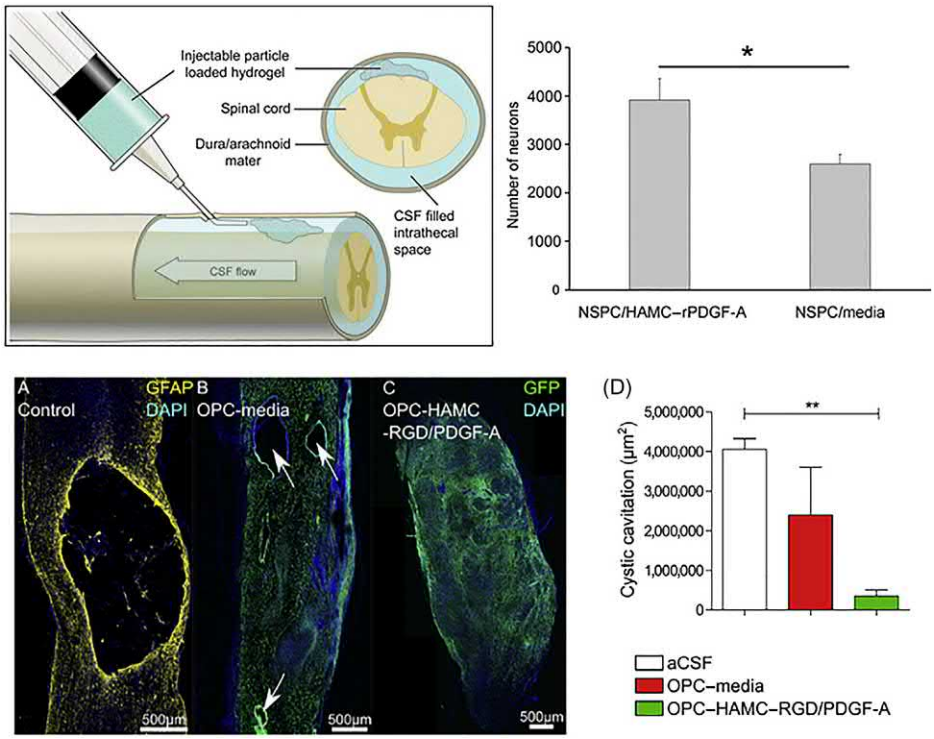

FIGURE 58.9 Hyaluronic acid. Composite polymers of HAMC form a unique injectable delivery system for neurotrophic molecules, extracellular matrices, and therapeutic cells. The hydrogel may be delivered onto the surface of the spinal cord (upper panel left), into the substance of the cord adjacent to an injury, or may be used to fill an injury cavity. Hydrogel delivery of NSPC along with chemically conjugated biotin-recombinant platelet derived growth factor-A after clip compression injury promoted neuronal sparing and improved absolute numbers of neurons surrounding the lesion site relative to NSPC alone (upper panel right). (Lower panel, A–D) iPSC-derived OPCs, with PDGF-A and an RDG motif peptide, reduced cystic cavity size after clip compression and attenuated teratoma formation when transplanted in HAMC. *HAMC*, Hyaluronic acid and methylcellulose; *iPSC*, induced pluripotent stem cell; *NSPC*, neural stem/progenitor cells; *OPCs*, oligodendrocyte precursor cells; *PDGF-A*, neurite outgrowth inhibitor A. *(Upper panel left) Adapted from Baumann MD, Kang CE, Stanwick JC, Wang Y, Kim H, Lapitsky Y, et al. Biomaterials 2016;83:23–36, with permission.*

thermoresponsive but typically gels at temperatures lower than physiologic 37°C. This property has been useful in designing injectable in situ constructs that conform well to the spinal cord defect upon rapid cooling [155]. Gels have been used for delivery of neurotrophic factors [83,154], for localized methylprednisolone delivery from gels embedded with drug-eluting nanoparticles [156], and thermostabilized chondroitinase ABC (chABC) enzyme from an agarose hydrogel microtubule delivery system [157] for CSPG degradation in vivo.

In a series of publications that have been fundamental to the field, agarose biomaterials have been developed that provide longitudinally oriented scaffold templates for axonal extension, with parallel channels ranging from 120 to 200 μm in diameter. The scaffolds are templated by either a freeze–drying method which creates longitudinally oriented ice crystals as porogens [158,159], or by casting the agarose over polystyrene microfibers [67]. Templated agarose scaffolds have been functionalized with ECM and neurotrophic factors [158,159], including integrated gradients, and modified for small molecule elution. These studies have been more recently extended to combinatorial treatments, including preconditioning sciatic nerve compression lesions and lentiviral delivery of NT-3 into the spinal cord adjacent to the scaffold to achieve long-tract axonal regeneration through the injury site [160]. Templated agarose has also been used to deliver MSCs genetically modified to secrete BDNF [161], and hydrogel-bonded BDNF [162] (Fig. 58.11). Recently, neural progenitor cell delivery in templated agarose was directly comparable to delivery in a synthetic polymer scaffolds fabricated by 3D printing [69] (Table 58.3).

Alginate is a linear polysaccharide derived from brown seaweed [246], which is cross-linked with sodium or calcium ionic salts. It has many of the same advantages

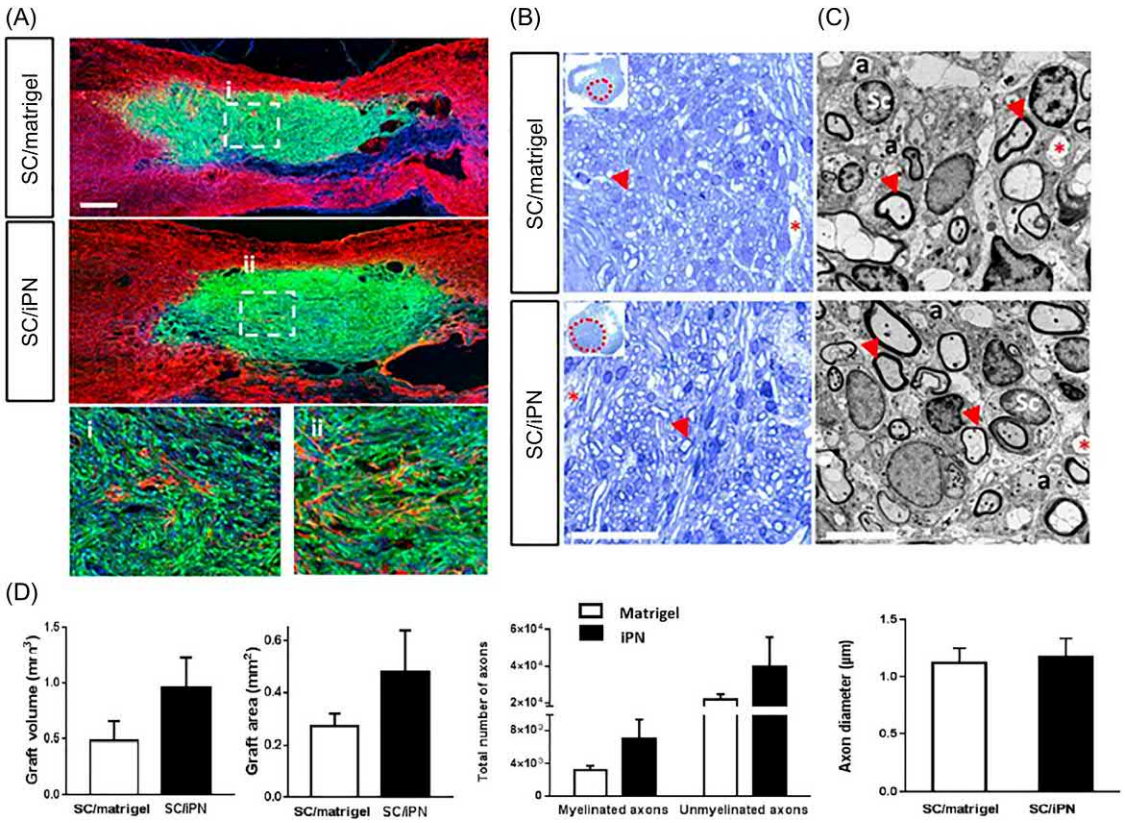

FIGURE 58.10 **Decellularized ECM: acellular iPN matrix.** (A) Sagittal spinal cord sections at 8 weeks post-transplantation of GFP-positive SCs in either Matrigel or iPN demonstrate that the engrafted cells occupy the contusion injury cavity, surrounded by GFAP-positive astrocytes (red). Higher magnifications of the central areas of SC grafts in Matrigel (i) or iPN (ii) are also shown. (B) Semithin, toluidine blue-stained transverse sections and (C) electron micrographs of the spinal cord injury site indicate axonal myelination by engrafted SCs (arrowheads) after 8 weeks in a typical peripheral nerve myelin pattern. Asterisks denote blood vessels. Decellularized peripheral nerve supports Schwann cell transplants and axon growth following spinal cord injury. Biomaterials 2018;177:176–85, with permission.*

to agarose. It is a soft and immunologically inert material that has been used as an SCI biomaterial in similar ways. Alginate also is relatively poor in directly supporting axonal growth and requires modification. Used in the form of injectable gel systems and hydrogel disks, alginate is a highly effective matrix for incorporation of ECM peptides [163], controlled release of neurotrophic factors [164–166] or small molecules [167], and cell encapsulation [168–170], including gene-modified cells delivering therapeutic factors [171,172]. Freeze-dried sponges [173] and ice-templated linear conduits [174] releasing NT-3 and chABC [175] have been developed. Capillary hydrogel designs [176,177] (Fig. 58.12) have been used for macroarchitectural and anisotropic support for tissue regeneration in combination with ECM surface modification [178] and astrocytes, and as microchanneled scaffolds delivering MSCs, SCs, and cellular or viral delivery of BDNF [179,247] (Table 58.3).

The glycosaminoglycan chitosan is a carbohydrate polymer derived from the chemical deacetylation of chitin, a structural polysaccharide found abundantly in the shells of crustaceans, shellfish and insects. Depending upon the extent of the deacetylation, chitosan has an intrinsically positive surface charge which supports cellular adhesion onto the material surface, along with chemical modification of the surface [248]. Improvements in cell attachment to the polymer have been achieved by modifying the surface with ECM peptides [249,250]. A thermoresponsive polymer has also been produced with the addition of poly-L-lysine, and glycerol phosphate salts [251]. The use of chitosan for spinal cord tissue engineering has evolved from the bioengineering of single lumen conduits [180] and characterization of cellular interactions [181]. Early work demonstrated that chitosan conduits could support axonal regeneration and functional recovery after complete spinal cord transection [182]. When

(B) Gross appearance of the scaffold implantation site with three dural sutures, 1 month after implantation into a complete spinal cord transection at the T3 level. (C–F) Nissl staining in longitudinal sections shows scaffold integration into the injury area with formation of regenerating tissue bridges, after either GFP-expressing (C and E) or BDNF-expressing (D and F) bone marrow stromal cells were loaded into the scaffold for implantation ("W" indicates scaffold wall). *BDNF*, Brain-derived neurotrophic factor; *SEM*, scanning electron microscopy. *From Gao M, Lu P, Bednark B, Lynam D, Conner JM, Sakamoto J, et al. Templated agarose scaffolds for the support of motor axon regeneration into sites of complete spinal cord transection. Biomaterials 2013;34(5):1529–36, with permission.*

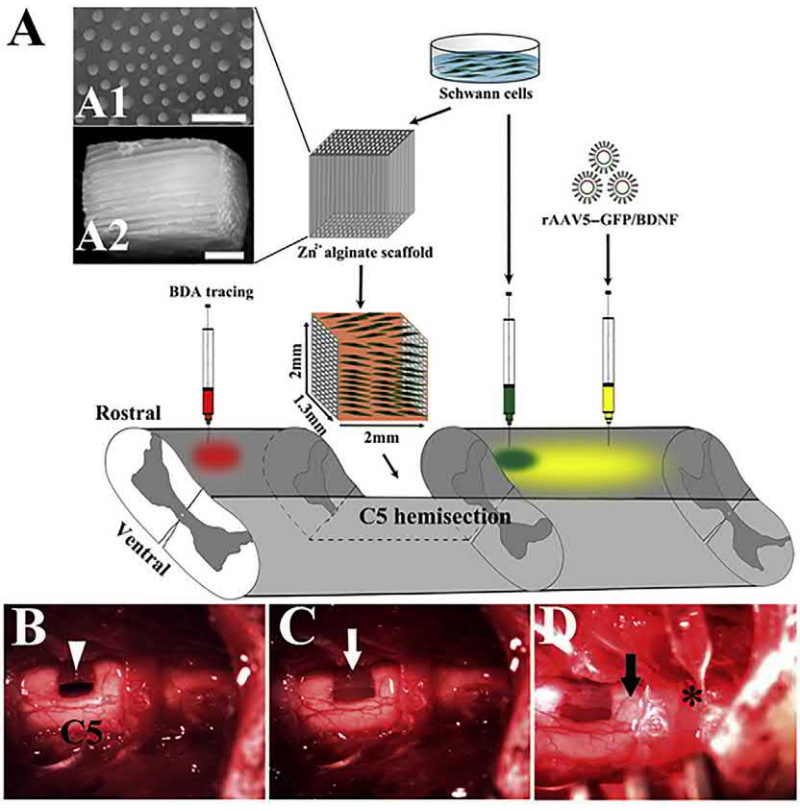

FIGURE 58.12 Alginate scaffolds. (A) A combinational approach is exemplified through the implantation of an SC-seeded alginate capillary hydrogel into a C5 dorsal hemisection injury. AAV5 serotype viral vectors (yellow) were injected into the adjacent caudal spinal cord for the expression of GFP or BDNF. Additional SCs (blue) were also injected into the adjacent cord. BDA (red) was injected rostrally for anterograde axonal tracing of descending axons. (B–D) A 2 mm hemisection (B) is grafted with the SC-loaded scaffold (C), and SCs and virus were injected into the spinal cord were indicated by the arrow and asterisk, respectively (D). *AAV*, adeno-associated virus; *BDA*, Biotinylated dextran amine; *BDNF*, brain-derived neurotrophic factor; *SCs*, Schwann cells. *Adapted from Liu S, Sandner B, Schackel T, Nicholson L, Chtarto A, Tenenbaum L, et al. Regulated viral BDNF delivery in combination with Schwann cells promotes axonal regeneration through capillary alginate hydrogels after spinal cord injury. Acta Biomater 2017;60:167–80, with permission.*

formulated as a topical gel, chitosan was shown to conform well to the shape of a transection injury [183,184] and to mediate secondary injury mechanisms, including suppression of reactive oxygen species [185]. Neural progenitor cells survived subcutaneous transplantation and differentiated within a chitosan gel [186], and MSCs were encapsulated and delivered into a complete transection for their paracrine activity and immunomodulation [63]. When chitosan was fabricated as a conduit, transplanted NSCs differentiated into astrocytic and oligodendrocyte lineages in the spinal cord to form regenerated tissue bridges [187,188]. These studies subsequently led to the key observation that a biomaterial could modify the distal and proximal stumps of a severe transection injury by inducing the alignment of endogenous radial glial cells for axonal guidance into the conduit [189].

Chitosan has proven to be a particularly versatile material for polymer-mediated delivery of molecular therapeutics, including modification as a carrier for PLGA microspheres eluting protein [190], and for neurotrophic factor elution to induce stem cell differentiation [191,192]. Recently, a chitosan conduit that eluted NT-3 provided for robust migration of endogenous neural progenitor cells from the adjacent cord into the lesion area, along with their differentiation into neural networks of ascending and descending tracts [193]. The findings of this key study, that endogenous neurogenesis could be elicited by the biomaterial, were then robustly validated in a second study, confirming anatomic bridging of neural tissue, locomotor recovery, and partial restoration of motor and sensory evoked potentials [194] (Fig. 58.13). Other investigators have used chitosan for exogenous neural progenitor cell delivery and differentiation aided in part by cyclic adenosine monophosphate (cAMP) elution from PLGA microspheres embedded within the conduit [186,195,196] (Fig. 58.14). Reformulations of chitosan as hydrogels and sponges have been successful in encapsulating MSCs as a source of paracrine trophic factor support [63,197] and as a reservoir of OPCs for axonal remyelination after injury [198]. A large animal primate study bridged a 1 cm thoracic cord hemitransection with an NT-3 eluting chitosan conduit, demonstrating motor and sensory functional recovery in addition to electrophysiologic and magnetic resonance imaging improvements with neural regeneration [199]. For molecular therapies, microglial activity has been targeted with small inhibitory RNA [200] and microRNA-based strategies [201] by eluting from chitosan nanoparticles.

Natural silk fibroin, including Tussah silkworm silk, *Antheraea pernyi* silkworm and *Bombyx mori* silkmoth fibers [252], have been used in biomaterial scaffolds for SCI repair as copolymer systems [202]. Silk fibers

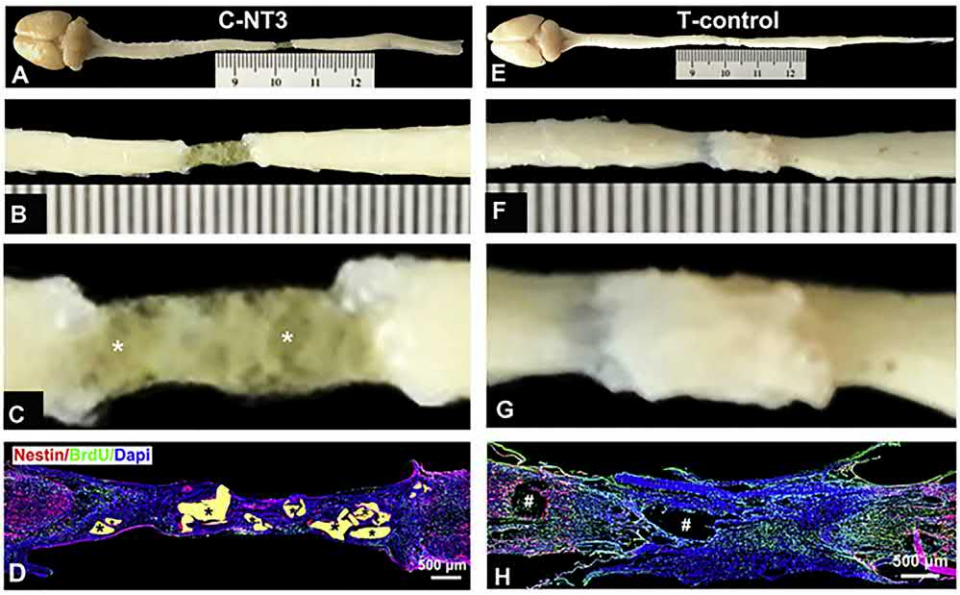

FIGURE 58.13 Validation study of NT-3 releasing chitosan scaffolds. Chitosan tubes filled with NT-3 releasing chitosan carriers were implanted into a 5 mm long segmental transection injury. Gross morphology demonstrated differing appearances of tissue cables after 3 months across the transection gap in animal receiving NT-3 scaffolds (A–D) and animals without implants (E–G). Longitudinal immunohistochemistry identified neural tissue with nestin, Tuj-1, and NeuN positive cells within the NT-3 supported tissue bridging. This key validation study indicated that NT-3 releasing scaffolds could facilitate neural regeneration by eliciting endogenous neurogenesis. Asterisks denote residual chitosan NT-3 carrier; number signs denote open cysts in control animals. *NT-3*, Neurotrophin-3. *From Oudega M, Hao P, Shang J, Haggerty AE, Wang Z, Sun J, et al. Validation study of neurotrophin-3-releasing chitosan facilitation of neural tissue generation in the severely injured adult rat spinal cord. Exp Neurol 2019;312:51–62, with permission.*

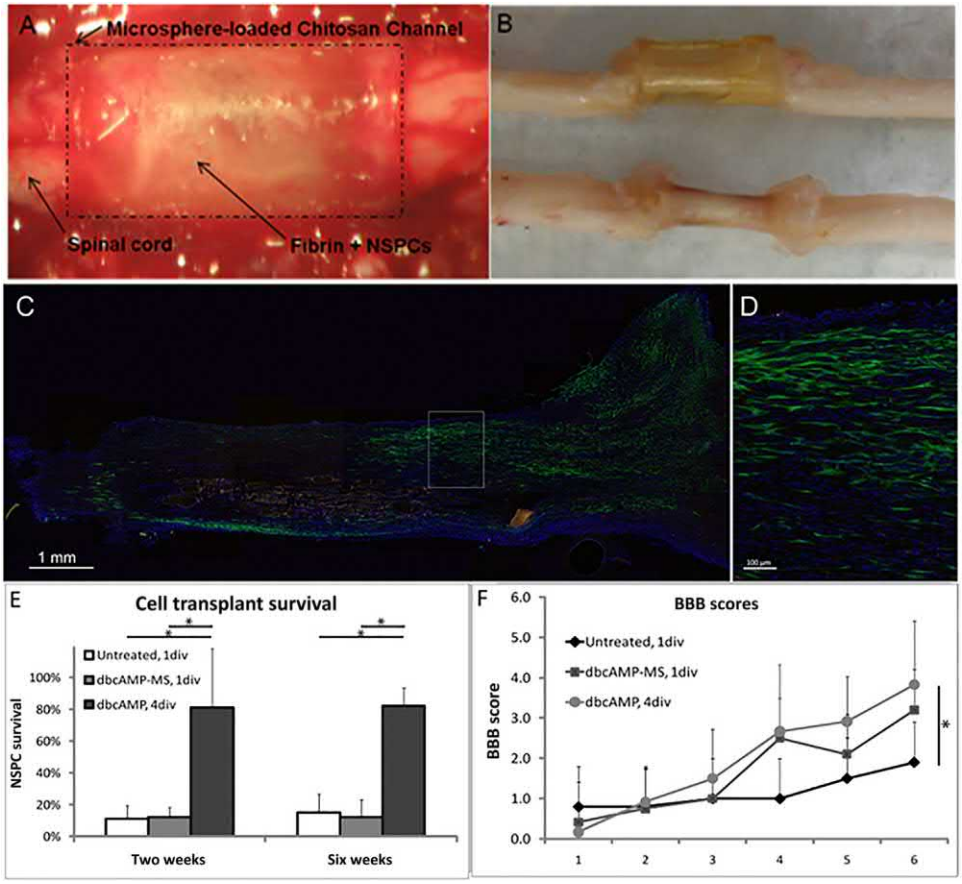

FIGURE 58.14 **Chitosan scaffolds and stem cell transplantation.** A chitosan conduit facilitated spinal cord tissue bridging, NSPC survival, and locomotor behavioral improvement over time. (A) Photographs of the surgical implantation of chitosan channels filled with fibrin and NSPCs also demonstrate (B) the formation of tissue bridges in completely transected animals 2 weeks after implantation. (C and D) Longitudinal section of the tissue bridge confirmed NSPC survival after 6 weeks in an animal receiving cells that were pretreated for 4 days with dbcAMP (dbcAMP, 4div). (E) NSPC survival after 2 and 6 weeks is represented for various treatment groups, comparing pretreatment with NSPCs transplanted in the presence of blank (untreated) or dbcAMP-releasing MS embedded into the scaffold wall after 1 day (1div) of incubation. (F) Assessment of functional recovery was performed according to the BBB locomotor scale. After 6 weeks, rats receiving transplants of dbcAMP-pretreated NSPCs show a statistically significant increases in hindlimb function relative to untreated animals. *BBB*, Basso, Beattie, and Bresnahan; *dbcAMP*, dibutyryl cyclic adenosine monophosphate; *MS*, microspheres; *NSPC*, neural stem/progenitor cell. *From Kim H, Zahir T, Tator CH, Shoichet MS. Effects of dibutyryl cyclic-AMP on survival and neuronal differentiation of neural stem/progenitor cells transplanted into spinal cord injured rats. PLoS One 2011;6(6):e21744, with permission.*

provide bioactive cues by means of structural tripeptide repeats. The use of silk in animal models of injury follows several years of in vitro characterization, to define the extent to which fibers could support longitudinal neurite outgrowth [253], and determine how cells might behave on the fiber surface [254]. The guidance of migrating olfactory ensheathing cells [255–257] and differentiation of stem cells [258] have been of particular interest. Silk may also be used by dissolving fibers in aqueous solution and conforming against a shaped surface for freeze–drying. Combinations of silk fibers with alginate microspheres for GDNF [203] or NGF release [204] by seeded MSCs enhanced the sparing of spinal cord tissue and improved the number of surviving neurons. Silk fiber matrices themselves can incorporate growth factors as they form in aqueous solution and may be applied as bioactive films onto the surfaces of other polymers. Sustained release of NT-3 from silk films lining a conduit of the synthetic polymer poly-ε-caprolactone (PCL) filled with NSCs yielded improved stem cell survival and rates of differentiation, axonal ingrowth, and functional outcomes after transplantation in a complete transection injury [205]. When recombinant analogs of the spider dragline silk spidroins were electrospun as a copolymer with PCL, the addition of neural progenitor cells promoted neural tissue ingrowth along parallel silk microfibrils, and neurogenesis from stem cell differentiation [206].

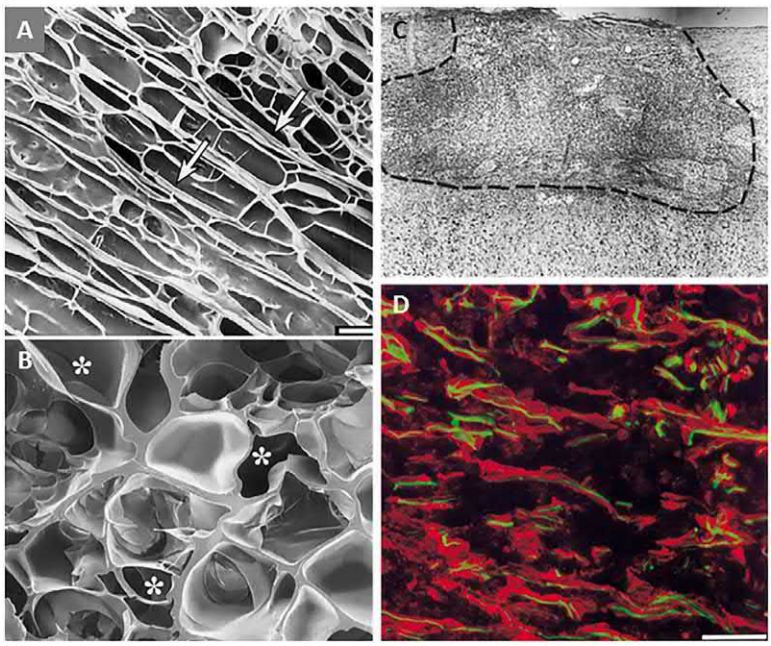

FIGURE 58.15 Fibronectin scaffolds. (A) SEM photomicrographs of a fibronectin mat detail longitudinally oriented strands of aggregated fibronectin (*arrow*). (B) In cross section, the strands form porous structures (*asterisks*) of approximately 20–100 μm in diameter. (C) Nissl staining of a fibronectin scaffold after 1 week post dorsal hemisection injury shows clean scaffold integration and cellular engraftment within the mat. Mats made from fibronectin support oriented growth of axons in the damaged spinal cord of the adult rat. Exp Neurol 2003;182 (2):383–98, with permission.*

Polymers derived from the blood

Biological matrices derived from blood, including frozen syngeneic peripheral blood, have been shown to support the formation of neural tissue, in addition to bone and cartilage tissues, when implanted in a complete spinal cord transection [259]. Fibronectin and fibrin, as two principle components of blood plasma matrices, are in use as spinal cord scaffolds. Their advantages include the ease of obtaining source materials as autologous grafts, as well as their inherent properties as fibrillary ECM proteins supporting cell adhesion, proliferation, and migration during provisional wound healing. Fibronectin mats have been produced with linearly aligned fibers to orient axonal outgrowth (Fig. 58.15), using embedded antibody therapies (transforming growth factor-β) [207] and sequestering neurotrophic factors (BDNF, NT-3) [208,209] within a porous architecture for slow release. Fibrinogen mat implantation supported axonal regeneration and deposition of laminin matrices around axons, the migration of endogenous SCs and OPCs with evidence of remyelination, and vascularization of the graft [210]. Additional benefits of neuroprotection were demonstrated with reductions in lesion size, rates of apoptosis in the adjacent cord, and secondary axonal injury following fibronectin mat placement into a hemisection injury [211]. Injectable formulations as fibronectin and fibrin copolymers also conformed well to laceration injury sites and supported axonal outgrowth [212].

Fibrin scaffolds are formed following the cleavage of fibrinogen by thrombin and cross-linking with Factor XIIIa [57,260]. The implantation of fibrin polymer scaffolds into a dorsal hemisection model delayed astrocytosis and gliosis of the adjacent cord, and improved neuron fiber extension into the graft [213]. The use of fibrin scaffolds as an affinity-based delivery system for molecular therapeutics in combinatorial approaches is a particularly powerful technology for spinal cord repair [261] (Fig. 58.16). Cross-linking heparin moieties [262] to fibrin through a Factor XIIIa-heparin bidomain peptide has allowed for the controlled release of noncovalently sequestered neurotrophic factors, including NT-3 [214,215], GDNF [216], and NGF [217,218]. The growth factors are slowly released via plasmin-mediated degradation of the fibrin scaffold by infiltrating cells. Codelivery of NT-3 from fibrin scaffolds improved neuronal fiber sprouting and reduced the extent of the adjacent glial scarring over controls in a complete transection model of injury [214,215]. Fibrin scaffolds have been used to direct embryonic stem cell–derived neural progenitor cell differentiation [219–221]. Controlled-release of trophic factors [222] enhanced transplanted stem cell survival and the efficiency of differentiation to neurons and other favorable cell types [223]. Additional stem cell enrichment using antibody selection to derive purer populations of progenitor motor neurons [224] yielded high rates of differentiation into neurons, oligodendrocyte, and astrocyte cell lineages when transplanted into a dorsal hemisection within an NT-3 eluting fibrin scaffold [225]. However, combination strategies with progenitor motor neurons and molecular approaches to reduce inhibitory factors in the cord, including controlled release of

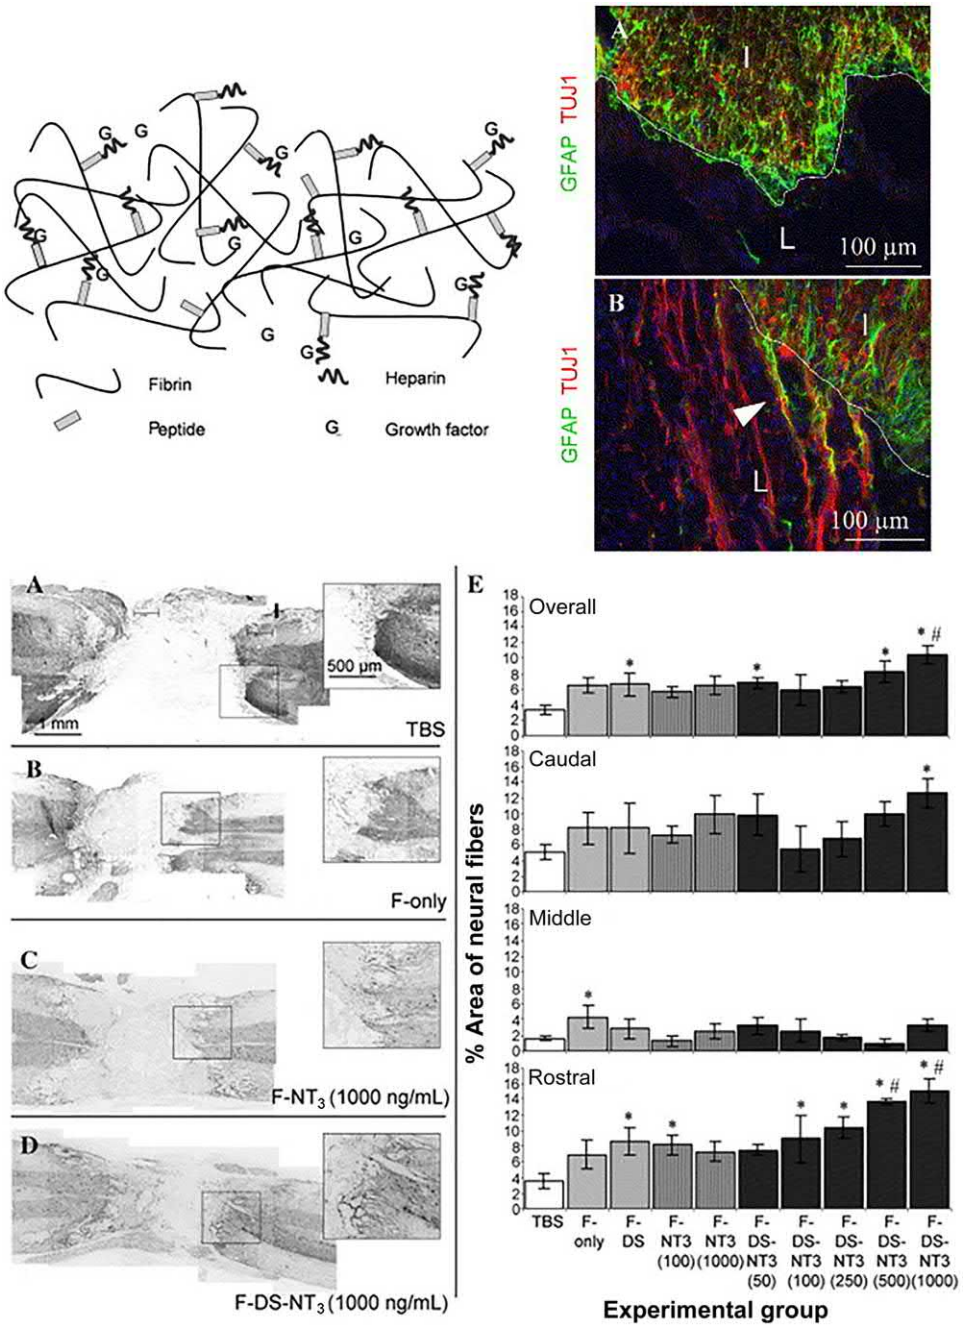

FIGURE 58.16 Fibrin scaffolds and the heparin binding delivery system. (Upper left panel) A schematic diagram of the heparin binding system details the covalent cross-linking of a bidomain peptide ($\alpha_2PI_{1-7}-ATIII_{121-134}$) with Factor XIIIa and electrostatic interactions with heparin at opposite ends of the molecule; heparin in turn sequesters a growth factor, which is slowly released upon degradation of the fibrin. (Upper right panel) Following complete spinal cord transection and placement of the fibrin scaffold alone (A) or with an NT-3 releasing system (B), neuronal fiber sprouting (red, Tuj1) (*arrowhead*) was observed to occur along an elongated astrocyte process (green, GFAP) in the NT-3 treated animal (*white dotted line*, lesion border). (Lower panels) Neuronal staining (Tuj1) (A–D) in transection only, fibrin only, fibrin with NT-3 dissolved at 1 μg/mL, and the heparin-fibrin DS with 1 μg/mL NT-3 demonstrated improved neuronal fiber sprouting with controlled release of NT-3 at higher loading doses, at various scaffold levels upon quantification (E). *DS*, Delivery system; *GFAP*, glial fibrillary acid protein; *I*, intact cord; *L*, lesion; *NT-3*, neurotrophin-3. *Adapted from Taylor SJ, Sakiyama-Elbert SE. Effect of controlled delivery of neurotrophin-3 from fibrin on spinal cord injury in a long term model. J Control Release 2006;116(2):204–10, with permission.*

ChABC and the NOGO receptor antagonist NEP1-40, appeared to increase macrophage infiltration into the graft and reduced stem cell survival [226]. Several highly promising approaches to select for other specific neuronal lineages from stem cells, including V3 [263] and V2a interneurons [264], could be combined with biomaterials for transplantation to reduce teratoma formation risks from undifferentiated cells, and promote improved differentiated cell survival and function in vivo [265].

Biomaterials for spinal cord tissue engineering: synthetic polymers

Compared to natural polymers, the use of synthetic polymers offers wider scope to design and control multiple characteristics of the biomaterial. Synthetic polymers may have varying degrees of biodegradability. Common biodegradable materials include those designed around polyesters of lactic and glycolic acid (PLA and PGA), or

hydrogels based on a polyethylene glycol (PEG) chemical structure. Hydrogels that are based upon methacrylates typically do not biodegrade well. PLA and PGA were among the first materials used in the field, in part because they had a long track record of established safety in other clinical applications, including as absorbable sutures, as skin grafting materials, and as conduits for peripheral nerve repair [266,267]. Rapid advances in the development of hydrogels, in their chemical and structural versatility, have produced softer materials which are more suitable to spinal cord implantation in their mechanical properties than more firm and less aqueous lactic and glycolic acid polyester materials. Synthetic polymers have wider scope than natural polymers for chemical functionalization, including surface gradients of ECM or integrated neurotrophic factor gradients, and surface charge modification for cell adhesion and controlled release. A wide range of novel mechanisms for drug delivery and provision of molecular or genetic therapies have been highlighted. Complex surface topographies have been produced to optimize macro- and microarchitecture features through sophisticated molding or lithography techniques.

Poly α-hydroxy acid polymers

PLA, PGA, and their copolymer PLGA are polyester linkages of lactic and glycolic acid, which are hydrolyzed in vivo to release lactide and glycolide. PLA was among the first biomaterials used for SCI repair, characterized in a seminal study in 1998 to be a resorbable material that was compatible with SCs and with the spinal cord [268]. A single-channeled PLA scaffold loaded with SCs was then used within a complete transection model [269], demonstrating that axons and a vascular bed could regenerate into the construct, despite some degree of structural instability of the scaffold itself. A freeze−drying technique was then used to fabricate longitudinally aligned pores from a PLA foam impregnated with BDNF for sustained release. BDNF did not improve a relatively low yield in axon numbers [270]. Further modifications were made to incorporate SCs into the foam that had been genetically engineered to secrete a bifunctional neurotrophic protein (D15A) with BDNF and NT-3 activity [271]. Axonal regeneration was demonstrated over 6 weeks, while few SCs survived after the first week of scaffold placement. More recently PLA scaffolds with highly refined porosity and nanofibrous surface topographies have been developed, promoting neurite extension along the microarchitecture after complete transection [272] (Table 58.4).

The use of PLA alone has been superseded by scaffolds fabricated from the copolymer PLGA, which remains among the most widely used materials for single and multichannel spinal cord scaffolds and for controlled release of biological and small molecule therapeutics [273]. Initial studies demonstrated that multichannel PLGA scaffolds supported robust axonal regeneration when seeded with SCs, initially without functional improvements [274] (Fig. 58.17). The in vitro biomechanical characteristics of bending, swelling, deformation, degradation, and permeability of varying PLA:PGA ratios were subsequently determined for PLGA spinal cord scaffolds implants [275]. Surgical techniques for implanting these scaffolds with and without rigid spine fixation were optimized following complete spinal cord transection [276], and it was shown through fast blue retrograde tracing studies that regenerating axons traversed the length of the scaffold and extended into the opposite spinal cord [277]. Unmodified SCs, transplanted in PLGA in association with recombinant NT-3 injection into the caudal cord, improved functional recovery after complete transection [278]. Seeding scaffolds with SCs within PLGA multichannel augmented the number of regenerating axons when compared directly to NSCs [279,280]. Additional studies have explored the impact of NSCs in large animal models [281], and stem cell differentiation in vivo on electrospun PLGA copolymer nanofiber conduits [282]. MSCs have also been delivered from PLGA conduits [283] and microfiber mats [197].

The rate at which these PLGA scaffolds will dissolve can be controlled by modifying the proportions of lactic-to-glycolic acid, with an 85:15 PLA to PGA degrading significantly more slowly than a 50:50 ratio. This property in particular has extended the use of PLGA from being a physical conduit toward its principle, contemporary use in nanosphere or microsphere technologies for controlled release of therapeutic molecules (Fig. 58.18). Micro- and nanospheres are produced by microemulsion techniques, where an aqueous solution containing the molecule intended for delivery is emulsified in an organic phase polymer solution to create spherical droplets, which are then extracted into another external aqueous phase [333] and dried. The size of the droplet is controlled by the emulsion agitation rate, the composition of the aqueous and organic phases, and the addition of surfactants to modify the surface tension between the phases [72]. Other techniques include freeze−drying of aerosolized droplets. The rate of drug delivery depends on the initial concentration within the sphere, and the size of the sphere for a given polymer and its degradation kinetics.

Drug-eluting nano- and microspheres been used to deliver neurotrophic factors, including NT-3 and GDNF [273,284], biomolecules to modulate the immune response and wound healing, including methylprednisolone and minocycline [285], flavopiridol [286], FGF-2 [287,288], and to promote angiogenesis [289]. The particles may be injected as a suspension into a contusion or

hemisection defect, or can be suspended in a scaffold of another material such as alginate [164] and chitosan [190]. The delivery of genetic therapies by viral [240] and nonviral PLGA composites are also being explored to transduce the local spinal cord tissue to overexpress neurotrophic factors and angiogenic factors [132,290] (Table 58.4).

PCL is a relatively stiff biodegradable material, favored for its ease of use in electrospinning techniques [291], and in microgrooved topographies in flat and rolled−spiral sheets [76,292] to longitudinally orient axonal extension. PCL has been shown to be more effective as a scaffold material after such modifications are made to the microarchitecture. PCL nanofibrous scaffolds incorporating immobilized BDNF have also been used in the setting of in vitro NSC differentiation [293], the delivery of NSCs into a hemisection model in association with NT-3 overexpressing cells [294], and for the delivery of SCs with iPSC−NSCs [295]. Additional functionalization of microtubules of PCL with salt-leaching for porosity promoted axonal extension throughout the open volume of the graft [296]. A multichanneled scaffold fabricated from the PCL derivative, poly-ε-caprolactone fumarate (PCLF), loaded with SCs, was shown to have a comparable regenerative capacity to PLGA scaffolds, but was inferior to a PEG-based hydrogel [314] (Table 58.4).

PEG is a highly versatile, water-soluble, linear hydrogel polymer that has been extensively used in SCI repair in a variety of chemical formulations [334]. The principle applications have included being applied directly as an injectable gel to a spinal cord defect as a sealant or surfactant [298,299] (Fig. 58.19). PEG in this form may aid in the physical fusion of severed axolemma [335,336], as well as prevent free-radical membrane lipid oxidative stress through mitochondrial protection, and reduce calcium influx-mediated excitotoxicity [337]. Locomotor and electrophysiologic recovery after complete transection has been demonstrated using PEG as a "fusogen" to reappose the ends of the defect in rat [300] and canine models [301] and to direct long-distance axonal regeneration through the grafted area [302]. PEG sealants have also been used to encapsulate cells, including MSCs within complete transections [303], to grow neurons [304] and to differentiate NSCs [305]. Injectable PEG gels have delivered neurotrophic factors, including BDNF and NT-3 [306−308], PEGylated pharmacologics, including ionic magnesium [309,310], ECM proteins as molecular gradients [305], or copolymer systems for in situ gelation [338] (Table 58.4).

Solid phase, porous PEG-based polymers for the delivery of cells and neurotrophic factors have also been developed [304,339]. As an example that highlights several properties of PEG hydrogel scaffolds, the positively charged PEG derivative oligo[poly(ethylene glycol)fumarate] (OPF +) is a photo-cross-linked soft, porous, biodegradable hydrogel with biomechanical properties similar to spinal cord tissue [311,312] (Fig. 58.20). Implantation of OPF + scaffolds with and without SCs in Matrigel reduced collagen scarring, cyst formation and proteoglycan accumulation at the injury interface to the same extent over transection injury alone [313], indicating that the presence of the PEG-based scaffold itself may reduce the

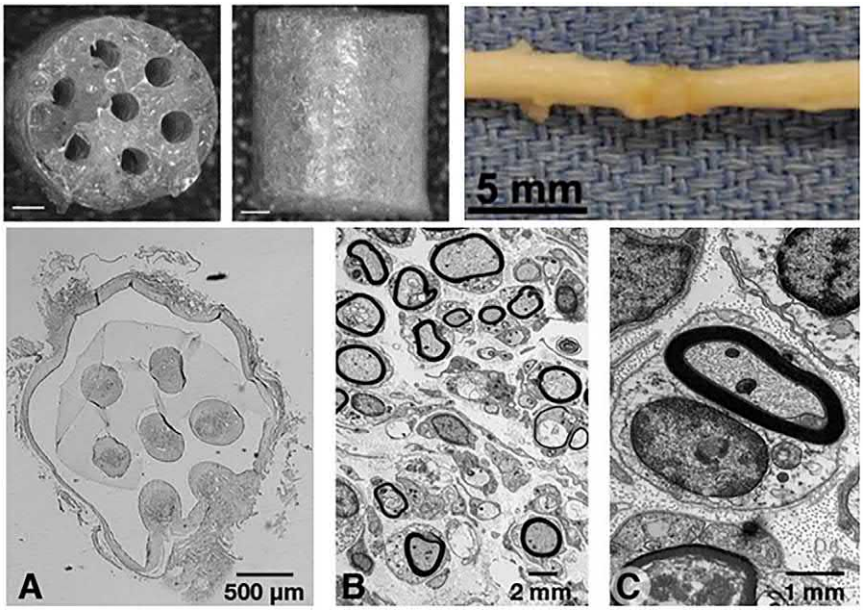

FIGURE 58.17 PLGA scaffolds. (Upper panels) A multichannel PLGA scaffold for placement into a complete transection in rats measures approximately 3 mm in diameter, 2 mm in length, and contains 7 parallel channels of 450 μm in diameter. The scaffold was loaded with Schwann cells, and integrated well between the free ends of spinal cord after 8 weeks. (Lower panels, A) Axons and blood vessels regenerated within a central core area within channels, which was circumferentially surrounded by more dense fibrotic tissue devoid of axons. Regeneration was observed both within and through the implant into the opposite cord tissue, as demonstrated by retrograde fast blue axonal tracing. (B and C) Schwann cells myelinated axons in a typical one-cell-to-one-axon ratio as seen by transmission electron microscopy, including extracellular deposition of collagen fibrils and basal lamina. *PLGA*, Poly(lactic-*co*-glycolic acid). *Adapted from Moore MJ, Friedman JA, Lewellyn EB, Mantila SM, Krych AJ, Ameenuddin S, et al. Multiple-channel scaffolds to promote spinal cord axon regeneration. formation of barriers to regeneration. Astrocyte infiltration and glial scarring were also reduced, consistent with the observations of others [340]. OPF+ scaffolds loaded with primary SCs improved axonal regeneration density over transplanted MSCs [41], and the accuracy of growth orientation when systematically compared to other SC-loaded polymer constructs [314] including PLGA and PCLF. OPF+ hydrogel scaffolds have also been designed to incorporated the antifibrotic drug rapamycin within PLGA microspheres, which reduced the foreign body inflammatory response and scar tissue formation and promoted partial functional recovery after 6 weeks [66]. SCs that have been genetically modified with retrovirus to secrete a high concentration of GDNF in hydrogel scaffolds further enhanced axonal regeneration, remyelination, and promoted the outgrowth of ascending intraspinal motor neurons through the polymer implant [48] (Table 58.4).

Nonbiodegradable hydrogels

Poly(2-hydroxyethyl methacrylate) (pHEMA) is a nonbiodegradable hydrogel used to fabricate soft contact lenses, and therefore has advantages in spinal cord repair

FIGURE 58.19 PEG as a fusogen. applications as a clinically-approved polymer. pHEMA and pHEMA-*co*-methyl methacrylate (pHEMA-MMA) have been extensively developed for use as spinal cord scaffolds. Early applications as pHEMA sponges placed into dorsal hemisections [315] soon evolved into multilayered guidance channels [316] which immobilized NGF [341] and BDNF [317] for sustained release and which had longitudinally oriented channels of tunable size created by templating the pHEMA over PCL microfibers [318]. Templated conduits were subsequently functionalized with ECM peptide gradients in a pHEMA copolymer system with 2-aminoethyl methacrylate [319] and in a methacrylamide-chitosan composite [250]. A variety of surface modifications improve cell adherence and axonal extension, including incorporation of poly(L-lysine) and gradients of NT-3 [320]. Microfluidic techniques were employed to create functional concentration gradients by casting the scaffold using two or more inlet ports for differential mixing coupled with rapid polymerization.

Modification of surface charge, with the addition of quaternary amine groups or of a second methacrylate subtype [321], is another approach taken to improve cell/neurite migration and encapsulation, as many cell types adhere better to a positively charged surface. Macroporous pHEMA scaffolds [322] were evaluated in a dorsal hemisection injury bridged with four pHEMA composites, demonstrating an improvement in axonal regeneration into the core of the scaffold and a reduction in astrocyte infiltration in the positively charged scaffold. Cell surface interactions in longitudinally

oriented macroporous scaffolds were further modified using pHEMA copolymers with cholesterol methacrylate and ethylene dimethacrylate [342], or with ECM peptides [323], to successfully bridge a hemisection cavity with regenerated neural tissue. ECM peptide scaffolds were subsequently loaded with MSCs in a complete transection model, with MSCs not improving the degree of tissue and axon infiltration [324]. Recently, positively charged pHEMA scaffolds, coated with laminin and loaded with iPSC-derived NPCs in a balloon compression model reduced the degree of cavitation, supported axonal sprouting and stem cell survival [325] (Table 58.4).

pHEMA-MMA formulations of conduits were produced using a liquid–liquid centrifugation casting technique to produce a gel-like outer layer and a macroporous inner layer [326] (Fig. 58.21). Long-distance axonal regeneration through a T8 thoracic transection was demonstrated, with retrograde tracing studies identifying several brainstem nuclei to be the neuronal source of some axons traversing the graft [327]. A similar casting technique was employed for sustained release of NGF from inner lumen coatings or embedded microspheres [328]. Further improvements in supraspinal neuronal regeneration were achieved by filling the conduit channels with extracellular matrices and soluble trophic factors (FGF-1 and NT-3). Structural instability of the channel architecture was addressed by coil reinforcement and polymer with greater elastic moduli [329], but densities of axons did not improve, and the more rigid scaffold lead to

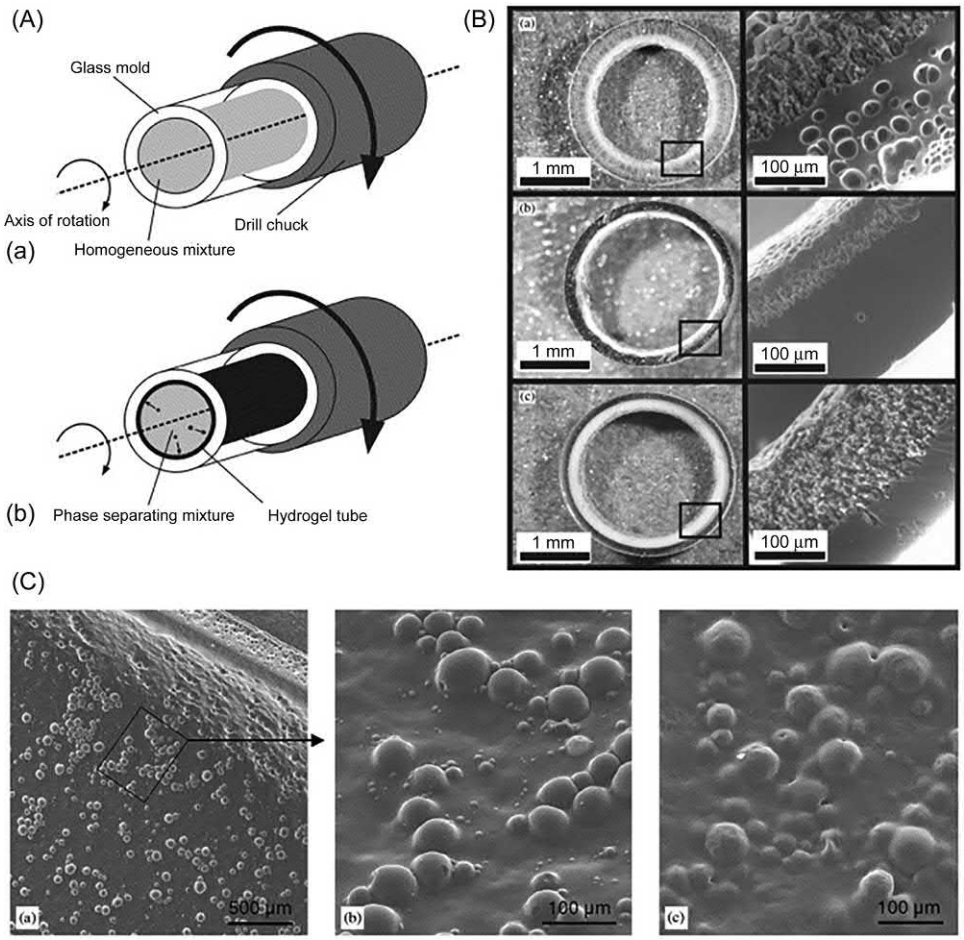

FIGURE 58.21 pHEMA tubes as copolymers with MMA. (A) Liquid–liquid phase separations in spinal cord conduit manufacture are produced by rotational force, (B) creating multiple layers of varying polymer porosity which dependent upon the concentration of MMA added to the pHEMA monomer mixture [in (B), 25% monomer that includes (a) 5% MMA, (b) 7% MMA, and (c) 10% MMA]. (C) NGF releasing PLGA microspheres were cast against the inner surface of the conduit lumen by a similar method, using pHEMA-MMA channels coated with an inner layer of pHEMA and 1 wt.% PLGA 85/15 microspheres: (a) at 40× magnification for a 5 wt.% pHEMA layer; (b) a close-up of (a) at 220× magnification for a 5 wt.% pHEMA layer; and (c) at 200× magnification for a 10 wt.% pHEMA layer by SEM. *MMA*, Methyl methacrylate; *NGF*, nerve growth factor; *pHEMA*, poly(2-hydroxyethyl methacrylate); *PLGA*, poly(lactic-*co*-glycolic acid); *SEM*, scanning electron microscopy. *Adapted from Dalton PD, Flynn L, Shoichet MS. the development of syringomyelia and caudal migration of the rostral stump in some transected animals (Table 58.4).

Poly[*N*-(2hydroxypropyl)methacrylamide] (pHPMA) represents an additional methacrylate based polymer with more limited use for SCI repair. Early work demonstrated the capacity of a colloid pHPMA gel, with [330] or without [331] the incorporation of ECM peptide, to support regeneration when injected into a complete transection defect. When formulated as a hydrogel block, insertion of pHPMA into a thoracic hemisection improved animal locomotor scores and electrophysiologic parameters over controls in addition to supporting axonal regeneration within the hydrogel matrix [332] (Table 58.4).

Conclusion and future directions: the promise of clinical translation

SCI remains a devastating medical condition, with one-third of patients never to recover any neurologic function below a complete injury, and two-thirds of patient living with severe debility. With no effective clinical treatments beyond the acute phase of injury, tissue engineering to regenerate functional spinal cord tissue is poised to be a therapeutic intervention in the subacute to chronic phases. Remarkable progress over the last 20 years has been made using biomaterials to restore spinal cord neural tissue and to improve motor, sensory and autonomic nerve function in animal models, progress which has accelerated over the last 10 years. Engineering principles of material compatibility, macro- and microengineering strategies, and the ability for bridging biomaterials to deliver cellular and molecular therapeutics in combinations, have begun to effectively address the complexity of the injury process as a physical, cellular, and molecular continuum of barriers. This chapter has highlighted current strategies in a range of natural and synthetic polymers and their functionalization.

The ultimate goal of tissue engineering for spinal cord repair is to develop patient-specific therapies to facilitate functional recovery in injured people. Current Good Manufacturing Practices (cGMP) protocols and Investigational New Device and Device Exception applications within the United States Department of Health and Human Services Food and Drug Administration (FDA) are appropriately robust to ensure scientific rigor and patient safety. They are also compatible with the development of first-in-human trials along defined regulatory pathways [343]. Currently, an FDA-approved, multicenter clinical trial (NCT02138110, The INSPIRE Study) is evaluating the safety of implanting a PLGA biomaterial scaffold into spinal cords of patients with complete thoracic (AIS-A) SCI [344]. This study in turn will have implications for additional scaffold-based clinical trials with other polymer types and with biomaterial, cellular, and molecular therapeutics. Scaffolds in combination with autologous transplantation of patient derived SCs may be the logical next step, given the pioneering work of investigators at the Miami Project to Cure Paralysis to establish cGMP standard operating procedures for SC isolation from patient nerve biopsy specimens. The feasibility and safety of using autologous human SCs in Phase I (NCT01739023, NCT02354625) clinical trials for subacute and chronic SCI has been demonstrated [345], paving the way for the first-in-human combinatorial biomaterial trials for SCI.

Introduction

Deafness is the United States' primary disability, with hearing loss affecting more than 35 million individuals. The cause of hearing loss can generally be divided into two major categories: genetic hearing loss and acquired hearing loss. Genetic hearing loss is commonly separated into syndromic and nonsyndromic hereditary hearing loss [1−3], while acquired hearing loss can be caused by numerous etiologies accumulated over a lifetime, such as exposure to excessive noise, the use of ototoxic medications, bacterial or viral ear infections, head injuries, and the aging process. Importantly, these effects may coexist and thereby confound investigations in both animal models and humans. With our increasing aging population, age-related hearing loss (ARHL, presbyacusis) becomes a common problem in the elderly population, affecting one in three individuals over the age of 65 and 50% of individuals over the age of 75.

An improved understanding of the mechanisms underlying genetic, acquired, and "mixed" deafness has driven the development of new interventions and treatments as well as the refinement of previous approaches to prevent hearing loss and restore hearing after deafness. Hearing loss induced by cochlear damage from overstimulation, ototoxic drugs, trauma, infections, and/or aging can be reduced by reducing oxidative stress to the cochlea with antioxidants and enhancing endogenous protective systems with agents such as neurotrophic factors and HSPs. Treatment with antiinflammatory agents can also reduce acquired hearing loss. Genetic modification has now been successful in animal models and may become clinically feasible, with development of safe and effective vectors to treat genetic hearing loss as well as induce regeneration of hair cells. Placement of exogenous stem cells and transdifferentiation of endogenous cells is being developed as a strategy to replace lost hair cells or auditory nerve (AN) and to supplement remaining function. Survival and growth factors can be applied to the cochlea to improve AN survival following deafness and to induce the regeneration of its peripheral processes. Major advances have also been made in region specific delivery of therapeutics to the cochlea to allow these interventions, including gene transfer, microcannulation, and biomaterials placed into the middle ear or directly into the cochlea. Auditory prostheses are being refined, with significant improvements occurring in cochlear prostheses as well as in development of central auditory prostheses. Prostheses can also be engineering for application of therapeutics through microchannels. Biomaterial on prostheses can not only improve function and histocompatibility but also provide a means for delivering therapeutics. Artificial cochleae capable of transforming sound-induced movement of cochlear fluids into electrical signals are also being developed. The strategies for tissue engineering interventions based on recent scientific discoveries are the focus of this chapter. The chapter will examine interventions for protection from acquired sensory cell hair cell loss as well as loss of sensory cell—AN connections as well as for genetic hearing loss. It will then examine interventions for repair and replacement.

Protection from "acquired" sensory hair cell loss

While there may be some common mechanisms underlying the loss of sensory cells from noise, drugs, aging, and other cause of acquired deafness, there may also be

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00061-7

differences. The following section will also focus on the underlying mechanisms that have given rise to therapeutic interventions against noise-induced and drug-induced hearing loss.

Oxidative stress and stress-related mitochondrial pathways

Oxidative stress, the overproduction of reactive oxygen species (ROS; free radicals) in the cell, has now emerged as a common mechanism for many traumatic insults, including noise and ototoxic drugs. In an unchallenged cell, ROS are products and by-products of normal metabolism and contained within a physiological range (redox homeostasis) by endogenous antioxidant systems. However, an excess of ROS will cause cellular damage, ultimately triggering cell death pathways of apoptosis and necrosis. The formation of ROS, such as superoxide, hydroxyl radical, and nitric oxide, may occur by different mechanisms depending upon the stress, but in each instance it appears early and continues throughout the traumatizing events. ROS can be formed by nonenzymatic reactions via redox-active iron complexes of drugs [4,5] and by enzymatic reactions in the cell. On the cellular level, oxidative stress may originate in the mitochondria [6,7] or may be due to the activation of NADPH oxidase via Rho-GTPases, a primary source of superoxide radicals [8–10]. Furthermore, overproduction of ROS may result in transient cellular energy depletion as documented by increased p-AMPKa in sensory hair cells [8,9,11]. Because a cellular redox-imbalance can be influenced by external manipulations, ROS-mediated hearing loss is a potential target for interventions to prevent hearing loss.

Calcium influx

Dysregulation of cytosolic calcium homeostasis is involved in noise- and aminoglycoside-induced hearing loss. Noise exposure increases free Ca^{2+} in outer hair cells (OHCs) immediately after acoustic overstimulation, mainly through mechanoelectrical transduction channels, but liberation from intracellular stores might also contribute [12]. Calcium influx appears to be associated with exposure at higher noise intensities. Guinea pigs exposed to 110-dB sound pressure level (SPL) noise displayed increased free calcium in isolated OHCs followed by OHC death and hearing loss, while a nonpathologic sound level of 75-dB SPL did not alter intracellular calcium levels [13]. Further evidence of modulation of intracellular Ca^{2+} levels after noise exposure can be deduced from an increase in the Ca^{2+}-binding protein calmodulin (CaM), a critical mediator of calcium signaling [13]. In addition, influx may be linked to increased endolymphatic calcium levels, which generates a high concentration gradient, driving calcium into sensory cells through voltage-gated calcium channels (VGCCs), particularly in inner hair cells (IHCs) [14]. These elevated calcium levels may contribute to sensory hair cell death via triggering of mitochondria-mediated caspase-dependent cell death pathways in sensory hair cells [15,16]. Furthermore, the mitochondrial calcium uniporter (MCU), which is a specific calcium channel in the mitochondrial inner membrane, affects the cell sensitivity to apoptosis through regulation of calcium uptake [17,18]. An elevation of MCU and reduction of Na^{+}/Ca^{2+} exchanger (NCLX) (sodium calcium exchanger), which extrudes calcium from mitochondria, leads to calcium overload in mitochondria, and initiates the loss of IHC synaptic ribbons and OHCs during noise exposure [19]. As another potential mechanism, calcium overload in IHCs can stimulate the excessive release of the neurotransmitter glutamate. The overactivation of glutamate receptors then causes excitotoxicity. Finally, the endoplasmic reticulum (ER) is a major subcellular compartment for intracellular calcium stores, and ER stress–mediated apoptosis has been associated with noise-induced, ototoxic drug-induced hearing loss, or ARHL [20–23].

Endoplasmic reticulum stress

In addition to being an intracellular calcium store the ER is involved in the process of protein folding and transport. Perturbations in protein-folding capacity caused by hypoxia, starvation, or ROS lead to ER stress [24–27]. When the stress response is initiated, cells can reduce the synthesis of general proteins through the activation of the unfolded protein response and induce the formation of intracellular synthetic molecular chaperones to restore proteostasis [28–30]. When the stress overwhelms the protective capacity of the unfolded protein response (UPR), the accumulation of unfolded or misfolded proteins can result in induction of ER-related apoptotic pathways. Under intense noise exposure the UPR does not completely eliminate misfolded proteins, ultimately activating ER-related apoptosis [31]. The expression of ER-related proapoptotic factor C/EBP homologous protein is increased in the cochleae of aged mice, indicating that ARHL may be related to ER stress [22].

Prevention of ototoxicity

Aminoglycoside antibiotics, including neomycin, kanamycin, tobramycin, amikacin, gentamicin, and the chemotherapy anticancer agent cisplatin (CDDP), are the most commonly used drugs that cause the loss of hair cells and consequently of hearing (ototoxicity). Although this review will emphasize the cochlear effects of ototoxic agents, we should note that aminoglycosides can also

cause vestibular toxicity resulting in the loss of balance. In accordance with the stress responses outlined above, ROS increase significantly in inner ear tissues following aminoglycoside treatment both in organ explants and in vivo [4]. Conversely, cellular antioxidant defense system constituents, such as glutathione, decrease after aminoglycoside treatment [32].

The redox imbalance resulting from increased ROS production and decreased antioxidant function then initiates competing signaling pathways of cell death and survival, involving intracellular organelles such as mitochondria and lysosomes and a network of interfacing signaling systems based on enzymatic actions (e.g., activation of proteases) and changes in gene expression (e.g., via transcription factors or epigenetic modifications). Indicative of this complexity, cell death from aminoglycosides includes both apoptosis and necrosis of hair cells in cochlear and vestibular organs [5,33,34]; and both caspase-dependent and -independent pathways appear to contribute to hair cell pathology [35,36]. The proapoptotic mediator c-Jun NH2-terminal kinase (JNK) is often involved, since pharmacological inhibitors (e.g., CEP-1347) can offer some protection in vitro from aminoglycoside damage [37,38]. Like the caspase pathway, involvement of the JNK pathway is reported mostly in cultured explants but may contribute to the overall pattern of cell death in vivo. A dominance of caspase-independent cell death emerges in a chronic kanamycin-treated mouse model, where the onset of cochlear functional deficits is delayed and continues to develop after the cessation of treatment, akin to the clinical situation. In this model, activated calpain and cathepsins are the major mediators of cell death [10]. Impacting a different pathway to cell death, the autophagy activator rapamycin prevents CDDP and gentamicin-induced hair cell apoptotic processes through the induction of autophagy and elimination of oxidative stress, while autophagy inhibitor 3-methyladenine (3-MA) accelerates hair cell apoptosis via the suppression of autophagy [39,40]. More recently, inhibitors of histone deacetylation have emerged as promising candidates for intervention. Histone deacetylase (HDAC) inhibitors, trichostatin and butyrate, can reduce gentamicin ototoxicity in explants by inhibiting the epigenetic histone modifications induced by aminoglycoside treatment [41]. Furthermore, the FDA-approved HDAC inhibitor vorinostat (SAHA) attenuates gentamicin-induced hair cell loss in explants [42] and in an acute mouse model in vivo [43]. However, it is not effective in chronic in vivo ototoxicity models using gentamicin in guinea pigs or kanamycin in mice [42], underscoring the complexity of translating preventive intervention from in vitro to in vivo models, let alone from animal models to the clinic.

Nevertheless, understanding of the mechanisms underlying both apoptotic and necrotic cell death in ototoxicity is the best basis for rational approaches to prevention. For example, small synthetic molecules designed to inhibit one of the many steps in the apoptotic cascade can potentially stave off cell death. For a clinical application, however, a systemic application of such powerful signaling molecules may have far-ranging physiological consequences, particularly when applied to antibiotic treatment, which may last for weeks or, in the case of tuberculosis, for months. Local gene therapy, the process of virally introducing a potentially protective gene locally into a tissue, may be more suitable in such a situation [44]. However, given the complexity of cell death mechanisms, targeting a single pathway may not be sufficient, as the inhibition of one might be bypassed by the activity of others. Furthermore, susceptibility to ototoxicity can be influenced by factors such as diet [32,45] or genetic predispositions, such as the mitochondrial mutations that can render people hypersensitive to aminoglycosides [46].

Currently, the most applicable method of prevention is antioxidant therapy, which has become a successful clinical approach for pathologies that involve free radicals. This type of intervention would act directly on the ROS upstream of the ensuing cell death pathways and therefore suppress toxic mechanisms at the very onset. A wide variety of antioxidant molecules have been shown to attenuate ototoxicity in vivo, constituting the most compelling support for ROS as major mediators of aminoglycoside-induced hearing loss [47–49]. Further support for the ROS is found in the mitochondrial peroxiredoxin 3 (Prx3); the radical scavenger *p*-phenylenediamine attenuates gentamicin-induced hair cell death through maintenance of Prx3 levels [7]. The attenuation achieved with various antioxidant treatments in animal models can be dramatic. For example, a gentamicin-induced hearing loss of 60–80 dB could be reduced to a negligible loss of 10 dB or less [47]. Since neither the serum levels of the drugs nor their antibacterial efficacy are compromised, antioxidant therapy provides a promising approach for clinical application.

A clinically feasible prophylactic therapy requires drugs that by themselves are nontoxic and easily administered to patients. One such example that emerged from laboratory studies is salicylate, the active ingredient of aspirin [50]. The efficacy of aspirin was tested in a randomized double-blind and placebo-controlled study in patients receiving gentamicin for acute infections [51]. Fourteen of 106 patients (13%) met the criteria of hearing loss in the placebo group, while only 3 out of 89 (3%) sustained a hearing loss in the aspirin group, for a 75% reduction in the incidence of ototoxicity. Aspirin did not influence the course of therapy. The protection from gentamicin-induced hearing loss with aspirin was confirmed by a second clinical trial [52]. Although aspirin is widely used in the United States as daily prophylaxis

against myocardial infarction, as well as for treatment of inflammation, fever, and pain, aspirin carries with it a small risk of reversible gastrointestinal side effects. Other antioxidants utilized in clinical trials to date include vitamin E and *N*-acetylcysteine (NAC). NAC reduced hearing losses in a small study of patients receiving gentamicin for bacteremia and in a study of peritonitis patients receiving aminoglycosides for peritoneal dialysis [53,54]. In contrast and despite success in animal studies, vitamin E did not reduce hearing loss in a small clinical study, underscoring the complexity of aminoglycoside responses in humans and the potential pitfalls of translation of animal studies to clinical medicine [55]. CDDP also generates ROS as well as reactive nitrogen species (RNS) in the cochlea, and several antioxidants have been shown to provide protection from CDDP-induced ototoxicity, including L-methionine, NAC, glutathione, and ebselen [56]. A potentially confounding factor is the propensity of some antioxidants to mitigate the efficacy of CDDP cancer treatments. An appropriate choice of the preventive agent or local cochlear application may circumvent this problem [57,58].

Prevention of acoustic trauma

The mechanisms of acoustic trauma-induced pathology may be more complex than those of drug-induced ototoxicity, as they include not only the formation of ROS but also calcium influx, vasoconstriction, and direct mechanical damage to the organ of Corti at higher intensities [59,60]. In addition, the sources of noise trauma can be highly variable, ranging from impulse noise in form of a single, high-energy burst, such as an explosion to chronic noise exposure at various levels of intensity. These conditions may induce different variations of stress or variations in the response of cell death and survival pathways. Furthermore, while a protective antiototoxic therapy can be timed with drug administration, patients may report noise-induced hearing loss (NIHL) days, months, or years into the trauma. To what extent a delayed intervention may be successful is yet another question that remains to be resolved.

There is good direct evidence that ROS are formed in the inner ear following intense sound exposures, specifically in the stria vascularis and the organ of Corti [61]. Indicators of ROS formation can be detected at the onset of the noise exposure and may persist for hours or even days following the exposure. Attesting to the importance of endogenous antioxidants, decreased glutathione in the inner ear enhances noise trauma, while dietary supplementation with glutathione attenuates these effects [62].

While the precise origin of ROS in the cochlea following noise exposure remains speculative, there are several sources most likely to contribute. A surge of superoxide radicals followed by chain-reaction formation of other free radicals (via Fenton-type reactions) may be due to the inefficiency of mitochondrial activity, prolonged tissue hypoxia due to vasoconstriction, and rebound hyperfusion [6,63]. RNS may additionally arise from the activation or induction of the enzyme nitric oxide synthase. The different isoforms of this enzyme serve a variety of physiological processes in normal tissue metabolism, and the product of the enzymatic reaction, nitric oxide, is an important second messenger molecule. When produced in excess, not only is nitric oxide potentially damaging as a free radical, but it can also combine with superoxide to produce the highly reactive and destructive peroxynitrite. Nitric oxide levels can rise after noise exposure [64,65], perhaps as a consequence of an enhanced release of excitatory amino acids [66,67], and may contribute to the overall pathophysiology of noise-induced hair cell loss.

Restoring redox balance is therefore one of the potential means of intervention in NIHL, another being an interference with cell death pathways. However, some approaches effective in animals may not be feasible for clinical application. For example, blocking cell death pathways succeeded in animal experiments in vivo [37,68], but similar concerns may arise here as in the prevention of drug-induced hearing loss, in that systemic intervention with important physiological processes may have unwanted consequences. Likewise, the upregulation of antioxidant defenses by systemically administered *R*-phenyl isopropyl adenosine has adverse physiological effects [69]. A local application may bypass systemic problem but is more invasive and may afford less control over drug concentrations. Another important point is that a protective treatment targeting a specific pathway may be counterproductive by inhibiting a potential rescue response. While reducing oxidative stress by scavenging ROS may be beneficial under certain stress conditions, early mild increases in ROS, such as under TTS-noise exposure, stimulate autophagy and remove cellular debris, allowing hair cell survival [40,70].

As with ototoxicity, antioxidant therapy is currently the most viable approach for the prevention and/or treatment of NIHL, with a variety of drugs as possible protective agents [59,60]. NIHL can be attenuated effectively by scavengers such as superoxide dismutase and allopurinol, antioxidants and iron chelators, and by antioxidant drugs that may have clinical appeal, such as ebselen or NAC [71]. Multidrug combinations are promising in animals, for example, acetyl-*l* carnitine with *d*-methionine or NAC [72,73]. Alternative strategies aimed at vasodilation and providing adequate blood flow to the cochlea during noise exposure may also indirectly attenuate ROS formation. Drugs such as pentoxifylline and sarthran improved blood flow to the cochlea and also reduced the temporary

effects of noise exposure [74,75]. Magnesium supplementation can maintain cochlear blood flow under noise exposure and reduce the resulting hearing loss [76]. A combination called "ACE-Mg" consisting of several antioxidants (vitamins A, C, and E) acting by different mechanisms and magnesium as a potential vasoactive agent has proven effective in preventing NIHL in animals [77,78]. While most strategies for interventions in animals rely on applying the protective treatment prior to or concomitant with noise exposure, evidence indicates that the formation of free radicals continues for days following noise exposure and that, consequently, an antioxidant treatment may still be effective during a short period post-exposure [65,79].

The translation from animal models to practical use in humans has been only partially successful in tests on populations exposed to high levels of noise during military exercises and leisure activities. These studies also clearly show the influence of genetic and physiological conditions on susceptibility to noise trauma and the limitations that these factors impose on protection. Daily supplementation with magnesium reduced the incidence of permanent threshold shifts (PTS) in hearing in military recruits from 21.5% to 11.2% [80] and, likewise, reduced temporary threshold shifts (TTS) in a group of young volunteers [81]. However, the severity of PTS was negatively correlated with an individual's monocyte Mg^{2+} content (which may be genetically regulated) regardless of treatment. As another example, NAC showed significant protection on TTS only in subjects with a null genotype in glutathione *S*-transferase T1 and M1 [82]. Perhaps not surprisingly, a group of nightclub visitors taking NAC sustained the same TTS as the control group [83].

Aside from the theory of ROS, calcium influx and overload after noise exposure may be the next most accepted notion. An involvement of calcium influx via calcium channels is supported by the fact that channel blockers attenuate NIHL. The L-type is the predominant VGCC in IHCs, but it may be also present in OHCs [84]. Under normal conditions, blocking of this channel reduces the calcium content of guinea pig IHCs and OHCs [85]. Delivery of L-type channel blocker diltiazem into guinea pig OHCs protects from acute noise damage [86], and several L-type channel blockers (diltiazem, verapamil, nicardipine, and nimodipine) attenuate noise-induced hair cell loss and auditory threshold shifts in female ddY mice [87]. In addition, T-type channel blockers also prevent noise-induced hair cell loss and hearing loss in C57BL/6 mice [88]. Calcium channel blockers are generally used to lower blood pressure in clinic so that their safety and potential side effects are known.

Multiple other cell death pathways, partly independent and partly overlapping, may be triggered by a spectrum of radicals generated in response to noise. The fact that both necrosis and apoptosis are observed attests to the existence of such multiple cell death pathways. This notion is also supported by the emergence of caspase-dependent and caspase-independent cell death pathways and the involvement of the transcription factors that code for different signaling cascades, such as AP-1, endonuclease G, and the calcineurin-related activation of BCL-2 family proteins [59,60]. The pan-caspase inhibitor ZVAD and receptor-interacting protein (RIP) 3 siRNA modulate noise-induced necrosis and apoptosis in OHCs by reduced caspases and RIP kinases, respectively. However, inhibition of noise-induced apoptosis shifts the prevalence of OHC death to necrosis adding an additional layer of complexity to pathway interactions and potential remedies [89].

Recently, epigenetic modification has shown promise to shed new light on strategies for prevention of NIHL as is the case for ototoxicity. FDA-approved HDAC inhibitor vorinostat (SAHA) attenuates noise-induced hair cell loss and hearing loss [41]. Furthermore, BIX 01294, a specific histone lysine methyltransferase inhibitor of G9a encoded by the human *EHMT2* gene, also reduces noise-induced hair cell loss and hearing loss [90] indicating suppression of genes by noise.

Antiinflammatory agents

There is increasing evidence that inflammation contributes to the loss of sensorineural elements from both ototoxic drugs and noise, and antiinflammatory agents are therefore another potential approach to prevention and treatment [91]. Reducing the inflammatory response by controlling signal transducer and activator of transcription (STAT)-dependent pathways decreased cisplatin ototoxicity [92]. Likewise, the corticosteroid dexamethasone protected against several ototoxic agents and against trauma from insertion of a prosthesis into the cochlea [93,94], as well as against noise exposure [95]. It should be kept in mind when considering prevention that the immune response can play an important and necessary role in response to stresses in the cochlea, and there may be occasions when enhancement rather than reduction provides benefit.

Heat shock proteins

HSPs constitute another natural protective mechanism against various forms of stress. HSPs can achieve their protective role by influencing the stress-related denaturation of proteins (either reducing the denaturation or enhancing renaturation and regaining the correct tertiary structure), as chaperones or through an influence on cell death cascades. Several families of HSPs (commonly designated by their molecular weights) include HSP 25/27,

HSP 32, and HSP 70/72. Expression of the inducible form of HSP 70 in the cochlea has been shown in response to heat [96,97], transient ischemia [98], noise [99], and ototoxic drugs [100].

A protective role for HSPs in the inner ear is suggested by two types of studies. In one type, HSP levels are upregulated by an initial innocuous stress, either low-level noise [101] (Altschuler et al., 2002) or controlled heat [96], followed by a noise exposure that would normally cause a significant hearing loss. Either of these preexposures resulted in a significant (30 dB) reduction in NIHL and hair cell loss. Similarly, preexposure to a heat stress protected hair cells in the utricle from aminoglycoside induced loss [102]. Geranylgeranylacetone, a drug that can cause induction of HSP 70 (HSP 70) provided protection from noise-induced [103] and CDDP-induced loss of hair cells [104]. Celastrol, another drug to upregulate HSPs attenuated aminoglycoside-induced hair cell loss in the utricle via HSP 32 induction [105]. HSPs can also protect hair cells from cisplatin (a cancer fighting drug)-induced cell death [106]. Transgenic mice overexpressing HSP 70 were less susceptible to kanamycin-induced hair cell loss and hearing loss [107]. In addition, increased HSP 70 alleviated hearing loss through the promotion of autophagosome formation and removal of noise-induced oxidative stress products [108]. The second type of study examined heat shock factor 1 (HSF1), a major transcription factor for the HSPs, present in hair cells and the stria vascularis in the rodent cochlea [109]. HSF1 knockout mice show increased hearing loss with increased loss of hair cells after noise exposure [110,111].

Neurotrophic factors

Neurotrophic factors play an important role in the development of the cochlea, in regulating differentiation of sensory and neuronal elements, and in the formation of afferent and efferent connections [112–114]. Many neurotrophic factors and/or their receptors remain expressed in the mature cochlea, including glial-line-derived neurotrophic factor (GDNF), neurotrophin 3 (NT-3), and brain derived neurotrophic factor (BDNF) (Ylikoski et al., 1993) [114–117], where they play a role in cellular homeostasis. Neurotrophic factors have a protective action against stress through a mitigating influence on ROS or intervention in the cascade of downstream events induced by ROS formation. While removal of neurotrophic factors is proapoptotic, neurotrophic factors themselves can induce prosurvival pathways and provide protection. As a possible mechanism, neurotrophic factors may reduce oxidative stress–driven increases in intracellular Ca^{2+} [118–120] through the induced expression of calcium-binding proteins [121,122] or antioxidant enzymes [118,119].

Infusion of neurotrophins into the inner ear fluids prior to stress provides protection from hearing loss. When levels of GDNF or NT-3 are increased in the inner ear prior to noise overstimulation or the administration of ototoxic drugs, there is significant protection, with decreased hearing loss and hair cell loss [101,123–127, 134]. This protection is less effective if the neurotrophic factors are provided after the stress rather than before, suggesting that they play a greater role in protection than in repair. BDNF and fibroblast growth factor (FGF) were less effective in preventing hair cell loss [127,128].

Protection from excitotoxicity: "acquired" loss of auditory nerve connections to hair cells

The connection between IHCs and the AN is very sensitive to loss from the excitotoxicity generated by overrelease of the IHC transmitter, glutamate. This excitotoxicity can be induced by noise overstimulation or trauma to IHCs from hypoxia, changes in inner ear fluids or conditions that induce ROS in the hair cells. This can result in a "bursting" and loss of the unmyelinated portion of the peripheral process of the AN, normally connecting to the IHC. While there is potential for regrowth and reconnection [67] there is also potential for permanent loss. This can lead to subsequent death of the AN somata (spiral ganglion neurons—SGN) and loss of the central nervous system connection in the cochlear nucleus. A typical IHC may have connections to 10–30 AN peripheral processes (this varies depending on the position in the cochlear spiral and between species). Studies have shown that a mild to moderate level noise that produces only a temporary loss of hearing and no loss of sensory cells can still result in 20%–30% of these connections being lost, reducing the dynamic range of AN responsiveness [129,130]. Drugs that reduce excitotoxicity in the cochlea can be used to prevent or reduce the loss of IHC–AN synaptic connections. d'Aldin et al. [131] found that Piribedil, a dopamine agonist, reduced loss from a glutamate agonist. We found that the combinations of antiexcitotoxicity agents—Memantine, Piribedil, and ACEMg—when given prior to noise significantly reduced noise-induced loss of IHC-AN synaptic connections [132,133].

When there is loss of IHCs, a series of pathophysiological changes follow, including scar formation, a loss of the peripheral processes of the AN, and, over time, a substantial loss of the AN itself. This loss of AN can be related to the loss of survival/maintenance factors from hair cells and/or supporting cells. Loss of these survival/maintenance factors causes these auditory neurons to enter into the cell death cycle. Cochlear prostheses (discussed in a later section) depend on the stimulation of the

AN, so large AN loss would impair function. Replacing lost survival factors can help maintain this population. Placement of GDNF, BDNF, or NT-3 into cochlear fluids following IHC loss significantly reduced subsequent loss of SGN [115,123,134–138]. Chronic electrical stimulation also reduced SGN loss [139–144]. The combination of neurotrophic factors and ES is particularly effective [145,146].

Infusion of neurotrophic factors such as BDNF, NT-3, and FGF can induce regrowth of the peripheral process of the AN that regress following IHC loss [101,138,147,148]. There is interest in inducing the regrowth of AN processes toward specific sites on the cochlear prostheses. Cochlear prostheses might have reduced thresholds if their target is closer, making them more energy efficient and reducing battery requirements, and it might also allow a greater number of channels to be used, resulting in more and better frequency separation.

Neurotrophic factors delivered into cochlear fluids can also be used to induce IHC-AN reconnection when hair cells are not lost. NT-3 delivered into cochlear fluids by poloxamer on the round window, given 1 day after a noise, induced significant reconnection of IHC-AN synaptic connections [149].

Gene transfer for the prevention and treatment of genetic deafness

One in 1000 newborns suffers from hearing impairment. In developed countries, more than half of the afflicted babies are deaf for genetic reasons. Genetic inner ear impairments can be nonsyndromic, affecting only hearing, or syndromic, with multiple defects occurring in several body systems. Many of the genes for deafness, as well as their products, have now been identified, with mutation of connexins being the most common cause of nonsyndromic deafness in people. Many stereocilia-related mutations have also been found, including in several myosins and adhesion proteins [150]. Identification of the genes that are mutated in families with genetic inner ear impairments is important not only for diagnostic purposes but also for the potential for prevention and cure. Gene transfer has been successful in mouse models if applied early enough. Probst et al. [151] demonstrated that in transgenic "shaker-2" mice destined (genetically) to become deaf, insertion of the wild-type (correct) myosin MYO15 gene sequence into the fertilized egg corrected the genetic deficit, leading to normal inner ear structure and function in the adult mouse. This demonstrated that addition of the correct copy of the gene can rescue the inner ear from genetic deficits. Mice lacking vesicular glutamate 3 (VGLUT3) are born deaf and adeno-associated virus (AAV)–mediated gene transfer of VGLUT3 into IHCs partially restored normal cochlear morphology and hearing [152].

Development of gene transfer into the cochlea has therefore been a major focus of research. One application has been to induce repair after deafness (discussed later) and the other application has been to prevent or treat genetic deafness. There have been many successes in mouse models of human deafness. Several groups have shown full or partial restoration of hearing with neonatal gene transfer into cochlear hair cells in mouse models of Usher syndrome (e.g., [153–156]). György et al. [154] were also able to show gene transfer in the cochlea of nonhuman primate. Chang et al. [157] used neonatal AAV gene transfer to restore hearing in a mouse model of Jervell and Lange-Nielsen deafness syndrome. Chien et al. [158] rescued hair cell morphology in deaf whirler mice.

There are many remaining challenges in bring the use of AAV related vectors to human application for cochlear gene transfer; these include the following: (1) gene transfer in mice is most successful in early cochlear developmental periods—corresponding to in utero in human, when human application would be more difficult. (2) The cochlear cell types where there is best gene transfer may not always correspond to the needed treatment target(s), (3) there can be limited transport cargo capacity in many AAV vectors that can limit gene transfer; (4) potential for immune response and damage from the vector must be limited. A recent study addressed two of these challenges, using a dual AAV approach, each with a different recombinant vector, to correct mutation in the otoferlin gene that caused DRNB9 a common genetic deafness [159]. This was also successful at a later age in mice, which could correspond to neonatal in human.

Interventions for hair cell repair: gene therapy for transdifferentiation

While cochlear type hair cells in nonmammalian vertebrates are naturally capable of regeneration [160,161], in mammals there is no such regeneration, and once mammalian hair cells are lost, there is no natural replacement by new hair cells [162]. The main approaches for replacing hair cells are the introduction of new cells from an exogenous source such as stem cells, or converting endogenous cells that have a nonsensory phenotype to become new hair cells [147,163–166]. Since there is little evidence of endogenous stem cells in the mammalian cochlea, other endogenous cells would need to dedifferentiate and then redifferentiate into hair cell; this is called transdifferentiation, one of the mechanisms utilized for hair cell regeneration in chick and nonmammalian vertebrates [167–170]. Naturally occurring transdifferentiation of less mature supporting cells can occur during the periods of cochlear development in mammals, early postnatal

periods in mouse and rat models (e.g., [171]). This ability of mammalian supporting cells to transdifferentiate, however, disappears as the cochlea further matures, suggesting epigenetic regulation that turns off this capacity ([172] for review). There has therefore been considerable recent research on genes and signaling pathways that regulate the proliferation and differentiation of hair cells during cochlear development ([173,174] for review; [175–181]). As mentioned in the previous section, there has also been considerable research on development of gene transfer and gene therapy, and this has been used both to test hypotheses on the signaling pathways and to test for inducing transdifferentiation and repair/replacement.

The function of several gene families in hair cell development has been characterized by manipulating expression of these genes in mice. In general, these transgenic manipulations use several strategies for increasing or decreasing the levels of gene expression, in fashions that can be temporally regulated and cell specific. Cre-loxP and CRISPR technology has been especially useful for inducing conditional gene expression inhibition in a cell-specific manner in the inner ear [182]. With the use of mouse transgenics, it is possible to eliminate the generation of hair cells [177,183] or to induce ectopic hair cell formation next to the organ of Corti [184,185].

Hair cells and supporting cells develop from common progenitor cells [175]. Their phenotype is determined by a set of genes expressed in a sequence and influencing neighboring cells in an interactive way, with additional influence of microRNAs [186,187] and other epigenetic regulators [172]. *Atoh1* is a gene encoding a transcription factor that is necessary and sufficient for hair cell differentiation in the developing epithelial ridges [177,183,188]. Since *Atoh1* is a master regulator gene for hair cell development, manipulating its expression levels has been used to generate new hair cells both in transgenic animals and by overexpression using other methods. Ectopic hair cells could be found after virally mediated expression of *Atoh1* in nonsensory areas of the auditory epithelium in a mature guinea pig ear in vivo [189,190] and in culture [191]. Together, these studies have shown that the nonsensory cells retain the competence to respond to developmental genes and to convert to new hair cells after the onset of deafness, but the ability of the auditory epithelium to respond to overexpression of Atoh1 appears to diminish in mature animals and after the tissue is severely traumatized [192,193]. New hair cells induced by the overexpression of *Atoh1* had the surface morphology of hair cells, but their detailed morphology is immature [190,194]. Nevertheless, new hair cells that are generated by *Atoh1* overexpression are electrophysiologically active, and several aspects of the maturation process recapitulate the normal development of hair cells ([192,195].

Gene therapy is used to manipulate levels of specific proteins in cells and tissues. It can also be used to inactivate specific proteins or to overexpress them. In most cases, this is accomplished either by introducing a foreign gene into the target cells or by using siRNA approaches. Viral vectors are the most efficient vehicles for gene transfer. Adenovirus, herpes simplex virus, AAV, and lentivirus can mediate gene transfer into cells of the inner ear [165,196–201]. Gene-transfer protocols can be used either for influencing the target cell proper or to accomplish secretion of diffusible factors that act in a paracrine way. Example for the former is the overexpression of Atoh1 for inducing transdifferentiation of supporting cells to new hair cells. Examples for therapy with genes encoding secreted and diffusible proteins include neurotrophin therapy, used for the protection of epithelial and neural elements in the cochlea [44,125,136,202,203].

Because hair cell loss depletes the cell population in the organ of Corti, some of the genetic manipulations performed on mice were aimed at influencing proliferation in the cochlea. This is important because it may be possible for some of the new cells to become new hair cells without any further exogenous manipulations. In the normal mature ear the $p27^{Kip1}$ gene is expressed in nonsensory cells and keeps them quiescent [204,205]. Mice with deficient expression of the $p27^{Kip1}$ gene exhibit an excessive number of hair cells in the organ of Corti. It appears that in the absence of cell cycle arrest, cells continue to proliferate after they normally would have stopped, had $p27^{Kip1}$ been active. Interestingly, mice with this induced mutation have a severe hearing loss, despite the large number of hair cells [205,206]. It is currently unclear whether the hearing deficiencies are due to dysfunction of the hair cells proper or due to more general cochlear pathologies related to the presence of ectopic hair cells. Inhibition of the cell cycle can also be removed by blocking the expression of other genes, including Ink4d and Rb1 [207–209], leading to supernumerary hair cells and supporting cells in the tissue. The ability to use genetic manipulation for inducing proliferation in the organ of Corti is a considerable breakthrough that can be combined with transdifferentiation therapy and lead to feasible clinical applications.

There are several challenges remaining for gene therapy to induce regeneration or treat deafness-related pathology; these include (1) reaching the appropriate target population/cell type in the cochlea; (2) the target population of cells (auditory epithelium) changing as scar-formation progresses following hair cell loss; (3) the ability of vectors to carry sufficient load of genetic material to transfer; and (4) the vector not inducing immune response or damage.

The challenge of reaching the appropriate target cells has been partly met by placement of vectors into the scala

media that induces expression of transgenes in the supporting cells in animal models [210–212]. Still, this route of inoculation is not easily accomplished in the human ear.

Interventions for repair: hair cell and auditory nerve replacement—exogenous stem cells

The use of exogenous stem cells is another approach for hair cell replacement as well as for replacement of lost AN. Embryonic stem cells or stem cells derived from bone marrow can be induced to reach a hair cell-like phenotype (e.g., [213–221]). There has now been successful generation of organoids containing cells with hair cell phenotype [222–224]. Two major challenges for hair cell replacement however remain, efficiently generating large numbers of stem cells reaching the needed hair cell-like phenotype as well as placing these into an appropriate niche in the cochlea to allow function.

Embryonic stem have been induced into an AN-like phenotype both in vitro and in vivo ([225] for review). The in vivo studies have shown that mouse embryonic stem cells can be placed into the cochlear fluids of scala tympani or directly into the AN, survive, differentiate into a neuronal phenotype [226–231] and can migrate into the remaining spiral ganglion cell population [232]. Stem cells that reach a neuronal phenotype will send processes that reinnervate hair cells [233,234] and have been shown to make connections in the cochlear nucleus and improve auditory brain stem responses (e.g., [8,9]). Differentiation into an AN-like phenotype typical of SGN can be improved by genetically engineering the stem cells to produce factors that guide AN differentiation during normal development and/or by providing neurotrophic factors that influence the development of the SGN phenotype [227]. Challenges remain for making appropriate central nervous system connections.

Interventions for repair/replacement: cochlear prostheses

Auditory prostheses can provide direct stimulation of the auditory pathways for return of hearing following deafness. In severe and profound sensorineural hearing loss the sensory cells of the cochlea are destroyed. Cochlear prostheses bypass the damaged receptor epithelium and electrically excite the AN fibers directly. The development of the cochlear prosthesis has been the success story of the field of neuroprotheses. It has provided a therapy for the profoundly deaf, where none previously existed. The first FDA-approved inner ear implants, approximately 30 years ago, were single-channel devices that provided crude input and were an aid to lip reading. Now multichannel devices, combined with many advances in signal-processing strategies, routinely provide intelligible speech perception with open set speech discrimination and even use of the telephone in the majority of implant recipients (e.g., [235,236]). With the success of cochlear implant performance and the low risk associated with its placement, the age at which implantation is considered has decreased to where very young children receive implants and show benefit from early placements, taking advantage of critical periods for auditory system development. There is also increasing bilateral placement to allow binaural hearing, important for spatial localization [236–238]. Recently, the candidate pool for cochlear implants has expanded to include people with remaining hearing. Shorter implants provide electrical stimulation in the basal cochlea and acoustic stimulation remains possible in the more apical cochlea. The use of such "hybrid electrodes" allows acoustic—electrical hearing with improved speech recognition, particularly in noise and subject also report better appreciation of sounds such as musical melodies [239].

Fully implantable cochlear prostheses

The typical currently used cochlear prostheses/implants (CI) have an external microphone/processing unit, a radio frequency inductive link, and intracochlear electrodes. Although the CIs enable speech recognition, they have major limitations including high cost, high power consumption (20–40 mW), cosmetic concerns, and safety issues associated with the external processing unit [240–242]. These limitations contribute to an international market penetration for CIs of approximately 0.7% [243]. A fully implantable cochlear implant is attractive, because it would improve cosmetic and safety issues. Unlike traditional CI where external components must be removed for many activities including sleep and showering [244], a fully implantable CI could remain on at all times. One key advantage of a fully implantable cochlear implant would eliminate the inductive link between the processor and CI electrodes that causes 60% of the power drop [241] in the device, thus reducing power consumption [240].

There have been several attempts to build fully implantable cochlear implants [245–250]. Each requires an internal microphone of some kind. For instance, Cochlear Corporation developed the totally implantable cochlear implant (TIKI), which used a subcutaneous microphone. In a clinical study of this device [246], subjects reported benefits from TIKI and had continued to use it on a daily basis because of cosmetic advantages and the ability to hear while showering, sleeping, and doing physical work. However, speech

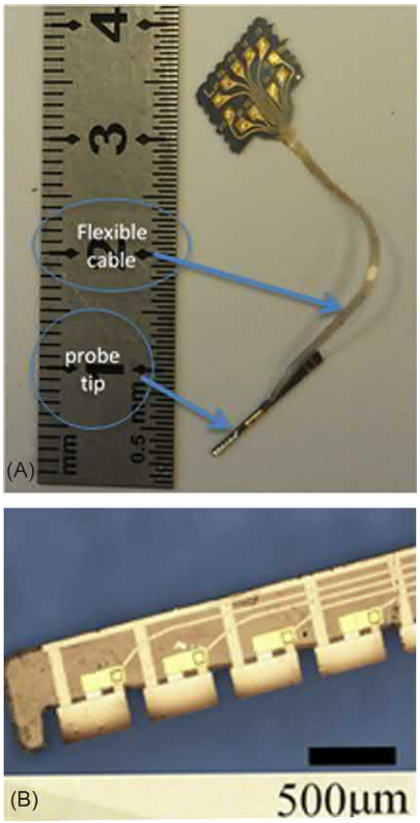

FIGURE 59.1 Prototype of intracochlear pressure sensor [255]: (A) shows prototype including five-element probe tip (elements are submillimeter and too small to be seen in 4A, see 4B for micrograph). Only the probe tip is inserted into cochlea. This configuration includes a flexible parylene gold cabling that terminates in an electrode bay, which enables functional testing of the cochlea exterior to the cochlea. (B) Probe tip close-up showing piezoelectric bimorphs.

perception results were significantly lower when compared with the traditional CI because of the reduced sensitivity and increased body noise contamination of the subcutaneous microphone. The TIKI has not been adopted in great numbers, however. The state-of-the-art for implantable acoustic sensors for hearing devices is well reviewed (e.g., [251]) where they also present a transtympanic microphone to measure ear canal pressure for hearing aids or cochlear implants. This approach, while promising, also faces issues such as ventilation tube migration and liquid contamination which would reduce the effectiveness of the device [251]. An intracochlear transducer is an attractive alternative for patients with a functioning middle ear, because the intracochlear acoustic pressure is typically higher than the ear canal pressure. Implantable acoustic sensors must be small. Creighton et al. [252] and Pfiffner et al. [253] implanted a miniature microphone in the cadaveric human temporal bone and measured intracochlear sound pressure in vitro. Recently, a PVDF-based intracochlear microphone prototype was developed and used to measure sound in a living gerbil cochlea [254]. Zhao et al. [255] (Fig. 59.1) have a different approach to fabricating an implantable acoustic transducer, one based on an aluminum nitride (AlN) microelectromechanical systems xylophone along with physiological testing in a living guinea pig to sense the voltage response due to external acoustic excitation.

This sort of micro-piezoelectric technology includes its use in an intracochlear speaker (receiver) for a hearing aid or in a hybrid electroacoustic stimulator for a cochlear implant. In current prosthetics the stimulation is extracochlear, either outside the tympanic membrane or in the middle ear [256]. Luo et al. [257,258] fabricated and used just such an intracochlear PZT (lead zirconante titantate) actuator to evoke an auditory brainstem response by generating acoustic signals inside a cochlea. Although there are some questions regarding the biocompatibility of a produce containing lead, it might be possible to shield the patient from lead, and certainly other lead-free materials are available (e.g., AlN or PVDF) [255].

Another approach to enabling a completely implantable CI is to replace the external digital signal processor for a cochlear implant with a cochlear analog processor. The goal of such an approach is to miniaturize the processor and reduce the power required to do the computations compared to the traditional digital processor. In addition, an analog processor holds the potential to do the nonlinear computations in real time. Two approaches to such an analog computer are (1) a microelectromechanical system analog model (e.g., [259]) or (2) an analog integrated circuit model (e.g., [260]). While a fully implantable CI will provide for a more usable device, miniaturization of the acoustic sensor and interface to the electric neural stimulator are needed, and the device will still need power and energy storage. All these aspects must be part of the larger engineering design to make the fully implantable device a reality.

Interventions for repair/replacement: central auditory prostheses

Central auditory prostheses can be advantageous when the cochlea is not suitable for implantation, when there is insufficient AN survival, or when AN must be removed in patients with VIII nerve tumors (acoustic neuroma). While a peripheral cochlear implant allows for more "normal" auditory pathway processing, the central implants can take advantage of the tonotopic organization of auditory nuclei for frequency separation. Central auditory prostheses can also have reduced thresholds because of the close proximity to neurons as well and increased dynamic range. Cochlear nucleus implants have been successfully applied in many subjects, with excellent performance possible

[261,262] in nontumor patients; however, when there is a tumor (the most frequent need for central auditory prostheses), the complications of the tumor and its removal can compromise the long-term function of the cochlear nucleus implant (e.g., [263]). Auditory prostheses have also been applied in the inferior colliculus in both humans and in animal models [264] with animal models showing improved thresholds, increased dynamic range, and better frequency discrimination than cochlear implants [265].

Local delivery to cochlear fluids

The fluid spaces of the cochlea provide for a closed environment well suited to receive local delivery of chemicals. Local delivery provides improved access and avoids the side effects that systemic delivery could entail. One method of local delivery utilized in animal models is miniosmotic pumps with cannula into the inner ear fluid of scala tympani or into the middle ear with access through the round window has been developed in animal models (e.g., [266]) and effectively utilized for local application of chemicals that provide protection from acquired deafness or enhanced survival of AN (see earlier sections). While devices for fluid delivery to the inner ear can be developed for human application [267–269], many recent efforts have focused on combining fluid delivery with cochlear prostheses since combining electrical stimulation and chemical delivery is more effective in enhancing AN survival following deafness than either applied by itself [145,146]. Moreover, more patients with some residual hearing have been shown to benefit from cochlear implants and more patients with surviving hair cells are now considered candidates for cochlear implants. These subjects would benefit from the protection of these remaining hair cells from the trauma of cochlear prosthesis insertion. There is also the potential of inducing regrowth of peripheral processes toward the stimulation sites, which could lower thresholds and enhance selectivity and separation. Therefore recent efforts have been made by cochlear implant manufacturers and research groups to develop cochlear prostheses capable of both electrical stimulation of the AN and delivery of pharmaceuticals into the cochlear fluids [270]. These have been successfully applied in animal studies [146] and clinical application is beginning.

Biopolymers and nanoparticles can be used for timed release of specific factors. Nanoparticles can be placed directly into the cochlear fluids (e.g., [271–274]). These can be designed with different sizes, shapes, and release properties and can also be designed to target specific cochlear elements. They can also be placed directly on prostheses. Biomaterial can also be placed on prostheses that can not only improve function and histocompatability but also provide a means for delivering therapeutics. Specific placement of biopolymer and microchannels could provide different factors to different regions.

Another approach to delivery from prosthesis is to place cells capable of secreting the substance of interest directly onto the prosthesis, where they can deliver to cochlear fluids after placement into scala tympani. With ex vivo gene transfer, cultured cells are transformed to produce a specific gene product and placed into a specific area of the body for region-specific release. One problem has been that the transformed cells can migrate to a different region. With the use of biopolymers with fibronectin or laminin, transformed cells (e.g., fibroblast and fibronectin; Schwann cells and laminin) can be securely attached by the biopolymer to a neuroprobe or prosthesis, which is then inserted into the region of interest. The cells will then remain in place and have their highly localized action. One such study has recently shown the ability of BDNF, secreted by cells attached to the implant, to enhance the survival of SGN in a deafened guinea pig ear [275]. It may also be possible to place stem cells (discussed previously) on a prostheses, either to release drugs of interest or as new neurons close to the stimulation sites that can create a new connection either directly to the central auditory system or to remaining SGN.

The middle ear more easily accessible than the inner ear fluids and drugs can be delivered into the middle ear through the tympanic membrane (ear drum). This can be for middle ear infections but can also cross the round window and diffuse into the cochlear fluids. Slow release formulations have been developed that can be placed close to round window for this purpose [276]. These have not only been used in preclinical animal studies for dexamethasone [277], ciprofloxacin [278], and testing NT-3 delivery [149] but have now moved into clinical application for treating Meniere's disease.

Conclusion

Major advances in our understanding of the molecular mechanisms underlying deafness and of the factors that influence and modulate its expression and progression have occurred since the mid-1990s. We can expect, as progress in these areas continues, that this knowledge will form the basis for *molecular otology*. Novel tissue engineering–based therapeutic interventions may become a major part of the practice of otolaryngology in the 21st century.

Introduction

A stem cell is defined by its capacity for differentiation and self-renewal. Stem cells are generally divided into two broad categories, embryonic stem cells (ESCs) and adult stem cells. The ESCs are derived from embryos at a developmental stage and are pluripotent, that is, a cell that has the ability to differentiate into all the types of cells that are in all three germ layers. During replication, ESCs retain their undifferentiated state; after appropriate stimulation, ESCs can differentiate into lineage-specific cells. However, ethical controversies exist in the use of ESCs for scientific research. Therefore adult stem cells have been also explored in research and tested in clinical studies. In contrast to ESCs, adult stem cells are multipotent, and thus they can only differentiate into cells of a given germ layer. Pluripotent stem cells (PSCs) are similar to ESC and have the ability to differentiate into cells of mesoderm, endoderm, and ectoderm lineages. PSC can be reverted from adult cells through two different mechanisms: somatic cell nuclear transfer and by induction with transcription factors into inducible PSC (iPSC). Both approaches have the potential to generate "patient"- specific PSCs.

The eye is a complex organ consisting of epithelial, mesenchymal, connective, and neural tissue. Vision is dependent on carefully regulated structural and functional integration of these tissues. Over the last two decades, it has become increasingly apparent that there are a number of stem cell niches in ocular tissues that are important in maintenance and repair. Moreover, there are nonocular-derived stem cells from sources exogenous to the eye that has been developed as therapies for retinal degeneration diseases (Fig. 60.1). *This chapter will consider our current knowledge of ocular and nonocular stem cells and examine their therapeutic potential in repairing damage to ocular tissue.*

Endogenous ocular stem cells

Corneal stem cells

Epithelial stem cells

The corneal epithelium is the outermost corneal layer. Its functions include transparency and protection from external environment. Corneal epithelium comprises 5−7 layers of cells and is a stratified squamous epithelium that constantly sheds the uppermost dead cells and is replenished from the peripheral stem cell source during homeostasis. The fairly rapid cell turnover contributes to a uniform structure and corneal thickness avoiding transparency loss. Corneal epithelium is renewed and repaired throughout life by the limbal epithelial stem cell (LESC) pool residing at the peripheral corneoscleral junction called the limbus that separates cornea and conjunctiva [1,2]. The distribution of LESCs does not appear to be uniform; the population of LESCs shows regional differences, with the greatest number being in the superior and inferior quadrants [3,4]. LESCs are slow-cycling and normally quiescent cells and are part of the basal layer of the multilayered limbal epithelium. During wound healing, they become activated and their progeny ensures epithelial wound closure [5]. In humans, LESCs are located in a specific limbal niche called palisades of Vogt and may also be found in the deeper epithelial crypts [3,6,7]. Their progeny called transient amplifying cells (TACs) migrate toward the central cornea and upward from the basal epithelial layer. LESC location at the limbus and centripetal migration of their progeny has been recently confirmed in several studies using Confetti mice with color-based lineage tracing of individual epithelial stem cells [8−10]. Central corneal cells further divide and differentiate before being shed from the epithelial surface as terminally differentiated superficial cells.

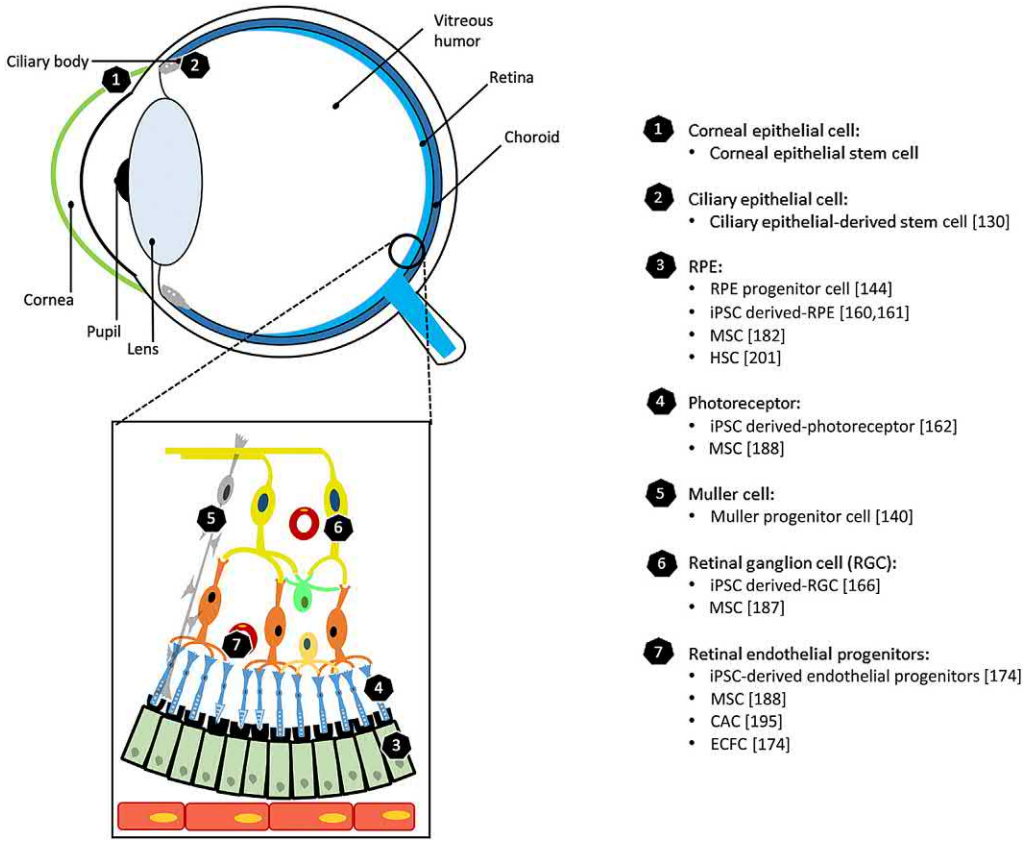

FIGURE 60.1 Ocular stem cells are important in maintenance and repair ocular tissue. Nonocular stem cells are developed as therapies for retinal degeneration diseases.

Each epithelial stem cell maybe capable of producing TACs throughout one's lifetime, but a fraction of LESCs could remain in the resting G_0 state for at least part of their lifetime [11–13]. LESCs have been characterized based on their colony-forming ability (forming holoclones), proliferative potential, slow-cycling nature (BrdU or EdU label-retaining cells), expression of specific markers, and lack of terminal differentiation markers [13–15]. A number of markers [16] sequestered to the limbal epithelium were proposed for identification of LESC but all of them eventually were ruled out as specific stem cell markers. For this reason, investigators have used a set of putative LESC markers (Table 60.1) to assess the fraction of progenitor cells in cultures and predict transplantation outcomes in pathological conditions [9,18,19].

The limbal stem cell niche

Epithelial stem and progenitor cells in the limbus intimately interact with stromal cells in a highly vascularized environment. The general contention is that epithelial-adjacent stromal mesenchymal components forming the limbal stem cell (LSC) niche are important for maintenance and support of LESC [3,20]. These vimentin-positive cells have a capacity to support limbal epithelial cell expansion in vitro and are closely associated with epithelial cells, so that they are coisolated upon collagenase digestion [21]. The precise molecular mechanism by which the stromal niche cells regulate LSC fate is unclear, although it is likely to be due to intricate and direct interactions between the stem cell and its microenvironment [22–24], as well as short- and long-range signals. Recently, a role of exosomes in maintaining epithelial-stromal communications has been suggested [25,26].

Regulation of limbal epithelial stem cells and transient amplifying cells

The regulation of stem cell homeostasis involves both internal and external factors. The environments associated with LESCs and TACs differ in several key ways and are critical to determining cell fate in each region [27,28]. Notably, there are differences that exist between the extracellular matrix/epithelial basement membrane that underlies these cells in the limbus and central cornea, including distinct expression of laminin and collagen IV

LESC, Limbal epithelial stem cell.

isoforms, tenascin-C, collagen XII, etc. [29–31]. Other important effectors include cell adhesion molecules, cytokines, and growth factors that modulate corneal wound healing responses through complex mesenchymal-epithelial interactions [5,32] and are thought to play important roles in the regulation of LESCs and TACs. Depending on the interactions that cytokines are involved in, they can be assigned to groups. Epithelial cells secrete Type I cytokines [transforming growth factor-β (TGF-β), interleukin 1β (IL1β), platelet-derived growth factor-BB (PDGF-BB)] to modulate fibroblasts. Mediators of both epithelial and fibroblast cells are Type II cytokines [insulin-like growth factor 1 (IGF1), TGF-β1, TGF-β2, TGF-β3, FGF-2]. Corneal epithelial cells produce Type III cytokines [keratinocyte growth factor (KGF/FGF-7), hepatocyte growth factor, various epidermal growth factors (VEGFs), and opioid growth factor/5-met-enkephalin]. The interplay between epithelial cells and stromal fibroblasts in the central cornea and limbus is likely to influence cell behavior and phenotype [33–37]. A good example is the presence of TGF-β1, 2, and 3 and receptors in the limbal epithelium. TGF-β inhibits LSC proliferation [35] and may therefore influence stem cell maintenance in the limbus. Stem cell and TAC are regulated by many cytokines/growth factors, including the Notch and Wnt systems [38–43].

Evidence of corneal epithelial cell plasticity

Possible plasticity of corneal epithelial progenitor cells has been suggested by recent data. In the limbal area of mouse eyes, clusters of cells (compound niches) expressing goblet cell mucin and keratins 8 (conjunctival) and 14 have been found and increase in number during wound healing [44]. Another example came from Di Girolamo's group that transplanted keratin 14-positive mouse corneal epithelial progenitor cells onto corneas with experimentally induced to LSC deficiency (LSCD). After transplantation, these cells were able to transdifferentiate into keratin 8-positive conjunctival and keratin 10-positive cutaneous epithelia [45]. Interestingly, ablation of LESC can trigger the expression of progenitor marker keratin 15 in central corneal cells that dedifferentiate to progenitor cells during wound healing [46]. These findings suggest that corneal epithelial progenitor and even differentiated cells can be reprogrammed. The mechanisms that control these processes are still to be determined.

The pursuit of corneal epithelial stem cell markers

LESCs are operationally recognized as slow-cycling label-retaining (BrdU or EdU) cells residing in the basal cell layer of the limbus [13]. This small population (about 2%–3%) of cells has a high nuclear/cytoplasmic ratio [47,48] and is relatively undifferentiated as demonstrated by their lack of epithelial differentiation markers, such as 64 kDa keratin 3, cornea-specific keratin 12, and connexin-43 [16,17,49–58]. LESC progeny (TACs) are rapidly cycling cells that are thought to form the bulk of limbal basal epithelium and coexpress vimentin and keratin 19 [52]. As TACs migrate centripetally across the limbo-corneal margin and in the process acquire differentiation markers, for example, keratins 3 and 12 [28,49,56]. At least in some species, they might retain some progenitor markers as well, which would explain data on the expression of such markers also in the basal cells of the central mouse cornea, although this does not happen in humans [54].

To date, no definitive and specific marker characterizes LESC. Currently, negative LESC markers as well as some putative positive markers have been proposed [5,9,16,17,19,48,58]. Table 60.1 shows a list of the available negative and positive markers that maybe used to

discriminate basal limbal epithelial cells from basal central corneal epithelial cells. When used in combination, these markers can aid in LSC isolation and characterization of their differentiation state. Most putative stem cell markers are not exclusively expressed in a subpopulation of cells in the basal limbal cell layer, but they are rather found across the limbal basal epithelium and only a selected few (e.g., N-cadherin) show clustering in this layer compatible with LESC. High expression of the transcription factor ΔNp63 was proposed as a potential LESC marker for predicting success of expanded limbal cell transplantation [51]. However, the limbal basal epithelial cells, including LESC, express predominantly one p63 isoform (ΔNp63α) but the available antibodies do not specifically recognize it creating some confusion when interpreting data.

In the limbus, estimations for the stem cell population that maintains the corneal epithelium indicate less than 5% of the basal limbal epithelial cell population [17,47,48] or 100 cells in the rodent cornea. Like other stem cells, a subpopulation (side population on flow cytometry) of limbal epithelial cells, approximately 0.4%, is able to efflux Hoescht 33342, a property attributable to the ATP-binding cassette transporter G2, or ABCG2 [51,57–59]. A study of the rabbit limbal epithelial side population cells showed that they represented about 0.7% of the total population, were small in size, were undifferentiated and noncycling, and could be induced to enter the cell cycle upon wounding [51]. Whether the side population cells proliferate and form colonies in vitro remains controversial [51,59].

Overall, researchers still need to use several putative LESC markers together. The definitive identification of LESC markers may soon become reality with the advent of new technologies, such as time-controlled GFP expression [17] and single-cell RNA sequencing.

The potential for tissue engineering of limbal epithelial stem cells in ocular surface disease

Loss or dysfunction of LESC leads to LSCD that may result from mechanical injuries, chemical and thermal burns, genetic defects (e.g., aniridia, Stevens–Johnson syndrome), or chronic diseases, leading in severe cases to conjunctival ingrowth with neovascularization, corneal opacity, scarring, ulceration, and in some instances, corneal perforation and eventual vision loss [5,56]. Central corneal button without inclusion of the limbal region will not restore vision. Initially, autologous conjunctival transplantation was attempted to treat LSCD-related ocular surface disease [60–62]. However, in the absence of the limbal epithelium, conjunctivalization of the cornea resulted in an abnormal corneal surface [63,64], because "conjunctival transdifferentiation" does not occur [64–66]. Then, other methods were investigated, including keratoepithelioplasty, consisting of the transplant of lenticules of peripheral cornea [67] and human keratolimbal autografts were performed in the late 1980s [68]. A recent variant of such grafts for unilateral LSCD called simple limbal epithelial transplantation consists of placing small pieces of an autologous limbal biopsy on human amniotic membrane glued or sutured to a diseased eye. Cells migrate out of these pieces and substitute missing LSCs [69,70]. Human limbal autografts use the limbal cells of the healthy contralateral eye, whereas bilateral disorders necessitate stem cell allografts isolated from living tissue-matched eyes or nonmatched cadaver eyes [63,71,72]. In the case of allografts, immunosuppression is required to prevent epithelial rejection.

It should be noted that limbal biopsies from a healthy eye are not entirely safe, because stem cells do not repopulate the biopsied area. For this reason, and for bilateral LSCD treatment, the culture-expanded LESC therapy has been developed. This concept minimized the risk of LSCD in the donor eye [73], since only a small biopsy was required, and allograft rejection was reduced due to the elimination of Langerhans cells during culture [74]. Pellegrini et al. [72] reported the first successful autologous graft for unilateral severe ocular surface disease, using limbal epithelial cultures enriched in stem cells. Since then, culture-expanded LESCs have been used with reasonable success for transplantation in India, the United Kingdom, and Germany [75], and the first standardized cultured LESC treatment was approved in the European Union in 2015 [16,19].

A number of substrates for the culture of epithelial stem cells have been introduced, including fibrin, amniotic membrane, and thermo-responsive plastic [19]. The latter allows cultured epithelial cells to be released upon temperature change, so that only the epithelial sheets are transplanted [76]. The fibrin gel used as a carrier [72] is degraded following transplant, whereas the amniotic membrane appears to persist following transplantation and is only gradually resorbed [77]. Amniotic membrane remains the most used substrate for cultured LESC transplantation. Its benefits include provision of growth factors important in reepithelialization, antiinflammatory effects, inhibition of conjunctival fibrosis [78], and antibacterial properties. It is also thought that the amniotic membrane provides LESCs with a new niche, especially that the amniotic basement membrane is similar to the limbal epithelial basement membrane in composition [79,80]. A number of studies have evaluated the use of intact versus denuded (with epithelial cells removed mechanically or enzymatically) amniotic membrane as a substrate for LSC culture [80–83]. Limbal epithelial cells demonstrated stem-like properties on intact amniotic membrane, including slow-cycling and lack of expression of the

differentiation markers keratins 3 and 12, and connexin 43. However, cultivation on denuded amniotic membrane showed increased limbal epithelial cell migration and produced a better stratified epithelium [81].

Bioengineered epithelial tissue equivalents have been derived from both limbal explants and cell suspensions isolated from limbal epithelium [81]. Both techniques generate epithelial cell sheets that express differentiated markers keratins 3 and 12, although they are more evident in superficial cells of the cell suspension−derived sheets. The latter also resulted in the formation of a greater number of desmosomes, smaller basal intercellular spaces, and secure attachment via hemidesmosomes to the underlying basement membrane. The use of the air−liquid interface method of culture, whereby the level of media is reduced below the epithelial cell surface, ensures that a well-differentiated, stratified epithelial tissue is produced for transplantation.

Donor epithelial cells have been identified in the recipient bed for up to 30 months after limbal allograft transplantation [84], but the long-term duration of donor-derived epithelial stem cell viability remains uncertain [19,84−86]. In fact, some studies note rapid disappearance of transplanted cells in limbal allografts or cultured LESC; yet, in many cases, the ocular surface remains healthy long-term [19,87]. Whether donor LSC survival is sustained or activation of resident recipient stem cells occurs on reestablishment of niche signals has yet to be determined. In any event, if the LESC grafts eventually fail, repeat transplants can be made successfully, as a study in burn patients has shown [88].

Tissue-engineered stem cells from noncorneal sources as an alternative to limbal epithelial cells

Transplantation of LESC-enriched cultures faces some problems related to limited number of possible cell passages, allograft rejection risk and disease transmission, as well as shortage of donor corneas in many countries [89]. This necessitated search for alternative cell types that are able to differentiate into corneal epithelial cells and to restore corneal surface. The tested cell sources include cultured oral mucosal epithelium, hair follicle, conjunctival and epidermal epithelium, amniotic epithelial cells, umbilical cord lining epithelium, mesenchymal stem cells (MSCs) from adipose tissue, bone marrow, orbital fat, and immature dental pulp [2,90−92].

Nakamura et al. [78] pioneered the idea of using cultured oral mucosal cells expanded on denuded amniotic membrane in autologous grafts to reconstruct rabbit corneal epithelium. The resultant epithelial cells showed expression of keratin 3 (but not keratin 12) and the formation of a 5−6 layered−stratified epithelium with desmosomes, hemidesmosomes, and tight junctions. Subsequently, autologous-cultured oral mucosal epithelial constructs have been used clinically, usually for treating chemical burns. The success rates of their transplantation were slightly lower than with cultured LESC [2,91].

Most other abovementioned cell types have only been examined in preclinical models with varying success [9,19,64,93,94]. More recently, embryonic and induced PSCs have been differentiated into corneal epithelial cells. Because they can be made autologously, propagated in large quantities, and are bankable; they may become a promising source of limbal cells for transplantation in LSCD of various etiologies [95−99].

Stromal stem cells

Cells expressing Pax6 and ABCG2 progenitor markers as well as MSC markers and capable of differentiating into corneal keratocytes in vitro have been isolated from human limbal stroma [100]. Such stromal stem cells are multipotent and fulfill the International Society of Cellular Therapy criteria for MSC [101]. Similar MSCs have also been found in the central corneal stroma [102]. Corneal stromal stem cells have been used for stromal engineering in vitro [100]. In a lumican-null mouse model of corneal opacity, intrastromal injection of isolated human stromal stem cells was able to restore transparency [100]. Importantly, in a corneal wound model, injection of human stromal stem cells from limbal biopsies prevented fibrotic scar formation, with inhibition of neutrophil migration into the wounded stroma and preservation of normal structure of the stromal extracellular matrix [103,104]. Exogenous MSCs in vivo were also able to significantly reduce stromal neovascularization, corneal opacity, and inflammation in alkaline burn and penetrating injury models [105,106]. The use of compressed collagen as injected cell matrix was shown to enhance their antiscarring ability [107]. These data hold promise for the future clinical use of corneal stromal stem cells and other MSCs for the treatment of burns and reduction of stromal fibrosis. An alternative source for future stromal cell transplantation is represented by keratocytes derived from induced PSCs [108].

Endothelial stem cells

Unlike rabbit cells, human corneal endothelial cells (CECs) can hardly be expanded in vivo or in vitro [109,110]. The existence of human corneal endothelial stem cells was hypothesized for a long time but only recently received experimental corroboration. Expanded neurosphere-forming cells could be incorporated into the endothelial layer in a model of CEC deficiency [109]. Slow-cycling endothelial cells expressing stem cell

markers Oct3/4, Wnt, Pax6, SOX2, SOX9, and with elevated telomerase activity were observed at the corneal periphery [111–113]. Recently, the identification of neural crest–derived progenitors from corneal endothelium of normal subjects and those with Fuchs endothelial corneal dystrophy has been reported. These cells expressed stem cell–related genes as well as neural crest marker genes and were able to differentiate into CECs with typical transcellular resistance [114].

To enhance corneal endothelial repair, other progenitor cells were tested, including MSCs, from umbilical cord blood [115]. As an alternative source for CEC transplantation, such cells can be obtained by in vitro differentiation of human PSCs. As corneal endothelium is derived from neural crest stem cells, such cells could also be used to generate autologous endothelial substitutes [116]. The availability of corneal endothelium differentiated from embryonic or induced PSCs and expressing a set of endothelial markers has been reported [117,118]. Such cells could restore transparency in the eyes of rabbits with corneal endothelial dysfunction [119]. In summary the ability of producing CECs from human PSC-derived neural crest cells provides a possibility to generate endothelial replacements suitable to treat corneal edema and wound-related complications of corneal surgeries.

Conjunctival epithelial stem cells

The conjunctival epithelium, like the corneal epithelium, undergoes constant renewal. It is still unclear which regions of the conjunctiva harbor stem cells, including the fornix, palpebral, and mucocutaneous zones. Slow-cycling cells with higher proliferative capacity were demonstrated in these regions [65,120,121]. Conjunctival stem cells can differentiate into either a mucin-secreting goblet cell or epithelial cell. Interestingly, clusters of corneal epithelial cells residing ectopically in human conjunctival epithelium have been described [122]. The field of conjunctival stem cells as another stem cell source for ocular surface epithelia needs to be expanded.

The bioengineered cornea

The idea of a bioengineered cornea has arisen with corneal equivalents being reconstructed from corneal cell lines. Griffith et al. [123] reconstructed a human cornea from immortalized cells. It was reported that the resultant corneal equivalent behaved similarly to a normal cornea in terms of morphology, transparency, ion and fluid transport, and gene expression. However, corneal bioengineering to produce replacement implants for wounded or diseased human corneas is still at the investigatory stage and needs significant further development in order to generate a corneal equivalent with the same tensile strength, transparency, and durability as a normal cornea. The ideal bioengineered implant is likely to be a composite of biomaterials and pertinent cell types, to provide a transparent, flexible, but strong biocompatible implant, which can withstand surgical procedures, as well as normal day-to-day mechanical stresses. It may also need to provide a compatible scaffold for eventual repopulation by host's epithelial cells. Composite constructs using a combination of limbal epithelial and stromal cells showed superior differentiation and biological properties [124,125]. A recent report described a full corneal equivalent consisting of acellular porcine corneal matrix with seeded human limbal epithelial cells and endothelial cells differentiated from ESCs. This construct was reportedly repopulated by stromal keratocytes within 3 weeks providing a complete corneal equivalent [126]. At 8 weeks, after transplantation to rabbits, the grafts remained transparent with some peripheral neovascularization. The graft morphology resembled that of a normal cornea and the cells expressed their typical markers. This exciting result holds significant promise for the emergence of bioartificial corneal equivalents suitable for human use in the near future. Advances in stem cell differentiation and graft engineering should help overcome technical problems and accelerate translation into clinic.

Retinal progenitor cells

It has been extensively reported that stem cells exist in the retina of fish and amphibians and that these cells add to the retina throughout their lifetime [127]. Furthermore, these cells, which are located at the ciliary–retinal interface, are also able to regenerate a complete retina, including retinal pigment epithelium (RPE), under appropriate experimental conditions [128]. By contrast the neural retina and RPE in mammals are primarily developed by the early postnatal period and show no evidence of the adult regeneration observed in fish and amphibians [127,129].

Interestingly, retinal progenitor cells were not identified in mammals until 2000 [130,131] and were located at the ciliary marginal zone, similarly located as the retinal progenitor cells of fish and amphibians. Retinal progenitors represent only about 0.2% of pigmented cells in the ciliary margin and display many of the properties associated with stem cells. They are multipotent, self-renewing, and proliferating and express the neuroectodermal marker nestin. Other potential markers can include CD133, CD15, Notch, Numb, and FGFR4 [132]. Retinal progenitor cells can clonally proliferate in vitro to form spherical colonies of cells that exhibit differentiation markers for a variety of cell types, including photoreceptors, intermediate neurons, and Müller glia [130,133]. Thus, it would appear that these progenitors have the potential, given the right environment, to be engineered into the morphological and functional layers associated with the retina.

To date, the primary challenge in the use of retinal progenitors is their limited number and their difficult isolation. To circumvent these issues, investigators have used brain-derived neural progenitor cells [134,135], embryonic retinal progenitor cells [136], bone marrow–derived stem cells [137], and ESCs from the inner mass of the mouse blastocyst [138].

Müller stem cells

During the development of the neural retina, Müller cells are generated late in neurogenesis and are not considered to be neuronal progenitors. However, when injury occurs, Müller cells display features of neural stem cells; they self-renew and generate neurons, glia, and retinal neurons [139]. Roesch et al. have found a subset of Müller cells expresses progenitor genes such as Car2, Dkk3, Chx10, and Pax6 [140]. Studies have suggested that the neural stem cell properties of Müller cells typically remain dormant in the normal adult retina [141]; however, during injury activation of the Wnt and Notch pathways act in concert to regulate the stem cell properties of Müller cells [141]. Müller stem cells migrate to the damaged retina layer and can differentiate into neurons [129,142]. Furthermore, it appears from studies in the chick that Müller glia have the potential to become neurogenic retinal progenitor cells [143].

Retinal pigment epithelium stem cells

The RPE cell maintains its proliferation only during the early stage of embryonic development and then remains nonproliferative throughout life. However, human RPE cells can proliferate during pathological conditions, which suggests RPE plasticity during adulthood. Salero et al. have reported a subpopulation of adult RPE cells express stem cell features that can be self-renewed and exhibit multipotency, produce new RPEs or cells with neuronal phenotype [144].

Nonocular stem cells

There are currently many ongoing clinical trials using nonocular stem cells which aim to test the safety and efficacy of transplanting cells in the eye. Ideally, transplanted cells should have a long-term effect by integrating and surviving in the eye. The cells can potentially regenerate damaged retinal vasculature and restore retinal neurons. Also transplanted cells should have limited proliferative potential after integration into the eye to minimize the risk of adverse effects such as teratoma formation in the eye.

Induced pluripotent stem cells (iPSCs)

In 2006 Takahashi and Yamanaka reported that mouse fibroblasts could be "reprogramed" by the use of transcription factors into cells with pluripotency similar to ESCs, and they call these cells induced PSCs (iPSCs) [145]. In the following year, Takahashi et al. and Yu et al. demonstrated independently that human somatic cells were able to be reprogrammed into iPSCs by using different cocktails of transcription factors; they are called: Yamanaka Cocktail (Oct3/4, Sox2, Klf4, and c-Myc) [146] and Thomson Cocktail (Oct3/4, Sox2, NANOG, and LIN28) [147]. They all reported that iPSCs were able to differentiate into all three germ layers and subsequently differentiate into any adult cells.

Because iPSCs can be derived from somatic cells of a donor, such as skin or fibroblast, therefore they are easily accessible and plentiful. Moreover, they can be autologous cells and thus the recipient may not require immunosuppression when administered. iPSCs provide a promising donor source for cell therapy in retinal regeneration (Fig. 60.2). In 2013 the world's first clinical trial involved in the use of iPSCs-derived RPE cells was conducted in age-related macular degeneration (AMD) patients (http://www.riken.jp/en/pr/press/2013/20130730_1/).

Embryonic stem cells/iPSCs in retinal regeneration

Generating retinal pigment epithelial from embryonic stem cells/iPSCs

Currently, there are two main methods to differentiate iPSCs to RPEs, either the use of floating embryoid body-like culture or adherent culture technique. First, fibroblast iPSC amplification is performed by clump passage, followed by differentiation, and mechanical removal of the pigmented colonies for RPE purification [148,149]. The second, more commonly used method uses pluripotent cells that are amplified by clonal propagation using myosin inhibitor (blebbistatin) followed by spontaneous differentiation of pigmented colonies, and then, two rounds of passage to enrich for RPE cells [150].

Various molecules or compounds are used in cell culture to facilitate the differentiation process of iPSC-derived RPEs. In some studies, fibroblast growth factor (FGF) was removed from the culture condition to allow spontaneous differentiation of iPSC-derived RPEs [151]. Other studies supplemented the culture media with retinal differentiation-inducing factors such as inhibitors of Wnt, Nodal, and BMP-4 pathways [152]. In addition, other growth factors or compounds, such as insulin growth factor 1 (IGF-1), retinoic acid (RA), activin A, nicotinamide,

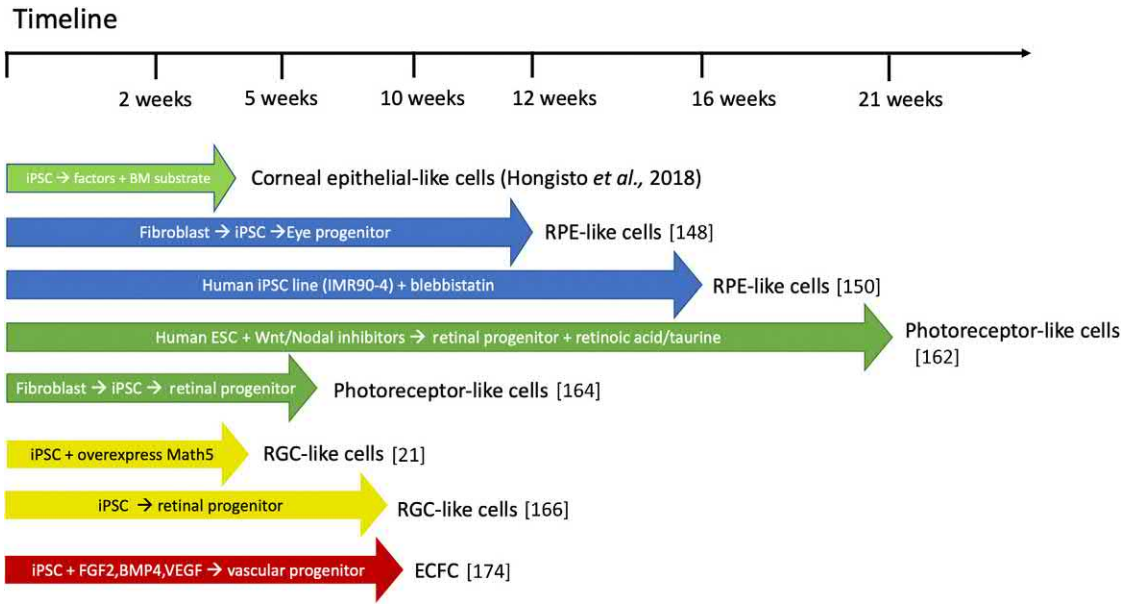

FIGURE 60.2 Differentiation timeline of iPSC/ESC into retinal cells (RPE, photoreceptors, RGC, and ECFC). *ECFC*, endothelial colony-forming cell; *ESC*, embryonic stem cell; *iPSC*, Induced pluripotent stem cell; *RPE*, retinal pigment epithelium; *RGC*, retinal ganglion cell.

SB431542, B27, and N2, have been shown to induce RPE fate [153–155].

In vitro, iPSC-derived RPE cells have been shown to express key RPE markers such as Mitf, OTX2, bestrophin 1 (BEST1), ZO1, PEDF, LRAT, PEML17, and CRALBP; in addition, they have been shown to exhibit essential phenotypic functions, including phagocytosis of photoreceptor outer segments, ion transport, and VEGF secretion [150,151,154,156–158].

In a RPE degeneration rodent model, human iPSC-derived RPEs injected into the subretinal space showed phagocytosis of photoreceptor outer segments and maintained long-term visual function [157]. Similar results by Li et al. demonstrate that subretinal injection of human iPSC-derived RPE cells integrate into the host RPE and improve visual function in recipient mice; importantly, no evidence of tumor formation was observed up to 6 months [159]. These studies provide evidence for the safety and efficacy of iPSC-derived cells in clinical trials.

Of note, a trial using human iPSC-derived RPE to treat exudative AMD has been done in 2017 [160]. The study assessed the feasibility of transplanting a sheet of RPE cells differentiated from iPSCs in a patient with neovascular AMD—at surgery the neovascular membrane was removed and transplantation of the autologous iPSC-derived RPE cell sheet under the retina was performed. At 1 year after surgery the transplanted sheet remained intact, best corrected visual acuity had not improved or worsened, and cystoid macular edema was present. A second trail used ECS-derived cells for individuals with Stargardt's macular dystrophy (age >18 years) and individuals with atrophic AMD (age >55 years). Three dose cohorts (50,000, 100,000, and 150,000 cells) were treated for each eye disorder. Transplanted patients were followed up for a median of 22 months by the use of serial systemic, ophthalmic, and imaging examinations. There was no evidence of adverse proliferation, rejection, or serious ocular or systemic safety issues related to the transplanted tissue. A total of 13 (72%) out of 18 patients had patches of increasing subretinal pigmentation consistent with transplanted retinal pigment epithelium. Best corrected visual acuity, monitored as part of the safety protocol, improved in 10 eyes, improved or remained the same in 7 eyes and decreased by more than 10 letters in 1 eye, whereas the untreated fellow eyes did not show similar improvements in visual acuity. The results suggested that hESC-derived cells could provide a potentially safe new source of cells for the treatment of various unmet medical disorders requiring tissue repair or replacement [161].

Generating photoreceptors from embryonic stem cells/iPSCs

Several methods are used to generate photoreceptors from ESCs/iPSC. Normally, ESCs/iPSCs are derived into retinal progenitor cells in 35 days by blocking Wnt and Noda pathways, then after 170 days, only 20% of the progenitors become photoreceptor precursors. Retinoic acid (RA) and taurine were used to promote maturation of photoreceptors by the expression of rhodopsin and opsin, and this process normally takes 130 and 200 days [162]. A

modified protocol to generate photoreceptor precursor from iPSC by combining Matrigel-coated culture dishes with the addition of Noggin, DKK-1, IGF1, Lefty A 3,3′,5-triiodo-L-thyronine (T3), FGF, RA, taurine, Shh, and Activin A, greatly shortens the process [163,164].

Few transplantation studies were published using human iPSC-derived photoreceptors. One of the studies showed that a limited number of donor iPSC-derived photoreceptors migrate into the outer nuclear layer (ONL) by subretinal injection [165]. In contrast, injection of iPSCs into the vitreous appeared less effective at promoting outer retinal integration [166]. Tucker et al. identify disease-causing USH2A mutations in an adult patient with autosomal recessive retinitis pigmentosa [167]. Induced PSCs (iPSCs) were generated from the patient's keratinocytes and were differentiated into multilayer eyecup-like structures with features of human retinal precursor cells. Transplantation into 4-day-old immunodeficient Crb1 (−/−) mice resulted in the formation of morphologically and immunohistochemically recognizable photoreceptor cells, suggesting that the mutations in this patient act via postdevelopmental photoreceptor degeneration. Wiley et al. developed clinically compatible methods for manufacturing photoreceptor precursor cells from adult skin in a Good Manufacturing Practice (GMP) environment [168]. They obtained biopsies from 35 adult patients with inherited retinal degeneration and fibroblast lines were established. Patient-specific iPSCs were then generated, clonally expanded and validated. Postmitotic photoreceptor precursor cells were generated using a stepwise GMP-compliant 3D differentiation protocol. Transplantation into immune-compromised animals revealed no evidence of abnormal proliferation or tumor formation suggesting that future human trials maybe safe and efficacious using patient-specific photoreceptor cell replacement in humans. Gagliardi et al. showed that the cell surface antigen CD73 was exclusively expressed in hiPSC-derived photoreceptors by generating a fluorescent cone rod homeobox (Crx) reporter hiPSC line using CRISPR/Cas9 genome editing [169]. They demonstrated that CD73 targeting by magnetic-activated cell sorting was an effective strategy to separate a safe population of transplantable photoreceptors. $CD73^+$ photoreceptor precursors were isolated in large numbers and transplanted into rat eyes and showed capacity to survive and mature in close proximity to host inner retina in a model of photoreceptor degeneration. Their results may facilitate future clinical translation. Since single cell injection typically results in poor cell survival and integration posttransplantation, scaffolds can be used to promote donor cell viability, control cellular polarity, and increase packing density [170]. A challenge has been developing suitable scaffolds that can be used to deliver stem cell–derived photoreceptors in an ordered columnar orientation (i.e., similar to that of the native retina). Obstacles to refinement of polymer scaffolds include difficulties in controlling the microstructure of biocompatible substances in three dimensions. Thompson et al. showed that two-photon polymerized acrylated poly(caprolactone) (PCL) scaffolds successfully supported human iPSC–derived retinal progenitor cells in vitro. Subretinal implantation of cell free scaffolds in a porcine model of retinitis pigmentosa did not cause inflammation, infection, or local or systemic toxicity after 1 month supporting the utility of PCL scaffolds for retina cell delivery.

Generating retinal ganglion cells from embryonic stem cell/iPSCs

Different from the photoreceptor that has a single synapse to interneurons, transplanted retinal ganglion cells (RGCs) not only have to integrate into the retinal ganglion layer but also develop long axons that migrate to the optic nerve. This poses a great challenge for replacing damaged RGCs in cell therapy. Nevertheless, progress has been made in generating cells with RGC features from stem cells. Fibroblast-derived iPSCs were induced by addition of DKK1, Noggin (DN), DAPT, and overexpression of Math5 and then differentiated into RGC-like cells. These cells display long synapses and express RGC gene patterns; moreover, transplanted iPSC-derive RGC-like cells into mouse vitreous were able to survive but rarely engraft into the normal host retina [171]. In a different study, iPSCs were induced into neural progenitors with neural induction factors, including N2, B27, insulin, transferrin, sodium selenite, fibronectin, FGF, and Noggin. Then, neural progenitors were cultured in conditioned medium from E14 rat retinal, and a subset of cells expressed mature RGC markers. Moreover, the study found that a subset of iPSC-derived RG-like cells innervate into the mouse superior colliculus ex vivo [166].

Generating hematopoietic/vascular progenitors (CD34/endothelial colony-forming cells) from iPSC

iPSCs are also used to differentiate into vascular progenitor cells and explored as potential cell therapy. Fibroblast-derived human-iPSCs under feeder-free endothelial culture condition give rise to multipotent $CD34^+$ $CD45^+$ hematopoietic progenitors [172]. Cord blood–derived iPSCs differentiate into vascular progenitors that express endothelial/pericytic markers ($CD31^+$ $CD146^+$); moreover, systemic or intravitreal injection of these cells enhanced repair of damaged retinal blood vessels in an ischemic retinopathy model [173]. Prasain et al. generated endothelial colony-forming cells (ECFCs) from human cord blood–derived iPSCs that showed the capacity to form vessels and repair ischemic mouse retina and limbs;

moreover, these cells lack teratoma formation potential [174].

Bone marrow stem cells

Although not resident in the eye, it appears that bone marrow stem cells (BMSCs) play an important role in retinal homeostasis and repair. The heterogeneity of the BMSC population promotes differentiation into various cells. There are two classes of BMSCs that are commonly studied; MSCs and hematopoietic stem cells (HSCs).

Mesenchymal stem cells

MSCs are fibroblast-like cells with a capacity to replicate and differentiate into osteoblast, adipocytes, and bone marrow stromal cells [175]. In bone marrow, MSCs constitute less than 0.1% of the total cells [176]. Yet, they are heavily explored in cell therapy credited by their ability to quickly expand in culture condition while retaining their multilineage potential. Furthermore, MSCs can be administrated intravenously and appear to be safe in clinical trials.

MSCs can be harvested from bone marrow, umbilical cord blood, adipose tissue, placenta, Wharton's Jelly, dental pulp, liver, and heart [177]. Expression of surface markers is used to identify MSCs and include CD105, CD73, stromal antigen 1, CD44, CD90, CD166, CD54, and CD49. MSC is also characterized by the absence of hematopoietic cell (CD14, CD45, CD11a, and CD34), erythrocytes (Glycophorin A), and platelet (CD31) markers [177].

MSCs have been reported to contribute to tissue regeneration through at least three different mechanisms. First, the primary mechanism involves paracrine trophic effects in vitro and in vivo. These paracrine trophic factors include neuroprotective and angiogenic factors such as ciliary neurotrophic factor, bFGF, VEGF, and TGF-β [178]. In pathological conditions such as hypoxia, the production of paracrine trophic factors is further enhanced. In addition, new paracrine trophic factors have been packaged in extracellular vesicles that are secreted by the MSCs [179]. Secondly, MSCs are able to differentiate into damaged tissues [177]. Lastly, MSCs have immune-modulating capacity including immunosuppression and features similar to T-regulatory cells with ability to produce cytokines such as IL-10, IL-17, TGF-β, LIF, soluble HLA, and IL-1 receptor antagonist [180]. Hence, MSCs can be potentially used in treatments for autoimmune diseases, such as Crohn's diseases and multiple sclerosis [181].

Mesenchymal stem cells for cell therapy in the eye

The in vitro study performed by Duan et al. has shown that bone marrow–derived MSCs can be differentiated into cells with RPE features [182]. Subretinal injection of bone marrow–derived MSCs has shown direct integration into the RPE layer and prolongs the survival of photoreceptor [183] and ameliorates the retinal degeneration in animal models [184]. Intravitreal injection of MSCs has been explored in preclinical studies. In an animal model of diabetic retinopathy, intravitreally injected bone marrow–derived MSCs integrate into the inner retina and improve visual function [185]. In an animal model of retinal ischemia-reperfusion injury, bone marrow–derived MSCs administrated intravitreally have shown a protective effect on damaged ganglion cells [186]. In addition, intravitreal injection of MSC into a laser-induced retinal damaged rat model that mimic retinal neovascularization has shown that MSC can migrate into the neural retina, especially in the ONL, inner nuclear layer, and ganglion cell layer [187]. Systemic administration of MSCs preserves photoreceptors, reduces retinal vascular leakage, and improves visual acuity in an animal model of retinal degeneration [188]. Locally and systemically injected bone marrow–derived or adipose-derived MSCs differentiate into cells with photoreceptor and RPE features in an animal model of hereditary retinal dystrophies as well as in mechanical and chemical impaired RPE rat models [137,188–190]. However, it is still unclear whether the observations resulted by differentiation of transplanted MSCs or fusion of MSCs with preexisting photoreceptors [191].

Hematopoietic stem cells/CD34$^+$ cells

Bone marrow has the highest concentration of HSCs, and most of the HSCs can be isolated on the basis of their surface markers, the most common marker is CD34 [192]. Besides bone marrow, CD34$^+$ cells are also found in adipose tissue, umbilical cord blood, and fetal liver [177]. CD34$^+$ cells are capable of self-renewal and responsible for hematopoietic reconstitution in the irradiated host [192,193]. Since then, CD34$^+$ cells were largely explored in clinical testing to repopulate hematopoietic lineage cells [177]. In 1997, Asahara et al. have found that CD34$^+$ cells enriched from human peripheral blood have the ability to on endothelial linage capability characteristics and are capable of being recruited to ischemic sites; moreover, they participate in tissue regeneration and angiogenesis [194]. This suggested that CD34$^+$ cells can mobilize from the bone marrow and be recruited to the injured tissues via blood circulation.

Hematopoietic stem cells/CD34$^+$ and retinal disease

Intravitreal and systemic infused human CD34$^+$ cells enriched from peripheral blood of healthy donors have shown to integrate into the damaged retinal vascular in

diabetic retinopathy and ischemia-reperfusion mouse models, where cells from the diabetic donor were unable to integrate into damaged vasculature [195]. The migratory defect of diabetic $CD34^+$ cells was due to reduced phosphorylation and intracellular redistribution of vasodilator-stimulated phosphoprotein, an actin motor protein for cell migration [196]. In addition, upregulated of the HSC quiescence factor TGFβ-1 in diabetes also contributes to hampering the migratory function of the $CD34^+$ cells [197]. Long-term diabetes can lead to changes in hematopoiesis, in which more bone marrow–derived proinflammatory monocytes and fewer reparative circulating endothelial progenitor cells (EPCs) are migration into the circulation [198]. Moreover, circulating EPCs are trapped in the bone marrow niche in diabetes [199]. Lack of reparative circulating EPCs in diabetes may contribute to the development of retinal degeneration.

A subpopulation of bone marrow derived progenitor cells expressing CD14 was discovered to have vascular reparative function as $CD34^+$. Unlike $CD34^+$, diabetic CD14 appears to retain the robust homing capacity to the damaged retinal vasculature [200]. Moreover, coadministration of MSC with diabetic $CD34^+$ enhanced the migration and colocalization of $CD34^+$ within the retinal vasculature [200]. The study supports the notion that combinations of cells may serve as an enhanced strategy; moreover, it provides evidence for the paracrine effect of MSCs and their ability to enhance the vascular function of defective diabetic $CD34^+$ cells.

Cell-specific gene RPE65 promotes the fate determination of bone marrow–derived stem cells into RPE-like cells for tissue repair. Systemic delivery RPE65 reprogrammed HSCs regenerate the RPE layer in an RPE ablation mouse model (sodium iodinate) [201] and in Sod 2 knockdown mouse model that has similar pathological features of AMD [202], and importantly, restored the visual function of these animals. Besides preserving damaged retinal vasculature, intravitreally injected bone marrow–derived lineage-negative HSCs contain endothelial precursors that have been shown to rescue photoreceptors without direct integration in nonischemic murine neurodegenerative diseases [203]. The indirect preservation of retinal neurons is, in part, via the neurotrophic effect of injected EPCs. Fukuda et al. showed that intraocular-injected EPCs recruit neuroprotective macrophages by secreting neurotrophic factors [204]. A similar neuroprotective function by paracrine factors was observed with bone marrow–derived $CD34^+$ cells [205].

EPCs such as $CD34^+$ cells represent a heterogeneous population of progenitor cells. The nomenclature is unable to match the increasing complexity of the cell. Moreover, murine stem/progenitors are characterized by different surface markers than humans and make it difficult to directly compare animal studies to human studies [206]. Therefore, a consensus was made in the field to give a more accurate terminology to define EPCs. In general, there are two main subtypes of EPC. One subtype is circulating angiogenic cells (CACs) or myeloid angiogenic cells (MACs) (Fig. 60.3). They represent a population of cells of hematopoietic origin that express CD45, CD14, and CD31 but are negative for CD146 and CD34. CACs/MACs both promote angiogenesis in a paracrine manner [207].

Endothelial colony-forming cells

Another subtype of EPCs is ECFCs (Fig. 60.3). This endothelial progenitor population has high proliferative capacity in vitro and capable of direct incorporation into

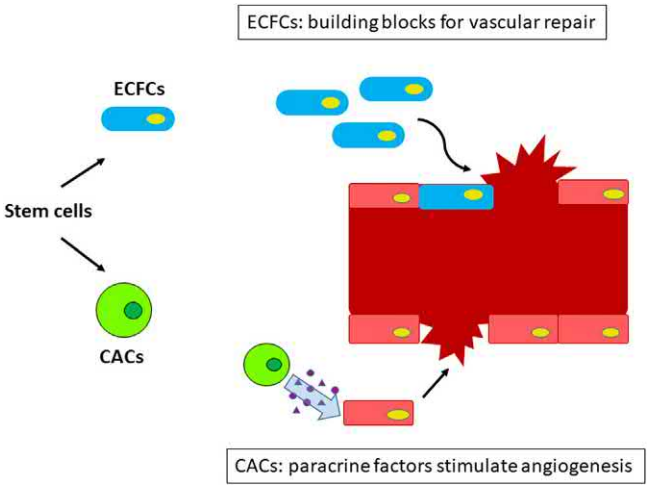

FIGURE 60.3 Stem cell–induced endothelial progenitors participate in retinal vascular repair. CACs release paracrine factors as stimulants of angiogenesis. ECFCs are the bona fide endothelial progenitors capable of direct incorporation into the injured endothelium. *CAC*, Circulating angiogenic cell; *ECFC*, endothelial colony-forming cell.

injured endothelium or de novo blood vessel formation in vivo [207–210]. ECFC represent the cell population with the expression of CD31, CD105, and CD146 and negative for CD45 and CD14 and these cells are vascular wall derived. Although these cells express CD34, the expression level may decline during in vitro expansion [207].

Administration of ECFC, a bona fide endothelial progenitor, has been demonstrated in preclinical studies to promote vascular repair in ischemic tissues, such as in myocardium [211], brain [212], hind limb [213], and kidney [214]. Recently, the vascular repair and vasoregenerative function of ECFCs were also examined in the murine ischemic retina [174,215,216]. In preclinical studies, intravitreal and systemic delivery of ECFCs has shown equal efficacy in retinal vascular repair; moreover, intravitreal delivery of ECFCs did not evoke an inflammatory response in the mouse [216]. These studies suggest the remarkable potential of these cells for clinical trials.

Therapeutic uses of ECFCs are primarily focused on harnessing their blood vessel-forming capacity. Recent studies have shown that ECFCs can exert trophic functions in support of engraftment of MSC [217]. Besides, CD44 cells, a subclass of ECFCs can promote vascular and neuronal protection by secretion of trophic factors in animal models of retinal diseases [215].

The potential for stem cells in ocular repair and tissue engineering

The realization of the existence of undifferentiated cells, which self-renew and show plasticity, in adult tissues offers great potential in the treatment of both ocular and nonocular diseases. It is now becoming evident that both intraocular and extraocular stem cells can play a critical role in the maintenance of ocular tissues. Furthermore, the plasticity of these cells means that they can be engineered to repair injured or diseased ocular tissues. Corneal LSCs are now routinely used in the restoration of the injured ocular surface, and BMSCs hold great promise in the repair of retinal damage. Ocular stem cells are an ideal starting point for tissue engineering of ocular tissues and offer a means of therapeutic intervention in a variety of pathologies involving cell/tissue loss (e.g., AMD, retinitis pigmentosa, glaucoma, and diabetic retinopathy). The future holds the promise of stem cells being used for gene delivery to correct genetic abnormalities in specific ocular tissues.

Chapter 61

Corneal replacement tissue

Maria Mirotsou[1], Masashi Abe[1] and Robert Lanza[1,2]
[1]Astellas Institute for Regenerative Medicine, Westborough, MA, United States, [2]Institute for Regenerative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC, United States

Introduction

Corneal blindness is the fourth leading cause of vision loss worldwide. It is caused by a variety of pathologies, including trauma or infection of the corneal surface, as well as congenital diseases that lead to degeneration of corneal cells [1]. Trauma and infection are the most common cause of corneal blindness in developing countries [2], whereas corneal degeneration is predominant in Europe and the United States [3]. Regardless of causation, the end stage of all corneal diseases is characterized by irreplaceable tissue loss. In these cases, patients have no therapeutic option other than undergoing surgery to replace part of their damaged cornea with donor corneal tissue (corneal transplantation, also called corneal allograft or keratoplasty) [1] (Fig. 61.1).

The first corneal transplantation was successfully performed in 1905, by Eduard Zirm, on a blind patient suffering from lime burns [4]. Since then, corneal transplantation has become one of the most frequent types of transplantation performed worldwide, with thousands of procedures performed each year. As a reference, in 2012, 185,000 corneal transplants were performed globally [5]. Due to the immune privileged environment of the eye, corneal transplants are quite successful, with an estimated graft survival rate of approximately 80%−90%, at 1 year after transplantation [6−8]. Still, a significant number of patients, particularly among those who exhibit inflammation and vascularization of the cornea, show rejection and require a new graft within 5 years of transplantation [9]. Unfortunately, access to good quality corneal tissue at an affordable price remains a significant challenge in many parts of the world. Currently, 12.7 million patients worldwide are waiting for a corneal transplant, without taking into consideration patients in remote rural areas with poor access to eye care [5]. This donor shortage will likely continue due to population growth and a demographic shift toward an aging population.

To address such a challenge, new therapeutic approaches have gained considerable experimental and clinical attention. The use of artificial corneas composed of clear plastic, for example, has increased over the past decade. However, this approach is limited to extremely severe cases due to complications and high host rejection rates [10,11]. The use of biocompatible materials alone or in combination with cells has emerged as a promising alternative. In this chapter, we will describe recent developments of such new therapeutic approaches in the context of different corneal cell types and functions.

Corneal anatomy and structure

The human cornea is a transparent, avascular tissue at the outermost part of the eye. It forms a barrier that protects the eye from damage or infection. The cornea also serves as the primary lensing unit of the eye refracting and focusing light to ensure proper transmission through the pupil and lens onto the photosensitive retina. Maintaining corneal transparency is therefore paramount for visual acuity.

The cornea is composed of three layers from anterior to posterior: epithelium, stroma, and endothelium (Fig. 61.1). The epithelium is separated from the stroma by the Bowman's membrane, while the endothelium is separated from the stroma by the Descemet's membrane (DM). Both the Bowman's and DMs are enriched with various types of collagens and proteoglycans, performing structural and physiological functions to maintain healthy corneal epithelial and endothelial cells, respectively [12]. Recently another distinct layer, termed pre-DM or Dua's layer, was identified in between the stroma and the conventional DM. The exact significance of this membrane awaits further study, but one potential role is to provide additional mechanical strength and support for the DM [13,14]. The cornea is also densely innervated and one of

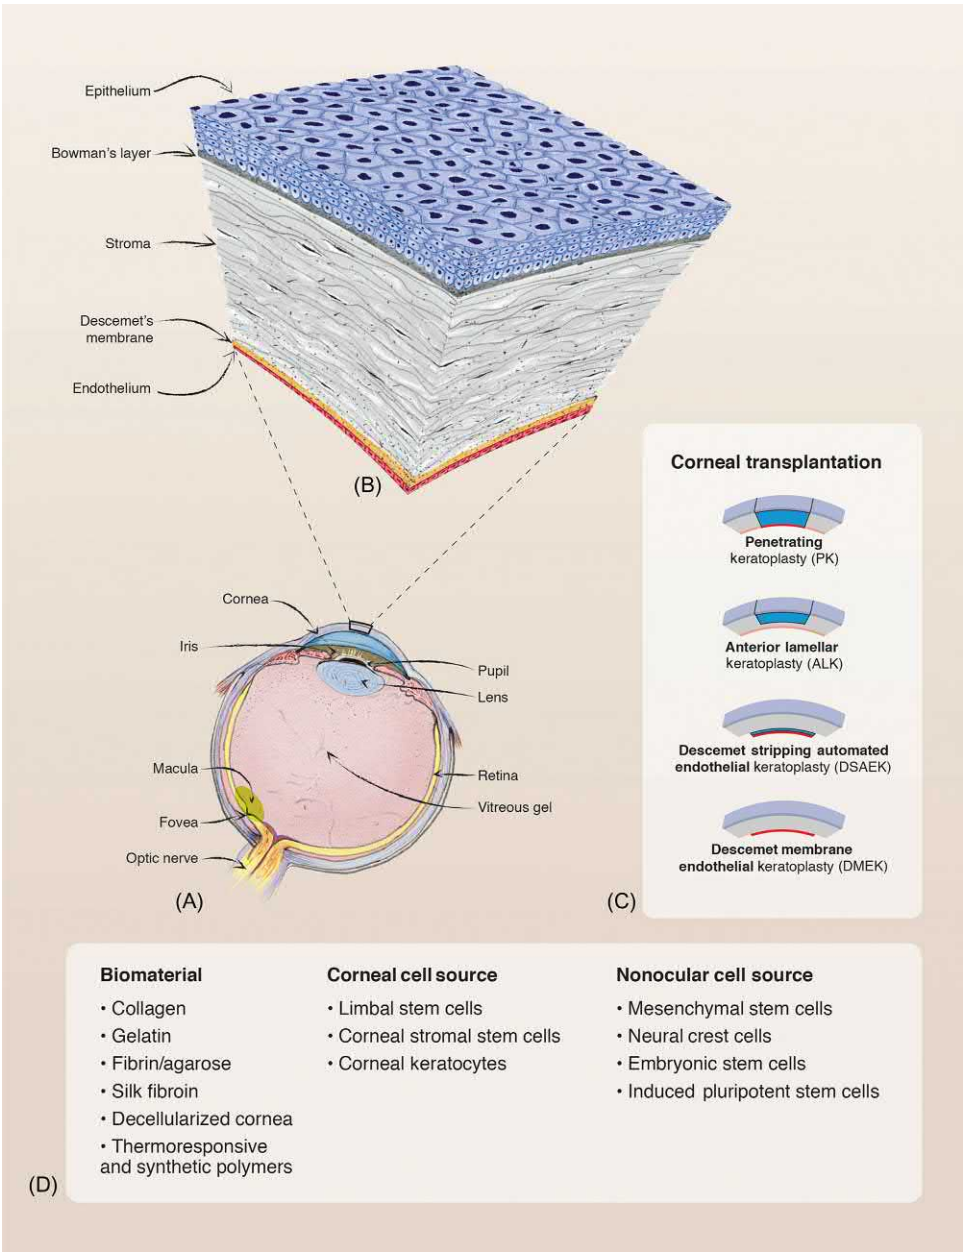

FIGURE 61.1 (A) Representation of the eye indicating the different anatomical structures, including the cornea; (B) schematic of human cornea cornea layers: the outermost stratified squamous epithelium layer with underlying the Bowman's layer, followed by the stroma containing keratocytes, the Descemet's membrane, and the single-layer endothelium; (C) schematic of different types of corneal tissue transplantation: PK: full-thickness corneal transplant replacing the central part of cornea, ALK: when only the stroma is replaced; DSAEK and DMEK: partial thickness corneal transplants used to replace the endothelium layer of the cornea. DMEK is a pure replacement of the endothelium and does not contain any stromal cells; (D) overview of bioengineering approaches for corneal tissue replacement.

the most sensitive tissues in the body. These nerves are essential for sensations of touch, pain, and temperature, as well as for controlling blinking, production of tears, and overall corneal health and structure [15]. Since the cornea does not contain any blood vessels, all nutrients are supplied through diffusion from the tears and the aqueous humor, a clear liquid found in the anterior chamber inside the front part of the eye.

Considering this highly organized structure, the development of an adequate replacement for cornea tissue should encompass strategies that effectively recapitulate both the correct corneal structure and function. For example, any bioengineered corneal tissue replacements should withstand proper ocular pressure and be transparent. For this purpose, not only cells but also the combinations of cells, small molecules, scaffolds, and proteins are currently being explored at the preclinical and clinical levels.

Epithelium

The corneal epithelium is the most superficial layer of the cornea. Along with tears, it creates a smooth surface that allows the refraction of light, protects the eye from environmental insults (microbial and chemical), and transfers water and solutes in and out of the stroma. The corneal epithelium consists of a single layer of basal cells and

4−6 layers of stratified, transparent, nonkeratinized wing cells (Table 61.1). The cells of the outermost 2−3 layers are squamous, flattened cells (Table 61.1) that are continually shed and regenerated every 7−10 days. This regenerative capacity depends on adult stem cells located at the border of the cornea and the sclera in a location called the limbus [16]. Under normal conditions or during the healing process following a moderate injury, these limbal epithelial stem cells (LSCs) give rise to transient cells that proliferate, migrate to the center of the cornea, and gradually differentiate to basal and wing cells. These new cells replace the superficial squamous cells at the outer layer of the corneal epithelium [17]. Although an exclusively LSC selective marker remains unknown, certain proteins such as P63a, ABCG2, cytokeratins, and ABCB5 are commonly used to define LSCs [18].

Chronic pathological conditions, such as Stevens−Johnson syndrome, or severe trauma (e.g., chemical or thermal burns) can disrupt the limbal stem cell niche or permanently damage LSCs, causing limbal stem cell deficiency (LSCD) [19]. As limbal stem cells fail to regenerate and maintain the corneal epithelium, new vascular vessels are formed, and conjunctival epithelium invades the cornea resulting in corneal opacity and vision loss. Corneal transplantation is not effective for LSCD as it addresses neither the continuous need for epithelial regeneration nor the risk for early graft rejection due to the invasion of the cornea by conjunctival cells. LSC transplantation, therefore, represents the only promising therapeutic approach for LSCD. Due to the accessibility of corneal epithelium at the outermost layer of the eye, research on LSCD cell therapy has a long history spanning nearly five decades [20].

LSCs can be transplanted either as autologous or allogeneic limbal tissue, or as single cells that have been expanded outside of the body. The first successful limbal transplantations were reported in 1989, in which autologous limbal tissue from the uninjured or less injured donor eye was used on the severely injured recipient eye [21]. The majority of those patients showed sustained regeneration of the corneal epithelium and vision recovery without any complications. These salutary results paved the way for the widespread use of autologous limbal tissue grafts for LSCD, establishing this approach as the standard of care in the United States. Allogeneic tissue grafts are also in use, particularly for patients with bilateral disease, but require long-term immunosuppression and have significant rejection rates after 3−4 years limiting their success and application [22].

To circumvent these challenges, in 1997, autologous limbal stem epithelial cells were expanded in vitro, followed by transplantation into unilateral LSCD patients resulting in the successful restoration of corneal epithelium in patients with moderate to severe LSCD [23]. Developments based on this method have led to the first cell-based treatment (Holoclar) for LSCD caused by burns in Europe [24]. Clinical investigations for Holoclar are still ongoing in the United States and are expected to be completed in 2020.

Using autologous LSCs would work well for unilateral LSCD patients. However, bilateral LSCD patients have limited numbers of LSCs, and alternative sources of cells are required. In 2004 two groups reported that autologous oral mucosal epithelial cells can be cultured and differentiated into corneal epithelial-like cells in vitro, using appropriate scaffolds. When these cells were transplanted into patients with LSCD, 70% of patients showed improvement [25,26]. Studies using allogeneic LSCs have also reported positive outcomes, potentially due to loss of immunogenicity during culture and improved cell retention after transplantation [27].

Unfortunately, using primary cell sources for replacement of the corneal epithelium comes with significant logistical challenges that can preclude their clinical use. Appropriate donor tissue needs to be identified and screened for pathogens. In addition, cells need to be isolated, cultured in vitro, and extensively characterized prior to transplantation to ensure that there is no product variability due to donor or process variants. For instance, it is rather common that primary isolated cells fail to expand in culture due to technical variability or due to the age and disease state of the donor. Thus it would be highly desirable to have an unlimited allogeneic cell source to generate transplantable cells. The use of pluripotent stem cells (PSCs), such as embryonic stem cells (ESCs) and induced PSCs (iPSCs), offers such an option. The first study to successfully differentiate corneal epithelial-like cells from human PSCs used limbal fibroblast conditioned media as a means of replicating the conditions of the corneal stem

cell niche [28]. Since then, more than 10 protocols have been published describing the generation of LSCs or corneal epithelial cells from PSCs using various growth factors, undefined or animal-derived components, alone, or in combinations [29].

Regardless of the cell source used (primary or PSC-derived cells), most recent culture protocols include a variety of scaffold materials such as human amniotic membranes, fibrin substrates, and collagens [30]. Of these the human amniotic membrane has been the most extensively tested with a relatively high rate of success. However, the production of clinical-grade amniotic membrane is laborious and expensive and can result in variable stability in vivo, carrying a significant risk for graft rejection [31]. Fibrin, due to the ease of preparation, has been widely tested as an alternative and it is the substrate used in the manufacturing of Holoclar [32]. Recently, cell sheets and contact lenses have gained more attention as they allow for the utilization of FDA approved materials. Questions regarding how to optimize the attachment, alignment, and maintenance of cells in these structures remain, although some initial successes have already been reported using this approach. Indeed, a team in Japan has already initiated tests to treat four patients with a corneal transplant. The transplant will be a 0.05 mm thick cell sheet composed of corneal epithelial stem and progenitor cells derived from iPSCs cultured in a specifically designed laminin E8 matrix [33]. The first patient treated has already shown visual improvements, 1 month after cell transplantation, without any adverse effects [34,35].

Stroma

The stroma is a highly organized structure, crucial for maintaining the transparency and mechanical strength of the cornea. Among the three distinct corneal layers the stroma constitutes the largest part of the cornea (approximately 90% of thickness) (Fig. 61.1). It is mainly composed of extracellular matrix, primarily type I collagen, forming tightly packed parallel collagen fibrils (lamellae). The size and spacing of these fibrils are regulated by the presence of the proteoglycans, as well as by the ratio of the different types of collagen (collagen type I to type V ratio). The corneal stroma also contains a small population of specialized cells called keratocytes [10], (Table 61.1). Keratocytes make up only 3%−5% of the stromal volume and are embedded between the collagen lamellae. Developmentally, keratocytes are derived from neural crest cells (NCCs) and are characterized by the expression of keratan sulfate−containing proteoglycans, such as keratocan and lumican, as well as human aldehyde dehydrogenase 3A1 (ALDH3A1), prostaglandin D2 synthase (PTDGS), and the transcription factor KLF4 [36,37]. The primary function of the keratocytes is to deposit the extracellular matrix protein found in the stroma [38].

Keratocytes are typically nonproliferative. However, upon injury, they begin to divide and secrete extracellular matrix components promoting scar resolution and healing of the cornea [10,39,40]. Intriguingly, keratocytes can also secrete neurotrophic and pro-inflammatory factors, such as IL-8, IL-15, MCP-1, eotaxin, and RANTES, which can promote nerve regeneration in the damaged stroma [41]. During severe injuries, activated keratocytes progressively express vimentin, αSMA, and desmin and become myofibroblast cells. The development and persistence of these myofibroblasts can lead to disorganization of the collagen lamellae, clouding of the stroma, and eventually to permanent scar, fibrosis, and loss of visual acuity [40]. In these cases, alternative approaches are required to reconstitute the proper structure and function of the stroma.

Reflecting its mostly collagenous nature and in contrast to the cell-centric nature of epithelial and endothelial tissue engineering, the main approaches for stromal tissue engineering are scaffold-based. To mimic the collagenous structure of corneal stroma, several studies have used collagen scaffolds, such as collagen hydrogels, sponges, films, and augmented collagen scaffolds [10]. Other materials such as synthetic polymers and silk fibroin, as well as more elaborate methods such as cornea decellularization, have also been explored [10]. Zhang et al., for example, have used decellularized porcine corneas for transplantation in patients with corneal fungal ulcers. More than 70% of these patients recovered their corneal transparency and showed visual improvement [42]. Still, the use of xenogeneic material carries the risk of rejection or allergic reaction [43−45]. A recent intriguing approach that circumvents this risk is the use of 3D printing to deposit recombinant human collagen to create collagen layers that mimic stromal structure. Corneal stromal cells successfully grew and penetrated into these 3D-printed scaffolds, opening up the possibility of more customizable stromal tissue engineering [10].

In recent years the strategies for corneal stroma tissue engineering have expanded to include the combinations of scaffolds with cells. Initial efforts have been focused on the culture of isolated primary keratocytes; however, the isolated cells lost their keratocyte characteristics in vitro [46]. To preserve keratocyte identity, Che et al., cultured the cells on an ultrathin layer of amniotic membrane and developed a multilayer, stroma-like construct that they then transplanted in a rabbit model. Four weeks post-surgery, the implants appeared to be well integrated into the cornea, promoting collagen lamellae formation [47]. Corneal stromal stem cells present in the limbal niche below the basement membrane have also been isolated. These cells can adopt a more mature keratocyte

phenotype in culture and can deposit collagen and other stromal extracellular proteins [48]. When these cells were transplanted in mice with corneal stromal defects, they restored stromal thickness and collagen fibril organization [49]. In addition to corneal cells, multiple sources of mesenchymal stem cells (MSCs) such as bone marrow, adipose tissue, and umbilical cord have been used to generate cells with a keratocyte phenotype [50]. At the clinical level, adipose-derived MSCs from patients were transplanted, alone, or in combination with decellularized human corneal stroma, in patients with advanced keratoconus. No complications were observed after a 1 year follow-up, and corneal transparency was recovered in all patients [51]. Though promising, this approach still has challenges as it heavily relies on autologous sources of cells and donor-derived corneal stroma. Consequently, recent efforts have been focused on generating keratocytes derived from human-iPSC (hiPSC). As an example, Naylor et al. have seeded hiPSC-derived NCCs onto cadaveric human limbal rims. After 21 days in culture the cells acquired a morphological and molecular profile similar to that of native corneal keratocytes [37]. Whether these cells can functionally replace corneal keratocytes, alone or in combination with scaffolds in vivo, remains to be tested.

Endothelium

The corneal endothelium constitutes the innermost layer of the cornea, separating it from the aqueous humor in the anterior chamber of the eye (Fig. 61.1). The endothelium consists of a single layer (approximately 4 μm) of squamous epithelial cells, which are characterized by the distinct expression of ion pumps such as Na + /K + /ATPase and tight junction protein such as ZO-1 (Table 61.1). This layer serves as a barrier to maintain the proper corneal dehydration state via a pump-leak mechanism [52,53].

Loss or dysfunction of the corneal endothelial cells (CECs) creates excess fluid buildup in the cornea, resulting in progressive swelling, stromal disorganization, reduced transparency, and impaired vision [54]. The leading causes of corneal endothelial loss and dysfunction are endothelial dystrophy, trauma/surgery, or chronic anterior uveitis. Fuchs' endothelial corneal dystrophy and congenital hereditary endothelial dystrophy are among the most common corneal endothelial dystrophies caused by genetic mutations and potential environmental factors [55]. Another frequent cause of endothelial dystrophy, pseudophakic bullous keratopathy, is induced by damage to the endothelium during cataract surgery. Diabetes and aging are also significant risk factors for corneal endothelial loss.

Unlike epithelial cells that can repair by proliferation, adult CECs have limited proliferative capacity. Instead, endothelial cells tend to repair by sliding toward the area of injury and enlargement of adjacent cells. Although this mechanism maintains the corneal endothelial barrier after injury, it also reduces endothelial cell density and alters their hexagonal morphology and pumping capacity. When the reduction in cell density reaches a range of 500−1000 cells/mm^2 or less, the only available therapeutic option is partial or complete corneal transplantation [54]. Currently, corneal transplantation for endothelial loss accounts for 60% of all corneal transplants performed in the United States [56].

To overcome the above-described corneal tissue donor shortages, initial efforts have focused on the isolation and ex vivo expansion of primary CECs. The first successful culture of human CECs was reported in 1965 [57]. Since then, several modifications in isolation techniques, extracellular matrix substrates, and culture media have been developed to overcome the cells' limited propagation capacity and the loss of the CEC phenotype in culture [58,59]. For instance, Okumura et al. examined the expression of different laminin isoforms in the cornea and identified laminin-511 and 521 as the predominant laminin forms in adult DM [60]. Using these two laminins as a substrate for the in vitro culture of human CECs, they managed to significantly improve the attachment, survival, and expansion of CECs [60]. Other groups have tried culturing human CECs on human donor−derived DMs as substrates. The advantage of this approach is that it mimics the in vivo corneal environment to achieve proper CEC maintenance and growth [61,62]. The importance of DM in supporting CEC expansion was also confirmed by a recent study conducted in a rabbit corneal endothelial injury model. Through this, it was demonstrated that the absence of DM impaired native CEC migration and cornea regeneration [63].

Despite the advantages, the use of scaffolds complicates delivery into the cornea, necessitating elaborate surgical procedures. A much simpler approach would be to deliver CECs in cell suspension. The injection of cells in suspension would allow simpler manufacturing methods and theoretically be less invasive [64]. However, this approach increases the risk of the removal of injected cells by the flow of aqueous humor, limiting cell survival and engraftment in the cornea. Two methods developed to improve the delivery of cell suspensions into the corneal endothelium include the use of magnetic field guided delivery and the coinjection of cells with a ROCK inhibitor. For magnetic cell delivery, CECs are labeled with magnetic particles and delivered to the appropriate location on the posterior corneal surface with the help of an external magnet [65−67]. In a recent example, CECs were labeled with superparamagnetic nanoparticles and injected in the anterior ocular chamber of adult rabbits with CEC injury. Similarly to native CEC, the injected

cells formed a monolayer and restored corneal transparency without any adverse effects [68]. Alternatively, Okumura et al. used coinjection of CECs with the ROCK inhibitor Y27632 to enhance CEC survival and proliferation. This approach resulted in better engraftment of the cells and improved recovery of corneal transparency in a rabbit model of corneal injury [69]. These salutary effects were confirmed in a monkey model of corneal endothelial dystrophy [69], leading to the initiation of human clinical studies. In 2018 the same group reported the results of transplantation of CECs, in combination with ROCK inhibitor, in 11 patients of bullous keratopathy; more than 80% of the treated patients showed recovery of corneal thickness and improved visual acuity 24 weeks after treatment [70]. This study provided the first clinical evidence that the minimally invasive transplantation of cultivated human CECs can be utilized as a new therapeutic option to treat corneal endothelial dysfunction. At the same time, it raised questions regarding the future development of this approach. These include the need to determine a suitable donor age range for the production of high-quality transplantable CECs, the mechanistic contribution of ROCK inhibitor to the clinical outcomes, the precise dosing of cells to balance efficacy and safety, and the development of a means of tracking the fate of delivered cells after transplantation [71]. In addition, the limited availability of high-quality donor CECs and the limited capacity of the cells to expand in vitro are pausing some significant challenges for the clinical translation of this approach.

For this reason, several groups have been trying to generate CEC-like cells from alternative stem cell sources, such as MSCs, skin-derived cells, corneal stromal cells, and PSCs [72–77]. These studies applied our current understanding of embryonic development of CECs by isolating putative CEC progenitor populations, such as NCCs, from primary cells and differentiating them to more mature CEC-like cells. For example, corneal stroma cells and skin-derived precursors containing NCCs were isolated and cultured in the presence of retinoic acid and GSK 3β inhibitor (Wnt signaling pathway activator) to induce CEC-like cells. These cells showed upregulation of Pitx2, a key transcription factor for the development of the anterior eye segment, as well as upregulation of the CEC markers Atp1a1 and Cdh2. Importantly, the cells exhibited functional characteristics of CECs, such as pump function. When the cells were transplanted using a collagen sheet as a carrier, they restored vision in a rabbit model of keratopathy [72,73]. Using a similar approach, Shen et al. differentiated skin-derived precursors by coculturing with B4G12, an immortalized human CEC line. Within 1 week of differentiation, the cells exhibited marked expression of typical CEC markers. Transplantation of these cells resulted in the successful recovery of corneal thickness and corneal transparency in both rabbit and monkey models of corneal endothelial dystrophy [74].

NCCs can also be generated in vitro from PSCs, offering an unlimited and expandable source of cells for clinical application. Zhang et al. reported the differentiation of human ESCs to periocular mesenchymal precursor cells (POMPs), a subtype of NCCs, by transwell coculture with human corneal stromal cells. These induced POMPs were cultured in conditioned media from lens epithelial cells, and differentiation was confirmed by testing the gene expression of typical CEC markers such as N-Cadherin, FoxC1, and PITX2. To enrich for CEC-like cells, the cells were then sorted and seeded on a decellularized porcine corneal matrix followed by successful transplantation and induction of corneal repair into a rabbit model of corneal dystrophy [78].

To avoid the use of xenogeneic material from decellularized corneas, recent approaches are employing small molecule compounds and xeno-free growth factors to induce the CEC cell fate. Several groups, for example, have shown differentiation of PSCs to NCCs following the inhibition of the TGFβ/SMAD pathway [75–77]. These NCCs were then cultured in media containing PDGF-BB and Dkk2, which induced the cells to acquire the hexagonal appearance and express molecular markers of CEC cells [75,77]. Importantly, the cells could deposit collagen generating an in vitro-generated DM and expressed major components of the corneal endothelial pump function such as Na^+K^+ATPaseα1 [75]. Although promising, the functional aspect of these PSC-derived CEC-like cells awaits further investigation. Some critical future questions include the ability of these PSC-derived CEC-like cells to function as a leaky barrier and maintain the dehydration state of the cornea, as well as the exploration of their in vivo therapeutic potential.

Conclusion

Cornea transplantation is constrained by a lack of donor corneas, leaving many patients with visual impairment and blindness. Parallel advancements in bioengineering and the stem cell fields have significantly progressed our understanding of corneal biology and allowed for the development of novel strategies for corneal tissue replacement. Due to the relative simplicity of their isolation and expansion in vitro, corneal epithelial limbal stem cell transplantation for LSCD treatment has progressed the farthest along the clinical development path. Current success rates are in the range of 60%–80%, and further improvements are expected as we discover specific LSC stem cell markers that allow better isolation methods and use of the cells. In parallel the development of innovative methods to produce 3D tissue-like structures that mimic

the microarchitecture and physiology of the native cornea offers opportunities to reconstruct cornea tissue shape, organization, and function, particularly in regards to corneal stromal repair [11,79]. The recent clinical advancements, along with the rapidly expanding development of methods for generating CEC-like cells from multiple stem cell sources, will also increase the emphasis on endothelium replacement via cell therapy and tissue engineering in the coming years.

The use of PSCs as a starting source to generate corneal cells is also expected to gain traction as new differentiation protocols are developed, and the regulatory path to the clinic is established. One advantage of corneal diseases for cell therapy is the immune-privileged environment in the eye, which is permissive to allogeneic PSC sources for generating corneal cells. Still, some level of immunosuppression regimen is required to prevent cell rejection, and unfortunately some patients are unable to tolerate this regiment for long term. Cell engineering, or a combination of cells with new materials, is bound to play a significant role in addressing this concern.

In addition, the use of stem cells−derived extracellular vesicles (EVs), which are presumably less immunogenic than cells, has recently emerged as an alternative therapeutic option. Several studies have reported the secretion of EVs from corneal cells, such as limbal epithelial cells and mesenchymal stromal cells, establishing their potential function in proliferation and repair in the corneal environment [80,81]. Further investigations are required to explore the significance of these findings and provide clear evidence of in vivo functionality. Finally, one of the key considerations for the translation of cell-based approaches to real world therapies is the complexity of the processes and materials needed to generate the cells or the scaffolds. To have a wider clinical applicability, therefore, it is necessary to develop streamlined robust protocols using xeno-free materials that ensure the manufacturing of these products in safe and effective ways.

Epidemiology of visual impairment and blindness

An estimated 1.3 billion people globally suffer from some form of visual impairment. Of those, 188.5 million people have mild visual impairment, which can be defined as a best corrected visual acuity (BCVA) of worse than 6/12 but at least 6/18 or better in a standard Snellen eye chart test. This means that a person with mild visual impairment needs to stand 6 m from a letter chart in order to read letters that a person with "normal" vision could see at a distance of either 12 or 18 m, respectively. An estimated 217 million have moderate-to-severe impairment (a BCVA of worse than 6/18 but at least 3/60 or better) and 36 million people are blind (with BCVA of worse than 3/60) [1]. The age of onset for visual impairment can vary depending on the underlying disease, but those over the age of 50 are at an increased risk since visual impairment in general is associated with aging [1,2]. The five most common causes of visual impairment are uncorrected refractive errors (e.g., myopia, hyperopia, presbyopia, and astigmatism), cataracts (clouding of the lens), and the retinal degenerative diseases: age-related macular degeneration (AMD), glaucoma, and diabetic retinopathy (DR) [2,3]. Although cataracts can be treated with surgery, limited access to appropriate medical intervention, particularly in lower income countries, means they often go untreated and make cataracts the leading cause of blindness worldwide [4]. In higher income countries where access to surgery is more common, the relative prevalence of blindness due to retinal degenerative diseases such as glaucoma, AMD, and DR increases.

Retinal degeneration involves the progressive loss of specific cell types within the retina. Depending on the disease, different cells are more severely affected than others, yet the net result of retinal degeneration is progressive visual impairment, which may lead to blindness. Although some drugs are available to treat these disease, such as anti-vascular endothelium growth factor (VEGF) treatment for wet AMD and DR or intraocular pressure (IOP)–lowering drugs to treat glaucoma, these medications cannot replace cells that have already been lost due to the degenerative process and often do not provide enough support to rescue cells that are damaged and at risk of dying. Cell-based therapies and tissue engineering have an opportunity to do both upon engraftment in the retina; they may (1) provide trophic support for sick or dying cells and/or (2) functionally replace host cells that have already been lost due to degeneration. The chapter discusses cell-based therapies and tissue engineering approaches to the most common retinal degenerative diseases.

Structure/function of the retina and cell types affected in retinal degenerative diseases

In order to understand how cell-based therapies and tissue engineering can be used to treat retinal degenerative diseases, it helps to understand the basic structure/function of the retina, its cell types, and their role in the visual transduction cascade. The retina is a stratified, light-sensing tissue that resides at the back of the eye adjacent to the choroid layer, which contains vasculature and, beyond that, the sclera, which is the white-colored collagen-containing outer lining of the eyeball. Each layer within the retina contains neuronal cells with specialized functions that work together to convert light signals to electrical ones and relay these signals to the brain. The most distal layer of the retina comprises retinal pigment epithelium (RPE), which is a single layer of hexagonal-shaped, polarized epithelial cells (Fig. 62.1).

The RPE attaches to the choroid through Bruch's membrane and supports the health of adjacent rod and cone photoreceptors through processing of retinoids,

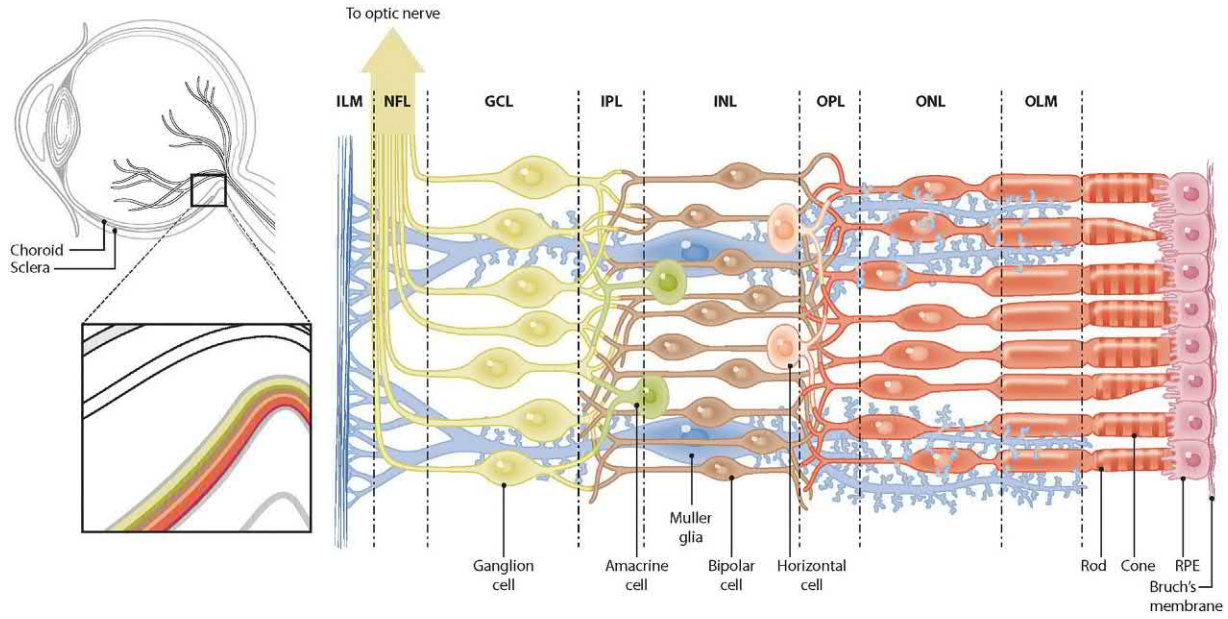

FIGURE 62.1 The eye and the cellular layers of the retina.

absorption of scattered light, ion and fluid transport, and phagocytosis of shed photoreceptor outer segments [5]. Tight junctions between individual RPE cells help form a barrier that works in concert with the blood retinal barrier to maintain the immune privileged status of the eye and regulate ionic exchanges between the circulation and retina. The RPE may also play a more active role in suppressing the immune responses in the eye. It has been found that RPE cells can suppress T-cell activation by altering expression of T-cell activation markers such as CD69 and CD25, and secretion of IL-10, induce a regulatory T-cell phenotype, and trigger T-cell apoptosis [6–9].

As the main light-sensing cell type within the retina, photoreceptors traverse the next three retinal layers in a highly polarized fashion. The outer and inner segments of rods and cone-shaped photoreceptors about the RPE and form the rod/cone layer. The outer limiting membrane (OLM), comprising adherens junctions between photoreceptors and supporting Müller glia, comes next and provides structural support as well as a barrier function for the retina. The outer nuclear layer (ONL) contains photoreceptor nuclei and is located on the other side of the OLM followed by the outer plexiform layer (OPL), which contains photoreceptor synaptic bodies [10] (Fig. 62.1). There are about 120 million rods and 6 million cones in the human retina, with cones being highly concentrated in the macula, or center of the retina to provide central vision [10]. Within the macula, the fovea is a pit-like structure that contains the highest density of cones, which thereby provides the highest resolution visual acuity. Cones are responsible for vision and color discrimination in well-lit environments. Subtypes are classified by the absorption spectra of the light-sensitive opsin protein they contain: L cones respond to long (red) wavelengths of light, M cones respond to medium (green) wavelengths, and S forms respond to short (UV/violet or blue) wavelengths. Rods, on the other hand, are excluded from the macula and reside throughout the periphery of the retina. They contain rhodopsin that is extremely efficient at absorbing green to blue wavelengths of light to provide vision in dimly lit environments [11]. The outer segments of both rods and cones capture photons of light through ordered stacks of opsin-containing disks while the inner segments contain mitochondria to produce ATP needed to regulate ion channels.

Through a process known as visual phototransduction, captured light triggers the dissociation of retinal molecules from opsin proteins in rods and cones followed by ion channel closing, subsequent photoreceptor hyperpolarization, and inhibition of glutamate release from the synaptic region of the cells. In the dark, glutamate is received by bipolar and horizontal cells and inhibits their activity. In the light, the lack of glutamate relieves the inhibition of these retinal neurons, leading to their activation. Bipolar cells then amplify and transmit the electrical signal downstream to amacrine cells through interplay among various ON and OFF bipolar subtypes. Horizontal cells help fine-tune this signal and provide feedback to photoreceptors. Nuclei of all three classes of secondary neurons, bipolar, horizontal, and amacrine cells, reside within the inner nuclear layer (INL) while their processes either extend distally to the OPL (bipolar and horizontal) or proximally to the inner plexiform layer (IPL) as in the case of amacrine cells (Fig. 62.1). The IPL is where most

dendrites of amacrine cells synaptically connect with dendrites of retinal ganglion cells (RGCs), while the ganglion cell layer consists mainly of RGC cell bodies and a few amacrine cells. In response to receiving signals from amacrine cells, RGCs send action potentials through their axons, which comprise the nerve fiber layer, into the optic nerve to relay the visual message to the lateral geniculate nucleus of the thalamus and then into the visual cortex in the occipital lobe of the brain. The inner limiting membrane (ILM) is the innermost layer of the retina and separates the nerve fiber layer from the fluid-like vitreous humor, the large cavity located between the lens and the back of the eye. The ILM comprises Müller glia footplates and a basement membrane containing various extracellular matrix proteins. Müller glia themselves traverse all the layers of the retina to provide structural support and functional stability to all the other retinal cell types (Fig. 62.1).

Retinal degenerative diseases cause targeted dysfunction and loss of specific cell types within the retinal layers, and this in turn disrupts the visual phototransduction cascade. For example, AMD involves dysfunction and loss of RPE cells first, followed by the loss of cone photoreceptors in the macula and leading to loss of central vision. In severe cases, loss of rods and thus peripheral vision may follow. Retinitis pigmentosa (RP) involves initial loss of rod photoreceptors, leading first to loss of peripheral and night vision, while more severe cases lead to loss of cones and central vision as well. In extreme cases of RP, secondary neurons in the INL and IPL may degenerate, become disorganized, and undergo aberrant rewiring due to loss of proper input from the ONL [12]. Glaucoma involves damage to the axons of RGCs in the proximal-most layer of the retina, often leading to their death and progressive loss of vision. Lastly, DR involves disruptions to retinal vasculature due to repeated bouts of elevated blood glucose. This disturbs blood flow and nutrient supply of neuroretinal cells, leading to retinal neovascularization, neuroretinal degeneration, and ultimately visual impairment. Preclinical and clinical data suggest that engraftment of cells, which can provide functional replacement or trophic support to the impaired cell type holds therapeutic promise to treat these otherwise intractable diseases (Table 62.1). Details on each retinal disease and tissue engineering approaches to treat them are discussed in the next sections.

Age-related macular degeneration

AMD is the third leading cause of blindness worldwide after cataracts and glaucoma and the leading cause of blindness in industrialized countries [2,13]. Its global prevalence was 170 million people in 2016 and is projected to be 200 million by 2020 and 288 million by 2040 [13,14]. In the United States alone, 3 million people are projected to have AMD by 2020 [15]. As its name suggests, aging is the biggest risk factor for AMD along with environmental factors such as smoking, diet, alcohol consumption, and sunlight exposure. Evidence also suggests that there is a genetic component to AMD. In a large-scale study of 16,144 late AMD patients and 17,832 controls, 34 loci encompassing 52 genetic variants independently showed association with late AMD cases [16]. There are several detailed clinical grading scales for AMD [17], although disease severity is generally classified as early, mid, and advanced stages based on the number and size of drusen, the lipid, and protein containing deposits that form between the RPE and the underlying Bruch's membrane. The "dry" form of AMD accounts for 80%–90% of all AMD cases where there is loss of RPE or geographic atrophy (GA) in the macula but without neovascularization. The "wet" or exudative form of AMD is characterized by neovascularization and is considered more severe than dry AMD as it often leads to blindness. As dry AMD worsens, 10%–20% of cases will progress to wet AMD. In situations where the disease leads to blindness, 80%–90% of them are in patients with wet AMD and up to 20% of blindness results from severe dry AMD with GA [18].

Strategies to prevent or delay progression of AMD include taking supplements containing zinc and the antioxidants, vitamins C and E, and beta carotene [19]. Further supplementation with the carotenoids, lutein and zeaxanthin and/or omega 3 fatty acids may also help, but there are conflicting reports as to the actual benefit of these strategies [20–22]. Antiangiogenic therapies, including the anti-VEGF drugs ranibizumab (brand name Lucentis), bevacizumab (Avastin), and pegaptanib (Macugen), have shown promise in preventing further visual acuity (VA) loss in wet AMD patients [23–25]. For atrophic AMD/GA, most therapies evaluated to date, including the complement inhibitors, eculizumab (Soliris) and lampalizumab, have not proven to be very effective [26–28]. Cell-based therapies may be an alternative for AMD patients who do not respond to other treatments mentioned earlier.

History of retinal pigment epithelium as a cellular therapy for age-related macular degeneration

Historically, the culture of RPE in vitro dates back to 1980, when Flood et al. [29] successfully maintained human RPE from adult donors in culture for several months. Shortly thereafter, the feasibility of RPE transplantation was demonstrated by injecting human RPE into owl monkey eyes [30,31]. In the late 1980s, groups began

TABLE 62.1 Major retinal degenerative diseases and cell-based therapies in development.

Retinal degenerative disease	Est. worldwide prevalence (million)	Cause(s), risk factors	Primary cell type affected	Cell therapies in clinical trials (or preclinical development)
AMD	200	• Age • Genetic risk (≥52 genetic variants at ≥34 loci) • Smoking • Diet and alcohol consumption • Sunlight exposure	RPE	• Adult 1 degree RPE • Fetal RPE • Adult 1 degree IPE • hESC-RPE cells and sheets • iPSC-RPE
RP	2.5	• Genetic mutations (>3100 mutations in >66 genes cause primary RP) • Genetic mutations (>1200 mutations in >31 genes cause RP as part of a larger syndrome)	Rod photoreceptors	• Adult 1 degree photoreceptor sheets • Fetal neuroretinal cells and sheets • Fetal retinal progenitors • (PSC-derived retinal cells in preclinical development)
Glaucoma	60–70	• Age • Genetic risk (>70 single-nucleotide polymorphisms associated with POAG form) • Ancestry (POAG higher in African, Hispanic populations while NTG form is more prevalent in Asian populations)	Retinal ganglion cells and TM cells	• CNTF-expressing, encapsulated ARPE-19 cell line • (PSC-derived RGC and TM cells in preclinical development)
Diabetic retinopathy	95	• Diabetes mellitus, both types I and II, particularly those with diabetes for >20 years	Retinal vasculature	• Adipose-derived MSCs • (PSC-derived vascular progenitors in preclinical development)

AMD, Age-related macular degeneration; *hESC*, human embryonic stem cell; *IPE*, iris pigment epithelium; *iPSC*, induced pluripotent stem cell; *MSC*, mesenchymal stem cell; *NTG*, normal tension glaucoma; *POAG*, primary open-angle glaucoma; *PSC*, pluripotent stem cell; *RP*, retinitis pigmentosa; *RPE*, retinal pigment epithelium; *TM*, trabecular meshwork; *CNTF*, ciliary neurotrophic factor.

using the Royal College of Surgeons (RCS) rat as a preclinical model for evaluating the therapeutic properties of transplanted RPE [32,33]. The RCS rat strain contains a mutation in the gene for MERTK, a receptor tyrosine kinase involved in RPE phagocytic functions. Without functional MERTK, RPE phagocytosis is disrupted and thus unable to support the natural process of engulfing and recycling of shed photoreceptor outer segments. This leads to atrophy of the RPE followed by the loss of photoreceptors. By 10–12 weeks of age, RCS rats are blind, providing an accelerated model of the retinal degeneration process observed in human AMD. Since the 1980s the RCS rat model has become one of the most well-studied and commonly used models to evaluate new therapies for AMD and has helped support the development of such therapies for clinical trials.

In the 1990s the first RPE transplantation studies in humans were performed, targeting patients suffering from severe AMD with GA [34–36]. A variety of different delivery methods were used in these early studies, with cells contained as part of an autologous pedicle graft, an allogeneic patch with attached Bruch's membrane, a patch containing fetal RPE, or as a cellular suspension of allogeneic RPE [34–36]. Collectively, these studies established early safety and feasibility of RPE transplantation but reported only modest if any effects on visual acuity. Rejection of the transplanted cells was also noted anywhere between 3 and 12 months following the treatment. Additional preclinical studies focused on ways to improve the survival of transplanted cells, including different immunosuppression regimens [37,38]. In the early 2000s the use of autologous pigmented epithelium from other areas of the eye was also explored. Iris pigment epithelium (IPE) [39–42] and RPE harvested from peripheral retina [43,44] or nasal retina [45,46] were transplanted onto the macula with limited success. IPE was found to phagocytose outer segments more slowly than RPE and also lacked essential retinoid metabolizing enzymes that RPE contain [40,42]. Advanced age, health of Bruch's membrane, and/or genetic predisposition to retinal

degeneration may also have precluded greater success with these autologous sources [47–49].

Many studies from 2000 to 2015 focused on the use of membranes or scaffolds to improve engraftment, orientation, and function of transplanted RPE. Potential scaffolding material should be biocompatible (i.e., nonimmunogenic) and porous to allow for diffusion of nutrients and oxygen into and waste products out of RPE. This material should also amenable to RPE attachment, viability, and growth and be flexible enough to ease of handling during surgery. Amniotic membrane [50–52], anterior lens capsule [53], and human ILM [54] are natural compounds reported to improve attachment and/or function of cells such as primary adult human RPE, fetal RPE, porcine RPE, primary human IPE, and the RPE cell line ARPE-19. Other substrates that have been tested for their use as RPE scaffolds include elastin-like recombinamers [55] and modified poly(hydroxybutyrate-*co*-hydroxyvalerate) thin films [56]. Extracellular matrix from corneal endothelial cells may also be used as a resurfacing agent to improve attachment of RPE onto aged or unhealthy Bruch's membrane [57,58]. It remains to be determined which substrate(s) or scaffold material is optimal for the health, survival, and function of RPE after transplantation.

Retinal pigment epithelium from pluripotent stem cells

Studies with primary RPE such as those described earlier helped pave the way for the generation and preclinical testing of RPE from pluripotent stem cell (PSC) sources. In 2004 Klimanskaya et al. were the first to demonstrate differentiation of human embryonic stem cells (hESCs) into RPE [59]. The hESC-RPE had characteristic RPE polygonal morphology, pigmentation, and expression of the RPE markers: bestrophin, CRALBP, and PEDF. The gene expression profiles and phagocytic properties of the hESC-RPE were also similar to those of primary RPE [59]. The hESC-RPE was injected into RCS rats prior to the naturally occurring loss of photoreceptor at postnatal day (P) 21–23 to determine if the transplanted cells could slow down or stop the retinal degenerative process. By P60, animals that had received hESC-RPE showed significantly better electroretinogram (ERG) response than untreated or sham-treated controls. By P100, treated animals displayed better visual acuity (as assessed by optomotor response) than untreated or sham-treated controls, and histology at P100 confirmed extensive preservation of photoreceptors in animals that had received the hESC-RPE transplant [60]. Follow-up dose–response studies demonstrated the long-term safety and function of hESC-RPE in RCS rats and ELOVL4 mice, which are a model for Stargardt's disease, the juvenile form of macular degeneration [61]. Studies in immunodeficient mice likewise supported their safe use by demonstrating lack of tumorigenicity from the transplanted cells [61]. A multitude of additional reports have since been published in the last 10 years describing the generation of RPE from hESCs [62–68] as well as human induced PSCs (iPSCs) [69–73]. Methods of differentiation and delivery (e.g., as cell suspension, sheets, or on scaffolds) vary in these studies, yet many of them provide additional evidence for therapeutic efficacy of PSC-derived RPE in preclinical models of retinal degeneration.

Clinical studies testing hESC-RPE in humans first began in 2011 with subretinal injections of cellular suspensions in patients with dry AMD and Stargardt's in Phase 1/2 trials [74]. Results showed the safety and tolerability of up to 150,000 cells in a single transplantation, with 18 patients (9 AMD and 9 Stargardt's) being treated. Fundus imaging taken at baseline and 3 and 6 months after transplantation showed a stable region of pigmentation in the area of the graft for several patients, which may or may not correspond to the transplanted cells (Fig. 62.2).

Overall, there was no evidence of rejection, hyperproliferation or tumorigenicity for up to 22 months following transplantation even after immunosuppression had been

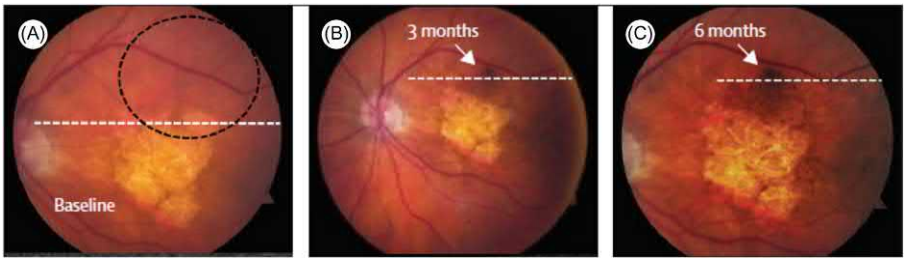

FIGURE 62.2 Fundus image of an AMD patient eye after transplantation of hESC-derived RPE shows evidence of a pigmented patch that increases with time. Dotted circle shows area for transplantation; *AMD*, Age-related macular degeneration; *hESC*, human embryonic stem cell; *RPE*, retinal pigment epithelium. *Reprinted with permission from Schwartz SD, et al. Human embryonic stem cell–derived retinal pigment epithelium in patients with age-related macular degeneration and Stargardt's macular dystrophy: follow-up of two open-label phase 1/2 studies. Lancet 2015;385(9967):509–16.*

tapered and stopped [75]. In the last 4−5 years, additional trials have confirmed the safety and tolerability of RPE cellular suspensions in patients with dry AMD or Stargardt's [76,77]. The safety and tolerability of RPE sheets in humans in AMD have now also been reported. In a Phase 1 study, a scaffold-less sheet of RPE derived from autologous iPSCs was subretinally transplanted without immunosuppression into a patient with wet AMD, following removal of the neovascular membrane [78]. A monitoring period of 12 months showed evidence of graft survival without any serious adverse events. A second patient had been planned for the study, yet concerns over the genetic stability of the autologous iPSC-RPE preparation stopped the trial short [78,79]. In another Phase 1 study, investigators transplanted a vitronectin-coated polyester membrane containing 100,000 hESC-RPE into two wet AMD patients with long-term local immunosuppression. This approach showed no evidence of adverse events in the 12 months following transplantation [80]. In a third Phase 1/2a trial, investigators transplanted a synthetic parylene substrate mimicking Bruch's membrane containing 100,000 hESC-RPE into four patients with GA dry AMD [81]. At a mean follow-up of 260 days, the graft was well tolerated with no signs of adverse events even though immunosuppression had been tapered and stopped by day 60 [81]. As these initial trials were focused on safety and often used subtherapeutic doses of RPE, follow-up clinical trials should help address the potential efficacy of PSC-RPE for preserving or improving visual acuity in patients with AMD and Stargardt's.

Retinitis pigmentosa

RP is a rare, inherited form of progressive retinal degeneration that involves development of night blindness and/or increasing loss of peripheral vision. In more severe cases, it can lead to loss of central vision and eventually blindness. It affects roughly 2.5 million people globally, or about 1 in every 4000 people [82,83]. The disease begins with the dysfunction and degeneration of rod photoreceptors in the peripheral retina followed by the loss of cones, and thus central vision. Upon clinical examination, there is evidence of pigment deposits caused by death of photoreceptors, retinal vessel attenuation, narrowing of visual field (tunnel vision), and a change in ERG patterns [83,84]. Although the age of onset, clinical features, rate of progression, and underlying genetic causes are highly variable, underlying genetic heterogeneity is a root cause. Over 3100 mutations in more than 66 genes can cause RP while more than 1200 mutations in another 31 genes cause RP as part of a larger syndrome, including Leber congenital amaurosis, Usher syndrome, Refsum disease, Bardet−Biedl syndrome, and neuropathy ataxia and RP [82,84]. RP may be inherited in an autosomal-dominant (15%−25% of cases), autosomal-recessive (5%−20%), X-linked (5%−15%), or unknown (40%−50%) manner [83]. Genes commonly associated with RP are involved in photoreceptor-specific functions such as retinal metabolism, phototransduction and outer segment structure, connecting cilium structure, rod-specific transcription factors, and splicing factors [83]. A study of 270 families with autosomal-dominant RP found that mutations in the gene encoding rhodopsin were the most common, accounting for 30.7% of cases [82]. Another commonly mutated gene in this study was RPGR, which encodes a GTPase-binding protein located in the connecting cilia, a structure that connects photoreceptor inner and outer segments. RPGR is located on the X chromosome and accounts for 70%−90% of X-linked form of RP [85].

There is no effective therapy for curing or preventing RP due to its underlying genetic cause. Supplementation with antioxidants such as vitamin A, docosahexaenoic acid, and lutein may help delay the progression of RP [86]. Other potential therapies that may delay progression include neurotrophic factors such as ciliary neurotrophic factor (CNTF) [87,88], unoprostone isopropyl, an activator of calcium-activated potassium channels [89,90], and the histone deaceylase inhibitor, valproic acid [91,92]. Yet there is still a high unmet need for therapies that can stop, prevent, or reverse vision loss in RP patients.

To be effective in treating RP, transplanted cells must engraft and either provide significant neuroprotection to save deteriorating photoreceptors or functionally compensate for photoreceptors that have already been lost. In 1987 Klassen and Lund transplanted embryonic rat retinal tissue onto the brain stem of neonatal rats, and after 5 months he found that the transplant could drive a light-stimulated pupillary reflex in the host eye. This was among the first studies to provide evidence that transplanted retinal tissue could survive and make functional synaptic connections to drive a natural response even though it was not in retina itself [93]. Isolation and transplantation of rat neonatal photoreceptors into a degenerative retinal environment was demonstrated shortly thereafter using a high-level illumination photoreceptor injury model [94]. In another study, Gouras et al. subretinally transplanted photoreceptor microaggregates or papain-dissociated photoreceptors into rd1 mice, a model in which mutation of the Pde6b gene causes early onset photoreceptor degeneration. Cells were transplanted at a time when endogenous photoreceptors have already been lost [95]. These neonatal photoreceptors survived for at least 2 months and, in the case of the transplanted microaggregates, displayed mature outer segments, which could be phagocytosed by endogenous RPE [95]. Later studies showed that wt photoreceptors could provide significant neuroprotection of cones away from the transplantation

site in rd1 mice, suggesting the secretion of neurotrophic factors could provide therapeutic effects for degenerating photoreceptors [96,97]. Additional studies were aimed at identifying the most appropriate developmental stage of photoreceptors for optimal integration, maturation, and, more importantly, greater evidence of functional synaptic connectivity to downstream retinal neurons [98–100]. Maclaren et al. showed that rod precursors isolated from postnatal day 1–7 mice, a time when the rod-specific transcription factor (NRL) is expressed, can integrate into the degenerate adult ONL and form synaptic connections, which translated into improved visual function [98]. Moreover, Bartsch et al. came to a similar conclusion that early postnatal photoreceptors represent an ideal developmental state for functional integration [99]. Additional studies provided further information regarding the visual function improvement and synaptic connectivity of transplanted photoreceptors in various models [101–103]. One such study examined the integration of NRL-GFP^{+} rod precursors in six different models of photoreceptor-focused retinal degeneration, each with its own unique features, severity, and speed of photoreceptor loss. The authors found that the amount of glial scarring and changes in the integrity of the OLM were key determinants of transplanted cell integration and visual improvement, suggesting that more than just the severity of photoreceptor loss needs to be considered when developing cell-based therapies for RP [102]. In another study, differential fluorescent labeling of donor and host cells provided evidence that transplanted photoreceptors can fuse with host cells and that cell fusion may be a previously unrecognized mechanism for the effects of transplanted cells on visual function [104]. Additional analysis suggested that cytoplasmic, but not nuclear, material passes between the cells. Differential labeling of cytoplasmic material and DNA in donor and host cells, the labeling of sex chromosomes to distinguish transplanted male photoreceptors from female recipients, and a Cre/lox-based approach (to demonstrate transfer of Cre recombinase from donor to recipient or recipient to donor) all suggested transfer of cytoplasmic material [105–107]. Cytoplasmic transfer could partially explain the visual improvement observed after photoreceptor transplantation in models when host rods and cones are still present but likely does not account for the visual improvement in models where endogenous photoreceptors are completely gone at the time of transplantation.

Photoreceptors from pluripotent stem cells

PSCs represent an attractive alternative starting material for cell-based therapies to treat RP given issues with sourcing postnatal retinal tissue in scale. In 2006 two studies demonstrated the feasibility of using hESCs as a starting material. Lamba et al. differentiated hESCs into retinal progenitors that could give rise to photoreceptor-like cells. Coculture with retinal explants, and in particular degenerative retinal explant tissue, provided appropriate cues to stimulate specific differentiation toward photoreceptors, whereas isolated retinal progenitor cultures without the explant tended to differentiate more toward ganglion and amacrine cells [108]. In the same year, Banin et al. showed that hESC-derived neural progenitors could give rise to cells expressing key photoreceptor markers upon subretinal transplantation in rats [109]. Lamba et al. confirmed that their retinal progenitors could differentiate in vivo into photoreceptors in 2009 using the Crx$^{-/-}$ model of LCA [110]. The presence of these transplanted cells restored light responsiveness to the animals. Osakada et al. were able to avoid the use of retinal tissue to further differentiate their progenitors into photoreceptors by using retinoic acid and taurine in vitro [111]. In 2009 the same group successfully applied their protocol to iPSCs [112]. In 2010 Lamba et al. also reported the successful differentiation of iPSCs into photoreceptors. Here, they drove GFP expression off a photoreceptor-specific promoter, interphotoreceptor retinoid-binding protein (IRBP), to isolate the photoreceptors from differentiating cultures. Subretinal transplantation of the GFP + cells into wt mice showed that they survived at least 3 weeks and integrated into the retinal architecture while maintaining expression of photoreceptor-specific markers such as rhodopsin, recoverin, and Otx2 [113]. Additional studies have confirmed the ability of hESCs and iPSCs to give rise to retinal/photoreceptor progenitors using similar standard 2D, growth-factor-enriched protocols, which can last up to 4–5 months [114–116]. Among them, Barnea-Cramer et al. showed that both hESC- and human (h)iPSC-derived photoreceptor progenitors can integrate into the degenerate rd1 mouse retina following subretinal injection (Fig. 62.3).

Transplanted cells survived at least 3 weeks and expressed mature photoreceptor-specific markers such as rhodopsin, recoverin, PDE6b, and cone arrestin. Moreover, animals receiving either hESC- or hiPSC-based therapy displayed improvement in visual function compared to untreated rd1 controls, as assessed by optomotor response and light–dark box vision dependent behavioral tests [116].

Recently, several groups have been exploring 3D organoid-based cultures as a way to increase the efficiency of hESCs/iPSC differentiation into photoreceptors and more faithfully recapitulate the structured environment of the developing eye. Nakano et al. first described the generation of hESC-derived optic cups in 2012 through modification of their mouse ESC organoid culture system [117]. In this hESC 3D culture system, it was

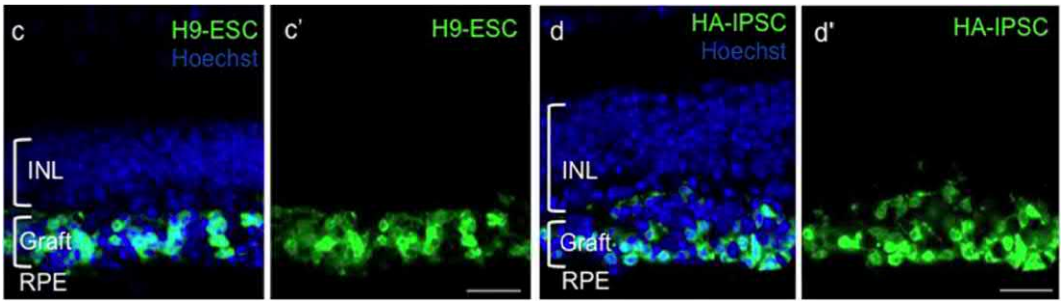

FIGURE 62.3 hESC- and iPSC-derived photoreceptor progenitors engraft and survive in rd1 mice, a model of severe photoreceptor degeneration. GFP-labeled H9 hESC-photoreceptors (left two panels) or HA-human iPSC-derived photoreceptors (right two panels) engraft between the RPE and INL of retina in rd1 mice 3 weeks after subretinal injection. Function of human pluripotent stem cell–derived photoreceptor progenitors in blind mice. Sci Rep 2016;6:29784.*

found that Notch inhibition starting at day 29 and lasting for ~2 weeks can increase the percentage of recoverin containing photoreceptors up to 78%. They have since used an improved version of their 3D protocol to generate retinal sheets for transplantation, showing engraftment of the sheets in two monkey models of retinal degeneration [118]. They have also now demonstrated survival and maturation of the retinal sheets in two immunodeficient mouse models of retinal degeneration, where retinas from animals that received the sheets showed evidence of greater light-driven responses on multielectrode array recordings than those without the transplanted sheets [119]. Additional groups have also reported the use of 3D organoid technology for human PSC differentiation into stratified retinal tissue, including photoreceptors [120–124].

The technical feasibility and safety of subretinal injections of retinal tissue and cell suspensions to treat RP were first explored in the late 1990s and continue to be explored today. In 1997 cadaveric sheets of photoreceptors were harvested and subretinally transplanted into two RP patients without immunosuppression. Although no improvements in visual function were observed, there were no signs of adverse events or rejection either [125]. In 1999 Das et al. subretinally injected a suspension of cells isolated from human fetal neuroretinal tissue (from 14 to 18 weeks gestational period) into 14 RP patients. The 40-month follow-up period suggested no major adverse effects, except for a single case of retinal detachment in one patient, which was noted 3 days after the surgery [126]. In the same year, Radtke et al. reported successful subretinal transplantation of fetal retinal tissue sheets into two patients with autosomal-recessive RP with evidence of some potential visual improvement [127]. Additional clinical studies by this same group have confirmed that transplantation of fetal retinal tissue sheets is safe and may provide visual improvement [128,129]. In one particular study, 10–15-week–old fetal neural retinal cell layers, including RPE, were transplanted into 10 patients: 6 with RP and 4 with AMD. Long-term follow-up showed that the grafts were well tolerated and potentially efficacious; 7 out of 10 patients showed some degree of sustained visual acuity improvement as assessed by EDTRS, out as far as 6 years posttransplant.

Twenty years after the first of these studies, additional groups are still testing fetal neuroretinal cells in clinical trials as a potential therapy for RP. In a 2017 study a 1×10^6 cellular suspension of 12–16-week-old fetal retinal progenitors was subretinally injected into eight patients with rod–cone dystrophy while 1×10^5 of the same cells was injected into RCS rats for comparison [130]. Six weeks postinjection, the preclinical study showed that the retinal progenitor cells (RPCs) engrafted into the host ONL and expressed photoreceptor markers, recoverin and rhodopsin. Animals given the cell therapy also showed improved ERG b-wave recording compared to nontreated animals. In the clinical study the cells were well tolerated yet visual acuity only improved transiently; improvements were seen between 2 and 6 months postsurgery but returned to pretreatment baseline levels by 12–24 months [130]. Two companies, jCyte and ReNeuron are also testing cellular suspensions of fetal retinal neuronal progenitors for RP. In December 2017 jCyte reported intravitreal injection of their fetal RPC suspension, jCell, which showed a favorable safety profile and potential therapeutic benefit in a Phase 1/2a trial involving 28 RP patients [131]. They are currently conducting a Phase 2b masked and controlled follow-up clinical trial with 85 RP patients using BCVA, visual fields, contrast sensitivity, quality of life metrics, and maze navigation ability as endpoints. ReNeuron is testing subretinal injection of their human RPCs (hRPCs) in Phase 1/2 clinical trials for RP as well. The ReNeuron hRPCs are from a 10- to 12-week-old human fetal source conditionally immortalized with a temperature-sensitive SV40 antigen [132] to allow expansion of the progenitors only at the permissive temperature of 33°C instead of at body

temperature of 37°C. Preclinical data obtained 12 weeks posttransplantation suggested subretinal injection of these progenitors preserved the ONL and visual function in RCS rats, likely through paracrine-mediated trophic support. The engrafted cells did not stain positive for any photoreceptor markers upon histologic evaluation, suggesting they did not functionally replace photoreceptors but likely rescued the function of endogenous photoreceptors [133]. ReNeuron expects to report clinical trial results in mid-2019. Retinal progenitors or photoreceptor precursors derived from human PSCs will likely also enter clinical trials as a potential therapy for RP within the next 10 years although it remains to be determined if they will be in the form of cellular suspensions or engineered onto sheets.

Glaucoma

Glaucoma involves damage to the optic nerve and degeneration of RGCs, the results of which can lead to visual impairment and, if left untreated, blindness. It affects 60−70 million people worldwide and of these, 8.4 million will go blind [134,135]. Normal aging and genetics both contribute to increased risk of developing glaucoma. Glaucoma can be classified based on clinical features of the disease. Primary open-angle glaucoma (POAG) is a leading cause of irreversible blindness globally [136] and accounts for nearly 90% of all glaucoma cases. People of African or Hispanic ancestry appear to be more at risk for POAG than those of European ancestry. Other forms of glaucoma include normal tension glaucoma (NTG), congenital glaucoma, and angle-closure glaucoma. The differences between these forms and underlying pathophysiology of glaucoma are as follows. POAG is characterized by elevated IOP (eIOP) (e.g., $\geq$21 mmHg). The ciliary body, located at the front of the eye, generates aqueous humor that flows into the anterior chamber. Aqueous humor provides sufficient ocular pressure to keep the spherical shape of eye as well as helps transport nutrients and antioxidants. Normal efflux of aqueous humor out of the anterior chamber occurs at the angle between the iris and cornea. Trabecular meshwork (TM), Schlemm's canal, collector channels, and aqueous veins residing at this angle represent the normal outflow pathways. In POAG, eIOP occurs even though this angle is open. The normal aging process causes outflow to be less efficient. Increasing age leads to a decline in TM cellularity and health. In glaucoma, accumulation of extracellular matrix and reactive oxygen species contributes to senescence and death of TM cells [137]. Dysfunction of the TM in turn contributes to a blockage in the outflow of aqueous humor and leads to the elevation in IOP. Long-term eIOP blocks retro- and anterograde transport of neurotrophins along RGC axons at the optic nerve head, which normally serve to maintain RGC survival and health [138]. Through this sequence of events, eIOP contributes to progressive damage of the optic nerve, which in the early stages, causes no visual symptoms and may go unnoticed. Visual impairment begins to occur when the progressive degeneration of the optic nerve and RGC axons hinders normal visual transduction signaling to the brain. More than 70 single-nucleotide polymorphisms have been found to be associated with POAG, including those in the genes for myocilin, optineurin, neurotrophin 4, and caveolin 1,2 [139]. POAG is usually treated with eye drops containing IOP-lowering drugs or with laser trabeculoplasty to increase outflow through the TM. Various classes of IOP drugs are used clinically and include beta blockers (e.g., betaxolol and timolol), alpha 2 adrenergic agonists (apraclonidine and brimonidine), carbonic anhydrase inhibitors (brinzolamide and dorzolamide), cholinergic muscarinic agonists (pilocarpine), and prostaglandin analogs (latanoprost and travoprost) [140]. In 2017 two new IOP-lowering drugs were approved, latanoprosten bunod, a nitric oxide-releasing prostaglandin analog, and netarsudil, a rho kinase inhibitor. Both help to loosen TM to lower IOP [140].

In NTG the angle for aqueous humor drainage is also open as it is in POAG, yet there is no eIOP and optic nerve damage occurs despite no large increase in IOP. NTG is more prevalent in Asians and usually begins at around 60 years of age. IOP-lowering drugs may be given to help slow the disease in NTG even though the IOP is not abnormally high. In angle-closure glaucoma the angle for aqueous humor drainage is partially blocked or too narrow. This usually presents in an acute situation, with severe pain, nausea, and red eyes, and can best be treated with trabeculectomy surgery, which involves making a small hole in the sclera to allow aqueous humor outflow [141]. Congenital glaucoma presents at birth and can be treated with surgery.

Vascular dysregulation, including changes in blood pressure, disruptions in ocular blood flow, endothelial dysfunction, vasoconstriction, systemic hypotension, and vascular inflammatory conditions, can be the source of pathophysiologic stress and development of glaucomatous optic neuropathy (GON). Migraine headaches, autoimmune diseases, and obstructive sleep apnea represent risk factors for developing GON. On a mechanistic level, oxidative stress and neuroinflammation from the abovementioned situations can promote demyelination of the optic nerve, axonal damage to RGC, and eventually RGC apoptosis. IOP-lowering drugs are the mainstay of currently available glaucoma treatments, yet progression of the disease may still be difficult to control. Patient compliance with administering eye drops at prescribed intervals or failure to administer the drops properly can be problematic. Moreover, IOP measurements taken at the doctor's office may underestimate elevations that occur at night.

24-hour IOP monitoring devices are in development [142], yet the search for additional therapies to help treat glaucoma is ongoing.

Stem cell–based therapies to treat glaucoma

Regenerative medicine approaches to treat glaucoma are an active area of investigation. Cell-based therapies fall into three main categories: (1) support for or replacement of TM to lower IOP, (2) neuroprotection to slow down or stop progressive degeneration of the optic nerve and RGC, and (3) replacement of RGCs already lost in progressive stages of disease. In 2006 Gonzalez et al. reported the identification of resident stem cell/progenitor population in isolated human TM cultures [143], suggesting they may be exploited as a source of therapeutic cells. A few years later, Du et al. isolated primary human TM stem cells and showed that, upon injection into the anterior chamber of wt mice, these cells could home to the TM, survive at least 4 months, and express the characteristic TM marker, CHI3L1 [144,145]. Another report describes optimization methods for the isolation and culture of these primary human TM stem cells/progenitors [146]. Investigators are now exploring the use of iPSCs to generate TM cells. Mouse iPSC–derived TM cells increased aqueous humor outflow and restored normal IOP levels upon transplantation into a transgenic mouse model of glaucoma, Tg-Myoc^{Y437H} [147,148], largely through their ability to elicit a proliferative response of endogenous TM cells. These therapeutic effects were observed when the cells were injected into both 4- and 6-month-old animals, which display moderate and severe disease phenotypes, respectively. Human iPSCs can also differentiate into TM stem cells and progenitors. Abu-Hassan et al. cultured hiPSCs on TM-extracellular matrix to promote their differentiation. They demonstrated that these iPSC-TM progenitors were able to restore IOP homeostasis in an ex vivo human organ culture system. In this system, resident TM cells were depleted from the anterior chamber to drive up IOP; transplantation of the hiPSC-TM progenitors could restore IOP homeostasis, whereas negative control cells had no effect [149].

Researchers are developing neuroprotective cell-based therapies to treat degenerating optic nerve and RGCs as well. The most advanced of these approaches is already in clinical trials and involves encapsulated ARPE-19 cells (an RPE cell line) engineered to overexpress CNTF. The encapsulation device measures 1 mm in diameter and 6 mm in length and consists of a semipermeable polyethersulfone exterior membrane and an interior matrix of polyethylene terephthalate with 200,000 embedded CNTF-secreting ARPE-19 cells [150]. This combination product, termed NT-501, has been shown to be safe in clinical trials for GA–AMD and RP and was found to provide a constant source of CNTF for at least 2 years following transplantation [150]. More recently, it has been found to be safe for use in macular telangiectasia type 2 with evidence suggesting it can slow the progression of disease [151]. Intravitreal implantation of NT-501 is being tested in a Phase 2 trial (https://clinicaltrials.gov, NCT02862938) for glaucoma as well.

Another cell-based therapy approach under development involves intravitreal transplantation of RGCs. Here, transplanted cells may provide neuroprotection and/or functional replacement of degenerating RGCs. Three different sources of RGCs are under evaluation, including primary, Müller glia derived, and PSC derived. For primary RGCs, Venugopalan et al. demonstrated that RGCs, isolated from p1-5 GFP$^+$ mouse retinas, could engraft cross-species into recipient Sprague-Dawley rats following intravitreal transplantation. The transplanted cells oriented their axons toward the optic nerve and extended neurites toward the optic nerve head. A small percentage of them integrated into the host RGC layer with many dendrites extending into the IPL. Evidence suggested that they made synaptic connections with and responded to light-induced signaling from host cells [152].

Reports also indicate that Müller glia may be a suitable starting material for the generation of RGCs. Singhal et al. isolated human Müller glia and differentiated them in vitro toward a Brn3b+ RGC phenotype. These cells were transplanted into an N-methyl-D-aspartate (NMDA)-induced RGC depletion rat model along with an antiinflammatory, triamcinolone, and matrix-degrading enzyme, chondroitinase ABC, to facilitate their engraftment. Four weeks posttransplantation, animals treated with the cell therapy showed an improvement in negative scotopic threshold response on ERG recording, a readout of RGC function, and the authors suggest the effect may be from neuroprotective effects but cannot rule out the potential for synaptic connections also contributing [153]. Another study reported similar therapeutic effects using feline Müller glia–derived RGCs. In this study, cells were seeded onto collagen scaffolds to facilitate their survival and attachment upon allogeneic transplantation into an NMDA RGC ablation feline model. Two weeks after transplantation, animals that had received the cells showed improved scotopic threshold response on ERG versus controls. The cells did not show evidence of integration with host retinal layers, therefore the authors concluded the improved visual function may be due to neuroprotection of residual RGCs, or regrowth of axons due to secretion of neurotrophic factors from the transplanted cells [154].

Several groups have been developing 2D culture protocols and/or optimizing protocols with chemically defined

media to generate RGCs from PSCs [155–160]. In another study, immunopanning of dissociated 3D organoids was used to isolate RGCs differentiated from hiPSCs [161]. In many studies, in vitro characterization of the resulting cells has confirmed expression of RGC markers such as Atoh, beta 3 tubulin, and Brn3b. In some studies, electrophysiologic characterization confirmed the ability of the RGCs to display action potentials, as well as spontaneous and evoked postsynaptic currents [156,159]. Some investigators also consider the length of neurite outgrowth from PSC-differentiated cells as being a desirable RGC-like characteristic [158,161]. One study also reported the presence of rare, melanopsin-expressing RGC cells in their differentiating cultures, potentially reflective of intrinsically photosensitive RGCs [157]. Although none of these studies report on in vivo transplantation of PSC–RGCs, two studies have reported that retinal progenitors can engraft into RGC layers upon intravitreal transplantation [162,163]. In one of these studies, investigators transplanted the progenitors into an NMDA-induced RGC depletion mouse model. Four to five weeks posttransplantation, cells were found within the RGC layer and some even expressed the RGC marker, Brn3a [163]. At this point, it is unclear which starting cell source and developmental stage of RGCs may be best for engraftment and long-term therapeutic benefit in a glaucomatous setting. It still also remains to be determined if transplanted cells will be able to functionally replace RGCs lost due to degeneration or if neuroprotection will serve as the main mechanism of therapeutic action.

Diabetic retinopathy

Hyperglycemia, or elevated blood sugar, may occur chronically in diabetes and can lead to a condition known as DR, which involves the degeneration of retinal vasculature leading to visual disturbances or even blindness. Oxidative stress, mitochondrial dysfunction, and inflammation from the chronic exposure to hyperglycemia lead to thickening of vascular basement membrane and premature death of endothelial cells, pericytes, and vascular smooth muscle that comprise the blood vessels. Degeneration of the vasculature impairs the delivery of oxygen to the retina, which may result in areas of ischemic death of retinal cells, including RGCs and photoreceptors, which may be apparent upon optical coherence tomography imaging as thinning of retinal layers. Of the estimated 285 million people worldwide who suffer from diabetes, one-third of them will likely develop some form of DR in their life [164]. DR can be classified by the stage of severity, beginning with nonproliferative DR (NPDR). Mild NPDR involves the accumulating appearance of microaneurysms and recruitment of inflammatory cells. Moderate NPDR also includes some swelling of retinal vessels, and, in severe cases, NPDR can involve many more vessels, leading to the secretion of pathologic cytokines, such as TNFα, IL-8, TGFb1, iNOS, and angiogenic factors such as VEGF [165]. Secretion of VEGF in severe NPDR can lead to proliferative DR, which is characterized by the appearance of new, pathogenic, fragile, and leaky blood vessels, often with scar tissue that may also cause retinal detachment. During the course of DR, leakage of blood vessels causes breakdown of the blood retinal barrier and may contribute to swelling of the macula, a condition termed diabetic macular edema, which can occur at any stage of DR and is a common cause of blindness [164].

Standard of care for DR includes glucocorticoids, anti-VEGF, and laser photocoagulation, yet none of these therapies can reverse or repair ischemic damage to tissues. Other therapies in development include other mediators of angiogenic signaling, immunosuppressants, NSAIDs, and oxidative stress inhibitors [166]. Cell-based therapies that involve the transplantation of vascular progenitors may help preserve and/or replace degenerating endothelial cells, and potentially also vascular pericytes and smooth muscle. Restoration of capillary blood flow can, in turn, preserve the viability of inner retinal cells, glia, and photoreceptors. Determining the right stage of progenitor differentiation for maximal therapeutic benefit is an area of ongoing investigation. Early in embryonic development, mesoderm tissue gives rise to small regions of clustered cells termed "blood islands," which will give rise to both hematopoietic and endothelial lineages. It is thought that a bipotential progenitor, termed the hemangioblast precedes this division of labor and can give rise to both hematopoietic stem cells and endothelial progenitors [167]. Human retinal vasculature is thought to develop around 14 weeks of gestation [168]. A large body of evidence suggests vascular progenitors can be found in adult bone marrow, heart, skeletal muscle, and other tissues and contribute to various types of vascular repair and maintenance [169]. Although the human body is equipped with these progenitors, chronic diabetic hyperglycemia impairs the ability of these endogenous progenitors to properly migrate in response to the chemokine SDF-1 or repair vascular endothelium. Caballero et al. found that human vascular/endothelial progenitors from healthy donors could repair injured retinal vasculature in four different DR rodent models while the same population from diabetic donors could not [170]. This has led to the exploration of suitable, allogeneic cell sources to provide vascular repair in DR.

Stem cell–based therapies to treat diabetic retinopathy

Several studies have evaluated adult tissue–derived mesenchymal stem cells (MSCs) in preclinical models of retinal vascular injury. Adipose-derived MSCs have been

shown to facilitate repair of retinal capillary damage in streptozocin-induced diabetic rats [171]. Adipose-derived MSCs were also found to be able to differentiate into a pericyte-like cell type that is capable of providing protection in an oxygen-induced retinopathy model [172]. Another study showed that intravitreal injection of adipose MSCs can increase ERG signal and decrease vascular leakage and apoptosis in streptozocin-induced diabetic rats. Here, in vitro studies also show adipose MSCs can withstand hyperglycemic stress and can form vascular networks when cocultured with retinal endothelial cells [173]. A more recent study shows extracellular vesicles derived from adipose MSCs have therapeutic properties in a retinal ischemic reperfusion model [174]. These and other studies suggest that the main therapeutic mechanism of action for MSCs is to provide paracrine-delivered trophic support. Other cell types, which are capable of engrafting, may provide longer term therapeutic benefit.

In 2007 multiple groups reported the differentiation of hESCs into progenitors with vascular repair abilities [175–177]. For example, Lu et al. differentiated hESCs into a putative hemangioblast population, which could differentiate into both hematopoietic and endothelial lineages. Intravitreal or systemic delivery of these cells into an ischemia–reperfusion retinal injury model showed evidence of vascular repair. In addition, intravitreal injection of the cells into diabetic rats with an NPDR phenotype showed reparative potential of these cells as evidenced by their incorporation into damaged vessels (Fig. 62.4) [175].

Follow-up studies confirmed the retinal vascular-repairing properties of these hemangioblasts in an oxygen-induced retinopathy model [178]. Additional groups have confirmed that hESCs as well as iPSCs can differentiate into VPs endowed with the ability to repair ischemic retinal vasculature [179–181]. A study by Park et al. compared the reparative properties of cells derived from different iPSC lines. They showed that iPSCs derived from cord blood (CB) gave rise to CD31 + CD146 + vascular progenitors that could home and engraft into injured retinal capillaries in a retinal ischemia–reperfusion injury model out to 45 days [168]. These CB-iPSCs were a better starting an iPSC population than fibroblast-derived iPSCs, suggesting their CB origin facilitated the generation of therapeutic VPs [168]. It remains to be determined which specific vascular progenitor population may provide the best therapeutic effects for human DR. Neither hESC- nor iPSC-derived VPs have yet been tested in clinical trials, but current efforts are underway to make this a reality.

Future directions and competing therapies

As described in this chapter, several different types of cell-based regenerative medicine therapies are under development to treat retinal degenerative diseases that arise due to aging, diabetes, and/or inherited mutations. Among these, RPE-based therapies to treat AMD are currently in clinical trials, while photoreceptor, retinal ganglion, and vascular progenitor–based therapies to treat RP, glaucoma, and DR, respectively, may enter into clinical trials within the next several years. Efforts are already under way to endow these cells with even greater therapeutic properties. Overexpression of trophic factors such

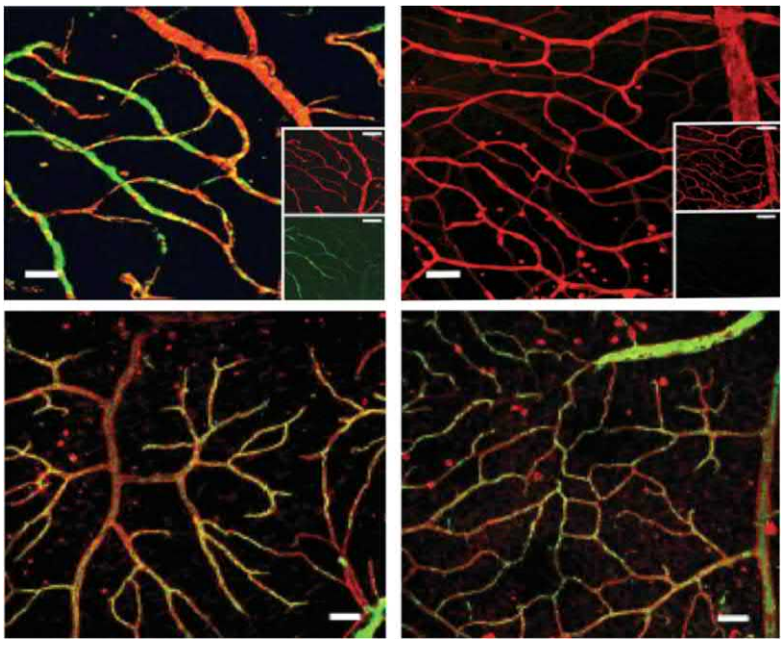

FIGURE 62.4 hESC-derived hemangioblasts incorporate into retinal vasculature of animals with retinal ischemia–reperfusion injury or nonproliferative diabetic retinopathy. *Upper panel*: (Left) Intravitreally injected, GFP (green) labeled hemangioblasts incorporate into and repair damaged vasculature in ischemia–reperfusion injured mouse eye, 1 day after injection. (Right) Retinal vasculature in normal, uninjured eye 1 day after saline injection for comparison. *Lower panel*: Intravitreally injected, GFP (green) labeled hemangioblasts incorporate into and help repair both small and large retinal vessels; images of retinal vasculature from two separate BBZDR diabetic rats are shown in left and right panels. Nat Methods 2007;4(6):501–9.*

as brain-derived neurotrophic factor (BDNF) and CNTF may help stabilize endogenous retinal cells at risk of degeneration. Optogenetic sensors may allow the transplanted cells to overcome the loss of native photosensitive cell types [182,183]. Yet engineered cell therapy efforts will meet competition from the gene therapy field, which can deliver such factors directly to endogenous retinal cells. For example, adeno-associated virus (AAV)-mediated delivery of BDNF is being developed as a way to treat glaucoma [184]. In addition, two active Phase 1 clinical trials (NCT03326226, NCT02556736) are testing intravitreal delivery of AAV virus to deliver optogenetic sensors directly to endogenous inner retinal cells. Preclinical studies have shown that this approach can bypass degenerate photoreceptors and overcome loss of visual transduction by conferring light sensitivity to inner retinal cells instead [185–187]. Given the wide range and complex pathophysiology of retinal degenerative diseases, there is likely to be room for both approaches in the future armamentarium of treatment options.

Introduction

This chapter provides an overview of visual system properties in health and disease, with an emphasis on the stages in visual-signal processing that are most commonly affected by disease and dysfunction. It then provides an overview of current approaches to vision restoration and of approaches that promise to migrate from the lab to the clinic in the coming years. In the third section the potential roles for engineered cells and tissues in this restoration process are discussed. The chapter closes with an estimate of the developments that can be expected to occur in the next 5–10 years.

Thirty years ago, the best hope vision researchers had for the enhancement of impaired vision was to build a better magnifier, by integrating optics and electronic image processing. Since then, restoration of vision to functionally blind individuals has become not just an engineering target but a realistic goal for which engineering milestones are being set and reached. The role of tissue engineering in this field may as yet be modest, but it has a great promise, as will become clear in the following pages.

In this chapter's overview of approaches to the restoration and enhancement of impaired vision in human patients, inspired by tissue-engineering principles and related technologies, we argue that the nature of eye disease and the fragility and complexity of ocular tissues such as the neural retina do not (yet) lend themselves to application of the techniques emerging in the repair of other tissues. Thus while some of the approaches presented here can function independently of tissue engineering as presented elsewhere in this volume, they at least complement those engineering approaches and lend themselves to future integration. This is particularly true in the areas of cell transplantation and neural prosthesis development, presented in the later part of this chapter, but to a lesser extent also for the optical and optoelectronic aids presented.

Visual system, architecture, and (dys) function

Human vision is mediated by one of the most highly developed sensory systems found anywhere in nature. Its capacity to combine high spatial resolution near the center of fixation with a wide peripheral field of view, accurate depth perception, color discrimination, and light–dark adaptation over 12 orders of magnitude is unparalleled. Every stage in the system is organized to accomplish this. The photoreceptor layer in the retina provides the high signal amplification of the rods required for night vision and the dense packing of three cone types required for detailed central and color vision. The intricate local preprocessing performed by subsequent retinal cell layers augments these functions by performing brightness and color comparisons and helps to condense the information stream acquired by over 100 million photoreceptors, to allow transport across a mere 1 million fibers in the optic nerve to the visual centers in the brain, where further parsing and interpretation of the image take place.

From a functional point of view, the visual system can be understood as depicted in Fig. 63.1, with sensors, preamplifiers, preprocessors, transmission lines, and several central processor stages. The two most crucial stages in this process—the conversion from light into chemical and electrical signals, and the signal transmission from the eyes toward the brain—are also the most vulnerable ones. Light conversion and signal amplification in the photoreceptors require a highly complex interplay between the molecules inside these cells and ion channels and other permeable structures in the cell membrane. These components participate in interlocking cycles of conversion and regeneration and are assisted by surrounding cells—in particular, the retinal pigmented epithelium (RPE) cells, which provide nutrients to, and digest cell membrane discarded from, the photoreceptors. Any step in this intricate

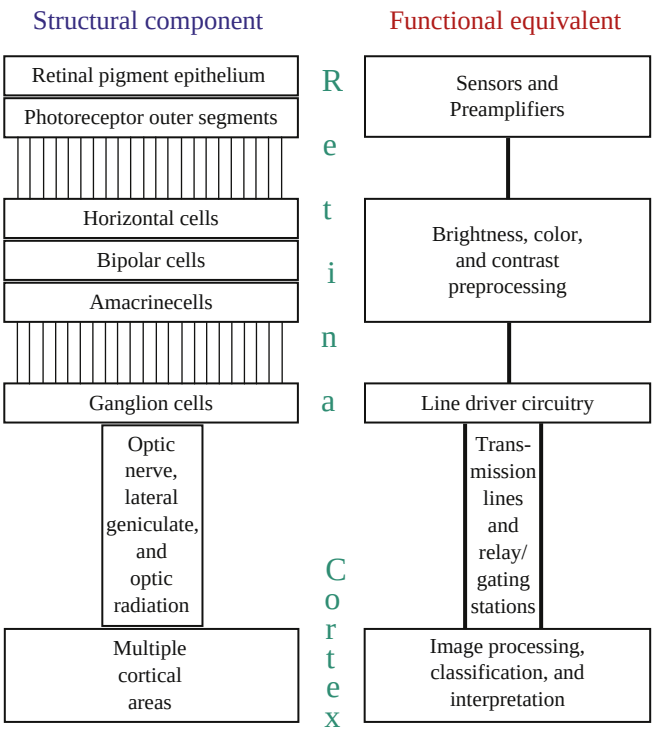

FIGURE 63.1 Schematic representation of the visual system: the outer retina (RPE and photoreceptor layers) forms the sensor array, followed by several inner retinal preprocessing stages, the ganglion cell transmission stages, and further central processing stages in subcortical and cortical brain centers. *RPE*, Retinal pigmented epithelium.

process can easily be disrupted by nutritional deficits, overexposure to short-wavelength light (presumably causing oxidative changes), attacks by pathogens, and especially genetic miscoding of one or more participating molecules. Since the mid-1980s the list of mapped (>225) and identified (>185) gene loci has grown at an ever-increasing rate. For each identified gene, there may be multiple mutations, often leading to distinct disease phenotypes; for an up-to-date list of the known mutations leading to loss of outer retinal function, see the Retnet website [1]. Not only do such mutations directly cause impaired signal transduction, but the additional energy demand, the presence of abnormal molecules, and excess shedded cell membrane may exceed the RPE cells' support capacity, which inexorably leads to degeneration of both photoreceptors and RPE cells. The most common group of disorders caused by genetic miscoding of molecules involved in the phototransduction cycle is jointly known as retinitis pigmentosa (RP), while another group is caused by a breakdown of RPE function in the central retina due to either a genetic defect (Stargardt macular dystrophy) or a combination of genetic predisposition and environmental factors [age-related macular degeneration (AMD)]. Jointly, all these disorders are known as retinal degenerations (Fig. 63.2A and B).

Retinal neurons communicate in a variety of ways, with ion-gating channels fulfilling a role in reaching and maintaining an operating level (also known as the adaptation state) and neurotransmitters and gap junctions fulfilling the principal messenger roles in carrying information in chemical and electrical form, respectively. The loss of outer retinal function, and therefore of neurochemical and electrical signal transmission to the inner retina, will affect secondary retinal cells (horizontal, bipolar, amacrine, and ganglion cells) but not necessarily threaten their survival. Until a few years ago, morphometric studies of donor retinal tissue such as that shown in Fig. 63.2B suggested survival of bipolar and ganglion cells at rates of 80% and 30% in the macula [2] and 40% and 20% at eccentricities up to 25 degrees [3], respectively, in retinae practically devoid of photoreceptors. In recent years a series of highly detailed and elegant microanatomical studies using a technique called computational molecular phenotyping [4] has demonstrated that the connectivity patterns of these inner retinal cell populations are fundamentally altered by the degeneration process (Fig. 63.3). Survival of these cells is predicated on their continued activity, and this they accomplish through the formation of new axonal and dendritic branches and through self-organization into clusters called microneuromas. These new and functionally random connections allow spontaneous oscillations to occur in the absence of meaningful input signals from the erstwhile photoreceptors, and RP patients may experience such spontaneous activities as photopsias, or "light shows" [5].

At the retinal output signal transmission stage, where retinal ganglion cells (RGCs) convert the neurotransmitter signals into electrical spike trains that travel along RGC axons toward the thalamic relay nuclei and other brain

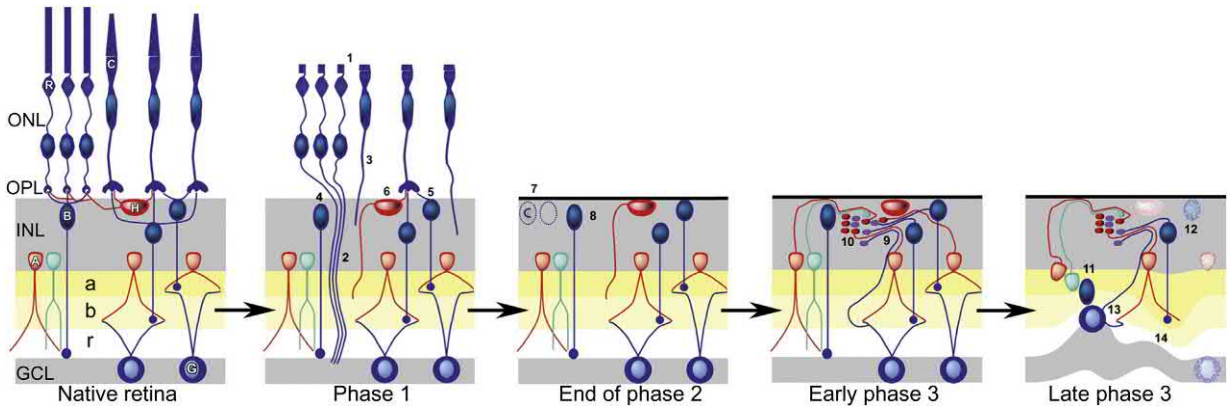

FIGURE 63.3 Simplified schematic of possible alterations during retinal remodeling. The first panel shows a representative "native" mammalian retina with its basic complement of rods (R) and cones (C) driving bipolar (B) and horizontal (H) cells. In turn, bipolar cells drive amacrine (A) and ganglion cells (G) of the proximal retina to form the major cone OFF (sublayer a), cone ON (sublayer b), and rod ON (sublayer r) zones of the IPL. Remodeling occurs in phases, as indicated under each panel. In phase 1, rod and cone stress lead to truncation of outer segments (1) and, in some instances, extension of rod (2) and cone (3) axons deep into the INL, IPL, and even GCL. Both rod and cone bipolar cells truncate their dendrites (4 and 5), and some rod bipolar cells may transiently switch to surviving cones (not shown). Horizontal cells also send axons into the IPL (6). Phase 2 is a complex period of cell death, ablation of the ONL, and resolution of the distal margin of the neural retina into a largely confluent glial seal (7) formed by the distal processes of Müller cells. Surviving neurons may continue to alter their phenotypes by changing receptor expression patterns (8), and some cone cells may even escape cell death (C). Neural remodeling becomes even more extensive during phase 3, with the formation of complex axon fascicles (9) and new synaptic complexes termed microneuromas (10). As remodeling continues throughout life, some neurons begin to migrate along glial columns (11), others die (12), and the IPL becomes transformed through new synapse formation (13) and laminar deformation (14). *GCL*, Ganglion cell layer; *IPL*, Inner plexiform layer; *ONL*, outer nuclear layer. *©2005 Robert E. Marc. Used by permission.*

areas, the system is vulnerable to mechanical insults rather than to genetic dysfunction: injury to the optic nerve (trauma), increased pressure inside the eye [crushing the fragile axon fibers at the optic nerve head (glaucoma)], and inflammation (optic neuritis) or impaired blood supply (ischemic neuropathy) of the optic nerve itself. Each of these can impair or interrupt the signal-carrying capacity of optic nerve fibers (Fig. 63.2C/D).

In addition to damage occurring at these distinct stages, more generalized damage to the retina can occur. Common mechanisms for this are the leakage of capillaries in diabetic retinopathy and the interruption of the blood supply to the inner retina (retinal vascular occlusive disease), especially in individuals with a predisposition toward the development of blood clots. Each of these can lead to widespread cell death in the inner nuclear and ganglion cell layers throughout the affected area. Vascular occlusive disease provokes angiogenesis: new retinal vessels sprout in response to growth factors signaling ischemia, but these vessels tend to leak and damage the retina's fragile structure. Diabetic retinopathy is a major cause of preventable blindness in the developed world and increasingly in developing countries as well.

Current- and near-term approaches to vision restoration

As in all biomedical engineering, approaches to restore function can be based on interruption of the disease process and tissue regeneration (autologous or grafted) or on hybrid techniques combining biological tissue with synthetic materials and devices. To support the cells affected by disease or injury, neuroprotective substances, growth factors, and genetic modifications of cell function may be used, postponing or preventing further loss of function. In addition, as long as usable function remains, one can strengthen the stimulus and internal response signal, counteracting visual impairment as much as possible.

If little or no sensor function remains, one can seek to restore it in limited form through newly grown or transplanted photoreceptors and/or RPE cells, through a prosthetic device that will electrically stimulate the remaining secondary retinal cells or through man-made tissues that mimic photoreceptor function. At the RGC level, substitution for lost signal transmission may be sought through protection of any remaining cells and administration of factors promoting axon regeneration. This may require the use of synthetic tissues and factors enabling reconnection of axons with central structures—or through in situ growth of new cells, promoted to differentiate into RGCs and to send new axons through the optic nerve.

In preliminary form, many of these approaches exist in the laboratory or are entering clinical testing, while others are merely ideas. In the following sections, both existing and prospective methods are presented.

Enhancing the stimulus through optoelectronic and optical means

Most of these devices are based on a combination of optical and electronic image enhancement techniques. Their common principle of operation is to improve visibility of the image to the diseased retina, through magnification, contrast and/or color enhancement, and filtering or feature extraction. Early incarnations, such as the low vision enhancement system—no longer in production; see Fig. 63.4A and Ref. [6]—used optical magnification, zoom, and automatic focus and—for applications limited

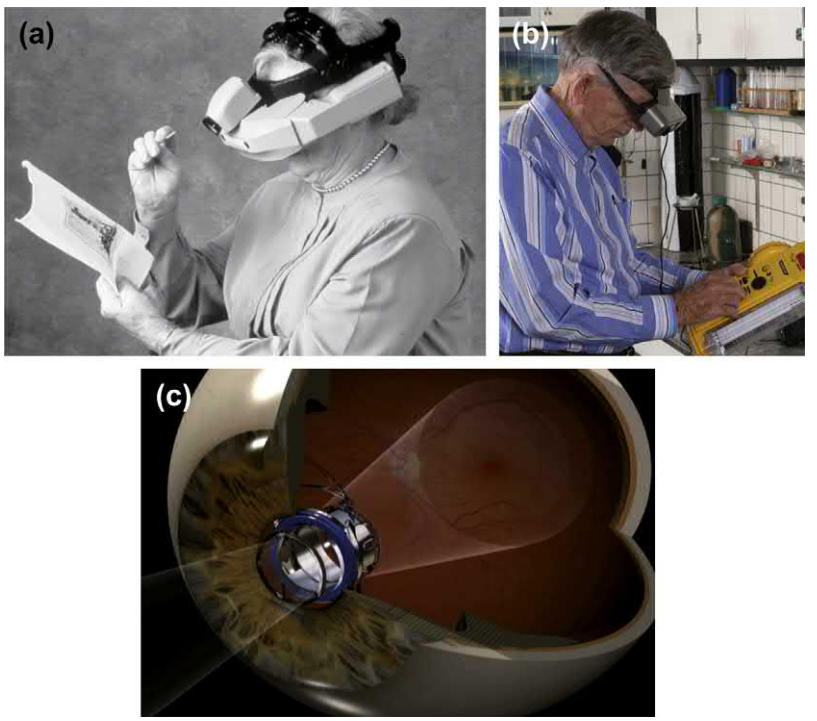

FIGURE 63.4 (A) The LVES, developed at the Johns Hopkins University's Lions Vision Center, with support from NASA and the Department of Veterans Affairs, was the first head-worn optoelectronic vision enhancement systems. This system featured binocular orientation cameras, a centrally placed 1.5−10× zoom camera with automatic focus, contrast enhancement, and a binocular projection path with 36 × 48 degrees field of view and built-in refractive correction and alignment for the wearer. (B) The eSight 3 video visor has a narrower field of view, but much higher resolution and a wide range of image enhancement capabilities. It is much lighter thanks to its LCD screens and has a full color display. (C) The Implantable Miniature Telescope (IMT provides monocular 3× magnification, to benefit patients with large central scotomas. *LVES*, Low vision enhancement system. *(B) Photo courtesy eSight Corporation and (C) diagram courtesy VisionCare Ophthalmic Technologies.*

by available contrast, such as face recognition—analog image enhancement. Digital video technology has completely replaced the analog approach, and component miniaturization and mass production have drastically reduced the production cost of head-worn video magnifiers, but today's crop of lightweight and cosmetically attractive video visors, such as Jordy (Fig. 63.4B; Enhanced Vision Systems, Huntington Beach, CA) and eSight 3 (eSight Corp, Toronto, ON, Canada), is based on the same image enhancement principles. More advanced image processing techniques such as gaze-contingent remapping, currently under development across the video gaming and virtual reality market, will allow wearers to avoid losing crucial information in blind areas of the visual field. Field of view and angular resolution, that is, the number of pixels across the screen, have also dramatically improved in the past decades. The widespread penetration of high-definition video and telepresence applications in industry and entertainment is enabling cost-effective application of this technology to low vision aids. Similarly, smaller, lighter, and more luminous flat panel displays are allowing these devices to become light and cosmetically acceptable.

A useful property of the cameras in portable video visors is their built-in automatic gain control, resulting in constant internal image brightness over a wide range of environmental illumination levels. This makes these image acquisition systems highly suitable for use in prosthetic and tissue-based image enhancement systems.

Optical systems can also be used to increase the visibility of the stimulus. One such system, approved by the US Food and Drug Administration (USFDA) for clinical application in 2011 and aimed at patients with a large central scotoma (blind spot) in both eyes due to advanced AMD, is an implantable miniature telescope (IMT, Fig. 63.4C; VisionCare Ophthalmic Technologies, Saratoga, CA), placed behind the iris in the location of the crystalline lens. It provides one eye with a magnified view of the central visual field, while the other eye is not implanted, to preserve the wide peripheral view of the fellow eye.

Following an adaptation and rehabilitation training period of 3–6 months, most wearers have no difficulty switching between the magnified view in the implanted eye and the unenhanced view in the fellow eye. Note that this is a true prosthetic device, since it is permanent.

A different type of optical vision restoration is used in patients with recurrent corneal opacification and failed corneal transplants. This so-called osteo-odonto-keratoprosthesis was first developed by Strampelli et al. [7] and typically uses a slice of autologous tooth or bone, with a small lens in the center, to replace the central portion of the opaque cornea, this restoring an image to the retina. More modern synthetic devices, such as the Boston type 1 keratoprosthesis (KPro; J.G. Machinw Co Inc, Woburn, MA), have not been compared in randomized trials against the original device, but the general impression is that the results are similar. Failure rates of the KPro are on the order of 10% after 2 years [8], suggesting that there is a rich opportunity for tissue engineers to make further progress in this area.

Visual prostheses based on electrical tissue stimulation

As was already mentioned, retinae with severe degeneration of the sensor layer retain high numbers of secondary cells. In analogy with the principle of operation of the cochlear prosthesis, that is, restoring limited hearing through stimulation of spiral ganglion cells in the cochlea [9], this provides the opportunity to convey rudimentary vision to the degenerated retina by a prosthetic device stimulating remaining secondary cells with a two-dimensional array of microelectrodes, reminiscent of the images produced by dot matrix printers a few decades ago [10]. From an engineering point of view, one can envisage a range of possible approaches (stimulating electrodes under vs over the retina; fully integrated photosensing, image processing, and stimulating systems vs external image capture and processing linked to an intraocular stimulating matrix, to name a few) but also a host of questions concerning biocompatibility, signal processing, and power management.

The most pressing question, conveying, whether visual imagery can be conveyed to patients blind from retinal degeneration, has been answered affirmatively. In a series of experiments started at Duke University in 1992, continued from 1993 until 2000 at the Johns Hopkins Wilmer Eye Institute, and since then confirmed through similar experiments in university clinics around the world, volunteers with end-stage RP—whose remaining vision was limited to, at best, light perception—as well as several patients with advanced AMD have participated in tests where, during a surgical procedure under local anesthesia, the inner surface of the retina was electrically stimulated with small and brief biphasic current pulses applied through a single or multiple electrodes [11–13]. Among the most salient findings are the subjects' ability to see small punctate light flashes (phosphenes), whose perceived location corresponds exactly to that of the stimulation, and the ability to see simple patterns of multiple phosphenes when multiple electrodes are activated simultaneously. Stimulation at rates greater than 40–60 pulses/s is perceived as continuous stimulation, and perceived stimulus intensity increases with pulse duration and amplitude as well as repetition rate. Independent tests in blind volunteers and in amphibian retina [14] have demonstrated that stimulus pulses 1 ms or longer in duration preferentially stimulate the (deeper) bipolar cells rather than the (more superficial) RGCs.

Over the past 15 years, research in this field has moved from acute experiments to chronic implants, and academic research has been joined by start-up companies and in some cases government labs to develop dedicated technologies enabling chronic implants. A good example is the relocation of the implant group formerly at Johns Hopkins to the Doheny Retina Institute at the University of Southern California, the founding of Second Sight Medical Products LLC (SSMP; Sylmar, CA) as a corporate partner, and the collaboration of these two entities with laboratories at state universities [e.g., the University of California in Santa Cruz (Fig. 63.5A), San Diego, and Berkeley] and in the US Department of Energy (Oak Ridge, Sandia, Livermore). The SSMP-led consortium, with cumulative private and public funding levels of $100 M each, introduced the 16-electrode Argus 16 to clinical testing in 2003 and the 60-electrode Argus 2 in 2007. Following a clinical trial with 30 end-stage RP patients in the United States and Europe, the Argus 2 was approved for routine clinical implantation in Europe in 2011, with a more limited approval in North America, under a humanitarian device exemption by the USFDA, granted in early 2013. Recipients of the device during the clinical trial have demonstrated the ability to localize and track objects [15,16] and recognize high-contrast letters and short words [17].

Simultaneously, several other groups are pursuing intraocular prosthetic devices. Such devices come in two variants. Stimulating "photodiode arrays," typically placed under the retina (subretinally) and stimulating electrode arrays with external image capture and preprocessing placed between sclera and choroid, subretinally or epiretinally. The latter, more common, prosthesis type is being pursued by additional groups in the United States—Harvard/MIT [12], France—Pixium (Fig. 63.5B), and a consortium of German universities [18]. All three groups have designed prototypes with 50 or more electrodes and wireless transmission to the freely moving eye, but only Pixium has been able to test such prototypes in a series of clinical pilot studies [19] and has obtained CE mark approval for clinical use in Europe. Other groups, most notably one in Korea, are experimenting with similar implant designs [20]. Other groups seek to stimulate the retina from outside the eyeball, to avoid the risk associated with retinal surgery, while accepting the reduced resolution inherent in the greater separation between electrodes and target cells.

The less common type of retinal prosthesis, a subretinal chip that uses photovoltaic elements for image capture in the location once occupied by the native photoreceptors, is conceptually simpler but in practice more challenging. In a primitive version [21] (Fig. 63.5C)

of the subretinal array, a 2-mm diameter silicon chip with approximately 5000 small photodiode units was placed under the retina in 20 late stage RP patients with remaining central vision. These devices were located near the arcades, well away from the area of functional photoreceptors. The photodiodes converted incident light into small DC electrical currents and, while the precise mechanism of action of these currents remains to be elucidated, it appears that they may have caused secondary release of neurotrophic factors in the surrounding retina, which in turn exerted a beneficial effect on the remaining photoreceptors. This implant may therefore have preserved some remaining vision, but it did not substitute an image by stimulating the secondary neurons, as a prosthetic implant would.

A true prosthetic, photosensitive, subretinal implant, with additional circuitry to provide signal amplification and pulse generation, was introduced in 2011 and received CE mark in 2013 (Alpha IMS; Retina Implant AG, Reutlingen, Germany) [22] (Fig. 63.5D). It is placed at the level of the missing photoreceptor/RPE layer, collects a sharp image of the outside world mediated by the eye's optics, and generates localized electrical impulses that stimulate nearby (bipolar) cells in the overlying retina. Such an integrated prosthesis has great simplicity and elegance, but its feasibility hinges on four important premises: that nutrients and oxygen from the inner retinal vasculature will suffice to nourish the retina overlying the implant; that external energy can be provided to drive the amplifier and pulse generation stages; that the heat generated by the implant's electronics can be safely dissipated into the underlying choroid without appreciably heating the overlying retina; and that the encapsulation be able to transmit light to the photosensitive elements, yet withstand the intraocular saline milieu. Power and control signals for the system electronics are supplied by a subcutaneous cable and a transdermal wireless link placed on the back of the head developers designed surgical methods to safely insert the array under the retina [23]. Clinical implantation for periods of up to a year has been carried out in several dozen patients, with positive functional outcomes reported [24], but problems with the insulating material limited its life span; the Alpha AMS, a version with improved insulation properties, developed in 2013, overcame this limitation, but due to limited commercial success the manufacturer ceased operations in 2019.

A novel, integrated, subretinal prosthesis, developed by a consortium centered at Stanford University, circumvents the need for electronic amplification, and thus an external power supply, by capturing an image of the scene in a head-worn visor, converting it into high intensity pulsed infrared monochrome image, and projecting this image onto the implant through a dichroic mirror that allows the wearer to simultaneously observe the visible scene [25]. The device entered clinical trials in patients with advanced dry AMD in Paris (2018) and Pittsburgh (2019) (Pixium Vision SA, Paris); it therefore aims to "fill in" the central scotoma left by the retinal degeneration process, while unhindered peripheral vision is maintained by virtue of the dichroic mirror.

In addition to retinal stimulation, three other approaches to electrical stimulation of the visual system are being pursued. One of these is direct stimulation of optic nerve fibers, either through a set of electrodes mounted on the inside of a cuff placed around the optic nerve [26] or through an array of penetrating electrodes placed on the inside of such a cuff [27]. Implantation around the optic nerve is surgically less invasive than placement of a device inside the eye, but it has the drawback that either large numbers of fibers are stimulated simultaneously (with the simple cuff) or correspondence between electrode location and retinal origin of the axon (and therefore location of the elicited phosphene in the visual field) cannot be predicted. Thus selective stimulation of individual optic nerve fibers will require a sophisticated mapping system to establish the correspondence between visual field locations of the perceived phosphenes and individual stimulating electrodes. A second approach to an electronic visual prosthesis is through stimulation of cells in the lateral geniculate nucleus, an important relay station along the visual pathway. Precise stimulation of the *lgn* with a large bundle of electrodes is challenging; however, since placement will have to be performed stereotaxically through small openings in the skull, similar to the placement of deep brain stimulating electrodes used to reduce the effects of parkinsonism [28]. Preliminary tests in rodents have shown the feasibility of this approach [29], but barring the development of novel electrode technologies for deep brain stimulation, it is doubtful that major developments of this approach will occur in the near future.

The oldest attempts at vision restoration involved stimulation of the visual cortex through intracranial electrodes, controlled by external image acquisition and signal-conditioning circuitry. Half a century ago, Brindley and Lewin [30] took the first steps in this direction by implanting a set of electrodes over the visual cortex of a blind volunteer; the phosphenes described by this volunteer were similar to those elicited by intraocular stimulation. More recently, a team at the National Institute for Neurological Disorders and Stroke (NINDS) performed tests with over 30 electrodes penetrating the cortical surface [31], and scientists at the University of Utah experimented with implantation of denser intracortical electrode arrays in cat and monkey

visual cortex [32] (Fig. 63.5E). The same group was also the first to perform simulation studies to establish minimum requirements for prosthetic vision [33], an approach followed by several other groups (for a review, see Dagnelie [34]). The cortical work that originated at NINDS continued through primate studies at the Illinois Institute of Technology (IIT) [35] and through evaluation of unsuccessful previous approaches [36,37]. A consortium centered at IIT has developed modular 16-electrode implants that are implanted subdurally, with electrodes penetrating into the visual cortex; the implants are powered and controlled wirelessly. Human implantation, expected in the near future.

In a separate development, SSMP (Sylmar, CA) has developed a 60-electrode array (Orion) based on the Argus II retinal implant and is conducting a feasibility study of cortical surface stimulation. The array is placed subdurally over the peripheral visual field projection on the medial wall of one cortical hemisphere, thus generating phosphenes away from fixation.

The cortical prosthesis bypasses both retinal and optic nerve problems and might therefore be seen as a universal approach to vision restoration. Admittedly, it may be the only viable approach for patients whose inner retina and/or optic nerves have been destroyed by glaucoma or trauma. However, cortical stimulation requires complex surgery of an otherwise healthy brain; moreover, the convoluted layout of the visual cortex complicates mapping of objects and locations in the outside world into a pixelized image that can be understood by the prosthesis wearer. Algorithms to establish such a map have been tested in primates [35] and through simulations in sighted volunteers [38], but thus far only for small sets of (simulated) phosphenes. Finding an efficient approach to mapping hundreds of phosphenes will be a crucial aspect of cortical implant research.

A final point of consideration for all visual prostheses for which the input image is acquired outside the eye is the altered role of eye movements. In natural vision the intent of most eye movements is to bring an object of interest to the center of the retina, where it can be resolved with greater detail and receive directed attention. If a head-mounted or handheld camera is used for prosthetic image acquisition, movement of the camera rather than the eye will recenter the image, whereas movement of the eye is ineffective, unless it is captured by an eye tracker and used to shift the image accordingly. Thus a visual prosthesis with a head-mounted camera must be equipped with eye movement monitoring and processing capability, or the prosthesis wearer must learn to suppress eye movements as a means to acquire visual information and use camera (i.e., head or hand) movements instead.

Detailed reviews of visual prosthesis development and simulation studies can be found in Dagnelie [34,39–41].

Retinal cell transplantation

Cell transplantation in the neurosensory system can, in principle, restore function through two mechanisms: rescue of threatened cells (either by restoring a failing support system, or through trophic factors secreted by the transplanted cells) and replacement of degenerating cells and functional integration of the transplanted cells into the host tissue. Both mechanisms may play a role in retinal cell transplantation, and the distinction is not always obvious, as will become clear.

There are two important distinctions in the choice of transplant modality. First, there is the distinction between autologous cells—harvested from the same individual who is to receive them, typically following amplification and/or differentiation in tissue culture—and allografts—harvested from a different donor, typically unaffected and immunologically matched. Second, the developmental stage of the transplanted cells may range from pluripotent stem cells, to organ-specific undifferentiated cells, to postmitotic (e.g., photoreceptor precursor) cells. Since the range of possible approaches far exceeds the scope of this chapter, only major developments will be indicated; a recent review of stem cell approaches to retinal degeneration can be found in Tibbetts et al. [42,43].

Some important categories of retinal disease are mediated by loss of RPE function, and both transplantation of autologous pigment epithelium and allografts have shown success in rescuing photoreceptor function. In the Royal College of Surgeons rat, rescue of photoreceptor function can be accomplished by replacement of the degenerating RPE with a wide range of transplants, from RPE xenografts (harvested in a different species) [44] to autologous iris pigment epithelium [45]. In human retinal disease, macular translocation surgery in AMD has demonstrated the feasibility of rescuing threatened vision by relocating the neural retina over a relatively healthy area of RPE [46], although visual outcomes of this surgical approach have been mixed and appear to be highly dependent on the surgeon's skill and experience. Immunologically mismatched RPE allografts and xenografts may not provide viable treatments in human retinal disease: contrary to the neural retina, where immune response appears to be muted or absent, a slow inflammatory response to mismatched transplanted RPE tissue is commonly observed [47].

Such an inflammatory response is less likely to occur when the transplanted cells are grown in vitro. In the last few years, RPE replacement has shifted toward experimental procedures involving cultured RPE cells grown from pluripotent embryonic stem cells [48]. These cells,

which can be grown in the laboratory under conditions meeting the standards of good manufacturing practice, have now been awarded an investigational device exemption by the USFDA, and as of this writing 27 clinical trials are recruiting participants with AMD for RPE transplantation (http://www.clinicaltrials.gov, date accessed 18.04.19).

Retinal diseases that originate as a photoreceptor cell defect do not lend themselves to treatment with autologous cell transplantation, since the same defect is likely to plague the transplanted cells, unless these can be genetically modified; novel techniques such as CRISPR−Cas9 may indeed make this possible in the near future (NCT03872479; http://clinicaltrials.gov, accessed 18.04.19). As early as the mid-1990s, transplants with cell suspensions and organized sheets containing mature photoreceptors or photoreceptor precursors (with or without RPE) were used as allografts, with varying degrees of claimed efficacy. In a light-damaged rat model, morphological evidence of synapse formation [49] and behavioral evidence of regained function [50] were among the earliest indicators that transplanted photoreceptors may be capable of assuming visual function. More recent evidence in the same direction from other laboratories suggests that functional synapse formation is possible in some animal models, while in others a gliotic seal under the retina effectively inhibits integration of the transplanted tissue with the host retina [51]. The mechanisms responsible for such widely different results remain to be elucidated but are most likely associated with varying patterns of reorganization occurring in response to different retinal degeneration genotypes [4].

Fetal tissue has thus far proven more successful than fully developed retina or stem cells in forming synaptic connections and retinal morphology resembling that of intact retina, and it has become the tissue of choice in most transplantation attempts. This tissue also carries a lower risk of rejection by the host immune system, at least in photoreceptor grafts; indeed, rejection does not appear to occur in rat or mouse photoreceptor transplantation [52]. Admittedly, some caution in extrapolating this finding to other species is warranted, for immune reactions in rodents tend to be less severe than in humans. The use of fetal tissue for research and transplantation purposes is subject to legal and ethical concerns in a number of countries, and this is an important reason for continued efforts to develop transplantation techniques that use adult donor tissue.

Preliminary attempts at retinal cell transplantation in blind volunteers, performed primarily to demonstrate safety, have yielded mixed, and at best modest, results. Allografts of cultured RPE appear to provide protection to functional AMD through trophic factors, but in exudative AMD the graft is quickly overwhelmed by an inflammatory reaction [53]. Photoreceptor transplants appear to convey an improvement in vision in some cases [54], but whether this is mediated by graft−host synapse formation or trophic support to the few remaining photoreceptors remains a matter of debate [55].

The ciliary body in the human eye contains pluripotent stem cells that can, under appropriate conditions, be coaxed to differentiate into retinal neuron precursors [56]; more recently, progress in the creation of induced pluripotent stem (IPS) cells from skin biopsy has greatly expanded the potential of both auto- and allografts [57]. Theoretically, therefore, the potential for photoreceptor cell replacement from tissue culture does exist. At this time, however, any attempts to use IPS cells to replace degenerating photoreceptors in human patients through injection into the vitreous or subretinal space, as repeatedly claimed in the popular media, seem highly premature. Without thorough research in animal models of retinal degeneration, and until photoreceptor cells can be cultured with the same level of control as has been achieved for RPE cells, it is unlikely that such attempts will lead to effective and reliable vision restoration, or even to long-term survival of the remaining native photoreceptors.

Optic nerve protection and regeneration

RGCs behave as central nervous system neurons in their inability to recover from severe injury: RGCs whose axons are damaged by cutting or crushing the optic nerve undergo apoptosis within days following injury, although this particular mechanism of cell death may be restricted to certain classes of RGC [58]. And while the axons of peripheral (motor or sensory) neurons can regenerate following surgical reconnection of nerve fascia, CNS neurons appear to lose such plasticity once their original outgrowth during ontogenesis is completed, due to changes in both their internal makeup and their environment. Oligodendrocytes that form the protective myelin sheath around optic nerve axons and astrocytes appear to play a major role in preventing axon regeneration following injury [59]. It has been known since the 1980s, however, that this environment can be effectively modified. Cut optic nerve axons in the rat and cat will not form new neurites in their natural optic nerve environment, yet they can be made to regenerate into a peripheral nerve graft and reach the superior colliculus [60−62]. Two basic steps are thus necessary for therapeutic intervention in advanced optic nerve disease to become a reality: protection of RGCs from apoptosis following severe damage to the optic nerve, and axon regeneration, including formation of functional synaptic connections in the *lgn* and other midbrain target structures. In recent years a third aspect, functional enhancement of remaining RGCs, has been added to the basic glaucoma research repertoire [63].

Studies in the last decade have provided encouraging indications in both areas. Intravitreal injections of antiapoptotic drugs and neurotrophic factors can limit the loss of RGCs and prolong the window for application of other therapeutic modalities [62]. Most of these therapies are aimed at preserving the RGC soma so that it can sustain a partially damaged axon, but there is still a need for targeted therapies that can either repair damaged axons or stimulate new axon growth [64]. Some progress is being made in stimulating axonal growth: oncomodulin has been identified as a factor that is particularly effective in promoting growth following optic nerve crush [65]. In addition, there is increased interest among researchers in free radicals, immune response, and nerve growth factors in the retina remaining unbalanced even after the primary causes of glaucoma (such as increased intraocular pressure) have been treated [66]; these are areas of active investigation that may benefit from tissue-engineering insights and methodologies.

Drug delivery

Since 1995 our understanding of photoreceptor and RGC death has changed dramatically. While it was previously thought that these cells die because a functional part—the photoreceptor outer segment and the axon, respectively—becomes dysfunctional, both events are now widely understood to trigger cell death through apoptosis and similar mechanisms. Better understanding of these mechanisms has led to the search for pharmacological interventions that may prevent cell death.

The process of RGC degeneration following transsection or crushing of the optic nerve can be halted, at least in animal models, with the use of neuroprotective agents such as neurotrophin-4/5 (NT-4/5) [67]. It turns out, however, that this protection has only a limited duration. Most RGCs die within 2−4 weeks, even with sustained administration of NT-4/5 [68]. Various other neuroprotective strategies have been attempted in animal models, but their long-term efficacy as well as the feasibility of long-term delivery near the threatened site remains to be demonstrated [69].

In the case of photoreceptor degenerations, a variety of nerve growth factors and neuroprotective agents have been used, both in vitro and in animal studies, and several of these have shown promise [70]. What remains to be worked out for most of these substances is the optimal delivery route. Systemic administration is not an option, since many of these agents do not easily pass the blood−retina barrier and/or have unwanted systemic side effects. Administration as an eye drop is not effective, because the active substance would need to diffuse through the cornea or sclera, and most of it would be washed away in the tear film. Repeated injection into the vitreous is unattractive to the patient, and it is not clear how long the active substance would persist in the eye and reach the outer retina.

Three relatively recent delivery techniques have all been successfully applied to ocular drugs in recent years: delivery by macromolecules, slow-release implants, and encapsulated cell technology (ECT). The first of these approaches caused a revolution in the treatment of exudative AMD about 15 years ago and is now widely known as photodynamic therapy (PDT). Liposomes with an embedded antiangiogenic substance (verteporfin) are injected into the bloodstream, and irradiation of the retina with a low-energy laser beam is used to release verteporfin in the choroidal space under the retina. The resulting oxygen-free radicals attack vascular endothelial cells and stop angiogenesis [71]. Unfortunately, this endothelial-cell cytotoxicity is not an effective long-term treatment, so, following the demonstrated safety of locally administered vascular endothelial growth factor inhibitors, PDT has now been replaced as the treatment of choice by intravitreal injections of such substances (notably Avastin and Lucentis) [72], even though such injections have to be repeated, in most cases several times over a 6-month period. The longer term outlook for these substances is very good. They can be embedded in poly(lactic−glycolic) acid microspheres to create slow-release implants that could be inserted into the eye through a small incision and attached to its inside wall, or they may even be effective when placed on the outside of the eyeball [73]. The third delivery method, ECT, is elegantly exemplified by the NT-501-permeable membrane delivery system developed by Neurotech SA (Lincoln, RI). When loaded with a transgenic cell line producing ciliary neurotrophic factor (CNTF) and implanted in the vitreous cavity, it will release a flow of CNTF for many months [74]. Applications are sought in the area of photoreceptor protection in retinal degenerations; a Phase I trial in RP was completed successfully [75]. Follow-up studies in RP and AMD showed modest positive results, but a clinical trial using the more advanced NT-503 implant in patients with exudative AMD was halted because the amount of CNTF produced was insufficient to control the disease process, and most study participants required supplementary intravitreal injections for effective control [76].

In some diseases, even the simplest method of drug delivery may be effective. In retinal ischemia, just as for other vascular blockages, “clotbuster” drugs, such as tissue plasminogen activator, can be intravenously injected. If this is done soon (hours or even days) after the ischemic event, much of the damage may be prevented; experimental therapy with these drugs has had promising results [77].

Genetic interventions

Delivery issues also play a role in the introduction of new genes into the degenerating retina. Most retinal degenerations are genetic in nature, either inherited from one or

both parents or caused by a new mutation. The premise of gene therapy is that intervention at an early stage may restore normal function to the cell and prevent the degeneration process that might otherwise ensue. Several strategies are needed to combat inherited retinal degenerations.

- In recessively inherited diseases, both copies of a gene are defective, and an introduction of a third copy may be sufficient to achieve adequate production of a functional protein to replace the defective one encoded by the mutated gene. A virus is used to introduce a healthy copy of the gene. Following a number of demonstrations of successful gene transduction into RPE cells and photoreceptors in vitro and feasibility studies in rodents, a highly publicized study of vision rescue in a canine model of Leber congenital amaurosis (LCA) [78] provided proof that gene therapy for some human retinal degenerations may soon be a reality. Since then, several small trials in children with LCA have demonstrated some improvements in ambulatory vision, but limited long-term treatment effects; for a review, see Ref. [79].
- In X-linked disease, males carry only one copy of the X-chromosome, including the defective gene; here, too, introduction of a healthy copy of the gene may be enough to achieve normal function.
- In dominant disease, a single bad copy of the gene suffices to "poison" the delicate balance of the cellular machinery, or, at the very least, to prevent its proper function. To reduce or prevent this a therapeutic intervention must block a step along the transcription pathway from the defective gene to its product protein but not inhibit expression of the good copy of the gene; a gene for such a blocking agent could, in principle, permanently neutralize the defect. This technique has been used in a transgenic rat model, using ribozymes to block mRNA produced by the P23H mutant gene defect responsible for one to form of autosomal dominant RP [80]. In a rat model with a naturally occurring degeneration, a gene for ribozyme production was successfully introduced into photoreceptors and proved effective even when introduced at a time when many photoreceptors had already succumbed to the effect of the defective rhodopsin gene [81], which bodes well for therapeutic interventions in dominant RP. These forms of RP tend to preserve substantial levels of vision into middle age, and this remaining vision might thus be rescued.
- An entirely separate class of retinal degenerations, typically asymptomatic until middle age and often associated with multisystem disease, is caused by mutations of the maternally inherited mitochondrial DNA, responsible primarily for cellular energy supply. Mitochondrial DNA has multiple copies, and it remains unclear whether single or multiple copies are responsible for these disorders. Moreover, the mitochondrial DNA does not lend itself to normal viral transduction techniques, which adds a level of complexity to potential gene therapeutic approaches. Recent reports suggest that proteins may be used to deliver expression-blocking factors or new functional genes into the mitochondrial milieu [82].

Vision-related gene therapy research is concentrated around RP, Stargardt macular dystrophy, LCA, and related diseases with known inheritance patterns. Due to the multiple genes that can lead to these disorders and the enormous number of specific mutations that have already been identified, many gene therapeutic variants will be needed to address a substantial proportion of these disorders. This is an extremely active area of research; recent reviews can be found in Farrar et al. [83] and Smith et al. [84].

Still, this means that a true cure may become available for these retinal degenerations. AMD and optic nerve diseases such as glaucoma and ischemia, on the other hand, have no known genetic causes, though some genes associated with predisposition for such diseases have been identified. Genetic interventions may assist in preventing some forms of these diseases, but the prospects of other therapeutic approaches are more promising in the near term than those of gene therapy.

A recent finding that may play an increasingly important role in genetic as well as other therapeutic approaches is the potentially rescuing role of modifier alleles such as Nr2e3 on homeostasis in photoreceptor cells affected by a disease-causing mutation [85]; such modifiers may play a role in many inherited diseases, either alone or as an adjuvant to other forms of therapy.

Emerging application areas for engineered cells and tissues

Of the current approaches to vision enhancement considered earlier, strictly speaking only the use of stem and transgenic cells falls within the realm of tissue engineering. The complexity of ocular structures such as the retina and optic nerve poses daunting challenges to anyone seeking to recreate their function. While this may explain the lag in progress when compared to other organ systems, it should not keep researchers who are working to restore vision from drawing on the remarkable progress of tissue-engineering approaches. We next briefly consider four application areas, corresponding to the aforementioned three processing stages in the early visual system where severe vision loss may occur and the supporting retinal infrastructure.

Photosensitive structures

Current efforts in the areas of retinal cell transplantation and intraocular prosthesis design, while promising, are in no way guaranteed to lead to reliable—that is, long term and stable—restoration of useful (let alone high quality) vision. As was explained earlier, each of the approaches currently being explored has inherent drawbacks. Implanted electrode arrays require external image acquisition and preprocessing, which may necessitate real-time eye movement tracking and compensation. Integrated implants require signal amplification and thus external energy supply. Both implant types may be limited in resolution to ambulatory vision due to the 100−200 μm distance separating the electrodes from the target cells. As a rule of thumb, resolution in the underlying tissue will be no better than this distance. Retinal cell transplantation efforts are likely to be limited by the spotty record of transplanted cells in making functional contacts with the native inner retinal circuitry. And all three approaches are limited by microneuroma formation, destroying the functional diversity of the inner retina and limiting its resolution to 50−100 μm, that is, at best 20/200 visual acuity—legal blindness.

To achieve improved retinal prosthetics, electrodes will have to make more intimate contact with the target cells. If successful, this would improve resolution to the limit imposed by the repatterned inner retinal neuronal circuitry. One can envisage such a penetrating array as the Normann microelectrode in Fig. 63.5E, but the damage such an array might do to the delicate microvasculature of the retina is a distinct risk. As an alternative, one might envisage inserting or growing, in situ, an array of artificial "neurites." These might branch out of cells grown on the surface of implanted stimulating chips, penetrating the retina until they reach a specific target environment, for example, the inner nuclear layer (INL), where they would make synaptic contacts with the native cell population; these neurites would act as "transport tubes," releasing either electrical charge or a neurotransmitter that would activate the target cells. An alternative approach would be an electrode structure that stimulates nearby retinal cells to form new neurites, spurred on by favorable growth conditions and a coating on the implant. Such coatings promoting cell growth, formed by microcontact printing, are under investigation [86].

The distance between implant and target cells could also be reduced by enticing native retinal cells to migrate toward the electrode surface, adding a new twist to the cell migration seen in naturally occurring retinal repatterning [4]. Such approaches are not as farfetched as they may sound. Several groups are experimenting with surface modifications on semiconductor chips that will allow cells to adhere to these surfaces and be activated by neurotransmitters [87], while researchers at Stanford University have reported the tendency of retinal neurons to migrate around pillar-shaped electrodes forming an array placed under the photoreceptor layer (Fig. 63.6) [88]. Combinations of such technologies may lead to improved implant−tissue interfaces.

A fundamentally different approach to improving (sub)retinal prostheses may be the use of high-yield photoconversion systems. Such high-yield conversions are known to be performed by photosystem I (PSI), a macromolecule present in the membrane of thylakoids, which can be found inside the chloroplasts that give the green color to plant leaves and algae. Early experiments with thylakoids [89] showed that it is possible to anchor these structures onto a metal surface and use them as miniature photovoltaic elements. Lee et al. [90] also demonstrated that it is possible to chemically modify thylakoid surface membranes to create charge displacement in a specific direction. Kuritz et al. [91] demonstrated the ability of PSI to impart photosensitive polarization and Ca^{2+} ion movement to retinoblastoma cells in tissue culture, as a first example of cellular engineering that may eventually lead to artificial photoreceptors. The engineering successes of thylakoids and PSI open the opportunity to create cells that assume a dipole charge distribution or, with the help of intracellular electronics, produce a biphasic pulse between the "poles"; in a subsequent stage of development, automatic gain control could be incorporated, as a limited form of light/dark adaptation. If these cells can be made to attach to the outer retinal layers or to migrate into the INL, one could achieve microscopic local current sources with sufficient conversion efficiency to ensure vision at a broad range of (day)light levels. To achieve true night vision, an external device, such as a night vision scope, could be used.

Note that in this idealized situation, the synthetic "photoreceptors" might be small and sensitive enough to provide good vision without external image preprocessing (e.g., magnification and contrast/edge enhancement). It is to be expected that preliminary forms of such light-sensing units will be neither small nor sensitive enough to provide the dynamic range and resolution required; at this intermediate solution level, external image processing with an advanced portable low vision visor would be a necessary complement to this intraocular light conversion array.

Optogenetics

Since 2006 research into sight restoration has been exploring the prospects of conveying artificial phototransduction to the cell membrane of retinal and cortical neurons [92,93]. These optogenetic approaches, as termed by Deisseroth et al. [94], introduce DNA to the target cells

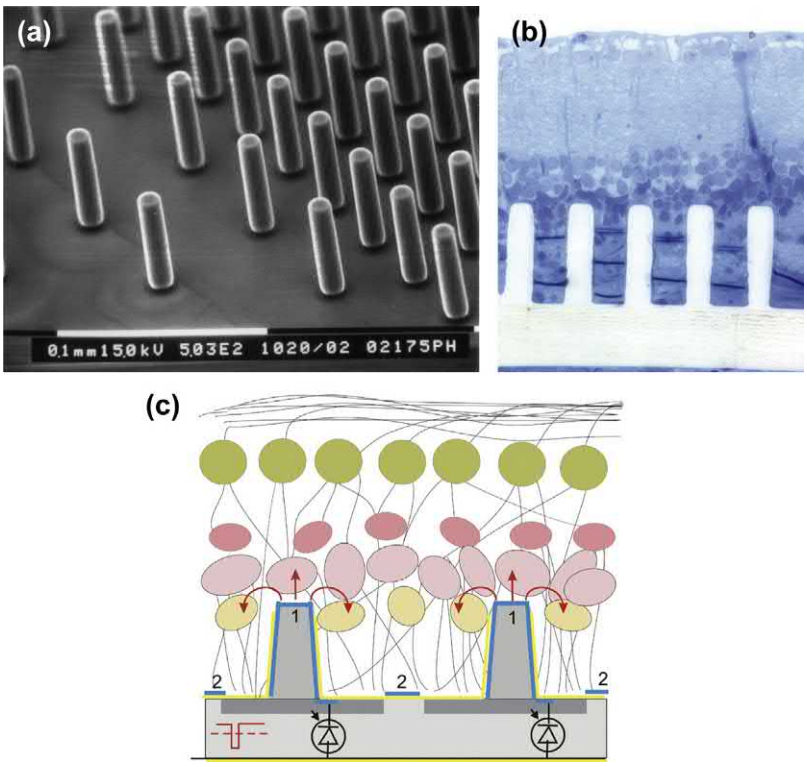

FIGURE 63.6 Pillar electrodes penetrating into the middle of the inner nuclear layer of degenerated retina. D., Stanford University.*

that code for proteins reacting to certain wavelengths of light by depolarizing or hyperpolarizing the cell membrane. The two primary proteins used in this research are channelrhodopsin-2 (ChR2) and halorhodopsin (NpHR), although melanopsin [95] is also considered a candidate for gene therapy.

Neuron depolarization is achieved by stimulating ChR2. This protein is a microbial-type rhodopsin from the green alga, *Chlamydomonas reinhardtii*. Nagel et al. [96] found ChR2 to be a plasma membrane channel that passively conducts both mono- and divalent cations upon capture of a photon by its attached chromophore. Similar to melanopsin ($\lambda_{max} = 480$ nm), ChR2 has an absorption peak at approximately 460 nm [96].

Conversely, neuron hyperpolarization can be achieved by stimulating NpHR. Originally thought to be an outward-directed cation pump, Schobert et al. [97] identified halorhodopsin as an inward-directed Cl^- pump. Although these experiments were performed on halorhodopsin from *Halobacterium halobium*, a variant (NpHR) from *Natronomonas pharaonis* is used for current experimentation because of its higher affinity for extracellular Cl^- [98,99]. Both forms of halorhodopsin absorb light at longer wavelengths than ChR2, with λ_{max} at approximately 580 nm. The two labs simultaneously reported the use of NpHR to optically hyperpolarize neurons.

These tools can be delivered to retinal cells by a variety of methods. The most widely used delivery system is that of adeno-associated virus type 2 (AAV2) vectors. These vectors were first reported for human preclinical gene therapy trials by Flotte et al. [100], applied to cystic fibrosis. Since then, the use of AAV2 for human gene therapy has expanded to cover a number of conditions [101]. Encouragingly, Simonelli et al. [102] reported the use of AAV2-based treatment for LCA with maintained single-dose efficacy and no serious adverse events as of 1.5 years posttreatment.

Bi et al. [92] injected AAV2, loaded with ChR2/GFP coding attached to a strong ubiquitous promoter, into the intra- and subvitreal spaces of mice. The authors found expression of the ChR2/GFP chimera in ganglion, amacrine, horizontal, and to a lesser extent, bipolar cells of the retina. Light responses were confirmed by whole-cell patch clamping in retina slices and visually evoked potential (VEP) recordings from the visual cortex of otherwise blind mice. These authors further demonstrated that even nonspecific transduction of ChR2 in degenerated retinae can produce light responses in the visual cortex. The quality of such information reaching cortex, however, may not be particularly meaningful. Specifically, the simultaneous activation of pathways that normally exhibit direction selectivity, lateral inhibition, and ON, OFF, or ON–OFF

responses would likely generate a highly corrupted rendition of the original images.

One way to avoid such signal corruption would be to limit the classes of cells that receive photic input. Busskamp et al. [103] reported transducing surviving cone cell bodies with eNpHR [104], a variant of NpHR with improved cell membrane localization. The target cones were in mouse models of RP and in human ex vivo retina explants. In mouse models the authors demonstrated that such cone transduction could create light responses in the retinal network that displays lateral inhibition, direction selectivity, and ON and OFF responses. Live mice with transduced cones also displayed visually guided behavior. In human retinal explants, the authors showed that their AAV2 delivery method successfully transduces human cones and results in the generation of photocurrents indicative of eNpHR activity. Although cone transduction would not be a viable treatment for patients with too few remaining cones, the authors identified an existing population of RP patients that had some remaining cone cell bodies, despite the apparent loss of their outer segments.

Another set of targets for cell-specific transduction in the retina is ON bipolar cells. While there is no promoter that is known to specifically target OFF bipolar cells [103], ON bipolar cells can be targeted using the promoter for the gene encoding the metabotropic glutamate receptor, mGluR6 [105,106]. Although not as advantageous as stimulating the retinal network from the level of the cones, specifying ON bipolar cells should allow for signals far less corrupted than one would expect from indiscriminate stimulation. Doroudchi et al. [105] used AAV2 to transduce ON bipolar cells in mouse models of blindness with ChR2. The authors observed ON-type RGC responses and visually guided behavior in the test animals. Unfortunately, when Fradot et al. [107] performed a similar experiment in human retina explants, only a very small fraction of ON bipolar cells was transduced. More efficient promoters and/or delivery methods will need to be explored before useful, selective transduction of ON bipolar cells can be realized [93,107].

While AAV2 delivery has been shown to be very productive, a number of researchers are doubtful of its practical use in the clinic. Specifically, the use of viral vectors may introduce its own risk of immune responses, and it imposes limits on the size of DNA packages to be delivered [108]. Parallel to research using AAV2 vectors are experiments that create pores in target cells through which desired genetic material can be absorbed. These pores can be generated using electric fields [109] or a femtosecond-pulsed laser beam [110].

In 2008 Lagali et al. [106] used electroporation to transfect ON bipolar cells of mouse models of retinal degeneration. Actually predating the analogous AAV2 experiments, these authors also observed expected ON ganglion cell responses and optomotor behavior, as well as center-surround organization and cortical responses. There is no indication, however, whether electroporation would have any more success than AAV2 at transfecting human ON bipolar cells. More recently, Gu and Mohanty [111] also transfected ganglion cells with ChR2 in mouse models of retinal degeneration, generating visually guided behaviors.

Electroporation, by its nature, acts over a relatively wide area and does not offer more spatial specificity than AAV2 vector delivery. Should the treatment be aimed at specific parts of the retina, as in RP patients with remaining central vision, a more focal method of transfection may be desirable. By applying a 10^{12} W/cm 800 nm laser beam using femtosecond pulses, researchers can create transient perforations in specific cells through which DNA can enter [112].

Gu and Mohanty [111] used this optoporation to transfect RGCs of goldfish with ChR2. Using multiphoton targeting, the authors were able to specify the 3D location of each pore, which had radii of approximately 400 nm and was laid out in 3 μm intervals over the targeted area. In a follow-up study, Villalobos et al. [110] transfected retinae of the same species using both optoporation and photothermal poration with carbon nanoparticles. Stimulation through ChR2 was observed by intracellular calcium imaging.

Separately from these experiments on targets and delivery methods, Nirenberg and Pandarinath [113] recently addressed the issue of optogenetic signal fidelity using a computational approach. Unlike other groups discussed here, these authors bypassed the typical issue of transfection by growing a transgenic mouse line that models retinal degeneration and possesses ChR2-expressing RGCs. To determine proper stimulation parameters for these ganglion cells, the authors observed the spiking patterns of different classes of ganglion cells from normal retinae in response to movies with both natural and artificial scenes. Using these data, they constructed encoders, specific for each type of ganglion cell, which combined to model the signal processing performed by the normal retina. The models were data driven, in that parameters for each model were chosen so the output for any given input would have the highest probability of matching actual retinal spike trains, as tested by cross-validation.

Nirenberg and Pandarinath stimulated the retinae of blind mice using either patterns generated by their encoder or the unprocessed spatial patterns of the stimuli. The authors demonstrated that cells stimulated by the encoder's patterns more closely matched the firing patterns of normal retinal neurons. Further, the authors used a drifting grating on an LCD screen to elicit optomotor tracking, which was only possible when the stimulus was

presented though the stimulation encoder. No tracking was observed with the unprocessed stimulus or in control animals. These data imply that, although cerebral cortex is plastic, meaningful perception of visual information may depend on the preservation of the neural code normally exhibited by the retina.

For clinical purposes, Nirenberg and Pandarinath acknowledge that it may not be practical to target multiple classes of ganglion cells, each receiving its own coded version of a given stimulus. They do argue, however, that targeting a single ganglion cell class, with proper encoding, may be sufficient to provide more faithful percepts than those generated by conventional stimulation patterns. Their experiment inducing optomotor tracking, in fact, only utilized transient ON cell encoders.

Once applied to human subjects, optogenetic approaches to vision restoration may outpace less target-specific electrical retinal processes. Reactivation of cone remnants using NpHR could provide many benefits related to intrinsic retinal processing. For patients in whom such treatment would not be viable, stimulation of bipolar cells, or of ganglion cells in the fashion described by Nirenberg and Pandarinath, could provide similar benefits. To introduce light-sensitive properties into the target cells, electro- and optoporation may offer new avenues of treatment, should cases arise in which AAV2 vectors are insufficiently effective or specific to use as a delivery system.

Outer retinal cell transplantation

Despite almost two decades of careful investigation, reliable, and widespread formation of synapses between transplanted photoreceptor precursors and native inner retinal cells—and thus full integration of the transplanted cells into the host retina—has remained elusive. Also, the effects of the host immune response on graft survival—especially of transplanted RPE—cannot be ignored, even if it appears to be mild, and this host reaction will have to be effectively controlled without long-term systemic immune suppression. Both areas can profit from tissue-engineering approaches. A complex set of conditions—cells in the proper stage of development, properly matched to the host retina, and spurred on by a proper combination of neuroprotective and neurotrophic modifications to the host environment—needs to be met for successful graft−host integration. Recent reports indicate that even widely held beliefs regarding the proper developmental stage of the transplanted cells may need to be revisited. In a mouse model, early postnatal photoreceptors showed widespread synapse formation with native retinal cells [114], whereas most previous research has been directed at the use of postmitotic photoreceptor precursors in a much earlier stage of development.

Even if the cell population affected by the primary degeneration process is successfully replaced, secondary degeneration stages—of RPE cells in photoreceptor degenerative disease and of photoreceptors in RPE degeneration—may still prevent restoration of visual function. This problem can be addressed adequately only by performing a combined graft of RPE and photoreceptors, presumably prepared in a tissue culture environment and stimulated toward integration through a carefully tuned combination of neuroprotective and neurotrophic factors. Culturing stem cells or differentiated cell lines might allow the creation of heterogeneous structures such as RPE/photoreceptor double sheets. Culture conditions and the growth stage of these sheets should be modulated to prepare the cells for integration with the host retina. In order to provide sufficient structural support to these fragile sheets during growth and transplantation, a resorbable polymer layer could be used as a substrate.

Cell matrices supporting axonal regrowth

Cell culture conditions and retinal integration alone will not be sufficient in the case of ganglion cell transplantation with the objective of repopulating the optic nerve with axons carrying visual information to the brain. As discussed earlier, this will require the (re)creation of conditions favorable for axonal growth over distances of many centimeters and the ability of sprouting axons to contact target cells with the correct retinotopic mapping. This feat is accomplished effortlessly by RGC axons in the developing embryo, but to recreate the conditions for this to occur in an adult organism will be a considerable challenge.

As was noted earlier, an RGC axon damaged by glaucoma, optic nerve disease, or injury can only form new neurites under optimal environmental conditions, which essentially mimic those in a developing organism. At the same time, neuroprotective factors are required to sustain the RGC long enough for the axon to assume this support function. If the glaucoma diagnosis is made early, and safe and effective neuroprotective agents become available, it may be possible to save most of the threatened axons and thus spare most RGCs and the patient's vision. In practice, however, many axons may have been lost by the time the diagnosis is made, and protection of the cell somata and stimulation of axon regrowth become the treatment objectives [115]. The experimental conditions employed thus far, using peripheral nerve sheaths to create a substrate for axonal regrowth, are less than ideal, because they do not provide an integrated environment in which regrowing axons combine with intact remaining axons and in which protection of the threatened RGCs is built into the environment. This is a very active field of research, offering great potential for tissue-engineering

approaches, and one may expect such approaches to play a major role in achieving these objectives. Understanding the necessary conditions to create an integrated environment for axonal regrowth and creating novel synthetic materials to provide these conditions should provide wonderful challenges to tissue engineers.

One approach to such an integrated solution might be that engineered cells could be grown in situ, as a loose skeleton of supporting tissue, to follow the course of the optic nerve to the chiasm and optic tract; these cells would be programed to exude the necessary factors promoting axon growth and RGC protection. Alternatively, it might be possible to modify the normal environment of the optic nerve (temporarily) to allow or even stimulate axonal growth. Assuming that it would be possible to guide outgrowing axons through the optic chiasm toward the appropriate structures and retinotopic projections in the midbrain, RGCs may restore their connections to the target cells and resume functional visual processing.

Repopulating ischemic or diabetic retina

As mentioned earlier, new capillaries—formed under the influence of an angiogenic tissue response—tend to be poorly organized and fragile, causing leakage and thus a great deal of damage to already stressed retinal tissue. Therefore the prospects of restoring vision in such retinal areas are, at the present time, poor.

This may change, however, if cell populations can be grown in vitro and introduced into the retina under physiological conditions mimicking those during embryonal development. In that case the formation of new blood vessels could follow a more orderly pattern, and implanted cells would have a much better chance of forming functional connections. Whether and when it will be possible to recreate embryonal conditions and grow such integrated retinal tissue as is required to restore vision to an ischemic portion of the retina, from RPE to RGC axons, is difficult to predict. It is a challenge whose magnitude exceeds that of RPE/photoreceptor transplants, functional stimulation of inner retinal cells, and RGC protection/axonal regrowth combined.

Assessing the functional outcomes of novel retinal therapies

Electrophysiologic assessment of the functionality of a therapeutic intervention is considered a gold standard by many researchers and clinicians, but recording the responses in eyes that have undergone experimental treatments may not always be feasible. Retinal implants are in a unique position that they allow clinical functional evaluation directly from the implant provided that the necessary signal collection hardware is available. This is exemplified by developments in cochlear implants. Cochlear implants were approved for clinical use in the United States in 1984 [116], and over the years advanced built-in electronics based on reverse telemetry [117] have been developed to record electrically evoked auditory nerve responses (electrically evoked compound action potentials, or eCAPs). eCAPs are recorded by stimulating the auditory nerve through a subset of electrodes in the implant array and recording the elicited neural activity at a more distant electrode. The recorded data is sent back through the same wireless radiofrequency link that is used to stimulate the implant. eCAP recordings are nowadays routinely applied intraoperatively [118], enabling the surgical team to assess functionality of the implanted device while the patient is still under general anesthesia. In addition, eCAPs can be used for rehabilitation purposes such as automated device fitting [119,120] and fitting of cochlear implants in young children [121,122].

The visual equivalent of the eCAP is the electrically elicited electroretinogram (eERG), which could fulfill similar purposes to the eCAP. However, none of the present retinal implant systems, such as the Argus II device, has reverse telemetry capabilities sufficient for recording the eERG. Recording the eERG with standard ERG methods such as corneal electrodes is difficult, due to the small signal amplitudes and the presence of electrical as well as physiological artifacts in the eERG signal [123]. Electrical artifacts generated by the implant can be effectively reduced by using filtering techniques such as stationary wavelet transformation [123–126]. Physiological artifacts are more difficult to deal with, because filtering techniques reducing these contaminations will inevitably also reduce the retinal responses of interest. In a recent conference presentation reporting on recordings from monocularly implanted Argus II recipients [123], it was demonstrated that a physiological artifact attributable to pupil innervation responses in both eyes can be largely eliminated through subtraction of the contralaterally recorded pupil response from the combined retinal + pupil response recorded at the implanted eye (Fig. 63.7). Although the decontaminated corneal recordings have negative polarity, as seen in the eERG of rats with retinal implants [127], and show increasing amplitude with increasing stimulus level as expected from any compound action potential, their retinal origin remains to be definitively confirmed. It is likely that this confirmation will have to await direct recording, with high temporal and dynamic resolution, from implant electrodes through improved telemetry.

In the interim, cortical responses, that is, electrically elicited VEPs (eVEPs) recorded from the scalp, can provide a promising alternative [128,129] to retinal responses (Fig. 63.8). Cortical [130] and brainstem [131] responses have been used to assess cochlear implant function, but

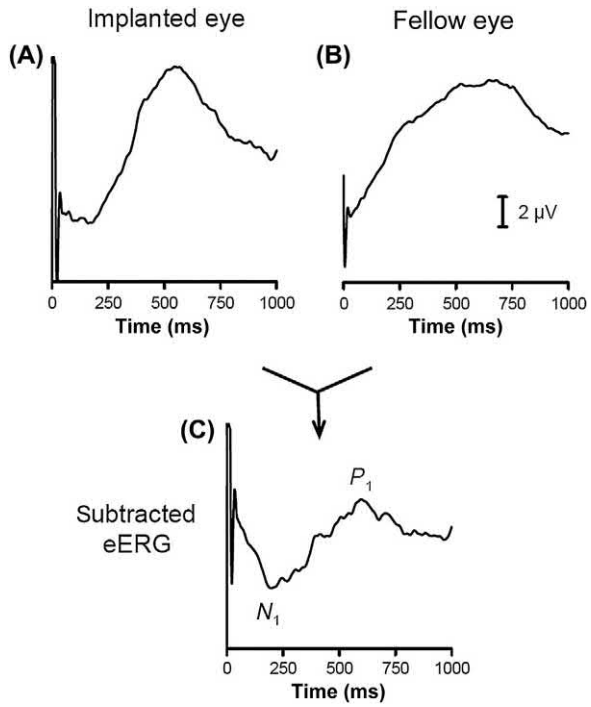

FIGURE 63.7 Electrically elicited electroretinograms (eERGs) evoked by unilateral stimulation of the implanted eye and recording the eERG bilaterally (A and B). The decontaminated eERG (C) was obtained by mathematically subtracting the physiological artifact recorded from the fellow eye. *eERGs*, Elicited electroretinograms.

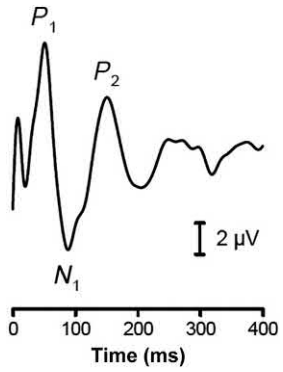

FIGURE 63.8 Cortical response of retinal implant stimulation: the electrically elicited visually evoked potential (eVEP).

eCAPs are applied more widely, due in no small measure to the availability of high-quality reverse telemetry systems [132]. Nevertheless, advantages of cortical over peripheral potentials include the fact that cortical responses represent central nervous system activity (V1 in case of eVEPs) and may provide a more accurate indication of perception than eERGs. In addition, eVEPs can also be recorded in case of visual prostheses implanted in the optic nerve [133] or central nervous system; are relatively easy to acquire; show the expected dependence on stimulus level; and accurately reflect subjective threshold [129]. Unfortunately a single eERG or eVEP recording can take up to 15 minutes to complete, using current technology, thus limiting the usefulness of this approach at the present time. For the eERG and eVEP to be of clinical value, recording times will have to be substantially reduced; once this is accomplished, these recordings can be used for system fitting in a similar fashion as is currently the case for eCAPs in cochlear implants.

Conclusion: toward 2020 vision

The potential applications of tissue engineering sketched in the previous sections pose enormous challenges, well exceeding the competency of any single group or institution. Concerted research efforts by multidisciplinary groups may allow the implementation of the complex systems required to restore and enhance vision. As researchers improve, on the one hand, their fundamental understanding of processes such as photoconversion, graft integration, immune regulation, and neuroprotection and, on the other, the engineering ability to control tissue properties and neurite growth, both in vitro and in situ, crude but functional vision restoration at the RPE/photoreceptor level and at the RGC level may advance to the level of experimental and even clinical therapy. Integration of all these areas to recreate the full range of retinal processing is a much more distant goal, for which the header of this section is much too ambitious.

To accomplish any of these forms of vision restoration, however, funding mechanisms for multidisciplinary research and interest from the corporate sector will have to rise well beyond their current levels. While the number of severely visually impaired individuals and the economic impact of vision restoration alone may not justify that these approaches receive priority over the treatment of life-threatening conditions, the investment required is relatively modest, and the improvement in quality of life for (nearly) blind patients can be very significant.

Introduction

Teeth might not at first seem to be an obvious organ for developing biological methods for replacement or repair. Teeth are nonessential organs, and modern dental treatments enable most dental problems to be treated using traditional nonbiological approaches. Teeth do, however, offer unique opportunities to develop tissue-engineering-based approaches on an organ that is not only easily accessible and nonlife-threatening but one where there are a large patient numbers and a significant clinical problem. The challenges of developing methods needed to restore and repair complex organs are immense, but the biggest challenge will be the testing of any such organs on patients. Patients requiring repair or replacement of major internal organs (heart, liver, lungs, pancreas, etc.) are by definition likely to have a serious illness. Access to these organs requires major surgery; should the treatment fail, the consequences will be severe and life-threatening. Teeth do not present any such problems and thus provide an opportunity for the proof of concept to be tested safely, with little chance of danger to the patients.

Although there are an increasing number of alternative treatments in dentistry, most are nonbiological and many are based on techniques that have been practiced for thousands of years. Dental implants, for example, involve the replacement of missing teeth with metal rods that are screwed into holes drilled into the jawbone. The practice of replacing missing teeth with metal implants can be traced back to the ancient Romans and Egyptians [1,2]. The number of dental implants installed is increasing each year, and thus there is a need to develop new biologically based approaches. Similarly, many tooth fillings still use mercury-based amalgams, and the possibility that repair of dental hard tissues (dentine and enamel) might involve the use of cells to remineralize the damage to teeth naturally is an exciting prospect. This chapter explores the current status of research directed toward whole tooth replacement and repair of dental disease.

Tooth development

Teeth are ectodermal appendages (hair, sweat glands, salivary glands, etc.) that develop from an increasingly well-understood series of reciprocal epithelial mesenchymal interactions (Figs. 64.1 and 64.2). In mammals, these interactions take place in the developing oral cavity between the oral ectoderm (epithelium) and cranial neural crest-derived mesenchyme (ectomesenchyme). The cellular origins of the signals that initiate tooth development have been the subject of much controversy over the years, but modern molecular and animal techniques have confirmed that the oral (predental) epithelium is the source of the signals that initiate odontogenesis (reviewed in Refs. [3,4]).

Recombination experiments between dental cells and nondental cells have identified temporal changes in the direction of inductive signals. Following the initial epithelial-to-mesenchymal inductive signals, a long series of temporally and spatially controlled exchange of signals governs each step in the increasingly complex development of a tooth. With the exception of the nerve supply, all the cells of a mature tooth originate from the oral epithelium and ectomesenchyme. The epithelial cells form only one functional cell type, the ameloblasts that are responsible for enamel formation. All of the other cell types, including the odontoblasts that are responsible for dentine formation, periodontal ligament cells, the pulp cells, etc., are derived from ectomesenchyme. The ability of ectomesenchyme to differentiate into these different cell types illustrates the stem cell–like properties of these cells. Classic recombination experiments in the 1980s established that nonneural crest cell populations of mesenchymal cells cannot respond to tooth-inductive signals,

and, more recently, the requirement for dental mesenchymal cells to have stem cell properties has been established (see later). An understanding of the properties of predental epithelium, mesenchymal cells, and the interactions and molecules involved is the key to developing biological approaches for replacement and repair.

Whole tooth-tissue engineering

Stem cell-based tissue engineering of teeth

The aim of this approach is to reproduce an embryonic tooth primordium from cultured epithelium and mesenchymal cells. Since it is established that embryonic tooth primordia are able to continue their embryonic development in ectopic adult sites such as the kidney, the expectation is that the artificial primordia will develop into teeth following implantation as tooth rudiments into the adult mouth. Thus rather than a metal dental implant, a cell-based biological implant will be transplanted. Since the ectomesenchymal cells of the tooth primordium form the majority of tooth cells and regulate tooth shape, it is finding replacements for these cells that has been the main initial focus of research. The early inductive interactions that take place in vivo show that the mesenchymal cells must have stem cell−like properties. Cultured populations of stem cells have thus been used to replace these ectomesenchymal cells in recombinant tooth explants. Cultures of mouse embryonic stem (ES) and neural and adult bone marrow cells were aggregated to form a semi-solid mass, on which embryonic oral epithelium was placed [5]. When cultured for 2−3 days, the initiation of an odontogeneic response in the stem cell "mesenchyme" cells could be visualized with molecular markers. Transfer of the explants in the kidney capsules of adult mice was then used to assay for tooth formation. "Bioteeth" explants made with mesenchyme derived from ES and neural stem cells proved difficult to transfer intact into kidneys. Explants made from adult bone marrow stromal cells, however, were substantially more robust and survived transfer. Following incubation of explants in kidneys for 10−14 days, clearly identifiable tooth crowns were formed, surrounded by bone. By using cells from genetically distinct transgenic mouse lines (GFP, LacZ), the stem cell origins of dental mesenchyme cells and bone cells could be confirmed. Cells derived from adult bone marrow stromal were thus capable of contributing to tooth formation is a way identical to ectomesenchyme cells. Moreover, development of the tooth crowns appeared to follow the normal pathway of embryogenesis, with the formation of new bone completely surrounding the tooth. New bone formation is an essential (but often overlooked) component of biotooth formation. A biotooth has to be able to anchor itself to the jawbone with roots and a periodontal ligament. Concomitant bone formation must therefore occur during tooth development.

The growth of tooth primordia following surgical transplantation into the adult jaw appears remarkably straightforward. Transplantation into ectopic sites or into tooth sockets following extraction provides a suitable environment to support continued development, postnatal growth, root formation, and eruption [5−7].

Bioteeth from cell-seeded scaffolds

In the early 1950s, Glasstone Hughes demonstrated that when early-stage embryonic tooth primordia are physically divided into two halves; each half develops into a normal-sized tooth [8]. This pioneering experiment demonstrated the developmental plasticity and regenerative capacity of embryonic tooth germs. This regenerative capacity has been exploited to devise a simple, biodegradable scaffold-based approach to biotooth generation. The early pioneering work of Vacanti et al. on the use of biodegradable scaffolds to act as supports for guided tissue regeneration has provided the basis for using the reorganizational properties of dental primordia cells to reform teeth in vitro [9]. The basic principle is to create scaffolds in the shape of the tooth required. These are then seeded with cells isolated following dissociation of third-molar-tooth germs. Third molars, or wisdom teeth, erupt late in human development and thus in young adults are present as dormant primordia. Both pig and rat third-molar primordia have been used with essentially the same procedure, utilizing biodegradable polymer scaffolds [10−12]. Cells from third molars at the late bud stage of development were dissociated by incubation with collagenase and dispase, and the cells were then either seeded directly into scaffolds or cultured for up to 6 days in Dulbeccos modified eagle medium plus 10% fetal bovine serum before seeding. The scaffolds were composed of polyglycolate/poly-L-lactate and poly-L-lactate-*co*-glycolide prepared using polyvinyl/siloxane and molded into the shape of human incisors and molars. For pig cells, scaffolds of $1 \times 0.5 \times 0.5$ cm were used, whereas for rat cells, rectangular scaffolds of $1 \times 5 \times 5$ mm were used. Scaffolds containing seeded cells were surgically implanted into the omentum of rats (athymic rats for pig cells) and left for 12−30 weeks. Histological sectioning of the explants revealed the formation of tiny tooth-like structures. The structures were between 1 and 2 mm in size and showed many of the features of molar-tooth crowns, including differentiation of ameloblasts and odontoblasts. Experiments using pig cells detected the tooth-like structures after 20 weeks, whereas with rat cells, these formed after 12 weeks. In all cases the shapes of the toothlets formed were independent of the shape of the scaffold, and, unlike natural tooth formation, no bone was formed in

association with the teeth. Based on the previous results of Glasstone Hughes, the most likely explanation for these results is one of reorganization rather than de novo formation. The small size of the teeth indicates that small numbers of dental epithelium and mesenchyme cells reassociated to form tooth germs. The fact that cells could be cultured for up to 6 days indicates that either the epithelial and/or mesenchymal cells are able to retain their odontogenic properties, or the possibility exists that stem cells were present in the cell populations, but this remains to be demonstrated. A functional biotooth must be able to form roots; in order to do this, new bone must form at the same time as the tooth. In the scaffold approach, no new bone is formed. In order to address this, scaffold tooth-like structures have been generated together with bone implants produced from osteoblasts induced from bone marrow progenitor cells seeded onto polyglycolide-*co*-lactide-fused wafer scaffolds [13]. The codevelopment of bone and tooth-like structures permitted the early formation of roots and thus demonstrated the possibility of utilizing a form of hybrid tooth/bone-tissue-engineering approach.

The phenomenon of reorganization of dental primordia cells into teeth has been investigated in detail by Lesot et al. Using cap-stage-tooth germs (E14—mouse) (Fig. 64.1), they showed that following complete dissociation of both the epithelium and mesenchymal cell derivatives, teeth could be produced when the cells were reaggregated and reassociated [14,15]. Thus as observed with third-molar-tooth primordial, the cells retained their odontogenic capacity following dissociation. This property was utilized as a method of investigating the potential of nondental cells to participate in tooth development. The experiments of Ohazama et al. [16] showed that bone marrow stromal cells were able to replace all dental mesenchyme cells. Bone marrow cells were mixed with dissociated dental epithelial cells and reassociated with dental mesenchyme [17]. The bone marrow cells were found to contribute to ameloblast formation. In order to determine which cells within the crude marrow population might give rise to epithelial ameloblasts, cell sorting with c-kit was used to separate hematopoietic progenitor cells. When mixed with dental epithelial cells, these cells were observed to form both ameloblasts and odontoblasts. The ability of bone marrow mesenchymal progenitors (stem cells) to contribute to ameloblast formation was not assessed in these experiments. However, the principle, as originally proposed by Ohazama et al. [16], that bone marrow cells can be a potential source of cells for tissue-engineering bioteeth is further supported by these reaggregation experiments. In all the experiments reported by Lesot et al. the ability of nondental cells to contribute to tooth formation occurs only when the cells are mixed with dental cells from cap-stage tooth germs. The experiments reported by Ohazama et al. [5] did not require a mixed population. It remains to be seen therefore whether any commercial biotooth procedure could feature the use of dissociated embryonic third-molar dental cells. Since bone marrow can be used totally to replace dental mesenchyme in the absence of any dental mesenchyme cells, the prospect exists that if a source of epithelial cells can be identified that can replace dental epithelial cells in the absence of any epithelial cells, then bioteeth could be formed entirely from adult cells. Dental epithelial cells produce the signals that initiate the whole process of tooth formation, and, thus, a nondental source of these cells must in part be capable of reproducing these signals.

One signal that has been identified is bone morphogenetic protein (BMP)4, which is specifically expressed in early predental epithelium before bud formation. When exogenous BMP4 is added to nondental embryonic explants, odontoblast and ameloblast differentiation can be detected [16]. Although these cells are organized together in cell layers as they appear in vivo, they are not present in a recognizable tooth structure. Nevertheless, the fact that one molecule applied to cells early can stimulate the differentiation of nondental cells into both epithelium and mesenchymal dental cells offers the possibility of engineering a dental epithelium from nondental epithelial cells.

Root formation

In order to be functional, bioteeth must develop roots. Root formation is a complex and little-understood process. However, although little is known of the molecules that stimulate and coordinate root formation, the absolute requirement for bone is established. If teeth form in the absence of bone, they cannot form roots, as observed in the seeded scaffold tooth-like structures. When these scaffold teeth develop alongside new bone, root formation is stimulated [13]. Tooth formation is most often studied experimentally by the transplantation of tooth primordia to ectopic sites in adult rodents. The anterior chamber of the eye, the kidney capsule, the omentum, and the ear have all been used as sites that permit tooth formation. Root formation can occur at all of these sites if accompanied by bone development [17]. A prerequisite of any method of biotooth formation therefore is that tooth primordia are able to form teeth and roots integrated into jaw bone in the mouth. The mouth is, however, not routinely used as an experimental ectopic site for tooth development because of the difficulty of the surgery involved. In order to determine whether the adult mouth can support tooth formation, embryonic tooth primordia have been surgically transplanted into the mouths of adult

mice. Not only do these develop into teeth in the mouth, they also produce functional roots and erupt [5].

Cell sources

The biggest hurdle to a successful clinically translatable protocol for whole tooth-tissue engineering is the issue of the source(s) of cells to be used. Both epithelial and mesenchymal cell sources need to be identified and with the exception of the use of bone marrow stromal cells, all other reports of whole tooth "bioengineering" have employed cells dissociated from tooth primordia. A feature of the successful experiments using dissociated tooth germ cells is that the cells are not expanded in vitro before use. In order to obtain sufficient cells to generate one tooth, many tooth primoria need to be dissociated to produce at least 5×10^4 cells [18]. For any viable clinical approach the cells, whatever their source, will have to be expanded in vitro. However, when tooth primordia cells are expanded in vitro, they rapidly lose their ability to reparticipate in tooth formation, and adult dental cells do not retain any tooth-inductive capacity [19,20]. A major challenge therefore is to develop ways of maintaining tooth forming capacity following in vitro cell expansion.

Since tooth formation requires both epithelial and mesenchymal cells and these cells exhibit reciprocal signaling interactions, one of the cell types used must be able to induce odontogenic capacity in the other. In the bone marrow stromal cell experiments, embryonic tooth epithelium was used to induce this capacity in the bone marrow–derived cells [5]. Cells isolated from adult oral mucosa are capable of responding to odontogenic-inducing signals from embryonic tooth mesenchymal cells and forming tooth-like structures [21,22]. Potential adult cell sources are thus available, but none have inherent odontogenic-inducing properties.

The key to advancing this approach further therefore is to understand the molecular basis of this loss of inductive capacity. When cultured embryonic mesenchyme cells (noninductive) are mixed with noncultured embryonic mesenchyme cells (inductive) and combined with a responding epithelium, the noninductive cells acquire inductive potential and participate in biotooth formation [23]. This "cell community" effect is cell concentration dependent and provides an opportunity to investigate the gene expression changes that are associated exclusively with inductive capacity.

When tooth primordia mesenchyme cells are expanded in culture, they immediately lose contact with the opposing epithelial tissue (a source of signals) and tight cell contacts are lost as the condensed mesenchyme becomes a single layer of cells. Mesenchymal cell condensation is an important phenomenon that is involved in mesenchyme to epithelium signaling and is required for tooth development beyond the bud stage [24]. Maintenance of cell contacts may be established by growing cells in hanging drops. A method has proved successful for hair dermal papilla cell however the large numbers of cell needed for tooth induction make this method inappropriate [25]. Gene expression screens have been used to identify signaling factors whose expression is lost in cell culture [26]. An issue with these however is identifying loss of inductive signals from all the other gene expression changes associated with monolayer culture and loss of cell contact, etc. Such screens have been successful with hair cells because hanging drops have been used to restore lost inductive capacity. This is a powerful tool since gene expression can be compared between inductive cells, cells that have lost inductive signals, and cells where inductive signals have been restored in hanging drops.

Dental-tissue regeneration

An important long-term goal for dental-tissue engineering is developing strategies for biotooth formation, thereby addressing many of the clinical problems arising from developmental anomalies and dental disease. However, in the shorter term, there are many opportunities to be exploited for partial reconstruction of the tooth organ by tissue regeneration. Such approaches may be more readily achieved and still provide the potential for very significant impact on delivery of oral health care. Natural tissue regeneration, that is, wound healing in the dental environment, is well recognized but represents a rather serendipitous event, and the approaches used to encourage such processes are somewhat empirical. A key factor in encouraging natural tissue regeneration is facilitating a conducive tissue environment in which the regenerative processes can take place, including moderation of chronic inflammatory events, control of bacterial infection, and minimizing tissue injury during any restorative surgical intervention. A good understanding of how to control these influences on tissue regeneration is fundamental to clinical success. There are also significant opportunities for the application of agents, whether directly through bioactive molecules or indirectly through agents that can release tissue-sequestered pools of these molecules locally, to promote regenerative processes and tip the balance between tissue degeneration and regeneration.

Natural tissue regeneration

Natural tissue regeneration implies a cellular basis to regeneration, and the nonvital nature of mature dental enamel provides major hurdles to its regeneration by any but physicochemical remineralization processes. However, the vitality of the dentin–pulp complex provides significant opportunities for regeneration. Regeneration in the dentin–pulp complex will only take place, however, if there is

a conducive tissue environment. Early studies highlighted the causal link between bacteria and inflammatory events in the dental pulp, and the presence of pulpal inflammation provides an effective barrier to initiation of regeneration therein [27]. Thus if natural tissue regeneration is to be facilitated, it is essential that bacterial infection and the consequent inflammation in the tooth are controlled. The inhibitory action of inflammation on regeneration may represent an effect more on signaling events than stem/progenitor cell survival, since inflamed pulp tissue can allow isolation of cells with some stem cell properties [28,29]. The close interplay that is emerging between inflammation and tissue regeneration [30], however, emphasizes the complexity of events in the postinjury tissue environment where intervention should be carefully targeted. Traditionally, bacterial control has often been achieved through extensive surgical removal of infected dental hard tissues, although the trend toward minimal intervention therapy during tooth restoration potentially places the tooth at risk through incomplete bacterial control. Sealing or "entombing" the bacteria within the restoration may help to compromise their viability, as may some of the chemical agents used in the placement of dental materials. The complex relationship between bacteria and inflammation is still emerging as highlighted by the identification of the novel bacterial-killing mechanism termed neutrophil extracellular traps, which localize and kill invading bacteria using antimicrobial peptides and histones, thereby constraining infection progress [31]. Control of pulpal inflammation is critical in the context of tissue regeneration, and an improved understanding of the inflammatory mediators involved [32,33] may allow specific targeting with novel antiinflammatory molecules. Epigenetic approaches offer exciting directions to influence the pulpal inflammation—regeneration balance [34].

The concept of tissue regeneration in the dentin–pulp complex has been recognized since the first report of tertiary dentinogenesis in response to injury from caries by Hunter in the 18th century, and dentistry has long been a pioneer in regenerative medicine through the use of calcium hydroxide to stimulate reparative dentinogenesis to bridge pulpal exposures in the dentin [35]. Tertiary dentinogenesis (reactionary and reparative dentinogenesis are subvariants) represents the upregulation of the dentin-secreting cells, the odontoblasts, in teeth after completion of tooth formation to initiate tissue regeneration in response to injury. With mild injury the odontoblasts underlying the injury survive and respond by upregulation of their secretory activity to form reactionary dentin, while with injury of greater intensity, a number of these odontoblasts undergo necrosis and may be replaced by a new generation of odontoblast-like cells secreting a reparative dentin matrix [36] (Fig. 64.3). Reactionary and reparative dentinogenesis are a consequence of the tissue damage and reflect the intensity of the injury rather than its nature [37].

Importance of the injury-regeneration balance

Dental caries is one of the most widespread infectious diseases globally and continues to be a major health care problem. Initially, colonization of bacteria on the tooth

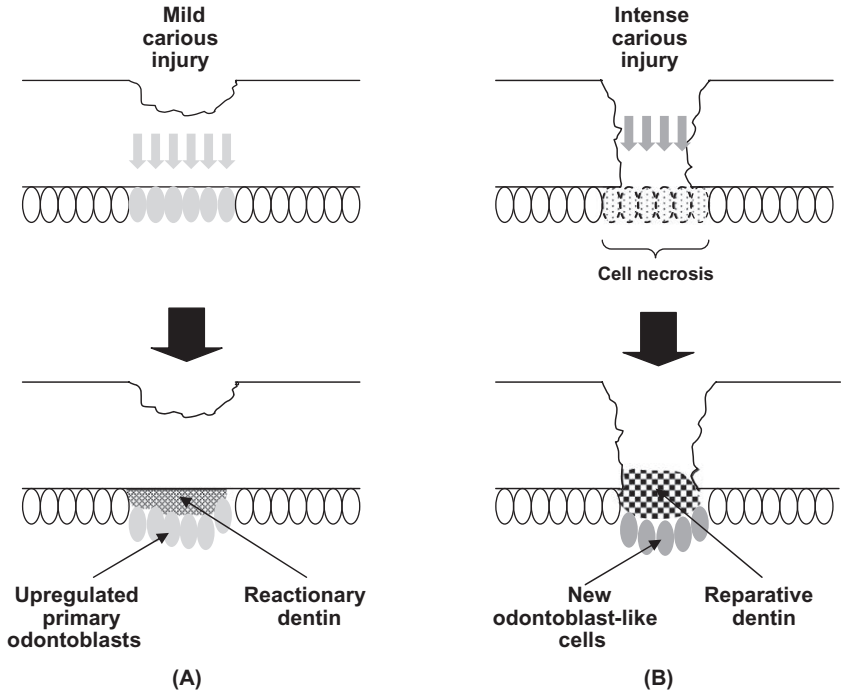

FIGURE 64.3 Schematic diagrams of reactionary (A) and reparative (B) dentinogenesis. (A) Mild carious or other injury signals upregulation of the primary odontoblasts underlying the injury site, leading to secretion of reactionary dentin. (B) More intense injury causes necrosis of the odontoblasts underlying the injury site, and progenitor cells are recruited from the pulp to differentiate into a new generation of odontoblast-like cells, which secrete reparative dentin. Dentin bridge formation at sites of pulpal exposure arises from reparative dentinogenesis.

surface within the dental plaque biofilm leads to demineralization and proteolytic degradation of the dental hard tissues following diffusion of bacterial acids and metabolites. As the disease progresses, both the hard and soft tissues of the tooth become infected, and a sustained bacterial challenge ensues, with consequent host inflammatory responses. The dynamics of the disease process determine the opportunities for tissue regeneration through tertiary dentinogenesis—with a rapidly progressing lesion, little tertiary dentinogenesis or regeneration is seen, but in a more slowly progressing lesion, induction of tertiary dentin secretion occurs immediately beneath the lesion [38]. Classically, this has been assumed to reflect the intensity of microbial challenge, but more recent data indicate that the response is in part due to local release of dentin matrix components. During intense carious injury, appreciable levels of dentin matrix components are released, and these compromise the survival of the odontoblasts [39]. It is possible that growth factors contained within the dentin matrix, particularly those from the TGF-β family, contribute to this loss of odontoblast survival, since levels of TGF-β similar to those released from the dentin matrix have a comparable effect on odontoblast survival in vitro [40]. At lower doses, however, these dentin matrix components and the cocktail of growth factors contained therein can stimulate regenerative events.

It has long been recognized that particles of dentin displaced into the pulp during surgery can act as a nidus for regeneration. Implantation of solubilized dentin matrix components in the base of either unexposed [36] or exposed cavities [41] induces a regenerative response of tertiary dentinogenesis. Such responses mirror those seen beneath more slowly progressing carious lesions [38] and suggest that the natural regeneration seen during carious and other dental tissue injury is induced by local release of bioactive tissue matrix components. If such processes are to be successfully mimicked for development of novel regenerative therapies, it is important that we understand the nature of the signaling molecules involved.

Signaling events in dental regeneration

It seems probable that the signaling events during tertiary dentinogenesis and regeneration in the dentin−pulp complex recapitulate many of those occurring during embryonic development. During tooth development the cells of the inner enamel epithelium of the enamel organ induce the ectomesenchymal cells at the periphery of the dental papilla to differentiate into odontoblasts through the mediation of the dental basement membrane, which may function in the immobilization and presentation of the signaling molecules [42]. Growth factors, especially those of the TGF-β family, may be the key signaling molecules during induction of odontoblast differentiation [43,44]. While an epithelial source of these molecules is not available in the mature tooth for signaling regeneration, sequestration of these molecules in the dentin matrix [45,46] following secretion by the odontoblasts may provide such a source. Their release during carious demineralization [39] by lactic and other bacterial acid metabolites would allow their diffusion through the dentinal tubules to the odontoblasts and pulp cells, which express receptors for these growth factors. Application of recombinant members of the TGF-β family, either in vitro [47−49] or in vivo [50−52], has been demonstrated to induce a regenerative response of tertiary dentinogenesis.

BMP and Wnt signaling pathways play pivotal roles in regulating tooth development [53] and also come into play after pulpal injury. Activation of the Wnt/B-catenin signaling pathway occurs following pulp injury with rapid upregulation of Axin2 with Axin-2 expressing cells going on to differentiate into odontoblast-like cells secreting reparative dentine [54]. Wnt pathway activators, such as glycogen synthase kinase inhibitors, have been demonstrated to stimulate reparative dentinogenesis by activating resident dental pulp stem cells (DPSC) to differentiate into odontoblasts [55] and offer interesting opportunities for the development of novel therapeutic approaches to natural tooth repair.

Although aspects of the signaling events after injury mirror those of embryonic development, their pathological nature means that there is likely to be altered control over this signaling. The activation of signaling pathways seen during repair and the rates of release of molecular signals from the dentin matrix will likely be variable, and the spectrum of cells with which they can interact will differ from embryogenesis.

Control of specificity of dental-tissue regeneration

During wound healing in the dentin−pulp complex a broad spectrum of tissue responses may be observed, ranging from regeneration of dentin tissue virtually indistinguishable from primary physiological dentin in terms of its tubularity and structure to secretion of atubular tissue with many of the structural features of bone. While terms such as tertiary dentin, reparative dentin, and irritant dentin have been used to encompass all of these responses, the dentinogenic specificity of some of the responses remains to be demonstrated. It is unclear, though, as to what the determinants are of the specificity of the response during natural tissue regeneration. Is it control of the molecular signaling processes, is it heterogeneity in the types of cells participating in the regeneration, or is it some other factor? There is still a lack of

consensus on the precise derivation and phenotype of odontoblast-like cells, and it seems probable that the phenotype is broader than sometimes acknowledged [37]. Answering these questions about determinants of response specificity will be fundamental to future strategies for exploiting tissue regeneration in the tooth in a controlled manner. The ability to determine whether tissue regeneration gives rise to tubular or atubular dentin matrix could be of great value in developing designer regenerative clinical approaches. For example, there may be significant benefit in directing secretion of a tubular dentin matrix in the tooth crown during regeneration to restore the normal physiological tissue architecture and function. However, it could be advantageous in possible exploitation of tissue regeneration for endodontic applications, such as root canal therapy, to generate an atubular dentin matrix, thereby providing an effective seal to the periapical region of the tooth.

Dental postnatal stem cells

The cells of the dental pulp have traditionally been considered to be neural crest–derived ectomesenchymal cells, although it is clear that during embryogenesis, the migrating neural crest cells will intermingle with mesenchyme in the first branchial arch [56]. Thus cells of the pulp may not all share the same lineage, although those at the periphery, including the odontoblasts, appear to be of neural crest origin. In reparative situations, there are potentially a variety of possible progenitors in the pulp for differentiation of a new generation of odontoblast-like cells, including undifferentiated mesenchymal cells in the cell-rich layer of Höhl adjacent to the odontoblasts, perivascular cells, undifferentiated mesenchymal cells, and fibroblasts. This highlights the diversity in reparative response, which may occur after injury to the tooth. While the tissues that regenerate in such situations are all referred to as tertiary dentin (reactionary or reparative variants), in reality they represent a spectrum of tissue responses, dependent on the origin of the formative cells [37].

During normal tooth development, it has been suggested that cells destined to differentiate into odontoblasts have to achieve a level of competence before they can respond to an inductive signal for terminal differentiation [42]. If this is the case, it may be a very restricted population of cells able specifically to give rise to odontoblasts during regeneration in the mature tooth. Just prior to terminal differentiation during tooth development, the preodontoblasts align perpendicular to the dental basement membrane, and after the final cell division, one daughter receives the inductive signal to differentiate into an odontoblast, while the other daughter shares a similar developmental history, with the exception of this final inductive step. It has been presumed that this latter group of cells resides in the cell-rich layer of Höhl just beneath the odontoblast layer in the mature tooth and as such, these cells would be prime candidates as progenitors for odontoblast-like cells during regeneration. Certainly, there is a decline in the numbers of cells in this subodontoblastic site with age [57], which mirrors anecdotal clinical reports of impaired tissue regeneration with age. Interestingly, many of the cells in the Höhl layer express the stem cell marker Thy-1 and those cells showing high expression of Thy-1 demonstrated enhanced potential to differentiate into hard tissue–forming cells [58]. Undifferentiated mesenchymal cells are also found within the central core of the pulp, which could contribute to regenerative processes. A specific population of postnatal DPSCs has also been described [59], which show many characteristics of postnatal stem cells, although it is possible that this population of cells may be heterogeneous in its phenotype. Transplantation of these cells subcutaneously into immunocompromised mice in association with hydroxyapatite/tricalcium phosphate powder generated ectopic deposits of reparative dentin with expression of dentin sialoprotein [60]. These DPSCs appear to be distinct from the stem cells from human exfoliated deciduous teeth (SHED) [61] and stem cells from the apical part of the papilla, the latter of which have been isolated from apical areas of the tooth [62]. Despite this focus of looking for specific cell populations in pulp, it is unclear whether these various populations simply represent mesenchymal stem cells (MSCs) recruited through the circulation from sites outside the tooth and if their exposure to the niche environment within the pulp provides their phenotypic characteristics. Genetic lineage tracing provides evidence to support such an origin for some cells involved in odontoblast-like cell differentiation [63], which has significant implications for regenerative strategies in dentin–pulp. Issues with phenotypic change of pulp cells during expansion culture [64] also highlight the opportunities to source stem/progenitor cells from nonpulp tissue, such as bone marrow and adipose tissue [65,66] for dentin–pulp regeneration.

As interest in dental regeneration increases, it is important that detailed characterization be performed of the progenitor cells involved. Primary cultures of dental pulp cells give rise to many cells with myofibroblastic characteristics, and similar results have been observed during extended serial expansion of such pulp cultures [39]. Whether this represents asymmetric growth of these cells or the myofibroblast phenotype represents a default phenotype is unclear, but it is probable that such cells are not true postnatal stem cells, and any attempt to label them as such should be resisted in the absence of fuller characterization. Caution is required in the interpretation of in vitro data though. Pericytes are commonly found in

perivascular locations and can give rise to multiple mesenchymal cell types, including myofibroblasts, when expanded in vitro. In vivo, however, stromal cell differentiation is restricted to tissue-specific cell types, and pericyte populations appear to be molecularly obstructed from differentiating down certain lineages in vivo [67].

Clearly, there is potential for a spectrum of derivations for the cells potentially involved in regeneration of the dentin–pulp complex, and the consequences of this may be a variety of phenotypic responses. It seems probable that only some of these responses may involve true postnatal stem cells. However, the diversity of cellular responses highlights the potential benefits of achieving control over these regenerative processes and the opportunities for developing strategies for directed tissue regeneration.

Directed tissue regeneration

The concept of directing tissue regeneration will be successful only if it builds on the foundation of our knowledge of natural tissue regeneration, which in turn exploits our appreciation of the molecular cellular signaling events during normal tooth development. Focus on both cell- and signaling-based approaches has provided many interesting initial avenues for directed tissue regeneration in the tooth, but it is probable that the combination of these two approaches will prove the most effective in providing us with novel solutions for regenerating tooth structures. For example, seeding of SHED cells in a poly-lactic acid scaffold within a tooth slice has allowed the regeneration of pulp-tissue resembling that seen physiologically [68] and the acidic conditions created by the scaffold were hypothesized to be responsible for release of signaling molecules from the dentin matrix.

Signaling-based strategies

Signaling-based strategies have generally aimed to mimic those signaling events responsible for cell differentiation and secretion during embryonic tooth development and natural tissue regeneration. Thus there has been a strong focus on the application of growth factors, as well as various matrix-derived molecules, which also appear to stimulate regenerative events. Growth factor application has also been investigated for chemotaxis-induced cell homing in pulp regeneration [69], which lends support to the concept of MSC recruitment from nondental locations [63]. Approaches have been used to upregulate secretion by existing cells (reactionary dentinogenesis) as well as to induce the differentiation of new odontoblast-like cells (reparative dentinogenesis) for tissue regeneration, although the former has been constrained by our lack of understanding about the physiological control of odontoblast secretion during primary dentinogenesis.

Both in vitro [47–49] and in vivo [50–52] application of growth factors, particularly of the TGF-β family, to the exposed pulp in pulp-capping situations induces regeneration, although the tissue formed has shown a range of appearances, from osteodentin to tubular dentin-like. There have also been several reports of the application of matrix molecules [70–73] promoting dentin regeneration, and a Phase II clinical trial with a synthetic peptide derived from matrix extracellular phosphoglycoprotein is presently in progress. While all of these approaches provide the foundation for a new era of biologically based regenerative therapies for the teeth, there are a number of limitations. The half-life of free growth factors is generally short; for instance, that of free TGF-β1 is estimated to be of the order of 2–3 minutes. In fact, when the growth factors are sequestered within the dentin matrix, they are remarkably well protected from degradation by association with extracellular matrix components. This protective mechanism can allow the growth factors to remain "fossilized" for the life of the tooth, thereby providing an exquisite life-long potential for natural regeneration. Also, the consequences of short half-life of these molecules and the ubiquitous presence of proteolytic enzymes in the tissue milieu at sites of injury require high concentrations to be applied for regenerative signaling.

Partial proteolytic degradation of signaling molecules sequestered within dentin matrix, however, may in some instances lead to enhancement of their bioactive properties [74]. Implantation of decellularized dental pulp as a scaffold has been proposed for regenerative endodontics [75,76], although we should not ignore that such matrices may also contribute to signaling regenerative events by the presence of bioactive molecules therein.

As for all tissue regenerative and engineering strategies, the mode of delivery of signaling molecules is the key to their effective action. To date, most signaling molecules have been simply applied as lyophilized powders or aqueous solutions, but considerable potential exists for development of novel delivery systems. An alginate hydrogel has shown encouraging results for the delivery of TGF-βs for the induction of de novo dentinogenesis on cut surfaces of pulp tissue [77], and innovative approaches are needed to deliver such molecules through the dentin matrix via the dentinal tubules. While passive diffusion through the tubules will have some effect, histomorphometry of restored human teeth suggests that natural regeneration occurs optimally when there is only a very limited residual dentin thickness, and a challenge will be to develop systems for delivery across greater distances in the dentin matrix. Gene therapy (see later) offers interesting opportunities for targeting signaling molecules

to the regenerative site, although safe and suitable delivery systems are still required.

Calcium hydroxide has long been used to stimulate dentin bridge formation for dental regeneration, although its mechanism of action has remained largely elusive. Recent studies, however, have indicated that both calcium hydroxide, and the closely related material mineral trioxide aggregate, probably act by the release of stores of endogenous bioactive molecules and growth factors sequestered within the dentin matrix, which are responsible for the cellular signaling [78,79]. The limited control of growth factor dissolution from the dentin matrix by calcium hydroxide may in part help to account for its rather variable activity during regeneration. However, its action does point to an interesting approach for regeneration, whereby agents target release of endogenous signaling molecules from the tissue, thereby obviating some of the issues associated with the application of exogenous sources of these molecules. Such agents might also include some of the cavity etchants and irrigants commonly used in restorative dentistry [80,81].

Cell- and gene-based strategies

Cell- and gene-based strategies offer exciting opportunities for dentin–pulp regeneration, although many hurdles have to be overcome before these can become a clinical reality. Using electroporation, Gdf11 gene transfer to an exposed pulp in vivo failed to provide effective regeneration [82], although the use of ultrasound for transfer of the Gdf11 plasmid provided an osteodentinogenic regenerative response [83]. In vivo gene transfer of a recombinant adenovirus containing a full-length cDNA encoding mouse BMP7 failed to induce reparative dentinogenesis in inflamed ferret dental pulps, while ex vivo transduced dermal fibroblasts induced regeneration in the same model, although the dentinogenic specificity of this response requires further characterization [84]. These studies highlight the negative impact on the regeneration of a nonconducive tissue environment, due to inflammation and, also, the limited numbers of stem/progenitor cells in the pulp for recruitment to participate in regeneration. The latter issue might be overcome by the transplantation of suitable stem/progenitor cells for regeneration at sites of injury, especially if transduced with suitable signaling molecules. Ex vivo gene therapy by transplantation of Gdf11 [85] or BMP2—electrotransfected pulp stem/progenitor cells [86]—is seen to be promising for the induction of regeneration, although the tissue formed was osteodentin-like in appearance. It is unclear whether the lack of dentinogenic specificity in these responses can be ascribed to the nature of the cells transplanted or to the inductive signaling molecules. However, the results highlight the importance of considering not only the cells and signaling molecules involved but also the delivery mechanisms for effective therapies to be developed. Novel approaches may also include epigenetic modification of pulp cells with histone deacetylase inhibitors and DNA-methyl transferase inhibitors to stimulate regenerative events [34,87,88].

The anticipated low numbers of stem/progenitor cells for regeneration in the dental pulp indicate the need to optimize recruitment strategies for these cells, whether locally recruited from within the tissue or transplanted from without. A pilot clinical study has demonstrated pulp regeneration after transplantation of pulp stem cells [89] reinforcing evidence from animal transplantation studies [90]. Despite these very encouraging results, challenges still remain both with possible issues of immune reaction to nonautologous cellular material and the introduction of cellular transplantation surgical techniques into everyday dentistry. Targeted stem cell therapy or local cell recruitment require both selection of those cells of appropriate lineage and phenotype and appropriate factors to attract the cells to the injury site. Cell markers for potential selection of stem cells from embryonic first branchial arch tissue have been investigated [91], and low-affinity nerve growth factor receptor is being targeted for the selection of odontoblast-like cell progenitors from the mature dental pulp [39]. A combination of c-kit, CD34, and STR-1 has been reported for selection of stromal stem cells from human deciduous dental pulps, which can be induced to differentiate into osteoblasts for bone regeneration [92], while c-kit has been used for selection of odontoblast progenitor cells from bone marrow [17]. CD105 has been reported to allow for selection of pulp cells capable of regenerating pulp tissue including nerves and vasculature followed by new dentin formation [93]. Use of such cell selection approaches may overcome problems associated with recruitment of stem/progenitor cells for odontoblast differentiation from a relatively small niche within the pulp during dental regeneration. Future strategies might include ex vivo selection of these cells for transplantation or immobilization of antibodies or other capture molecules for selection at regenerative sites for recruitment of the cells. Various bioactive molecules have been demonstrated to recruit stem cells for homing to injury sites [94–96], and their therapeutic use many be envisaged either by direct local application to the injury site or by indirect local release from the endogenous matrix at the injury site using chemical irrigants and tissue-conditioning agents. A combination of these various approaches with novel delivery of signaling molecules may prove effective in optimizing the regenerative response. Use of DPSC-derived conditioned medium also warrants further exploration as a clinical tool [97].

Conclusion

Tissue-regenerative strategies offer exciting possibilities for the development of novel clinical solutions for treatment of dental developmental anomalies and disease. The exquisite natural tissue-regenerative capacity of the dentin–pulp complex in the tooth provides an invaluable foundation on which to develop novel biologically based regenerative therapies. Particular attention will need to be focused on both the control and the specificity of the regenerative processes, and a combination of natural and directed tissue regeneration offers many exciting opportunities for the future.

Progress in the identification, isolation, and understanding of the differentiation of embryonic and adult stem cells, together with a continuing understanding of the control of tooth development, will undoubtedly aid the production and refinement of approaches for biotooth formation. Although there remain many potential problems and pitfalls, biological tooth replacement is now a realistic possibility.

Introduction

The oral and maxillofacial region is defined as the mouth and surrounding structures, bounded superiorly by the cranial base and inferiorly by the lower jaw. It is a highly complex area that includes morphologically intricate skeletal elements (Fig. 65.1), organs responsible for the special senses, lining and covering tissue (i.e., skin and subcutaneous fat), a rich neural and vascular network, and teeth. The prominent position adopted by this area makes it particularly vulnerable to injury, while the complicated interplay of events during embryogenesis of the craniofacial skeleton increases the possibility of developmental aberrations. Regular exposure to various disease-inducing agents, including complex carbohydrates (e.g., sugar), ultraviolet rays, thermal insults, and carcinogens (e.g., tobacco products), produces a variety of common pathological conditions such as dental caries, burns, and malignant neoplasms. The loss of tissue integrity and continuity resulting from trauma, developmental deformities, and pathology imposes upon both physicians and dentists considerable reconstructive challenges. Meeting these requirements in the 21st century will include strategies based upon tissue-engineering (TE) principles. While the discipline itself is several decades old, clinical applications for the reconstruction of the oral and maxillofacial region are currently absent. The purpose of this chapter is therefore to describe the special challenges posed by oral and maxillofacial reconstruction, outline existing reconstructive techniques, and review the available literature on TE protocols that may be relevant. Providing tissue engineers with a description of current reconstructive modalities and, in particular, their shortcomings create a reasonable starting point to base the development of revolutionary, new methods. We have specifically excluded descriptions of TE of teeth and special sensory organs, because these subjects have been covered elsewhere in this textbook.

Special challenges in oral and maxillofacial reconstruction

Virtually, all tissue types of ectodermal, mesodermal, and endodermal origin are candidates for TE strategies and are present in the oral and maxillofacial region. However, certain structures are more commonly impacted by disease, trauma, and developmental failures and constitute the focus of our discussion, though the reconstructive methods described can be applied to more rare conditions. Common *pathological* entities include both benign and malignant cystic and neoplastic processes affecting the upper (maxilla) and lower (mandible) jaws as well as degenerative conditions involving the mandibular articulation [temporomandibular joints (TMJs)] (Pictures 65.1–65.4). These diseases, or the subsequent removal of pathologically involved tissue, can produce continuity defects of the jaws requiring the replacement of bone, cartilage, and lining epithelium. Since many of these conditions are frequently silent and the dimensions of the structures involved relatively small, their initial presentation is usually associated with significant tissue involvement. In addition to disease, nonphysiological loading of bone can also produce loss of skeletal tissue affecting the jaws and joints. *Edentulous bone loss* involves the resorption of the alveolar processes of the jaws (i.e., that portion

Principles of Tissue Engineering. DOI: https://doi.org/10.1016/B978-0-12-818422-6.00067-8

of the jaw bone surrounding the tooth roots) following tooth removal (Fig. 65.2). This phenomenon is believed to be the result of direct loading of bone during mastication and the loss of physiological maintenance forces transmitted by the teeth. Over time the loss of bone produces severely atrophied alveolar ridges, posing significant challenges to prosthetic reconstruction of the dentition and a predisposition to pathological fracture of the mandible [1].

Degenerative diseases of the TMJs are commonly the result of nonphysiological mechanical forces produced by excessive ranges of motion of the joints or chronic microtrauma from various parafunctional habits [2]. The habits in question include jaw clenching or tooth grinding (nocturnal bruxism) and repetitive motion habits such as nail biting and gum chewing. Injury to the TMJs commonly affects both the articulating surfaces of the condylar head and glenoid fossa as well as the interpositional disk, producing a spectrum of disease from chondromalacia to severe osteoarthritis. As a synovial joint, the TMJs can also fall victim to various immune-mediated disease processes such as rheumatoid or psoriatic arthritis. The inflammatory component is responsible for progressive structural tissue loss leading to changes in skeletal

relationships and malocclusion [3]. In advanced forms of disease, replacement of both cartilage and bone as a total joint reconstruction maybe necessary to restore function or skeletal support to the mandible.

Maxillofacial trauma constitutes another group of conditions providing opportunities for TE reconstruction. Whereas most forms of blunt trauma result in fractures where tissue loss is minimal, penetrating injuries produced by high velocity missiles and projectiles often create significant loss of bone and overlying soft tissue (Fig. 65.3). Finally, consideration should be given to the various forms of congenital facial clefts that commonly affect the oral and maxillofacial region. In a limited form, failure of the maxillary processes to fuse unilaterally or bilaterally produces alveolar clefts (Fig. 65.4). When the upper lip, maxilla, and palate are involved, a constellation of deformities associated with unilateral or bilateral cleft lip and palate patients is present.

In the reconstruction of anatomical defects, the causative events must be taken into account to ensure long-term success. Defects produced by traumatic, developmental, and pathological conditions are associated with a defined end point. Assuming that pathology has been completely eradicated or further traumatic insults do not occur, defects produced by these mechanisms can be fully characterized with respect to size and missing tissue types. In contrast, tissue loss as a result of parafunctional habits, nonphysiological loading patterns, and immunologically mediated degeneration often continues following reconstruction. This set of circumstances will adversely affect any biological constructs produced by TE techniques and impose an important limitation on the clinical application of their usage. Before biological, rather than alloplastic materials can be employed, correction of the underlying etiology is of paramount importance.

A special concern in oral and maxillofacial reconstruction is the potential exposure of grafted tissue to the external environment. Constructs used to restore defects involving the jaws, orbits, nose, and ears are potentially in direct contact with the mouth, sinuses (maxillary, ethmoidal, and frontal), nasal passages, and external environment (Picture 65.5). These areas are characterized by high

moisture content, significant bacterial populations, and functional loads imposed by physiological activities such as chewing. If biological (i.e., tissue engineered) constructs are to survive under these conditions, modifications to account for the dilutional effects of moisture, presence of infective organisms, and mechanical loads must be provided by the engineered tissue. For example, when in vivo polymerization of materials is intended, the presence of fluid must be considered. Alternatively, preformed constructs can be used. Colonization of constructs with a mixed population of aerobic and anaerobic bacteria is expected with reconstructions involving oral, nasal, and sinus-related structures. Porous constructs, capable of harboring potentially pathological organisms, might be modified to reduce either bacterial attachment or replication until lining tissue develops over the implant forming a barrier to the external environment. In addition to contaminated wound sites, tissue constructs may be exposed to complicated mechanical loads before anisotropy is restored with the regeneration of biological tissue. Both the mandible and TMJs are subject to a combination of compressive, shear, and tensile loads depending on the type and degree of function [4,5].

Another special feature of the maxillofacial region is the number of tissue types within a relatively small region. As a result of this proximity, traumatic, pathological, and developmental events often lead to the creation of composite defects requiring reconstruction of multiple tissue types. This results in a special challenge not only to engineer composite tissues but also to attach the various constructs to each other in their normal anatomical relationship.

Facial symmetry is an important consideration in oral and maxillofacial reconstruction. Since most structures are paired or contiguous (e.g., the orbits, zygomas, and left and right maxillae and mandible), accurate reproduction of the external form is an important aspect to preserve facial esthetics. The paucity of overlying soft tissue as camouflage contributes to the exacting nature of oral and maxillofacial reconstruction and these requirements impose upon TE methods the ability to compose and maintain accurate morphology. The advent of new three-dimensional (3D) imaging techniques with the capacity to produce stereolithographic skeletal models that mirror both the normal anatomy and defect is a valuable adjunctive tool (Fig. 65.5). These models assist in the fabrication of scaffolds to support the reconstruction of missing tissue.

Current methods of oral and maxillofacial reconstruction

There are several methods used for oral and maxillofacial reconstruction and the selection of a particular modality takes into account a number of important issues. Major factors that guide this process include the presence (or absence) of associated soft tissue, the vascularity and vascular pattern present, a multidimensional characterization

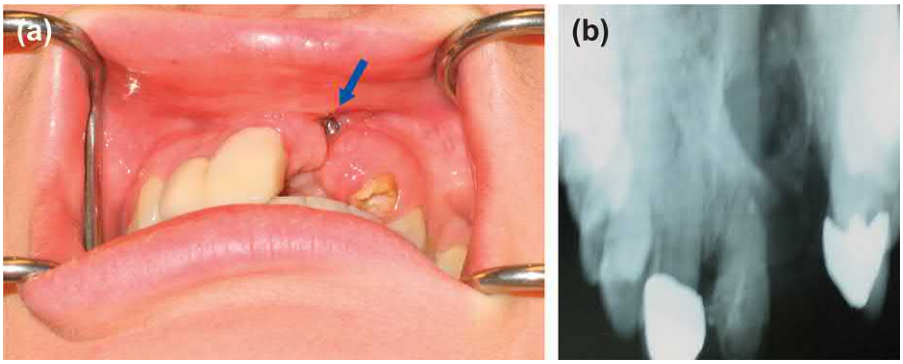

FIGURE 65.4 (A): Intraoral view of a left maxillary alveolar cleft. An oronasal fistula is present at the superior-most aspect of the cleft (see *arrow*). (B): Radiograph of a cleft of the maxillary alveolar bone.

PICTURE 65.5 Ablative defect of maxillary squamous cell carcinoma involving large defect of the midface.

of the defect size, the types of missing tissue, availability of tissue for transfer, and both patient and surgeon preference. Most reconstructive techniques can be categorized into four categories:

1. soft tissue pedicled flaps;
2. nonvascularized soft and hard tissue grafts (the graft establishes in a delayed fashion, a vascular network following implantation, relying upon tissue diffusion to preserve the viability of the transplant);
3. soft and hard tissue vascularized grafts (the graft is immediately perfused through an existing arterial-venous system); and
4. alloplastic reconstructions with prosthetic appliances.

On occasion, composite techniques can be used, such as the staged reconstruction of a defect where soft tissue is first added to a defect site followed by bone at a later time.

A newer technique using a hybrid of vascularized soft and hard tissue with nonvascular tissue engineered allogenic grafts has been reported in a limited number of cases but has shown promising results [6].

Mandibular defects

Reconstruction of the lower jaw is indicated following removal of tissue during surgical excision of a pathological lesion or following loss of tissue from a traumatic injury. When malignant disease is present, not only is more radical removal of tissue required but postoperative radiation therapy produces lasting compromise to both the cellularity and vascularity of the remaining tissue. Blast effects from missile injuries can also produce significant composite injuries with loss of bone soft tissue and diminished vascularity of the tissue bed. Two techniques are commonly employed for the reconstruction of mandibular defects. Vascularized grafts are indicated when the vascularity of the tissue bed is compromised by radiation or excessive scarring. They are also valuable when there is a requirement to replace both hard and soft tissue at the same time [7]. Hard and soft tissue defects can also be reconstructed using nonvascularized grafts, but their success relies upon an adequately vascularized tissue bed, which can be compromised in irradiated or traumatically injured tissue, to support the survival of transplanted cells before a new supply is established [8] (Picture 65.6).

As composite structures, vascularized grafts contain either soft tissue alone (muscle, subcutaneous tissue with or without epithelium) or include hard and soft tissue components (bone and soft tissue). Since the vascular supply to bone is contained within a peri-osseous cuff of muscle and fibrous tissue, it is not possible to transplant only bone. The additional tissue transferred into the site of a bony defect often produces a bulky graft. While this can be easily excised once a new vascular network is established, a second procedure performed several months after the initial transplantation is required. Another potential limitation to the use of vascularized bone grafts for the reconstruction of mandibular defects is the amount of bone available, since the dimensions of the graft are determined by the morphology of the donor site and not the size of the defect. Special techniques such as osteotomizing the graft and folding it upon itself have been described, but this can compromise the blood supply to

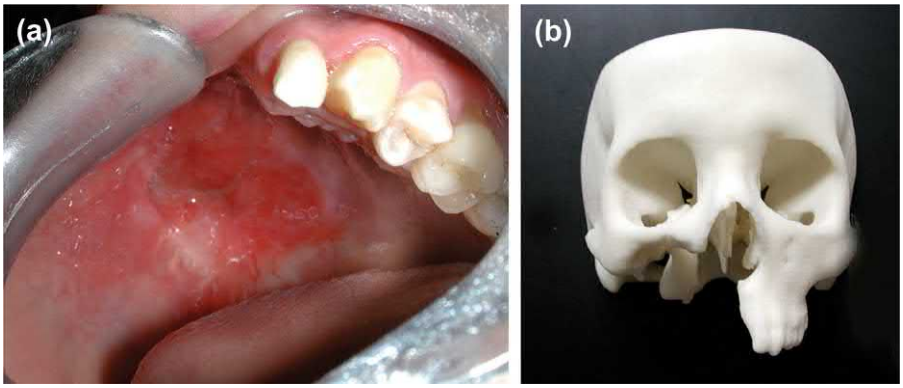

FIGURE 65.5 (A) Patient following a right maxillectomy for removal of a benign odontogenic neoplasm. Defect has filled in with fibrous tissue stimulated by grafting the site with an allogeneic dermal matrix. (B): Stereolithographic model of the same patient demonstrating the extent of the maxillary hard tissue defect.

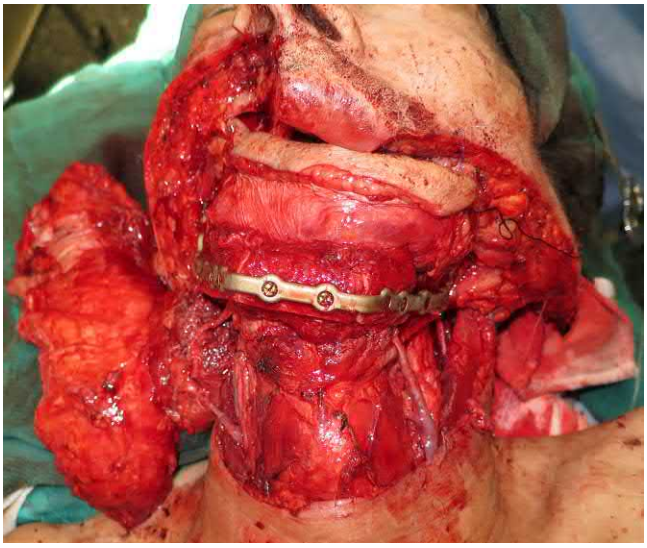
PICTURE 65.6 Placement of avascular bone graft in an infection-free bed via trans-cervical neck incision.

PICTURE 65.7 Massive squamous cell carcinoma of the lower lip.

the graft. Vascularized grafts are harvested from a limited number of anatomical sites characterized by a dominant arterial supply—venous drainage system. In addition, the en bloc harvesting of the graft must not compromise either the function of the donor site or the vascular and neural supply of structures distal to the harvest. Commonly used donor sites that meet these requirements include the fibula, ilium, scapula, and distal radius. Vascularized grafts transplanted to mandibular defects are anastomosed to patent vessels adjacent to the mandible, such as the facial, lingual or superior thyroid arteries, and veins. This reconstructive approach is highly technique-sensitive and while experienced microvascular surgeons achieve successful outcomes in over 90% of cases, less experienced surgeons or patients with underlying vascular disease (e.g., diabetes) enjoy less success (Pictures 65.7–65.10).

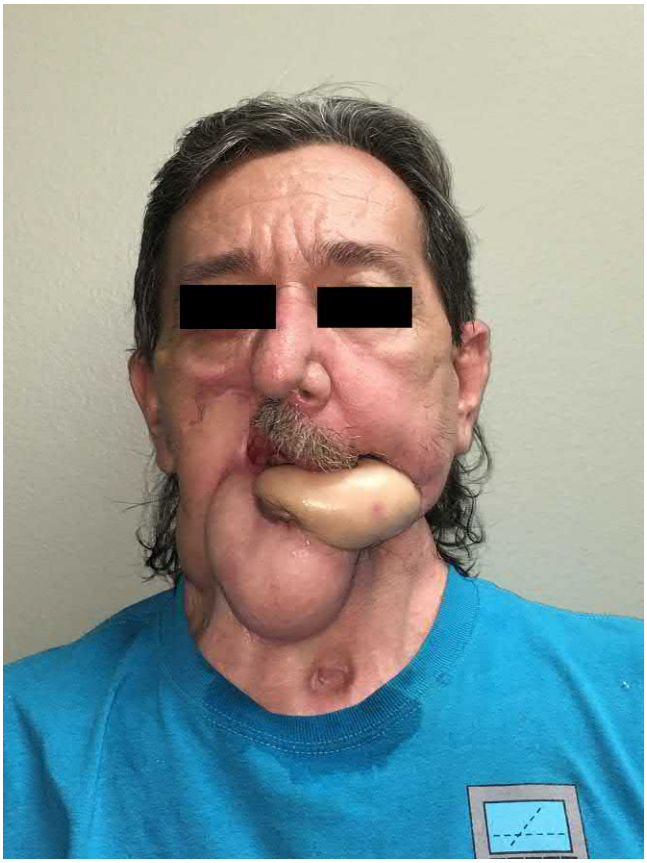
Mandibular defects can also be reconstructed using nonvascularized transplantations of autologous bone from various sites. Successful bone grafts rely upon adequate cellularity and a sufficiently cellular and vascular recipient bed. When the soft tissue bed is deficient or lacks a decent blood supply, an addition of well-vascularized soft tissue is achieved by the rotation of a muscle flap (with or without skin) into the mandibular defect. The pectoralis major, latissimus dorsi, and delto-pectoral flaps have all been described for this purpose. The bony reconstruction is delayed for a period of 3–6 months until the soft tissue flap has healed. In patients, whose soft tissue is adequate but avascular as a result of radiation therapy, hyperbaric oxygen therapy can improve the quality of the vascular supply in a course of treatments lasting between 4 and 6 weeks, where repeated exposures to pressurized room air promote tissue angiogenesis. This process adds both time and considerable expense to the reconstructive process but has been shown to be effective in improving the quality of the recipient bed. Once the soft tissue in a mandibular defect has been optimized with respect to quantity, cellularity, and vascularity, autologous bone is transferred from a donor site and molded to fit the dimensions of the defect. The bone graft can be retained with screws fixed to a rigid bone plate or held in position with the aid of cribs fashioned

PICTURE 65.8 Resection involving lower mandible, including right midface and nose.



PICTURE 65.9 Use of anterior lateral thigh fasciocutaneous and fibula osteocutaneous vascularized free flaps for mandibular reconstruction.

either from processed allogeneic bone or alloplastic materials. Depending upon the size of the defect, bone can be harvested from the anterior ilium (suitable for defects up to 4 cm in length), the posterior ilium (defects up to 8 cm in length), and the tibia or mandibular symphysis and rami (defects of less than 2 cm in length). Nonvascularized grafts, especially those combined with allogeneic bone, are susceptible to infection especially following exposure to the intraoral environment, and in one case series, this was associated with a failure rate of

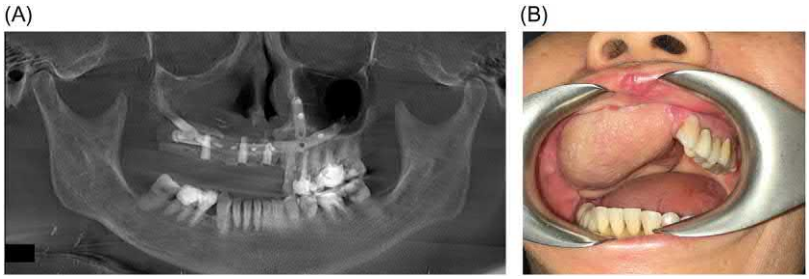


PICTURE 65.10 Patient 3 years postsurgery with no evidence of disease.

43% [9]. When a nonvascularized graft is colonized by organisms, infection often ensues and the graft fails to survive or integrate with the host bone. Aside from the potential for infection, nonvascularized grafts are less technique sensitive, allow "complete" reconstruction of a defect by customizing the volume of bone harvested, and are associated with less donor site morbidity [10].

Maxillary defects

Defects of the upper jaw pose difficult reconstructive challenges from several perspectives, but must be undertaken to preserve speech, prevent the escape of food and fluids during eating, and maintain esthetics. Unlike the mandible, which is related to the oral cavity alone, the maxilla is bounded inferiorly by the mouth and superiorly by the nasal cavity and maxillary sinuses. Even when present, the thin lining epithelium does not provide a sufficient cellular or vascular bed to support the transplantation of sufficient quantities of nonvascularized bone and the potential for exposure of the graft to oral and nasal environments is high. Postoperative or posttraumatic scarring reduces the tissue envelope even more, further



PICTURE 65.11 (A and B) The use of fibula osteocutaneous vascularized free flap for reconstruction of maxilla. Panoramic radiograph of reconstruction showing fibula, reconstruction plate, and dental implants (A). Intraoral postoperative photograph of the same patient showing bulk of soft tissue associated with flap (B).

complicating reconstructive efforts. Staged reconstructions have been described involving the initial transfer of vascularized soft tissue with a pedicled flap, such as the temporalis muscle or temporoparietal flap, followed by the addition of bone several months later [10]. As an alternative, vascularized flaps have been used because of their ability to transfer both hard and soft tissue at the same time [11]. However, the accompanying soft tissue and vascular pedicle may not be accommodated by the smaller dimensions of a maxillary defect and this has limited their use to hemi- or total maxillary reconstructions. The simultaneous transfer of a large bulk of overlying soft tissue also results in a postoperative recovery period of several months, where the flap can prevent mouth closure and compromise eating (Picture 65.11A and B).

As a result of these challenges, prosthetic appliances have become the most commonly used method to reconstruct maxillary defects. These devices incorporate teeth and a fitted base to separate the mouth from the superior defect [12]. Excellent restoration of both esthetics and function can be achieved, but the fact that they are not permanently fixed in place and, in fact, require daily removal and cleaning, reduces their acceptability by patients. In addition, adjustments are required periodically to account for remodeling of the underlying tissue bed.

The reconstruction of maxillary alveolar clefts is one exception to the use of prosthetic appliances as a primary reconstruction technique, even though they can be used very effectively to restore missing teeth in the cleft site or obturate an oral–nasal communication. When teeth are present in a cleft site, provision of bone is essential for eruption and support [13]. Alveolar grafting is therefore timed according to the presence and stage of development of adjacent teeth and is usually performed between the ages of 8 and 11 years. The procedure involves the development of soft tissue flaps to isolate the mouth from the nasal cavity and placing autogenous bone between the cleft segments to restore maxillary continuity. Loss of the graft from infection, insufficient vascularity, or lack of functional stimulus are not infrequent occurrences and opportunities for TE alternatives exist. This would be especially true if new interventions minimized the extent of surgery, since postsurgical scarring has been associated with restricted growth and development of the maxilla.

Relevant strategies in oral and maxillofacial tissue engineering

Driven by the limited supply and inherent shortcomings of various autogenous, allogeneic, and prosthetic materials currently used for the reconstruction of oral and maxillofacial tissues, the potential for tissue-engineered biomaterials as alternatives is under serious investigation with the hope that significantly improved therapies will result.

While a diverse number of strategies are presently under development, the fundamental tenets of TE remain the same. These include consideration of the biological and mechanical properties of the scaffold material and its interactions with relevant bioactive molecules and cell populations.

Although multiple tissue types exist in the oral and maxillofacial region, TE research in this field has focused primarily on the regeneration of single tissues: the bony craniofacial skeleton, lining epithelium, the cartilages of the TMJ, auricle, and nose, and the teeth and surrounding periodontal tissue (please refer to Chapter 69, Cutaneous epithelial stem cells and Chapter 71, Bioengineered skin constructs for teeth and periodontal regenerative initiatives, respectively).

Bone applications

An ideal biodegradable TE bone construct should combine the biocompatibility and osteoinductive potential of autologous bone, with the availability and structural characteristics of allogeneic bone. Additional scaffold design considerations include porosity, pore interconnectivity, surface chemistry, and the ability to reproduce complex 3D defects.

Scaffolds are responsible for a construct's initial mechanical integrity and provide surface area for cell attachment. Several biocompatible scaffold materials are currently used in oral and maxillofacial surgery, including naturally derived materials such as collagen, gelatin, or hyaluronic acid, synthetic polymers such as poly(lactic acid) (PLA) and poly(glycolic acid) (PGA), and ceramics such as calcium phosphate granules, blocks, and cements [14]. In addition to those materials clinically used, several

materials have been tested using in vivo models for craniofacial bone, including alginate, chitosan, poly(propylene fumarate), oligo(poly(ethylene glycol)-*co*-fumarate), poly(caprolactone), and polyurethanes [14]. These materials are typically processed as porous structures or hydrogels that guide the morphology of regenerated tissue, allow for tissue in-growth, and control the release of bioactive molecules such as growth factors or nucleic acids.

Other approaches to TE use novel biomaterials capable of implantation through minimally invasive surgery. This can be achieved via in situ cross-linking or polymerization via chemical reactions initiated by mixing chemicals immediately before injection, transcutaneous photopolymerization, or thermogelation [15–19]. Delivery of osteogenic factors or cells has been demonstrated with these techniques; however, parameters such as cell viability must be weighed against gel stiffness with such materials.

Growth factors act as mediators of cellular growth and differentiation during tissue regeneration and play an important role in extracellular matrix synthesis. Used as recombinant proteins in TE strategies, growth factors require a local population of target cells capable of affecting the desired response [20]. This constituency of cells maybe naturally present at the wound site or added to the scaffold at the time of fabrication [21] prior to implantation.

Factors that have been used for the regeneration of in vivo TE craniofacial bone include the bone morphogenetic proteins (BMPs) [21,22], transforming growth factor-beta (TGF-β) [23], fibroblast growth factors (FGFs) [24], insulin-like growth factors (IGFs) [25], and platelet-derived growth factor (PDGF) [26]. The bulk of experience concerning the use of growth factors for bone repair has involved BMPs [27] and this popularity has been extended into clinical investigations using recombinant human BMP-2 (rhBMP-2) for alveolar ridge augmentation [28,29], maxillary sinus floor augmentation [30,31], mandibular reconstruction following tumor resection [32,33], distraction-assisted alveolar cleft repair [34], and the treatment of medication-related osteonecrosis of the jaw [35,36]. A review by Herford et al. covers several cases of BMPs used in mandibular reconstruction secondary to tumor excision, trauma, and infection, highlighting the versatility of growth factor–mediated bone regeneration [37]. However, the review notes a relatively small number, 37, of documented clinical cases in the literature with a significant failure rate of 13.5%. This highlights the need for further investigation of these growth factor–based technologies in the craniofacial complex.

BMP-2 has found some definitive success in other aspects of oral and maxillofacial surgery, such as dental implants and sinus floor augmentation. Jung et al. [28] examined the effect of combining rhBMP-2 with a xenogeneic bone substitute in order to improve membrane-guided bone regeneration therapy of osseous defects in the areas of dental implant placement. Although there was not a statistically significant difference in percentage of newly formed bone at the rhBMP-2-treated site versus the control site at 6 months, a larger fraction of mature lamellar bone (76% vs 56%) was present in the experimental sites, as well as increased graft to bone contact (57% vs 29.5%). In addition, Boyne et al. [30] completed a phase II–randomized controlled study investigating the safety and efficacy of rhBMP-2 combined with an absorbable collagen sponge (ACS) versus bone graft for staged maxillary sinus floor augmentation. It was concluded that rhBMP-2 had a similar safety profile to bone graft with the added benefit of lacking donor site morbidity. In addition, the rhBMP-2/ACS treatment induced similar amounts of bone to the bone graft group, allowing for the placement and long-term functional loading of dental implants in approximately 75%–80% of the patients treated. More recently, Kim et al. [31] reported on a randomized controlled trial of 127 patients undergoing maxillary sinus floor augmentation. The safety and efficacy of rhBMP-2 mixed with hydroxyapatite granules was compared to bovine bone xenograft. Similar to previous work, new bone formation in the rhBMP-2-treated group was noninferior to that seen in the xenograft-treated group in the early stages after sinus augmentation with minimal side effects.

The clinical use of rhBMP-2 to regenerate much larger bone defects has also been reported in the literature. Melville et al. [32] described a case series in which five patients with mandibular continuity defects underwent immediate transoral reconstruction using a combination of bone allograft, bone marrow aspirate concentrate, and rhBMP-2. Despite the small number of patients in the study, a success rate of 100% was observed with all patients showing excellent bone quality both clinically and radiographically for endosseous dental implant placement (Pictures 65.12 and 65.13). Carstens et al. [34] described the use of "distraction-assisted in situ osteogenesis" to treat a severe facial cleft, in which rhBMP-2/ACS implantation was combined with distraction osteogenesis to create the patient's ramus and condyle as part of the surgical reconstruction. A similar spectacular application of rhBMP-7 has been described by Warnke et al. [38] for the reconstruction of a 7 cm mandibular continuity defect in a patient who had received ablative tumor surgery and subsequent radiation treatment. A bone-muscle-flap prefabrication technique was used, in which computed tomography and computer-aided design techniques were used to fabricate a custom titanium mesh cage replicating the contours of the missing mandible. Within this cage a combination of xenogeneic bone mineral blocks coated with rhBMP-7 and autologous bone marrow were placed,

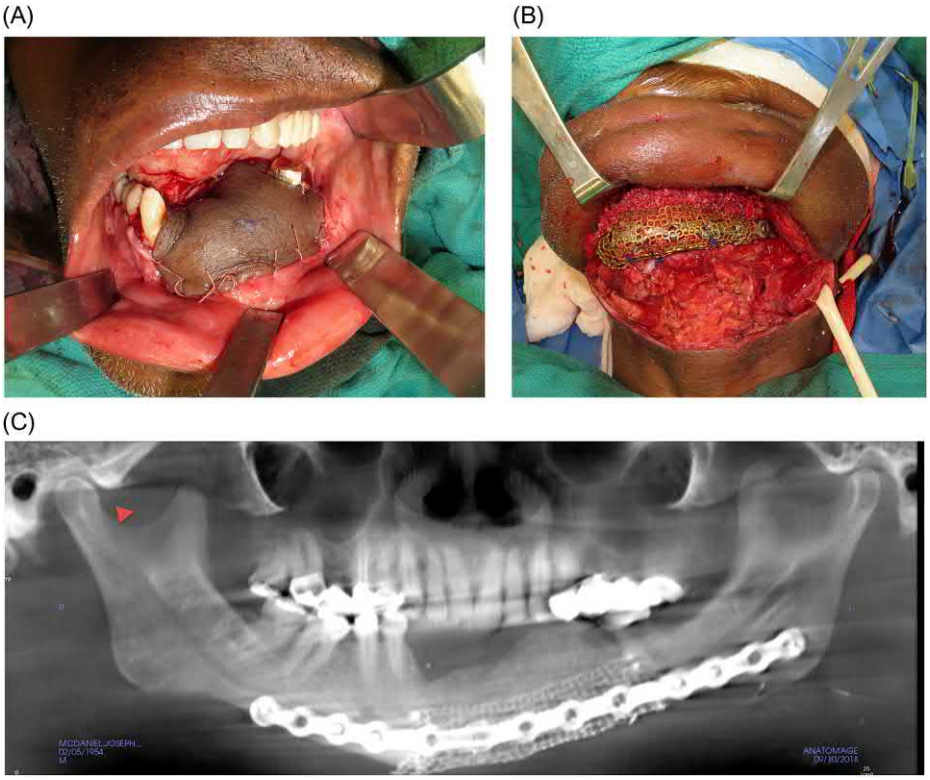
prior to implantation of the entire construct within the latissimus dorsi muscle of the patient. Following 7 weeks of implantation within this "in vivo bioreactor," the viable mandibular replacement was harvested from the patient along with part of the muscle containing a major artery and vein which were subsequently anastomosed with vessels at the recipient site using microsurgical techniques. Four weeks after this transplantation surgery, the patient was able to undertake a small amount of mastication and enjoy more solid foods. In a similar case of prevascularization, Mesimäki et al. implanted a titanium mesh containing β-TCP granules seeded with adipose-derived stem cells (ASCs) cultured in rhBMP-2 into the rectus abdominis muscle of a patient who had undergone hemimaxillectomy [39]. The mesh was harvested with a vascular pedicle 8 months later and anastomosed to vasculature in the face replacing the resected bone. This patient went on to receive dental implants for complete dental rehabilitation. Others have reported the use of "hybrid" surgical approaches, in which a vascularized free flap is combined with autologous bone grafting [6] (Picture 65.14A–C).

A significant drawback to growth factor strategies in TE is the shortage of naturally derived factors isolated from biological tissue. This deficiency has been addressed with the development of techniques to produce biologically active proteins using recombinant engineering techniques. However, the use of recombinant proteins is not without concern [27]. Compared to animal models, bone regeneration in humans does not appear to be as robust. In order to overcome this species recalcitrance, administration of factors in excess of naturally occurring concentrations appears to be necessary. The augmented administration of exogenous factors may potentially stimulate harmful biological effects such as malignant transformation of cells and also prove to be too expensive when compared to alternative techniques for tissue regeneration. In an effort to mitigate cost, potential for harmful stimulation or disease transmission, autologous supplies of growth factors have been investigated, primarily through the use of platelet-rich plasma (PRP). As a natural source of growth factors, PRP has been applied to craniofacial bone TE scaffolds, but with limited success, illustrating the inherent difference in the effect of therapies across species [40,41].

Attempts to address the shortcomings of recombinant protein-based strategies have spurred investigation into the use of gene delivery for TE. By delivering the gene for the expression of a protein with specific effects on a target cell population, successfully transfected cells will elaborate the protein constitutively. This results in higher and more constant levels of protein production [42]. However, while both viral [43,44] and nonviral [45] gene



PICTURE 65.14 (A, B, and C) Hybrid combination of radial forearm osteocutaneous vascularized flap for intraoral soft tissue coverage (A) with rhBMP-2 + bone marrow aspirate concentrate + allogeneic bone graft (B). delivery vectors have been used for bone regeneration in cranial defect animal models, compromises must be made with each. Adenoviral constructs have commonly been used as viral vectors to transfect craniofacial tissues and have the advantage of efficiently transfecting both replicating and quiescent cells [46]. In addition, adenoviruses are easily manipulated, can be produced in high titers, and large amounts of genetic information can be inserted into them. However, concerns related to viral vectors include in vivo homologous recombination and the possibility of an immune response from the expression of viral antigens on the surfaces of transfected cells. These concerns have led to the development of nonviral vector agents [42].

While numerous nonviral gene delivery systems exist, a common problem is their low in vivo transfer efficiency [46]. Nonetheless, such systems are able to deliver much larger genes with minimal immunogenicity. One promising modality of nonviral gene delivery for craniofacial applications is the use of cationic liposomes which have been used to regenerate cranial bone defects in rabbits by delivering BMP-2 plasmid cDNA [47]. The low transfection efficiency of uncondensed, naked plasmid DNA has also been addressed by the use of the cationic macromer poly(ethylene imine), which has been used to condense BMP-4 plasmid DNA and deliver it in a sustained and localized manner from poly(lactic-*co*-glycolic acid) scaffolds within critical size cranial defects [45].

Gene transfection can take place directly within the defect site by releasing the delivery vector in vivo from the TE scaffold [43,44]. Indirect delivery methods have also been described using a target cell population harvested from the patient, performing in vitro transfection of the cells, and then reimplanting the transfected cells into the defect along with the TE scaffold material [48]. While the direct technique may be simpler, it has a lower transfection efficiency and target cells in a nonspecific manner [27]. The indirect ex vivo approach, on the other hand, requires additional harvesting and culturing procedures but avoids the risks associated with placing viral vectors directly into the patient and disturbing the host genome. Ex vivo—transfected cells are not immunologically privileged and may still express viral antigens on their surface which can lead to a host response following implantation.

As a corollary to gold standard approaches where bone grafts and flaps include the donor site cells, some TE approaches to craniofacial reconstruction employ cell-seeded scaffolds as implants. These have potential benefits for regenerating tissues in large defects or those with compromised healing capacity, such as those affected by radiation therapy [8]. The majority of cell-seeded scaffolds have investigated mesenchymal stem cells (MSCs) or ASCs. Reviews have covered some of the works in these areas looking at various stem cell sources, delivery, and other parameters such as in vitro expansion and

differentiation [8,49]. To highlight a few studies, MSCs were applied to ceramic and polymer scaffolds with and without PRP in both cranial and alveolar defects of rats and minipigs, respectively [40,41]. In both studies the addition of MSCs enhanced bone regeneration over all other groups irrespective of PRP presence. In another study, autologous, culture-expanded MSCs were used in combination with alginate hydrogels for the treatment of large cranial bone defects in sheep [50]. Finally, predifferentiated ASCs were applied to rabbit cranial defects on gelatin scaffolds showing enhanced bone regeneration within the defect [51]. However, in another rabbit cranial defect study, rhBMP-2 on collagen regenerated greater amounts of bone compared to ASCs or predifferentiated ASCs, indicating that although cell delivery for bone regeneration in the craniofacial complex shows promise, issues of cell sourcing, purification, and processing need to be investigated further [52].

Aside from the biological components of TE constructs, scaffold properties are also extremely important to the overall success of any particular strategy. A common misconception is that bone TE scaffolds for craniofacial applications do not require substantial strength, since the craniofacial skeleton is not subjected to heavy loading. However, in vivo studies demonstrate that many craniofacial bones undergo levels of strain similar to that experienced by the appendicular skeleton [53], substantiating the need for mechanical strength of potential bone TE scaffolds. Ideal scaffold design must therefore reconcile the need for high porosity and interconnectivity, which promotes tissue in-growth and scaffold degradability, with a requirement for mechanical strength. Computational methods for designing and fabricating scaffold architectures to optimize both pore interconnectivity and load bearing characteristics have been performed [54], and a proof of concept study has illustrated the effectiveness of scaffold design in fabricating a mandibular condyle for a minipig [55].

The surface characteristics of bone TE scaffolds also determine their ability to regenerate tissue in the wound-healing environment. Surface chemistry has a significant effect on the interactions between the cell populations present in the defect and the biomaterial. Hydrophilic synthetic polymers such as oligo(poly(ethylene glycol) fumarate) (OPF) have been shown to impede bone healing in extraction sockets as compared to the hydrophobic polymer poly(propylene fumarate), based on the OPF macromer's prevention of protein adsorption and hence cell adhesion [56]. Interestingly, the resistance of OPF hydrogels to generalized cell adhesion has been used to advantage in the fabrication of biomimetic scaffolds, which are able to selectively encourage the migration of osteoblasts in vitro through the addition of specific binding peptides to their surfaces such as osteopontin-derived peptide [57].

In addition to surface chemistry, surface topography can impact healing. In a series of studies, porous materials in the mandibles of New Zealand White rabbits were shown to enhance the healing of the overlying mucosal surface in a composite tissue defect model [58–60]. However, contrary to traditional TE materials with high porosity led to an increased inflammatory response not seen with lower porosity materials [58]. Two of these studies investigated porous poly(methyl methacrylate) (PMMA), a material currently part of many Food and Drug Administration–cleared products. By creating porous PMMA and enhancing soft tissue interaction with the implant, these materials show promise for rapid translation to clinical use in a staged approach, whereby the implant serves to temporarily maintain the bone space during soft tissue regeneration and is removed for the definitive therapy [61].

Cartilage applications

While there has been extensive research in bone TE in the craniofacial complex, there has been less research in cartilage TE. However, cartilage TE in the craniofacial complex remains a significant challenge due to the inherent lack of remodeling in cartilage due to decreased cellularity and vascularity and due to the various cartilaginous tissue types in the craniofacial complex. As in musculoskeletal TE, articulating cartilage is part of the TMJ on the mandibular condyle, while the TMJ disk has different morphology. In addition, there is structural cartilage in the nose and ears, which supports the skin to create openings critical for the senses.

The earliest TE study directed at reconstruction of the TMJ disk used a porous collagen scaffold seeded with articular cartilage cells. After 2 weeks the construct appeared similar to a disk with regards to gross morphology and cell shape [62]. Later efforts tested fibers of PGA and PLA and concluded that both materials were able to support cell attachment and matrix production and exhibited acceptable mechanical properties after 12 weeks [63]. Another study comparing PGA, polyamide filaments, expanded polytetrafluoroethylene filaments, and bone blocks [64] demonstrated cell attachment and limited collagen production, but neochondrogenesis was not observed after 4 and 8 weeks. While PGA is an acceptable scaffold substrate, the material degrades exceedingly rapidly, leaving constructs with limited mechanical integrity after only a few weeks. As an alternative, PLA nonwoven mesh has been tried and initial results show promise with retention of tensile and compressive integrity over a similar time scale [65]. However, replacement of fibrocartilage to restore the articulative surfaces or interpositional disk of the TMJ's constitutes a special challenge, including identifying a suitable source

of healthy fibrochondrocytes. In a review by Wang et al., cell sources for TMJ TE are discussed [66]. Primary cells such as chondrocytes from articular cartilage or the TMJ disk have enhanced phenotypic characteristics for TE but require expansion, which commonly results in dedifferentiation and loss of this phenotype [67,68]. To address this limitation, various protocols have been developed to reprogram expanded, primary cells back to a chondrogenic phenotype using a cocktail of growth factors and aggregate culture [69–72]. Stem cells, on the other hand, proliferate extensively and can be induced into a chondrocyte-like cell through growth factors and other parameters. In a study by Bailey et al., condylar chondrocytes were compared human umbilical cord cells on PGA scaffolds and were not only able to proliferate more but also produced more extracellular matrix with components similar to that of native articulating cartilage [73]. Beyond differences in cell type, chondrocytes from various anatomical regions have shown varied ability to proliferate or synthesize extracellular matrix components in vitro. Specifically, costal and ankle chondrocytes have shown greater synthesis of collagen and glycosaminoglycans (GAGs) compared to chondrocytes harvested from the TMJ disk [74,75]. Other studies have investigated paracrine and cell contact signaling by coculturing differentiated cells together or with undifferentiated cells [76–78]. In these studies, coculture of fibrochondrocytes with either chondrocytes or with embryonic stem cells resulted in greater extracellular matrix production.

In addition to cell types, growth factors have been used to enhance the regeneration of cartilage tissue for the craniofacial complex. This potential was first observed in an experiment comparing the effects of TGF-β_1 with prostaglandin E_2 (PGE_2) on bovine TMJ disk cells in monolayer. TGF-β_1 increased cell proliferation 2.5-fold, while PGE_2 had no significant effect [79]. The effects of PDGF, IGF, and basic FGF (bFGF) have also been assayed using monolayer cultures of porcine TMJ disk cells. The results of these studies suggest that lower concentrations favor biosynthesis, while higher concentrations favor proliferation [80]. The most beneficial growth factors appear to be IGF-I and bFGF, both of which produce significant increases in collagen synthesis and cell proliferation [75,80]. Since native tissue is exposed to a variety of growth factors, combination strategies are likely to prove more beneficial than single factor therapy. To explore this hypothesis, IGF-I and bFGF in low concentration were combined with bFGF and TGF-β_1. This cocktail successfully demonstrated increased collagen production when applied to porcine TMJ disk cells seeded on PGA scaffolds [81]. However, while constructs exposed to growth factor combinations improved structural integrity and overall cellularity, a statistically significant improvement in biochemical or mechanical properties was not demonstrated [82]. Finally, other combination strategies employed coculture with growth factor delivery, which were shown to increase matrix production and structural integrity of a gel construct over the individual strategies alone [76,77].

The TMJ is not the only cartilaginous tissue of the craniofacial complex, and research into cartilage TE of the ear has also been investigated. In vitro expansion and seeding of harvested chondrocytes into degradable polymer scaffolds is capable of producing cartilage following implantation in immunocompromised and immunocompetent animal models [83], but the clinical experience has been somewhat disappointing with resorption of tissue-engineered auricular cartilage after several months [84]. However, to enhance the structural aspects of engineered cartilage and to increase the viability and maintenance of overlying tissue, Lee et al. seeded porous polyethylene implants with chondrocytes in fibrin gels [85]. These implants showed dimensional stability unlike previous auricular tissue-engineered constructs.

Although growth factors have received the most attention, positive biochemical stimulation is also likely to come from culture conditions and cellular interactions, as well as matrix modifying enzymes. An ascorbic acid concentration of 25 μg/mL has been shown to produce constructs with higher total collagen content and higher aggregate modulus relative to concentrations of 0 or 50 μg/mL [86]. This was likely associated with improved seeding observed for the constructs cultured in 25 μg/mL of ascorbic acid. In addition, a concentration of 100 μg/mL of glucosamine sulfate was found to enhance condylar cell proliferation and matrix production as a media supplement [75]. Metabolic supplements have also been shown to impact cell proliferation and matrix synthesis. L-Glutamine, sodium pyruvate, and insulin increased cell proliferation, while L-proline at high concentrations decreased matrix production [87]. Initial cell seeding is another important consideration in any TE construct due to cell-to-cell interactions and signaling. It has been shown that PGA scaffolds seeded at saturation increased cellularity and extracellular matrix (ECM) content relative to scaffolds seeded below saturation [88]. Matrix modifying enzymes, such as chondroitinase ABC and lysyl oxidase–like 2, also have beneficial effects on constructs. When combined with TGF-β_1, these agents increased tensile Young's modulus and ultimate tensile strength in neofibrocartilage by 245% and 186% compared to controls, correlating with picrosirius red staining [89].

The native TMJ disk undergoes significant compression, tension, and shear [90]. While cells proliferate and produce ECM in static culture, mechanical stimuli maybe required to produce an optimal tissue–engineered construct. A variety of mechanical stimuli maybe beneficial, including compression, tension, hydrostatic pressure, and fluid shear

stress. Two extensive reviews of the mechanical bioreactors that have been used in engineering cartilaginous tissues have been published on the subject [91,92].

Several studies have investigated the effects of mechanical stimulation on TMJ disk constructs. A low-shear fluid environment by means of a rotating wall bioreactor created constructs with dense matrix and cell composition [93]; however, when the biochemical content of these constructs was compared to those grown in static culture, no clear benefit of the bioreactor was observed. When disk cells were exposed to hydrostatic pressure in monolayer or PGA scaffolds, constant hydrostatic pressure at 10 MPa increased collagen production compared to static culture [94]. In contrast, intermittent hydrostatic pressure from 0 to 10 MPa at 1 Hz frequency was detrimental to the constructs, producing less collagen and GAGs than unloaded controls. These results were consistent in both two-dimensional and 3D culture. In another recent study, dynamic tensile strain significantly reduced interleukin-1β-induced upregulation of matrix metalloproteinase (MMP) [95]. This may have implications on future TE studies, since MMPs play an important role in ECM degradation and remodeling. In a study examining tension for articular cartilage engineering, continuous tensile stimulation−coupled bioactive stimuli resulted in neocartilage with tensile properties 5.8-fold higher than untreated controls [96]. Using costal chondrocytes, passive axial compression has also been studied for articular cartilage engineering and has shown to increase compressive relaxation modulus with bioactive treatments when compared to just bioactive factors [97]. Models for other tissues, such as articular cartilage, might serve to further inform mechanical stimuli for the TMJ.

Until recently, TMJ disk TE was limited to the benchtop, and there was a small quantity of successful in vivo studies, particularly using large animal models. A recent orthotopic, in vivo study in the Yucatan minipig showed successful regeneration of the TMJ disk using allogeneic tissue−engineered constructs [98]. Implants were surgically inserted into the TMJ disk via the novel intralaminar fenestration surgical technique. Compared to empty defect controls, construct implantation resulted in 3.4-, 3.2-, and 4.4-fold higher tensile Young's modulus, integration, and defect closure. The study also cited a limited immune response via immunohistochemical stainings for macrophages, T cells, and B cells. This study demonstrates feasibility of regenerating the TMJ disk using TE, and studies such as these will continue to propel the field toward translation of TMJ cartilage TE.

Oral mucosa applications

Oral mucosa regeneration has followed many of the strategies of skin TE, in that cultured epithelial sheets showed inadequate results due to fragility, contractility, and failure due to lack of underlying supporting tissue. Thus many approaches have considered the use of thick cultured grafts containing single or multiple cell types. An extensive review by Moharamzadeh et al. covers scaffold materials, cell sources, and culture medium [99]. Many of the same materials have been investigated for oral mucosal engineering as in bone and cartilage such as collagen, fibrin, gelatin, PLGA, and PCL. In addition, various cell sources have been used, primarily keratinocytes and fibroblasts either from oral or skin origins. Finally, growth factors such as epidermal growth factor have been employed to promote proliferation. In one study, fibroblasts and keratinocytes were cultured on a collagen composite scaffold [100]. The culture led not only to cell-specific markers for a full thickness mucosa but structural components, including a basement membrane and extracellular matrix. A similar study used gingival fibroblasts and keratinocytes harvested from patients on a clinically available collagen matrix, resulting in cell markers and tissue structures similar to mucosal tissue [101]. In vivo, mucosal grafts of collagen precultured with gingival fibroblasts and keratinocytes have maintained their phenotype as mucosal tissue after 60 days of implantation [102]. Approaches which culture autologous oral keratinocytes and fibroblasts on a "scaffold" of fibrin obtained from autologous plasma have also been reported [103].

Several groups have shown translation of a tissue-engineered mucosal graft. Creating a mucosal graft in vitro using canine cells cultured on AlloDerm, the group translated this technique by first using human cells in vitro [104,105]. Subsequently, in a 30-patient study comparing AlloDerm alone to AlloDerm precultured with autologous cells, the precultured grafts show enhanced wound healing with earlier vascularization and maturation of the submucosal layer at 28 days after grafting [106]. Tissue-engineered oral mucosal grafts for urethral reconstruction have also been evaluated in a multicenter, prospective observational trial where they were shown to be safe and efficient in urethroplasty [107]. Lastly, Schmitt et al. [108] showed in a prospective clinical trial that the collagen matrix Mucograft could be used to regenerate peri-implant mucosa with sufficient long-term stability comparable to autologous free gingival grafts.

In addition to oral mucosa, composite grafts for mucocutaneous junctions such as the lips have been explored. Peramo et al. present a novel approach to creating these junctions, where oral mucosal cells and skin cells are cultured on AlloDerm in vitro with a separation barrier [109]. This barrier is lifted and the cells are allowed to migrate into the junction space and interact. The cell construct was then lifted to air−liquid interface for maturation of the construct and characterized for morphology and immunohistochemical staining for keratin content.

Biochemical markers were consistent with spatial distribution in mucocutaneous tissues, illustrating the possibility of this strategy to be employed for TE lips.

Composite tissue applications

Success with the regeneration of single tissue types such as bone and cartilage has encouraged investigators to attempt the reconstruction of structures composed of multiple tissue types. Such anatomic structures may exist as composites of hard and soft tissues, which differs in their cellular composition and mechanical properties, yet perform as a single functional unit [110].

The TMJ condyle serves as an example of a maxillofacial composite structure consisting of articular cartilage and subchondral bone and provides an excellent opportunity for composite osteochondral TE. A study performed by Alhadlaq et al. [111] used adult bone marrow MSCs, expanded in culture and induced to differentiate into separate osteogenic and chondrogenic lineages in vitro. The resultant cells were then encapsulated in poly(ethylene glycol)-based hydrogels and the cell−polymer solutions cross-linked in a mold which provided the correct stratified organization of the osteogenic and chondrogenic layers. Finally, the osteochondral constructs were implanted into the dorsum of immunodeficient mice for up to 8 weeks. Histological and immunohistological analyses revealed both structural and immunohistochemical differences between the osteogenic and chondrogenic layers, which served as a primitive proof of concept of the potential for composite tissue−engineered constructs in the craniofacial region. In a similar study, trying to regenerate tissue within an osteochondral defect, a gradient scaffold releasing BMP-2 on the osteogenic side of the scaffold and TGF-β_1 on the chondrogenic side was fabricated [112]. This construct showed increased osteo- and chondrogenesis on the respective sides.

Animal models

As TE strategies become more sophisticated, the complex interactions between multiple cell populations, growth factors, and scaffold biomaterials require testing within clinically relevant in vivo healing environments. While computational models and in vitro testing provide proof-of-concept verification of a particular TE strategy, more challenging test beds using animal models are ultimately required, to allow discrimination of the healing potential of different biomaterial constructs [113].

The ideal model for testing the validity of tissue-engineered bone constructs is the *critical size defect* (CSD): namely, an intraosseous defect which will not heal by bone formation during the lifetime of the animal [114]. Several CSD models have been described in the literature, including the calvarial defect [23,48] and long bone segmental defect [115,116]. These models do not accurately describe the oral and maxillofacial environment, because they do not simulate the unique masticatory stresses and cell populations seen in mandibular or maxillary wound healing. Mandibular defects have been described in rats, but they have the disadvantages of poor surgical access and a tendency for implanted materials to fall into the fascial spaces [114]. Conversely, larger animals such as dogs [117], minipigs [118], goats [119], and nonhuman primates [120] offer the advantages of easy surgical access and the ability to create large defects but are expensive to maintain. As such, a critical size mandibular defect in a rabbit was developed. This 10 mm, cylindrical, bicortical defect in the New Zealand White rabbit has been shown to be nonhealing after 16 weeks (Fig. 65.6) [121,122]. In addition, this model was

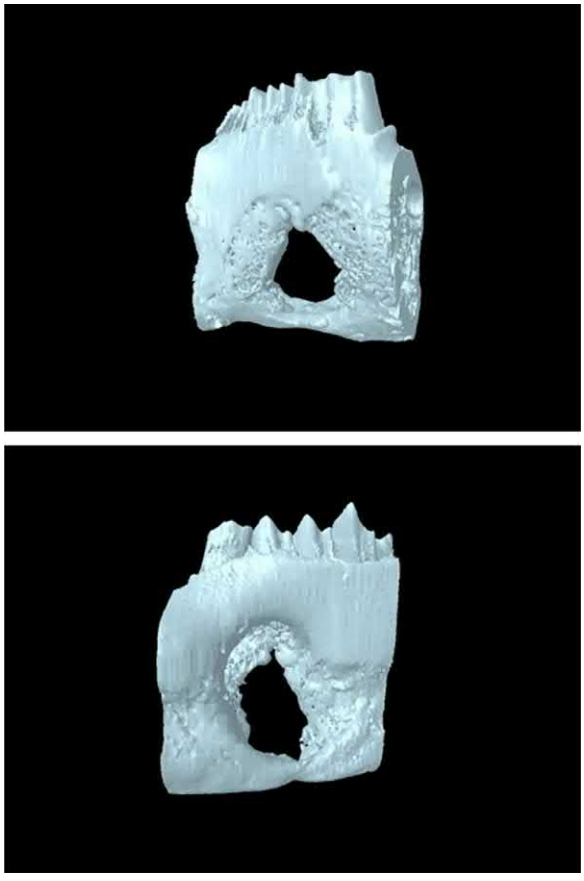

FIGURE 65.6 Micro-CT-generated representative three-dimensional reconstructions. Note the buccal aspect of the specimen is shown on the top, with the lingual aspect on the bottom. The critical size defect at 16 weeks shows a "through-and-though" defect and a lack of bony bridging across its center. *CT*, Computed tomography. *Reprinted from Young S, Bashoura AG, Borden T, Baggett LS, Jansen JA, Wong M, et al. expanded into a composite tissue defect model, whereby an overlying mucosal defect is created (Fig. 65.7) [58–60]. Composite tissue defect models represent an important direction for evaluation of tissue-engineered constructs. Defects resulting from trauma and resection of pathology frequently involve multiple tissue types and the combination of successful therapies for each individually may not suffice when both tissues need regeneration.

The future of oral and maxillofacial tissue engineering
