Abstract

This chapter explores current literature and initiatives in the field of integrated palliative care. The chapter starts with an exploration of the concept of integrated palliative care, followed by practice examples across Europe, models from the literature, and examples from guidelines. After this, barriers and opportunities for integrated palliative care are investigated. Finally, proceedings from the World Health Organization are highlighted to picture an international perspective. We conclude that integrated care has often been considered and discussed from the perspective of better integrated healthcare delivery, which is needed and valuable. But efforts for better integration of palliative care should move beyond a better organization of medical care and need to be rigorously designed from the perspective of the suffering patient in the last phase of life, and their families.

1 Introduction

Increasing numbers of people are living with, and dying from, advanced stages of cancer and chronic diseases. In the Western world, cancer is regarded as a most important disease, and many efforts are taken to improve survival. The burden of dying with cancer is greater in resource-poor regions of the world because more people are diagnosed late, with metastatic disease (Fadhil et al. 2017). Although a lot of research and attention was – and will be – invested in finding better treatments and strategies for these diseases, it is also clear that not every patient can be cured. Therefore, optimal care and efforts to improve the quality of a patient's remaining life are valuable. This is where palliative care comes to the fore. Although the demand and the need for palliative care are expected to increase in the coming years, many countries still struggle to deliver sufficient care for palliative patients and to ensure that palliative care is given adequate prominence in their health policies, health systems, and healthcare. The ideal is often that a very ill patient dies in a comfortable place, free of pain and other symptoms, surrounded by a caring and loving family. The inconvenient truth is that too many patients still experience hospital transfers in the last phase of life, suffer from pain and distressing symptoms, are surrounded by stressed and overburdened family members, and eventually die at a place that was not their initial preference.

The purpose of this chapter is to explore if and how better integration of palliative care can resolve or at least ameliorate these problems.

This chapter therefore starts with an exploration of integrated care based on a published definition and shows some clinical practice examples from a European project to illustrate the topic. Secondly, recent investigations in the field of integrated palliative care will be highlighted, revealing models and topics that may be relevant to better integrate palliative care. Thirdly, the state of the art of palliative care integration in professional guidelines will be explored. Fourthly, policy strategies will be introduced and the mapping of integrated palliative care will be discussed, including barriers and opportunities. Finally, next steps to progress integrated palliative care will be identified and discussed.

2 A Description of Integrated Palliative Care

Integrated care mostly focuses on giving the right care, at the right time, by the right caregiver. When translated into the field of palliative care, this involves questions like: "what is appropriate palliative care at a given moment in the trajectory of a patient with advanced illness?", "what is the right moment to start or enhance palliative care?", and "which informal and professional caregivers are involved at what moment and how do they interact?"

In the context of a European Commission-funded project on integrated supportive palliative care (http://www.insup-c.eu), a working definition for integrated palliative care has been agreed that reads as follows:

> Integrated palliative care involves bringing together administrative, organisational, clinical and service aspects in order to realise continuity of care between all actors involved in the care network of patients receiving palliative care. It aims to achieve quality of life and a well-supported dying process for the patient and the family in collaboration with all the caregivers, paid and unpaid. (Van der Eerden et al. 2014)

To investigate integration in the context of palliative care, the model proposed by Valentijn et al. (2013), originally developed for primary care, may be helpful. In its essence, the model distinguishes six elements of integration, namely, clinical integration, professional integration, organizational integration, system integration, functional integration, and normative integration. Furthermore, these elements of integration have a role at a microlevel, a mesolevel, and a macrolevel (Table 1).

When considering integrated palliative care, several of these elements resonate. Examples of *clinical integration*, with a focus on person-centered care, are improving a patient's quality of life and prevention and relief of suffering. But also the multidimensional investigation of physical, social, and spiritual problems in palliative care reflects an important element of clinical integration. The call for early applicable palliative care could be considered an example of *professional integration*, where professionals from several disciplines work together in a multidisciplinary team to provide timely palliative care. *Organizational integration*, referring to organizational relationships to deliver comprehensive services, could emerge in developing a support system to help patients and their families live as actively as possible, by arranging a package of social care, home care, and volunteering. *System integration* can refer to the financial healthcare structures that support or not support palliative care development, the presence of healthcare plans for

Table 1 Aspects of integrated care. (Based on Valentijn et al. 2013)

	Microlevel	Mesolevel	Macrolevel
Description of integrated care elements	*Clinical integration*: refers to the coordination of person-focused care in a single process across time, place, and discipline	*Professional integration*: refers to interprofessional partnerships (competences, roles, responsibilities) to deliver a comprehensive continuum of care to a defined population *Organizational integration*: refers to organizational relationships like contracting and strategic alliances, network, including governance mechanisms to deliver comprehensive services	*System integration*: refers to a tailor-made combination of structures, processes, and techniques to fit the needs of people and populations
	Normative integration (all levels): refers to a common frame of reference with shared values, culture, and goals to ensure coherency *Functional integration* (all levels): refers to supportive functions and activities (e.g., financial, management, and information) structured around the primary care process		

palliative care, but also the financial and medical sources and education available for palliative care at a country and at a regional level. Normative integration of palliative care can be traced back in the WHO definition when it is said that palliative care affirms life and regards dying as a normal process and intends neither to hasten nor postpone death. Finally, *functional* integration considers supportive functions and activities with a management, financial, and informational background, needed to align the work of care professionals. It is important for any palliative care service to have appropriate management, possibilities for (digital) information sharing, and financial resources to pay staff. As will be seen in the next paragraph, palliative care services sometimes struggle with this.

3 Five Examples of the Organization of Integrated Palliative Care Across Europe

In 2010, the European Association for Palliative Care (EAPC), in its white paper on standards and norms, introduced a graded system of palliative care services (Radbruch and Payne 2010). They make a distinction between a palliative care approach, general palliative care, and specialist palliative care. General palliative care is provided by all kinds of healthcare professionals like, for example, oncologists and geriatric specialists, whose primary focus is not palliative care but who have a profound knowledge and experience with death and dying in their practices. In addition, specialized services like palliative care units, inpatient hospices, or hospice at home teams are available for patients with complex palliative care needs, based on a multidisciplinary team approach. A palliative care approach requires, for example, that basic principles of palliative care are integrated in the education of physicians, nurses, and other related professions. Considering this theoretical model, it is of interest to see how palliative care is organized in practice, in particular what examples of integrated palliative care can be found.

Recently, a European project about integrated palliative care (InsupC) investigated 22 promising initiatives in 5 European countries, namely, the Netherlands, Hungary, Belgium, England, and Germany. The project has been described in a free e-book (Hasselaar and Payne 2016), where the below offered case descriptions can be found in more detail. Initiatives were eligible to be included when:

- The initiative was an established local palliative care collaboration.
- The collaboration contained at least two different organizations.
- A hospital could be part of that collaboration.
- Collaborating healthcare professionals provided direct patient care.
- The collaboration had a multidisciplinary background.
- The collaboration aimed to provide palliative care for one or more target groups (cancer/advanced COPD/chronic heart failure).

Integrated palliative care initiatives selected for participation in the InsupC study mainly involved hospital- or hospice-based services in conjunction with home care services. Although initiatives were selected based on accepting referrals of patients with cancer, COPD, and heart failure, the majority of included initiatives mainly treated patients with cancer. Table 2 and Fig. 1 show the InsupC research design and the

Table 2 Number of included patients in European InsupC study

	Belgium	Germany	Hungary	The Netherlands	UK	Total
Number of patients included	14	34	42	31	35	156
Cancer	*11*	*30*	*14*	*22*	*18*	*95*
CHF	*0*	*0*	*11*	*3*	*10*	*24*
COPD	*3*	*3*	*17*	*6*	*7*	*36*
Number of family caregivers included	14	9	30	22	13	88
Number of IPC initiatives included	3	4	5	5	5	22

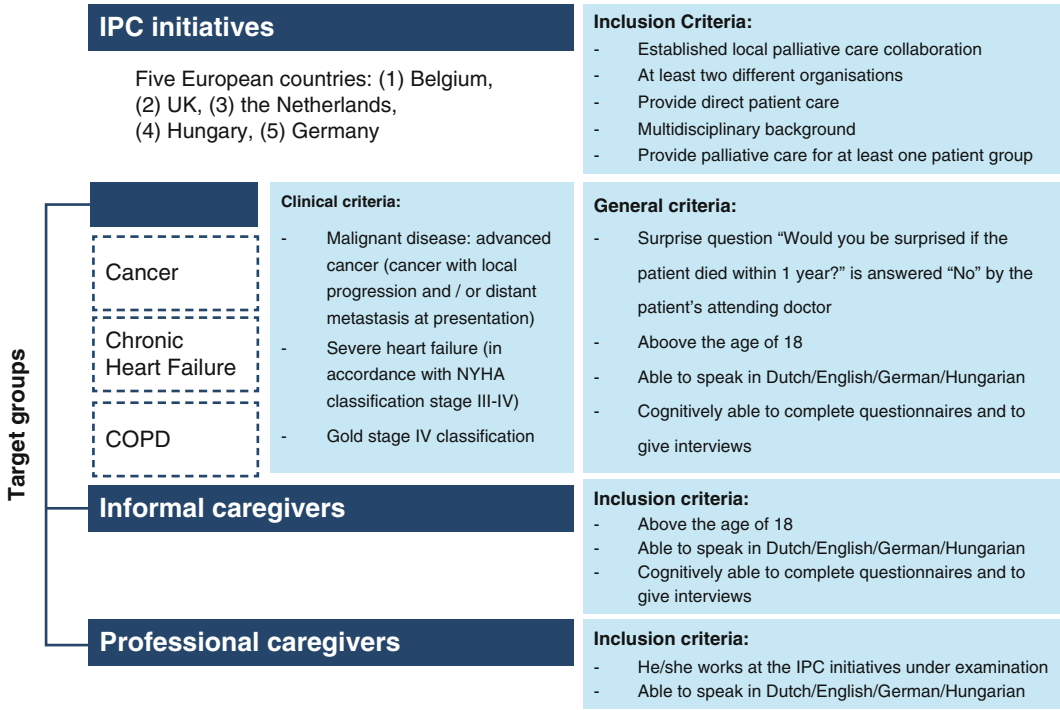

Fig. 1 Inclusion criteria for the InsupC study

inclusion of patients ($n = 156$) and informal caregivers ($n = 88$) within the InsupC project. Semi-structured interviews were performed with patients and with their informal caregivers. In addition, group interviews were held with professional caregivers at each initiative.

From all selected initiatives, five examples were further selected and described (Hasselaar and Payne 2016). Below, short descriptions of these five initiatives in five European countries are given in order to get a better understanding of integrated palliative care but also to see how inspiring initiatives work toward better integration.

3.1 A Palliative Care Pathway at Home in Belgium

In Belgium, a regional home care initiative called "White Yellow Cross" was investigated that has developed a care pathway to enable patients to stay at home until death. When a patient meets predefined palliative care criteria, the pathway becomes activated, nurses consult with the GP, and systematic pain and symptom monitoring is started. Specialist palliative care nurses act as case managers for the palliative patients. Strong relationships have been developed with the general practitioners and local hospitals in order to support patient transfers and to treat patients at home as well as possible. A specialist palliative care team (Pallion) is available when needed. This enables the initiative to offer family care and medical supplies alongside nursing care. Information is exchanged via an electronic system, including pain and symptom monitoring. After a patient has died, evaluation meetings among involved professional caregivers take place. Aftercare is part of the pathway, and once a year a memorial ceremony is organized to remember deceased patients. Improvement opportunities were identified including that palliative care is often limited to terminal care, that there are too few specialized nurses, and that electronic information exchange with hospitals is virtually nonexistent.

3.2 A One-Stop Integrated Palliative Care Facility in Germany

Germany offers an example of a one-stop integrated palliative care facility in Tübingen. The "Tübinger" project started in 1994 as a fundraising project and offers different options for palliative patients, like inpatient care, outpatient care, and palliative care in home settings. It has a specialized unit with ten beds served by a multidisciplinary team also including psychological and social support as well as art and music therapy. There is a specialized palliative home care team (SAPV team) consisting of physicians, a coordinator, and nurses, all trained in palliative care. This SAPV team also collaborates with two other regional hospitals, general practitioners, home care services, other professionals involved in palliative care, and pharmacies. The majority of referrals were initiated by general practitioners or self-referrals. About one third of admissions came from hospital. Upon referral, a first visit takes place, and, if the patient meets the inclusion criteria, a care plan will be developed. Although treatment at earlier stages of disease (early integration) is possible, this is often not compensated by health insurers. Charitable funding is still possible through the initial fundraising group, which enables the initiative to offer extra services, for example, a car for the home care team. In the "Tübinger" project, hospital and home care work closely together to offer palliative care, for example, palliative care professionals are often simultaneously employed. This enables a single point of reference and caregiver continuity for patients and family. Using a cloud-based system, information within the team is easily spread. The fact that the initiative had already existed for 25 years fostered acceptance of coordination and participation in local care networks. In three quarters of patients who preferred to die at home, their wish could be realized. Still, there is a predominance of advanced cancer patients; reimbursement can be cumbersome, in particular, when it comes to early integration; and continuity of care in transfers between hospital and home sometimes remains vulnerable.

3.3 Integrated Inpatient and Outpatient Palliative Care in Hungary

In Hungary, there is a general lack of well-trained care personnel in the field of palliative medicine and care. Inpatient hospice services are unevenly distributed across the country and concentrated in a few urban areas. Access to hospices is mostly limited to advanced cancer patients. A promising example of well-integrated palliative care can be found in Pécs, located in the South of Hungary. The clinical center of Pécs is one of the largest healthcare providers in Hungary and part of Pécs University. It hosts academic staff for research and education in palliative care together with a clinical consultation team (started 2013), an outpatient clinic (started 2012), and inpatient beds on the oncology ward (started 2016). There are close connections with the hospice (inpatient and at home; founded in 2004), partly sharing the same employees. Altogether, the palliative care network includes palliative care consultants, general practitioners, nurses, physiotherapy, psychology, and social work. The problems reported were lack of qualified staff, mainly physicians and nurses with many professionals only part-time working in palliative care. Furthermore, there is lack of funding and understanding of services, leading to late and limited use of hospice care. Currently, IT systems for patient documentation are fragmented, hampering transfer of information.

3.4 A Network Approach in the Netherlands

The Netherlands has a geographical coverage of regional networks for palliative care established in the early 2000s. The exemplary initiative involves a network connecting advanced cancer care in primary and secondary care in Schiedam (close to Rotterdam). The initiative started from a regional hospital with the goal to provide continuity of palliative care for patients with cancer, regardless of where they are. As patients often moved between care settings, a network was needed to connect these care settings and to

optimize collaboration. Therefore, the oncology unit started weekly multidisciplinary meetings as a part of the regional palliative care network "Nieuwe Waterweg Noord," covering four medium-sized towns. This network is supported by the comprehensive cancer center in Rotterdam. What makes this initiative exemplary is the way they succeed to create a seamless web of care around a single patient in need of palliative care and his/her family.

The multidisciplinary meetings consist of the hospital staff, a nursing home physician also palliative care consultant, a network coordinator also representing home care and palliative care units, and general practitioners by invitation. Caregivers however stay employed at their own organizations. Collaborations have been built with other care providers like mental healthcare, general practitioners, family care support, home care, volunteers. Every participant can list patients to the meeting and inpatients as well as outpatients can be discussed. Workplans are written after each meeting and spread to involved caregivers. Altogether the initiative succeeds in connecting primary and secondary care within a well-functioning regional network, not at least due to the presence of a coordinating nurse as a linchpin function. The network would benefit from better involvement of general practitioners, for example, in attending the weekly meetings, and better electronic information exchange like video conferencing or transmural electronic patient records. Finally the daily running of the network depends on a few highly committed professionals and is mainly dedicated to advanced cancer patients.

3.5 A Hospice Without Walls in England

One final example concerns a hospice at home in a rural area in West Cumbria, in the North of England. This initiative was established in 1987 when there was a need for specialist palliative care, but funds were lacking to establish a hospice building. Alternatively, an approach was chosen where patients were supported at their usual place of care, regardless whether this is their home, a hospital, or a nursing home. This service works alongside the National Health Service (NHS) in a "service level agreement" and delivers services from a town center building. It accepts referrals from patients with all life-limiting diseases, like cancer, COPD, and chronic heart failure. It receives one quarter of its funding from the NHS and the rest through public donations. It offers home nursing, a lymphedema service, family and bereavement support provided by trained volunteers, one-to-one support, and complementary therapies. There is no inpatient unit, but the service collaborates with local community hospitals, nursing homes, social work, and NHS-funded general practitioners and palliative care nurse specialists. There is an important place for volunteers in a variety of roles, from administrative tasks to massage therapy and bereavement support. Collaborations are built via weekly multidisciplinary meetings, one meeting covers current patients receiving care, and one meeting covers patients with complex palliative care needs. Due to the rural area, caregivers work in rather small teams, and emphasis is put on well-developed interprofessional relationships. Improvement opportunities involve an electronic system for information sharing which is planned, funding is uncertain and highly dependent on local donations, due to rural location staff can be difficult to recruit, and there is still a challenge to integrate healthcare and social care.

3.6 Patient and Informal Carer Interviews

In the analysis of the InsupC patient and family caregiver interviews, it was considered how relational, informational, and management continuity were considered important aspects of *functional integration* (Den Herder-van der Eerden et al. 2017). Experiencing close relationships with their palliative caregivers was considered important in all countries, in particular, that professionals were not only interested in the disease progress but also considered the patient as a person. Although general practitioners were generally considered important actors in the network of

the patient, some complaints were made about a lack of GP involvement. For patients in the last phase of life, not only continuity of care but also continuity of carer is important. Retelling their stories to different professional caregivers was therefore considered frustrating and decreased trust. However it appeared that information continuity became very vulnerable when healthcare providers didn't share and transfer information well. Management continuity became blurred when healthcare professionals worked in a fragmented fashion and lost sight at the patient as a whole person. In the study this was often related to hospital settings or hospital-home transfers. Collaborative team approaches were considered pivotal to facilitate relational, informational, and management continuity.

3.7 Current Challenges

It is of interest to see that across European countries, initiatives increasingly start to pay attention to the integration of their services in the local and national healthcare system. This often results in the building of networks between regional healthcare providers. Palliative care teams frequently exist of professionals of several organizations who work together in a multidisciplinary setting. It also happens that palliative care professionals have a labor contract in several organizations, for example, working as a GP and working in a hospice at home environment or working as a medical specialist in a hospital and in a palliative care consultation team. In particular connections between primary and secondary care are sought after but also are experienced as a challenge. This is partly due to the fact that electronic sharing of information outside the specialized palliative care team is mostly lacking, for example, an electronic patient record that can be shared between professionals from different organizations. Paper documentation and informal communication channels like mobile phones are often used but limit a structural and systematic approach to information exchange and joint action.

An important observation is that integration of palliative care earlier in the disease trajectory and beyond cancer is often not well supported by current healthcare culture and policies and difficult to implement. For example, reimbursement is often directed at terminal care with an expected life expectancy of less than 6 months, patient referrals come in late, advance palliative care planning may therefore be difficult, and services are mostly originating from (and still highly linked to) advanced cancer care.

Despite these challenges, interesting developments are currently ongoing. Inpatient palliative care providers recognize the value of integration and facilitate regional palliative care networks, connecting a diversity of service providers that deliver generalist palliative care. And at the same time, there seems a wider recognition that specialized palliative care should become available where the patient is, including his/her home. The UK hospice at home, for example, although partly born out of a lack of budget to build a hospice, proved to be very supportive in treating patients at home. The Dutch developed a network approach to support this, the Belgians have a primary care pathway, the Germans developed a one-stop shop, and in Hungary they established a hospice at home connected to a hospital consultation team. However, the long-term success of these initiatives requires that collaborations and reimbursement structures in primary care are supportive to palliative care, which is not always the case, for example, when indication and reimbursement for patients are limited to end-of-life care in the last months. Vulnerability exists where initiatives hinge upon the involvement and drive of a few dedicated professional care professionals but may be overcome when federal regulations support the building of teams. In the end, integration also should define roles and make space for generalist as well as specialist palliative care.

4 A Synthesis of Five Models of Palliative Care Integration

In an example of professional integration, the WHO definition states that palliative care "is applicable early in the course of illness, in

conjunction with other therapies that are intended to prolong life." In previous years, an increasing number of papers have been published showing the positive effects of this "early palliative care integration" with efforts to identify and assess patients earlier in the disease trajectory. In addition, end-of-life care pathways have been developed and investigated together with primary care initiatives. In this section, some recent developments from the literature will be shown.

4.1 Early Integration in a Hospital Setting

One important example of clinical integration in a hospital setting is early integration, which has been increasingly investigated after a landmark RCT study by Temel et al. (2010), showing that newly diagnosed metastatic non-small cell lung cancer patients assigned to an early palliative care visit had a better quality of life and less depressed mood after 12 weeks. In addition they used less aggressive care and reported a longer survival, compared to those receiving normal US oncology treatment. A secondary qualitative analysis of the medical records of 20 patients revealed that key elements of the early ambulatory palliative care visits (compared to standard oncology visits) included addressing of symptoms and coping with relatively more attention to psychosocial care. Furthermore, building of relationships, better illness understanding, and prognostic awareness were important ingredients of these visits (Yoong et al. 2013).

In 2014, Zimmermann et al. published a cluster RCT involving 461 advanced cancer patients with a limited prognosis (6–24 months) in 24 medical oncology clinics, investigating palliative care team involvement at least once a month. Although the primary outcome of quality of life at 3 months did not statistically improve in the intervention group, it did improve at 4 months, which was considered a promising finding. Studies like these (for example Bakitas et al. 2015) will probably be more in-depth discussed in another chapter of this book, but for this chapter it is interesting to consider the possible working mechanism for early integration from the perspective of the so-called CMO approach based on *context*, *mechanism*, and *outcome* (Busetto et al. 2017). Based on the aforementioned literature exploration, it can be illustrated how the CMO approach can apply to early palliative care (Fig. 2).

Early integration in a hospital setting is often achieved by means of outpatient palliative care consultation, directed toward advanced cancer patients. In this setting, promising results have been achieved in terms of better quality of life, less depressed mood, less aggressive care, and in some studies even improved survival. Studies in this field are ongoing, and the results increasingly find their way to practice.

Based on the emerging evidence for the early integration of palliative care in oncology, the American Society of Clinical Oncology (ASCO), in a recent update (Ferrell et al. 2017:120), formulated as a key recommendation that: *"•Patients with advanced cancer, inpatients and outpatients, should receive dedicated palliative care services early in the disease course and concurrent with*

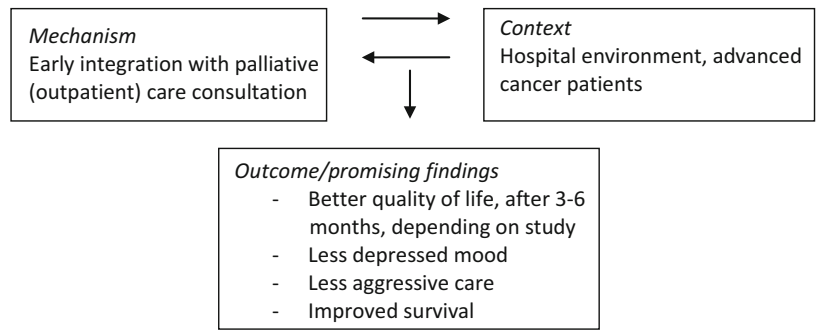

Fig. 2 Context, mechanism, and outcome for the early integration of palliative care

active treatment. Referring patients to interdisciplinary palliative care teams is optimal, and services may complement existing programs. Providers may refer caregivers of patients with early or advanced cancer to palliative care services."

4.2 Integrated End-of-Life Care in Hospitals: The Amber Care Bundle

Amber stands for assessment, management, best practice, engagement, and uncertain recovery. The Amber care bundle is focused on hospital patients whose recovery is uncertain and who are at the risk of dying the next 1–2 months (see www.ambercarebundle.org). It offers a systematic approach to help staff to realize when to start talking with patients and family members about the treatment and the care they prefer when their disease progresses. It combines identification questions, four clinical interventions, and monitoring of patients.

A recent qualitative study among 20 healthcare professionals based at 3 tertiary NHS hospitals in London investigated its potential use in labeling of patients, changing care delivery, and influencing the behavior of involved individuals and teams (Bristowe et al. 2018). Adequate exposure, training, and implementation were considered important preconditions for success. In another study from this group, patients ($n = 19$) were interviewed, and a survey was performed. It was shown that patients with the Amber care bundle had an effect of increased conversation about prognosis between professionals and patients, although the information received seemed not always easy for patients to understand (Bristowe et al. 2015). A retrospective chart review among 149 patients in 5 hospital wards showed that the Amber care bundle is more often applied in cancer patients and that patients received the Amber care bundle on average 10 days after admission, for a median period of 9 days (Carey et al. 2015). Despite positive initial experiences, more rigorous research is required to establish its efficacy in larger samples (see also Currow and Higginson 2013).

4.3 Integrated End-of-Life Care Pathways

A much debated example of an attempt to integrate palliative care in the last days of life, not limited to cancer patients, is the multidisciplinary care pathway for the dying. Although some positive evaluations have been available (Veerbeek et al. 2008), evidence underlying such pathways has been considered limited (Chan et al. 2016). Recently however, a large cluster randomized trial in acute geriatric wards in ten Flemish hospitals was published. Hospitals were randomly assigned to the CAREful intervention, a "care guide for the last days of life, training, supportive documentation, and an implementation guide" (Beernaert et al. 2017). Positive outcomes were found for nurse-assessed comfort of the dying, but not for family-assessed comfort of the dying or symptom improvement.

This is a promising conclusion in the light that a few years earlier, a well-known care pathway for the dying, namely, the Liverpool Care Pathway (LCP), became heavily criticized. One important conclusion from an independent review in 2013 reads that the Liverpool pathway seemed to work well in settings where it was operated by well-trained, well-resourced, and sensitive clinical teams. But when used without much attention, as a tick box exercise, it runs the risk of not showing enough respect to patients (Neuberger 2013). Due to the political concerns raised, the Liverpool Care Pathway became phased out in England. In other places however where the experiences were more positive, like the Netherlands and Flanders, care pathways for the dying are still being implemented. However, the aforementioned experience shows that care pathways should not only be studied in an experimental setting but require a well-thought implementation trajectory before large-scale introduction takes place.

4.4 Integrated Palliative Care for Non-cancer Patients

The aforementioned approaches of integrated palliative care focused on a hospital environment,

mostly related to cancer. Another approach however was taken by Higginson et al. (2014) who studied the effect of a breathlessness service integrating palliative care, respiratory medicine, physiotherapy, and occupational therapy. In a single blinded randomized trial, the service improved breathlessness mastery (the primary outcome) together with survival after 6 months in the intervention group.

In addition, this group also investigated the integration of palliative care as a complementary service for multiple sclerosis treatment in a randomized phase II trial (Higginson et al. 2009). They found lower mean service costs in the first 12 weeks of follow-up. In a related paper, they also reported an improvement in five key symptoms, although the main outcome measures "palliative outcome scale" (POS) and "the multiple sclerosis impact scale" remained unchanged (Edmonds et al. 2010). The experiments give rise to further thinking about the integration of palliative care and home care.

Bone et al. (2016) developed a model of short-term integrated palliative and supportive care for frail older people in community settings, based on the perspectives of older people, carers, and other stakeholders. Their model is designed for people with nonmalignant conditions living at home. The model involves ongoing general practitioner and community nursing team support and integrated working with specialist palliative care services, for example, visits, holistic assessment, single point of contact for general practitioner, and skilled workers for patient/carers. Potential benefits, according to the respondents, involve improved symptom management, improved carer well-being, and reduced hospital admission. This model however needs more empirical research.

4.5 Gold Standard Framework (GSF) in UK Primary Care

The UK Gold Standard Framework, originally developed to improve palliative care in primary care, became an important driver to integrate palliative care in the community setting as well (Clifford et al. 2016). The GSF is considered a quality improvement program with the aim to enhance proactive care at the end of life. It uses a three-step approach based on early identification, better assessment of clinical and personal needs, and focused planning and coordination. Goals are to improve quality of care, to improve coordination of involved care teams, and to reduce hospitalization. Patients considered to be in the last year of life are identified and registered in a GP-based palliative care register in order to improve care coordination. A survey among 6495 primary care practices in the UK showed that GSF uptake was achieved in about 60% of practices (Hughes et al. 2010).

Notwithstanding this, a primary care audit in 2009 showed that of all dying patients in the investigated 502 primary care practices, only 27% were identified in an end-of-life care register, suggesting a significant space for improvement. However, the identified patients seem to have received better end-of-life care (Omega report 2009). Besides, a finding of limited identification but better outcomes in identified patients was also reflected in a Dutch primary care study (Thoonsen et al. 2015). Lessons learned from the GSF program were formulated as follows (Clifford et al. 2016):

- Although many primary care practices reported using the foundation level of GSF, the uptake was still patchy and variable. A new accreditation program for GSF may stimulate better implementation.
- It is considered important that the GSF does not replace local practices and initiatives. There is no "one size fits all," and local primary care practices are stimulated to develop at their own pace, and the overarching framework needs to give opportunities for this.
- Local champions are important together with whole team commitment. Despite busy practices, it is possible to implement the GSF and to improve end-of-life care, not only for cancer patients but also for other target groups like frail elderly people.

The underlying principles of GSF have been adopted in other initiatives like PaTz (Palliatieve Thuiszorg) in the Netherlands. This initiative

attracted national attention and is increasingly implemented in home care (van der Plas et al. 2014). In 2016, almost 100 groups were reported all over the Netherlands. Altogether initiatives like the Gold Standard Framework seem a promising way to integrate palliative care in primary care, although the actual percentage of identified palliative patients in GP practices seems still limited.

4.6 Synthesis

Examples I–III (early integration, Amber care bundle, care pathways) mostly address a micro-level where clinical integration is aimed for in a specific setting. The described examples for non-cancer (example IV) however are more related toward the community, connecting a variety of disciplines like physiotherapy and occupational care. The Gold Standard Framework is a program based in primary care but also has the ability to unite key players involved in the care at home, as happens in the Dutch PaTz project. These models (non-cancer models; GSF) move beyond a clinical perspective and also approach integration from an organizational (meso)perspective, even with elements of a macro – program-based – perspective.

Benefits of integrated palliative care have been shown in cancer care, but there is less evidence of initiatives in other conditions (Siouta et al. 2016a). There is increasing evidence of early integration in hospital-based cancer care. However, integration of palliative care across different sites and settings is much less well developed and may vary by country. In the UK, for example, the Liverpool Care Pathway, one of end-of-life care pathways, was heavily criticized for its poor implementation and has now been discontinued (DoH 2013). However there may be beneficial aspects of structured care pathways as were shown in a rigorous evaluation in Flanders in geriatric care (Beernaert et al. 2017). The Amber care bundle has demonstrated initial promising outcomes and is currently the focus of a large clinical trial. There is accumulating clinical trial evidence on the benefits of structured integrated care in palliative care for those with breathlessness and MLS (Higginson et al. 2009, 2014), but not much research has been done in this area. So far, the Gold Standard Framework seems the most widely implemented initiative in primary care and in nursing homes, although its evidence base and application is rather limited to the UK and needs further rigorous research.

To conclude Siouta et al. (2016b) searched the literature to investigate the evidence from empirical models of integrated palliative care. They recommended the following elements for a successful integration of palliative care:

- Focus of intervention: The focus of intervention will be placed on symptom treatment, consulting of patients/family and training of the personnel.
- Setting: The design of the framework is such that it can be applied to every care setting.
- Timing of intervention: The intervention can be initiated throughout the disease trajectory either concurrently or in the end of life.
- Composition of team: The framework requires a multidisciplinary team with members that are trained in the delivery of PC. This team can consist of GPs, physician specialists, nurses and specialist nurses, psychologists, social workers, and administrative assistants.
- Collaboration strategy: The collaboration strategy, which refers to the ways that the represented disciplines cooperate and assess emerging issues, should be based on the involvement of the multidisciplinary team and its meetings and the utilization of protocols.

The next section will consider the integration of palliative care within professional guidelines more in-depth.

5 Palliative Care Integration: Lessons Learned from Five Professional Guidelines

Van Beek et al. (2016) investigated the integration of palliative care in 60 cancer guidelines and 14 pathways, originating from 6 languages. Relevant

items were categorized using 11 criteria for integrating palliative care in guidelines as proposed by Emanuel et al. (2004). They found that four out of five cancer guidelines advocated a multidimensional assessment and about three out of five mentioned palliative care interventions to reduce suffering and the involvement of a palliative care team. In less than half of the cases, cancer guidelines paid attention to care during the last hours, to advance care planning, to bereavement care, and to (referral) criteria for palliative care involvement. Based on an assessment of five good examples, van Beek et al. made recommendations for integrated care criteria in guidelines (Table 3). However, they also admit that implementation of these criteria in current guidelines can be cumbersome.

Considering the integration of palliative care in guidelines for heart failure (HF) and chronic obstructive pulmonary disease (COPD), a review has been carried out by Siouta et al. (2016a). They investigated European guidelines published between 1995 and 2013 and included 17 guidelines and 2 pathways in their review. Applying the Emmanuel criteria as mentioned above, they concluded that almost all documents addressed suffering reducing interventions, and most (15/19) paid attention to illness prognosis and limitations. About two third of guidelines/pathways mentioned a holistic approach, a palliative care involvement, assessment of the patients' goals of care, and advance care planning. Only few texts included grief and bereavement. The authors conclude that there is a growing awareness but that many areas still need improvement. Although there is no space to discuss all guidelines related to palliative care in non-cancer, it is worthwhile to mention that palliative care in dementia is also emerging, for example in a recent white paper (van der Steen et al. 2014). The Delphi procedure underlying this white paper mentioned the following domains of importance: person-centered care, communication, and shared decision-making, optimal treatment of symptoms and providing comfort, setting care goals and advance planning, continuity of care, psychosocial and spiritual support, family care and involvement, education of the healthcare team, societal and ethical issues, and prognostication and timely recognition of dying. Quite a few recommendations reflect the abovementioned Emmanuel criteria for integrated palliative care. Despite promising examples on the horizon however, a lot of work still needs to be done to fully integrate palliative care into disease guidelines.

6 Five Policy Strategies and Their Value for Integrated Palliative Care

In this section, some current attempts and proposals to map the development of integrated palliative care will be briefly discussed. One approach clarifies barriers and opportunities for integrated palliative care and will be discussed more in detail because this will demonstrate the current state of the art of integration of palliative care. The section closes with a description of WHO strategies about integrated care.

6.1 Indicators for Integrated Palliative Care

Hui et al. (2015), in collaboration with the European Society for Medical Oncology (ESMO), conducted a Delphi survey to establish indicators for the integration of oncology and palliative care programs in hospitals with more than 100 beds. After 3 rounds, they identified a list of 13 major indicators among which:

- Presence of an inpatient consultation team
- Presence of an outpatient palliative care clinic
- Presence of an interdisciplinary palliative care team
- Place of death consistent with patient preference
- Combined palliative care and oncology educational activities

A reply from Verna et al. (2016) however pointed to the necessity of not only drawing program criteria for big hospitals but also to develop sustainable indicators for integrated –

Table 3 Emmanuel criteria for integrated palliative care based on five good examples

Criterion	Recommendations based on cancer guidelines
1. Discussion of illness limitations and prognosis	The guidelines/pathways agree that this can be realized through open and honest communication with patient and family, based on their needs and preferences, and enabling shared decision-making. One pathway also suggests the employment of the surprise question or the Palliative Performance Scale can be used as triggers for initiating such discussions
2. Recommendations for conducting a whole patient assessment including the patient's physical, social, psychological, and spiritual issues, their family, and community setting	There is a unanimous consensus on the utilization of a combined physical, psychological, social, and spiritual assessment
3. Recommendations for when to make these assessments (e.g., at baseline and periodically thereafter)	Assessment should take place early in the disease trajectory. Further, it is recommended that holistic assessment should occur "at any time of day or night" for physical and psychological support and as long as possible for patient's social participation. Also, its realization should vary depending on changes in the disease or on the appearance of new symptoms and based on application of, e.g., a "distress thermometer"
4. Recommendations on when palliative care should be integrated	Three strategies are identified: (i) the use of the surprise question, (ii) the evaluation of the patient's and the family's needs, and (iii) illness stage – disease-/cancer-related prognostic indicators (e.g., like the indicators mentioned in the Gold Standard Framework)
5. Assessment of the patient's goals for care	All the guidelines/pathways agree that this assessment should be based on the continuous communication between the patient and the PC specialists to identify patient goals
6. Continuous goal adjustment as the illness and the person's disease progresses	It is suggested that PC specialists regularly consult the patient and adjust goals accordingly
7. Palliative care interventions to reduce suffering as needed	The guidelines/pathways elaborate on the use of appropriate medication and strategies aimed in reducing both physical and psychological suffering
8. Advance care planning	Decision-making should be based on patient's wishes and preferences. One pathway proposes the identification of the ACP via the use of three models (covenant model, contract model, or DNR code)
9. Recommendation of involving a palliative care team (interdisciplinary team, palliative care consultation, or other palliative care services)	All of the guidelines/pathways strongly recommend the involvement or formation of a multidisciplinary PC team (consisting of physicians, nurses and other health professionals, psychologists, mental health counselors, social workers, spiritual counselors)
10. Recommendations on care during the last hours of living	The following steps are recommended: identification of the dying phase, communication, support based on patients and family's needs and wishes, and symptom control
11. Recommendations on grief and bereavement care	The main proposed strategy involves the immediate and ongoing bereavement, emotional and spiritual support appropriate to the family's needs and preferences

Based on Van Beek et al. (2016). Incorporated guidelines: Ayestáran MA. 2008. Guía de práctica clínical sobre cuidados paliativos Clinical practice guidelines on palliative care (Spain); Muszbek K. 2013. Practice and opportunities of the Hungarian hospice care provided at home. (Hungary); Van den Eynden B et al. 2012. Zorgpad palliatieve zorg eerstelijn Vlaanderen (Belgium); Royal College of General Practitioners and Royal College of Nursing. 2012. Matters of life and death: helping people to live well until they die. General practice guidance for implementing the RCGP/RCN end of life care patient charter; National Institute for Health and Care Excellence. 2011. CMG42 End of life care for adults

community-based – palliative care, in particular in countries who have less resources for implementation. This is also reflected in the report of a German working group that reported best practice recommendations for the integration of palliative care and oncology (Berendt et al. 2016). After three rounds, high agreement was reached for having an organizationally and spatially independent palliative care unit ($\geq$6 beds), a mobile multiprofessional specialized palliative

care team, and cooperation with community-based palliative care.

In 2016, Ewert et al. published a taxonomy for integrated palliative care initiatives, based on a consensus meeting with expert, including the following categories:

- Background of disease
- Type of initiative (pathway, model, guideline)
- Sector (inpatient, home care)
- Time frame of intervention (early integration, concurrent, end-of-life care)
- Coordination strategy (network, protocol, team, case manager)
- Primary contact point (palliative care, team, other)

This taxonomy is designed as a tool to identify and describe integrated palliative care, rather than to measure it. It offers insight in the various ways integration of palliative care can take shape but is not restricted to hospital care.

This short investigation shows that indicators to describe palliative care integration have been developed but not widely implemented. More work is needed in this field.

6.2 Barriers and Opportunities for Palliative Care Integration

An investigation from a public health perspective has been performed by Centeno et al. (2017) who used the EAPC Atlas to draft a picture of palliative care integration in Europe. The EAPC Atlas is based on the views of national palliative care associations in Europe about the current state and development of palliative care in their countries. These perspectives are presented in graphics to illustrate palliative care development across Europe and other parts of the world. Drawing from the palliative care Atlas database, it was considered which indicators – through the eyes of European national associations – were barriers and opportunities to the further development of integrated palliative care. The following figure shows the barriers identified (Fig. 3).

It is of interest to see that one third of the identified barriers fall within the policy dimension, about regional regulation and coordination. The integration of palliative care within non-cancer that appeared an important issue in the aforementioned analysis of promising examples is also listed here. Secondly, the most frequently mentioned barriers concerned the lack of basic training in palliative care in courses and curricula, followed by limited options for formal certification or subspecialization within the field of palliative care and medicine. A third group of barriers was related to the integration of palliative care services like human resources, coordination of services, and maturity of the discipline including the availability of multidisciplinary care.

Interestingly (Fig. 4), many of the aforementioned barriers are also considered opportunities, for example, the expansion of basic training for palliative care and the inclusion of palliative care at universities. Expert training and certification are also considered major opportunities. In the field of policy-making, the regulatory framework has been mentioned by many experts. This refers, for example, to changes in the law favoring palliative care and the development of palliative care strategies and programs. In the context of the previous analysis of inspiring practices, changes in policy strategy like, for example, restricted palliative care reimbursement for advanced cancer may be a solution for better integration toward non-cancer and integration earlier in the disease trajectory. This may also have a positive influence on service development like business plans and resources and the integration of palliative care in professional guidelines which was also discussed earlier in this chapter. Remarkably, research is also mentioned as an opportunity, in particular, by Belgium, Iceland, and the UK. In their study, Centeno et al. (2017) also pointed out that countries with more mature palliative care service availability more often report barriers and opportunities in the area of integrated palliative care, probably related to increasing expectations of palliative care development. Contrary, in countries with less palliative care development, basic palliative care provision seems to be the highest concern.

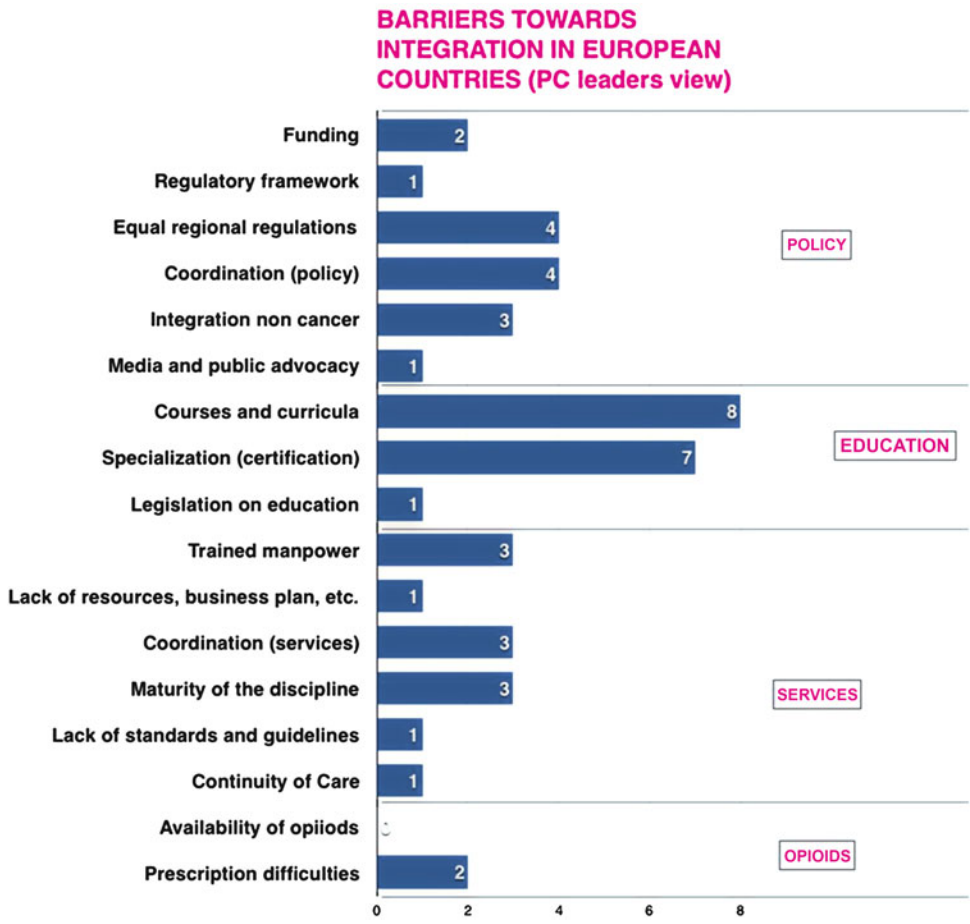

Fig. 3 Barriers toward integration of palliative care in European countries. Figure developed by the Atlantes group, Navarra, Spain (Prof. Centeno, published with permission). The European palliative care atlas is based on the WHO European region involving 53 countries whose national palliative associations nominated an expert to answer the Atlas questionnaire. In this figure only answers to specific questions about palliative care integration are listed

6.3 Policy Initiatives from the World Health Organization

In 2016, the World Health Organization (2016) launched a new framework on integrated people-centered health services based on a vision that all people have equal access to quality health services in a way that meets their life course needs. According to the WHO, integrated care involves five strategies which can be described as follows:

1. *Engaging and empowering people and communities.* Patients and families need to be active participants in care that is delivered in an equal and reciprocal relationship, in order to achieve better clinical outcomes. It is also about communities to organize themselves and to make changes in living environments, in particular, toward the underserved, and to provide place and training for informal care.
2. *Strengthening governance and accountability.* This involves involvement in policy formulation and decision-making but also evaluation and societal accountability. Enhancing welfare requires a stewardship role for governments and participatory involvement of communities.
3. *Reorienting the model of care.* This involves a reorientation toward life course needs of

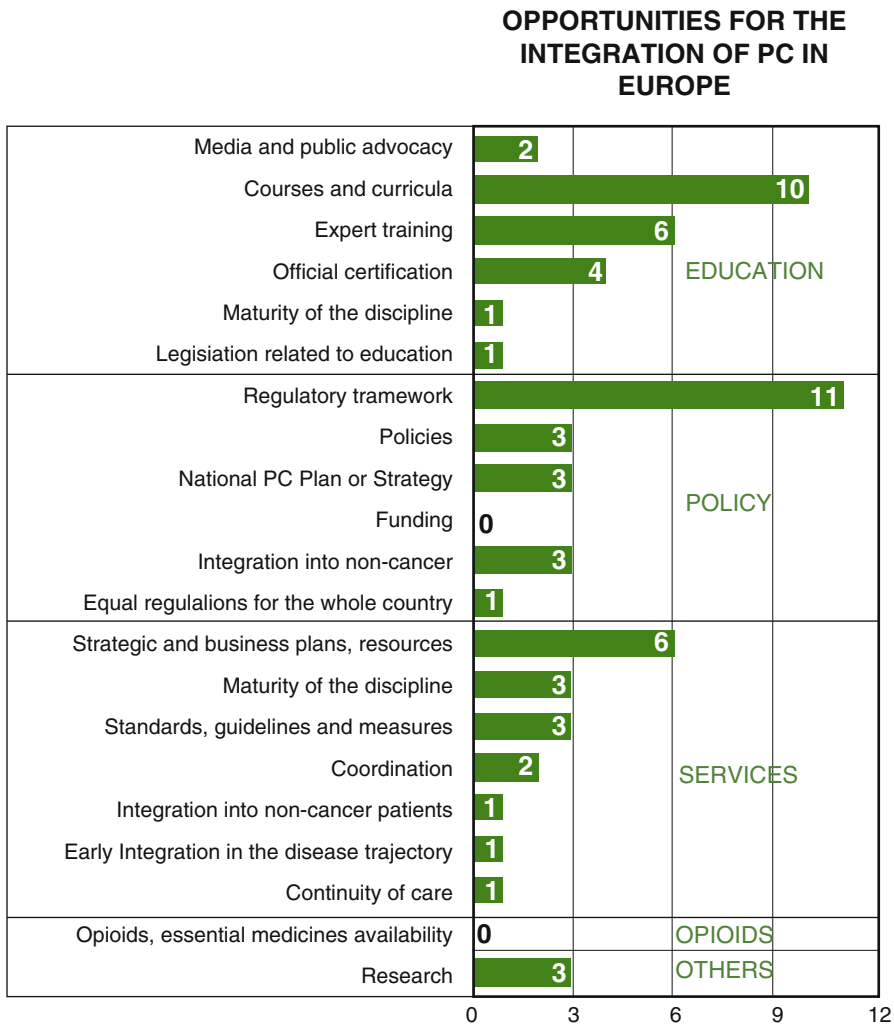

Fig. 4 Opportunities for the integration of palliative care in Europe. Figure developed by the Atlantes group, Navarra, Spain. (Prof. Centeno, published with permission). The European palliative care atlas is based on the WHO European region involving 53 countries whose national palliative care associations nominated an expert to answer the Atlas questionnaire. In this figure only answers to specific questions about palliative care integration are listed

populations. Furthermore a shift from inpatient care to outpatient and ambulatory care, based on a publicly available primary care to reach the entire population. It calls for multiprofessional teams and family- and community-oriented care models where modern technologies and mHealths are embedded.

4. *Coordinating services within and across sectors.* Services should be organized around the needs and demands of people. This requires integration across health settings. It involves intersectoral alignment and harmonizing of processes and information, not necessarily the merging of institutions. It is centered around care for individuals but also coordination of health programs and providers to bridge administrative, informational, and funding gaps. Finally, it involves multiple sectors like healthcare, social care, labor, and housing.
5. *Creating an enabling environment.* In order to make transformation happen, the involved stakeholders need to be brought together

which requires collaborative leadership where improvements in information and knowledge development, regulatory frameworks, and funding incentives take place.

Although it would be interesting to examine to what extent (inter)national palliative care plans and programs use these five strategies, this chapter can only briefly examine one initiative, namely, the WHO resolution on palliative care.

6.4 The WHO Resolution on Palliative Care

In 2014, the World Health Assembly approved a resolution called "strengthening of palliative care as a component of comprehensive care throughout the life course" aiming to integrate palliative care policies in healthcare systems and healthcare education. Soon after this agreement, a Technical Advisory Group for palliative care was installed. In 2017, an accompanying book was released by the Technical Advisory Group in 2017, emphasizing that palliative care should be implemented as a comprehensive and integral part of the care for patients with advanced and life-limiting diseases. Short- and long-term actions have been formulated, among which the involvement of health ministries at a country level, WHO agencies, policies for resource-poor countries, ethics, the relation toward complex and chronic care, a community perspective, and leadership empowerment (Gómez-Battiste and Connor 2017). WHO demonstration projects for palliative care, among others the Catalonian public health program, are described, and the expansion of palliative care to non-cancer patients is stressed.

Altogether there seems to be a momentum to foster the implementation and integration of palliative care in health systems, where several initiatives could reinforce each other. The book as released by the WHO could guide an implementation program to better integrate palliative care, making use of the five WHO policy strategies for integrated care. This implementation program could be monitored by an indicator set based on already existing platforms for palliative care mapping like the Atlas project including the support of the EAPC (European Association for Palliative Care) and the IAHPC (International Association for Hospice and Palliative Care). Such a supportive joint collaboration could support the further implementation of the WHO palliative care resolution toward better palliative care integration.

7 Summary and Conclusion

This chapter started with a definition of integrated palliative care and a brief exploration of several elements of integrated care in relation to palliative care (clinical, professional, organizational, functional, normative, health system integration). Examples from five European countries were described and discussed. Here, functional integration in terms of relational, informational, and management continuity appeared to be vulnerable. Furthermore, based on the literature, five models supporting integrated palliative care were discussed mostly at a clinical or a mesolevel, namely, early integration, the Amber care bundle, care pathways for the dying, integration in multiple sclerosis and a breathlessness service, and the Gold Standard Framework in primary care. In previous years, most research and evidence generation about integration has been directed at early integration for hospital-based cancer care. Promising models outside cancer and in community settings could be identified but often need more rigorous investigation and development. Considering the integration of palliative care in professional guidelines, recommendations were summarized based on an analysis of five promising guidelines. Studies investigating a broader analysis of guidelines however showed that full integration still leaves a world to win. Finally a macrolevel policy approach was taken by discussing current initiatives to map integrated palliative care with indicators. In addition, the newly launched integrated care framework of WHO was summarized together with the WHO resolution for palliative care.

Integrated care has often been considered and discussed from the perspective of better integrated

healthcare delivery, which is needed and valuable. However, coming at the end of this chapter, it should be acknowledged that real integration goes beyond health service delivery. In the 1960s, Cicely Saunders coined the concept of "total pain" to show that patients cannot be reduced just to their physical problems but that social and life views need to be incorporated as well. Integrated palliative care is in its essence about whole patient care in the last phase of life. The welfare of the patient in this last phase is not only dependent upon the medical services he or she receives but also includes the social environment, the housing, the support, and well-being of family members and informal caregivers. In this respect, it is interesting to refer to the concept of a new public health approach for palliative care, which is based on engaging communities (Sallnow et al. 2016). Efforts for better integration of palliative care should move beyond a better organization of medical care and need to be rigorously designed from the perspective of the suffering patient in the last phase of life. This means that the whole living environment of the patient needs to be taken as a starting point, including family care, social care, place of living, health education and (il)literacy, and healthcare arrangements.

Abstract

In the context of palliative care, rehabilitation aims to improve quality of life for people living with life-limiting illness by enabling them to be as active and productive as possible with minimum dependence on others, regardless of their life expectancy (NICE. Guidance on cancer services: improving supportive and palliative care for adults with cancer. The manual. National Institute for Clinical Excellence, London, 2004). Palliative rehabilitation helps enable people to participate as fully as possible in all aspects of their daily lives. It represents an important route for people to fulfill meaningful goals, maintain dignity and adapt constructively to the uncertainty and loss that is often intrinsic in the lived experience of advancing illness. In its simplest sense, palliative rehabilitation is about enabling people to live fully until they die (Tiberini and Richardson, Rehabilitative palliative care: enabling people to live fully until they die. A challenge for the 21st century. Hospice, 2015. ISBN:978-1-871978-91-9). Rehabilitation in palliative care combines the specialist contribution of physiotherapists and occupational therapists together with the interdisciplinary practice of "rehabilitative palliative care."

1 Introduction

The interface between rehabilitation and palliative care is not a new concept, with principles of rehabilitation evident as central themes in Dame Cicely Saunders' philosophy and vision:

> The work of all the professional team is to enable the dying person to live until he dies, at his own maximal potential, performing to the limit of his physical and mental capacity with control and independence whenever possible. Dame Cicely Saunders

However, the contribution of rehabilitation to modern palliative care provision is gaining importance in the context of today's society where personal autonomy is paramount. People are increasingly expressing the importance of choice

and independence as major components of dignity in advancing illness and old age. These values underpin the concepts of "rehabilitative palliative care," an important paradigm shift endorsed by Hospice UK to respond to the challenges facing palliative care provision in the twenty-first century.

Rehabilitative palliative care calls for all members of the interdisciplinary team to adopt and actively embed rehabilitative practices and an enabling culture in their delivery of palliative care (Tiberini and Richardson 2015). It draws on the expertise and specialist rehabilitation contribution of physiotherapists and occupational therapists (Box 1) but recognizes that it is crucial to engage the whole team in a rehabilitative approach to best address the multiple needs of the patient living with advanced, complex, and progressive illness (Tookman 2011).

Box 1: Specialist Rehabilitation Contribution of Physiotherapists and Occupational Therapists

- Specialists in palliative rehabilitation.
- Trained in both rehabilitation and palliative care theory and practice.
- Provide expert holistic assessment and personalized rehabilitation interventions.
- Advocate for patients' independence, autonomy, and choice irrespective of prognosis.
- Core members of the interdisciplinary palliative care team (NICE Guidance on Cancer Services 2004).
- Lead the wider team in adopting and implementing rehabilitative palliative care.

This chapter will present the conceptual constructs informing rehabilitation in palliative care and the evidence base for its importance, acceptability, and impact. We will introduce key principles and interdisciplinary practices of "rehabilitative palliative care," in which enabling patients to fulfill their personal goals and priorities is "everybody's business," and explore the specialist rehabilitation contribution of physiotherapists and occupational therapists. A case scenario, Ali, runs through the chapter to illuminate the clinical application of rehabilitation concepts into practice.

2 The Interface Between Rehabilitation and Palliative Care: Are They Compatible?

Rehabilitation can be a misunderstood concept when described in terms of life-limiting illness. At first impression, the term "palliative rehabilitation" may appear contradictory as it brings together two somewhat paradoxical concepts – that of *rehabilitation*, frequently associated with recovery, and *palliative care,* frequently associated with dying (Leslie et al. 2014). This reductionist view of both concepts has contributed to a misperception that active rehabilitation is at odds with palliative care provision, with an ensuing reluctance on behalf of some healthcare professionals to integrate the two, inadvertently depriving patients of opportunities for enhanced quality of life (Platt-Johnson 2007). However, upon closer inspection, the domains of rehabilitation and palliative care are compatible and complementary and share common characteristics, ethos, and values (Fig. 1).

Both rehabilitation and palliative care are holistic, multidisciplinary, person-centered specialisms which place the patient and their family at the heart of the treatment paradigm to ensure the collaborative team input is tailored to best support their needs. Combined, rehabilitative palliative care has the potential to enhance the quality of life for both patients and families, where the sum of these two complementary approaches is greater than the individual parts. Rehabilitative palliative care transcends diagnosis, prognosis, and location of provision and should be viewed as the shared responsibility of all working in this field (Table 1) (Fig. 2).

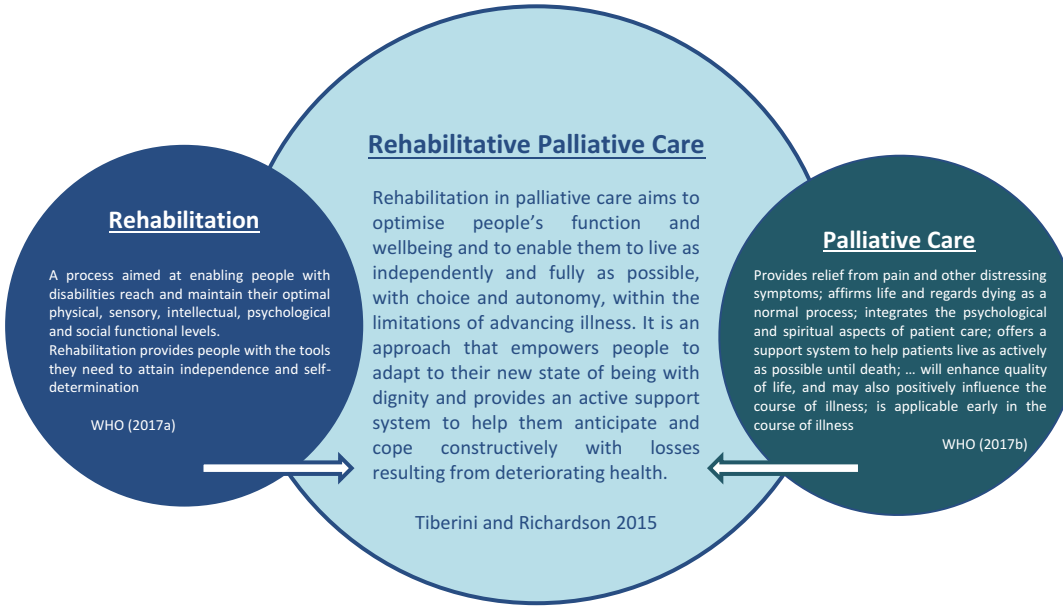

Fig. 1 Rehabilitative palliative care

Table 1 What is rehabilitative palliative care?

Rehabilitative palliative care *is*	**Rehabilitative palliative care *is not***
Person-centered: focusing support to best meet people's goals and personal priorities	Focused on and driven by the allied health professional agenda but led by patients' priorities
An effective integration of rehabilitation and palliative care to actively enhance people's quality of life irrespective of diagnosis or prognosis	The clash of two contradictory and opposing treatment paradigms
Interdisciplinary and multiprofessional: all members of the palliative care team actively contribute to rehabilitative palliative care A collaboration between patients, relatives, and carers and the multidisciplinary team	The sole domain of allied health professionals (AHPs): physiotherapists, occupational therapists, dietitians, speech and language therapists, rehabilitation assistants
About optimizing people's ability to function in the widest sense including moving around, eating and enjoying food, communicating with others, managing activities of daily living, and participating in meaningful activities	About promoting false hope that someone will recover or return to a previous level of function when this is unrealistic Just about mobility and walking
About adopting an enabling approach to provide patients and their relatives or carers with enough support and empowering them to manage on their own	About being less caring but promotes adopting an enabling approach to the way in which we provide care and having a greater focus on support
A way to give people greater independence, autonomy, choice, and dignity	About moving away from the ethos and values of palliative care but enhancing these through shared characteristics of rehabilitation
About living with dying	About ignoring dying or pretending it isn't happening
Everybody's business	

Tiberini and Richardson (2015)

Rehabilitation Case Study: Introducing Ali

Ali is a 74-year-old gentleman who lives at home on his own after his wife died 3 years ago. He is a retired teacher and has two children and five grandchildren who he sees regularly.

Ali has stage 3 lung cancer and has recently undergone chemotherapy. He has a history of COPD and osteoarthritis in both knees.

Ali has been referred to outpatient hospice services because of:

- Increasing breathlessness and fatigue
- Difficulty managing with his normal activities of daily living

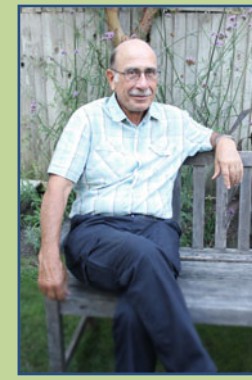

Fig. 2 Introducing Ali – a rehabilitative case study

3 Why Is Rehabilitation in Palliative Care Important?

3.1 Rehabilitative Palliative Care Actively Supports Priorities of Patients with Advanced Illness to Live Life Fully Until They Die

3.1.1 Maintaining Normality of Daily Life

Despite a diagnosis of advanced illness, patients' priorities consistently reflect the importance of maintaining continuity of daily life and living a normal life for as long as possible (Carter et al. 2004; La Cour et al. 2009; Johnston 2010; Reeve et al. 2010). Research has shown that, for patients and their carers, maintaining normality was the most important priority for patients alongside preparing for death. Maintaining normality of daily life is valuable for patients to preserve their dignity when they are losing independence and control in so many areas (La Cour et al. 2009; Johnston 2010). Through actively living a daily life and maintaining routines, patients strive to maintain an overall sense of well-being in the face of terminal illness, but most importantly, they work to maintain a strong sense of who they are and what is important to them.

3.1.2 Maintaining Independence and Choice

Physical function and independence are high priorities for patients living with advanced illness as they represent important routes to maintaining autonomy, control, and dignity (Carter et al. 2004; Cotterell 2008; Waterworth and Jorgensen 2010; Baile et al. 2011; Strohbuecker et al. 2011). While people living with advanced illness identify practical issues of daily living – including maintaining function, the ability to care for oneself, and the ability to do what one wants – as specific issues that are important to them (Carter et al. 2004; Baile et al. 2011), their overarching priorities relate to having a sense of control and choice in life (Cotterell 2008; Waterworth and Jorgensen 2010; Strohbuecker et al. 2011). Independence in the wider sense concerns attaining the right to be free of the influence and control of others (Cotterell 2008). From this perspective, independence, while linked with physical function, is not inherently determined by a person's ability to function. A person with advanced illness may experience a loss of physical functioning which necessitates assistance from others to fulfill tasks of daily living. However, this support can be delivered in a way that enables them to maintain their independence and control their own lives

Fig. 3 Patient's Priorities – 'what matters to you?' not 'what's the matter with you?'

(Cotterell 2008) preserving their sense of dignity and inherent worth (Chochinov et al. 2002) (Fig. 3).

3.2 Rehabilitation in Palliative Care Is Feasible, Acceptable, and Effective for Patients with Life-Limiting Illness

A growing body of robust evidence supports the feasibility, acceptability, and effectiveness of rehabilitation interventions for patients with advanced disease including cancer (Oldervoll et al. 2011; Henke et al. 2014; Jensen et al. 2014; Mayo et al. 2014; van den Dungen et al. 2014); respiratory (Sachs and Weinberg 2009; McCarthy et al. 2015), cardiac (Taylor et al. 2014), and neurological disease (Trend et al. 2002; Khan et al. 2007); and dementia (Pitkälä et al. 2013).

Randomized control trials of rehabilitation in palliative cancer populations have demonstrated improvements in patients' strength, fatigue, physical functioning, Activities of Daily Living (ADL) functioning, social functioning, independence and quality of life (Oldervoll et al. 2011; Henke et al. 2014; Mayo et al. 2014) – wide ranging effects which are also found in real-world clinic settings (Talbot Rice et al. 2014). Gains in physical function are particularly impressive when considered alongside the tendency for function to deteriorate with advancing disease. This demonstrates the potential for rehabilitation to not only prevent or delay deterioration in function but for some patients to actively *improve* their functional status with regard to physical independence, irrespective of advanced disease.

Qualitative research illustrates how rehabilitative approaches can be transformative in empowering patients living with advanced disease to regain a sense of normalcy and control in their lives (Malcolm et al. 2016; Turner et al. 2016).

3.3 Rehabilitation Offers Solutions to Respond to the Changing Needs of Populations Requiring Palliative Care

The global society is aging. In 2010, an estimated 524 million people were aged 65 or over – 8% of the world's population. This number is rapidly increasing and projected to triple by 2050, to 1.5 billion people representing 18% of the world's population (WHO Global Health and Aging 2011). A consequence of increasing age is that longevity frequently becomes compromised through a picture of progressive disability and/or frailty. As treatments continue to improve and

survival for most diseases increases, typical dying trajectories are evolving and converging toward one of chronic illness. While this model is amenable to longer-term control, with a slower progression toward death, it is characterized by increased disability preceding death (Gill et al. 2010).

Disability and frailty can have significant detrimental impacts on a person's ability to undertake normal activities of daily living and are associated with negative patient outcomes including reduced independence and autonomy, decreased participation in meaningful activities, depression, and poorer quality of life. However, both disability and frailty are dynamic states that can be made better or worse.

There is a robust body of evidence that supports the effectiveness of rehabilitation in the prevention and reduction of disability and frailty in people living with advancing illness and/or old age (Crocker et al. 2013).

3.4 Rehabilitation Can Contribute Economic Efficiencies in Palliative Care Service Provision

Reducing the levels of disability arising from disease and health-related conditions is one important key to holding down escalating health and social care costs. Functional disability and reduced independence with ADLs are significantly associated with both hospital stay and need for long-term care which, in the UK, are the primary determinants of cost in the last year of life (Kelley et al. 2012; Portegijs et al. 2012; Georghiou and Bardsley 2014). It has been shown that severe disability and functional decline are significantly associated with increased hospital days in patients in the last year of life (Kelley et al. 2012). Similarly, failure of older patients to regain function in the three months following a hospital admission is recognized as a significant predictor of their being institutionalized within the next twelve months, irrespective of the person's pre-admission ADL impairment (Portegijs et al. 2012).

Considered from an economic perspective, the relationship between rehabilitation and cost savings is simple: the longer people can remain independently mobile and capable of self-care, the lower their use of hospital services and the lower the costs for long-term care to families and societies (WHO Global Health and Aging 2011). Timely access to rehabilitation services has the potential to prevent or slow functional decline, avoid unnecessary hospital admissions, reduce length of hospital stay, help patients counteract the loss of function following hospital admission, and reduce or delay the need for institutionalization (Kelley et al. 2012; Portegijs et al. 2012).

At a population level, small improvements in an individual's functioning can translate into considerable cost savings, demonstrating the economic value of rehabilitation in palliative care (Tiberini and Richardson 2015).

4 "Rehabilitative Palliative Care": Rehabilitation as Core Business for the Interdisciplinary Team

Rehabilitative palliative care is an evolving approach to palliative care where all members of the interdisciplinary team have an active role to play in supporting patients to live fully until they die through integrating rehabilitation, enablement, self-management, and self-care into the holistic model of palliative care provision (Box 2).

Box 2: Rehabilitative Palliative Care Definition

Rehabilitative palliative care is a paradigm which integrates rehabilitation, enablement, self-management, and self-care into the holistic model of palliative care. It is an interdisciplinary approach in which **all members of the team**, including nurses, doctors, psychosocial practitioners, and allied health professionals, work collaboratively with the patient, their relatives, and carers to support them to achieve their personal goals and priorities. Rehabilitative palliative care aims to optimize people's function and well-being and to enable them to live as independently and fully as possible, with choice and autonomy, within the limitations of advancing illness.

(*continued*)

Box 2: (continued)

It is an approach that empowers people to adapt to their new state of being with dignity and provides an active support system to help them anticipate and cope constructively with losses resulting from deteriorating health.

Rehabilitative palliative care supports people to live fully until they die (Tiberini and Richardson 2015).

To realize this approach in practice requires attention to the culture of how we conceptualize and deliver palliative care to:

- Focus our support on the experience of living rather than dying.
- Place patients' personal priorities and goals at the core of any support we provide.
- Work collaboratively to fulfil these through the conscious, active commitment of all members of the interdisciplinary team to adopt these rehabilitative approaches in their daily practice.

A rehabilitative palliative care culture holds two paradigms in balance, embracing concepts of *enablement* alongside *care* (Box 3). Together, these complementary approaches create a spectrum of support, ranging from supportive self-management through to total care which allows palliative care teams to better tailor their input to patients with differing levels of need and to individual patients as their needs change over time. Importantly, a balance of enablement and care ensures we offer just the right amount of support, at the right time, in the right way.

Box 3: Rehabilitative Palliative Care Embraces "Enablement" Alongside "Care"

These paradigms are complementary: enablement is caring and nurturing while actively seeking to preserve people's choice, participation, and autonomy. Care delivery underpinned by these same values can be enabling (Wosahlo 2014).

4.1 Four Key Practices of Rehabilitative Palliative Care

At the heart of rehabilitative palliative care are four key practices: person-centered goal setting, focus on function, supported self-management, and enablement (Box 4).

Box 4: Four Key Practices of Rehabilitative Palliative Care

1. **Person-Centered Goal Setting:** to work in partnership with patients to actively identify their priorities and tailoring our interdisciplinary support to address these
2. **Focus on Function:** to ensure all members of the interdisciplinary team consider the impact of symptoms on a person's ability to function, proactively recognize change in patients' function, and take appropriate actions to optimize their physical potential
3. **Supported Self-Management:** to enable patients to "take charge" – through a consistent interdisciplinary approach which encourages patients (and families) to play an active role in managing their health and well-being, and the effects of their illness, *themselves*.
4. **Enablement:** to empower patients to have maximum choice and control over their own lives – through all members of the interdisciplinary team actively creating opportunities for patients to choose what they want to do, to undertake what they can themselves, and to provide just the right amount of support to meet their individual needs and preferences (Tiberini and Richardson 2015).

4.1.1 Person-Centered Goal Setting

NICE guidance for best practice recommends that patients should "receive an active and planned approach ... involving assessment, goal setting, care planning and evaluation" as an intrinsic part

of palliative care provision. While goal setting is recognized as an important component of palliative care, professionals have a tendency to focus on problems and symptoms, which represent something that we can fix or manage, whereas patients focus on what they want to "do" (Boa et al. 2014). The implication for those working in palliative care is that by failing to explicitly ascertain patients' goals and priorities, teams may be providing "professional-centered" care based around what we can influence or what we perceive to be important to the patient. To provide truly "person-centered" palliative care that is tailored to each patient's personal priorities, an essential starting point is establishing what is most important for that person. Goal setting around these priorities provides a meaningful focus for collaborative action planning between the patient, family, and the whole interdisciplinary team which places the patient actively at the center of their care. It also provides a unifying framework for different professions within the interdisciplinary team to contribute their unique expertise – including symptom control, rehabilitation, psychological, social, and spiritual support – to collectively best support the patient to achieve their goals (Fig. 4).

Reframing interdisciplinary palliative care practice with greater collaborative focus on patients' personal goals has potential to help patients:

- Feel listened to and that their priorities are paramount.

Fig. 4 Person-centered Goal Setting

- Have a more linked up experience of care and support across the interdisciplinary team.
- Find focus and meaning in life.
- Increase motivation and effort to achieve what is important to them.
- Develop resilience and coping – enabling reframing of goals as illness progresses and mourning for unachievable goals as an important aspect of adapting to illness.
- Live actively while dying.

Person-centered goal setting is not about creating an environment of false hope. While goals should be realistic, research suggests the process of setting goals and working toward them is more important than achieving them and that this can be constructive in helping patients understand, and come to terms with, what is manageable and what is not (Boa et al. 2014).

Rehabilitation Checklist for Person-Centred Goal Setting

- Ask patients:
  'What is important for you to achieve in the next few . . . weeks/months?
  'What are your best hopes for . . . this admission/ the next week while?' Boa et al. (2014)
- Make patients' goals the center of all interdisciplinary support – embedding them in the structure of patient notes, ward rounds and team meetings
- Celebrate patients' achievements
- Work in partnership with patients to reframe their goals if their circumstances change and the goal is no longer a priority or no longer realistic

4.1.2 Focus on Function (Beyond Symptoms)

Maintaining function is a high priority for patients with advanced illness as it represents an important gateway to preserving independence and autonomy and participating in meaningful activities that add quality to life. As such, "maximising patients' independence and minimising experiences of dependency should be a priority for those working with people who have life-limiting conditions" (Cotterell 2008).

Function requires greater attention in older populations who are at increased risk of functional decline and frailty. For this group, small deteriorations in function can have a disproportionate impact on capacity for independent living. It is easier to maintain function than it is to regain function once it has been lost. Proactive assessment and identification of factors that may compromise function is key to allow for strategies to prevent avoidable deterioration, e.g., deconditioning arising from inactivity, to be put in place. Functional assessment is also essential to proactively recognize patients' needs for specialist rehabilitation input and ensure appropriate early referral to allied health professionals. (Fig. 5)

Symptoms can be a profound source of discomfort and distress in their own right; however, frequently, the magnitude of patients' experience can only be fully appreciated when symptoms are contextualized within the realm of function. Function is frequently compromised by symptoms and is extrinsically linked to a host of wider losses, which if not properly assessed and addressed can become significant sources of distress for patients and families (Chochinov et al. 2002).

While palliative care defines itself through early identification and impeccable assessment, research suggests that functional concerns of palliative patients are not well identified. Patients' primary concerns were found to relate to loss of function, the future and caring for themselves; however, these were not recognized as priorities by assessing palliative care clinicians (Baile et al. 2011).

Systematic, routine assessment of function by all members of the interdisciplinary team, as a core part of the holistic palliative care assessment, is essential to proactively identify functional concerns and ensure these are adequately addressed. This is important at all stages of symptom control, to ensure that intervention is not ended prematurely at the point where a patient's symptoms are well controlled at rest, but rather, symptom management aspires to have symptoms well controlled when patients are operating at their maximal level of functioning.

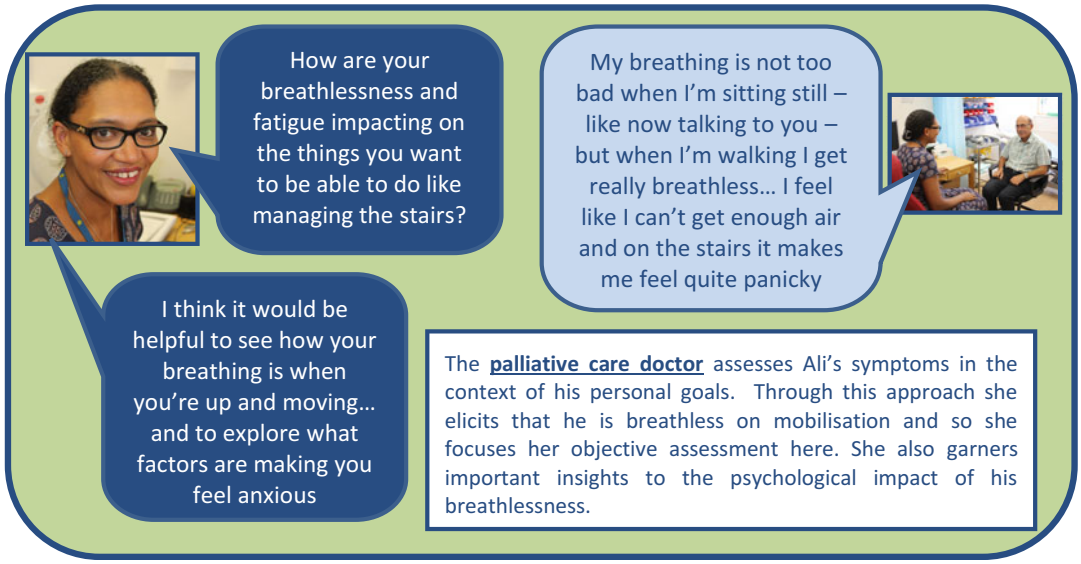

Fig. 5 Focus on Function Beyond Symptoms

Rehabilitation Checklist for Focus on Function Beyond Symptoms

- Incorporate functional assessment as a routine aspect of all holistic palliative care assessments by all team members.
- Proactively screen for functional difficulties by asking patients: Are you having any difficulty with moving around or managing your day-to-day activities?
- Consider the impact that symptoms are having on a patient's ability to function and go beyond symptom control at rest to optimize symptom control when a patient is functioning to their best potential.
- Refer to physiotherapy and occupational therapy early when function difficulties are recognized so patients can benefit from specialist assessment and rehabilitation.

4.1.3 Supported Self-Management

For people living with advanced illness "taking charge" represents a central priority. The right to exercise choice and control, even when extremely ill, is important to patients and is often related to preserving their dignity and maintaining normality. Self-management is about supporting people to take responsibility for their own health and well-being and is closely related to, and often used interchangeably with, self-care. Collectively, these terms aim to empower patients to play an active role in managing their illness and the effects of their illness, *themselves* (Johnston 2010).

In the context of palliative care, supported self-management and self-care do not necessarily mean remaining entirely self-maintaining or fully functional; instead, it involves "maintaining one's usual practices of self-care; those things that are important and unique to oneself in maintaining one's sense of self" and "being given the means to master or deal with problems, rather than relinquish them to others" (Corner 2002). Supported self-management is about redressing the power relationship between health professionals and people (patients) to put the person and their family back in charge.

Rehabilitation Checklist for Supported Self-Management

- Seek to identify what a patient is managing well independently and positively reinforce their self-efficacy.
- Encourage patients to assertively express their needs and wishes and work in

(*continued*)

partnership with them to co-create solutions and coping plans.
- Support and encourage patients to use non-pharmacological symptom management approaches to self-manage their symptoms.
- Support patients to undertake the elements of self-care they can manage themselves which are important to maintaining their sense of self.
- Enable patients to practice positive risk taking to fulfill their goals.

4.1.4 Enablement

Patients living with advanced illness describe priorities of maintaining normality of daily life, physical functioning, and independence and express a clear desire to be supported to manage their health with choice and control right up until they die. Enablement in healthcare is a therapeutic paradigm or process which aims to "recognise, support and emphasise the patient's capacity to have control over her or his health and life" (Hudson et al. 2011).

In the context of palliative care, where realities and losses associated with progressive, advancing illness can erode a sense of control, the practice of enablement can help actively restore the experience of perceived control and self-efficacy for both patients and families. It has been suggested, however, that "considerable paternalism" exists in palliative care (Randall and Downie 2006). Rather than enabling patients to carry out activities they are able to, we can sometimes "over-care" inadvertently disempowering patients by doing these activities for them. By integrating enablement as a core dimension of holistic palliative care provision, all members of the interdisciplinary team can better ensure that care is actively tailored to recognize and support individual patient's capacities and preferences.

Enablement actively supports patient independence and participation; however, this is always led by patients' capacity and willingness to engage. In situations where patients make an informed decision to decline to participate, e.g., in daily care even if they have the capacity to do so, an enablement approach recognizes and respects the patient's choice. A defining characteristic of "enabling care" is that all patients are consistently offered the opportunity to make the choice for (or against) independence and participation in the first place (Fig. 6).

An enablement approach lies at the heart of rehabilitative palliative care (Box 5). It is the route to realizing patients' priorities of normality and functional independence and the bridge between caring and fostering autonomy necessary to be alongside patients as they experience functional losses. Inherent to enablement is the distinction between autonomy and independence. This recognizes that while a person's independence may reduce due to advancing illness, their autonomy to make decisions about what they do and how they are supported can be preserved.

Box 5: How to Adopt an Enablement Approach to Your Practice

- Work in partnership with patients to identify their *person-centered goals and priorities.*
- Start from the underpinning assumption that a person would like to choose if they want or need support.
- Shift your focus to offering *support* to a *person* (rather than the default of providing care to a patient).
- Ensure any support or care you provide is led by people's priorities, goals, and preferences (as opposed to a professional need to "care for" or "fix" patients problems to make everything better).
- Begin by checking what support or assistance a person would like and how they would like this (before making assumptions and automatically providing it).
- Provide support which involves "being alongside" or "doing with" the person (rather than a default of "doing for") whenever possible.
- Practice *enablement* by empowering people to play an active role in their support and care whenever possible – even small acts of participation such as washing

(*continued*)

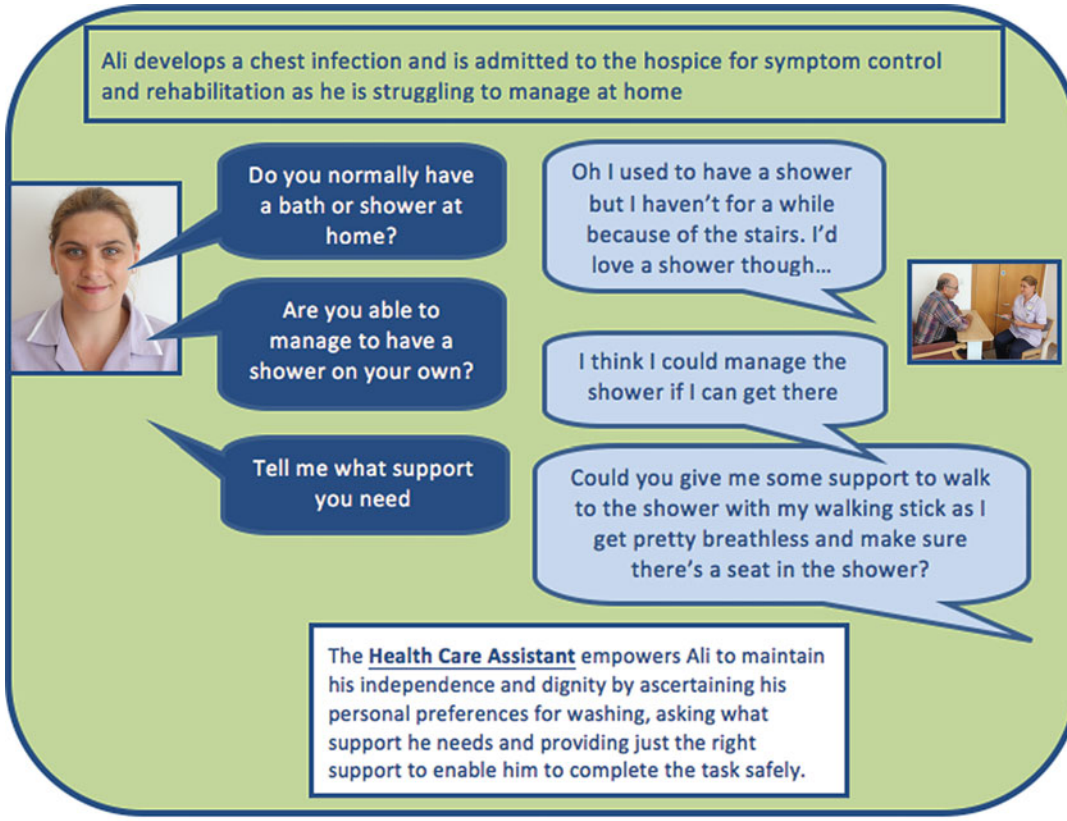

Fig. 6 Enablement and Supported Self-management

Box 5: (continued)

one's own face or genitals can make a big difference to a person's dignity.

- *Focus on function:* by always considering symptom control in the context of a person's function.
- Consciously create opportunities for patients to play an active role in *supported self-management* of their condition and well-being.
- Always work to promote choice and foster autonomy.
- Be conscious that you don't unintentionally "over-care" for patients which may diminish their function, independence, autonomy, and dignity.
- Respect when people make an informed decision not to participate, even if they have the capacity do so – this recognizes that they are exercising personal choice.

5 The Specialist Contribution of Physiotherapy and Occupational Therapy to Rehabilitation in Palliative Care

For physiotherapists and occupational therapists, rehabilitation lies at the heart of their approach to palliative care. With dominant values of "enabling function and independence" underpinning their professional practice, physiotherapists and occupational therapists focus in on what is most

important to people and what they need to be able to do to achieve this. Drawing on holistic assessment skills, physiotherapists and occupational therapists identify physical impairments alongside psychological, social, and environmental factors impacting on a person's ability to function and cocreate a rehabilitation plan in partnership with the patient to address these.

Physiotherapists and occupational therapists are experts in the delivery of rehabilitation interventions and have an important role to play in leading the interdisciplinary team in the practice of rehabilitative palliative care, where all team members adopt an enabling approach to their clinical practice (Boxes 6 and 7).

5.1 Capacity, Needs, and Wishes

To ensure rehabilitation initiatives are tailored to both individual and changing needs of palliative care patients, physiotherapists and occupational therapists have a working knowledge of the relationship between capacity, needs, and wishes (Fig. 7).

Capacity is a person's ability to do things. **Needs** are the things that day-to-day functioning depends on – such as eating, washing, and dressing. **Wishes** are the things like hobbies or leisure pursuits some of which a person can survive without but which ultimately can bring value, purpose, meaning, and quality to life. In an unimpaired state (1), a person will have capacity to meet all of their day-to-day functional needs (they will be "self-caring"). Although some wishes will be unattainable, e.g., running fast for a bus or completing a marathon, most wishes can be met. But a reduction in capacity (2) through illness or treatment may limit participation in more demanding wishes and prevent participation in hobbies or leisure pursuits. As capacity deteriorates further (3), more wishes cannot be met, and some needs are beyond their ability. This is when independence decreases and dependence on others increases, signaling the need for assistance and help.

At its core, rehabilitation in palliative care is about enabling a person's capacity to remain at its maximum potential and allowing someone to be the best that they can be – fulfilling their needs and wishes independently whenever possible – despite advancing illness. It is to support living in the face of life-threatening illness and deterioration and to adapt constructively as capacity diminishes.

5.1.1 Aims of Rehabilitation in Palliative Care

Specialist rehabilitation provided by physiotherapists and occupational therapists is focused around the following aims:

1. **To minimise the effects of advancing disease or its treatment on people's function**

   Life-limiting illnesses including cancer, respiratory diseases, heart failure, and

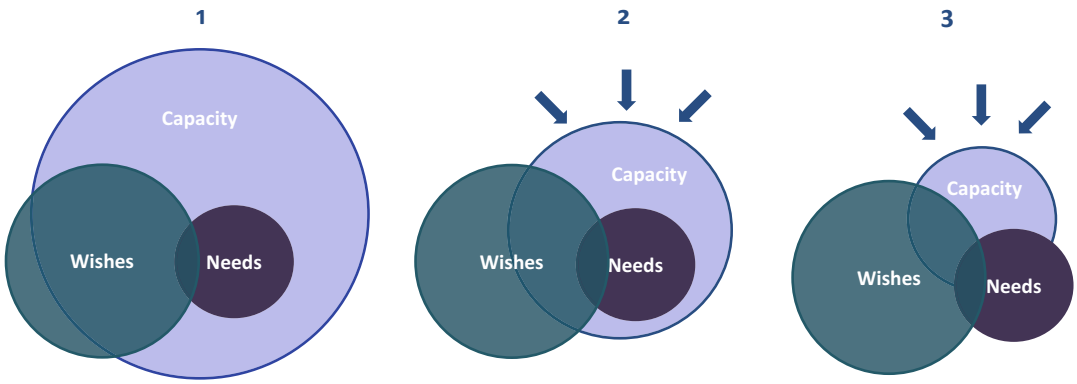

Fig. 7 The Relationship between Capacity, Needs and Wishes in Advancing Illness (Adapted with kind permission of Matthew Maddocks)

neurological conditions can cause disability and impairment. This can be from the disease itself or from the treatment of the disease (e.g., steroids causing proximal myopathy or radiotherapy causing fatigue). Rehabilitation aims to minimize these effects.

2. **To maintain and support people's independence**

   For people facing a life-limiting illness, one of the biggest reported fears is of *being a burden* on family or friends (Waterworth and Jorgensen 2010). Maintaining independence and supporting people to be able to do as much as they can for themselves is paramount. Rehabilitation always aims to promote independence as much as possible, encouraging a person to do as much as they can for themselves.

3. **To empower people to cope effectively with symptoms and associated distress**

   Evidence is increasingly proving the effectiveness of non-pharmacological symptom management to enable people with advancing illness to understand, manage, and live well alongside symptoms of breathlessness, fatigue, pain, and insomnia (Javier and Montagnini 2011). Rehabilitative approaches go hand in hand with appropriate pharmacological interventions and have an important role in increasing people's self-efficacy to cope with symptoms and minimize associated distress, especially earlier on in the pathway.

4. **To enable people to participate in meaningful activity**

   Paramount to good palliative rehabilitation is the ability to support a person's maintenance of their role, identity, and sense of self through participation in activities that are important or meaningful to them. Through creative approaches, this is frequently possible irrespective of their disabilities, symptoms, or prognosis. An example would be to enable a person who loves to cook to access their kitchen and participate in meal preparation despite being in a wheelchair.

5. **To provide expert education and open communication**

   Education and open communication are central to effective rehabilitation provision to both elicit engagement in the rehabilitation process and as a means of empowering patients, families, and carers to fully understand their condition. This may include tailoring education and advice to help people consider risks and limitations and make informed choices in line with their personal values, priorities, goals, and wishes. For example, working alongside a person with a spinal cord compression and resulting paralysis involves educating both the patient and their family. It is essential that they understand what spinal compression is, why it occurs, the impact on their function, and potential for recovery and this information needs to be communicated in an open, sensitive, way to enable them to consider the practical and emotional impact that loss of function will have on their lives.

5.1.2 Specialist Palliative Rehabilitation Interventions

With these aims in mind, the core interventions of specialist palliative rehabilitation are presented below alongside the evidence for acceptability, feasibility, and effectiveness.

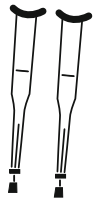
5.2 Exercise and Activity

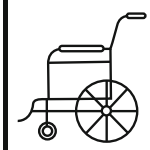
Exercise and activity are critical interventions for maintaining and, where possible, improving patients' physical functioning and independence. They are interrelated in that, for some patients with diminishing capacity, participation in functional activities that support their mobility will represent their dominant and most appropriate form of exercise.

A core focus of any rehabilitation assessment undertaken by an occupational therapist or physiotherapist will be to determine a patient's level of mobility. Mobility is the capability to move or be supported to move, and it is best understood as a spectrum: ranging from being able to move oneself in bed by rolling over or bridging right through to being able to climb stairs or run (Fig. 8). A person's level of mobility is qualified by their use of mobility aids (Fig. 9) and the

Bed Mobility	Lying to Sitting	Sitting to Standing	Transfers	Walking	Stairs	Outdoor Mobility
						The ability to move oneself on the bed includes rolling and bridging to move up and down the bed on one's back	The ability to move oneself form a horizontal lying position to upright sitting	The ability to move oneself from sitting to standing	The ability to move oneself between locations such as from a bed to a chair or from a wheelchair to a toilet	The ability to walk	The ability to climb and descend a flight of stairs	The ability to walk around outside

Fig. 8 Mobility as a Spectrum

Walking Stick	Crutches	Walking Frame		Wheelchair		
		Zimmer	Rollator	Manual		Electric
				Self Propelled	Attendant Propelled	
						




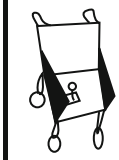


Fig. 9 Walking Aids

degree of support they require from another person to undertake a task, which may involve assistance, supervision, or no support in the case of independence (Table 2).

Mobility levels will differ from person to person, but it is important to note that a patient who is not able to get out of bed without assistance could gain as much achievement from being able to roll over and change position independently as another patient does from being able to climb the stairs to get to their bedroom. Importantly, mobility levels are changeable and in most cases can be improved through rehabilitation interventions. This can be achieved either directly by rehabilitating a person's impairments such as strength, balance, or breathlessness or indirectly through the provision of aids or environmental adaptations.

Exercise, activity, and mobility go hand in hand. At a very basic level, the phrase is true "if you don't use it, you lose it." So at the heart of specialist, palliative rehabilitation must come the offering of exercise-based interventions. Tailored

Table 2 Levels of support for mobilization

Independent	Supervision	Assistance of one person	Assistance of two people	Assistance of hoist
The ability to move oneself without the assistance of a person One can be independent even if they use a walking aid	The ability to move without hands on manual assistance but requiring supervision to ensure safety – for example, when balance or cognition is compromised	The ability to move with physical hands on assistance of one other person	The ability to move with physical hands on assistance of two other people	When a person cannot be safely supported through the assistance of two people, a hoist is required to assist movement

exercise prescription frequently falls under the professional expertise of the physiotherapist (Fig. 10).

The feasibility and acceptability of exercise to patients with advanced disease are now well established. Studies offering a range of exercise rehabilitation interventions to patients with advanced stage cancer unanimously found it was feasible for this population to participate in exercise rehabilitation, including aerobic, endurance, and resistance training (Oldervoll et al. 2011; Henke et al. 2014; Jensen et al. 2014; Mayo et al. 2014; van den Dungen et al. 2014). A large retrospective analysis of 572 terminally ill cancer patients found that physical exercise (alongside breathlessness management and relaxation strategies) was acceptable to over 90% of patients (Jensen et al. 2014), while the majority of patients with advanced cancer consider themselves physically capable of undertaking some form of exercise and over two-thirds feel prepared to undertake a program (Maddocks et al. 2011).

This strong and growing body of evidence supports the view that rehabilitative interventions are effective in improving strength, fatigue, physical functioning, ADL functioning, social functioning, independence and quality of life in palliative populations (Oldervoll et al. 2011; Henke et al. 2014; Jensen et al. 2014; Mayo et al. 2014; van den Dungen et al. 2014).

Exercise interventions for patients with respiratory or cardiovascular disease are also well established, with randomized controlled trial evidence supporting the effectiveness of pulmonary and cardiac rehabilitation programs. Large Cochrane Collaboration systematic reviews show that pulmonary rehabilitation for patients with COPD (65 trials with 3822 participants) can relieve breathlessness and fatigue; improve physical function, emotional function and feeling of control; and reduce the frequency of hospital admissions regardless of disease severity (McCarthy et al. 2015). Similarly strong evidence exists for cardiac rehabilitation, which, for patients with heart failure (33 trials with 4740 participants), reduces hospital admissions and improves quality of life, irrespective of the degree of heart failure (includes NY Heart Failure Association Class IV) (Taylor et al. 2014).

Several small qualitative studies in the UK have explored the patient-reported impact of participating in exercise on their quality of life. Turner found that in addition to perceived physical and emotional improvements in their well-being, patients felt that engaging in exercise classes gave them a sense of meaning whereby they reclaimed control though active, positive involvement in their own health, greater choice, the opportunity to prolong independence, and confidence and hope to face the future (Turner et al. 2016).

> . . . I am actually doing something to keep well. That feels really good in the situation where cancer makes you feel very powerless because it's out of your control. I can get to the gym, I can walk, I can make my heart rate increase, I can strengthen my limbs as much as I'm able. That control is very good for someone who feels they have so little control...

Fig. 10 The role of the Specialist Palliative Care Physiotherapist

Malcolm's findings reinforced the importance of rehabilitation as a means of enhancing a sense of normalcy, where patients had greater independence and ownership of their health (Malcolm et al. 2016).

> ... it means that I'm able to just be, just feel like I'm normal, feel like things are normal for me.
>
> I think it helps you to ... just get on with being and helping yourself... all of it is leading up to you making that decision for yourself to sort of keep healthy.

Box 6: The Specialist Contribution of Palliative Care Physiotherapists

Physiotherapists work as autonomous practitioners offering specialist, evidence-based assessment, diagnosis, treatment interventions, and guidance. They optimize patients' quality of life by maintaining and improving physical function to attain the

(*continued*)

Box 6: (continued)
highest level of independence possible in advanced illness through:

- **Robust clinical reasoning skills** underpinned by knowledge of anatomy and physiology of advanced illnesses including oncological, respiratory, cardiac, and neurological conditions and multiple comorbidities associated with aging
- **Specialist skills in holistic assessment:** Utilizing both subjective and physical assessment, including respiratory, neurological, musculoskeletal, lymphedema, and functional assessments, to systematically identify factors impacting on a patient's ability to function and make clinical diagnoses
- **Palliative rehabilitation:** Specialized interventions and guidance to optimize a person's mobility and functioning by analyzing, treating, and managing impairments, including muscle weakness, fatigue, balance, breathlessness, pain, lymphedema, and anxiety, to work in partnership with patients to achieve their personal goals
- **Advanced communication skills** to help patients and their families proactively plan for the future, anticipate potential functional changes, avert functional crises, and adapt constructively to the spectrum of losses related to functional decline in advancing illness
- **Non-pharmacological symptom management** of breathlessness, fatigue, pain, lymphedema, and anxiety in advanced illness through provision of specialist treatment interventions including personalized exercise prescription, manual treatments, provision of equipment and aids, rehabilitation, and expert guidance
- **Self-management** education and strategies to empower patients and carers to understand and cope with symptoms, maintain function and participation in meaningful activities, reduce dependence on others, and foster a sense of control and self-efficacy
- **Positive risk taking, assessment, and management:** Including comprehensive evaluation of patients' safety to manage functional activities; recommendations to actively manage risks through provision of support, activity modification, and use of equipment and aids; and enabling supportive risk taking to support patient choice and quality of life even when risks are evident
- **Complex moving and handling**: Risk assessment, personalized management plans, education, and support to patients, carers, and multidisciplinary team (Tiberini and Richardson 2015).

5.3 Participation in Activities of Daily Living

Enabling participation in activities of daily living (ADLs) which include toileting, bathing, dressing, or preparing a meal is a core element of palliative rehabilitation, central to supporting patients' priorities for maintaining normalcy and independence. Occupational therapists and physiotherapists are experts in the assessment of function with attention to a patient's capacity to manage ADLs. This holistic assessment routinely takes into account each individual's impairments, their environment, level of motivation and support relationships, alongside their personal goals and priorities.

Participation in ADLs is an important route to maintaining patients' dignity, which remains important even when a patient's capacity has diminished to a point where they require assistance to meet their basic needs. Examples of this may include patients living with advanced neurological conditions or those in the last days of life where continuing to enable participation in tasks,

where it is important to that person, such as supporting them to wash their own genitals or face when undertaking a bed wash, can make a real difference right up until death.

In advanced neurological conditions, rehabilitation has been found to be both acceptable and effective in supporting people to manage symptoms, maintain function, prevent secondary impairments, adapt constructively to change in function related to their illness, and proactively avert crisis situations (Trend et al. 2002; Khan et al. 2007; Simmons 2013). A Cochrane systematic review of 954 adults with multiple sclerosis of all severities found there was strong evidence to show rehabilitation produced short-term gains with improved levels of participation, patient experience, and quality of life (Khan et al. 2007).

Physiotherapists and occupational therapists are well placed to develop "enablement plans" for patients which provide clear recommendations for the interdisciplinary team on how to best optimize patient participation. This aspect of rehabilitative palliative care requires conscious attention on behalf of all members of the interdisciplinary to ensure patients are not unintentionally deprived of opportunities to undertake tasks themselves, especially where this may take longer than doing the task for them.

Occupational therapists are skilled in managing complex discharges which enable palliative patients to return safely to their preferred place of care, frequently home, following an inpatient stay. Due to the variable nature of advancing illness, patients' condition and their functional abilities can change quickly. This requires proactive planning to ensure the patient will be safe and supported both in phases of stability and deterioration, including at the end of life if they wish to die at home. Occupational therapists and physiotherapists work in partnership to undertake a comprehensive assessment of patients' function, environment and support network, to explore the risks and opportunities of a person returning to live in their own home. Areas of assessment may include a person's ability to climb stairs to access the bedroom and bathroom versus setting up a microenvironment on a single level or their ability to safely access and get on and off the toilet to maintain personal hygiene versus using a commode beside the bed. Home assessment is paramount, and where needed, adaptation of a person's environment can enable them to continue to actively participate in ADLs, maintain independent living, and remain at home. Simple adaptations such as installing a stair rail can allow a patient to safely, independently navigate stairs – a small intervention which can make the immense difference between being house bound and accessing the local community (Fig. 11).

Supporting patients to participate in ADLs and to return home requires an important balance to be struck which is enabling both *choice and safety*, managing both *risk and opportunity*, and acknowledging both *expectation and reality.* Positive risk taking and parallel planning, discussed later in this chapter, are effective practices to help achieve this.

Box 7: The Specialist Contribution of Palliative Care Occupational Therapists

Occupational therapists work as autonomous practitioners offering specialist assessment, interventions, and guidance specifically focused around occupation. Occupation encompasses all activities of daily living and dying. They optimize a person's quality of life by supporting maintenance of role, identity, and sense of "self" through participation in activities that are important or meaningful to them despite their disabilities or prognosis through:

- **Specialist assessment of a person's ability to function** in the unique context of their physical environment and interpersonal relationships with attention to cognitive, psychological, social, and physical aspects of a person:
  - Analysis of the individual components of occupation to enable targeted interventions to modify or adapt the activity to support participation, independence, and quality of life

(*continued*)

Fig. 11 The role of the Specialist Palliative Care Occupational Therapist

Box 7: (continued)

- Cognitive and perceptual assessment to identify factors affecting a person's ability to plan, sequence, and execute activities in order to improve or maintain existing capacities
- Assessment of care and support needs to determine a person's ability to participate in ADLs, with attention to both risk and independence in order to tailor support to enable personal choice and priorities while optimizing safety, including analysis of carer's ability to provide support
- Assessment of complex posture, seating, and manual handling issues in order to provide recommendations and interventions to manage pressure and other risks and to maximize participation in occupation

(*continued*)

Box 7: (continued)
  - Environmental assessment to evaluate a person's functioning within their home (or other) physical and social environment to identify difficulties and risks and to help maintain the person within their own home and maximize participation in occupation
- **Environmental adaptation, assistive technology, and equipment prescription**: To optimize safety in the home (or other) environment to enable people to be as independent as possible, reengage with activities of purpose and meaning, reduce burden on carers, and support people to achieve their preferred place of care and death
- **Advice and guidance on symptom control and self-management strategies** for fatigue, breathlessness, pain, anxiety, and sleeplessness using a range of interventions to facilitate occupational engagement
- **Complex discharge planning**: Including environmental modification, equipment provision, rehabilitation, supportive risk management, care support recommendations, creative problem-solving, and leadership to the multidisciplinary team to enable a safe and timely inpatient unit discharge and thereby optimize inpatient service efficiencies and to achieve the persons preferred place of care and death
- **Adjustment to loss of occupational engagement** due to progression of illness and a focus on the occupation of living with dying (Tiberini and Richardson 2015).

5.4 Non-pharmacological Symptom Management

Physiotherapists and occupational therapists play a key role in providing non-pharmacological strategies and practical advice to empower patients to understand and effectively self-manage symptoms. For many people living with advanced illness, symptoms are refractory which means that they persist despite optimizing the treatment of any underlying causes. Subsequently, it is essential that the focus of non-pharmacological symptom management is on symptom *mastery* rather than symptom reduction, although this is also a possible outcome. Mastery over a symptom is about having control over it rather than it having control over you – a concept which patients find helpful and empowering. In other words, the approach can be explained as "while we may not take away this symptom, we can help it to have less of an impact on your life."

Breathlessness is a common, distressing symptom in advanced disease, present in about 90% of people with moderate to severe COPD, 80% of people with advanced heart failure and more than half of those living with incurable cancer (Solano et al. 2006), which is amenable to non-pharmacological management. The experience of breathlessness is characterized by the distressing sensation of being short of breath but also by the reduction in physical activity and function which frequently ensues as patients seek to avoid this unpleasant experience. The resultant downward spiral, where breathlessness leads to inactivity, which leads to muscle deconditioning, which further exacerbates breathlessness and functional decline, is frequently accompanied by escalating anxiety levels and panic attacks.

In the palliative care setting, there is evidence that non-pharmacological interventions for breathlessness, including breathing techniques, exercise, facial cooling with a handheld fan, pacing and positioning, and anxiety management strategies (Bausewein et al. 2008) are "the most effective interventions currently available to palliate breathlessness in the mobile patient" in the advanced stages of malignant and nonmalignant diseases (Booth et al. 2011). These strategies equip patients with the knowledge, skills and confidence to be more in control of their breathlessness. A recent randomized controlled trial found that a comprehensive

multiprofessional approach to support patients with advanced disease and refractory breathless – integrating input from physiotherapists, occupational therapists, as well as doctors from palliative care and respiratory medicine – effectively enhanced patient mastery and ability to self-manage their breathlessness (Higginson et al. 2014). This approach focused on patients gaining control over their breathing, being functionally active and living fully alongside breathlessness, rather than just targeting the intensity of the symptom.

Through non-pharmacological symptom management, physiotherapists and occupational therapists help people live with breathlessness, enabling patients to better manage their *functioning, breathing, and thinking* so that the breathlessness has less impact on their life and they are able to achieve their best potential (Fig. 12).

For many symptoms there are non-pharmacological treatment options that may help a person have better control over the symptom or even reduce the intensity of the symptom. Examples are found in Table 3.

6 Key Strategies for Rehabilitative Palliative Care Success

In addition to the practices and specialist interventions described above, the following are strategies that are key to realizing rehabilitative palliative care in day-to-day practice.

6.1 Create a Shared *Culture* of Rehabilitative Palliative Care

Work to build a culture across the interdisciplinary team where everyone understands what rehabilitative palliative care is and what their role is to bring it to life for patients through their day-to-day clinical practice:

- Start by raising awareness of the dominant *values* for people living with serious, advanced illness – *choice, autonomy, and dignity* – and make a conscious and active commitment across the team to support these.
- Attend to the *language* we use and critically appraise whether it is fit for purpose. Adopt and integrate the active language of rehabilitation into our palliative care dialogue such as "support" (alongside care), "living with" (instead of dying from), "goals," "empowering," "enabling," "being alongside," "coping," and "managing."
- Build rehabilitative palliative care principles and practices into service strategies, operating frameworks, service standards, job descriptions, and education initiatives – including mandatory training.
- Ensure physiotherapists and occupational therapists are core members of the palliative care team to lead and support the approach.

6.2 Champion *Early Referral* for Specialist Physiotherapy and Occupational Therapy Rehabilitation

Maximize the benefit of rehabilitation interventions for people living with life-limiting illness, by making early referrals to your physiotherapist and occupational therapist for a specialist rehabilitation assessment:

- The earlier rehabilitation begins, the better the chances of preventing avoidable deterioration, delaying physical decline, and maintaining or improving function, while there is a window of opportunity.
- Proactively equip patients to deal with distressing symptoms, unwanted functional limitations, or disability before they happen – through access to individually prescribed non-pharmacological techniques and coping strategies to self-manage their condition.
- Establish personalized enablement plans to guide the interdisciplinary team in their provision of rehabilitative palliative care support.

6.3 *Engage* and *Motivate* Patients to Achieve the Things that Are Most Important to Them

The way we engage with patients and their families sets the scene for rehabilitative palliative care to take place, starting from our very first interaction:

- Create a *collaborative partnership* based on an implicit understanding that the patient and the professional each bring expertise and solutions to the relationship and that these are equally valuable.
- Make the **first priority and goal** of our professional assessment about establishing the **patient's priorities and goals**. This is key to building engagement and rapport as it values patients as *people* and ensures any support is tailored to what is most important to them.
- Place the patients' priorities at the heart of the dialogue by making simple changes in our questioning style such as asking "What matters to you?" rather than problem-focused questions such as "What's the matter with you?"
- Empower patients to come up with their own solutions and to express what support they need to achieve what is most important to them.
- Be aware of and seek to raise patients' *activation*. This describes a patient's involvement and levels of active engagement and participation in their health and care (Hibbard et al. 2005) – or put simply describes the gap between a person having the ability to undertake an activity and whether they actually do it or not. Proactively explore factors that can lower a patient's activation such as fatigue, refractory symptoms, anxiety, or loss of confidence, and bring these out into the open to overcome or work around them.

6.4 Proactively Acknowledge and Plan for *Uncertainty*

We should ensure that rehabilitation in palliative care is both meaningful and realistic by actively inviting uncertainty into the conversation and then, as far as possible, planning for how to manage it:

- Openly acknowledge that we cannot be certain what the future holds. This is upfront, honest, and frequently welcomed by patients and families who recognize the truth in this.
- Begin from the starting point of **maximizing opportunities** for people **rather than minimizing risks**. Develop a culture of *positive risk taking* which supports patients to take risks to achieve positive personal outcomes and recognizes that while the negative consequences of risk must be managed appropriately, we can't be certain of the outcomes. This involves balancing the positive benefits gained from taking risks with the negative effects of attempting to avoid risk altogether (Morgan and Williamson 2014). In the context of palliative care, avoiding risks due to concerns of negative outcomes can deprive patients of opportunities to take positive risks that may enable them to fulfill their potential or personal goals and maintain personal agency and identity.
- Support realistic hope alongside patient safety by practicing "parallel planning" – the process of actively acknowledging and planning for two or more possibilities at the same time or put simply "hoping for the best while planning for the worst" (Tiberini and Richardson 2015). Planning for several possibilities concurrently can help to (i) introduce and allow for anticipation of possible deterioration in a safe way and (ii) help prevent crisis situations which place the patient at undue risk (Fig. 13).

6.5 Provide a Support System for Patients and Their Families to *Actively Anticipate and Cope with Loss*

Losses in physical functioning frequently represent the tip of the iceberg for a cascade of less visible "network" losses, which are intrinsically

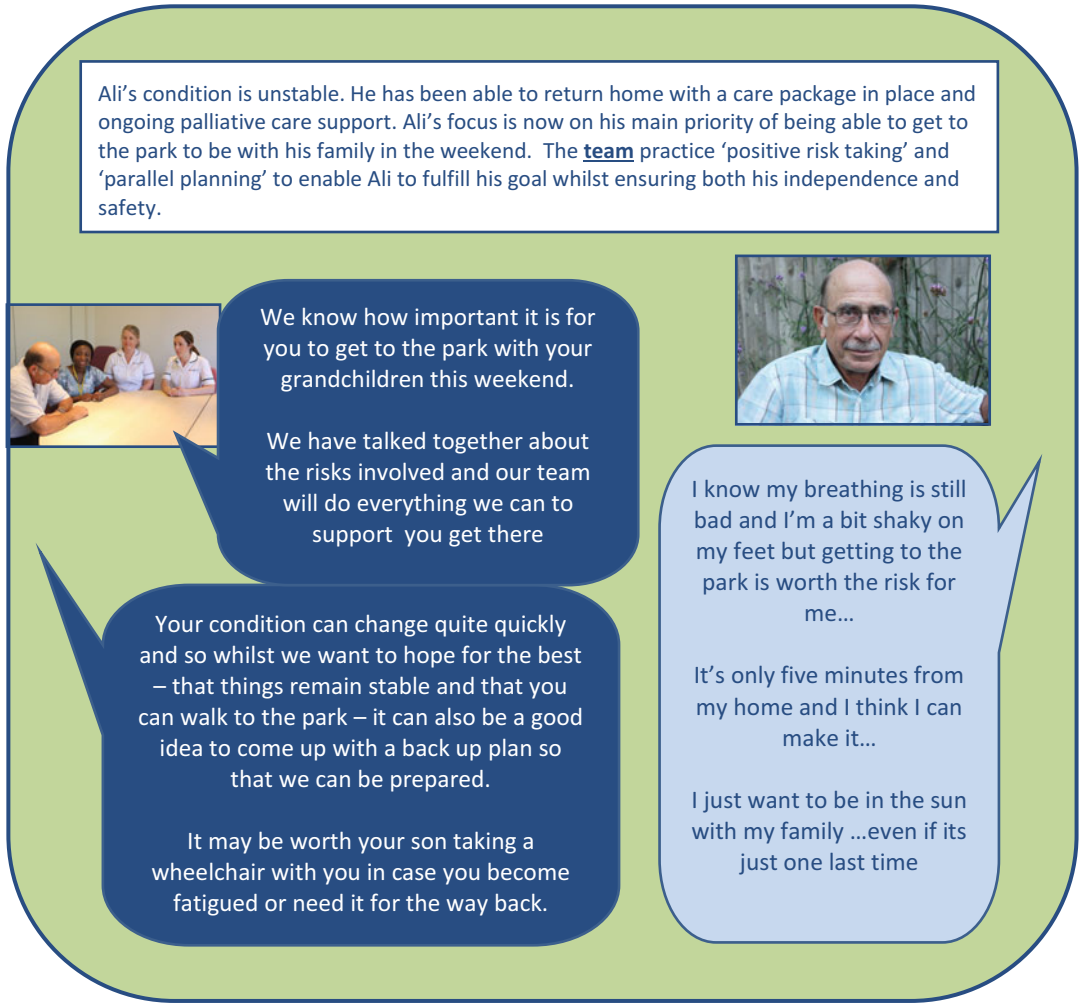

Fig. 13 Positive Risk Taking and Parallel Planning

linked with and arise from functional decline. These may include loss of independence, freedom, sexual function, career, roles, sense of self and identity, control, hope, dignity, certainty, and meaning (Jackson 2014).

- Recognize functional losses and proactively explore how these are impacting on a person's psychological, spiritual, and social well-being.
- Facilitate open, safe discussions for patients and families to share their experience of current losses and fear of future losses related to their diminishing functional capacity.
- Practice active, therapeutic listening – this can be just as rehabilitative as actually "doing" something.
- Acknowledge and validate people's grief – which can be complex as the losses are frequently permanent, unresolvable, and cumulative.
- Where possible, work in partnership with patients and families to openly anticipate future losses and come up with action and coping plans – this can be an empowering and reassuring exercise even if in the best case scenario they are never needed (Fig. 14).

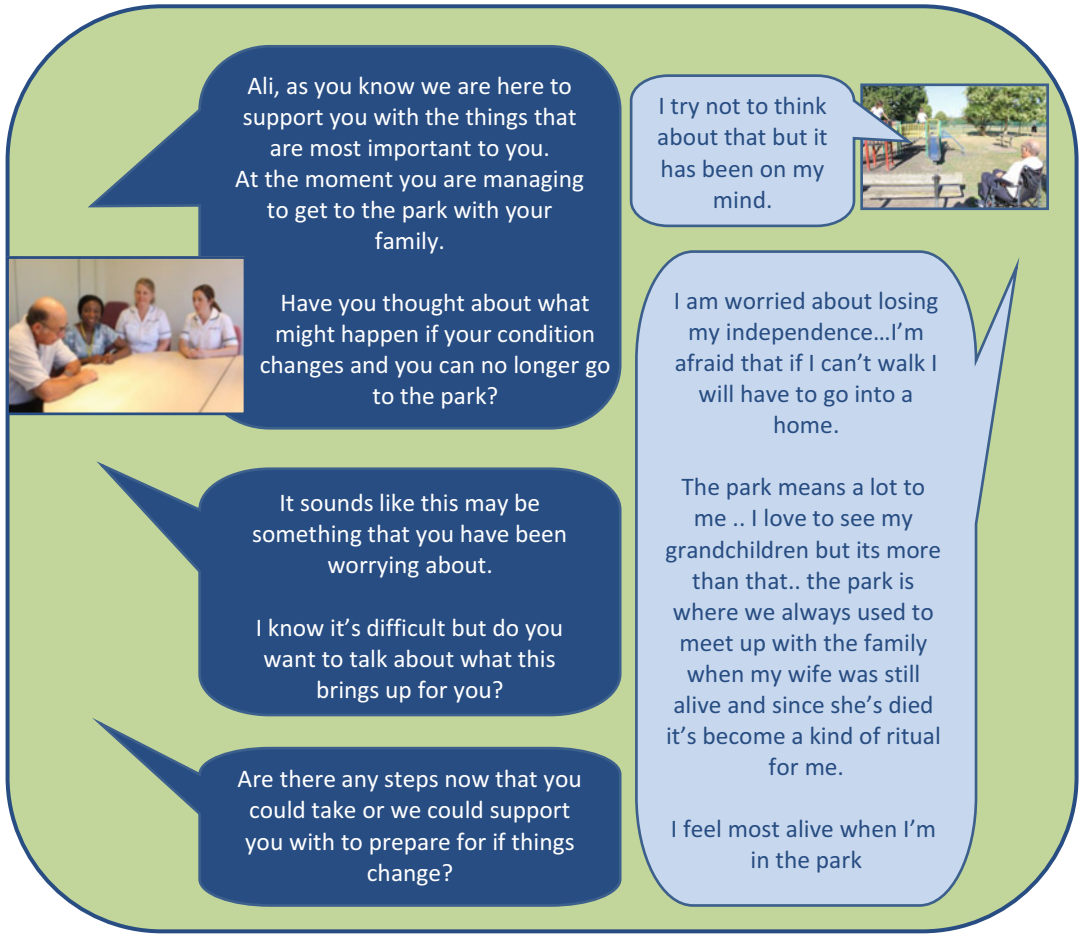

Fig. 14 Actively Planning for and Coping with Loss

7 Summary

Rehabilitation in palliative care aspires to optimize patient's choice, independence, autonomy and dignity and provides an active support system for people to live life fully until they die. It encompasses both the specialist rehabilitation contribution of occupational therapists and physiotherapists together with the crucial involvement of the wider interdisciplinary team through the practice of "rehabilitative palliative care." With patients' personal goals and priorities firmly at the heart of the approach, rehabilitation in palliative care creates a culture of enablement, through which the whole team can support patients to *live their priorities* right up until they die. Rehabilitation in palliative care is an important route to transforming people's quality of life and represents a key consideration for palliative care provision both now and in the future.

Dietetics and Nutrition in Palliative Care

36

Cathy Payne

Contents

Abstract

Good nutritional care is a fundamental component of palliative care provision. Managing issues associated with eating and drinking, weight loss, and changes in body image towards the end of life can be challenging for many patients and families, as well as for healthcare professionals. The best nutritional care happens when patients and families are provided with early, consistent, and evidence-based dietary assessment and guidance. As well as direct provision of care to patients and families, dietitians have a significant role in educating all members of the multi-disciplinary care team on the provision of

optimal nutritional care for patients with life limiting illness and in supporting the evidence base to practice through engagement in research. The aim of this chapter is to provide an overview of the role of the dietitian as a member of the specialist palliative care team and to explore dietary interventions provided when incurable progressive illness is diagnosed and when a person approaches the end of life.

1 Introduction

Dietary issues in advanced illness can be a matter of particular concern for patients and families, turning each meal into a source of anxiety. Impaired nutritional status is associated with muscle loss, reduced muscle strength, functional limitations, and increased morbidity which all impact negatively on quality of life and may reduce length of survival (Shaw and Eldridge 2015). National reports and guidance for palliative care provision recommend that dietitians are included as members of specialist palliative care teams, or work in close liaison with them (Radbruch and Payne 2010). Specialist palliative care dietitians have an advanced knowledge and understanding of the dietary aspects of life-limiting conditions and of how nutrition impacts positively and negatively upon symptom burden. They are able to provide guidance on the management of dietary problems within palliative care settings, translating the most up-to-date knowledge on food, health, and disease into practical guidance. They also enable people to make dietary choices based on their likes, dislikes, and to lessen the impact of symptoms affecting dietary intake. Dietitians can also advise on food fortification and the appropriateness of macronutrient and micronutrient supplementation to correct dietary deficiencies, dependent on the stage of illness and goals for treatment and care (Ryan et al. 2014).

Assessing the patient's nutritional intake and requirements requires a comprehensive assessment of the patient's medical, treatment, and dietary history. This includes a review of relevant available blood biochemistry results, current weight and weight history, functional limitations, psychosocial concerns, current dietary intake, nutrition-related symptoms, and dietary goals (Shaw and Eldridge 2015).

Interventions which are employed by specialist palliative care dietitians can be broadly grouped into five types: health promotion and maintenance, support for specialized dietary needs, symptom management, nutritional support, and psychosocial support.

2 Health Promotion and Maintenance

Some patients with the diagnosis of advanced progressive illness can retain a good oral intake, with or without an appetite, until the very late stages of their illness. In the absence of sufficient anabolic drive, additional energy consumed by patients above their daily requirements may be preferentially stored as fat mass. This excess fat mass increases the metabolic demands imposed on bodily systems and may potentially lead to a worsened prognosis (Harvie et al. 2005). Dietitians can provide practical guidance on appropriate lifestyle and food choices to prevent excess fat storage while maintaining the fat free mass so vital for functional well-being and for the performance of daily activities.

3 Support for Specialized Dietary Needs

Some patients have longstanding restrictions to their dietary intake which make food choices challenging, especially if desire and ability to eat are compromised. In some situations, dietary restrictions may no longer be necessary, as the potential for burden significantly exceeds any potential for benefit, for example, the adherence to a low-fat diet for management of raised cholesterol level. In other situations, continued adherence to a specialized diet is necessary to prevent additional symptom burden, for example, the adherence to a gluten-free diet for someone with symptomatic coeliac disease. Dietitians are best placed to

provide sensible dietary advice to meet nutritional requirements without compromising patient safety or comfort. Factors affecting this decision are patient benefit, patient desire, and patient intake. This role extends to working alongside catering staff to ensure that appropriate meal options are available and that dietary choice is optimized (Pereira et al. 2016). Occasionally, a person may wish to maintain strict adherence to a special diet even if this is deemed against their best interest. Excellent communication and negotiation skills are required to ensure that the patient's rights to autonomy are maintained while ensuring that they are making informed decisions in relation to their diet.

4 Symptom Management

People with advanced incurable and life-threatening conditions often develop symptoms, associated with their illness and its management, which impact upon both their desire and ability to eat. Such symptoms include dysphagia, nausea, early satiety, sore mouth, taste changes, and constipation. Active management of such symptoms can lead to perceived improvements in quality of life. See Table 1 for examples of advice given to support nutritional intake where symptoms impacting nutritional intake are present.

4.1 Dysphagia

Dysphagia is caused by any condition that weakens or damages the muscles and nerves used for swallowing. There is a high incidence and prevalence of dysphagia among patients with neurological impairment and, with head and neck cancer. Dysphagia may also occur as a consequence of cachexia (Wakabayashi et al. 2015). While coughing during eating or drinking is a common symptom of the condition, some patients may aspirate silently due to central or local weakness or poor coordination of the pharyngeal musculature, reduced laryngopharyngeal sensation, or impaired ability to produce a reflexive cough. Speech and language therapists can assess swallow and provide recommendations on safe or safest consistencies to prevent or reduce aspiration risk (Brady et al. 2015). Dietitians can subsequently provide advice and support to patients and their families on eating a modified diet which supports food choice and enjoyment, promoting weight maintenance if appropriate.

4.2 Nausea

Nausea is an unpleasant feeling of the need to vomit. Reasons for nausea may be multifactorial and may be exacerbated by stress, fear, and anxiety. It is important to treat the symptom appropriately based on a thorough assessment of its root cause and recognizing the profoundly debilitating effect the symptom has if it persists over prolonged periods of time (Del Fabbro 2016).

4.3 Poor Appetite/Early Satiety

It is not uncommon for patients in the advanced stage of progressive illness to have little or no desire to eat or to lose their appetite after a few bites of food (Solheim et al. 2014). Some patients are able to continue to eat normally in spite of early satiety, while others require advice and support to overcome its impact. Potential causes of poor appetite and early satiety include delayed gastric emptying, abdominal ascites, constipation, and changes in food tastes and smells. Reversible causes should be investigated and the dietary plans considered in relation to irreversible symptom burden (Boltong and Campbell 2013).

4.4 Sore Mouth

A sore mouth can have many causes including infection, ulceration, micronutrient deficiency, dry mouth, tumor infiltration, and dental problems such as cavities or gum irritation due to ill-fitting dentures. It is important that pain relief is optimized before meals are offered and that oral hygiene is attended to regularly to prevent additional unnecessary discomfort at mealtimes.

Table 1 Examples of advice given to support nutritional intake based on presenting symptom

Symptom	Hints and tips
Constipation	Encourage fluid intake and review necessity of any fluid restrictions if present Encourage mobility if possible A warm drink taken first thing in the morning may stimulate bowel movement If appetite is good, encourage fiber (roughage) in the diet; if not, encourage soluble fiber sources such as soft fruit, oats, beans and pulses, or root vegetables If taking a supplement drink, consider changing this to one containing fiber
Dysphagia	Avoid mixed consistencies as the liquid portion of a food bolus may be aspirated before swallow onset Avoid distractions during eating Provide utensils to control bolus size and support independence at mealtimes, e.g., use of a teaspoon or a feeding cup with a valve to control fluid flow Ensure supervision or assistance to eat if required Discuss suitability of alternative feeding options if appropriate
Nausea	Try to stay calm and relaxed at mealtimes Ensure room is well ventilated and away from cooking smells, e.g., open a window If the smell of hot food is off-putting, offer cold meals or snacks. It may be beneficial to cool food to room temperature *before* it is provided to reduce smells Try dry foods such as toast or crackers. Having regular snacks can prevent worsening of symptoms caused by an empty stomach Encourage fluids to prevent dehydration. It may be best to drink between meals rather than with food Avoid greasy, fatty, or fried foods Foods or drinks containing natural ginger extract may also help to reduce feelings of sickness Encourage the person not to lie flat immediately after eating
Poor appetite/early satiety	Provide easy access to favorite foods Use small plates/cups and offer small portions frequently Encourage to eat small amounts even when no appetite is present Encourage eating at the table with others when possible as a distraction Encourage activity to stimulate appetite
Sore mouth	Avoid very hot food and fluids. Most people find cool foods and drinks to be soothing to a sore mouth Avoid very hot, salty, spicy or acidic foods or fluids which may sting the mouth Avoid rough textured food like toast, crisp-bread, or raw vegetables and sticky foods like doughnuts and peanut butter as they can scrape or stick to a sore mouth. Provide foods moistened with sauces and gravies Drinking may be more pleasurable through a wide straw
Taste changes	Concentrate on eating a variety of foods that taste good. Taste perceptions may change over time, so retry disfavored foods to maintain dietary variety If sense of taste has decreased, choose highly flavored foods If food tastes metallic, try using nonmetallic cutlery, marinating meat or chicken or garnishing with pickle or chutney Ensure foods are moist and easy to eat and avoid foods that remain in the mouth for long periods requiring lots of chewing Follow good oral hygiene practices Sip fluids through a straw to bypass the taste buds

Towards the end of life, oral complications increase in prevalence (Matsuo et al. 2016). Dry mouth is a common side effect of many prescription and nonprescription drugs, including antidepressants, analgesics, anxiolytics, antihypertensives, antipsychotics, diuretics, and anti-Parkinson's drugs. Dry mouth can also be a side effect of muscle relaxants and sedatives. It can also result from the side effects of certain diseases and infections including Sjögren's syndrome, HIV/AIDS, Alzheimer's disease, diabetes, anemia, cystic fibrosis, rheumatoid arthritis, hypertension, Parkinson's disease, stroke, and mumps. A review of medication can be helpful in

identifying which, if any, medications can be stopped to improve this symptom.

4.5 Taste Changes

Taste changes are a recognized contributor to loss of appetite in advanced illness, and especially in advanced cancer (Mahmoud et al. 2011). Foods can taste sweet, salty, metallic, bitter, fishy, like cardboard or cotton-wool. In a prospective cohort study of 192 Canadians with locally advanced or metastatic cancer, 74% of participants reported taste and smell aberrations. This corresponded with a consumption of 20–25% less calories per day, as well as a marked reduction in protein intake, compared to those without altered taste or smell. Symptoms included heightened, dulled, or altered perceptions in food smells, and these patients tended to lose more weight and report a poorer perceived quality of life (Brisbois et al. 2011). Other factors that influence these taste changes are many and include deficiencies in nutrients (such as zinc, niacin, or vitamin A), medications, poor oral hygiene, changes to saliva (too much and/or too little), nerve damage (in head and neck cancers), smoking or poorly fitting dentures because of weight loss, for example. It is theoretically possible to reduce the effect of these changes by supplementing the diet with nutrients and vitamins such as vitamin A, copper, nickel, zinc, niacin, or iron. These should only be added to a diet under the supervision of a health professional.

4.6 Constipation

Constipation is one of the most frequently encountered symptoms in palliative care impacting on a patient's quality of life and potentially requiring pharmacological intervention especially when the patient is receiving opioid pain relief. Both a softener and stimulant laxative are generally recommended for optimal management (Larkin et al. 2008). As part of the multidisciplinary team, the dietitian should ensure that there is early intervention and treatment of constipation and that laxative regimes and dietary intake is carefully re-evaluated when constipation has resolved (Linton 2014).

5 Nutritional Support

Unintentional weight loss is very common in advanced incurable illness, often prompting referral for dietary assessment and review. Concern over weight loss is not unreasonable since spontaneous weight loss is unnatural and poses a threat to health and well-being (Baracos and Parsons 2010). Nutrition support can be a life prolonging therapy for patients who are unable to meet nutrient needs due to mechanical or functional problems. Early intervention in such situations can prevent, minimize, or correcting reversible weight loss (Fearon et al. 2011). Calculating energy requirements in advanced illness is challenging as changes in body composition, including disease-related reduction in fat free mass, can significantly affect energy expenditure and macro- and micronutrient needs (Elmadfa and Meyer 2008). Metabolic disturbances, dietary and gastrointestinal symptoms, and psychosocial distress all combine to affect macro- and micronutrient requirements. In particular, the potential role that micronutrient deficiencies may have in inefficient energy processing and in the development and perpetuation of inflammation is a key target of ongoing nutritional research (Baracos and Parsons 2010).

Alongside the wider healthcare team, dietitians can ensure that an appropriate nutritional support care is plan is implemented, continuously evaluated, and revised to meet the individual's ongoing nutritional needs and preferences. It is never ethically defensible to withhold oral food or fluids from a patient; however, desire to eat and drink naturally declines during the dying process as the body's systems shut down (Maillet et al. 2013). As core members of the multidisciplinary palliative care team, dietitians can facilitate discussions on the potential benefits and burdens of supplemented oral, enteral and parenteral nutrition for individuals with life-limiting conditions and their families to enable

informed decision making (Schwartz et al. 2016). Nutritional support can be provided to patients orally, enterally (via a feeding tube placed within the stomach or upper bowel), or parenterally (via an intravenous catheter).

5.1 Oral Nutritional Supplements

Oral nutritional supplements (ONS) are widely used within the acute and community health settings for individuals who are unable to meet their nutritional requirements through oral diet alone. They come in a variety of different types. These include:

- Juice, milkshake, yoghurt, or soup type drinks
- Pudding or dessert type
- Flavored or unflavored powders and liquids can be used to fortify foods or drinks

These products are not intended to be a replacement for meals and snacks but rather complement or supplement usual diet (Shaw and Eldridge 2015). While these products are useful in counteracting normal starvation, ONS have not been shown to have survival benefits in those with disease-related malnutrition (Baldwin 2011; Balstad et al. 2014a, b). A recent systematic review (13 studies with 1414 participants) compared ONS interventions against standard care for malnourished patients receiving curative or palliative treatment for any cancer diagnosis (Baldwin et al. 2012). While the analysis was limited by study heterogeneity, but the authors stated that, although ONS increased dietary intake and improved some quality of life indices, such as poor appetite or global quality of life scores, there was no evidence that nutrition interventions alone could improve survival rates. Additionally, while oral nutritional supplements are frequently prescribed for those presenting with unintentional weight loss and reduced appetite, compliance with prescribed supplements is often poor and dietary counselling has been determined to be more effective in unintentional weight loss prevention (Balstad et al. 2014a).

5.2 Enteral Nutrition

Enteral feeding tube permits nutritional support for those who have a functional digestive tract but are unable to take adequate nutrition orally. Regular review by the dietitian is necessary to balance the delivery of adequate nutrition and fluids to meet the person's individual needs. Standard polymeric formulas are most commonly used, designed to mimic a normal dietary intake of carbohydrate, protein, fat, vitamins, and minerals (Shaw and Eldridge 2015). Special feeds are also available to support those who require nutrient modifications due to issues such as electrolyte imbalance, malabsorption, fluid overload, or critical illness. Where appropriate, the dietitian can advise the patient and/or their family on how to manage an enteral feeding regime at home (Howard 2009).

5.3 Parenteral Nutrition

Parenteral feeding is primarily used to permit nutritional support in those who have a nonfunctioning or inaccessible digestive tract. Since parenteral feeding bypasses the bodies' normal digestive processes, regular review is essential to ensure the delivery of appropriate levels of macro- and micronutrients. While standardized solutions can be used, total parenteral nutrition is frequently tailored to meet individual patient requirements (Pertkiewicz and Dudrick 2009). The use of parenteral nutrition within palliative care varies widely between countries and is generally discouraged in those with a life-expectancy of less than 2 months owing to the likelihood that the burdens of the intervention will outweigh any benefit (Bozzetti et al. 2009).

6 Psychosocial Support

As appetite reduces or unintentional weight loss is observed, families may feel it is their duty to encourage their loved one to eat more. Such encouragement in the face of deteriorating health can become distressing for all concerned,

especially when unintentional weight loss persists and meals are regularly refused (Amano et al. 2016). While oral nutritional supplements and artificial feeding using enteral or parenteral routes can compensate for micronutrient and macronutrient insufficiency, they are no substitute for the physical and psychosocial pleasures that most people gain from eating. If nutritional support is provided, it should not be so invasive or unacceptable that it impairs rather than improves quality of life. Dietitians are able to support families directly or to support other health professionals in the appropriate management of the physical, psychological, and social impacts of appetite loss and changes in body image. By explaining the causes of weight loss, patients and families may be able to better come to terms with body changes and are more prepared to deal with irreversible weight loss in the latter stages of active disease processes (Hopkinson et al. 2013).

Dietitians can do much to support psychological well-being and maintain positive family interactions at mealtimes. If weight loss is refractory, patients may still enjoy eating very small quantities of their favorite foods to savor their flavor and texture and to remain a part of family social gatherings. Maintaining optimal quality-of-life rather than optimizing nutritional intake is usually the primary goal of dietary interventions towards the end of life (Scott et al. 2016).

7 Dietitians as Palliative Care Researchers

Part of the role of specialist dietitians is to support the creation of better palliative care nutritional knowledge through engagement in clinical research. This is best achieved by working as part of a multiprofessional research team using robust trial methodology and recruitment strategies to ensure that nutrition-related trials are appropriately powered and conducted. Nutritional research is challenging and in the face of insufficient evidence every effort is taken to build nutritional guidance for palliative care that synthesizes all available sources of evidence (Eva and Payne 2014).

8 Conclusions and Summary

As members of the specialist palliative care team, dietitians exploit the potential to improve quality of life through the effective management of issues relating to nutrition, physical, psychological, social, and spiritual. Dietitians support the multidisciplinary team in developing nutritional management plans which reflect the best evidence and individual patient wishes and are constantly seeking to improve the evidence base for practice.

burnout and avoiding the potential damaging impact of vicarious traumatization or compassion fatigue. This chapter explores the palliative care work environment and identifies potential stressors. A range of activities is suggested that have been shown to be effective in mitigating the impact of various occupational stressors.

> The care of the dying and bereaved people is a great challenge. It can be the most stressful part of our work, but it can also be the most rewarding. The rewards are likely to outweigh the stress only if our needs for support are met. (Parkes et al. 1996, p. 30)

1 Introduction

This chapter will explore the palliative care environment and the challenges faced by health professionals when working with dying and death. We will examine specific stressors in the context of palliative care, as well as the subsequent possible experiences of clinicians. Outcomes discussed, that may arise from these experiences include: vicarious trauma, compassion fatigue, secondary traumatic stress, compassion satisfaction, and burnout. We then examine the role that resilience may play in mitigating the effect of such stressors. A range of personal, professional, and organizational obligations will be discussed. Finally, several strategies for identifying and managing potential stressors will be described along with strategies for enhancing one's professional and personal life.

A number of researchers over many years have explored the palliative care environment and have reported their views as to what it is that enables people to work in this complex, difficult, and challenging role. Mary Vachon (1995) talks of health professionals who choose to work in palliative care as having a personal belief around illness, death, and the meaning one makes of one's life. She believes that these dimensions of their lives and personal belief systems contribute toward enabling health professionals to work in this demanding role. In her 1995 review of the literature of stress in palliative care over the first quarter century of the movement, Vachon found that many studies reported staff working in palliative care as having either less burnout and stress than other professionals or that they experienced no more stress than other health-care professionals working with seriously ill and/or dying persons. More recently, Pereira et al. 2011 reviewed the palliative care burnout literature from 1999 to 2009 and also found that burnout levels in palliative care, or other related health-care settings, did not seem to be higher than in other contexts. This finding was also confirmed by Gélinas and colleagues in their 2012 study of Quebec nurses working in end of life care. They found that nurses working in hospital settings such as critical care and oncology showed higher stress indicators when compared with nurses working in specialized palliative care units.

Importantly, and fundamental to being able to work in palliative care, is the view that death is part of the life cycle and is not seen as a failure of medicine or of the health professional. Death can be regarded by some health professionals as the "final enemy" and dying, a failure on the part of staff to prevent that happening. This has contributed to the notion of the "good death." Richard Egan (2008) has argued that it is not death that is the failure; rather, it is our attitude toward death that may be the failure. He believes that it is the illusion that medicine can "cure all" that incapacitates us all. This "cure all" view of medicine contrasts markedly with hospice philosophy which has at the core the concept of a good death and embraces a philosophy of openness about death and an acceptance of its reality. Such views about dying and death mean that palliative care staff are less likely to have avoidance patterns to dying and death than peers in other health settings and particularly low levels of death anxiety. It may be that palliative care professionals with low death anxiety have chosen palliative care as a preferred work specialty or that the overexposure to death, along with the hospice philosophy and specific training on this topic and staff support, has served to decrease this anxiety. It is also possible that palliative care staff have confronted their own mortality and are therefore comfortable with the meaning of life and death.

For many staff, both clinical and administrative, the choice to work in palliative care can be directly linked to experiences they may have had in relation to the death of family, friends, or dying patients they have previously cared for (Huggard 2008).

This meaning-making appears to be a key "enabler" to working in palliative care and has been discussed by several researchers. Palliative care nurses' ability to find meaning in their work is well documented (Fillion et al. 2006). Research by Desbiens and Fillion (2007) involving 120 Canadian palliative care nurses examined the use of meaning-making strategies in association with emotional outcomes. Results from this study showed that the nurses' capacity to find meaning in the work they do with the dying enabled them to not only positively adapt to the deaths of their patients but also allowed them to have a better spiritual quality of life.

Despite the possibilities of a stressful and emotionally demanding work environment working in palliative care, clinicians working in this field have described feelings of satisfaction and a heightened appreciation of the spiritual and existential elements of their life. These experiences include an appreciation of the reciprocal healing process; inner self-reflection; connection with their peers, family, and their wider professional and personal community; and an enhanced sense of spirituality (Kearney et al. 2009).

2 The Palliative Care Environment

Early research by Vachon (1987) identified that 48% of the occupational stressors in palliative care came from the "work environment," with 29% deriving from one's "occupational role" and 17% from working with "patients and families." A small percentage, 7%, was derived from illness related variables such as addressing pain management and symptom control. While there have been numerous studies done since this time, the above broad themes still remain relevant today when looking at stressors in the field of palliative care. Environmental stressors, including work overload, team conflict, administrative problems, interprofessional communication, and role conflict, are all potential stressors and may be more stressful than any stress resulting from interaction with patients and their families. (Vachon and Huggard 2010). Vachon (1995) found that professionals working in palliative care did not have higher levels of stress than others working with seriously ill or terminal patients and, in fact, had less stress than professionals working in other settings. One possibility for this may be because the struggle to find a cure is over and the palliative approach, with its realistic goals and care plans, is more manageable, and that potential stressors are anticipated and coping mechanisms are implemented, and that hospice nurses have a level of autonomy that serves to mitigate stress. The shared philosophy of care, the recognition given to staff that the work they do is of value, the evidence of support, and that generally the staff-patient ratios are manageable are all factors that may contribute to less stress in this workforce.

2.1 Nurses

The concept of nursing being a potentially stressful occupation was identified by Florence Nightingale: "The concept of stress has been of concern to nurses since 1859" (Foxall et al. 1990, p. 578). A significant stressor for palliative care nurses, and indeed nurses working in many other sectors, is role confusion, particularly often around unresolved role definition conflicts and the subsequent conflict and tensions arising between multidisciplinary staff members. Being unsupported can leave staff feeling vulnerable and emotionally fraught, particularly if the work of individuals is not acknowledged or valued. Other potential stressors can be the management of complex symptoms, administrative and communication difficulties, dealing with family dynamics, and working with doctors unfamiliar with the palliative care and hospice culture. Further organizational stressor issues include communication difficulties with managers in relation to administrative issues, heavy workload, complexities of care, and insufficient staff allocations. There

may also be a sense of pressure around time constraints in being able to provide the degree of care that staff felt was needed. This can give rise to stress and frustration as it impedes the quality of time spent with patients and limits nurse's ability to be innovative in their practice.

As in many other areas of nursing, organizational stressors can include the degree of responsibility held, workload, physically arduous work, shift work, home/work conflict, interpersonal conflict, responsibility for training, uncertainty and unpredictability, and managing change.

2.2 Doctors

Work overload and the effects of the work on home life can be two of the most significant work stressors for physicians, as well as keeping up to date with current knowledge and fear of making mistakes. However, issues related to death and dying do not appear to be significant sources of stress for palliative care physicians. What can be distressing is the absence of control and workplace social support. Issues such as dealing with management, being on call, excessive paperwork, insufficient free time, lack of personal control over clinical practice, and dealing with the emotional aspects of life can all contribute as stressors in a physician's life. The constant exposure to the dying and their families, the complex issues of symptom control, relieving pain, and the very nature of the difficult conversations necessary to be had with patients all can increase the likelihood of role strain (Kearney et al. 2009).

2.3 Working with Families

For some professionals working in palliative care, communicating with distressed family members can be one of the major stressors. The terminal illness of a family member can bring with it significant disruption to the family, along with feelings of uncertainty, fear, anxiety, and anger. Adjusting to death is one of the most difficult of the life's transitions that individuals have to make. It should not be surprising therefore that managing family dynamics can be problematic for palliative care staff. Given the nature of the holistic care given to families, nurses and other palliative care professionals usually spend more time with family members than do staff in other fields of health care. These stressors can come about as a result of the time and emotional energy spent dealing with family issues, particularly with relatives of the patient. However, this is a necessary feature of the work of a palliative care clinician and the development of a therapeutic relationship with patients and families important for maximizing care. A study by Canning et al. (2007) of Australian palliative care nurses found that developing effective communication relationships with patients and their families was an important aspect of their care. Of significance was the need to share information between the nurses and the families, keeping open the channels of communication. The nurses in this study also reported the need for mutually agreed boundaries in the therapeutic relationship particularly when there are many interdisciplinary professionals involved in the care.

There may be additional communication problems faced by staff concerning patients and families from different cultural backgrounds. Bray and Goodyear-Smith (2007) found that palliative care nurses found working with people from ethnic minorities stressful as communication can often be difficult and can give rise to issues of cultural safety due to a lack of knowledge of cultural differences. The stress associated with looking after the terminally ill, however, needs to be counterbalanced by the satisfaction gained by working with these patients and their families. Palliative care professionals acknowledge the rewards experienced in having time to develop meaningful relationships with the dying and their families and gain a sense of making a difference in what they do.

2.4 Death and Dying

Although professionals working in palliative care are repeatedly subjected to loss and grief, exposure to death and dying has not emerged as a

major source of job stress in palliative care (Huggard 2008). This supports the notion that intimate contact with dying patients, such as that experienced by palliative care staff, does not contribute to the creation of an inherently stressful job. These experiences can reinforce the work that palliative care staff do. Working with dying patients can have many positive outcomes for staff and can be a source of much personal growth and satisfaction. Being present at the deaths of many patients can be a very professionally and personally positive and spiritual experience. However, those working with dying patients and their families can have specific emotional demands not realized by those who do not (Fillion et al. 2006). Palliative care staff are intimately involved with dying and death, and the nature of this work can lead to them experiencing personal loss and grief when their patients die. There are many losses for patients before their death, and witnessing their suffering may leave health professionals feeling vulnerable and at risk of becoming overburdened.

2.5 The "Good Death"

> We talk of good deaths. We mean that we will leave the world in a mindful way. We mean that in the fullness of time and after a satisfactory journey we will engage with our deaths, make peace with the past, complete whatever is left to be done in the present and die in a dignified and companionable way. (Ward 2008, p. 335)

One of the rewarding aspects of working in palliative care is seeing patients die a peaceful, dignified, and comfortable death. Such a "good death" is seen as a success. However, not all deaths are peaceful nor are they dignified, and it is important to acknowledge what may be unrealistic expectations around the pursuit of the perfect death and that such an "unspoken ideal" is often impossible to achieve and may lead to a sense of guilt or powerlessness for staff when these "imperfect" deaths occur. Many palliative care staff do have difficulty coping with the death of a patient if they feel it has not been well managed, and this may be because symptoms were complex and not able to be adequately controlled or that pain was not able to be fully managed. Additionally, patients and their families who struggle to accept the imminence of the death, along with difficult family dynamics, can contribute to difficulties in coping for palliative care staff. Particularly in this case, if the staff feel they have not been able to give the amount of time to the patients and their families, that they feel is necessary. Multiple deaths in a short period of time may also contribute to a sense of emotional vulnerability on the part of palliative care staff. It is clear that palliative care staff need to have sufficient time to be with patients and their families and to be able to manage the intense emotional aspects of their work.

2.6 Grieving and Mourning

Health-care professionals' grief experience and its impact have not been well understood (Shimoinaba et al. 2009). Palliative care staff, and in fact all health-care professionals, need sufficient time and support to process the death of patients. Sometimes, due to staffing levels and workload commitments, staff have to move straight away from a patient death to caring for other patients and their families. Time may not be immediately available to appropriately grieve, and the grief may be disenfranchised or hidden if recognition is not given to their need and time to grieve. The emotional pain experienced by witnessing the grief of others may intensify feelings of helplessness and inadequacy. Working with the dying can mean that palliative care staff may reflect on their own past losses and grief. If staff minimize or deny this emotional distress, and if it is not addressed in the longer term, the cumulative effects of grief can become overwhelming and lead to burnout or compassion fatigue.

Early research by Smith-Stoner and Frost (1998) described cumulative stresses as stress stored in the "shadow self," and call the unresolved sadness "shadow grief." These authors believe that nurses carry a heavy load of shadow grief due to the losses they encounter on a daily basis and suggest that the personal work nurses need to do is to find ways to "lift the shadow" by

acknowledging and grieving these losses. The grieving process is the way loss is reconciled. Time must be given to staff to fully grieve the losses. If staff are not given this opportunity, the impact of such grief experiences may be cumulative and lead to burnout and compassion fatigue which can prevent professionals from being able to be emotionally present for their patients. As a means of processing one's grief, there must be time to mourn. Activities such as attending funerals or memorial services for those who need to or want to are important ways of doing this. Other ways of managing this mourning process include establishing a memo board or scrapbooks to display thank you letters and cards of appreciation from families, having various bereavement events such as memorial services that honor and remember those that have died, acknowledging the deaths at regular team meetings, engaging in rituals such as lighting a candle for those who have died, and sending bereavement cards to families.

3 Resilience

Although much of the earlier research on resilience involved studies of children and adolescents (Aburn et al. 2016), more recent research has focused on health professionals (McCann et al. 2013). Although there appears to be no universal definition (Aburn et al. 2016), a variety of definitions have emerged for resilience. The literature review by McCann took, as a definition of resilience, the ability to maintain personal and professional well-being in the face of ongoing work stress and adversity. McCann's review focused on literature discussing a number of health professional groups and reviewed the studies in relation to coping as a means to improve well-being, resilience, and hardiness and the report of any components of resilience specific to each health discipline. They found that only gender (more specifically, being female) and maintaining a work-life balance have been found to consistently relate to resilience across all of the health professional groups reporting on resilience. Other factors related to resilience included laughter/humor, self-reflection/insight, beliefs/spirituality, and professional identity.

To manage workplace stress, engagement in a variety of coping strategies is needed. These strategies include problem-focused coping, taking time out, and giving and receiving support from co-workers, seeking emotional support, realistic belief systems, self-control, and positive reappraisal. In addition to these positive coping strategies, staff need to be alert to the presence of negative strategies, such as suppression and denial, which can significantly increase the negative effects of stress. Ablett and Jones (2007), in their study of hospice nurses, reported ten themes that related to interpersonal aspects and to the participant's beliefs as to their own ability to do the work required of them. The themes were (1) an active choice to work in palliative care, (2) that past personal experiences influence care-giving, (3) personal attitudes to care-giving, (4) personal attitudes to life and death, (5) awareness of one's own spirituality, (6) personal attitudes toward work, (7) aspects of job satisfaction, (8) aspects of job stress, (9) ways of coping, and (10) personal and professional issues and boundaries. Central to these ten themes were the nurses' beliefs about their commitment to their work in palliative care and their belief that they could make a difference. A recommendation from a literature review of personal resilience in the nursing literature by Jackson et al. (2007) was that resilience can be strengthened in nurses through strategies and mentorship programs. Their recommendation was that such programs should aim to develop positive and nurturing professional relationships and encourage positivity, emotional insight, life balance, spirituality, and personal reflection. What is clear from these studies is that nurses working in hospice and palliative care employ a variety of strategies that enable them to positively and effectively manage the demands of this work and enhance resilience.

Through a qualitative online survey of 30 American physicians practicing hospice and palliative medicine, Swetz et al. (2009) found exercise and physical well-being, nurturing professional relationships, discussing feelings, and valuing relationships with others to be the most

common wellness-promoting strategies reported. Commonly reported strategies also included coping activities aimed at improving the work environment, namely, ensuring clinical variety, making time within the day for oneself, and engaging in meditation, personal reflection, and reflection with others. Shapiro et al. (2011) have presented an individualistic model for identifying strategies physicians employ to gain and regain a sense of control when caring for patients. The model had four modes of control. Positive assertive and positive yielding represent the positive modes of control, while negative assertive and negative yielding represent the negative modes of control. They suggested that interventions that aim to increase self-awareness and reflective capacity and being mindful of emotion regulation might enable physicians to cope better with loss of control. Being self-aware assists physicians to recognize their responses and to interrupt negative behaviors and reactions through mindfulness emotion regulation. This can then assist them to recognize situations where they are attempting to regain a sense of control and, instead, engage in more positive responses, such as assertion and letting go. This model does not consider the impact of organizational factors on the physician's ability to cope with low control. Chittenden and Ritchie (2011), however, include both individual and contextual factors in recommendations for improving physician work-life balance and subsequent well-being. They suggest that to achieve work-life balance physicians should maximize job fit by finding work that is flexible, consciously slow down; cultivate mindfulness; make personal and professional values and goals explicit; take care of physical, emotional, and spiritual needs; learn to ask for and accept help; and identify sources of emotional and practical support.

In a study of 253 New Zealand physicians, Huggard (2013) examined the relationship between compassion fatigue and burnout and resilience, spirituality, empathy, and emotional competence. Findings from the study indicated negative and significant correlations between resilience, spirituality, and emotional competence and burnout and compassion fatigue. The survey item having strongest and negative correlation with compassion fatigue was *I feel able to initiate access to additional support, if required, to help me to understand and manage my emotions in relation to my patients*. This provides some insight into the role that having a well-developed level of emotional competence might have in mitigating the impact of emotional distress and identifies the need for them to have someone who can support them.

A pilot study led by the current authors gave individual hospice staff – nurses, physicians, and family support staff – the opportunity to define resilience from their perspective. Results were obtained using a Delphi consensus methodology. The most commonly identified themes reported were maintaining a good work-life balance, maintaining clear professional boundaries at work, having a sense of humor, developing strong and trusting collegial relationships and support at work, having a passion for palliative care work, engaging in self-reflective practice, and having a spiritual belief system. Of these themes, engaging in self-reflective practice has appeared in other research (Jackson et al. 2007; McCann et al. 2013; Aburn et al. 2016) and seems to be key to enabling staff to work in what is an emotionally demanding work environment.

The notion of "happiness" is a key concept in relation to resilience. An understanding of this is located within the field of positive psychology and explores ways of minimizing suffering and increasing happiness. Happy people have been shown to be healthier, more successful, and more socially engaged. Recent work by Seligman (2012) has offered ways of helping individuals find ways to flourish by focusing on developing positive emotions, through engagement and enhancing relationships, by finding meaning in one's work and life, and by gaining a sense of achievement. The role played by positive emotions assists in the development of psychological resilience. These positive emotions assist to manage negative emotions and to deal with challenging situations. Research by Bolier and colleagues in 2013, and earlier by Tugarde et al. in 2007, demonstrated the role of positive emotions and self-care in assisting the development of resilience. A recent example of using this approach,

utilizing the *Three Good Things* intervention approach, was reported by Rippstein-Leuenberger et al. (2017). This study emphasized ways to encourage positive emotions, through having supportive relationships, being open in communication, engaging in common activities, and making meaningful use of time away from work.

4 Vicarious Trauma and Burnout

Individuals working in health care have been shown to experience significant personal and professional distress related to factors such as lack of autonomy, difficulty balancing personal and professional life, excessive administrative tasks, and high work load. In addition to the personal impact, such workplace stressors and subsequent burnouts have been linked to the quality of patient care. For example, a study of 115 medical residents reported that 76 percent met criteria for burnout and were significantly more likely than those without burnout to report suboptimal patient care at least monthly (Shanafelt et al. 2002).

One of the greatest privileges offered to any clinician is to provide relief to the suffering – be it physical, mental, or spiritual – of others. However, bearing witness to the suffering of others can carry an additional risk of burnout for the health professional when such exposure results in the clinician becoming overwhelmed, which may result in vicarious traumatization – often referred to as compassion fatigue or secondary traumatic stress. Perhaps it is more important in the field of caring for the dying than any other to understand the potential impact of vicarious trauma on the clinician and those in their care and for both the clinician and those managing clinical services to actively engage in strategies to mitigate its potentially distressing effects. Although there is a growing body of literature reporting the possible effects of witnessing the suffering of others, there are few published studies of processes that mitigate these effects.

Three researchers are responsible for initial explorations on the nature of distressing emotional responses experienced by health professionals. They each describe such consequences from slightly different perspectives and using different terms. Charles Figley (1995) promotes the term "compassion fatigue" to describe this phenomenon, Laurie Anne Pearlman and Karen Saakvitne refer to it as "vicarious trauma" (1995), and Beth Hudnall Stamm employs the phrase "secondary traumatic stress" (2010). Although there are conceptual differences in compassion fatigue, vicarious traumatization, and secondary traumatic stress, they all are part of the larger picture of possible negative consequences of caring for traumatized patients and their families with some researchers disagreeing as to the individual nature of these three constructs. Although there are large overlaps and ambiguity in the characterization of these constructs, this highlights the need to appraise current understandings among the literature, when discussing the distinctions and differences between the terms "compassion fatigue," "vicarious trauma," and "secondary traumatic stress."

Although these terms may all be used to describe a secondary traumatic stress response, these processes may in fact differ on a phenomenological level. There have been attempts to address the confusion that exists regarding these various terms, and while there are reported differences, the constructs are not mutually exclusive – each contributes to the overall understanding and articulation of the positive and negative aspects of caring. Current thinking is that compassion fatigue occurs when there is a combination of burnout plus experiences that lead to the development of vicarious traumatization (Huggard et al. 2013).

While some view these three constructs as different, there are also differences between them and burnout. The differences appear to be that burnout relates to feelings of hopelessness, work-related problems, high workload, lack of professional support in the workplace, and feeling as if work efforts do not make a difference in the lives of those being served and usually has a slow onset and is often the result of long-term work-related issues. On the other hand, vicarious traumatization occurs as a result of specific secondary exposure to traumatic events.

A large variety of symptoms are linked to vicarious traumatization, including those normally associated with burnout (such as emotional exhaustion, a lack of personal accomplishment, and depersonalization), increasing difficulties in bearing further witness to the suffering of others, symptoms of posttraumatic stress disorder (such as hyperarousal, intrusive imagery, and hypervigilance), physical symptoms (such as insomnia, headaches, and somatization), a variety of avoidance behaviors (particularly avoidance of certain patients), feelings of helplessness and a diminished sense of enjoyment, and an increased sense of personal vulnerability and loss of hope (Kearney et al. 2009; Vachon et al. 2015).

A further construct – compassion satisfaction – was first reported by Stamm (2002). She describes the balancing act between compassion fatigue and job satisfaction, and while health professionals may experience compassion fatigue, their role can bring much satisfaction and with this many positive benefits. Stamm describes this as "compassion satisfaction" and suggests that the belief health professionals have that what they are doing is helping others may indeed be redemptive. Earlier, Lamendola (1996) used the phrases "burning brightly" or "burning dimly" as a different way to describe compassion enrichment versus compassion fatigue. When burning brightly, compassion flows and there can be peace and acceptance, whereas burning dimly is characterized by tiredness, a lack of energy, and an inability for health professionals to be fully present with the pain and suffering around them. Being sensitive to what is happening in this state and putting self-care measures in place can prevent moving from burning dimly to burning out.

5 Caring for Ourselves: Strategies and Practice

In 2001, Barbara Dane and Esther Chachkes, in the journal *Social Work in Health Care*, wrote "Staff support is a necessity, not a luxury" (p. 46). This is a fundamental "truism" for working in health care and in particular, palliative care. Their findings indicated that a positive work environment with supportive colleagues and supervisors was found to mitigate workplace stress. One important aspect of their findings was that support from friends and family was not sufficient to sustain them, as the reality of the work they did was not understood, thereby making it difficult for family and friends to empathize in the same way that colleagues in the field were able to. This emphasizes the need to undertake debriefing within the workplace and that this opportunity needs to be offered by ones employer.

5.1 Staff Support

Support can be present and felt in a variety of ways and through different processes. The challenge for health-care organizations is to find ways to care for their staff in the same way that staff care for their patients (Huggard 2003). Positive outcomes of effective staff support have been shown to include better personal health and satisfaction with work (Hulbert and Morrison 2006). Gathering together to share experiences, in either a formal or informal way, has been shown to have positive outcomes. The use of support groups has been recommended as important in providing social support (Hawkins et al. 2007), and as far back as reported in Alexander and Ritchie's 1990 study, their role in encouraging staff to reflect on their practice resulted in reduced stress and enhanced practice. In the Dane and Chachkes' (2001) study, staff found that support groups promoted the connections between them and other colleagues and reduced the isolation they sometimes felt.

Staff support practices, within any organization, generally fall into two broad categories. Firstly, there is the need for policies that provide a professional development framework for staff such as appropriate recruitment and orientation, performance management processes, and professional development and education opportunities and secondly, policy that acknowledges and provides for the emotional and psychological support for staff, such as supervision, debriefing, feedback, healthy rostering practices, and regular

forums for communication. Organizational support and understanding are critical, and this support should be integrated into the everyday working life, rather than at a time of crisis (Danieli 2006). There is a need for further research aimed at demonstrating the value and effectiveness of a variety of supportive processes. A systematic review of staff support practices in palliative care by Ieroo Ha and the current authors (2013) identified that positive changes occurred in how staff perceived their role as a result of either staff support or educational interventions.

5.2 Organizational Support Frameworks

Inadequate and ineffective organizational support structures to care for professional caregivers have been previously highlighted, particularly with respect to managing grief (Shimoinaba et al. 2009). Meier and Beresford (2005) described the need for efficient and effective infrastructures in palliative care services so that administrative systems can reliably support the health professionals to do their job. Such infrastructure includes human resource policies and procedures, adequate staffing, effective management structures, staff support and scheduled meetings, and team briefs. Additionally, inefficient management structures and communication systems, as well as ineffective leadership and blurred role boundaries, all contribute to unnecessary stress for hospice staff. It is important that both managers and clinicians monitor the organizational climate carefully, with particular reference to staff relations and any staff conflict evident. In palliative care services, the main sources of perceived conflict were lack of psychological support, the absence of staff meetings, and problems with the decision-making process (Azoulay et al. 2009) with conflict not being dealt with having major repercussions on team functioning and are a source of stress. Another factor for staff working in palliative care is the need to constantly project a persona of being a nice, compassionate, and caring person, which can be difficult, and has led to this being described as the "tyranny of niceness" (Lee et al. 2009).

Hospice policies, especially those that are values based, can have a positive effect on staff by encouraging a healthy balance between professional responsibilities and personal needs (Louie et al. 2007). Examples of such practices include family-friendly policies such as parental leave, part time or flexible work hours, unlimited leave to care for ill family members, and sabbatical leave options to study or to travel. Additional staff well-being policies include those for both physical and emotional safety, employee assistance programs, and having professional supervision and critical incident stress debriefing available. Having access to an ethics committee has been reported as a helpful way for health-care professionals to discuss, at a multidisciplinary level, the struggles that teams have with ethical issues and clinical decision-making (Davies et al. 2008).

Feeling valued is one of the most important indicator of job satisfaction. Valuing staff, and letting them know that they are valued, is one of the most important factors in job satisfaction and reduction in workplace stress (Huggard 2008).

5.3 Emotional Safety

While most organizations focus on the legislative and clinical requirements for physical safety in the work place, there is usually much less attention to the emotional safety needs of staff. An innovative approach by a major hospice in Auckland, New Zealand, led to the development of an emotional safety policy and committee, whose aims are to protect and promote staff emotional safety in order to minimize stress and fatigue. The guiding principles of the emotional safety committee were those of the mission and values of the organization: dignity, compassion, respect, quality, advocacy, and stewardship. The hospice has introduced a range of interventions aimed at better supporting the emotional needs of all staff – clinical, administrative, and volunteers. In addition to various organizational obligations, the policy acknowledges several personal responsibilities that staff are encouraged to engage in so as to minimize the burden of their work and enhance

their emotional safety. These activities have all been identified as contributing to hospice staff health and well-being (Vachon and Huggard 2010). Such activities include effective de-roling at the end of a shift; using professional supervision effectively; using appropriate ritual to acknowledge one's own losses and attending to grief work; nurturing, caring, and valuing oneself and accepting support and help when needed; and taking regular holidays and making the best possible use of time away from the workplace (Huggard and Nichols 2011). Supporting and caring for staff in this way leads to greater care being available for patients.

5.4 Supervision

Supervision is a wide-ranging term used to describe a number of supportive process such as clinical supervision, reflective practice, mentorship, coaching, and professional supervision. Each of these practices has differences in intention and in process; however, each of them have aims of enabling the health-care professional to reflect upon, develop, and enhance their clinical practice. Davys and Beddoe (2010, p. 19) describe supervision as an opportunity that "demonstrates an ongoing professional commitment to reflection, analysis and critique by professional practitioners who take individual responsibility to use supervision to renew and refresh their practice and ensure that they continue to work within the mandate for their work with other people. A commitment to supervision demonstrates a commitment to lifelong learning." Edmonds et al. (2015) describe a process for clinical supervision that is part of an overall wellness program for their palliative care team. The supervisee meets regularly (often weekly) with the supervisor with the meetings including discussions regarding assessment, diagnosis, treatment, and administrative matters. Using a psychodynamic model of supervision, exploration of important issues such as emotional responses, clinician defense processes, transference, and countertransference is key to the professional development of the clinician. They describe the ultimate goal of clinical supervision is to "remove the veil between clinician and client such that the clinician perceives the client clearly and provides exquisite patient care, all the while protecting the clinician from the costs of caring" (p. 275).

A form of peer supervision, mostly used by physicians and to a small extent by other health professionals, called Balint groups, offers a way of reflecting on one's practice and drawing upon the wisdom of ones colleagues. The key feature of Balint group work is to explore the clinician-patient relationship, with an outcome of increasing clinician self-awareness, contributing to an enhanced sense of well-being, and heightening ones resilience (Wilson and Cunningham 2013). Interestingly, there is very little evidence of research exploring the role of individual supervision and its impact on stress and vicarious traumatization experiences. One study (Wallbank 2010) did show a reduction of levels of such traumatic responses following a 6-month period of monthly individual supervision. Participants were midwives and obstetricians who were often exposed to tragic events such as fetal or newborn deaths. Measurements of subjective stress, compassion fatigue, burnout, and compassion satisfaction before and at the completion of the supervisory process showed statistically significant reductions in subjective stress, compassion fatigue, and burnout and a statistically significant increase in compassion satisfaction scores. In this study, systematic, individual supervision appeared to have a positive impact on the reduction of stress in the participants.

5.5 Debriefing

Palliative care clinicians have experiences that, to other health professionals, may seem overwhelming, yet the majority are able to appropriately and effectively cope with such potentially traumatic events. One of the ways in which such coping is possible is through the individual and shared experiences of defusing and debriefing processes. Huggard (2013) described the process for conducting effective team debriefing meetings and emphasized the role of a trained facilitator.

Having such a trained facilitator conduct the debriefing can be beneficial in helping staff feel more comfortable about being open regarding their feelings and experiences at a time that could potentially be quite vulnerable for them. One of the advantages in holding interdisciplinary team debriefing meetings is that they can provide an opportunity for staff to hear the perspectives of other professional groups (Keene et al. 2010). The value of such debriefing was demonstrated in a study of palliative care nurses exposed to terminal hemorrhage (Harris et al. 2011). However, there are other ways in which debriefing can occur, such as during individual or group supervision, participation in peer group processes such as Balint groups, or engaging in other forms of reflective practice. Or, the debriefing process may be quite informal and be as simple as sitting with colleagues and having a cup of tea at the end of a shift.

A useful process described by Huggard (2013) is the Personal Debriefing Model (PDM). This is a simple approach to completing the days' work and can become a valuable self-care practice. The two main components of the PDM are acknowledging the day, and what was able to be achieved, and putting strategies in place that assist in separating ones professional and personal lives. This brief process can take place at the end of the working day and before one leaves work.

5.6 The Reflective Practitioner

Reflective practice is a process where in a clinician can review their clinical practice and use insight gained to learn from that experience to guide and enhance further practice. Sarah Coulson, writing in the Australian Nursing and Midwifery Journal (2014 p. 45) wrote "Personal insight into our own values and the ability to respect, explore and learn from the values and experiences of others is fundamental to delivering quality palliative care." Through engaging in a variety of reflective practices, one can gain the personal insight Coulson writes of. Reflection on one's practice and relationships with patients and colleagues can occur through effective staff support processes such as supervision and debriefing. These can occur in a groups setting (Bailey and Graham 2007; Wilson and Cunningham 2013), one-on-one with a trusted colleague (Geraci and Thigpen 2017) or trained facilitator (Davys and Beddoe 2010) or as an individual exercise using such techniques as reflective writing (Borgstrom et al. 2016).

Mehta et al. (2016) have recently reported results of a pilot study aimed at increasing resilience in a multidisciplinary palliative care team. The intervention, called the *Relaxation Response Resiliency Program for Palliative Care*, aimed to reduce stress and increase resiliency. Designed using principals of positive psychology and cognitive behavior therapy, the program's aims are to elicit the relaxation response, reduce overall stress reactivity, and increase connectedness to oneself and others. A variety of reflective processes are a component of this program. Reflective practices in palliative care would appear to be a necessary component of practice in this specialty.

5.7 Mindfulness

Discussing a proposal by Balfour Mount for a paradigm change in the way patients and their families are cared for, Cory Ingram (2014) reflects on Mount's model of care as being one that embraces the whole person and all that he or she is. Within this model, an understanding of the role and practice of mindfulness is a necessary attribute of all clinicians. Mindfulness had its origins in a Buddhist tradition and was seen as a path for happiness and enlightenment. Mindfulness is a way of training one's mind to accept what is as part of the fabric of life. It teaches one to achieve a state of calmness through being fully attentive to the present and knowing and accepting of the emotional state one is in. Antonio Fernando et al. (2014) described one approach to experience this state of calm through a simple breathing and relaxing exercise. They advise beginners to start with a 5 min exercise and gradually increase this over time.

The process of mindful communication has received attention as a valuable communication

process within palliative care. Mindful communication is the bringing together of mindfulness and reflective, genuine and adaptive communication. In their study of palliative care leaders, Omilion-Hodges and Swords (2016) interviewed palliative care leaders and identified the leader's mindful communication practices. The effective key communication strategies were to consider your audience(s); ask questions, listen, and repeat; discard scripts; and recognize your role. They found that the use of mindful communication can "increase clinician well-being, decrease depersonalization, promote sound decision-making, and improve patient safety and care" (p. 330). Thus, the practice of mindfulness can impact directly on the clinician by reducing their levels of stress and, through the use of mindful communication skills, positively impact upon patients and their families and, in that, on the clinician and patient relationship.

5.8 Taking Stock and Committing to Change

A useful tool used for several years by the current authors in self-care and professional development workshops is a check list aimed at identifying individuals self-care practices – the Self-Care Questionnaire. This 62-item inventory covers 6 domains of self-care: physical, psychological, emotional, spiritual, workplace/professional environment, and balance within one's life. The tool, adapted from one developed by Saakvitne and Pearlman (1996), has been found to be helpful for workshop participants to focus on their self-care behaviors and perhaps identify gaps in practice that they might need to pay attention to. This tool is introduced in the psychoeducational phase of workshops and can provide a prompt for participants to complete a second tool: the self-care plan. The self-care plan prompts workshop participants to identify practices they will keep doing, stop doing, and start doing and considering these at an individual, team (or department), organization, or professional association level. In addition the plan prompts answers to the following questions: Think about how you are going to make sure your goals are achieved, who you need to talk to or gather together to discuss your plan, when are your goals going to be achieved by, and do you need to consider some small steps for any of the goals. Anecdotal feedback from workshop participants indicates that many will complete the plan and check in with what they have written regularly as a prompt to their practice. Others have said they use the plan as a discussion document with their supervisor as a way of receiving support for their planned activities. Additionally, the self-care plan can be a useful adjunct used in performance appraisal processes. Copies of the two tools can be obtained from the authors.

6 Conclusion

Nowhere is there more vulnerability than at the time of death. Patients and families are often in crisis, as they struggle to cope with suffering, loss, and impending death and the emotions of panic, fear, pain, and anguish (Johnson and Jackson 2005). Within this range of human experience, health-care professionals live their professional life. In order to fully "live your professional life," we have proposed certain practices that can assist health professionals working in the demanding field of palliative care. These include:

Acknowledgement that working in palliative care can be very demanding, and this acknowledgement needs to come from within oneself as well from those responsible for management of the organization the health professional works for.

Acknowledgement of one's own losses and grief. These may be personal losses or those from ones workplace. Not processing this grief can prevent professionals from being emotionally present for their patients.

Engaging in resilience-building through developing effective coping skills, creating a professional life and personal life balance that works, engaging in support processes such as reflective practice, using mindfulness techniques, and having the insight, or acknowledging the observations of others, to know when additional support may be required.

Developing awareness of the potential impact of vicarious traumatization as well as acknowledging this and seeking support to process such experiences.

Engaging in effective professional supervision, using individual, peer, or team processes.

Requiring appropriate organizational input such as effective human resource activities, for example, regular performance feedback, appropriate orientation and mentoring, family-friendly workplace practices, appropriate rosters, access to employee assistance programs, and professional development education opportunities.

Access to individual and team debriefing as well as adopting the Personal Debriefing Model.

Taking stock and committing to change through the use of the Self-Care Questionnaire and the self-care plan.

These techniques and activities, as well as others you identify as "working for you," will significantly assist you to be a safe and effective health professional in the rewarding field of palliative care.

supported by healthcare professionals. Still, most of the time, patients, together with their relatives, need to manage a huge part of their life and care themselves. In this chapter, we provide comprehensive insight into self-management for patients with progressive, life-threatening diseases. We describe the concept of self-management and its domains in this population, the role of the family, determinants and outcomes of self-management, the current state of affairs of self-management support programs, and possible innovations for the future.

1 Introduction

We are in the midst of a paradigm shift from paternalistic healthcare to more participatory healthcare, where patients' autonomy and self-determination are increasingly valued. This is also visible in healthcare policy and social policy. Healthcare policy is shifting toward out-of-hospital delivery of care, partly driven by a tendency to reduce costs while invoking the importance of the "participation society" in which people should create their own support and safety nets. As a result, patients are more and more expected to be in charge of their health. Patient engagement has made it to center stage in discussions of quality of care, enshrined by the Institute of Medicine's "quality chasm" report as one of the key elements of high-quality care (Baker 2001). Despite these developments, patient engagement in care is not always self-evident, especially when patients can no longer be cured and care needs are high, as is the case in palliative care.

Learning that one's disease has progressed to an advanced and incurable stage is for most patients and their relatives an overwhelming experience that often includes shifting ones goals from curative treatments to focusing on quality of life. Because patients have to live with the prospect of imminent death and are increasingly unable to continue working and fulfilling their usual social roles, they need to deal with considerable emotional, psychosocial, and lifestyle consequences (Rainbird et al. 2009). They do this in the face of increasing multidimensional symptoms, such as fatigue, pain, lack of energy, weakness and/or appetite loss, anxiety, and depression (Rainbird et al. 2009; Kirkova et al. 2012; Rosenstein 2011; Uitterhoeve et al. 2004; van den Beuken-van Everdingen et al. 2016). Managing the emotional, psychosocial, and lifestyle consequences of severe illness often includes making complex decisions and navigating through a complex healthcare arena, with care delivered by healthcare professionals from a variety of disciplines, such as nursing, oncology, general practice, social work, pharmacology, dietetics, and psychology. Patient self-management can be supported by healthcare professionals. Nurses in particular may play an important, interdisciplinary role through direct involvement in communicating with patients, relatives, and other healthcare professionals, and by providing medical, practical, and emotional support to patients and relatives (Johnston et al. 2014). Still, most of the time, patients, together with their relatives, need to manage a huge part of their life and care themselves.

Box 1 and 2 describe examples of patients who are managing the consequences of a progressive, life-threatening disease.

Box 1 Self-Management in Context: Mrs. Ying

Mrs. Ying was 45 years old when she got diagnosed with breast cancer. Despite intended curative treatment, 4 years later the cancer had metastasized to her bladder and kidney, and a renal drain was inserted. Mrs. Ying had a strong wish to live as long as possible. She had two sons aged 14 and 17 years and knew that they needed her daily support for at least another few years. In order to fully focus on therapy and healthy living she stopped working as a management assistant in her husband's store selling hearing aids. She went to the hospital one to three times a week (depending on the type of treatment she

(*continued*)

Box 1 Self-Management in Context: Mrs. Ying (continued)

received). She experienced many treatment side effects, such as alopecia, neuropathic pain, fatigue, nausea and vomiting, and serious anorexia and weight loss resulting in cachexia. She spent much time and energy on balancing her diet, while experimenting with pharmacological and non-pharmacological interventions, vitamins, and cannabis to decrease her nausea and anorexia. Furthermore, she went out for a walk every day. Her husband accompanied her during each hospital visit, cared for her when she was feeling ill, kept the house clean, and supported the boys in their activities at school and sports. Therefore, he eventually decided to close his store. When family or friends wanted to visit Mrs. Ying, she asked them to bring their walking shoes to accompany her outside. During these rounds she talked about (the joy of) living; she did not want to talk about death and the imminent parting from her husband and children. Gradually, her physical condition deteriorated and new metastases were found in the uterus, stomach, and liver. She increasingly experienced pain, fatigue, severe weight loss, sleeping problems, and anxiety. Every time a treatment failed to succeed she insisted on another therapy. She searched the internet for information and experiences from peers and learned about the value of peer support. Only at these moments she showed some awareness of her imminent death, although even then she kept hoping that her life could be extended a little more. After 1 year her oncologist initiated a discussion about her preferences regarding end-of-life care. Although she was shocked (do I really only have a few months left?), she realized she did not want to die at home. Home was a place to live and she aimed to protect her boys from the remembrance of her death at home. She continued her daily walking

Box 1 Self-Management in Context: Mrs. Ying (continued)

rounds in company of her sons, her husband, or a friend. Almost a year later, she was admitted to an inpatient hospice facility and started preparing for death. She sent all her friends a short message about her situation and only allowed very close family to visit her. Two weeks later, she passed away quietly and alone during her sleep.

Box 2 Self-Management in Context: Mr. Kenston

Mr. Kenston is 74 years old and diagnosed with chronic obstructive pulmonary disease (COPD) Gold III. His wife died 2 years ago and he is now living alone in a tiny house in a small village. He has three children; one of them is living abroad and the other two are living a 30 min drive away. Twice a week the community nurse assists him with his hygiene care and 2 days per week he has a few hours help to clean his house. Mr. Kenston increasingly suffers from dyspnea, fatigue, dysphagia, anorexia and weight loss, and concentration deficits. In addition, he feels lonely and has difficulties to find a meaningful way of spending his days. Luckily, he is still able to go to his favorite pub every Sunday, where he sometimes meets with some old friends, drinks a beer, and watches football or rugby. Mr. Kenston is participating in a rehabilitation program that is offered by the multidisciplinary care team in his hospital and consists of disease treatment and symptom management. As part of the program, he receives medication and oxygen therapy, which he manages at home himself, and for which he visits his pulmonologist on a two-monthly base. Furthermore, the program includes physical activity and breathing exercises (two group sessions per

(*continued*)

Box 2 Self-Management in Context: Mr. Kenston (continued)
week), speech therapy to improve his dysphagia (one session per week), and consultations with a dietician (two per month) and an occupational therapist (two visits per month) aimed at improving his nutritional and functional status, respectively. Sometimes one of his children accompanies him to appointments, but most of the times he goes by himself, by taxi. Mr. Kenston feels supported by the rehabilitation program. He finds it difficult, however, to plan all the appointments with the various healthcare providers. Recently, he forgot to arrange a taxi. Also, he has realized that he sometimes forgets to take his pills. He increasingly struggles to fulfill his daily activities, such as going to the supermarket and preparing his meals, not only because due to a lack of energy but also because he finds the planning and maintenance of the various activities of his healthcare program to be difficult.

Self-management has frequently been studied in the context of chronic diseases, such as arthritis and diabetes (Charmel and Frampton 2008; Coulter and Ellins 2007). Although self-management in the context of palliative care, that is, for patients with progressive, life-threatening diseases, is similar or maybe even more relevant, it has received less attention. In this chapter, we will provide comprehensive insight into self-management for patients with progressive, life-threatening diseases. In the next paragraphs, we will describe for this population:

- The concept of self-management and its domains
- The role of the family
- Determinants and outcomes of self-management
- The current state of affairs of self-management support programs
- Innovations for the future

2 The Concept of Self-Management and Its Domains for Patients with Progressive, Life-Threatening Diseases

To date, self-management has predominantly been studied in the context of chronic diseases, such as asthma or arthritis. Definitions of self-management developed in the context of chronic diseases do not usefully apply to the specific situation of progressive, life-threatening diseases. Therefore, in this chapter, we define self-management as: "The strategies used by persons with the aim of managing the physical, psychosocial and existential consequences of living with a progressive, life-threatening disease and its treatment." Key to this definition is that self-management involves more than the management of physical problems alone, as it also includes the management of problems in other domains, such as psychosocial problems. In the context of progressive, life-threatening diseases and palliative care, self-management is similarly or even more relevant compared to chronic diseases. Nevertheless, self-management in patients with progressive, life-threatening diseases has received considerably less scientific attention and, consequently, still lacks thorough theoretical underpinning and conceptual delineation.

Studies describing self-management strategies used by patients with progressive, life-threatening diseases appear to cover multiple domains: medicine and pharmacology, lifestyle, mental and spiritual well-being, social support, knowledge and information, navigation and coordination, and decision-making (see Table 1) (Chan et al. 2016; Hansen et al. 2015; Johansson et al. 2006; Levy and Cartwright 2015; Norris et al. 2009; Stephens et al. 2014).

As Table 1 shows, within each of the self-management domains, a wide range of different self-management strategies can be distinguished. In the domain of lifestyle for example, patients might self-manage the consequences of their advanced disease by exercising, making dietary

Table 1 Self-management domains and self-management strategies used by patients with progressive, life-threatening diseases

Self-management domains	Examples of self-management strategies
Medicine and pharmacology	Monitoring symptoms, bodily changes, treatment effects, and/ or disease risks Self-administering medication Adhering to prescribed treatment schedules Adjusting or discontinuing treatment schedules (e.g., taking extra drug doses during breakthrough pain, replacing conventional treatment with alternative therapies, omitting use of medications)
Lifestyle	Doing exercise, reducing sedentary behavior Reducing cigarette and/or alcohol consumption Adjusting nutrition and diet Engagement in complementary and alternative medicine (e.g., medicinal herbs, meditation, massage, Reiki, homeopathy) Performing leisure activities (e.g., engaging in physical or creative activities) Maintaining daily activities (e.g., by taking breaks/sleep during the day, dividing activities into smaller parts)
Mental and spiritual well-being	Engaging in psychotherapy Keeping a diary Using mindful self-help strategies (e.g., practicing assertive self-talk, focusing on feelings and thought of control, acceptance, positivity, channeling thoughts of own death toward future well-being of loved ones) Engaging in meaningful activities (e.g., volunteering, promoting cancer awareness)
Social support	Seeking support from relatives and friends Seeking support from healthcare professionals Seeking support from other patients (e.g., participating in (online) support groups) Providing social support to friends and relatives Limiting social interactions to certain people or moments (e.g., withholding emotions, restricting social contacts to close relatives or good moments)
Knowledge and information	Seeking information about disease and/or treatment (e.g., searching the internet) Seeking information about self-care Avoiding or ignoring information (e.g., not reading about symptoms or prognosis)
Navigation and coordination	Coordinating medical services (e.g., obtaining health-related documents) Delegating certain aspects of care (e.g., obtaining medications, decisions on pain treatment approach) to others Coordinating and staying in charge of information dissemination to, for example, relatives Making financial and practical plans (e.g., arranging funeral, inheritance)
Decision-making	Making informed decisions about treatment Engaging in advance care planning Short-term and longer term goal-setting to define and fulfill wishes

changes, practicing complementary and alternative medicine, or engaging in new or existing hobbies. Psychological self-management strategies could consist of engaging in psychotherapy, practicing mindfulness, keeping a diary, or doing meaningful activities. Coordination and navigation strategies include the coordination of medical services and making financial plans. Also in the other domains, self-management strategies are numerous. How and to what extent patients use these strategies might be highly dependent on personal preferences and circumstances. Furthermore, self-management styles and strategies may change during the course of advanced illness. In the case description provided in Box 1, Mrs. Ying started to self-manage the consequences of advanced breast cancer by engaging in healthy lifestyle activities (e.g., taking daily walks), seeking information and making informed decisions about treatment options and preferences, seeking social support from her loved ones, and delegating certain household, caregiving, and healthcare

tasks to her partner. When her health condition deteriorated, she shifted focus from seeking regular and experimental medical treatments to preparing and planning for death (for instance, by making plans about where and how she wanted to die). Mr. Kenston's life is dominated by the fulfillment of his COPD rehabilitation program that mainly requires self-management strategies within the domains of the medicine and pharmacological domain and navigation and coordination. Meanwhile, he tries to maintain his daily activities, and once per week he goes to his favorite pub for some distraction. Keeping up with all these activities becomes increasingly challenging.

Self-management in the context of progressive, life-threatening diseases thus comprises a heterogeneous, multifaceted concept. In the context of chronic, nonadvanced diseases, patients also self-manage in multiple domains by applying a variety of different strategies. However, for several reasons self-management in progressive, life-threatening diseases is different and probably even more challenging than it is in chronic conditions. These challenges concern the prospect of imminent death, the magnitude of the "work," and the involvement of the family.

2.1 The Prospect of Imminent Death

Although some patients might never stop hoping for cure, in advanced disease and palliative care, most people strive for life extension and optimizing quality of life. However, when living with the prospect of inevitable deterioration and imminent death, the concept of quality of life can be very diffuse and susceptible to competing values and priorities. Self-management strategies and attitudes might therefore not only be various, but (seemingly) ambivalent and strategies could change over time. Mrs. Ying, for example (see Box 1), initially wanted to support her sons for at least another few years. After a while, however, she became aware that her metastasized breast cancer would not allow her to. Whereas on the one hand, she might have wanted to keep fulfilling her usual caregiver role and remain the mother she had always been, on the other hand, she felt that she had to delegate certain aspects of care to her husband. Also, despite potentially needing the emotional support of her sons, Mrs. Ying decided not to share all her emotions with them to protect them from sadness.

Studies about self-management in patients with progressive, life-threatening diseases showed that social support might indeed range from providing and seeking social support to limiting and even avoiding social support (Johnston et al. 2014; Baile et al. 2011). Although most patients experience social support as essential, for some of them, seeking and accepting it is hampered by fears of becoming a burden to their loved ones and losing their established roles and identity. A recently published literature review on life values of elderly people suffering from incurable cancer (Ebenau et al. 2017) also found that besides seeking social support, many patients consider maintaining independence and withholding emotions to contribute to a good death, as this is perceived to minimize strain on their loved ones. Facing the end of life also demands strategies to prepare for life closure and death, which might include seeking support and care for children or a partner, making decisions about the arrangement of a legacy or funeral, and/or preferred care at the end of life. More generally, ambivalence in self-management strategies of patients with advanced diseases often seems to reflect a conflict between two seemingly opposing attitudes: appreciating life in the present versus planning for the future; readjusting purpose and expectations versus maintaining normality and a sense of established identity; preparing for death versus hoping to live longer; and taking control versus letting things happen.

2.2 The Magnitude of the "Work"

Problems and needs of patients with advanced diseases are highly multidimensional and complex, making their daily management far more

time and energy intensive than that of chronic nonadvanced diseases. The work has often been compared to a full-time job, like for Mr. Kenston who was treated for many symptoms and problems at the same time. Among advanced cancer patients a median number of 11 symptoms have been demonstrated (Higginson and Costantini 2008). Physical symptoms, such as pain, breathlessness, fatigue, anorexia, constipation, and insomnia, occurred in some combination in virtually all of these patients (Higginson and Costantini 2008). Managing physical symptoms involves taking numerous medications in different dosages at different times of the day according to the physician's instructions, and monitoring their therapeutic and adverse effects (Lau et al. 2009). Patients and family caregivers report that they are often not able to manage such complex medication regimes (Joyce et al. 2014). Further, although not always recognized and treated properly, depression and anxiety are common symptoms for a large proportion of patients (Delgado-Guay et al. 2009). Depression is associated with decreased health-related quality of life scores and poor treatment adherence (Arrieta et al. 2013). Patients and their family caregivers also have urgent psychosocial issues/problems, such as loneliness and hopelessness (Steinhauser et al. 2000). In addition, patients have deteriorating capacity to independently perform activities of daily living. All these problems and needs make healthcare navigation and coordination increasingly complex, because care is often delivered by various providers from a variety of disciplines in various settings, hampering integrated and coordinated care (Daveson et al. 2014). Furthermore, many complex preference-sensitive health and healthcare decisions need to be made, for instance, about medical care and changing or sacrificing certain lifestyle habits (e.g., reducing sedentary behavior, quitting smoking) that may potentially, but would not necessarily improve outcomes. Adequate and timely communication between patients, family caregivers, and healthcare providers is a prerequisite for adequate self-management, but this is often also time consuming and difficult (Higginson and Costantini 2008; Slort et al. 2011).

2.3 Involvement of Family Caregivers

Another reason why self-management is especially complex in advanced diseases concerns the people involved. As a result of progressive physical and/or cognitive decline, patients' self-management skills may be increasingly limited and family caregivers play an important role in the daily illness management. They spend on average 8 h per day on care tasks, often feel overwhelmed, and suffer from high levels of caregiver burden and numerous health-related problems, such as sleep-disturbances and depressive symptoms (Aranda and Hayman-White 2001). As such, they are often called the "hidden patients." In the next paragraph, we discuss the role of the family in more depth.

3 The Role of Family in Self-Management in Palliative Care

While most patients prefer to receive end-of-life care at home (Gomes et al. 2012), this is not possible without depending heavily on contributions by family (Aranda and Hayman-White 2001). Various terms are used to describe persons who are involved in the unpaid or nonprofessional care for a patient, such as informal caregivers, family caregivers, care from relatives and friends, and carers (Payne 2010). In this chapter, we will use the term "family caregiver" and the definition of Stajduhar et al. (2010) of family caregivers at the end of life, i.e., "Individuals who provide any physical, emotional, and instrumental support and assistance to individuals with life-limiting illness that they view as family members. These family caregivers are not acting in a professional or occupational capacity. They may or may not be co-residing with the care recipient and the care recipient may be either in a home or institutional setting" (Stajduhar et al. 2010). This definition implies a broad definition of family that goes beyond formalized relationships. In the past decades, there has been an increase in informal caregiving as a primary source of patient care. It has been estimated that family caregivers in Canada and Australia provide 80–90% of all

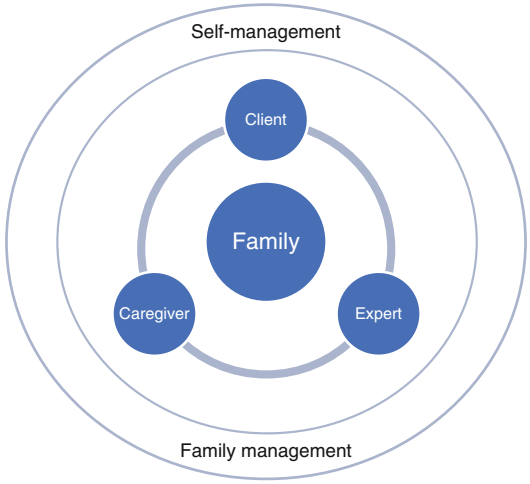

Fig. 1 Conceptual model of the family roles in self-management and family management at the end of life

care provided at home. Currently, 8–16% of adults in the European Union serve as family caregivers, a proportion that is expected to further increase (Börsch-Supan 2008).

Although some work has been done to conceptualize the roles of family caregivers in self-management of chronic conditions (Ryan and Sawin 2009; Schulman-Green et al. 2012), only little is known about these roles in palliative care. In this context especially, the role of the family seems to be multifaceted (see Fig. 1). First of all, a family caregiver supports the patient in uptaking self-management strategies (e.g., monitoring symptoms, providing assistance with activities of daily living). Second, a family is an expert, for instance, in the contact and collaboration with healthcare services. A family caregiver knows the patient usually best, including his or her personal history, values, goals, preferences, and self-management challenges and strategies. Finally, a family caregiver of a patient at the end of life can be considered to be a "client" as well, affected by the patient's disease and the imminence of approaching loss of their beloved. In addition, family members may have their own chronic conditions themselves (Turner et al. 2016).

The roles of caregiver, expert, and client may not always be distinguishable, and the family is moving between and within the various roles, depending on the patient's condition, their own condition, and other contextual factors at stake. When the roles of caregiver and expert predominate, the family takes over various self-management activities of the patient, such as monitoring symptoms, coordinating care, seeking information or support, and dissemination of information about the patient's condition to others. The role of the family then becomes "self-management by proxy," which is in the figure expressed as family management. In their role as client, family members have to take care of themselves, that is, to self-manage the situation in combining caring activities with preparing for loss of their beloved and with, for example, their own living, employment, and house holding. At the same time, they need to prevent overburdening.

Of the three family roles described in Fig. 1, the role of caregiver is most extensively studied and in practice probably best acknowledged.

From the patient's perspective, being cared for and dying at home is likely to improve quality of life and quality of dying (Gomes et al. 2013). However, for family caregivers this might be burdensome: family caregivers of patients with advanced cancer spend on average 25 h per week on family caregiving for a patient, with approximately 25% spending over 40 h a week (Van Houtven et al. 2010). Involvement in the life of and care for a beloved patient in the last phase of life can engender positive feelings for the family caregiver, such as self-esteem and a sense of meaning. These responsibilities may nevertheless be very demanding, physically, emotionally, and financially. As the death of a loved one does usually (fortunately) not occur frequently, many family caregivers lack (any or extensive) experience in caring. Many family caregivers have hardly any knowledge about disease management and do not know what they can expect in the last stages of life. Family caregiving causes physical, psychosocial, and existential strain, and family members are at increased risk for caregiver burden (Guerriere et al. 2016; Park et al. 2012), defined as a psychological and emotional experience related to the perception of the demands that are

specifically associated with accompanying and providing care for a dying person (Dumont et al. 2008). Reviews addressing the quality and problems related to end-of-life care found that intensive family caregiving is linked to numerous health-related problems (Stajduhar et al. 2010; Gysels et al. 2012), which worsen as the patient's physical function and symptom burden increase (Palos et al. 2011; Schulz and Beach 1999). Most reported are psychological difficulties, such as depression and anxiety, and physical and emotional stress; financial and occupational difficulties, e.g., occupational disruption and financial strain; and difficulties with patient care, such as being able to leave the patient unattended or dealing with the physical demands of providing care (Stajduhar et al. 2010; Gysels et al. 2012). The percentage of family caregivers experiencing moderate to severe burden has been showed to increase from 32% 3 months prior to death up to 66% in the last week of life (De Korte-Verhoef et al. 2014). Modifiable and nonmodifiable factors predicting the risk of caregiving burden have been identified, such as patient and caregiver gender, duration of family caregiving and of unpaid work, patient's functional status, increasing healthcare costs, and emergency department visits (Guerriere et al. 2016).

Self-management at the end of life often takes place in the dyad of patient and family caregivers. They are interdependent and are balancing their lives with all disease-related activities (Hardy et al. 2014), while trying to maintain a normal life (Turner et al. 2016). At moments during which the patient feels reasonably well and is able to self-manage her disease and related activities rather adequately, the family caregivers' role in disease management and decision-making may be fairly limited. Yet, family caregiver's support will be more demanding when the patient's condition deteriorates and for instance accompanying her to healthcare visits and treatment is needed. Vice versa, when family caregivers have to opt out for a while, for example, due to responsibilities at home or at work or because they feel exhausted, the patient needs to expand self-management activities or arrange assistance of other relatives or healthcare services. The same accounts for the expert role. When the patient is able to decide for himself, he does not necessarily need the support of family as expert in therapeutic relationships. Deterioration of the patient's condition increases the need for shared or surrogate decision-making. This need for balancing and flexibility of family caregivers is possibly very demanding. As most self-management strategies are built upon cognitive and mental skills, such as adherence to medication therapy, seeking information, coordinating care, and decision-making, family management may be especially demanding in patients with dementia. Then patients and family have to deal with patients' deteriorating cognitive and mental capacities and various self-management problems occur early in the disease trajectory. These mostly long-lasting and far-reaching processes of gradually changing roles in the patient and family dyad are an important risk factor for psychological distress in the family (Moore et al. 2017).

Being caregiver, expert, and client at the same time, family caregivers need acknowledgment of their position and contribution to the care and understanding of their experiences (Aparicio et al. 2017). They may need assistance in handling difficult situations, such as suffering from pain and anxiety, to improve quality of life and well-being of both the patient and themselves. A close therapeutic relationship, including supportive attitudes such as kindness, empathy, attention to the family, and closeness are important (Aparicio et al. 2017). By being concomitant caregiver and expert, family caregivers try to achieve a life as normal as possible. When self-management of both disease-related activities and daily activities are in balance, this so-called family management is effective (Hardy et al. 2014). However, family members are at risk of burden as they feel the responsibility but not the power to advocate for the best care for their beloved (Teno et al. 2001), especially when the patient is admitted to the hospital or nursing home. Family caregivers may fear that the needs of the patient are being neglected (Teno et al. 2001; Witkamp et al. 2016) when they have to leave.

4 Determinants and Outcomes of Self-Management in the Palliative Phase

As described in the previous paragraphs, patients are increasingly expected to be in charge of their health (Henselmans et al. 2015). It is questionable, however, whether all patients and their family members are able to fulfill this role. In addition, few studies have addressed the outcomes of self-management. To describe the determinants and consequences of self-management of patients and their family members in the palliative phase, we have developed a preliminary conceptual framework, visualized in Fig. 2. It builds on Stewart's palliative care model (Stewart et al. 1999) and on the revised self- and family-management framework of Grey et al. (Grey et al. 2015). The model hypothesizes that patient, family, and system factors (Rademakers et al. 2015) are related to self-management skills and practices of patient and family members. Studies in chronic diseases show that more than half of patients struggle with self-management (Rademakers et al. 2015), especially older people (Korfage et al. 2015), people with low SES (Rademakers et al. 2014), and people with low health literacy (Berkman et al. 2011). A few studies conducted in the palliative phase also give insight in possible related patient factors. Norris et al. (2009) showed that younger patients with advanced cancer tend to participate more frequently in cancer support activities, while patients with higher levels of physical functioning were more likely to practice physical exercise (Norris et al. 2009). Chan et al. (2016) showed that higher education scores, lower levels of depressive symptoms, and higher total and global self-efficacy scores were positively associated with perceived effectiveness of self-management behaviors (Chan et al. 2016). Furthermore, patients with more anxiety and/or depressive symptoms and lower self-efficacy reported more self-management concerns (Baile et al. 2011). In psychology, some constructs explain why certain people are better at dealing with harsh circumstances than others, which can be considered the crux of self-management. Coping refers to the way individuals deal with stress (Taylor and Stanton 2007); self-efficacy is the belief in the own ability to accomplish a difficult task (Bandura 1977), and resilience is the ability of positively adapting to adverse events and to thrive despite adversity (Cosco et al. 2016). It may well be that these constructs as mediators play an important role in explaining why some people have difficulties with self-management and others have not. A few studies already provide some evidence for the role self-efficacy (Lorig and Holman 2003; Lorig et al. 2001).

Fig. 2 Conceptual framework showing possible determinants and outcomes of self-management of patients with progressive, life-threatening diseases and their family caregivers

Drawing from mostly observational studies about problems and needs in the palliative phase (Higginson and Costantini 2008; Bekelman et al. 2016; Given et al. 1992), the model further postulates that poor self-management may be associated with a reduced quality of life, depressive symptoms, high treatment burden, high caregiver burden, and overuse of care (Hibbard and Cunningham 2008). Our ongoing research aims to study the proposed conceptual framework in depth.

5 The Current State of Affairs of Self-Management Support Programs in Palliative Care

A considerable group of patients is interested in self-management support (Henselmans et al. 2015). However, comprehensive self-management support interventions for patients in the palliative phase are lacking. Comprehensive self-management support programs have been developed for patients with chronic, nonlethal diseases (Bodenheimer et al. 2002). They were shown to improve self-management skills (Hibbard and Cunningham 2008) and resulted in reduced symptom burden (Barlow et al. 2002), less hospitalizations (Barlow et al. 2002), and improvements in quality of care (Coulter and Ellins 2007), patient safety (Coulter and Ellins 2007), and reduced healthcare costs (Charmel and Frampton 2008).

Within oncology, several attempts have been made to develop and evaluate intervention programs aimed at supporting self-management of patients and/or their family caregivers. However, most of these interventions have been directed at patients with early stage, curative cancer or cancer survivors (Bennett et al. 2016; Grimmett et al. 2013; Hochstenbach et al. 2017; Jahn et al. 2014; Kanera et al. 2016; Kim and Park 2015; Kuijpers et al. 2013; McCusker et al. 2018; Mishra et al. 2012; van den Berg et al. 2012, 2013). Thus far, only few interventions have addressed self-management in advanced, incurable cancer. An elaborate example of such an intervention concerns the ENABLE II (Educate, Nurture, Advise, Before Life Ends) project (Bakitas et al. 2009a, b), which aims to encourage patient activation and self-management in multiple domains by means of a case management, psychoeducational approach. During four-weekly educational sessions (either by telephone or during clinic visits) and monthly follow-up sessions conducted by advanced practice nurses with palliative care specialty, patients with advanced cancer are coached using an educational manual including modules of problem solving, communication and social support, symptom management, advance care planning and unfinished business, and an appendix listing supportive care resources. A randomized controlled trial that assessed the incremental effects of the intervention compared to usual oncology care only has shown promising, positive effects on quality of life and mood, yet limited effects on symptom intensity scores and use of resources.

In the past decades, several interventions to support self-management in COPD have been developed. The support of patients with advanced COPD requires a more integrated approach compared to support of less severely ill patients. Wagg (2012) has described a spectrum of support for COPD patients, showing that especially for the most severe patients a comprehensive pulmonary rehabilitation is of importance (Wagg 2012). This includes focus on self-management and the maintenance of ones' health status. According to Effing et al.

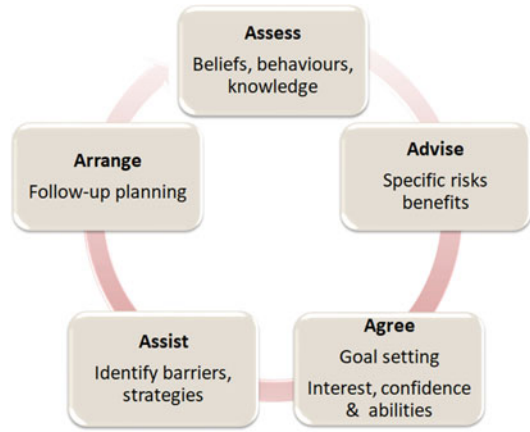

Fig. 3 5-A model of healthcare professionals' competences of self-management support (Glasgow et al. 2003)

(2012), the change of behavior, including cognitive behavioral techniques to achieve this, is a fundamental element of self-management programs in this patient population (Effing et al. 2012). In 2016, an international expert group reached consensus on the requirements of adequate COPD self-management interventions. Its core aims and elements are described in Box 3. The process of iterative interactions between patients and healthcare professionals as described in element 3 is also nicely conceptualized by the 5-A model (see Fig. 3) (Glasgow et al. 2003). In the 5-A model, five competencies of healthcare professionals are central to adequate self-management support: Assess patients' beliefs, behaviors, and knowledge, Advice on benefits and risks, Agree (e.g., on goal setting), Assist patients in their strategies of choice and possible barriers they may experience, and Arrange follow-up planning.

Box 3 Core Aims and Elements of COPD Self-Management Support Programs (Effing et al. 2012)

1. A COPD self-management intervention is structured but personalized and often multicomponent, with goals of motivating, engaging, and supporting the patients to positively adapt their health behavior(s) and develop skills to better manage their disease.
2. The ultimate goals of self-management are: (a) optimizing and preserving physical health; (b) reducing symptoms and functional impairments in daily life and increasing emotional well-being, social well-being, and quality of life; and (c) establishing effective alliances with healthcare professionals, family, friends, and community.
3. The process requires iterative interactions between patients and healthcare professionals who are competent in delivering self-management interventions. These patient-centered interactions focus on: (1) identifying needs, health beliefs, and enhancing intrinsic motivations; (2) eliciting personalized goals; (3) formulating appropriate strategies (e.g., exacerbation management) to achieve these goals; and if required (4) evaluating and readjusting strategies. Behavior change techniques are used to elicit patient motivation, confidence, and competence. Literacy-sensitive approaches are used to enhance comprehensibility.

In a meta-analysis of 22 studies among COPD patients with different disease stadia (including advanced COPD), Lenferink et al. (2017) summarized the effectiveness of COPD self-management interventions on outcomes of health-related quality of life (HRQoL), overall and respiratory-related hospital admissions, and mortality (Lenferink et al. 2017). They concluded that these COPD self-management interventions are associated with improvements in HRQoL and lower probability of respiratory-related hospital admissions. Not all studies included in the meta-analysis already met the requirements as described in Box 3 and not all studies provided detailed information regarding the intervention components. As many patients with COPD have comorbidities, the investigators recommended to take comorbidities into account when COPD self-management action plans are used in the wider population. Self-management interventions with a smoking cessation program showed significant improvements in HRQoL when compared to interventions without such a program. Neither the number of behavioral change technique clusters that were used in the intervention nor the duration of the intervention and the adaption and maintenance of medication did affect HRQoL.

6 Conclusions and Innovations for the Future

In an era where participatory healthcare is increasingly valued and stimulated, patients more and more need are expected to be co-responsible for their health and care. In this chapter, we showed that self-management of patients with progressive, incurable diseases is complex and multifaceted, covering multiple domains, such as medical and psychological self-care, lifestyle, the organization of social support, the acquirement of relevant knowledge and information about the disease, navigating the medical arena, and participating in decision-making about future treatments and care. The prospect of imminent deterioration and death further adds to its complexity. Patients' family caregivers have an important role in self-management in this phase of life, especially when the patient's health status further deteriorates. This is complex, as family members may have a role in supporting the patient, provide information to professional caregivers, and need to take care of themselves as well. In our chapter, we also demonstrated that people may differ in the extent to which they are able or prefer to engage in self-management strategies, and also in the type of strategies that they prefer. Disentangling why some people seem to be able to deal rather effectively, with what may be the hardest event in life – an approaching death – and others are not, is crucial. Such insight would highly advance theory-building of patient engagement and would yield important opportunities to close the gap between current policy and actual practice. This could promote effective and efficient self-management support interventions, that might benefit from a tailored approach, in the vulnerable population of patients with advanced cancer and their family caregivers.

Abstract

Advance care planning is a patient-centered process to enable a person to express his or her preferences for future healthcare. Advance care planning is an integral component of palliative care for people at various stages in the illness trajectory. This chapter provides an overview of advance care planning; the potential benefits, barriers, and facilitators; the key components of advance care planning at various stages of health; strategies for the advance care planning conversation; and areas for future research.

1 Introduction

Advance care planning is a process of supporting a person to express his or her preferences and priorities for future healthcare in consultation with healthcare providers, family members, and other people who are important to him or her. It typically includes a discussion about end-of-life care. It's a patient-centered initiative that facilitates shared decision-making. It is highly relevant to palliative care and core business for palliative care providers.

Advance care planning as a concept has been around for decades, initially developing in the USA as a legal mechanism to guide use of end-of-life care interventions. Legally binding documents such as advance directives were established to allow a person to specify his or her preferences for medical treatments prior to loosing capacity. However, various factors have limited the uptake of advance care planning.

This chapter explores definitions of various terms relevant to advance care planning, the benefits and evidence supporting advance care planning, the gaps in evidence and barriers to uptake of advance care planning, the advance care planning over the trajectory of health/illness, and the tips for advance care planning discussions in palliative care settings.

2 Definitions

2.1 What Is Advance Care Planning?

Two recently published international Delphi studies have been conducted to establish consensus around the definition of advance care planning. A European consensus process defined advance care planning as *"the ability to enable individuals to define goals and preferences for future medical treatment and care, to discuss goals and preferences with family and health-care providers, and to record these preferences if appropriate"* (Rietjens et al. 2017). Another international consensus process was led from the USA and defined advance care planning similarly as *"a process that supports adults at any age or stage of health in understanding and sharing their personal values, life goals, and preferences regarding future medical care. The goal of advance care planning is to help ensure that people receive medical care that is consistent with their values, goals and preferences during serious and chronic illness"* (Sudore et al. 2017).

2.2 What Is an Advance Care Plan?

An advance care plan is the ideal outcome of an advance care planning discussion. Regardless of whether or not the person wishes to formally

document his or her preferences in a legal way, the outcomes of advance care planning discussions should be documented to inform care provision. Advance care plans *"state a person's preferences about health and personal care, and preferred health outcomes. They may be made on the person's behalf and should be prepared from the person's perspectives to guide decisions about care"* (Australian Commission on Safety and Quality in Health Care 2015).

2.3 What Is an Advance Directive?

An advance directive is a type of advance care plan. It is a formal document signed by a competent adult. It can record the person's preferences for future care and include specific instructions, such as refusal of certain interventions. Other names used in various jurisdictions include advance health directive, advance care directive, living will, and medical directive. The legal standing of advance directives varies from country to country and state to state. In some Western countries, advance directives are supported by specific legislation (statutory advance directives) and are legally binding. In other jurisdictions advance directives may be recognized under common law. Advance directives only come into effect when the person loses capacity to make his or her own decisions.

3 Appointment of a Substitute Decision-Maker or Legal Healthcare Proxy

In many countries, people can formally appoint a trusted person to make medical decisions on their behalf should they lose capacity to do so. Substitute decision-makers have legal authority to make medical decisions on behalf of a person whose decision-making is impaired, with legislation varying between different jurisdictions. Various names are used for this role, such as enduring guardian, health attorney, medical agent, and guardian. This is usually different to a person appointed to make financial decisions (for whom terms include power of attorney).

4 Evidence/Benefits for Advance Care Planning

Patients cite the benefits of advance care planning as including preparation for end-of-life care and death, greater personal empowerment and hope, better medical care, avoidance of prolongation of dying, strengthening of personal relationships, and relieving burdens placed on family (Davison and Simpson 2006; Singer et al. 1995, 1999). Studies conducted in a range of healthcare settings suggest that advance care planning may improve patient and family satisfaction with care (Detering et al. 2010; Molloy et al. 2000), increase the likelihood of medical staff and family members' understanding and complying with patients' wishes for end-of-life care (Rietze and Stajduhar 2015; Houben et al. 2014; Martin et al. 2016), reduce hospitalization and aggressive medical care near death (Rietze and Stajduhar 2015; Martin et al. 2016; Khandelwal et al. 2015; Robinson et al. 2012), and increase palliative care and hospice use (Rietze and Stajduhar 2015; Robinson et al. 2012) and the likelihood of a person dying in his or her preferred place of care (Martin et al. 2016). Furthermore, advance care planning may also reduce levels of stress, anxiety, and depression in surviving relatives (Detering et al. 2010; Molloy et al. 2000; Silveira et al. 2010; Wright et al. 2008). At a clinician level, advance care planning can reduce moral distress related to decisions to withdraw treatment (Elpern et al. 2005). At a health system level, advance care planning has potential to increase cost-effectiveness by ensuring resources are not misspent on care that is unwanted or likely to be futile (Klingler et al. 2016; Dixon et al. 2015). Although evidence for benefit at a societal level is limited, improved bereavement outcomes in relatives seem likely to translate into quicker return to productivity both economically and socially.

5 Facilitators and Barriers to Advance Care Planning

While the range and extent of benefits demonstrated across the literature as a whole is impressive, there has been significant heterogeneity

between studies. This finding has refocused attention away from the overarching question of whether advance care planning *can* have benefits toward a more nuanced analysis of which advance care planning elements may be more or less effective and in what contexts. Advance care planning is a "complex intervention," as defined by the UK Medical Research Council, in that it has multiple interacting components, and is dependent on contextual factors for successful implementation (Medical Research Council 2006). Untangling the contributions of each component and contextual factor is challenging. However, research has identified a number of ingredients for success, as well as key problems.

5.1 Organizational Support

At the organizational level, systematic reviews suggest that advance care planning needs to be assigned due priority in terms of training, resources, and time and supported by an appropriate administrative system for communicating and reviewing advance care plans and monitoring adherence during end-of-life care (Gilissen et al. 2017; Travers and Taylor 2016; De Vleminck et al. 2013; Lovell and Yates 2014). Transitions between care settings (e.g., aged care and hospital) are especially disruptive to communication about advance care planning and other aspects of care (Coleman 2003). Ensuring advance care plans are kept up to date improves clinicians' confidence that they represent the person's current wishes; as concern that the person may have changed his/her mind since the plan was written is a common barrier to adherence. Other system-level approaches to advance care planning include embedding it into routine care (e.g., on admission) to ensure it is consistently offered; however, care is needed to ensure advance care planning is individualized to each person's needs rather than takes a "one-size-fits-all" approach. A further "double-edged" system-level approach is to defer advance care planning within an organization to one or more highly trained advance care planning specialist rather than allocate time and training to all clinicians. Although cost-effectiveness analyses are lacking, this approach may be less sustainable in cost terms and overlooks the importance of advance care planning occurring opportunistically within a trusting therapeutic relationship (Lund et al. 2015).

5.2 Clinician-Patient/Family Interaction

At the clinician level, good relationships with the patient and family involved are important, as are motivation, confidence, knowledge, and communication skills (Gilissen et al. 2017; Travers and Taylor 2016; De Vleminck et al. 2013; Lovell and Yates 2014). Clinicians may be uncomfortable with having "difficult conversations" about end-of-life care, even when they are competent communicators more generally. Difficulty with prognosticating often leaves clinicians uncertain about the best time to initiate advance care planning, with many concerned that they will undermine hope if they commence too soon. Even in the later stages of illness, clinicians may worry that patients aren't psychologically "ready" to discuss end-of-life care, so they wait for patients to initiate the discussion rather than doing so themselves. In fact, research suggests that patients typically welcome the opportunity to take an active role in deciding future care, but may not be sufficiently aware of advance care planning to request it. Patients and families may also have limited knowledge about their disease and available treatments and be unaware that they have management choices, including the option to have no treatment at all. Limited health literacy and low education in general have been found to be barriers to advance care planning (Lovell and Yates 2014), requiring communication to be appropriately tailored for content, timing, quantity, and form, as well as checking for comprehension (Dy and Purnell 2012).

5.3 Patient and Clinician Characteristics Associated with Increased Likelihood of Advance Care Planning

The likelihood of advance care planning being undertaken is associated with higher patient age and having a cancer diagnosis (Lovell and Yates

2014), perhaps reflecting clinician assumptions about conditions under which a conservative care pathway may be more or less desirable. While advancing age may increase the likelihood of cognitive decline and need for health-related decision-making, age alone should not influence decisions to forego life-sustaining treatments. Similarly, while religious views, family roles, and community support may confer genuine reasons why advance care planning is less attractive to people from certain cultural backgrounds (e.g., African Americans (Sanders et al. 2016)), care is needed to ensure that mistrust in the health system is not a reason for exclusion, and concerns that advance care plans may be used to reduce costs are addressed where these exist. Culture may influence the attitudes not only of patients but also of clinicians, making them more or less likely to offer advance care planning (Frost et al. 2011). An experiential approach to advance care planning training may help clinicians reflect on their own attitudes and values to limit bias in their practice, as well as develop empathy for patients and skills for sensitive communication (Weiner and Cole 2004). Clinicians' perceived norms may also be determined by their clinical experience, in turn dependent on their discipline and specialty. Multidisciplinary team meetings and case conferences have been used to ensure a diversity of professional perspectives, especially where considerations are complex, as in the context of multi-morbidity (Phillips et al. 2013).

5.4 Substitute Decision-Maker Considerations

With notable exceptions, patients typically prefer their substitute decision-maker to be a close family member (Kelly et al. 2012). However, the role can be burdensome, especially when the decision-maker is uncertain of his or her loved one's preferences or feels unable to enact known preferences because of emotional ties, or when there are divided opinions among the family more generally (Vig et al. 2007; Lord et al. 2015). If decisional conflict is not addressed at the time, it can damage family relationships and complicate bereavement and recovery following the patient's death. Addressing this problem requires skillful facilitation and support that, wherever possible, should engage with diverse perspectives across the family rather than focus only on the legal obligation to involve the substitute decision-maker.

6 Who May Benefit from Advance Care Planning?

Any adult may choose to start advance care planning when healthy before an unexpected health crisis. It may also be relevant for children with a life-limiting illness, although this is beyond the scope of this chapter. Advance care planning may be especially relevant for:

- People diagnosed with a life-limiting or chronic illness
- A person whose doctor would not be surprised if he or she were to die within 12 months
- Any person admitted to a residential aged care facility
- People 75 years of age of older
- Any person requesting to discuss advance care planning
- A person at risk of losing capacity to make decisions (e.g., due to progressive cognitive impairment)

7 Advance Care Planning Across the Trajectory

While advance care planning may be relevant for any adult, the approach and areas to be covered in an advance care planning discussion are different for people at different stages of the illness trajectory. Palliative care providers have various roles in the provision of advance care planning. This includes direct involvement in ongoing advance care planning and goals of care discussions with patients and families referred to palliative care services. Importantly it also includes provision of education and support for clinicians working in other settings to facilitate advance care planning discussions with their own patients, and an advocacy role in education of the public. The

following section shows the authors' recommendations for advance care planning across the trajectory of health.

7.1 Advance Care Planning for a Well Adult, Less Than 75 Years of Age

The main intervention for this population is public education and enabling family discussions about advance care planning. Health professionals do not necessarily need to be involved in the discussion. The key messages for this group are:

1. To prompt the person to consider who he or she would want to make medical decisions for him or her if he or she couldn't speak for himself or herself in case of a sudden illness or injury. If this person is different from the person who would normally be consulted according to the hierarchy in their jurisdiction, then encourage the person to consider formally appointing a legal medical SDM. In some jurisdictions only legally appointed medical substitute decision-makers can refuse treatment on behalf of the person, which is another reason the person may wish to consider such an appointment.
2. Suggest they have discussions with key family members about the values, goals, and preferences they would want considered if they ever had a serious injury or were in a prolonged period of incapacity. For example, what makes worth living, what level of function and ability to do things would be acceptable to them, their funeral wishes, other things that would be important for their family to know if they died suddenly, and any wishes regarding organ donation.

It is also important for well adults to know they are likely to be called upon to have input into decisions for their family members when they are dying or incapacitated. Resources for enabling early family discussions about advance care planning are shown in Box 1.

7.2 Advance Care Planning for Someone with Chronic Illness or a Well Elderly Person

This group has a greater risk of dying, and/or risk of losing capacity to make healthcare decisions, than a healthy adult younger than 75, but they are not yet likely to be approaching the final months of life. For these patients, health professionals should proactively educate and "plant the seed" about advance care planning. Some key components of advance care planning for this group include:

- Asking the patient about his or her preferred substitute decision-maker; prompting the patient to consider legally appointing a substitute decision-maker, especially if his or her preferred substitute decision-maker is someone different according to the hierarchy in their state; and ensuring there is a record of the patient's preferred substitute decision-maker in the medical record
- Encouraging the person to consider an advance care planning discussion with his or her preferred substitute decision-maker, a health professional(s), and any significant others to help him or her reflect on his or her values and preferences if he or she were ever to be unwell to speak for himself or herself.

If the patient is ready to discuss advance care planning, a workbook or web resource (see Box 1) may help patient reflect on his or her wishes and guide the discussion. Regardless of whether or not the patient wants to complete an advance directive, it's helpful to record a summary of where the discussion is up to in the medical record. It is also important that this documentation is accessible in emergency situations and at the time of transitions between care settings, for example, in the electronic medical record or in a patient-held medical record.

7.3 Advance Care Planning for Someone Whose Health Is Deteriorating and Approaching the Last Months (or Weeks/Days) of Life

This is the population where palliative care providers are most likely to be involved in the discussion. If the patient is likely to have only months to live, the clinician should review what advance care planning discussions have already taken place and any advance care planning documents that have been completed. The person should also be provided a further opportunity to reflect on his or her priorities and try to establish a clear plan for the goals of care if/when the person's health deteriorates. It is important to remember that, even if the patient likely has months to

live, he or she may still wish to pursue disease-specific therapies. Questions suggested by Atul Gawande (2014) to help patients consider whether particular treatments are worthwhile for them include the following: *"What is your understanding of the situation and its potential outcomes? What are your fears and what are your hopes? What are the trade-offs you are willing to make and not willing to make? And what is the course of action that best serves this understanding?"*

If the patient is already in the final weeks or days of life, discuss "good dying" rather than offering interventions like CPR if he or she is unlikely to have therapeutic benefit. Explore the person's preferred place of care during terminal phase and preferred place of admission if required.

For people whose health is already deteriorating (likely life expectancy is months or less), it is important to translate advance care plans into actionable medical orders that can transition across care settings in case of an emergency, e.g., Physician Orders for Life-Sustaining Treatment (POLST) or Medical Orders for Life-Sustaining Treatment (MOLST) forms, resuscitation plans and/or ambulance plans.

Once a person no longer has capacity to take part in decisions about his or her care, health professionals need to review any previously completed advance care plans and talk with the person's substitute decision-maker(s) to ensure treatment plans are consistent with the person's preferences and appropriate to his or her circumstances.

8 Tips for Advance Care Planning Conversations

The general aims of the advance care planning conversation are to:

- Establish who the person would like to speak for him or her, if he or she ever became unable to speak for himself or herself
- Ensure the person understands his or her medical situation to the level that he or she wishes
- Explore the person's
  - Values, beliefs, goals, fears, and concerns relevant to his or her current and future care
  - Concept of a "reasonable outcome" or health state (if appropriate and the person health is not already approaching the final days of life)
- Determine if there are any treatments that a person does, or does not want now or in the future
- Explore any other wishes the person may have about his or her care in the future and at the end of his or her life
- Facilitate documentation of the person's wishes in an advance care directive if he or she wishes and/or document any verbal wishes in his or her electronic and paper medical record

General recommendations for advance care planning discussions are shown in Table 1. Further strategies and example questions and phrases for advance care planning discussions are shown in Table 2. Other resources that may be useful are shown in Box 1.

The key to initiating advance care planning is to sensitively offer to discuss the topic. Describe simply and clearly what advance care planning is. Give a rationale for why having these conversations may be helpful for the person, their family, and the healthcare team. While it is important to be proactive about initiating advance care planning discussions, it is also important to give the patient the option not to discuss it or to defer the discussion to another time if he or she prefers. Not all patients want to discuss and plan for future care. If the patient does not currently wish to discuss the topic, raise it again when the person's condition or situation changes. Some patients prefer their families to be involved in such discussions on their behalf.

Subsequent steps in the advance care planning discussion include (Johnson et al. 2016):

- Assessing the patient's and/or family's readiness to discuss future care

Table 1 Summary of recommendations for discussing advance care planning and end-of-life issues with patients with advanced life-limiting illnesses and their families, modified from the PREPARED framework

P	**Prepare for the discussion**, where possible
	Confirm the clinical situation and appropriate treatment options
	Try to ensure privacy and uninterrupted time for discussion
	Mentally prepare yourself
	Gauge the person's readiness to discuss his or her future care
	Negotiate who should be present during the discussion
R	**Relate to the person**
	Introduce yourself and explain your role and develop rapport
	Show empathy, care, and compassion during the entire consultation
	Consider cultural and contextual factors which may influence preferences
	Use appropriate body language and actively listen
E	**Elicit patient preferences**
	Clarify the patient's or caregiver's understanding of their situation, and how much detail they want to know, before giving new medical information
	Identify the patient's preferred substitute decision-maker (if not already identified)
	Elicit the patient's goals, values, and beliefs relevant to the discussion
	Elicit the patient's priorities for care and preferences regarding current and future treatment
	Explore the family's concerns and priorities where applicable
	Summarize the patient's (and family's) most important priorities and check if you have it right
P	**Provide information** tailored to the individual needs of both patient and their family
	Ask permission to discuss what to expect
	Pace and tailor delivery of information about the clinical situation and prognosis to the patients'/families' current understanding and wish for information
	Use clear, jargon-free, understandable language
	Explain uncertainty, limitations, and unreliability of prognostic information
	Consider offering recommendations for the patient's medical care that are clinically appropriate and align with the patient's priorities
A	**Acknowledge emotions and concerns**
	Explore and acknowledge the patient's and caregiver's fears and concerns and their emotional reaction to the discussion
	Respond to the patient's or caregiver's distress regarding the discussion, where applicable, and consider their needs for additional support
	Acknowledge your own emotions – discussing end-of-life issues is challenging
R	**Realistic hope** should be fostered (e.g., peaceful death, support):
	Be honest without being blunt or giving more detailed information than desired
	Do not give misleading or false information to try to positively influence a patient's hope
	Reassure that all support and care will be given to control pain and other symptoms
	Explore and facilitate realistic goals and wishes and ways of coping on a day-to-day basis, where appropriate
E	**Encourage questions** and further discussions
	Encourage questions and information clarification; be prepared to repeat explanations
	Check understanding and if information provided meets needs
	Leave the door open for topics to be discussed again in the future
D	**Document**
	Assist the patient to document his or her wishes in an advance care directive if desired and/or the formal/legal appointment of a substitute decision-maker
	Write a summary of what has been discussed in the medical record
	Speak or write to other key healthcare providers involved in the patient's care. As a minimum, this should include the patient's general practitioner

Table 2 Strategies and example questions and phrases for advance care planning discussions

Strategy	Example phrase or question
Describe simply and clearly what advance care planning is. Give a rationale for why these conversations can be helpful for families and the healthcare team	*"Have you thought about the type of medical care you would like to have if you ever become too sick to speak for yourself? This is the purpose of advance care planning to ensure that you are cared for the way you would want to be, even when communication may be impossible"*
	"Have you ever talked about your wishes, values, and beliefs about medical treatment and care in case you were ever injured or became too ill to speak for yourself?"
	"It's often easier to talk through tough decisions when there isn't a crisis"
	"Is this something that you would like to discuss further?"
Involve the potential proxy decision-maker in the discussions and planning so that he or she understands the patient's wishes	"*Sometimes people with your type of illness lose the ability to make decisions or communicate their wishes as the illness progresses. Who would you like to make decisions for you if you were unable to do this yourself?"*
	If the person can identify a substitute:
	"Have you spoken to this person about what would be important to you about your care if you were very ill?"
	"Would you like to talk this through with them?"
	"Would you like me to assist you with this?"
Use open-ended questions to develop an understanding of the patient's values and to help him/her to work out goals and priorities related to their remaining life and treatment of the illness, and document the patient's preferences	*"What is most important to you now (or regarding your care in the future)?"*
	"What aspects of your life do you most value and enjoy?"
	"When you look at the future, what do you hope for?" "What concerns you?"
	"Do you have any thoughts about how you would like to be cared for in the future if you became more unwell?"
	"How would you want decisions regarding your care to be made?"
	"Is there a specific person that you would like us to speak to?"
	"Is there anything you worry about happening?"
	"What would you not want to happen to you in terms of your care?"
	"Are there any situations where you would regard life-prolonging treatments to be overly burdensome?"
	"Is there anything else you would like me to know about your values and priorities for care if you were very unwell?"
Consider using clinical scenarios to structure the discussion, particularly if the patient is still at an early stage of his or her illness	Consider referring to an advance care planning workbook; see consumer resources in Box 1
Emphasize that advance care planning is an ongoing process that will need to be reviewed and updated periodically, as the patient's wishes may change over time, particularly with major health changes	*"These are discussions we may need to revisit if there are changes in the course of the illness"*

(*continued*)

Table 2 (continued)

Strategy	Example phrase or question
Ensure that other health professionals who are involved with the patient's care are aware of the patient's wishes. If an advance care directive is completed, make sure its existence is known by all the treating health professionals and is available when the patient's place of care is being changed (e.g., from nursing home to hospital, during hospital transfers)	

Adapted from: Clayton et al. (2007). © Copyright 2007. The Medical Journal of Australia – adapted with permission. The complete guidelines can be downloaded from https://www.mja.com.au/journal/2007/186/12/clinical-practice-guidelines-communicating-prognosis-and-end-life-issues-adults

- Exploring the patients' understanding of their medical situation and any unmet information needs
- Providing information as appropriate to the person's information needs and medical situation
- Exploring the patient's values, goals, priorities, hopes, fears, and concerns for the future
- Exploring if there are any situations, treatments, or health states the patient would find unacceptable
- Summarizing your understanding of the person's most important wishes for future care
- Considering any other specific treatment options relevant to the person's circumstances that may need to be discussed
- Considering offering to make a recommendation for future medical care, if the person were to become too sick to speak for himself or herself, based on his or her values and wishes
- Helping the patient to document his or her wishes

Discussions about advance care planning can be thought of as a process that unfolds over many conversations and which evolves as the person's illness progresses. Preferably such discussions should commence prior to illness onset or early in the course of a life-limiting illness and revisited over time. A hypothetical question can be a useful way of gently initiating advance care planning discussions for patients who are still very focused on treatments for their underlying illness, for example, *"While we are hoping that things go well with this treatment, if by some chance you didn't get better, what would be most important to you?"* Phrases such as *"we can hope for the best at the same time as preparing for the rest"* may be useful. When patients or family members ask for treatments that you do not think will be beneficial, the use of an *"I wish"* statement can allow the clinicians to align themselves with the patient, being supportive as well as being honest (give reference), for example, *"I wish that that treatment would help. I am concerned in your case that it would make you more unwell rather than better."*

9 Future Research Directions

Much more research is needed to help us better understand how to optimally deliver advance care planning. The following are suggested as topics in particular need of research.

A wide range of tools have been developed to help with clarifying risks and benefits of treatment and eliciting patient preferences based on his or her values, but evidence is limited regarding their efficacy (Cardona-Morrell et al. 2017).

Certain populations have particular advance care planning needs that warrant special attention. For example, more research is needed into ways of involving people with dementia in advance care planning to whatever extent is possible.

While preferences for end-of-life care are relatively stable over time in people with advanced life-limiting illness versus earlier in the disease trajectory (Auriemma et al. 2014), more research is needed to explore why preferences change in a minority of patients and to confirm the utility of written advance care plans for future decision-making. Likewise, further research is needed to determine the best ways to support and prepare

substitute decision-makers for their role in future decision-making on behalf of a patient.

Rapid development in information and communications technology (ICT) affords exciting opportunities for advance care planning, including interactive tools to support decision-making and clarify values and preferences, as well as means of digitally recording, updating, and sharing advance care plans (Ostherr et al. 2016; Oczkowski et al. 2016; Luckett et al. 2015). There have even been a number of national initiatives linking advance care plans with electronic health records to improve accessibility at the point of care and enable regular updates (e.g., Australian Government Department of Health 2016). From the clinician user perspective, ICT solutions present an opportunity to see how plans may have changed over time and, when integrated with other electronic health systems, prompt on when to review plans with the patient (Huber et al. 2017). Evidence to date has largely been limited to processes (i.e., whether advance care planning was undertaken) rather than whether interventions improved end-of-life care.

Further evidence is also needed concerning the processes of advance care planning and mechanisms by which these translate into improved outcomes. For example, there is only low-level evidence that documentation of advance care plans or directives prompts clinicians to further discuss end-of-life care with patients rather than assume that no further discussion is needed (Lewis et al. 2016). Recent rhetorical emphasis on the importance of the advance care planning process over documentation has yet to be matched by research showing how the quality of the process – however measured – influences end-of-life care received.

Given established evidence for benefits from advance care planning versus usual care, head-to-head comparisons are now needed to evaluate the most cost-effective approaches in terms of clinician training (Chung et al. 2016), role allocation within multidisciplinary teams (Rietze and Stajduhar 2015), and intensity/frequency of initial advance care planning discussion and review. Evaluations of cost-effectiveness need to take into account the full extent of costs and benefits from the perspectives of the patient, healthcare system, and society, including any impacts on burden for informal carers and requirements for community-based care (Klingler et al. 2016; Dixon et al. 2015; Weathers et al. 2016).

10 Conclusion and Summary

Advance care planning is a core skill for palliative care professionals for direct care provision, to provide support and education for other clinicians involved with caring for patients with life-limiting illnesses, and as part of our role as advocates for improving end-of-life care more broadly in the community. This chapter has provided tips for advance care planning discussions across the disease trajectory. Evidence suggest that advance care planning can improve outcomes for patients and families and improve satisfaction with care. Nonetheless there remain many unanswered questions about the best ways to implement advance care planning in practice. Further work is needed to ensure that patient preferences that are discussed during advance care planning discussions are made readily available and able to assist decision-making at the point of care and to equip caregivers to be adequately prepared for their substitute decision-making role.

Abstract

Prognostication occupies a central role in medical decision-making. An understanding of prognosis and relevant disease trajectory models is key for healthcare professionals caring for patients with progressive life-limiting conditions. It is a challenging aspect of professional practice for many, both because of its inexact nature and fears regarding the impact of prognostic disclosure. The research literature presented provides insight into the fallible nature of clinical predictions of survival and factors that may mitigate against this, including an understanding of prognostic indicators. Prognostic indicators including biomarkers and prognostic tools, which may be applied in advanced cancer and life-limiting nonmalignant conditions, are reviewed. Desire for prognostic information varies between individuals and within individuals over time; the outcomes of research studies that elicited the views and preferences of patients and bereaved relatives regarding prognostic disclosure are presented. The challenges inherent in diagnosing dying and key considerations are discussed, within the context of recent discontinuation of the Liverpool Care Pathway in the United Kingdom.

We look for medicine to be an orderly field of knowledge and procedure. But it is not. It is an imperfect science, an enterprise of constantly changing knowledge, uncertain information, fallible individuals, and at the same time lives on the line. There is science in what we do, yes, but also habit, intuition, and sometimes plain old guessing. The gap between what we know and what we aim for persists. And this gap complicates everything we do. Atul Gawande, Complications: A Surgeon's Notes on an Imperfect Science, p. 7.

1 Introduction

To prognosticate is to foretell future events according to present signs or indications. It occupies a central role in assessment of patients' needs and decision-making, by clinicians caring for patients at the end of life. Yet, it is an inexact science, with many caveats. As a result, prognostic uncertainty can be a source of anxiety for both clinicians and patients and their families. The challenge for healthcare professionals imparting prognostic information to patients or family members is to provide information which is as accurate as possible using all relevant information and to communicate this sensitively while openly acknowledging the limitations of the information. In this chapter, the research literature relating to prognostic accuracy and possible determinants will be reviewed. Prognostic indicators in malignant and progressive nonmalignant conditions and available prognostic models or tools are presented, and key considerations to guide individualized prognostic disclosure are outlined. Finally, the evidence relevant to diagnosing dying is presented, with reference to key documents published since the discontinuation of the use of the Liverpool Care Pathway in the United Kingdom.

2 The Role of Prognostication in Palliative Care

A prognostication is a statement about what you think will happen in the future. Requests to prognosticate are a frequent occurrence for clinicians caring for patients with terminal illnesses.

However, readiness to seek a prognostication, or hear one, varies between individuals and within individuals over time. When seeking information about the future, patients and families often seek both qualitative information about what to expect from their condition or treatment and quantitative information regarding life expectancy. Knowing what to expect from one's disease and having one's family prepared for death are key priorities for patients with life-limiting conditions (Hagerty et al. 2005). Patients and families seek information regarding expected symptoms and effectiveness of symptom control, how the condition or treatment may impact on physical and cognitive functioning, and the prospect of recovery from acute complications.

Knowing what to expect from their condition and having an understanding of life expectancy can empower patients to choose how they spend their time. It also underpins their ability to engage in informed shared decision-making with clinicians regarding treatment options, including ceilings of medical care and resuscitation status. Families request prognostic information to help them prepare and to inform considerations such as the likely duration of a caring role or timing of taking time from work or visiting from abroad.

Prognostication also plays a key part in decision-making by clinicians. For many clinicians, prognosis determines the timing of referral to specialist palliative care services. In the United States, eligibility for Medicare hospice benefit is dependent on a physician certifying that expected prognosis is 6 months or less. For physicians, decision-making regarding potential treatment options for progressive disease is underpinned by consideration of both life expectancy and anticipated course of the disease. As an example, consider the case of a 50-year-old woman with metastatic breast cancer and lung metastases, who has recently had superior vena cava obstruction managed by stent insertion, who has a functional status of ECOG 3, and who has just been diagnosed with brain metastases. She doesn't wish for life-prolonging measures. Her preference is for optimal symptom control, and she is keen to avoid progressive dysphasia. In this situation the physician wishes to avoid subjecting the patient to cranial irradiation if she is unlikely to survive long enough to obtain benefit. The physician must assess the competing risks of death due to progressive extracranial disease and life expectancy exceeding time to dysphasia becoming refractory to steroid treatment. Such assessments can be informed by relevant literature where it exists, such as randomized controlled trials, which examine outcomes following treatment in similar cohorts.

3 Prognostication: An Inexact Science

The impact of erroneous prognostication at the end of life is well understood by patients, families, and the general public. Reports of inaccurate or unreliable predictions cause significant distress. Examples, which received significant media attention, include the case of Abdelbaset al-Megrahi who was convicted for the Lockerbie bombing and the results of recent systematic reviews of the accuracy of the "surprise question." Mr Megrahi was released from prison in Scotland in 2009 on compassionate grounds, after it was predicted that he would die from prostate cancer within 3 months; he died 2 years and 9 months later. The "surprise question (SQ)," which has been widely adopted as a method to identify patients with progressive nonmalignant life-limiting conditions, who may be nearing end of life and may benefit from a palliative approach to care, prompts clinicians to ask themselves if they would be surprised if the patient died within 12 months. The results of the reviews suggest that this method has poor to moderate accuracy and yields a high proportion of false positives (White et al. 2017; Downar et al. 2017). Media coverage of these findings prompted concern among the public that patients may have been inappropriately denied active treatment. Conversely, overestimations of life expectancy place patients at risk of being denied a good palliative care.

These high-profile cases demonstrate the fallible nature of prognostication in progressive or life-limiting conditions. In one pioneering study, which examined the accuracy of clinicians'

survival predictions, each physician referring a patient to outpatient hospice services within Chicago was asked to provide a clinical estimate of survival (CPS) for that patient. This data was compared with actual survival (AS). Three hundred and forty-three physicians provided survival estimates for 468 patients of whom 65% had a cancer diagnosis. Median AS was 24 days. The survival predictions were poorly accurate and systematically optimistic. An accurate CPS was defined as between 0.5 and 2 times the AS; only 34% of predictions were accurate. The mean ratio of CPS to AS was 5.3, and the correlation between CPS and AS was only 0.28. This study also shed some light on patient and physician factors associated with accuracy. Predictions for patients with longer AS had greater accuracy. Patients with cancer were more likely to have overoptimistic predictions. However, predictions of oncology specialists were more accurate than those of non-oncologists. Longer duration of doctor-patient relationship was associated with decreased accuracy (Christakis and Lamont 2000).

Vigano et al. studied the accuracy of oncologists in predicting survival for 233 cancer patients with terminal disease. The estimated median survival time for the group overall was 15.3 weeks. Again, prognosis was overestimated; the median overestimation was 4.8 weeks. The correlation between CPS and AS was moderate at 0.47 (Vigano et al. 1999). Although specificity of a CPS of less than 2 months was high (95%), the sensitivity was low (31%), indicating that participants failed to recognize a high proportion of patients with short life expectancy (see Box 1 for guide to methods of expressing the accuracy of predictive or diagnostic tests).

Box 1 Commonly Used Methods for Expressing the Accuracy of a Predictive or Diagnostic Test

Sensitivity, specificity, positive, and negative predictive values

Sensitivity, specificity, positive, and negative predictive values are illustrated using data extracted from Vigano et al. as referred to in the text (Vigano et al. 1999).

Actual survival (AS) ≤2 months	Clinical prediction of survival (CPS) ≤2 months		
	Yes	No	Total
Yes	23	51	74
No	8	151	159
Total	31	202	233

Sensitivity is the proportion of true positives correctly identified as such.

$= 23/74 = 31\%$

Specificity is the proportion of true negatives correctly identified as such.

$= 151/159 = 95\%$

Positive predictive value (PPV) is the proportion of patients with a positive test who are correctly diagnosed.

$= 23/31 = 74\%$

Negative predictive value (NPV) is the proportion of patients with a negative test who are correctly diagnosed.

$= 151/202 = 75\%$

Area under the Receiver Operating Characteristic curve (AUROC) and c-statistic

The area under the Receiver Operating Characteristic (ROC) curve represents the ability of a continuous measure (such as a prognostic score based on a number of variables) to discriminate between individuals who will experience one of two outcomes. The ROC is a plot of sensitivity against 1-specificity for different choices of cutoff. The higher the plotted line is above the 45° line (AUROC = 0.5), the better the prognostic ability of the tool. An AUROC of 1 would represent 100% sensitivity and specificity.

For binary outcomes, the AUROC is equivalent to the c-statistic or concordance statistic. The underlying assumption of the c-statistic is that for a discerning test or

(*continued*)

Box 1 (continued)
measure, for pairs of subjects within a dataset, an individual with a particular outcome will have had a higher probability for that outcome predicted than an individual who doesn't experience the outcome. The c-statistic represents the proportion of such pairs out of the total number of pairs with discordant outcomes.

Harrell's c-index is a variation of the c-statistic, which allows for inclusion of survival data that is censored. The interpretation of a censored survival is that the survival time represents the time at which an individual exited the study without experiencing the outcome of interest. Harrell's c-statistic is not equivalent to the AUROC.

Kappa statistic (κ)

This is used to express agreement between measures, which are categorical variables: in this case, predicted survival and actual survival. A weighted kappa statistic allows for classification into adjacent categories to be considered as partial agreement. $\kappa = 1$ represents complete agreement, and $\kappa = 0$ shows no more agreement than would be expected by chance alone (Kirkwood and Sterne 2003).

$\kappa > 0.67$ represent excellent agreement

$\kappa = 0.4$–0.75 represent fair to good agreement

$\kappa < 0.4$ represent moderate to poor agreement

Glare et al. conducted a systematic review of the literature on accuracy of physicians' CPS in patients with advanced cancer. They included survival predictions relating to 1563 patients, originating from 8 studies. In seven of the eight studies, survival was systematically overestimated; meta-analysis showed that AS was 30% shorter than predicted. They also demonstrated a linear relationship between CPS and AS until CPS reaches 6 months, after which it lacks predictive value, thus supporting the concept of a "horizon effect," a term borrowed from meteorology, whereby predictions are more accurate closer to the event. As the survival data was not normally distributed, correlation was assessed using nonparametric tests. Calculation of the Spearman rank correlation showed a strong association ($r = 0.60$) between log (AS) and log (CPS). The authors concluded that physicians' survival estimates are strongly correlated with actual survival but are miscalibrated, with systematic tendency to overestimation (Glare et al. 2003).

4 Impact of Characteristics of the Patient, Doctor, and Doctor-Patient Relationship on Accuracy of CPS

4.1 Patient Factors

The nature of the datasets included in the review and meta-analysis by Glare et al. precluded analyses of the impact of characteristics of the doctor and the doctor-patient relationship on accuracy. Regarding the effect of patient characteristics on accuracy of CPS, analysis of data from two studies that collected data pertaining to possible prognostic indicators, in addition to CPS, demonstrated greater accuracy of CPS in patients with lower performance status (Glare et al. 2003).

In a study of accuracy of CPS in 214 patients referred for palliative radiotherapy in Germany, researchers sought a CPS from referring physicians (A) and a radiation oncologist with more than 10 years experience (B) plus the cohort of radiation oncologists attending daily review meetings (C). CPS was recorded as a categorical variable of either less than 1 month, 1 to 6 months, or more than 6 months. They found, as per Vigano et al. that accuracy of CPS was extremely poor in the cohort of patients who died within the shortest time frame – in this case 1 month. Survival was overestimated in 96%, 71%, and 87% of the 33 patients by raters A, B, and C, respectively. The authors postulated that this might be due to physicians' reluctance to accept imminent death (Gripp et al. 2007). An alternative

hypothesis is that some deaths may have resulted from relatively unpredictable events: sepsis, venous thromboembolism, bleeding, or cardiac events. These have been shown to be the most common causes of death in patients who die with cancer and receive a postmortem (Pautex et al. 2013).

For patients with advanced disease, the nature of the diagnosis may impact on prognostic accuracy, specifically whether the patient has a cancer diagnosis or other progressive nonmalignant condition. Distinct illness trajectories have been described for progressive chronic illnesses (see Fig. 1). In malignant conditions, there is usually a slow overall decline in performance status, followed by a relatively rapid period of decline in function. Most weight loss, reduction in performance status, and impaired ability for self-care occur in patients' last few months (Murray et al. 2005). Recognition of these changes and lack of response to antineoplastic treatment facilitate relatively easy identification of the terminal phase of the illness.

It is noted that a change in trajectory has been observed in some cancers, such as breast or prostate cancer with bone metastases, which have increased survival but increased morbidity and lower functional level. Their illness course may

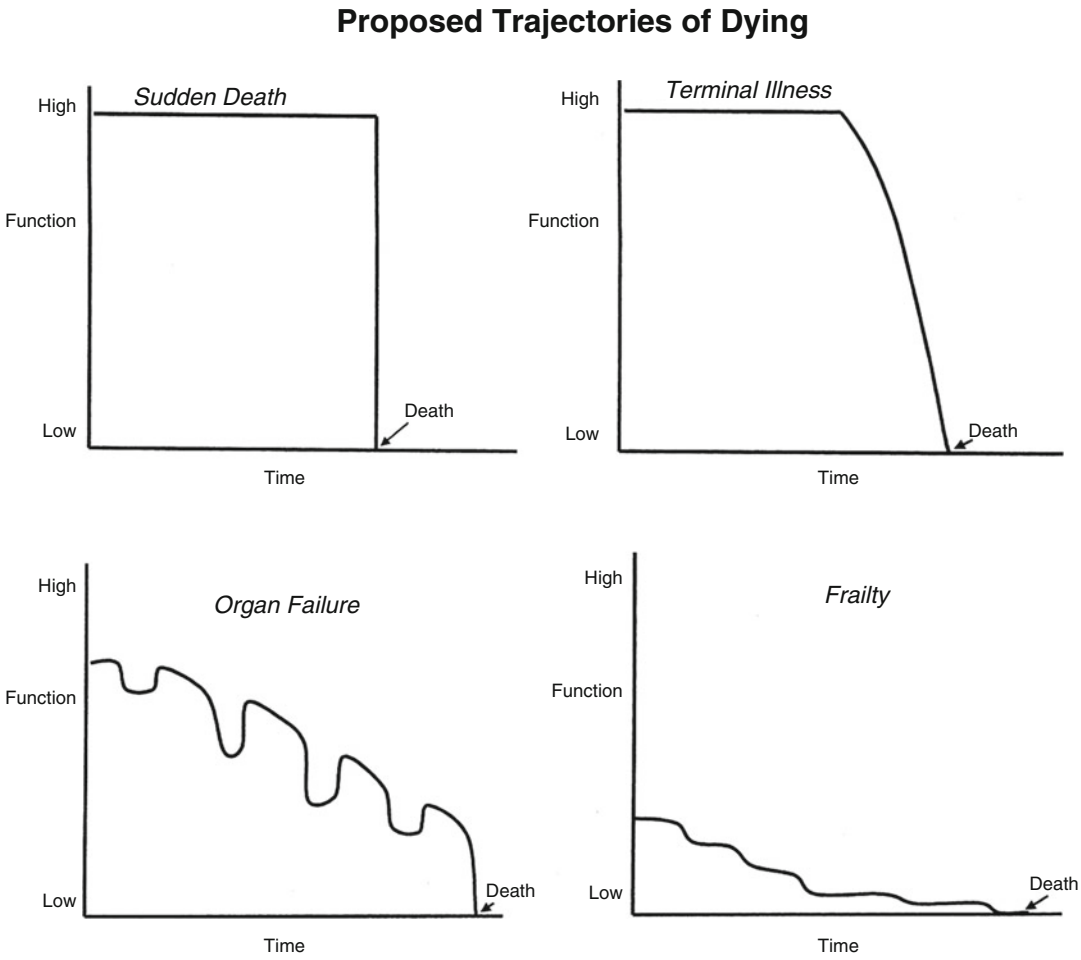

Fig. 1 Trajectories of dying. (Reproduced with permission from Lunney JR, Lynn J, Hogan C (2002) Profiles of older medicare decedents. J Am Geriatr Soc 50:1108–1112. Copyright © 1999–2017 John Wiley & Sons, Inc. All Rights Reserved)

be more similar to that of a chronic nonmalignant disease (Murtagh et al. 2004).

Patients with organ failure are usually ill for many months or years with occasional acute, often severe exacerbations. Deteriorations may be associated with hospitalizations and intensive active treatment, which may result in death or recovery, making recognition of dying or the terminal phase of illness especially difficult. With each episode the patient survives, a gradual deterioration in health and functional status is noted. The timing of death, however, remains uncertain. This is also referred to as "entry-reentry" disease trajectory.

Prolonged dwindling is a progressive disability from an already low baseline of cognitive or physical functioning as seen in brain failure (such as Alzheimer's or other dementia) or generalized frailty of multiple body systems. Such patients may lose weight and functional capacity and then succumb to minor physical events that may in themselves seem trivial but, occurring in combination with declining reserves, can prove fatal (Murray et al. 2005).

Hence, prognostication in progressive nonmalignant conditions is generally viewed as more challenging, and palliative care clinicians have professed to be more confident when estimating prognosis for patients with a cancer diagnosis. There is little data available to facilitate comparisons of prognostic accuracy. In one relevant study, researchers in the United States sought to assess the accuracy of prognostic estimates of hospital physicians, including trainees and specialists in internal medicine, cardiology, and oncology by asking them to estimate survival for three standardized patients: one with lung cancer and two with heart failure, one of whom had reduced ejection fraction and the other preserved ejection fraction. Accuracy of clinical estimates of survival was assessed against estimates generated by validated prognostic models: the surveillance, epidemiology, and end results (SEER)-Medicare database and Seattle Heart Failure Model, respectively. The proportion of accurate survival estimates was much higher for the lung cancer patient than the patients with heart failure (Warraich et al. 2016).

4.2 Clinician Factors

One might expect that prognostic accuracy improves with experience. However, there is limited reliable evidence to support this. Gripp et al. did not detect greater accuracy of CPS by the single prognosticating "experienced radiation oncologist with more than ten years experience" than the cohort of 15 more junior doctors who had a median of 1.7 years of professional experience in radiation oncology (Gripp et al. 2007). Conversely, Maltoni et al. assessed the accuracy of CPS against AS for four oncologists working full time for a Home Care Service for patients with advanced cancer. They observed that the correlation coefficient between CPS and AS was lower for the oncologist who had worked with the Home Care Service for the shortest time than for the oncologist with most experience with the Home Care Team (Maltoni et al. 1994). However, due to very small number of prognosticators in some or all of the comparator groups in both studies, it is quite possible that the observations relate to characteristics of the prognosticator other than years of experience. Authors of a recent systematic review sought to improve understanding of the impact of clinician-related factors on prognostic accuracy in advanced cancer (White et al. 2016). They encountered studies with apparently conflicting results. Due to heterogeneity between studies relating to characteristics of clinicians and patient populations plus, in some cases, limited description of clinician and patient cohorts, it was not possible to draw conclusions regarding the relationship between duration of experience and accuracy of CPS. However, examination of studies that describe characteristics of prognosticating clinicians and involve greater numbers of prognosticators might shed some light on this.

Bivariate analysis of data in the study by Christakis et al. showed no association between accuracy and years in medical practice, board certification, number of hospice referrals in past year, or number of medically similar patients in the past year. However, multivariate analysis showed that doctors in the top quartile of clinical experience were more likely to make accurate predictions (Christakis and Lamont 2000).

A multicenter study of the accuracy of survival predictions of palliative care clinicians relating to 1018 patients with advanced cancer did not demonstrate a relationship between prognostic accuracy and years of professional experience (Gwilliam et al. 2013). In the study by Gwilliam et al., results from bivariate analysis suggested that accuracy of palliative care clinicians' predictions is not affected by years of professional experience or board certification. The variation in observed relationship between accuracy and duration of professional experience between these two studies may result from differences relating to the analysis, characteristics of the prognosticating clinicians, or the duration of the doctor-patient relationship. Whereas in Christakis' study, the prognosticating physicians were heterogeneous in terms of specialty, all prognosticating clinicians were working in specialist palliative care in the study by Gwilliam et al. (2013). It is conceivable, that because consideration of prognosis plays such an integral part of assessment of patients' palliative care needs, that new palliative care staff quickly gain significant experience in prognosticating, acquiring knowledge relating to prognostic indicators from more senior staff relatively early. Early acquisition of these skills could account for the observed absence of relationship between duration of professional experience and accuracy.

This brings us to the question of whether prognostic accuracy varies with specialty. The report by an EAPC working group on prognostication in advanced cancer states that lack of experience in oncology and palliative care reduces accuracy (Maltoni et al. 2005). This was based on consensus opinion or inconclusive studies. Within the relevant literature, studies in which CPS is estimated by oncology or palliative care specialists do report greater accuracy than the study by Christakis, where CPS was estimated by a cohort of doctors from different specialties (Bruera et al. 1992; Glare and Virik 2001; Gwilliam et al. 2013; Christakis and Lamont 2000). This could be partly attributable to the difference in case mix, whereby all or the majority of patients in oncology or palliative care studies had advanced cancer, which has a slightly more predictable disease trajectory, than in the study by Christakis, in which 35% of patients had nonmalignant life-limiting conditions. However, one would expect experience and training in oncology and palliative care to be associated with greater accuracy, in predicting prognosis in patients with cancer. There is some evidence that specialty-specific experience and training can improve prognostic accuracy in other patient cohorts. In the study by Warraich et al. discussed above, cardiologists were more accurate at predicting prognosis in the hypothetical patient with heart failure and reduced ejection fraction than oncologists and generalists. No difference in accuracy for the patient with preserved ejection fraction was demonstrated. Cardiologists were less accurate than generalists and oncologists in estimating survival for the patient with lung cancer (Warraich et al. 2016).

Some researchers have sought to understand how prognostic accuracy varies among different members of the multidisciplinary team. In one early study, each member of a hospice inpatient team (a doctor, senior nurse, staff nurse, chaplain, and healthcare assistant (HCA)) estimated life expectancy of consecutive admissions, at the time of admission and at weekly intervals until death or discharge (Oxenham and Cornbleet 1998). For each team member, accuracy of the final prediction was more accurate than the initial prediction. While the doctor's predictions were the most accurate at time of admission and the HCA's the least accurate, the predictions of the HCA were the most accurate at the time of final prediction. The results of a similar study by Twomey et al. are not inconsistent with this; HCAs were the least accurate members of the multidisciplinary team (MDT) when it came to estimating survival of patients within 48 h of admission to an inpatient hospice (Twomey et al. 2008). The results of these small studies must be interpreted with caution because, again, the observations could reflect characteristics of the individuals involved, other than their profession. However, it may be that staff who work closely with patients and assist them with activities of daily living are well placed to detect changes in functional ability, severity of symptoms, and

patients' outlook, which are of prognostic significance in the last weeks of life.

There are conflicting results from other studies regarding the superiority of prognostic accuracy among doctors and nurses working within MDTs. Again, it is likely that these variances are attributable to heterogeneity among studies regarding other relevant factors such as timing of prediction, duration of clinician-patient relationship, or conclusions based on observed accuracy of a small number of prognosticators (White et al. 2016). One might expect that a CPS informed by MDT discussion would improve accuracy. The studies by Gripp et al. and Gwilliam et al. compared the accuracy of predictions by single prognosticators with consensus estimation by radiation oncology and palliative care MDTs, respectively. While both demonstrated that a higher proportion of patients had an accurate CPS when formulated by MDT consensus, the observed differences didn't reach statistical significance.

4.3 Doctor-Patient Relationship

In the study by Christakis et al., in multivariate analysis, longer duration of doctor-patient relationship was associated with decreased accuracy. In this study, the mean duration of the doctor-patient relationship was 159 weeks. Based on this, the authors proposed that accuracy of CPS might be improved by obtaining a second opinion from a colleague who doesn't know the patient well and is therefore less likely to have their judgment influenced by personal investment. Conversely, Gwilliam et al. did not detect a relationship between length of time that the clinician had known the patient and accuracy of predictions. However, in this study, in more than 90% of cases, the clinician had known the patient for less than 1 month.

There is some limited data to suggest that prognostic accuracy may improve with repeated measurements. In one study, doctors and nurses estimated survival of patients admitted to St Christopher's Hospice in London, on the day of admission. A subset of patients had a repeat CPS 7 days later. The correlation between AS and CPS was improved for both professional groups at 1 week compared with time of admission (Parkes 1972). Similarly, accuracy of final survival prediction before death was better for all members of the MDT, compared with the initial prediction at time of inpatient hospice admission, in the study by Oxenham and Cornbleet. Although there is evidence to suggest that treating a patient for an extended period of time may be associated with reduced prognostic accuracy, it stands to reason that a CPS formulated after an interval, such as 1 week in the case of a hospice inpatient, would be superior than one formulated at the time of admission. At the second time point, the clinician would have better knowledge of the patient, insight into their performance status, and be able to make an assessment regarding rate of deterioration.

5 How Do Palliative Care Clinicians Prognosticate?

This brings us to the question of what doctors consider when formulating a CPS for patients with progressive life-limiting diseases. It is probable that this varies somewhat, both between doctors and within the practice of individual doctors, depending on what the most salient prognostic factors are felt to be for a given patient. Specialist doctors and nurses in palliative care who participated in a qualitative study on prognostication referred to considering objective factors such as blood indices, extent of disease, and performance status, plus observations regarding rate of disease progression, symptom burden, and rate of overall deterioration. Rate of deterioration was considered to be particularly important, and participants highlighted the value of repeated patient assessments over time and incorporation of observations and opinions of nurses and HCAs, when formulating a CPS. Participants also described drawing upon relevant experience, pattern recognition, and intuition (Pontin and Jordan 2013).

In summary, while clinical predictions of survival are flawed, in that they are systematically miscalibrated and influenced by factors relating to the patient, doctor, and the doctor-patient relationship, they are strongly correlated with AS, at least

in the case of malignant diagnoses. The EAPC working group on prognostication in advanced cancer recommend that survival should be estimated using a combination of CPS and other prognostic factors, such as clinical signs and symptoms, biological markers, or prognostic tools which have been demonstrated to be of prognostic significance (Maltoni et al. 2005). They also recommend seeking a second opinion if the patient and doctor have a close relationship and repeated evaluations of CPS at fixed intervals.

Meta-analysis of data from two studies which assessed the accuracy of CPS and other possible prognostic indicators in advanced cancer demonstrated that CPS alone accounted for 51% of the variation in AS, while the other prognostic factors accounted for only 35% of the variance in AS, thus illustrating the supremacy of CPS over traditional prognostic indicators alone (Glare et al. 2003). This isn't altogether surprising, as physicians describe incorporating prognostic indicators, pattern recognition, and the other less tangible elements into their CPS (Pontin and Jordan 2013). In addition to the factors discussed above, CPS can encompass considerations such as the potential to respond to antineoplastic treatment or will to live.

6 Prognostic Indicators

Prognostic indicators are factors demonstrated to be associated with survival. They encompass features of the disease, characteristics of the patient, clinical signs and symptoms, biological indices, and complications of disease, such as hypercalcemia of malignancy or onset of dysphagia.

7 Prognostic Indicators in Advanced Cancer

Prognostic indicators in cancer can be considered to relate to the features of the patient, the tumor, or patient-tumor interaction. While at the relatively early stages of incurable cancer, selected characteristics of the patient, tumor, and patient-tumor interaction all seem to have prognostic significance, in the advanced stages of cancer, only clinical symptoms and signs, in other words, features of the patient-tumor interaction retain prognostic significance.

Hauser et al. conducted a systematic review of studies examining prognostic indicators in patients with incurable solid tumors and only included studies in which the median survival was 3–24 months. For each variable they reported the number of studies testing it, the total number of patients in the studies, the types of cancer examined, and the frequency of statistically significant results from univariate and multivariate survival analyses (Hauser et al. 2006). They did not comment on methodological quality of studies or level of evidence available for each variable. The variables found to have a statistically significant association with survival in multivariate analysis, in at least half of studies that conducted multivariate analysis for that variable, are listed in Table 1. In particular, performance status was shown to be associated with survival in multivariate analysis, in 33 of 34 studies, totaling more than 10,000 patients. The symptoms associated with the cancer anorexia cachexia syndrome shown to be associated with survival were weight loss, anorexia, and nausea.

The EAPC working group on prognostication in advanced cancer conducted a systematic review of prognostic variables identified in studies of patients with median survival less than or equal to 90 days (Maltoni et al. 2005). The authors graded the strength of their recommendations based on the level of evidence as determined by study design and methodological quality. Characteristics of the patient or the tumor were not associated with survival. A number of variables were shown to be associated with survival, all of which relate to signs and symptoms of advanced disease. These variables are listed in Table 1. For each, the association with survival has been demonstrated, either consistently in exploratory studies with low risk of bias or in one heterogeneous meta-analysis or confirmatory study with low risk of bias. The symptoms associated with the cancer anorexia cachexia syndrome shown to be associated with survival were anorexia, weight loss, dysphagia, and xerostomia.

Table 1 Prognostic factors in advanced cancer (see text for explanatory notes regarding level of evidence)

	Prognostic factors identified in patient cohorts with median survival 3–24 months (Hauser et al. 2006)	Prognostic factors identified in patient cohorts with median survival less than 90 days (Maltoni et al. 2005)
Patient factors	Number of comorbidities	
Tumor factors	Presence of metastatic disease	
	Lung primary versus other primary	
	Liver, visceral, or cerebral metastases	
	Pleural effusion	
Patient-treatment factors	Receipt of antineoplastic therapy	
	Response to antineoplastic therapy	
	Performance status	
Patient-tumor interaction	Symptoms associated with cancer anorexia cachexia syndrome	
	Dyspnea	
	Patient-rated emotional quality of life	Delirium
	Patient-rated physical quality of life	

As Table 1 shows, symptoms of the cancer anorexia cachexia syndrome, dyspnea and poor performance status, are of prognostic significance in both the earlier and later stages of incurable cancer.

7.1 Biomarkers

Biomarkers can be defined as objective, quantifiable characteristics of biological processes, quantifiable in bodily fluids and tissues. Researchers and clinicians have attempted to produce a variety of prognostic models incorporating biomarkers to determine patient suitability for treatments and predict longer-term survival. However, there is less evidence available for biomarkers and models that are useful in prognostication in the last weeks and days of life. If identified, we must consider the additional benefit of any biomarker, in the context of current best clinical assessment available for predicting prognosis. In the clinical setting, any biomarkers identified must primarily provide additional information that cannot be gleaned from other assessments, such as physical examination, clinical observations, or functional assessment. Secondly, the test must be accessible to clinicians, acceptable to the patient, and not be prohibitively time consuming, complex, or expensive. Finally, the results of the test should help inform decision-making. Biomarkers in nonmalignant diseases are discussed separately below.

7.2 Biomarkers of Prognostic Significance in Advanced Cancer

A recent systematically structured review by Reid et al. summarized the current evidence for prognostic biomarkers in patients with advanced cancer (defined as study populations with median survival $\leq$90 days) (Reid et al. 2017). In malignant disease, established prognostic biomarkers relate to the inflammatory response and hepatic and renal dysfunction.

7.2.1 Hematological and Systemic Inflammation

Malignancy prompts an inflammatory response, and evidence of progressive change in inflammatory markers toward the end of life has prognostic significance. Elevated levels of interleukin-6 (IL-6) have been demonstrated toward the end of life, particularly peaking in the last week of life. It is hypothesized that circulating macrophages and T lymphocytes produce IL-6 in response to tumor burden or plasma IL-6 is produced by the tumor mass itself (Iwase et al. 2004). Interleukin-1 (IL-1) and IL-6 both stimulate hepatic synthesis of C-reactive protein (CRP) and ultimately the

systemic inflammatory response. Accordingly, it has been consistently observed that elevated serum CRP is associated with poor prognosis, in predominately retrospective studies across different cancer groups. The magnitude of CRP elevation may correlate with survival; studies using >10 mg/l as the threshold for defining "elevated" CRP show higher mortality than those using >5 mg/l. In addition, there is clear evidence of variation across cancer types, and therefore it may be that the use of CRP in prognostication would be most helpful in predicting cancer-specific survival (Dolan et al. 2017).

Several studies have identified a positive correlation between white blood cell count (WBCC) and poor prognosis. Lymphopenia, in particular, has been identified as the key abnormality, with a high neutrophil: lymphocyte ratio also associated with poorer prognosis (Maltoni et al. 2005; Dolan et al. 2017). This is in keeping with the known, but not clearly understood, immunodeficiency toward the end of life in patients with advanced cancer.

7.2.2 Hepatic Dysfunction

It is recognized that an elevated serum lactate dehydrogenase (LDH) level is associated with a poor prognosis. It has also been used in some contexts to monitor tumor aggressiveness and response to treatment and has been incorporated into prognostic models for patients with malignancy. In addition, early evidence suggests that LDH levels may increase significantly in the last 2 weeks of life. This may identify it, among others, as a useful biomarker in prognosticating toward the end of life, although the quality of the evidence of its prognostic value in the dying phase is limited by small sample size in a single study (Reid et al. 2017). More research is indicated in this particular phase of illness before it could reliably be used in prognosticating in the last weeks of life.

An association between high vitamin B12 levels and poor prognosis in patients with advanced cancer has been established. One study carried out by Geissbühler et al. demonstrated this relationship, showing a significant correlation between poor prognosis and elevated serum B12 (Reid et al. 2017). Interestingly, this study again showed CRP to be one of the most significant biomarkers, but B12 remained an independent marker of prognosis. The mechanism is unclear.

Low serum albumin levels have been shown to be associated with poor outcomes across cancer groups. In meta-analysis, the association between serum albumin <35 g/l and overall survival in patients with advanced cancer was significant, with HR 2.21 (Dolan et al. 2017). Serum albumin has therefore been incorporated as a biomarker into prognostic models such as the Prognosis in Palliative care Study (PiPS) model (Gwilliam et al. 2011). Albumin levels have been shown to decline into, and including, the last weeks of life in some studies, while in other studies of patients in the last weeks of life, it did not have adequate prognostic impact to be retained in the final prognostic model. It has been postulated that this may be because other correlated variables, such as reduced oral intake, explain more of the variation during this phase (Maltoni et al. 2005; Hauser et al. 2006). Alanine transaminase (ALT) was found to be associated with prognosis in the last 2 weeks of life by Gwilliam et al. (Gwilliam et al. 2011). Elevated alkaline phosphatase (ALP) and aspartate aminotransferase (AST) have also been shown to be useful in predicting prognosis.

7.2.3 Renal Dysfunction

The utility of assessment of renal dysfunction in predicting prognosis in advanced cancer is unclear. An elevated urea level was identified as an independent predictor of 2-week and 2-month survival in patients with advanced cancer who participated in the PiPS development study (Gwilliam et al. 2011). However, the evidence for other markers of renal dysfunction being useful in prognostication at the end of life in this group is inconclusive.

8 Prognostic Tools in Advanced Cancer

A number of tools have been devised to assist prognostication in patients with advanced cancer. These are described in Table 2. The included components of the Palliative Prognostic Index

Table 2 Prognostic tools for use in advanced cancer and selected validation studies

Tool	Variables included	Patient cohort	Accuracy	Comments
Palliative Prognostic Index (PPI) (Morita et al. 1999)				
Total score predicts survival of less than 3 weeks or less than 6 weeks or 6 weeks or more Independent validation study	Palliative Performance Scale, oral intake, presence of edema, dyspnea at rest and delirium	Hospice inpatients $N = 95$	For prediction of less than 3 weeks PPV = 80%, NPV 87% Sensitivity 83% Specificity 85% For prediction of less than 6 weeks PPV = 83%, NPV 71% Sensitivity 79% Specificity 77%	
Independent validation study (Stone et al.)		Hospitalized patients or community-based patients referred to SPC Services $n = 194$	For prediction of less than 3 weeks PPV = 86%, NPV 76% Sensitivity 56% Specificity 94% For prediction of less than 6 weeks PPV = 91%, NPV 64% Sensitivity 63% Specificity 92%	43% were receiving palliative radiotherapy or chemotherapy
Palliative Prognostic Score (PaP Score) (Maltoni et al. 1999)				
Total score predicts probability of 30-day survival, according to three categories: (A) >70%, (B) 30–70%, and (C) <30%	CPS, Karnofsky Performance Status, anorexia, dyspnea, total white cell count, lymphocyte percentage	Multicenter study. Details of centers not described $N = 451$ Median survival =33 days	The 30-day survival = 86.6% for group A, 51.6% for group B, and 16.9% for group C	Patients with hematological malignancy or renal tumors excluded
Independent validation study (Glare and Virik 2001)		Hospitalized patients referred to SPC Service $N = 100$ Median survival =30 days	The 30-day survival = 66% for group A, 54% for group B, and <5% for group C	Patients with all cancer diagnoses included
Prognosis in Palliative care Study (PiPS) (Gwilliam et al. 2011)				
Total score predicts survival of less than 14 days ("days"), 14–55 days ("weeks"), or more than 55 days ("months")	PiPS-A and PiPS-B are separate models. PiPS-B incorporates blood test indices. Score is calculated using web-based algorithm.	Multicenter study Hospice inpatients and hospitalized patients or community-based patients referred to SPC services $N = 1018$	PiPS-A Harrell's c-statistic =0.69 PiPS-B Harrell's c-statistic = 0.67	Blood tests not conducted in patients who lacked capacity to consent
Independent validation study (Baba et al. 2015b)		Multicenter study Hospice inpatients and hospitalized patients or community-based patients referred to SPC Services $N = 2212$ (PiPS-A) (PiPS-B) $N = 1257$	PiPS-A; absolute agreement between PiPS and AS in 56–60% of cases Weighted kappa =0.39–0.48 PiPS-B; absolute agreement in 60–62% of cases Weighted kappa =0.48–0.51 (Results reported separately for each care setting)	Modification of original PiPS, whereby AMT ≤3 was determined by physician proxy rather than patient interview

See Box 1 for guide to interpretation of statistical tests used
PPV positive predictive value, *NPV* negative predictive value, *SPC* specialist palliative care, *CPS* clinical prediction of survival, *AMT* abbreviated mental test

(PPI) and Palliative Prognostic Score (PaP) generally reflect the variables that have been found to have prognostic significance in cohorts with median survival less than 90 days.

The PiPS incorporates two different models, one for patients who have had the relevant blood tests within 4 days (PiPS-A) and another for those who haven't (PiPS-B) (Gwilliam et al. 2011). In addition to factors relating to patient-tumor interaction or signs and symptoms of advanced disease, the models include some tumor-related factors and blood indices such as albumin. While this may initially appear inconsistent with the findings of the EAPC working group's systematic review, instead, it probably reflects the way in which the models were developed, with the aim of discriminating between patients who will live for "days" defined as up to 13 days, "weeks" defined as 14–55 days, or "months" defined as more than 55 days. While tumor-related variables and some of the blood result indices were not included in best-fit models for explaining survival of "days" or more, they did appear to explain some of the variation in survival between "weeks" and more. The median survival for patients predicted to survive "months" was 92 days and 101 days in the PiPS-A and PiPS-B models, respectively. The variables included and access to the web-based algorithm is available at http://www.pips.sgul.ac.uk.

It is difficult to directly compare the accuracy and utility of the different tools from results abstracted from separate validation studies due to differences in methods, patient cohorts, and methods of presenting results. One study, published in 2015, sets out to compare the feasibility and accuracy of the tools in a single cohort of patients (Baba et al. 2015a). The PPI, PaP Score, D-PaP Score, and modified PiPS were completed for 2361 patients referred to 58 palliative care services (hospital-based, hospice inpatient, and community-based) in Japan. The modification to the PiPS model was related to the method of determining the Abbreviated Mental Test variable as outlined in Table 2. Accuracy and feasibility was assessed for patients not receiving active chemotherapy for each setting and for patients receiving chemotherapy in any setting. The D-PaP Score is a modification of the PaP Score that includes delirium as a variable. The PPI and modified PiPS-A had highest completion rates (>90%) for all four subgroups. Progressively lower proportions of community and hospice-based patients had adequate data for completion of all items on the PaP Scores (PaP and D-PaP) and PiPS-B, respectively. This finding reflects the proportion of patients in these settings who had the relevant blood results available for completion of the PaP Scores (total white cell count and lymphocyte percentage) and PiPS-B (C-reactive protein, total white cell count, platelet count, lymphocyte count, neutrophil count, alkaline phosphatase, alanine transaminase, albumin, and urea). The PaP Scores were completed in 62% and 37% of patients in hospices and at home, respectively. Accuracy, defined as the sum of true positive and true negative cases, divided by the total number of cases was greater than 69% for all tools, in all subgroups. Differences in accuracy between tools across subgroups were within 13% in all cases. The c-statistic was calculated for the PPI and PaP Scores. Although all had a c-statistic $\geq$0.75 in all settings, this was lower for the PPI for all four subgroups, with the exception of predicting survival less than 3 weeks in patients receiving chemotherapy. The authors concluded that all tools have reasonable accuracy although this is marginally lower for the PPI. However the PPI was convenient to use as it contains only five items and can be calculated at the bedside without the need for blood results.

Is there evidence that using a prognostic tool can improve accuracy of CPS in patients with advanced cancer? Morita et al. compared the accuracy of experienced palliative care physicians at predicting survival in hospice inpatients using the PPI, with accuracy of the same physicians estimating CPS without the use of prognostic tools in an historical cohort. The use of the PPI was associated with reduced incidence of serious prognostic errors, defined as a difference between CPS and AS of $\geq$28 days or CPS at least twice or as long or half as long as CPS. A palliative care MDT in an Australian cancer center compared the accuracy of CPS estimated by the MDT, with accuracy of the PaP Score (which incorporated

the same MDT formulated CPS) for a series of outpatients and inpatients (Mendis et al. 2015). Correlation coefficients between AS and MDT CPS and AS and PaP Score were very similar at 0.53–0.57 for outpatients and 0.64–0.66 for inpatients. The Harrell's c-index for the PaP Score in outpatients and inpatients, respectively, was 0.611 and 0.709, while the corresponding Harrell's c-index for the MDT CPS was 0.658 and 0.720, respectively, thus showing no clear advantage of the PaP score over the MDT CPS alone.

Although we do not, as yet, have consistent evidence that the use of prognostic tools improves accuracy of CPS in advanced cancer, the available evidence demonstrates that the tools provide accuracy comparable to the CPS of physicians who are experienced in oncology and palliative care. The observed agreement between predicted and observed survival of at least 69% in the study by Baba et al. for the PPI, D-PaP and PaP Scores, and PiPS models compares favorably with the CPS of palliative care clinicians admitting patients to palliative care services as reported by Gwilliam et al. (56–57.5%) and is similar to reported accuracy of two experienced palliative care physicians at predicting survival less than 4 weeks (68%) (Bruera et al. 1992). It is also probable that, by virtue of their relatively objective nature, the use of a prognostic tool may improve accuracy of all physicians in circumstances associated with reduced accuracy of CPS, such as a close relationship between doctor and patient.

9 Prognostic Indicators and Tools in Life-Limiting Nonmalignant Conditions

Many tools have been developed to help predict outcomes for patients with progressive nonmalignant conditions. Although in the main, they incorporate key prognostic indicators, they have generally been designed to prognosticate over longer terms. The components of some have been determined by expert consensus, while others are derived from clinical cohorts attending specialist clinics or data obtained in the course of clinical trials. Hence, the utility of many of these tools within palliative care practice is uncertain, due to poor generalizability and lack of validation in patients considered to have palliative care needs.

9.1 Heart Failure

The prognosis for patients with heart failure is poor; 30–40% of patients diagnosed with heart failure die within 1 year. It is a disease that predominantly affects older people. The disease trajectory is characterized by a slow decline, punctuated by sudden dips in functioning related to acute exacerbations, from which the patient has a risk of dying or recovering. Prognostication is challenging, and widely used tools have been shown to be inaccurate at predicting survival of less than 12 months. The best-known and most widely used prognostic tool is the Seattle Heart Failure Model (SHFM) which incorporates demographic and clinical information, etiology, and blood result indices and takes account of the classes of medication and devices being used to manage the condition. However it has been shown to overestimate survival in cohorts of community-dwelling patients with heart failure, patients awaiting cardiac transplantation, and elderly patients with heart failure admitted acutely to hospital (Haga et al. 2012). The SHFM predicted that only 6 of 138 community-dwelling patients with New York Heart Association class III and IV heart failure would have a life expectancy of 1 year or less in a study by Haga et al. Forty-three of the 138 died within 1 year. The sensitivity of a predicted survival of 1 year or less was low at 12%, while specificity was high at 99%. The SHFM model was derived and validated from data collected during randomized controlled trials. Hence the participants were not representative of the general population of people living with heart failure, in that they were younger and did not have significant renal impairment, leading to reduced sensitivity of the tool. Neither renal impairment nor brain natriuretic peptide (BNP) is included in the SHF, although both have been demonstrated to be of prognostic importance

(Haga et al. 2012). Haga et al. also tested the ability of the Gold Standards Framework (GSF) Prognostic Indicator Guide to predict survival of a year or less in the same cohort. The use of the GSF is advocated within Europe to assist identification of patients who may be nearing end of life and would benefit from palliative care, based on an assessment that they meet two of the following four criteria: New York Heart Association (NYHA) stage III or IV heart failure, an answer of "No" to the "surprise question" "Would you be surprised if this patient died in the next 6-12 months?," repeated hospital admissions with symptoms of heart failure, and difficult physical or psychological symptoms despite optimized tolerated therapy. This predicted survival of 1 year with sensitivity of 83% but specificity of 22% and overall accuracy of 41%.

Biomarkers in heart failure have been isolated, which not only have prognostic value but, in some cases, show improvement in response to treatment escalation or have become a focus for targeted interventions. Inflammatory processes have been implicated both in the pathogenesis of cardiac failure and with adverse outcomes. Sympathetic nervous system activation and its negative consequences have been identified in heart failure, prompting research into associated neurohormonal markers, including BNP and endothelin (Braunwald 2008). Pro-BNP has been identified as useful in the context of predicting longer-term survival (Huang et al. 2016). It has also been identified as the most significant predictor of mortality and hospitalization for patients with heart failure (Braunwald 2008). Big endothelin, a neurohormone which stimulates smooth muscle contraction, proliferation, and vessel fibrosis, is also a useful biomarker in predicting prognosis. To date, better understanding of its role has not translated into effective novel treatments, as the endothelin-receptor antagonists trialled have not been successful.

In the context of pathological remodeling of the ventricles in patients with heart failure, markers of collagen biosynthesis have been shown to be particularly elevated in those with worse outcomes. ST2, a receptor for interleukin-33, has been implicated in cardiac remodeling. Raised levels of serum ST2 are indicative of ventricular biomechanical overload and of prognostic significance (Bhardwaj and Januzzi 2010).

Due to the challenges in prognosticating in heart failure, it is generally recommended that access to generalist and specialist palliative care is determined by need, in relation to symptom burden and psychosocial distress, rather than prognosis.

9.2 Chronic Obstructive Pulmonary Disease

A number of factors that indicate severity of disease have been identified for chronic obstructive pulmonary disease (COPD). The forced expiratory volume in 1 s (FEV1) is the best known of these but is imperfect on its own at predicting survival. It is combined with other prognostic indicators in the BODE index, a tool devised to predict outcomes in patients with COPD. The BODE index incorporates body mass index (BMI), the degree of airflow obstruction (FEV1), severity of dyspnea measured by the modified Medical Research Council dyspnea scale (MMRC), and exercise capacity measured by distance covered during the 6-min walk test. In the original validation study, its ability to accurately identify four differing survival profiles among patients with stable COPD attending outpatient clinics was demonstrated; the c-statistic was 0.74. However, it predicts survival over a relatively long time range. Median survival of participants in the quartile with the shortest survival was 39 months.

The B-AE-D is an alternative tool developed to address some of the limitations of the BODE relating to ease of application. It was designed to be applicable during acute exacerbations of COPD (AECOPD) and during periods of stable disease and was derived from a multicenter observational study of prognostic indicators (PROMISE). It doesn't require patients to perform either the 6-min walk or pulmonary function tests. Instead it incorporates BMI, frequency of AECOPD requiring hospital attendance in the past year, and dyspnea measured by the MMRC,

in order to predict 24-month mortality. The ability to discriminate 1-year and 2-year mortality, measured by the c-statistic, was comparable to that of the BODE index, when both were applied to the data from the PROMISE participants. External validation studies, conducted by secondary analysis of data from two separate COPD cohorts, showed that 1-year mortality was well predicted (c-statistic 0.68 and 0.74, respectively) (Smith et al. 2017).

In summary, the available tools have been derived from cohorts with relatively long survival and have not been designed to predict prognosis over a short time period, such as 1-year survival, and hence may be of limited utility in improving prognostic accuracy in patients referred for palliative care. Tools designed to predict short-term prognosis and derived from cohorts with median survival of 12 months or less may identify that alternative prognostic indicators or combinations of indicators best explain survival at this stage. Other factors associated with poor prognosis in patients with COPD include increasing age, comorbidities, partial pressure of oxygen in arterial blood, and cor pulmonale.

9.3 Renal Failure

Patients with end-stage renal failure (ESRF) may die as a result of either deteriorating renal function or other complications of associated comorbidities, such as diabetes or cardiovascular disease. Median survival for patients with stage 5 kidney disease is 21 months with conservative management and 67 months with renal replacement therapy (RRT). However, older age is associated with shorter survival as older patients and those with multiple comorbidities are less likely to be treated with RRT and the survival advantage associated with RRT decreases with increasing age. Ongoing tobacco use also is a negative prognostic indicator (Reindl-Schwaighofer et al. 2017).

With regard to biomarkers of prognostic significance in chronic renal impairment, there is some commonality with other life-limiting conditions; a chronic inflammatory process has been identified and is associated with survival in patients with end-stage renal disease. A systematic review by Desai et al. examined several biomarkers in relation to mortality. In this review, high CRP and IL-6, low lymphocyte counts, and hypoalbuminemia were found to predict poor prognosis (Desai et al. 2009). Fourteen studies were identified which examined the relationship between mortality and CRP. Of these, ten used relative risk as the measurement of effect; the weighted mean relative risk (RR) across the studies was 3.23 when examining the association between CRP and mortality. Cardiac troponin t (cTnT) was found to have a predictive value in patients with renal failure, out with the acute cardiac setting. The mean RR of mortality conferred by raised cTnT was 3.69 across 15 studies, encompassing 1700 patients.

Other biomarkers found to be associated with survival in those with renal failure included tumor necrosis factor, hematocrit, and markers of dialysis adequacy such as the urea reduction ratio (URR) and Kt/Vurea (k = dialyzer clearance, t = dialyzer time, Vurea = volume of distribution of urea). Interestingly, some of the markers traditionally thought to be useful in prognostication, such as parathyroid hormone, were not found to be statistically significant, and newer markers, not previously included in discussions around prognosis, such as CRP, have now come to the fore in this area.

9.4 Liver Failure

The use and application of prognostic models, incorporating biomarkers, is well established in hepatology, whereby models are commonly used both to provide prognostic information and trigger modification of treatment plans. The Child-Pugh score has been in use for over 30 years and uses prothrombin time (PT), bilirubin, and albumin, alongside subjective assessments of the presence of encephalopathy and ascites, to prognosticate in those with end-stage liver disease. The inclusion of subjective measures within this scoring system poses challenges for its generalizability. There is also debate regarding the weighting of the

biomarkers within the Child-Pugh score; for example, both albumin and coagulation strongly correlate, and therefore the inclusion of both gives the synthetic function of the liver significantly greater weighting (Durand and Valla 2005).

The older Child-Pugh score has been somewhat superseded by incorporating creatinine, replacing PT with INR, and removing albumin and clinical assessment from the calculation, to form the Model for End-Stage Liver Disease (MELD) (Kim and Lee 2013). This was originally developed to predict survival in patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) procedure. Subsequently the United Kingdom Model for End-Stage Liver Disease (UKELD) built on this by incorporating sodium. Both MELD and UKELD are useful in their generalizability due to the lack of subjective assessment. Recent evidence has suggested that the addition of sodium is helpful in prognostication and decisions regarding treatment, as it is an independent predictor of mortality in patients with cirrhosis (Kim et al. 2008). However, in post-transplant patients, MELD was better at predicting mortality than UKELD (Ling et al. 2017). The aim of these models has been to stratify patients into groups based on predicted mortality. It is worth noting that these models have been developed for predicting shorter to mid-term survival of 3 months to 1 year.

9.5 Dementia

Median survival from time of diagnosis of dementia is 3 to 6 years. While some patients with dementia have coexisting life-limiting illnesses, which may determine survival to a greater extent, the classically described disease trajectory in dementia is one of a slow progressive decline in physical and cognitive functioning. Prognostication is challenging. Negative prognostic indicators include increasing age, male gender, cardiovascular disease, low BMI, poor performance status, insufficient oral intake, weight loss, dyspnea, spending most time in bed, and at least one pressure ulcer. However prognostic tools incorporating key indicators have only moderate discriminatory capacity. The Advanced Dementia Prognostic Tool (ADEPT) was derived using minimum dataset information on more than 200,000 residents in licensed US nursing homes with advanced dementia and contains 12 items, including those listed above. It was shown to have an AUROC of 0.67 when used to predict 6-month mortality as a continuous variable in a prospective validation study. The optimal cutoff point for prediction of 6-month survival had an AUROC value of 0.63, sensitivity of 55.0%, and specificity of 71.3% (Mitchell et al. 2010). Recognition of sentinel events is suggested as a possible alternative method of identifying patients with a short prognosis. In a prospective study of care provided to patients with advanced dementia in US nursing homes, of the 323 participants, 55% died during the 18-month study period. Development of pneumonia, a febrile episode, or an eating problem heralded a poor prognosis; after adjustment for age, gender, and disease duration, the 6-month mortality rate for residents who had pneumonia was 46.7%; a febrile episode, 44.5%; and an eating problem, 38.6% (Mitchell et al. 2009).

10 Communication of Prognosis

Communication of prognosis is an emotive issue for both patients and doctors. Doctors describe avoidance of prognostic disclosure for fear of being wrong, of causing patient distress, or of damaging the doctor-patient relationships. Studies of patients with incurable cancer and their doctors consistently report that doctors overestimate their patients' understanding of their disease, that prognosis is infrequently discussed, and that consultations with oncologists tend to focus on scan results and logistical aspects of treatment options (Hagerty et al. 2005).

Patients' desire for prognostic information varies between individuals and over time. Some feel that they cope better without knowing their predicted life expectancy, while others describe not seeking prognostic information, as they perceive that it may be inaccurate or that it is an unfair request to make of their doctor.

In one US-based multicenter study, whereby several hundred patients with progressive cancer who had received at least one line of chemotherapy were interviewed, 71% said that they wished to know their life expectancy. Eighteen percent reported that their doctor had discussed prognosis with them. In analysis adjusted for age, gender, ethnicity, recruitment site, cancer type, and performance status, disclosure of prognosis was not associated with higher levels of sadness/depressed mood or feeling worried/anxious as measured by the McGill Quality of Life Questionnaire. There was no difference in the proportion of patients reporting a strong doctor-patient relationship between those who received prognostic information and those who did not. This was an observational study, which did not take account of patients' satisfaction with the way in which prognosis was disclosed or who initiated the conversation. Although it is plausible that patients who received prognostic information were a self-selected group, who perceived that knowing their estimated life expectancy would help them cope, this study does suggest that meeting patients' informational needs needn't cause ongoing distress or impact on the doctor-patient relationship. Of note, almost 30% of participants said that they did not wish to know their estimated prognosis (Enzinger et al. 2015). The variation in preferences, between individuals and within individuals over time, suggests that clinicians should assess patients' informational needs, with respect to prognosis, on an ongoing basis.

With regard to characteristics of communication of prognosis, some preferences, such as who is present during the discussion and physical aspects, such as proximity to the doctor or physical touch, vary between individuals. However, several themes consistently emerge from studies of patients' preferences regarding the nature of prognostic disclosure. Patients wish for honest and clear information, ideally from a doctor who is well known to them. In addition to information about estimated life expectancy, they want to know what to expect from their illness as it progresses, in terms of functional ability, symptoms, and ability to fulfill roles. They value having some control over what is discussed and the opportunity to ask questions. There is a need for honesty to be balanced with sensitivity and for the conversation to engender a sense of control and support hope (Hagerty et al. 2005). A good knowledge and understanding of the patient should facilitate this somewhat daunting task. By better understanding what is important to the patient, the clinician can identify where the opportunities lie to support hope and tailor information in a way that gives a sense of control.

As with delivery of bad news, the pacing and initial extent of prognostic disclosure should be informed by knowledge of what the patient already understands about the nature, extent, and implications of their disease. Patients should be informed that predictions of life expectancy are best estimates only and approximate. Patients may find it difficult to understand or misinterpret statistical data, which is not individualized, such as median survival time or probability of survival until a certain time point. Instead, it is common practice to express prognosis as the likelihood that the patient will die within days, weeks, or months and on some occasions to give an indication of whether we estimate this to be in the region of short days, weeks or months, or several. Although expressing prognosis in this way avoids conveying unfounded precision to patients and their families, it is not known how patients and families assimilate this information and whether they infer a specific numerical estimate from the information provided.

An understanding of prognosis plays an important role in informed decision-making by the patient regarding preferred treatment, ceilings of care, and place of care. Patients with cancer who have an understanding of their prognosis are more likely to opt for supportive rather than life-prolonging treatment, have a DNAR in place, and have completed a living will, than those who overestimate their survival (Enzinger et al. 2015).

For patients with other life-limiting illnesses, such as organ failure or frailty, prognostication can be particularly challenging. In one study conducted in Canada, telephone interviews were conducted with 67 bereaved relatives of patients who had died in hospital. In particular, they placed value on being informed early during the

admission that the patient was sick enough that they could die. Although doctors frequently cite uncertainty as a reason for not disclosing the possibility of death during severe exacerbations of diseases characterized by the entrant-reentrant trajectory, participants in this study who described being told of the lack of certainty regarding the possibility of death or recovery reported high levels of satisfaction with communication. Participants also valued clear information and avoidance of euphemisms, giving false hope, and conflicting information (Krawczyk and Gallagher 2016).

11 Diagnosing Dying

> Death is a process, not an event, despite medical and legal imperatives to give it a date and hour. James W. Green, Beyond the Good Death, p. 188.

11.1 Background

Diagnosing dying is not straightforward and can be difficult, even for an experienced physician. The process of diagnosing dying can be "viewed as part art, part science and is often regarded as skill of individuals rather than an objective assessment of signs and symptoms" (Kennedy et al. 2014). There are no definitive criteria for diagnosing dying. The ensuing uncertainty is often challenging for healthcare service providers. Current prognostic tools and models are limited and are not yet, or may never be, sensitive enough to reliably identify those who will die within hours or days. One literature review reported an "overarching theme of uncertainty." Diagnosing dying should be viewed as a process and not an event. Recognizing that death is imminent is integral to ensuring appropriate management that is focused on comfort and dignity and avoidance of unnecessary interventions and facilitates timely discussions and shared decision-making with patients and their loved ones.

Events in the United Kingdom (UK) during the past decade have brought scrutiny upon the scientific evidence-base for diagnosing dying. The Liverpool Care Pathway for the Dying Patient (LCP) was a care pathway covering palliative care options for patients in the final days or hours of life. The purpose was to help doctors and nurses provide quality end-of-life care. It was developed in the late 1990s for the care of terminally ill cancer patients and then extended to include all patients deemed to be dying. Its development was prompted by an increasing consensus within the UK medical community that standards of end-of-life care were variable. It was widely used throughout the United Kingdom and internationally, and initial reception was very positive. Key components included discontinuation of non-essential treatments and medications and prescription of medication for symptom control at the end of life and prompt to discuss dying with patients and families. However, its use was subject to heavy criticism in the media from 2009, with reports that it was being widely abused as a "tick box exercise" and some patients were being incorrectly diagnosed as dying. This naturally caused considerable distress to patients and their loved ones. It was claimed that patients had been inappropriately sedated and denied food and water, while some felt it had hastened death in relatives not dying imminently. Many patients and their relatives were not informed or consulted that the patient was being placed on the pathway. Controversially in some English NHS trusts, there were financial payments for meeting targets when using the LCP.

In July 2013, the results of More Care, Less Pathway, an independent UK government review into the LCP led by Baroness Julia Neuberger, were published (Neuberger et al. 2013). It acknowledged that the LCP can provide a model of good practice when used properly. However, it concluded that it was not being applied properly in all cases and that use of generic protocols was the wrong approach. They recommended that use of the Liverpool Care Pathway be replaced within 6 to 12 months by an end-of-life care plan for each patient. Following the review, it was also recommended that financial incentives for hospitals relating to care for dying patients, including the LCP, should cease immediately.

In response to the recommendations of the Neuberger Report, the Leadership Alliance for the Care of Dying People (LACDP) in 2014 published their report One Chance to Get it Right (Leadership Alliance for the Care of Dying People 2014). This advocates an approach to caring for people in the last few days and hours of life which keeps people and their families at the center of decisions about treatment and care. More Care, Less Pathway called on the National Institute for Health and Care Excellence (NICE) to issue clear guidance around death, and in 2015, NICE guidelines entitled Care of dying adults in the last days of life were published (National Clinical Guideline Centre 2015).

11.2 Factors to Consider when Diagnosing Dying

More Care, Less Pathway affirmed that diagnosing dying is an incomplete science and that there are no precise ways of telling accurately when a patient is in the last days of life. It recommended that there should be clear guidance on clinical decision-making processes at the end of life and, in particular, managing the uncertainties around diagnosing dying or recovery phases.

The NICE guidelines reported the following signs and symptoms that may suggest the person is entering the final days: multiple organ failure, progressive weakness, reduced mobility, reduced ability to carry out normal activities of daily living, and increased periods of sleep. Other features include reduced oral intake and a reduction in cognitive function, awareness, and communication (National Clinical Guideline Centre 2015). Spiritual and psychological changes including withdrawal, social isolation, declining interest in daily life, agitation, and anxiety, particularly in the evening may also occur. Social and psychological decline usually runs in parallel with physical deterioration.

Signs that may indicate death within hours include variations in respiratory cycle, weakening of pulse, shutting down of skin circulation, and noisy respiratory secretions. While some symptoms of death are specific, e.g., Cheyne-Stoke breathing and noisy respiratory secretions, these symptoms are not universal. A benefit of using clinical symptoms and signs to recognize death is that the technique is noninvasive and does not cause harm to the patient.

Functional performance scales can also be used to aid the diagnosis of dying. Specifically, deterioration in ECOG indicates a likelihood of entering the last days of life, although utility is limited in people with chronic disability (National Clinical Guideline Centre 2015). Other useful scores include Barthel Activities of Daily Living Index, Karnofsky Performance Status Scale, and Australia-modified Karnofsky Performance Scale.

It is very important that any potential reversible causes that may mimic dying are considered and excluded. These potential causes of deterioration include infection, dehydration, bleeding, acute renal impairment, drug toxicity, and hypercalcemia. These conditions are likely to be elicited by good history taking and clinical examination but may also require simple laboratory tests.

The evidence for diagnosing imminent death with laboratory tests is weak, and the use of measurements such as renal function or performing imaging may not be appropriate due to invasiveness and limitations of use. Clinical tests in the last 2–3 days of life should only be undertaken if there is a clinical imperative to do so.

When diagnosing dying, it is important to consider the patient's medical history and clinical context, including the underlying diagnosis and associated disease trajectory. Understanding trajectories may allow for more practical planning around death, but they do have their limitations. Individual patients will die at different stages along each trajectory, and the rate of progression may vary. Challenges can also arise from illnesses following different trajectories, and there may be numerous underlying conditions causing death. It is important to take into account the patient's underlying robustness or frailty, associated symptoms, and the speed of deterioration.

The setting may also play a role in diagnosis; studies have shown that care in an acute hospital is more likely to result in active treatment as opposed to the nursing home, where comfort or rehabilitative care may be the focus (Kennedy et al. 2014).

11.3 Challenges in Diagnosing Dying and Ongoing Care

Clinicians must be alert to signs of recovery in patients felt to be dying. This may be indicated by improvement in signs and symptoms or functional status. Assessment of whether a patient is nearing death, stabilizing, or improving should be informed by information gathered by the multiprofessional team, patient themselves, and those important to them (National Clinical Guideline Centre 2015). It is important that the clinical team discuss and reach agreement on the likely phase of care, in order to avoid provision of inconsistent care and advice.

Factors relating to the clinician, the doctor-patient relationship, and healthcare setting can potentially impact on how soon dying is recognized. As discussed above, a strong doctor-patient relationship can be associated with overly optimistic survival predictions, and there is every reason to assume that this may continue into the dying phase. There is sometimes a reluctance to diagnose dying if any hope of improvement exists. This may reflect the strength of the doctor-patient bond or characteristics of the healthcare setting. Making an assessment of the probability of survival in a disease-orientated context is inextricably linked with the perceptions of "success" and "failure." Murtagh et al. propose that there needs to be a willingness to switch focus away from the disease about which the clinician may know a great deal, toward a focus on the person before us, about whom we may know much less. Listening to patient preferences and enabling their end-of-life choices will lead to greater patient empowerment (Murtagh et al. 2004). Obtaining insights and information from the observations of other members of the MDT, or a second opinion from a colleague, may attenuate these biases.

When it is recognized that a patient may be dying, it is essential that this is communicated, not only to the clinical team but to the patient, if appropriate, and their loved ones. This should be communicated clearly and with sensitivity and avoidance of euphemisms (Krawczyk and Gallagher 2016). Recognizing death allows the dying person to spend valuable time with those who are important to them. This time may also give opportunity to ascertain the patient's wishes and goals, if not already known, and the views of those important to them and to focus on their physiological, psychological, social, and spiritual needs.

NICE recommends that doctors and nurses need to communicate with patients and relatives about the difficulties in diagnosing the dying phase. This includes admitting to and being explicit about uncertainty and dealing in likelihoods, not certainties. Although it can be uneasy to acknowledge uncertainty, this openness can clarify and build trust between patients and professionals. Uncertainty around recognizing dying can lead to poor communication and avoidance of frank discussions. This may cause delayed or inappropriate clinical decision-making and unnecessary distress (National Clinical Guideline Centre 2015).

Uncertainty may never be removed from the dying process, as dying can be as much a social as a medical process. The timing of a patient's death may be influenced by symbolically meaningful occasions such as birthdays, anniversaries, and festivals (National Clinical Guideline Centre 2015). It is poorly understood if a patient's will to live or desire to die affects survival, but their attitude to dying is likely to impact on their healthcare choices, such as acceptance or rejection of interventions to treat potentially reversible complications.

11.4 Biomarkers of the Dying Process

There has been increasing interest in the biology of dying and identification of biomarkers as indices of disease processes as a result of the LCP review processes. Biomarkers have the potential to assist clinicians in distinguishing dying from reversible acute deterioration. Few studies have specifically investigated changes in biomarkers in the last days to weeks of life. A number have been found to be elevated in the blood of cancer patients in the last 2 weeks of life including WBCC, platelet count, serum CRP, urea, urate,

alanine transaminase (ALT), lactate dehydrogenase (LDH), sodium, and plasma IL-6 (Reid et al. 2017). Explanations for raised serum urate concentrations have been hypothesized, including renal dysfunction and cellular injury caused by hypoxia and/or inflammation (Shin et al. 2006). In one small study of serial serum concentrations of inflammatory markers in terminally ill cancer patients, IL-6 was detected in all 28 terminal cancer patients sampled. It was seen to gradually rise during the early stages of cachexia followed by a sharp rise in the week prior to death (Iwase et al. 2004). The number of volatile organic compounds (VOCs) in urine has been shown to increase in the last weeks of life, using gas chromatography mass spectrometry (GC-MS), with the steepest rise is seen in the last week of life (Reid et al. 2017).

Increased understanding of the physiology of dying, along with interpretation of biomarkers and use of prognostic tools, will hopefully improve clinicians' identification of the dying process. This will, in turn, facilitate optimal care for patients and their families. However, the diagnosis of dying is likely to remain challenging despite ongoing work into diagnostic aids, and continued education and training is required. Meanwhile, clinicians must get better at accepting and acknowledging uncertainty and communicating this uncertainty to patients and their loved ones.

12 Conclusion

As clinicians caring for patients with life-limiting conditions, we must strive both to improve our understanding of prognostication and get better at accepting and acknowledging prognostic uncertainty.

Evidence from existing research literature highlights ways in which we might seek to improve accuracy in individual cases, such as basing prognostic estimates on serial assessments over time and seeking opinions from other members of the MDT and from distanced clinicians in situations where we know the patient very well.

Having an understanding of the typical disease trajectory and recognition of relevant biomarkers, clinical signs, and symptoms facilitates recognition of the period of terminal decline in advanced cancer. Prognostic tools are available which predict relatively short-term survival with accuracy comparable to that of doctors experienced in oncology and palliative care. However, we must be cognizant that advances in disease-modifying treatments may render traditional prognostic models inaccurate. One such example is the use of abiraterone for hormone-resistant prostate cancer, which Abdelbaset al-Megrahi is reported to have received following his release from prison.

Conversely, there are few tools available which have been designed to predict short-term survival in progressive nonmalignant conditions, and it is generally difficult to recognize the last weeks and months of life. Prognostic uncertainty should not be viewed as a reason to avoid discussions regarding prognosis with patients but instead serve as a trigger for discussions regarding this uncertainty.

Current and future research may help identify biomarkers for dying and prognostic indicators and tools designed to predict short-term prognosis in nonmalignant diseases. Other research questions, yet to be addressed, include whether doctors are more accurate when providing qualitative prognostic information compared with quantitative predictions and whether training on prognostication improves accuracy.

Spirituality in Palliative Care

41

Carlo Leget

Contents

Abstract

Patients who are confronted with a life-threatening disease may experience the limits of their existence. In many patients, this confrontation results in struggles and questions on an existential level, which can be discerned, but hardly separated, from questions that are primarily related to the psychosocial or physical dimension of human existence. In this contribution an overview will be given on the state of the art of spiritual care in palliative care. After having given a definition of spirituality, we will focus on how to identify the aspect of spirituality, what a spiritual process and a spiritual crisis look like, what is needed for a conversation on spirituality, how spirituality can be measured and how effective spiritual interventions are, how one can deal with the hope of patients and families, how one can deal with intercultural issues, what conditions are needed

for providing good spiritual care, and how to report and refer this dimension in palliative care.

1 Introduction

According to palliative care definitions of organizations like the WHO or the EAPC, providing spiritual care is an intrinsic part of providing good palliative care. How to define spiritual care and spirituality, however, is a subject of continuous debate (Steinhauser et al. 2017; Balboni et al. 2017). Reasons that it is hard to reach consensus on this issue are either related to a difference in cultural and academic backgrounds according to which the concepts that play a central role in the definition have a different meaning or they stem from the fact that the method used to come to a definition is different. Despite the difficulty to define what spirituality is, there seems to be a general agreement that spirituality is broader than religion. Religion is one specific way in which people live and express their spirituality.

In this text spirituality will be defined according to the world consensus definition of Puchalski et al. that was published in 2014. According to this definition spirituality is defined as follows.

> Spirituality is the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and to the significant or sacred.

The reason that this broad definition is chosen is that it has a wide span of agreement. It builds on an earlier consensus definition of palliative care experts from the United States, from which also the definition was formed that is used by the taskforce spirituality of the European Association for Palliative Care (Puchalski et al. 2009; Nolan et al. 2011).

Having defined how spirituality can be understood, in this chapter we will expand on how spiritual care can be delivered in palliative care as an aspect of interdisciplinary care.

2 Identifying the Aspect of Spirituality

As an aspect of humanity related to seeking and expressing meaning, purpose, and connectedness, spirituality can be identified in many ways and on many levels. It is intrinsically related to the physical and psychosocial dimensions of human existence and mutually influencing each other. It does not, however, mean that each patient at every moment is in need of spiritual care. Often the spiritual dimension in the lives of patients and families is implicit and hidden. On the other hand, attention to the spiritual dimension might be valuable to patients and families also when there are no specific questions or problems in this field. Moments of transition are meaningful moments, and paying attention to this meaningfulness is a way of providing care for the spiritual dimension.

Spiritual needs may be explicit, but often they are intertwined with needs in other dimensions. Kellehear distinguishes three situations of transcendence that are connected with spiritual needs: situational (purpose, hope, meaning and affirmation, mutuality, connectedness, social presence), moral and biographical (peace and reconciliation, reunion with others, prayer, moral and social analysis, forgiveness, closure), and religious (religious reconciliation, divine forgiveness and support, religious rights/sacraments, visits by clergy, discussions about God, eternal life, and hope) (Kellehear 2000).

As patients are different, the ways in which they live their spirituality may vary according to their character and culture. For some spirituality is lived in an intellectual way, studying and reading books, discussing and trying to understand what is happening to them, and relating it to a larger framework of meaning. For others the spiritual quest is more a journey to the inner world, using meditation or ways of soul searching that focus more on experiencing and feeling what is happening to them. A third group is more focused on action, bringing things in order, helping other people, or contributing to a better world (Weiher 2014).

Research has demonstrated the importance that patients and families attach to spiritual care (Cobb

et al. 2012). This might either be religious care in the form of being sustained in carrying out religious duties and needs, spiritual care in the sense of being helped in making sense of what is happening, or an attitude of attentiveness to implicit spiritual needs, by listening carefully to the spiritual dimension of the situational and moral biographical needs.

One could even argue that genuine humane and open nonjudgmental attention, as it is witnessed in dignity therapy, is also a form of providing spiritual care, as the patient is supported in finding meaning, purpose, and connectedness (Chochinov et al. 2011).

3 The Spiritual Process

People experience meaning at many levels in daily life. Situational meaning makes sense of everyday experiences and is often produced automatically and implicitly. As long as situational meaning is in congruence with the global meaning of a person – the larger framework of meaning which is related to existential values – the existential level often stays undiscussed. When the actual experiences are difficult to fit into the global meaning framework, forms of distress will begin to develop (Park 2010). A spiritual struggle is the struggle to deal with this stress and to search for ways to achieve a new balance between global meaning and situational meaning making processes. This can be achieved in a number of ways, including acceptance of the new situation, the integration of a stressful experience in a changed identity, and changes in personal goals. The process of struggling for meaning comes to rest when the discrepancy has sufficiently come to rest for the patient.

The process of spiritual struggle is a normal reaction to life-changing events like being confronted with a life-threatening disease. The way this process develops, however, may change from patient to patient. Some patients will experience a difficult process or even a spiritual crisis; other patients will hardly struggle with spiritual issues. There seem to be differences between the spiritual processes of patients suffering from different diseases.

As we look at the outcome of the spiritual process, however, there seems to be agreement that this may entail one or more of the following options: a sense of having "made sense," acceptance, reattribution and causal understanding, perceptions of growth or positive life changes, changed identity or integration of the stressful experience into identity, reappraised meaning of the stressor, changed global beliefs, changed global goals, and restored or changed sense of meaning in life (Park 2010). From a psychological perspective, all these outcomes may be good. From the perspective of a specific spiritual or religious tradition, however, one outcome may be considered as a better sign of spiritual development or growth than another outcome.

4 Spiritual Crisis

When the process of spiritual struggling results in an amount of stress that the patient is no longer able to manage, one can speak of a spiritual or existential crisis (Agrimson and Taft 2009; Yang et al. 2010). This crisis can be defined as an acute and profound questioning of the self, the world, and/or the transcendent, by external stressors, in which an individual reaches a turning point or crossroad, leading to a significant alteration of the way life and the world are viewed.

When people are confronted with a spiritual crisis, it is important to determine to whom they can be referred. In case of referral, it is important to look at the match between the identity and wishes of the patients on the one hand and the availability of specialist caregivers on the other. The first disciplines to think of in these cases are the chaplain, spiritual caregiver, or psychologist. Apart from these, one can think of a minister of the spiritual or religious network of the patient and family, like a reverend, priest, imam, or pundit.

Sometimes a spiritual crisis is accompanied by a psychiatric component. These are the cases when one has the feeling that perhaps a patient suffers from a major depression, rather than normal distress which is characterized by

demoralization, grief, loss of dignity, and loneliness. Or the experience of moral guilt is so strong and unbearable that one suspects an obsessive compulsive disorder. In cases like these, referral to a psychiatrist might be important in order to avoid undertreatment. In order to distinguish between normal spiritual distress and a psychiatric disorder, a number of questions can be asked. Griffith and Norris (2012) formulate seven helpful questions in such a case:

1. Did onset of the distress coincide sharply with a stressful life event?
2. Is the intensity of distress proportionate to the severity of the event?
3. Does distress remit when the stressful event remits?
4. Are there associated symptoms of a psychiatric disorder?
5. Are there identifiable biological or psychosocial risk factors for occurrence of a psychiatric disorder?
6. Is there a past history of a psychiatric disorder? If so, has it shown a pattern of relapse and recurrence?
7. Has there been a robust response to a psychiatric medication in the past?

After having answered these questions, plan for treatment and/or accompaniment can be made, in which the disciplines mentioned above might cooperate to the benefit of the patient.

5 Conversation About Spirituality

Because for many patients the spiritual dimension is interwoven with situational, moral, and biographical needs, a spiritual conversation may take place on different levels. Realizing that for many patients, spiritual issues are not clear-cut issues that can easily be separated from their situational and biographical context, and knowing that many patients are in search of language to address the existential level that in normal life often remains unarticulated, listening carefully and in a nonjudgmental way is perhaps the most important competence for spiritual care. Asking open-ended questions and being unconditionally interested in the patient fosters a climate of confidence and trust that is needed for communicating about personal and intimate issues such as spiritual ones. One needs to realize, however, that patients respond to caregivers anticipating on what they think is appropriate or desired. Generally speaking, a compassionate physician will get different answers than a compassionate nurse or chaplain will.

Developing the right attitude starts with being conscious of one's own inner space (Leget 2017). Working in a healthcare system can be demanding in terms of goals that have to be achieved and time constraints. Moreover, we all bring a specific intellectual, emotional, and spiritual framework into the conversation that is limited and determined by our cultural biography. All this, combined with the particular circumstances and moods we are in, has impact on our ability to listen with attentiveness and openness. The better we know our inner world, the more we are able to know our limitations and biases.

Next to developing an open and nonjudgmental attitude, one can educate one's ability to listen. Many things patients and family members say do not just have one meaning, but express many things on more than one level. The German chaplain Erhard Weiher developed a framework of listening to patients distinguishing between the factual, emotional, biographical, and spiritual content of what is said (Weiher 2014). When a woman of 43 years old, lying in the hospital for chemotherapy, says "It seems like I will not be able to be at home with my four children this weekend," any caregiver might hear a factual statement about her physical location. Every good caregiver will also hear an emotional content related to feelings of love, sadness, longing, and regret. There is, however, also a biographical content in this saying, revealing that she is a loving mother of four children. Interpreting this sentence in her biographical context might help to grasp its spiritual depth, referring to what is most meaningful in her life.

Having developed our listening capabilities, there are a number of easy tools to start a conversation with patients in an open and inviting way. A

somewhat structured way of getting into conversation can be making use of the three questions that were developed by the Mount Vernon Cancer Network (2007):

1. How do you make sense of what is happening to you?
2. What sources of strength do you look to when life is difficult?
3. Would you find it helpful to talk to someone who could help you explore the issues of spirituality/faith?

The three questions of the Mount Vernon Cancer Network open up the spiritual dimension of what patients and families experience, starting from what is important to them and what has been helpful to them. They do so in a very open way without directly asking for what this means for the care they receive.

A second example of a conversation tool which has been developed for patients, families, and caregivers is the ars moriendi model (Leget 2017). This model is based on five central themes that are important at the end of life and can be summarized in five questions that patients may be struggling with:

1. Who am I and what do I really want? (autonomy)
2. How do I deal with suffering? (control)
3. How do I say goodbye? (farewell)
4. How do I look back on my life? (guilt)
5. What can I hope for? (afterlife)

The ars moriendi model has been developed as a conversation tool for patients, families, and caregivers. In accordance with the WHO definition of palliative care, it was designed from the idea that dying is a social process. Nevertheless, the patient is the first and central person who should be offered assistance in answering the existential questions that may come up at the end of life. In the model this is facilitated by presenting the five central questions against the background of five tensions that are characteristic for the ways in which people answer the question: the tension between being able to connected to oneself versus the other (autonomy), doing versus undergoing (control), holding on versus letting go (farewell), remembering versus forgetting (guilt), and knowing versus believing (afterlife). The ars moriendi tool is used in different ways. In some Dutch and Belgian healthcare settings, it is offered to patients as a mirror to reflect on their position; in other settings it is used for structuring the work of general practitioners (Vermandere et al. 2015).

Other assessment tools are directly designed to gather information which is important to take into consideration for caregivers. A very direct and effective single question that proofs to be acceptable for patients is the so-called Patient Dignity Question (PDQ): "what do I need to know about you as a person to take the best care of you that I can?" (Johnston et al. 2015). This question expresses a person-centered concern and leaves it to the patient what he or she thinks is appropriate to tell the caregiver.

Next to the Patient Dignity Question, there are a number of spiritual history tools that are known by acronyms like FICA, FAITH, SPIRITual, and HOPE. Spiritual history-taking tools can have an important role in identifying the spiritual needs of patients at the end of life. According to a recent study, the "HOPE" tool seems to be most comprehensively addressing the spirituality themes identified as important within the healthcare literature (Lucchetti et al. 2013; Blaber et al. 2015). The HOPE tool asks for (H) sources of hope, meaning, comfort, strength, peace, love, and connection, (O) organized religion, (P) personal spirituality/practices, and (E) effects on medical care and end-of-life issues.

6 Measuring Spirituality

Next to conversation tools, instruments for measuring spirituality can be used. According to a literature review comprising 90 papers and 58 measures, it is important to specify what one really wants to know (Best et al. 2015). Dependent on the construct, Best et al. recommend different measures: suffering (PRISM, MSSE), hopelessness and demoralization (HAI, Kissane's Demoralization Scale), hope (HHI), meaning

(FACIT-Sp, LAP-R), spiritual well-being (FACIT-Sp), quality of life (FACIT-Sp, MQoL), distress (SAHD), and spiritual pain, distress, or struggle (no recommendation).

Measuring spirituality might be interesting for the purpose of doing research. The distress, however, of patients who are receiving palliative care will often take a toll on their reserves. This makes lengthy assessment tools burdensome in clinical contexts and pleas for using short measures. For that reason Best et al. propose further research in this area to focus on single-item measures like: "Are you at peace?" (Bayes et al. 1997) and "How long did yesterday seem to you?" (Steinhauser et al. 2006). Next to the issue of burdensomeness, it is important to realize that the nature of suffering is very personal in the way it is multidimensional, culture, and context specific. For this reason it is more important to be sensitive to subjective components and alertness to verbal and nonverbal cues to the patient. In the end, caring requires the ability to connect and be attentive to the patient, especially in this very sensitive area of deeply personal feelings and experiences.

7 Effectiveness of Interventions

Attention to the spiritual dimension of what patients and families experience is an intrinsic part of palliative care according to the WHO definition. It is an expression of the respect for persons and confirms their dignity. Research into the effectivity of spiritual interventions, however, is scarce and has produced only small evidence. Measured with the strict criteria of a Cochrane Review, one must conclude that there are so few RCTs, and the quality of them is so problematic that there is hardly any evidence for the effectiveness (Candy et al. 2012). Nevertheless researchers continue to study the correlation between interventions and positives outcomes. Narrative interventions seem to have a moderate short-term positive effect on the well-being of patients (Kruizinga et al. 2016). The combination of meditation massage seems to have a more positive effect on the quality of life than meditation alone in a population with end-stage AIDS (Williams et al. 2005). Also, a life review program among Chinese patients seemed to have a positive effect on the well-being of patients compared to standard palliative care (Xiao et al. 2013). The training of physicians and nurses by chaplains has also shown positive results reported by patients (van de Geer et al. 2017).

Other research has not been able to demonstrate positive effects on the quality of life of patients. There is small evidence that meditation compared to standard care or massage does not seem to improve quality of care (Williams et al. 2005). Neither have positive effects on quality of life been proven for dignity therapy and a structured spiritual anamnesis compared to standard care or counseling (Martinez et al. 2017).

Although the positive effect of spiritual interventions on the quality of life or quality of care for palliative patients is hard to prove, they can still be meaningful way of caring for patients. Because spiritual care interventions are so tied up with careful and sensitive communication, attention for the spiritual dimension is an important measure of good quality care, as can be demonstrated by the example of dealing with hope.

8 Dealing with Hope

Hope plays an important role in the lives of patients and families. It is a vital and helpful source that can have different contents simultaneously and shift during the palliative phase. Dealing with hope can be difficult when caregivers have the impression that the hope of patients and families is unrealistic or absent. Often this results in an ethical dilemma: on the one hand, caregivers feel that they have to inform their patients about a realistic prognosis; on the other hand, they do not want to demoralize patients and taking away hope as a positive life force. Moreover, in some cultures taking away hope from patients is equal to abandoning them and giving them not the support they deserve.

Research has shown that among caregivers three different perspectives on hope are used, often connected with the perspective of specific professions (Olsman et al. 2014a). Physicians and

nurses often adopted a realistic perspective on hope, seeing hope as an expectation that should be truthful, so that futile treatments are avoided and patients may focus on unfinished business. Hope, thus, could be destroyed by a negative prognosis or conversations about death and dying.

A second perspective, adopted by physicians, nurses, and psychologists, was hope as a way of coping with the impact of the disease. Hope was seen as something motivating and helpful in order to live life as normal as possible. Hope-fostering strategies according to this functional perspective were offering treatment, providing comfort or pain relief, and talking about death and dying.

A third perspective of hope, adopted by nurses and chaplains, described hope in terms of meaning. Important for people adopting this perspective was that hope was in line with the patient's life narrative. For this reason it is called a narrative perspective, focusing on what is important and meaningful to a patient. Here hope is seen as a meaningful imagined future that helps restoring the biographical integrity of the patients and families.

These three perspectives on hope do not necessarily exclude each other. When caregivers are aware of the way they are inclined to see hope, and the alternative perspectives that are available, they can use the three perspectives in order to sustain the patients and their families. Often patients and families also have a dominant perspective on hope that is the most important to them at that very moment. Being aware of this perspective and communicating with them on the same terms enables to attune to the needs and possibilities that are detected in a particular situation (Olsman et al. 2015a).

Hope is a phenomenon that can be directed to many things simultaneously, even conflicting from a logical perspective. A patient may be convinced that there no life after death and still hoping to see his diseased wife. He may hope that his death will be soon and painless, but simultaneously hoping to be around when his first grandchild is born in a couple of months. For this reason the many hopes can be compared with the many voices of a singing choir (Olsman et al. 2015b). Voices may be more or less dominant, loud, or continuously present: the better one listens, the more one may hear of the polyphonic self (Leget 2017).

Lastly it is interesting to realize that patients use different metaphors with regard to hope: grip, source, tune, and vision (Olsman et al. 2014b). Metaphors may be helpful to make the elusive phenomenon of hope a bit more concrete, but the limits of each metaphor can also block new ways of looking at things. Being aware of the limits and possibilities of the use of metaphorical language enlarges the repertoire of possibilities one can use as a caregiver.

9 Intercultural Issues

Although spirituality as an aspect of humanity is universal, the way it is experienced, understood, and expressed is very much determined by the cultural context of patients and families. As we have seen, e.g., in some cultures the importance of not taking away hope is so strong that realistic prognoses are not shared with the patients. In spiritual care for people with a different cultural background than one's own, it is important to inform one about the specific spiritual or religious practices that might be important to patients and families, as do the assessment tools we have discussed above. Intercultural communication always focuses on seeing the unique and individual patient in his or her cultural context and being open, nonjudgmental, and authentic. There is a growing awareness of the importance of research into the importance of culture sensitive care in a globalizing world (Schrank et al. 2017). Because the majority of research into spiritual care has been done in North America and North Western Europe, there's a great need for researching and developing tools and instruments for other parts of the world (Selman et al. 2013).

10 Conditions for Providing Good Spiritual Care

There are a number of conditions that are to be met in order to be able to provide good spiritual care. In the first place the attitude and frame of

reference of the caregiver should be open to providing spiritual care. Only by adopting an open, nonjudgmental attitude toward patients and their families, the basis of trust can be established that is needed to communicate about one's deepest hopes and fears. It also implies being aware of one's own spirituality and being able to articulate this when asked for. As regards the frame of reference, it is important to have some basic knowledge of spiritual and religious traditions in other cultures.

In the second place, communicative skills are important. Spiritual care requires the ability to be listening rather than speaking, receptive rather than active, and asking open questions in order to help a patient or family member articulate what is most important to them. Many times, the spiritual questions people have are not issues to be solved, but rather questions to be answered by a hopeful presence (Nolan 2011). As for patients from other cultures, it might be important to work with people who are able to translate.

A third precondition is care for the caregivers. People who provide palliative care are often confronted with situations that have a great impact on their own spiritual resilience. It belongs to good professional practice to be able to monitor one's own well-being and resilience. Caregivers who are under stress, whose inner space is too much occupied with their own coping process, or who feel that they have signs of a beginning burnout should share their experience with colleagues or take a form of supervision (Sansó et al. 2015). Being able to give full resonance to the inner lives of patients and family members presupposes inner space in the caregiver above all. The collective spirituality of an interdisciplinary palliative care team may be a helpful resource here (Sinclair et al. 2006).

Since spiritual care is a developing field in palliative care, and in many respects still in its infancy, education in spiritual care is a fourth important precondition. Multidisciplinary education has a number of advantages here: professionals learn to understand each other's perspective and role, and what is learned by the team can also be taken home by the team. Chaplains and spiritual caregivers should be able to organize educational meetings. This enables them to share some of their expertise in the field, informing other disciplines about their approach and building a shared framework for reporting spiritual care in the multidisciplinary team.

According to a white paper on generalist palliative care competencies, professionals working in the field should be able to:

5a: Demonstrate the reflective capacity to consider the importance of spiritual and existential dimensions in their own lives;
5b: Integrate the patients' and families' spiritual, existential and religious needs in the care plan, respecting their choice not to focus on this aspect of care if they so wish;
5c: Provide opportunities for patients and families to express the spiritual and/or existential dimensions of their lives in a supportive and respectful manner;
5d: Be conscious of the boundaries that may need to be respected in terms of cultural taboos, values and choices (Gamondi et al. 2013).

The last precondition for providing good and effective spiritual care concerns the organizational dimension. All preconditions mentioned before should be guaranteed by the context of the organization, including having enough time for providing spiritual care and being able to develop oneself in this area (Keall et al. 2014). The importance attached to spiritual care should be visible in policy documents, the possibilities of education and supervision, and special initiatives, e.g., the appointment of a professional who is responsible for promoting the quality of this dimension.

11 Reporting and Referring

As in most aspects of palliative care, providing the best possible spiritual care largely depends on the quality of collaboration in a multidisciplinary team. Obstacles may be that chaplains refuse to share information with the rest of the team because they consider their work more confidential than the work of other caregivers. Another obstacle may be that the team struggles with the

question how to report spiritual issues in a way that is clear and recognizable. Both obstacles ask for good communication and close collaboration. Patients should be asked whether they agree with the chaplain sharing important information with the rest of the team. Integration of the chaplain in the multidisciplinary team and close collaboration help developing a shared language for reporting spiritual issues. Sometimes a shared model, e.g., the HOPE or FICA tool or ars moriendi model, can be a helpful tool to put spiritual issues in a shared framework (Blaber et al. 2015; Leget 2017).

Referral may be due to different causes. Firstly, sometimes patients who belong to a spiritual community or religious tradition prefer to be accompanied by a minister of this tradition. With respect to an issue as personal, intimate, and culturally determined as spirituality, speaking with someone who understands the emotional and spiritual depth of one's spiritual process by being part of the same community can be a great source of support.

Secondly, internal or external reasons may ask for a referral. If one feels there is too little chemistry or confidence, another caregiver may be better as a conversation partner. Also the feeling of not being able to meet the specific demands of a patient, having no time or space, or discovering a spiritual crisis that asks for special expertise are legitimate reasons to refer to another healthcare professional.

12 Conclusion

Spiritual care is a strongly developing interdisciplinary field of research and studies, both within and outside of palliative care. Although much research still needs to be done, in this contribution we presented some helpful elements of providing spiritual care based on both research and clinical experience. Although much support can and should be drawn from instruments, spiritual care cannot succeed unless one is able to connect to one's own inner life. From there spiritual care can be developed including bedside skills in which hearing, sight, speech, touch, and presence are integrated (Sinclair et al. 2012).

Dignity in Palliative Care

42

Megan Best

Contents

Abstract

Community demands for death with dignity developed in modern times as a result of the medicalization of death. Confusion has often surrounded the meaning of the term "dignity" at the end of life due to its association with both euthanasia and a peaceful, natural death. While it is recognized that dignity is both intrinsic and inviolable as a universal characteristic of all human beings, it is also experienced as an extrinsic characteristic which can be impacted by external factors. Modern views of dignity conserving care recognize that patient dignity is preserved when healthcare workers refrain from transgressing the patient's standards and values, or refrain from forcing the patient to transgress his or her standards and values.

In this chapter, models of dignity in dying patients are detailed, along with empirically developed approaches to dignity conserving care. The essence of dignity conserving care is found to be socially constructed, individually perceived, culturally influenced, relational, and embodied. It is impacted by the perceptions of both the patient and the palliative care staff. The experience of dying with dignity is dependent on the dying person knowing that their loved ones, carers, and strangers perceive them to be as fully human as they are, regardless of their frailty.

1 Introduction

The goal of helping patients to die with dignity has been identified as a summary of the basic tenets of palliative care, and is an increasing priority in healthcare generally. Dignity, then, is such an intrinsic element of palliative care that it needs to be understood if individual practices are to be judged according to whether they are consistent with best practice. Palliative care occurs within the biopsychosocial-spiritual model of the human being (Sulmasy 2002), as it recognizes the need to address care for all dimensions of the person – physical, psychosocial, and spiritual (World Health Organization 2002). By upholding the preservation of dignity as a goal of care, management of dying patients can be tailored in a holistic way to the individual's personal needs and values, especially at the end of life when individual vulnerability increases and one's control over the environment reduces.

This chapter will examine the historical rise of the community call for dignified end-of-life care, the ways dignity can be understood, and its associations with requests for hastened death. Measures of dignity are outlined as well as ways dignity-enhancing care can be implemented.

2 Background

The call to be mindful of patient dignity in healthcare at the end of life developed as a result of the medicalization of death. Attitudes toward death have changed considerably over the last millennium. Madan describes the difference as one of hopefulness or confidence arising from the conviction that life encompasses death, compared to hopelessness flowing from seeing death as the end of a good thing, namely life (Madan 1992). Up until the eleventh century, historians describe an attitude toward death which was not fearful, as death was a collective experience that was not necessarily the end of existence (for those who believed in an afterlife). It was the emergence of individualism that led to the idea that death was a personal tragedy.

The Enlightenment, an intellectual and philosophical movement in Europe during the eighteenth century, led to the empowering of reason along with increased questioning of the church. Enlightenment thinking saw the mind and body as separate. As a result, science claimed the physical body as its domain, and in order to escape the control of the church, downplayed all the other domains. Since then, science and medicine have focused almost entirely on the biological or the biosocial model of human beings, where what is real is only that which can be empirically proven. Humans became masters of their own fate, and doctors gained power over other human beings through a supposed ability to prolong life.

The subsequent "medicalization" of death led to a view of death as something which was a failure. This view is held widely by both healthcare and general populations (Smith et al. 2018). Many scholars have described the subsequent loss of meaning in life, and therefore in death, that has ensued. Human life has been invaded by technology, and so death is redefined as not a natural phenomenon, which may be seen as meaningful and dignified, but something mechanical, "the ultimate form of consumer resistance" (Illich 2010).

There is a risk that those approaching the end of life in modern western society may be either under- or over-managed. Ageing or dying persons may be relegated to an institution, apart from family and friends, where they experience multidimensional loneliness and lose their former independence and identity. Any expression of excitement or distress leads to the administration

of medications which, while relieving immediate symptoms, lead to further dependence on others and loss of self-esteem. Alternatively, those who are dying may be caught up in the acute hospital system, disempowered as patients, where they are dehumanized by technology and the timing of the end of life becomes a decision for doctors.

The latter situation led to the public criticism of medical end-of-life care and calls for euthanasia, to allow individuals to escape the "living death" of technically assisted existence. In the USA, the legal cases of Karen Quinlan (d. 1986) and Nancy Cruzan (d. 1990), both diagnosed with persistent vegetative state (PVS, also known as post-coma unresponsiveness or unresponsive wakefulness syndrome), led to prolonged debates in a blaze of publicity.

In April 1975, Quinlan stopped breathing after consuming barbiturates and/or benzodiazepines with alcohol while on a strict diet. She lapsed into a coma and required ventilation and nasogastric feeding to live. After 5 months, when her family realized that she would never recover, they decided to remove the ventilator and let Karen die. However, at this time the American Medical Association equated withdrawing a respirator in order to allow death to occur with euthanasia, and equated euthanasia with murder. After a long legal battle, in January 1976 Quinlan's parents were granted the right to discontinue life support. However, she was still alive in April 1976, by which time she had pressure sores extending to the bone. As disconnecting the ventilator was still viewed as a form of euthanasia by the medical staff, rather than just disconnecting the ventilator, Quinlan was weaned off. She was transferred to a nursing home where she lived for over 10 years before dying from pneumonia.

Cruzan's case led to a landmark decision by the US Supreme Court. Cruzan had a cardiac arrest following a car accident in 1983. She also experienced anoxic brain damage. She remained in PVS for 7 years, being kept alive by a feeding tube. Cruzan's parents sought legal permission to remove their daughter's feeding tube, and it went to the US Supreme Court before it was decided that there was sufficient evidence to believe that, had she been competent, Cruzan would have wanted the tube removed, and it was allowed by the courts.

In the United Kingdom, the case of Tony Bland (d. 1993) went through a similar process before a court order was granted allowing him to "die with dignity." As a result, he became the first patient in English legal history to be allowed to die by the courts through the withdrawal of life-prolonging treatment including food and water. While all three cases were complex in their own ways, they represent the failure of modern medicine to ask not only, "how can we prolong life?," but whether we should. And, as concern for death with dignity followed a pattern of neglect of the needs of the dying, it also illustrates how the phrase "dying with dignity" came to be associated with not only the push for legalized euthanasia, but also with the call for holistic care in the context of a natural death.

As time has progressed, rather than escaping the fear of death through the ever-increasing list of therapies available in western medicine, paradoxically, the fear of death has increased, and its discussion remains taboo. Personal spiritual and religious beliefs that could ease this fear are less common in western countries. The decrease in perinatal mortality and rise in hospitalization of the dying means that most members of the public have never witnessed a death or seen a corpse, and for many the mystery of death remains obscure and menacing. The ever-increasing diagnostic capabilities of medicine make death an overshadowing presence on the lives of adults, increasing with their years, and leading to regular health checks and dependence on medical specialists. Death in this context is commonly seen as a final indignity. Good palliative care recognizes this fear and acknowledges the existential distress that is experienced by dying people and their families.

3 What Is Dignity?

The Oxford English Dictionary defines dignity as the quality of being worthy or honorable (Brown 1993); however, this does not cover the extent of the idea of dignity in palliative care (Abiven

1991). The medical literature encompasses many interpretations of the word, difficulty in arriving at a final consensus possibly being due to the nature of the phenomenon. Qualitative research has illustrated that the concept of dignity in palliative care is broadly understood and influenced by culture and personal history, therefore the experience of dignity will be different for everyone. Moreover, dignity for any one individual is dynamic and can be perceived differently by the family and carers compared to the patient (Hemati et al. 2016). Long lists of factors that are thought to promote or undermine dignity are a good start, but have limited usefulness if dignity itself remains undefined. There runs a risk of conflating dignified palliative care with high quality palliative care, or simply, "a good death." While both include respect for patient dignity, neither is synonymous.

In an attempt to clarify the concept of dignity in healthcare, some authors have taken a philosophical approach. While it has been argued that dignity itself is a useless concept as it adds nothing new (if dignified palliative care just means high quality palliative care, recognizing the patient's autonomy, privacy, etc.), others have suggested that human dignity lies in the ability to reason. This thinking can be traced back to the eighteenth-century philosopher Immanuel Kant, who argued that the intrinsic worth, or dignity, of humans resides in their ability as rational agents to make their own decisions. This equates dignity with autonomy, and so a patient has dignity when he is she is able to live in accordance with his or her standards and values. Others have challenged this view, which raises the question of how these attributes relate to individuals with profound intellectual impairment who are unable to rationalize. Instead they propose that dignity is inherent for those who belong to the species *Homo sapiens*, as this is what gives one the ability to reason, even if they are unable to express it at a particular time (Pellegrino 2005). It is this view that confers value on all human lives regardless of individual characteristics. Certainly, the understanding of inherent human dignity which is universal and incontrovertible is that which is referred to in international human rights documents, such as the United Nations' *Universal Declaration of Human Rights* (UN General Assembly 1948).

However, if dignity is inherent for all human beings, then the concept of death without dignity is fallacious. Allmark finds it more helpful to consider the meaning of death with indignity (Allmark 2002). An indignity can be inflicted on someone and infers an affront. It would include actions such as withholding information and depriving a person of the opportunity to make self-determining decisions, or providing inadequate symptom control so that a person suffers great pain. While these actions would represent a failure to recognize the inherent dignity of some persons, it would not remove their dignity. It seems then, that the goal of healthcare professionals needs to be not so much aiming for death with dignity for their patients (as dignity is intrinsic and cannot be lost), but to avoid causing a death where the patient suffers from *indignity*. They can try to do this in two ways: The first is by not imposing indignities – for example, not taking choices away from people at the end of their lives. The second is by acting so as to minimize indignities, such as pain or humiliation. But there would never be cause to criticize people who suffer such indignities, nor hold them in contempt, because they are not in control of whether or not they suffer them.

Allmark (2002) also suggests that dignity may be seen as a continuum, where some people are able to live in such an exemplary way that they are viewed as possessing a high degree of dignity, so that they are able to experience a dignified death despite indignities inflicted on them (such as Jesus Christ or Mahatma Gandhi). This is, however, beyond the scope of this chapter.

Pullman manages the breadth of usage of the term by identifying two types of dignity (Pullman 2002). The intrinsic dignity due to each human person regardless of individual characteristics he refers to as "basic dignity." The sense of dignity that is more subjective, and transient in nature, he refers to as "personal dignity." This type of dignity can be either enhanced or diminished by external factors beyond the control of the individual, and it is this sense of dignity which is usually

the focus of dignity discussions in palliative care. It is the area in which the palliative care worker must strive to have an impact.

Proulx and Jacelon's review of the concept "dying with dignity" (Proulx and Jacelon 2004) confirmed this dichotomy, identifying both an "intrinsic, unconditional quality of human worth" and "the external qualities of physical comfort, meaningfulness, autonomy, usefulness, preparedness, and interpersonal connection." In a review of the Oregon *Death with Dignity Act*, they note that, for patients whose dignity is primarily experienced through independence and autonomy, euthanasia may be a welcome option, particularly in the context of a healthcare system which does not uphold individual patients' dignity in other ways. They express concern that societal pressure to be a "good patient" experiencing a "good death," and not waste limited health resources, may result in patients exercising their extrinsic dignity (autonomously choosing euthanasia) at the expense of their intrinsic dignity (in terms of the inalienable right to life). This would represent discrimination against the vulnerable who may feel they have a duty to die so as not to burden society.

In a study of patients with advanced cancer, Chochinov et al. (2002a) asked patients whether dignity was internally held and inviolable, or externally bestowed and able to be withdrawn. They found that outpatients were more likely to agree with the former definition while nearly two third of inpatients believed that they could be stripped of their dignity by others. The authors suggest that this may reflect the greater ability for self-determination in those living at home. It also suggests that those living in an institutionalized setting may be more vulnerable to loss of dignity.

Killmister's suggestion that patient dignity is preserved when healthcare workers refrain from transgressing the patient's standards and values, or refrain from forcing the patient to transgress his or her standards and values, provides a foundation for understanding what constitutes a violation of personal dignity (Killmister 2010). It is our standards and values that inform our decision-making, thereby shaping our lives and giving meaning and purpose to our existence. It helps us maintain a sense of who we are, or personhood. Historical, social, and cultural perspectives of the individual will shape our standards and values. Dignity will therefore lie closely with spirituality, those relationships which give meaning to our existence and underlie our means of coping with the existential challenges of life-threatening disease (Best et al. 2015). Chochinov has described loss of the sense of dignity as a possible symptom of existential or spiritual distress (Chochinov 2006). The Enlightenment's exclusion of non-physical from science, as explained above, is one of the reasons why this dimension of care has been so long neglected in western medicine (Cassell 1982), contributing to considerable suffering in the medical context.

Killmister suggests that these standards and values may not be particularly distinguished but include our moral codes, religious commitments, cultural mores, sense of etiquette, and ideas about appropriate interactions with other people. This explains why we may feel shame at having our bodies exposed in medical procedures, or by experiencing loss of bowel function in public. The reason why being left semi-naked on a hospital trolley is experienced as humiliation is because it is a violation of dignity for the patient who has standards of public decency that they strive to maintain in their daily lives. Dignity is known to correlate with one's appearance and how one wants to be seen. It reminds us that dignity is embodied, and that the experience of dying is associated with altered, deteriorating bodies, the limits of which will dictate when life must end. Street and Kissane (2001) listed the sufferings of the body in illness associated with physical changes such as amputation, stomas, fistulas, bedsores, and ulcers, as well as physiological dysfunctions such as weakness and incontinence, so that the body may become a focus for shame, humiliation, and disgust. As all these factors can be impacted through the course of illness, the patient's sense of dignity can be challenged repeatedly throughout the trajectory of illness (van Gennip et al. 2015) and will thus need to be considered at all stages of palliative care.

While patient standards and values cannot be allowed to trump all other considerations in the performance of healthcare, Killmister's definition is the beginning of a more coherent understanding of dignity. Many authors agree that that the concept of dying with dignity is dependent on the dying person knowing that their loved ones, carers, and strangers perceive them to be as fully human as they are, regardless of their fragility. Moody perceived this insistent claim to dignity to reflect the part of human beings that is truly transcendent, or more than their physical body or social role.

4 Quantitative Associations with Loss of Dignity

Further understanding of what impacts dignity can be obtained by considering those factors with which it has been empirically associated. Wilson and colleagues found that burden to others was correlated with loss of dignity ($r = 0.49$, $p \leq 0.01$) in a group of 69 Canadian patients with advanced cancer (Wilson et al. 2005). In a study of 189 Canadian patients with end-stage cancer, Chochinov and colleagues found that existential variables, including dignity, had the most influence on the will to live (Chochinov et al. 2005). In both studies, physical sources of distress were less influential.

5 Carers' Attitudes to Dignity at the End of Life

Proulx and Jacelon (2004) found that healthcare providers and families of dying patients can be reluctant to accept that a dying individual's priority may be spiritual guidance rather than technologically advanced medical care, when aiming for dying with dignity. Holstein (1997) reported that physicians may recommend continuing active treatment to avoid peer criticism, and the family may agree to avoid blame or guilt, despite agreement that patient autonomy is important. Steinhauser and colleagues also reported on discrepancies between patient's views and carer's views on what is important at the end of life (Steinhauser et al. 2000). This suggests that the dignity-protecting needs of vulnerable patients are at risk of being misinterpreted or ignored by those caring for them. Nurses are reported to be more in tune with patient preferences.

A study of over 1000 American physicians found that 90% thought that the concept of human dignity was relevant to their practice, although there was not consistent understanding of what the word dignity meant (Antiel et al. 2012). Physicians who understood the word dignity as "basic dignity" (defined above) were significantly more likely to judge that the life of a patient in a case history of an end-of-life scenario was worth living, compared to those who conceive dignity as "personal dignity," or as a form of autonomy. This suggests that the physician's understanding of human dignity may impact their understanding of ethics in end-of-life care.

6 Measures of Dignity

6.1 The Patient Dignity Inventory (PDI)

Based on a qualitative study focusing on how dying cancer patients in Canada understand and define dignity, Chochinov and colleagues developed an empirical model of dignity (Chochinov et al. 2002a). Themes and subthemes from the model were used to devise 22 items, and terminally ill cancer patients were asked how much they thought that these items could influence their sense of dignity. The 22-item PDI prototype was later revised and became the 25-item PDI, a measurement instrument which can be used by clinicians to detect end-of-life dignity-related distress, which was validated in a cohort of Canadian palliative care patients (Chochinov et al. 2008). It is measured as five factors: symptom distress, existential distress, dependency, peace of mind, and social support. A study from the Netherlands using the PDI found that communication and care-related aspects were also important for the sense of dignity in the patient cohort (Albers et al. 2011).

7 Models of Dignity

7.1 Chochinov's Dignity Model

Chochinov and colleagues developed the "Dignity Model" of palliative care to understand how patients face advancing terminal illness and to inform dignity conserving care (Chochinov et al. 2002a). It was based on qualitative interviews and surveys with 50 terminally ill patients, who were asked how they personally understood and defined the term *dignity*, and what experiences supported or undermined their sense of dignity. Given the association between loss of dignity and death-hastening decisions, patients were also asked about how they thought dignity may impact end-of-life decision-making. Three domains that can impact on personal dignity (positively or negatively) were identified in the analysis: (1) illness-related concerns, (2) dignity conserving repertoire, and (3) social dignity inventory.

7.1.1 Illness-Related Concerns

This domain includes issues related to the illness that impact on the person's level of independence and symptom burden, and thus threaten or actually impact their sense of dignity. It includes (a) level of independence (the ability to remain cognitively alert and perform activities of daily living) and (b) symptom distress, which could be physical or psychological. Physical distress related to symptoms of the underlying illness, and psychological distress could refer to medical uncertainty about disease management or progression, or death anxiety associated with one's imminent death. All could threaten personal dignity.

7.1.2 Dignity Conserving Repertoire

This domain includes "dignity conserving perspectives," or promoting dignity by the way you view a situation, and "dignity conserving practices," or personal actions that can support one's sense of dignity.

Dignity conserving perspectives refer to established personal characteristics and values, such as (a) the sense of continuity of self (feeling you are still being treated with respect as you were before you got sick), (b) personal role preservation (still being able to function in a social role despite illness), (c) leaving a legacy (through one's accomplishments or connections), (d) maintenance of pride (maintaining self-respect despite diminishing independence), (e) hopefulness (associated with seeing life as meaningful and purposeful), (f) personal autonomy (the ability to maintain control over life circumstances), (g) acceptance (coming to terms with changing life circumstances), and (h) resilience (the mental determination to rise above the illness experience to optimize quality of life).

Dignity conserving practices refers to the techniques that patients can use to preserve personal dignity. These include: (a) living in the moment (rather than worrying about the future), (b) maintaining normalcy (carrying on with usual routines while going through the illness experience), and (c) seeking spiritual comfort (finding comfort in one's spiritual beliefs).

7.1.3 Social Dignity Inventory

This domain refers to relationship dynamics which can impact one's sense of dignity. It includes (a) privacy boundaries (the ability to protect one's personal environment from intrusion), (b) social support (having a supportive community of friends, family, or carers), (c) care tenor (the attitude taken by those interacting with the patient), (d) burden to others (whether feeling is actual or anticipated), (e) aftermath concerns (fears associated with the impact of death on those left behind).

This conceptual model of dignity suggests that where illness-related concerns and the social dignity inventory (both potentially having a deleterious effect on dignity) were moderated by a positive dignity conserving repertoire (including dignity conserving perspectives and/or dignity conserving practices), the patient could maintain a sense of dignity. The reverse, where a limited dignity conserving repertoire exists, puts the patient at risk of a diminished sense of dignity. Furthermore, this model proposes that dignity in palliative care is an interactive process between

the dying and their carers, a point suggested in an analysis of dignity by Johnson (1998). It therefore provides guidance for providing dignity conserving care, listing specific practices that could preserve patient dignity (such as by adopting a shared decision-making model), and/or act as interventions for patients with an impaired sense of dignity.

Chochinov's dignity model is also recommended by the authors in view of literature describing patients' preferences of hastened death when experiencing depression or hopelessness (Breitbart et al. 2000). As loss of dignity can be associated with depression, hopelessness, and a desire for hastened death, and dignity can influence the will to live (Chochinov et al. 2005), it is important for palliative care workers to understand the importance of dignity in the lives of dying patients.

8 Dignity Conserving Care

It is therefore obvious that, even if one has a general understanding of what constitutes dignity conserving care, and values it in the context of the dying patient, in order to provide it, one will need to take the time to ask, listen, and understand what it means for any particular patient. The more healthcare workers affirm the individual's value as a person, the more likely it will be that the person will perceive their dignity to be upheld. Respecting the dignity of the patient results in the reduction of her/his suffering and prepares her/him for a comfortable death (Hemati et al. 2016).

Many authors have noted that, once dignity is the goal of care at the end of life, management options will expand beyond symptom control to include physical, psychological, social, spiritual, and existential aspects of the patient's experience, which, as noted above, is consistent with the WHO definition of palliative care (World Health Organization 2002). In a review of dignity conserving care at the end of life, Ostlund and colleagues reported the evidence to support care actions in a broad spectrum of domains (Östlund et al. 2012).

8.1 A, B, C, D of Dignity Conserving Care

Chochinov developed a mnemonic to support dignity conserving care (Chochinov 2007):

(A) *Attitude:* Healthcare providers need to examine their approach to patients, because it is possible that they are based on preconceptions that do not reflect the reality for a particular patient. Chochinov gives the example of assumption of poor quality of life for a patient with chronic disability which may lead the health worker to withhold life sustaining choices. As the way they are viewed by healthcare workers impacts on a patient's view of him or herself, healthcare providers need to be aware of the attitudes and assumptions toward those for which they care. Trying to imagine what it would be like to be in the patient's position and self-reflection are encouraged.

(B) *Behavior:* Awareness or change of one's attitude can lead to behavioral change. The understanding that one's attitudes play an important role in mediating patient dignity should lead to a practice of treating all patients with kindness and respect. This would include actions such as treating all patient contact professionally (not avoiding those patients who are dying) and maintaining courtesy during physical examinations by recognizing the intimacy of the situation and asking permission to touch the patient. Small acts of kindness such as getting a patient a glass of water conveys the message that the person is worthy of this attention.

(C) *Compassion:* Attitude and behavior can be examined cognitively, but compassion will engage the emotions. Compassion refers to "a deep awareness of the suffering of another coupled with the wish to relieve it." Chochinov recognizes that compassion may not be instinctive and may require time and experience to fully develop, through growing understanding of human nature. It may be cultivated by exploring the medical humanities, the arts, or one's own experiences of illness and suffering. It will be conveyed to

the patient through some form of communication, a look or a touch that acknowledges the person, not just the illness.

(D) *Dialogue:* As communication of information is such an important part of healthcare, dignity conserving care requires that dialogue acknowledges the personhood of the patient and the emotional impact of their experience of illness. Dialogue can be used to get to know more about what is important to the patient, so that care can be tailored to their individual needs. Asking about an individual's values and beliefs allows the healthcare provider to build trust, honesty, and openness in the therapeutic relationship.

8.2 The Dignity Care Pathway

The Dignity Care Pathway (DCP) is a community nursing intervention based on the Chochinov theoretical model of dignity care. It was developed to support nurses caring for people at the end of life, and it was found to have high acceptability and feasibility in a trial in rural Scotland (Johnston et al. 2012). The community nurse makes a clinical judgment on when to apply the pathway. The DCP has three components: (1) The Patient Dignity Inventory (PDI, see above) is used to assess possible sources of dignity-related distress; (2) Reflective questions are used to explore the identified issues and the patient's preferences on how to address them; (3) Care actions are the implementation of the patient's wishes regarding dignity conserving care. With the patient's permission, they may be shared with the family. The goal is to give the patient a voice in their own care as a way of treating them as equals, respecting them, and acknowledging their value and worth. The PDI is then used to evaluate the interventions. If new issues arise, the pathway is recommenced. A manual has been produced to support the use of the DCP.

8.3 Dignity Therapy

This is the name given to a therapeutic intervention developed by Chochinov et al. (2005) to treat depression and spiritual suffering in palliative care patients. It is a form of life review and was designed to involve two sessions of 1 h or less each, where the patient has the opportunity to talk about their life to a staff member in a recorded interview which is then transcribed, edited, and returned to the patient. It would therefore assist in promoting the dignity conserving perspective of leaving a legacy (above). A recent systematic review of 12 quantitative studies trialing Dignity Therapy (DT) found that DT is highly acceptable to patients, who report high levels of satisfaction and benefits for themselves and their families. Families also report finding it helpful in bereavement (McClement et al. 2008). In all the studies examined in the review, the feasibility of DT was challenged due to the difficulties of recruitment and retention of seriously ill patients in longitudinal research. Also, DT is labor intensive for both the patient and the therapist, with one study reporting that four to six sessions were required for completion of therapy, with over 15 h devoted to each patient, plus significant costs for the interview transcription (Hall et al. 2012). Efficacy was demonstrated in single group studies, including improved sense of dignity; however, no randomized controlled trials have yet shown a significant impact for DT. The authors suggest that this may be due to technical errors, such as recruitment issues, measuring the wrong outcomes, or ceiling/floor effects. More research needs to be done to clarify the underlying mechanism of DT's impact.

9 Future Directions

As definitions of dignity in palliative care become clearer and our understanding of its breadth improves, we have come to appreciate how conceptions of dignity are socially constructed, individually perceived, culturally influenced, relational, and embodied. For example, a study of Japanese patients found that participants did not want dignity therapy and viewed a good death as an oblivious death (Akechi et al. 2012). It will therefore be important to investigate the factors that impact patient dignity across a wide range of

cultures and illnesses to ensure that appropriate dignity conserving care is offered in each context. It is possible that particular diseases may be associated with risks for loss of dignity that are not present in all situations. Vulnerable populations such as patients suffering from dementia may also be at risk in unique ways and require study. More work also needs to be done to fully understand the discrepancies between patient's and carer's views of dignity, in order to minimize risks to dignity for those unable to express their own care preferences.

Dignity therapy has high patient and family acceptance, but is labor and resource intensive. Research is required to identify which patients are most likely to benefit from specialist therapy, and which would be adequately managed with overall dignity conserving care, in order to clarify referral criteria (Lindqvist et al. 2015).

10 Conclusion

Evidence suggests that threats to preservation of dignity at the end of life can be cultural, institutional, and individual. Professional organizations have advocated that increased public discussion about death and dying is needed to improve understanding of normal end-of-life care. Cultural acceptance of the terminal stages of life which lead naturally and inevitably to death is required to ease the fear which is prevalent in western societies, and encourage more open conversations about end-of-life care preferences. There are recommendations in the literature that institutions need to consider the need to ensure proportionate treatment for patients, and to promote the importance of a dignified death to staff members who care for the dying. Healthcare workers are in the position to promote dignity in dying by encouraging patients to articulate their preferences and learning to listen to what they say. There are as many descriptions of a dignified death as there are dying patients. Palliative care workers need to be open to understanding what matters to each patient in their care if they are to succeed in supporting them in a dignified death.

Abstract

This chapter has an intentionally broad title to convey the breadth of ways that arts (with an emphasis on visual arts but also performative, poetic, tactile, and narrative art forms) contribute to whole-person wellness, hope, and engagement, across a range of stages encountered in palliative care services. This chapter looks at participatory arts, community and creative art facilitation, and art therapy. While there is considerable overlap in the utility of art and its benefits, such as creative enabling and expression for the patient, the range of approaches to art in palliative care herald from different disciplines, with different objectives, and are usually practised by people with distinctive professional backgrounds. It will also be clear that aspects of art facilitation in palliative care overlap substantially with approaches found in mental healthcare, dementia care, aged care, rehabilitation, and wellness initiatives in the general population. Specific to palliative care are the needs of the individual patient. Arts in palliative care now cross a range of settings, from hospital or hospice to residential care homes and community settings, variously with a dedicated studio space or a relatively mobile setup provided by the practitioner in any venue, even at the bedside. There is also some degree of nexus between arts in palliative care discussed here and psychotherapy and psychoanalysis, music engagement, "social clubs," and initiatives for art appreciation offered by art organizations, galleries, or museums and community-run art-making courses. However, this chapter focuses on the art experience tailored to people with palliative care needs.

1 Introduction

Serious illness brings with it various crises of selfhood; changing capacities and identity; adapting and scrutinizing expectations and long-term plans; undermining the sense of belonging to the community or changing communities; relaxing control of various aspects of one's life, organizational, physical, emotional, and temporal; and processing the feelings associated with approaching the end of life and death – its meanings and ramifications. These estrangements from the familiar all threaten the wholeness and integrity of humanness of the individual. Palliative care is uniquely positioned in medical disciplines to embrace this whole-person narrative and utilize nonmedical interventions that will help nurture wholeness and living fully until death.

1.1 Terminology

This chapter divides the delivery of arts in palliative care into two broad approaches. The first approach may be described as **art facilitation** which includes individual or group participatory art making (sometimes also called therapeutic arts), and also community arts, in which the facilitator is primarily an artist by training and experience, and the explicit objective for participants is creativity and expression along the path to making art. In regard to art facilitation, we have drawn on our experiences and learnings from a participatory art program delivered in Sydney, Australia, by HammondCare (a provider of aged care, rehabilitation and palliative care services) and the University of New South Wales. The program was based on the "Arts on Prescription" model originally developed in the UK (Rigby 2004, pp. 25–28). Our "Arts on Prescription" initially targeted older people with unmet health and wellness needs, including recent bereavement, living in the community, and, later, included a "home delivered" art program for carers and people living with dementia. Recently, we have extended the model further to the inpatient setting through its deployment into a cancer rehabilitation ward.

Art facilitators include artists who may or may not have training in a range of artistic contexts, e.g., people who may have trained as teachers of children or adults but with no formal experience within healthcare settings. This category best describes the painters, ceramicists, actors, musicians, and media artists who facilitated patient art in the HammondCare "Arts on Prescription" program (HammondCare 2016). For patients and the artists themselves, the authenticity of their artistic background and use of genuine quality art materials (such as good brushes, paints, clay, and paper stock) were integral to providing a real art experience, that would not be misconstrued as mere entertainment, and one that would ensure that legacy artworks would be of high quality and longevity.

Community artists are grouped here with art facilitators. Community artists often work in an urban environment with community groups, especially marginalized and minority groups, in order to give voice to their concerns collectively through making group artworks and installations in public places (Hartley et al. 2008, pp. 22–23). In Melbourne, Australia, for example, this includes facilitation of hip-hop music writing, dance groups, mural painters, and textile makers from indigenous and migrant groups, choirs for older people, and situating art studios in youth centers to enable marginalized, disadvantaged, and minority groups to build a community and express themselves, e.g., Footscray Community Arts Centre (2013).

Art facilitators and community artists could provide programs in palliative care settings even though they may not have a specific background in palliative care. Drawing on our experience with "Arts on Prescription," we suggest that artists are selected based on their skill and passion as artists and their ability to work with people, in individual and small group settings. Training in the specific needs of palliative care patients can be provided by training in a classroom setting and/or through mentoring offered to the artist by other palliative care team members.

The second broad approach to be discussed is **art therapy**, which is an extension that has grown out of psychotherapy as a tool for psychological exploration, communication, and developing the relationship with a therapist (sometimes a psychoanalytical relationship in which images are interpreted), where the practitioner is primarily an art therapist or psychologist by profession, and the artistic by-product is of secondary importance to the inner journey. The artifact can remain confidential in many art therapy situations, serving rather as the visual vehicle for relating emotions and uncovering subconscious themes. This is one of the greatest distinctions between art facilitation and art therapy: the purpose of the art making is to evoke private, safe conversation but not to express or share. "The current definition from the British Association of Art Therapists (BAAT) is as follows: Art Therapy is a form of psychotherapy that uses art media as its primary mode of communication" (Case and Dalley 2014, p. 1). The art therapist can work on a one-to-one basis and also with groups of patients.

Palliative care and supporting people who are aging is an important area for art therapists (Case and Dalley 2014, p. 11; Pratt and Wood 1998):

> Old people often feel lonely and isolated, and therapeutic work helps acceptance of old age and infirmity by focusing on the past, recollecting significant events that happened a long time ago. For those who are terminally ill, art therapy enables an experience of working towards acceptance of death. For younger patients and children, who have life-threatening illnesses such as cancer or AIDS, using art helps to express uncertainties, fears and anxieties about the future. (Case and Dalley 2014, p. 11)

People who deliver arts in palliative care programs may variously be referred to as arts therapists, community artists, and other art practitioners with a range of titles, including art facilitators, creative therapists, art teachers, art group leaders, or creative therapists (Hartley et al. 2008, pp. 17, 22) and even sponsored artists-in-residence. Many artists and musicians would argue that *art making* is therapeutic in its own right – through immersion, concentration, and creativity – that "can take you onto another level of thinking, existing and philosophising" (Hartley et al. 2008, p. 133).

This chapter focuses on the art experience tailored to people with palliative care needs. The emphasis will be on art facilitation, rather than the specifics of art therapy, a specialist area well discussed by others. In keeping with our broad approach, we will simply use the term "artist" where we do not see any necessity to differentiate between art facilitator and art therapist in the text and reserve the specific terms for situations where the difference is important or where other writers have specifically referred to one or other group. Some of the art facilitators in our HammondCare programs are also trained art therapists and have shown themselves able to work in either role.

2 The Purpose of Art

Alain de Botton and John Armstrong in *Art as Therapy* (2013) prioritize seven functions of art (primarily visual art, but the functions apply equally well to sculptural and other arts) that support human *wholeness*: remembering, hope, sorrow, rebalancing, self-understanding, growth, and appreciation.

Reinterpreted through the lens of palliative care, some of these functions adopt greater importance, such as:

- Remembering or encapsulating important moments, creating and sharing meaningful experiences to cherish with loved ones and to create a legacy
- Hope, exploring positive and thankful expressions that resolve and heal, manifest in aesthetics of beauty, focusing on values and "the good" rather than pathology, giving form to spirituality and philosophy
- Rebalancing – examining priorities and adjustment of horizons and attitudes
- Self-understanding and growth – reflection, contemplation, developing one's "best self" irrespective of circumstance, learning, passing on ideas
- Appreciation – gratitude, immersive focus through art and diversion from pain and disease

The functions perhaps of greatest relevance in healthcare and in palliative care specifically include the potential of art making to:

- Enhance identity
- Empower with new skills and an opportunity for discovery
- Give the patient control and choice
- Create a safe community of belonging and relatable experiences for the patient
- Think through existential, psychosocial, and emotional issues
- Give expression or voice (even in a nonverbal sense) to anxieties, tensions, gratitude, and growth
- Enhance social interaction and relationship formation

Part of integrating arts in palliative whole-person care involves recognizing the appropriate degree of activity and timing that will complement medical and other allied health treatment and identifying who can facilitate such experiences, ranging from art therapists to artists and

skilled volunteers or other skilled staff and family. The objective is always in supporting the expression and well-being of the patient.

For staff navigating a complex time in the patient's treatment, and for families experiencing an important part of their life together, the arts are an instrument of motivation and experience (Hartley et al. 2008, p. 13), an important psychological therapy. Palliative care occurs in a wide range of community settings, e.g., care homes and GP surgeries, and in the community. "Unlike much healthcare, which has taken place in large hospitals with an emphasis on biomedical science in medical treatments and nursing care, palliative care incorporates strong elements of *spiritual care* and *social work* and *welfare practice* along with biomedical science": an opportunity to interact with physical and mental deterioration, death, pain, and loss (Hartley et al. 2008, p. 13).

Payne and Hartley conclude:

> Creative work is a vital human activity that seeks to help people live until the moment that they die . . . Art and creative work enhances psychological and social stability, enriches human life and enables people to experience *self-fulfilment*. Art also supports patients and families to find solace and relief from distress and difficulty . . . The arts can be an instrument of psychological therapy . . .The arts facilitate communication where it is physically, socially or psychologically difficult. Participation and *inclusion* through creative work can enable patients and their families to *repair relationships* among themselves when facing the stress of an advanced and final illness. (Ch.15 by Payne and Hartley in Hartley et al. 2008, p. 186, emphasis added)

2.1 Art's Contribution to Individual Wholeness

McNiff (2004, p. 3) states that in the past, "Healing belonged to the 'soft' realm of spirituality, whereas clinical treatment aspired to a more technical and controlled realm of expertise. Our culture has lost the ancient insight of Socrates, who chided Charmides for trying to heal the body without first engaging the soul. 'Curing the soul', he said, 'is the first and essential thing.'" Today, people who suffer from illness want to be involved in their recovery, to contribute to the healing process, and not just to passively receive treatments administered by others. Participatory arts may constitute a form of active involvement in healing action.

2.1.1 Identity and Personhood

An important aspect of creative fabrication is weaving together and retelling narrative. It is important to give expression to each individual's story, whether a life story, a recount of significant events, viewpoints, or a message to family and friends. Sometimes it can be difficult to put these ideas into conversations; however the abstraction of poetry, song, painting, or assembled objects can liberate the message. In some instances, such as the participatory painting classes, patients are equipped with materials and techniques that enable them to directly create their own expression. In other instances, the role of the artist is as facilitator who helps put snapshots and ideas into an artistic form, e.g., to write songs and poems and create a collage or even a play script. We have found this partnership method can be especially effective for a person with dementia who relates experiences and moments nonchronologically or nonverbally. The skilled artist can help build an artifact that will serve as a legacy for family and friends (Hartley et al. 2008; Pratt et al. 1998, Loc.879; Connell 1992).

"Death, dying and bereavement are an important part of life, and while we all know that we will face them, we often do not think through our responses to these powerful elements of life in advance" (Hartley et al. 2008, p. 13). The arts are a mechanism for facilitating a response to current experience and giving it meaning. Stanworth (2003) says the arts create possibilities for motivation and growth, for coping and change, and for self-actualization and self-realization. For patients unaccustomed to the language of spiritual or reflective thought or unable to analyze their feelings, creative arts may help them express these ideas (such as hope, joy, or distress).

Arts also offer possibilities to make sense of situations, to create something of value, and to leave something behind – a legacy not only for patients but also for their families and carers and the inherently valuable role of such legacies as part of human experience. When great attention

is being given to the body, "the many other facets that make a person whole can feel neglected leading to a sense of *disorientation, disassociation and a loss of identity*" (Hartley et al. 2008, p. 141), and illness can permeate and consume one's whole being. Therefore, when people are nearing death, it is essential that people feel understood and recognized in order to feel alive and present.

Themes of identity re-formation that frequently appear in therapeutic arts include the patient's experience of their ill or failing body, in engaging with materials and linking bodily experiences with art making. This approach has also been utilized by art therapists working with psychotic clients and people with eating disorders (Levens 1995). Erskine and Judd (1994) articulate this *interrelationship of body and mind*. The symbolic capacity of art materials enables wordless layers of individual experience and self-image to be rendered in concrete form, which can be therapeutically powerful.

2.1.2 Diversity

As a means of communication alternate to language, engagement with arts can help palliative care services respond to diversity – to people with dementia, people with different language backgrounds and cultural experiences, people from varying educational and socioeconomic experiences, or people limited by intellectual or physical disabilities. Thus, the arts may help people with learning disabilities, cognitive impairments, dementia, or speaking difficulties to be heard. "Art, craft and music can help people express spiritual ideas, metaphors and preferences in ways that reflect different cultural traditions, and expand the arts in society" (Hartley et al. 2008, p. 17). Integrating culturally relevant and meaningful objects and images in art overcomes diversity, as does emphasis on the creative experience over and above the final artifact.

2.1.3 Nonjudgment

That the art product or artisanship is not a subject for criticism and that the creative environment is nonjudgmental and exploratory is central to this emancipation from the outcome. For many participants, they are learning a new artistic skill that they have never before utilized, which is both intriguing and liberating. Social interaction in a group setting should be fun and encouraging, not competitive or critical. Participants are often extending their experience.

2.1.4 Control

Virginia Hearth (Chap.11 in Hartley et al. 2008) particularly emphasizes that the arts can help people feel more in control, by gaining control of materials and ideas as part of the creative experience. For people who have lost control of many aspects of their lives and their own care and independence, the importance of making choices and having control is especially poignant and reassuring.

Art making is "tangible evidence of [a patient's] vitality and capacity to control their bodies" (Pratt et al. 1998, Loc.886).

2.1.5 Processing Illness, Dying, and Grief

The creative, abstract, and metaphoric side of human experience is largely ignored in a medical treatment model; however arts can help the patient develop their own understanding of their experience. Coming to terms with isolation caused by illness and an increased sense of autonomy and confidence, which consequently strengthens the patients' ability to cope with illness, are potential areas of "processing" that are supported by art making (Pratt et al. 1998, Loc.865).

Beyond self-fulfillment for the patient, arts are intended to contribute to an overall healthcare service for patients and their families and may also contribute to the community's engagement with death, dying, and bereavement. Therefore, the needs of the patients and their families should determine the arts selected and how they fit into the patient's overall care plan. The choice of art medium aims to enable patients to reach their creative best.

2.2 The Patient Experience

The arts can elicit strong reactions, and developing an understanding of these responses is part of understanding the whole patient.

Both the intellectual problem-solving and the emotional process adjustment can be facilitated by arts that offer time and space to reflect on, and adjust to, bad news or powerful feelings (Pratt et al. 1998, Loc.1123).

Patients in palliative care and people undergoing cancer rehabilitation share a traumatic experience; however they do not constitute a homogeneous population. Among them there may be patients with a psychiatric history (with revived vulnerability); patients who may have developed a dysfunctional coping mechanism, e.g., substance abuse; patients experiencing a temporary circumstantial stage of anxiety or depression; and others who cope in a mature way who ask for the help they need (Pratt et al. 1998, Loc.3777) – focusing on the inner *psychic* reality.

Palliative care outpatients and cancer patients may not be in pain but nevertheless "often the memory of the pain is still very alive, or the effects are visible in their body. They may be suffering from side effects of surgery, or radiotherapy, or chemotherapy, or bone marrow transplant. They may suffer from fatigue, weakness, migraine, swollen arms, [and difficulties] walking, talking, eating, [and] impairments in any area of functioning. The *body* becomes suddenly very important in the therapeutic relationship" (Pratt et al. 1998, Loc.3792).

Physical needs can include relaxation and soothing experiences, finding relief in relaxing forms of art practice, guided by principles of self-hypnosis and visualization, or as a form of cathartic expression (taking negative feelings out on the paper, making a mess, throwing out the paper, etc.) (Pratt et al. 1998, Loc.3802). Patients can use visual arts to represent pain, e.g., shapes and colors that symbolize, express, and contain pain. "In treating physical injuries, we know that symptoms, however uncomfortable, often function as messengers. They have stories to tell about how we live our lives and how sensitive we are to the body's needs" (McNiff 2004, p. 112).

According to McNiff (2004, Loc.89), art heals by accepting the pain and doing something (fruitful, productive) with it, i.e., a useful transformative process.

2.3 Expressing Fears and Finding Meaning

The arts offer us a way of making sense of the world and help us to define who we are and who we have been: "Our mind works in pictures, not words, and we grapple to express the inexpressible"(Waller and Sibbet 2005, p. 4). Throughout history artists, poets, writers, musicians, playwrights, dancers, and puppeteers have used *metaphor* to reveal wisdom through their creativity. Death has always been an inspiration for artistic imagination: a way to confront mortality, fears, and taboos. The arts are useful for confronting terminal illness, death, and bereavement through the use of metaphor and euphemisms, e.g., focusing on beginnings and endings, journeys and change, and seasons or transforming metamorphosing creatures like butterflies (Hartley et al. 2008, p. 142).

Metaphors allow people to step away from their reality and view it as a "witness" and also to look beyond the present to envisage the continuation of life without them.

"The images of ill health, pain, suffering, ageing, death and dying are some of the most poignant we retain and probably the most easily distorted" (Pratt et al. 1998, Loc.2239). Image making is a method to open and engage the imagination, enabling pictorial language and communication – a code of understanding, belonging only to the person who has created the image.

2.4 Art Modality and Materiality of the Medium

Interacting *with* the art media kindles creativity. Getting dirty hands, feeling the squelch and coldness of clay, the freewill of paint on wet paper, malleability, tactility, colors, textures, scratching, scraping, layering, adapting spontaneously to "accidents," and etching repeatedly are all part of the inspiration drawn directly from the chosen medium itself. Art making is somatic, experiential, physical, and sensual:

> I like getting messy! And experimenting! — R. (Cancer rehabilitation ward patient)

A function of the artist is to enable an experience of empowerment through the art materials so that the patient becomes "the expert" in telling their own story (Pratt et al. 1998, Loc. 916). Connell (1992) notes that capacity to contain *layers of meaning* (which carry the experiences, thoughts, and concerns of its creator) is characteristic of art (and music).

Interacting *about* the media enables communication between artist and patient – even more prescient in art therapy when the therapist-patient relationship is instrumental. Different art media can motivate or "jumpstart" hesitant patients. The materials and projects selected should facilitate an "achievable beginning, and lay the foundation for future development" (Hartley et al. 2008, p. 85), taking into account the constraints of the individual's strength and disease.

"There must be a large enough range of art materials from which the client can choose, as each medium lends itself to certain kinds of emotional communications" (Pratt et al. 1998, Loc.255). Case and Dalley (2014, p. 107) suggest a range of materials "from paint, paper and crayons to materials for three-dimensional modeling such as clay, plasticine, 'model magic' and 'junk' for making models and sculptures. The materials in art therapy can be used in many different ways to indicate states of mind, profound feelings, thoughts and ideas." Over time, patients usually progress from "safe" familiar materials to more adventurous ones.

2.4.1 Painting

Appropriately pitched projects are intended to give satisfaction and expression, which is valued over technique or mastery for those art forms with a steep learning curve, as well as accommodation of techniques that "unfold" themselves and include some spontaneity. For example, eliminating the need for sketching that many people find difficult and daunting, participants can paint directly onto the canvas or textured paper "wet on wet" which allows watercolor paints to run, blend, and shade, influenced by the texture of the paper. Again, there is no "right or wrong" implied, liberating the maker. Teaching general techniques such as different hue intensities to differentiate foreground and background, or the two-thirds sky "rule," scaling foreground, and important elements larger to create a sense of perspective without setting up perspective lines formally can be "shortcuts" that move the participant forward and equip people with creative tools and an appetite for exploration (Hartley et al. 2008, pp. 91–93).

Quality art materials are used in respect to the patient, to ensure that paintings do not distort while drying, and reinforcing the authenticity of the art experience, e.g., 300gsm artist-quality watercolor stock and artist-grade paints that will not fade.

A group painting – produced by a number of painters participating in the HammondCare "Arts on Prescription" program for older people with health and wellness needs – created around a single giant canvas, unified by a single theme and coherent color scheme, now hangs proudly in a medical center reception for the community to appreciate. A similar endeavor could be pursued in a palliative care setting, leaving a "legacy" for subsequent patients.

Painting is the genre that patients are most likely to have experienced before, sometimes with a frustrating school experience or notion that they cannot draw or depict lifelike images. In this regard, alternate media may be helpful; however exploring techniques and styles that do not superimpose precise expectations also facilitates greater freedom. Learning new skills allows even the very unwell patient to experience themselves in a different way (Hartley et al. 2008, p. 93), to feel enabled, capable, and excited by personal growth, influencing materials and making something aesthetically beautiful. Artworks also allow the friends and family to see the patient in a new way, expressing choice, showing their personality, and challenging limitations (Kennett et al. 2004, p. 254). Through artwork patients may also experience their environment more fully, noticing details, excited by color, observing nature, seeing afresh, more present in the moment, and actively involved.

2.4.2 Printmaking

Printmaking using lino cuts and multiple impressions of textured painted objects (such as feathers or leaves) and multiple color permutations and layers was a popular medium in HammondCare's cancer rehabilitation ward because prints could be made, dried, and returned to patients or displayed on the day of their making. Prints adapt well not only to wall mounting but also to cards and gifts that let participants share their art with friends and family. Printing en masse means that a group can literally cover a wall with joyous pictures and transform a space. Our artist recounts a patient's wish to illuminate a room with light and joy. The class together made prints of beaming flowers that filled the family room wall and collectively brought the patient's dream to fruition:

> "I want to adorn my walls with flowers: I want to wake up to beauty instead of a bare white wall."—L. (Cancer rehabilitation ward patient)

According to Hartley et al. (2008, p. 98), the most popular art forms with patients are mosaics, painting or printing on silk, and painting on glass or porcelain, inspired by seasonal interests. Once again silk painting, printing, or dying can be completed in a single day and suits people with limited mobility.

2.4.3 Pottery and Modeling Clay

Lynn Harmer, in "Pottery and Painting" (Hartley et al. 2008, p. 88), writes of clay's soft and receptive nature. It has a pressure-releasing tactile quality and almost hypnotic repetitious cycle of rolling, pinching, coiling, spinning, or smoothing that gradually evolves the three-dimensional object. Similarly repetitive brushstrokes or pastel marks can have this immersive and meditative quality.

Harmer describes a process in which patients are invited to decorate their pottery "usually in the form of a glaze; this makes it endure longer, making it stronger and more waterproof" (Hartley et al. 2008, p. 91). Brush-on glazes can be applied in a similar fashion to paint, and clay and earthenware glazes are more conveniently fired. Additional ornaments and textures may be applied within a scope and style that is rewarding.

Much consideration is given to equipment and resources, e.g., choosing clay that is responsive and tolerant, extremely reliable and resilient, and using earthenware glazes as they have a lower melting point and therefore fire at a lower temperature than other types, resulting in faster and more affordable firings so that work can be returned to patients and families promptly with pleasing results (Hartley et al. 2008, p. 97).

2.4.4 Dramatic Art

McNiff (2004, pp. 70–72) observes that patients instinctively tell stories in response to their art. These responses can grow to encompass "poetry, drama, movement, voice, and other expressions that emerge naturally when looking at images, contemplating them deeply, and letting them act upon our thoughts and feelings . . . Images generate stories, imaginal dialogue, and other forms of artistic expression, but they also act directly on our bodies, minds, and senses."

In other words, sometimes the movement, performative narration, or dramatic interpretation arises from the initial image-making act and the attempt to further convey its nuances and meanings for the creator to the artist or audience.

Like poetry, sometimes patients do not have the time or techniques to develop their own play script, so the artist "expert" can support the patient by crafting their ideas into a dramatic form. Patients can also engage in improvisation – a more direct explication of their experiences and thoughts.

Through performance art, the patient is given the opportunity to move with the image. People who respond to their art through performance experience release from debilitating self-consciousness (McNiff 1992, p. 120). "Theater offers clearly defined structures—preparatory procedures, beginnings, endings. The audience has a contributing role in making the performance an 'event' to be witnessed" (McNiff 1992, p. 120).

2.4.5 Poetry

In poetry, perhaps due to its concise yet distilled and saturated form, often metaphoric and symbolic language evocative of thoughts, feelings,

and experiences that are difficult to voice literally, there is a long history of so-called death poems. These range from John Donne's *Holy Sonnets* of the seventeenth century, said to be one of the English language's finest metaphysical meditations (or *Divine Meditations*) on the nature of death and dying and the journey of the soul, and similarly ancient Japanese death poems written in the dying hours or moments of Zen monks (Hoffmann 1985), to MacLeod's (2014) collection of poems, *The Unknown Sea: An anthology of poems on living and dying*, drawing on sources as disparate as Shakespeare to contemporary poets. Poetry may use familiar language, but it operates through imagery and abstraction that seems to condense intangible and elusive experiences into an economy of well-sounding text.

This economy of words also makes it plausible to record, or have someone else transcribe, poetry if the need arises. Hartley et al. (2008, p. 122) describe a blind and bedbound patient (Paul) who felt very isolated and desperate to have his voice heard. He recorded ideas about his body image and sense of self in poetry that was subsequently published on the Rosetta Life website (2007) through which he connected with other patients in different locations, which eased his feeling of being alone, and he was delighted by the positive response to his work.

In other instances, poets, rap singers (rhythmical lyric poets), and wordsmiths transform the stories related by patient conversations into poetry, song, drama, or puppet theater that can be performed to friends and family.

Describing their experience in a cancer hospital, Pratt et al. (1998, Loc.1902) state, "Much poetry and prose is written or quoted, so that *hope and understanding can be shared* even when the worst fears and losses are depicted." The therapeutic aim is for patients' greater openness toward themselves and to a better understanding of their situation. Pratt et al. (1998, Loc.1954) read poetry to patients for whom "it seems undeniable that the event is nearly always a source of psychological nourishment for both the patient and therapist." They describe choosing poetry that was familiar or relevant to the patient from an anthology in order to read aloud.

Poetry has catalytic, expressive, and transformative therapeutic potential. Allen Ginsberg and Carter (2001) affirms this: "The only thing that can save the world is the reclaiming of the awareness of the world. That is what poetry does" (p. 273). Transformation, here, refers to awakening a deep sense of authenticity, nourishing inner growth and expanded consciousness, exploring meaning, asking existential questions about death and identity, and openness to the spiritual dimension to life. "Poetic language, rich with metaphor, image and symbol, makes it possible for us to express the diverse, paradoxical, vibrant organisms we are – human beings that grow and struggle, sometimes get ill and heal, live and die, sorrow and sing" (Rappaport et al. 2014, p. 118).

Some of the participants in HammondCare's "Arts on Prescription" cancer rehabilitation program used poetry they composed to accompany paintings and prints they made, evoking inner qualities of atmosphere, emotions, and imagery.

2.4.6 Mixed Media and Collage

Objects from the patient's own environment may be incorporated into mixed media pieces, to convey perhaps some intimate symbolic meaning (Pratt et al. 1998, Loc.255): trinkets, keepsakes, reminders, icons of meaning, and memories relevant to the participant. The tactile and textural qualities of mixed media can be especially appropriate for people with dementia or people with visual impairment.

2.4.7 Digital Media: Film, Photography

Closely and "timefully" examining an object or an environment removes the viewer from focused activities that usurp thoughts and perceptions and, in turn, creates the opportunity to perceive experiences with greater mindfulness (McNiff 2004, p. 57). Through photography, people become more aware of their environments. Walking with a camera searching for images leads to a different kind of observation and concentration. Capturing that image gives the photographic stills camera or video camera a unique ability to hold moments of perception.

Beauty and aesthetic reverie are found in all the world's ancient and traditional cultures.

Appreciating beauty has a vital place in the process of meditation, stress reduction, relaxation, and an overall integration of body, mind, and spirit.

2.5 Art as Mindfulness Meditation

Mindfulness is a practice of bringing awareness to the present moment with an attitude of acceptance and nonjudgment. "Mindfulness and the arts can play an important role in psycho-spiritual growth and the evolution of human consciousness" (Rappaport et al. 2014, p. 2; Loc.15).

Mindfulness practices are found in most major wisdom traditions (including Old Testament Jewish prophets and desert aesthetes), but the clearest contemporary expression owes much to Buddhist thinking. Various secular contexts have adopted the practices of ancient mindfulness, e.g., psychotherapy, education, and work environments, and there exist numerous "techniques" available for practicing mindfulness and meditation in clinical settings (Rappaport et al. 2014, p. 2; Fjorback et al. 2011).

Over the past 40 years, neuroanatomy and physiology of internal composure have been found to impact brain science, e.g., the autonomic nervous system, polyvagal theory and the stress response, human brain evolution, hemispheric lateralization, attachment theory, pleasure and pain, trauma and PTSD, addiction, self-awareness, empathy, memory, and emotion (Rappaport et al. 2014, Loc.18). This has produced a growing body of clinical evidence demonstrating efficacy in reducing stress, decreasing depression and anxiety, improving quality of life, enhancing well-being, improving immune function, lowering blood pressure, and providing other benefits. Thus mindfulness can be viewed as an *integrative approach* for clinicians and patients. Practicing arts, especially tailored art practices that focus on attentiveness, concentration, repetitious gestures, and immersion (Rappaport et al. 2014, Loc.27), is a way to avail the benefits of mindfulness in a palliative care setting.

Early influences of mindfulness in psychoanalysis include the work of Sigmund Freud, Wilfred Bion, Karen Horney, and Erich Fromm, subsequently developed into contemporary approaches including mindfulness-based cognitive therapy, dialectical behavior therapy, and acceptance and commitment therapy. Kabat-Zinn's (1990) mindfulness-based stress reduction (MBSR) program has been especially influential. Caroline Peterson integrated art therapy with Kabat-Zinn's model to create an 8-week program – mindfulness-based art therapy (MBAT), which has demonstrated a positive impact on people living with cancer (Monti et al. 2006).

Meninger, Pennington (1982), and Keating (2009) developed the Centering Prayer method that is based on ancient practices by the Desert Fathers and Mothers of the Fourth and Fifth Centuries, and inspiration from Thomas Merton (1961). Blanton (2011) compares the Centering Prayer with contemporary mindfulness and discusses its application to psychotherapy. There are also some similarities to be found in the Jewish contemplative Kabbalistic meditation practices. The mystical branch of Islam is Sufism. The poet saint Rumi, born in 1207, founded the Mevlevi Order of Sufism and is often quoted to inspire states of awareness, mindfulness, compassion, and the divine. Mirdal (2010) describes "acceptance and acknowledgment of positive and negative experiences, unlearning old habits and looking at the world with new eyes" (p. 1206), breathing and walking meditation, intentions, and cultivating insight and compassion. Integrating Sufism and Rumi's philosophy and poetry with mindfulness-based approaches to psychotherapy may be a way of providing a culturally relevant service for patients with a Muslim background.

Mindfulness-based cognitive therapy (MBCT) and dialectical behavior therapy (DBT), developed by Marsha Linehan (1993), incorporate mindfulness along with interpersonal effectiveness, emotion regulation, and distress tolerance. The roots of mindfulness and the art therapies can also be found in arts in rituals to enhance spiritual and religious practices, intended to promote healing and transformation. "Artists engaging in the process of art-making can be absorbed into a state of flow," i.e., immersed in the process, and quieting of the mind (Csikszentmihalyi 1990;

Rappaport et al. 2014, p. 10). Rappaport et al. states that the "creative process is the healing agent" (2014, p. 20).

According to Carlson (Carlson et al. 2012), the diagnosis and treatment of cancer is associated with both physical and psychological distress which can have a negative effect on memory, behavioral inhibition, negative emotions, hypervigilance, and disruptive ruminative thinking (Britton 2005). Relaxational and stress-reducing art practices are therefore appropriate interventions in cancer care (Bultz and Carson 2006). Monti et al. (2006), in a National Institutes of Health randomized clinical trial of mindfulness-based art therapy with cancer patients, showed significant reductions in psychological distress and increases in health-related quality-of-life post-intervention for the experimental group. Reflection helps to deepen awareness within oneself and experience the benefits of expressive therapy.

Dannecker et al. (2008) suggest that art therapy can help to deepen observation of the pain experience and uncover its symbolic aspect "Most patients with chronic pain report that the suffering from pain significantly decreases while they engage in the creative process of art therapy" (Dannecker et al. 2008, pp. 288–289). Jürgen Fritsche describes seven stages in the Mind-Body Awareness in Art Therapy model (echoing Elisabeth Kübler-Ross' thinking) used with people experiencing chronic pain:

- Examination,
- Expression,
- Expansion,
- Energetic Release,
- Redirection,
- Recognition, and
- Relief (Rappaport et al. 2014, p. 61).

He suggests that this approach can be integrated into various disciplines by medical doctors, psychologists, physiotherapists, Feldenkrais therapists, art therapist, nurses, and other clinical disciplines.

Dance/movement therapy can facilitate the movement from mindfulness to *embodiment* by helping a patient to "kinesthetically engage with sensations, images, emotions and memories, leading to improved physical, mental and emotional well-being" (Rappaport et al. 2014, p. 73). Both mirroring and rhythmic variation are two fundamental techniques for cultivating embodiment in dance/movement therapy (Levy 1992).

2.6 Constraints in the Palliative Care Context

We have found that patients receiving palliative care and cancer rehabilitation services are receptive to learning new skills and trying art projects with an achievable outcome fine-tuned for this context by our artist. "Because patients in palliative care have limited time left to them in their lives, and an important principle in palliative care is 'to live until the moment that you die', doing something worthwhile in that time is important" (Hartley et al. 2008, p. 85). Art activities need to accommodate some limitations in order to maximize the quality of process and satisfaction it produces.

Many palliative care patients have limited energy for active pursuits, household chores, or their former pastimes. However, many forms of art practice can be approached on an appropriate scale and degree of effort to still achieve satisfying results. For many people, too, it is a first foray into a new art technique, such as painting or working with clay. The therapist or facilitator must work within the capacity of the patient's artistic development.

It is important to work within the physical limitations of the patient: conducting shorter sessions when the patient is tired or nauseated, disposing of leftover materials to avoid cross infections between patients, and using materials that are textured or have tactile properties for people with sight impairment (Pratt et al. 1998, Loc.847; Connell 1992).

One way to amplify the effects of individual effort is to make a collective (group) artwork, and another is to integrate different arts and skills into one project – either from multiple contributors or built up over several sessions.

Principally, the artist works within a timeframe that will allow the patient to develop their work in the presence of tiredness and any other symptoms that may limit their activity. The artist shows participants foundational techniques that will be useful for making other things, thus suggesting a creative future. Staff work hand in hand through the creative process and can collaborate or support as needed without usurping artistic control or making choices on behalf of the patient. Directed by the patient, for example, the artist can expedite technical or physically challenging steps. Projects are typically designed in incremental steps, and a whole session is designed to fit within a reasonable attention span for people who may be tired or frail.

Feelings of envy and disempowerment caused by the power differential between a healthy "expert" artist and physically weak or restricted patient may compound existing feelings of loss for the patient. This may be a challenge in the artist's encounter with the patient (Pratt et al. 1998, Loc.903).

3 Participatory Arts and Art Facilitation

3.1 Community, Integration, and Belonging

The HammondCare "Arts on Prescription" programs have shown the individual and family satisfaction gained through learning new skills, creating artifacts, experiencing facilitation by an expert artist, and creating works culminating in a form of acknowledgment, such as a collated collection, exhibition, publication, or performance. These forms of affirmation reinforce worth, contribution, and belonging, especially at a time when former capacities may be impacted by disease. A bespoke palliative care art program provides a respectful and "safe" environment in which patients can explore new expression without concern about technical experience. Outcomes from the HammondCare experiences have included paintings that now hang on the walls of a community medical center, participant stories with accompanying illustrations in an adult coloring book, legacies for families to keep, several exhibitions open to the public, and recognition by the broader community that perforates institutional boundaries.

Participatory arts, such as painting, printmaking, ceramics, drawing, photography, video making, movement, and music, provide a setting for agency, social interaction, enablement, self-discovery, learning, affirmation, and sharing in addition to the functions above. Some participatory arts may be most suitable earlier in the palliative care trajectory because they require movement and expending energy. Participatory arts can provide a positive counterpoint to the change and emotions associated with diagnosis. Participatory arts often occur in a group setting, though individual participation or participation in community-run art programs may also serve as therapeutic diversion and empowerment.

People receiving palliative care services or with a terminal diagnosis can find themselves isolated geographically and socially from their community groups and social circles, both due to their change in availability and capacity and because those around are not sure how to respond, similar to the experience of people with dementia. People can feel marginalized and emotionally isolated in their battle with disease, treatment, and time-consuming medical appointments or hospitalization. The group in which art is practiced can restore a degree of belonging and connection with people encountering similar concerns and circumstances and simply for companionship and normal interaction.

Art making is not perceived as an activity that has to be perfected, and there is a sense in which participants are sharing the learning experience, jovially comparing, laughing, telling their stories, and sharing feelings with nonmedical staff, with people who may understand from their own experience. The artifact is a vehicle for communication and expression in the group. Eventually the work may end as part of a bigger picture (an installation or exhibition):

> Groups provide a safe and supportive environment where staff and patients offer cooperation and

> camaraderie. It feels as if everyone enjoys each other's creative journey, and there is a very strong feeling that we are all sharing the same experience (Hartley et al. 2008, p. 95).

Kennett et al. (2004, p. 256) report patient feedback including: "enjoyment, lifting of mood, calming anxiety, relief of boredom, pride, achievement and pleasure at being able to make a gift for a relative or friend." As with music engagement, participatory arts often lead to increased personal attention and conversations about the music or art itself.

Members of a group "develop a shared experience, so that people feel they are trying something new in the knowledge that they are supported and encouraged by those around them . . . Symptoms, fears, worries and feelings of isolation are aired in discussion, as well as feelings of joy and relief when something positive is achieved" (Hartley et al. 2008, p. 114).

3.2 Participatory Arts for People with Dementia

In many ways, the needs of people living with dementia are similar to those of people confronting a life-changing physical illness: e.g.,isolation, challenges to identity, belonging, reduced capacity, changes, and losses, which are then compounded for people who require both palliative and dementia support. Many palliative care patients are elderly. It is also common to have complex comorbidities or for people in palliative care to have cognitive impairment for different reasons.

Our "Arts on Prescription" At Home project (a small pilot project) was targeting dyads – the carer and the person with dementia. The aim was to address the health and well-being needs of carers (and enhance the dyadic relationship). The carer and the person with dementia both made art (not necessarily the same project). Via individual interviews after the pilot, carers reported that they enjoyed the company of the artist, they also had something to share with their families, and they found it relaxing. It provided new dyadic interactions around a non-care shared creative experience, and some learned new ways of interacting with their loved one by watching how the artist interacted. Some carers also reported a sense of achievement and pride in their work and noted positive outcomes for their loved one, such as smiling, engaging with the artist, and ceasing repetitive behaviors while engaged with the artistic endeavor.

The creative arts can reach even the most cognitively impaired people because expression through the arts depends on something other than the intellect:

> Creativity comes from somewhere beyond the intellect; it flows from an intuitive non-rational place in the body and mind, so we can tap into the creativity of everyone, no matter how much their logic or sequential memory has been disturbed. The creative arts have the power to stir feeling and memory when a person seems to have lost contact with chronological time. The arts seem to reach below the conscious level of experience and move underground towards a hidden depth memory, accessing the feelings stowed away. (Hayes et al. 2011, p. 15)

It is also important to create opportunities for people with dementia to express their feelings in the present moment. Life can seem "full of loss and confusion, fear and frustration in states of dementia and it seems vital that such feelings are acknowledged and listened to" (Hayes et al. 2011, p. 16). Expression through arts and music can be effective when words are difficult to find, and improvisation or art generated in the present need not rely on cogent and sequential memories (Beilharz 2017).

Piecing together fragments and creating images has an important role in dementia when personhood seems to be disintegrating. Creative artifacts can encapsulate personality and emotions and can surprise and impress friends and loved ones. Hayes et al. (2011, pp. 32–33) suggest that brightening homes, day centers, and hospitals with art, with color, expressing hope and love, together with the opportunity for storytelling that arises in singing, dancing, and art making are important for the person with dementia. "In making a story about someone's life we celebrate the *spirit* of the person; we show that they matter, that they are important" (Hayes et al. 2011, p. 94).

Story making can utilize fabrics, paints, poetry, or writing. A person with dementia may be able to make substantial or partial amounts of their story with some degree of assistance putting it together (Craig and Killick 2012, p. 65). Mixed media collage is popular for story making because it is inclusive and works well as collaborative team effort. Oliver Sacks in *Musicophilia* (2007) writes about the benefits of music in the context of identity because dementia is most tragically often associated with a disintegration of identity. When people no longer hold their own stories, loved ones and the community take over this role of telling a person's story (Swinton 2012):

> In dementia we lose our sense of clock time. We can no longer locate ourselves on the sequential time line of our human life. We are no longer part of a chronological system. Our sequential thinking is damaged and we can no longer easily participate in conversation relating to shared events. Participation in life seems threatened because we cannot orient ourselves in time. (Hayes et al. 2011, p. 47)

John Swinton refers to this new nonlinear, slower time as "dementia time." Locating moments from patients' lives in time and gathering memories gives a sense of identity and value. Disoriented chronological time, spatial perception, as well as a number of sensory changes (visual, olfactory, touch, hearing, and taste) can affect people with dementia.

Hayes et al. (2011, p. 48) believe that in cultivating a greater awareness of our physical self and the movements, we become more sensitive toward the people we move around and who we touch. "Gentle, sensitive movements in relation to others convey a message of love, respect and acceptance." Touch is useful for connecting with people living with dementia when listening to music. Touch can also be harnessed in art through the use of tactile clays (Craig and Killick 2012, p. 72), interesting textures in collage and mixed media or textile work, or may even draw on old habitual memories such as the craft of knitting, or crochet, if it has been a part of a person's past. Claire Craig gives special status to hard and heavy substances – stone, wood, metal, and glass. "Stone, wood, metal and glass are solid and possess an air of permanence which means they will remain long after other organic materials such as fabric and paper have faded and decayed. This has been important for some people for whom the idea of leaving a mark, a legacy for future generations has mattered, something to say, 'I was here'" (Craig and Killick 2012, p. 78): these materials carry weight, suggesting strength and gravitas. Manipulating materials – shaping, moving, and positioning – demands engagement, placing the patient in control.

"Working with textiles is also inherently sociable and the act of taking part in rag-rugging or quilting where everyone sits and works together has inspired feelings of connectedness, fun and friendship, prompting participants to share stories whilst also promoting a sense of shared ownership in the final piece" (Craig and Killick 2012, p. 85). Crafting or art making begins with exploring the materials – yarns, silk scarves, raw wool fibers, and fleece squares – which embody a strong expressive quality. The artifact is then a tangible reminder of the textured journey traveled together (Craig and Killick 2012, p. 89).

Photographs provide an enduring tangible record, a prompt for memory, and potential recollection aid. John Berger (1992, p. 192) said, "The thrill found in a photograph comes from the onrush of memory." Photographs have been used extensively with people with dementia as a prompt for reminiscence and supporting communication while taking into account associated visual loss (from such causes as macular degeneration or glaucoma, etc.). The camera is a tool for exploration and experimentation with a focus on the present, offering an outlet for self-expression (Craig and Killick 2012, pp. 98, 100). Images are objects loaded with emotion.

"Our traditional view of dementia is one that focuses on *loss*" (loss of nerve cells, memory, and impairments in various types of cognition) measured by what people living with dementia *cannot do* (e.g., Folstein Mini-Mental Status Exam) (Lee and Adams 2011, Loc.92). Reducing a person to the sum of discrete tasks distracts from the many complex and integrative skills that continue even into advanced illness, not least

emotional responses. Power (2010) proposes that dementia is a shift in perception of the world that, in turn, can be better understood by shifting the therapist's understanding of personhood in terms of experience, not deficits.

Lee and Adams (2011, Loc.119; 133) define creativity as "a spirit that is ignited when the mind is fully engaged in the genesis of new thoughts. There is an inherent joy in beholding something that you have conceived in your own way." Engaging in creative arts can activate pathways that release thoughts and words previously held captive by limitations of language and conventional communication. Instead, connection can be made through art, music, visual stimulus, tactile sensation, humor, or strong emotion.

In the therapeutic creative space, there are no rules and regulations and no "right answer." This emancipation embraces an infinite array of approaches and outcomes. Lee and Adams (2011, p. 5) assert, "Creativity has a strong value within person-centred care because it enables the strengthening and expression of personhood while also providing opportunities for enriched relationships." According to Kasayka (2002, p. 9), the core functions of the expressive arts are "the reclamation, the regeneration and the celebration of the human spirit," i.e., the same primary goals as person-centered care.

Craig and Killick (2012, p. 39) advocate the suitability of spontaneous and intuitive arts, such as dance: "an ordinary and fundamental human activity hidden by a culture that has little regard for spontaneous movement as an expression of who we are and how we feel, in favour of more intellectual means," the "body's response to everything we do and see" (Coaten 2009), and "a different, non-verbal way of communicating" (Coaten 2008, pp. 19–22). Oliver Sacks (in *Musicophilia)* says: "When we dance together bonding is deeper. Moving together helps to regain a sense of physical identity" (2007). Furthermore, when people dance together, they share an experience and an equality that overcomes any clinician-to-patient differential.

3.3 Sharing Art and the Exhibition

Creative work and its exhibition may provide a context for integrating family and carers into the experiences of the patient in palliative care and a way of enabling communication among patients, between patients and professionals, and between patients and their families and social networks. According to Hartley et al. (2008, pp. 16, 19), exhibiting has a huge influence on the environment and how people then experience the work, e.g., presented, mounted, or hung, with a program or title, perhaps an opening event, family and community audience.

Not only does art brighten and stimulate the hospice or care environment, it also highlights the place of creative art group work within a hospice day care setting as an enhancement to emotional stability, personal enrichment, and *self-fulfillment* (Kennett 2001).

An "open studio" or exhibition generates a goal and a future horizon. Although some people may choose not to display the work they have created, painting, music, dance, poetry, and sculpture are created to be witnessed, and patients usually respond with pride, excitement, and satisfaction when others can appreciate their creations. It allows people to be acknowledged as capable, to experience a seal of validation:

> Although the expression and motivation of the artist who produces the art is central and the process of creating will have been integral to their own lives and experiences, the product created is then given over to the public who are entertained, moved, inspired or disturbed from their own personal perspective. Such responses give the artistic product value and can have an important part to play in the success of both the product and those who created it. (Hartley et al. 2008, p. 53)

4 Art Therapy

Individual or group psychotherapy is a more specialized provision needed by fewer patients. This process uses the creation of an art object, and the process of achieving it, to engage the patient or

family member in interactions with the therapist in order to resolve psychological and emotional difficulties, i.e., "art activity is a conscious process which gives concrete form to feelings, which are often unconscious" (Case and Dalley 2014, p. 86).

"The art therapist's attention to emotional detail opens up the possibility for the patient to explore on a deep level within themselves" (Jansen 1995; Wood 1990; Connell 1992). Art therapy is psychoanalytically oriented, "recognising the fundamental importance of the unconscious as expressed in the patient's dreams, day dreams and fantasies … Spontaneous graphic art becomes a form of symbolic speech which may serve as a substitute for words or as a stimulus which leads to an increase of verbalisation in the course of therapy" (Case and Dalley 2014, p. 2). The therapy is not directed by the therapist but rather follows the patient's lead (McNiff 1992) in the palliative care setting, often in order to express powerful, difficult emotions concerning their illness, treatment, mortality, and life. The process works through distress in order to normalize living with dying, which may address some of the psychological trauma of the realities of terminal illness (Beilharz 2017). The therapist creates a reflective space for the clients. The focus is on image or artifact making, alongside the process and relationship with the therapist, referred to as the "triangular relationship" (Schaverien 1998).

Art therapy, like participatory arts, can take place in a group setting, though the boundaries reflect the art therapy *milieu*. The therapy group should be contained and safe, though often open to carers and families who may wish to join in and explore some of their feelings, relationships, and memories that come up through image making:

> The nature of group work is inspiring as the clients can help each other along with image making and themes that can come up; a sense of belonging; and feeling that 'I'm not the only one' … The focus is on creating images, an empathetic environment and respect for each other and each other's image making … As with individual sessions, whatever is made in the group is confidential and the therapy is private. (Samantha Dobbs 'Art Therapy' in Hartley et al. 2008, pp. 131–132)

There is some difference of opinion in the art therapy (and psychotherapy, psychoanalysis) profession as to whether the role of the therapist extends to interpreting the images made by the patient. While some believe that interpreting an image "fixes" and seals it, or imposes meanings that do not necessarily concur with the patient's own, despite a long epistemology of symbols and archetypes in the Jungian tradition, others such as Susan Bach and Greg Furth in the field of terminal illness have endeavored to develop frameworks for "reading" pictures. McNiff (2004, pp. 69–70) is very critical of reductionist approaches in psychology that link colors, forms, and compositions to the particular pathologies of the people creating them. In his view, these systems of art diagnosis are built on narrow and typically idiosyncratic psychological theories. McNiff is particularly concerned by the literalism of such connections and the danger in drawing simple constructs from complex experiences (such as black connoting depression, red connoting anger, large eyes revealing paranoia, etc.), all of which may be further mediated or clouded by the patient's potentially limited artistic skill. Ultimately, he asks whether these reductionist analytical practices are beneficial either for art or for healing.

Art therapy can be helpful to develop awareness of Kübler-Ross's (1970) stages of death and dying: grief, anger, acceptance, shock, depression, bargaining, and denial. Patients may go through these stages *at any time and in no particular order.*

The issue of *control* is often present and powerful. In palliative care or after a particularly lengthy period of medical treatment, clients often feel that they have no control over their illness and their treatment or feel that they are on a "conveyor belt" of sequential highly standardized treatments. This leaves no room for the patient's proactivity or flexibility. The patient may also have lack of control over their bodily functions, which contributes to their *powerlessness* (Pratt and Wood 1998). In the midst of a medical model of care, it is not unusual for the disease rather than the patient to be the focus of care, rather than the patient's emotional and psychological concerns.

In the making of a picture or artwork previously unacknowledged, feelings can be *given form* and reflected upon and then discussed with the art therapist. "The artwork is a container for a rich breadth of issues, which may be contradictory, contentious or even bizarre and which may be difficult for them to articulate in any other way" (Pratt et al. 1998, Loc.210). Images developed and "worked through" in the therapeutic process form a useful lasting record for continuing exploration, reflection, and comparison. It has also been demonstrated that patients who are suffering emotionally and spiritually often have a lower threshold for physical pain, and so art therapy has an important role on a physical level (Corbett et al. 2017; Craig et al. 2013).

"Arts therapists are, at present, the only group of artists who are recognised as a profession to practise within healthcare [in the UK]" (Hartley et al. 2008, p. 22). In Australia, art therapists generally hold a degree in art therapy, psychotherapy, or psychology, as well as some personal art practice.

5 Challenges Facing Creative Arts in Palliative Care

5.1 Funding

In the UK, hospices that provide palliative care are often small independent charities involving local community support. Their independence often provides the flexible and supportive environment that can accommodate creative arts into palliative care within the scope of resourcing constraints that obviously favor essential medical services (Hartley et al. 2008, p. 11). Similarly in Australia, many people receive palliative care and supportive services in nonprofit private hospitals, or community services in the home, the latter currently governed under a system of consumer-directed care packages, in which complementary and whole-person therapies compete for attention with medical and convenience services (housecleaning, transport to appointments, etc.). HammondCare is trialling music engagement as a complementary therapy offered to patients through consumer-directed care packages. This envisages a future with creative arts and music available under national medical schemes and home care services, i.e., acknowledging its value and availing its accessibility as an integral part of every person's health consultation.

Many people say they would like to die in their own homes, but a high proportion are admitted to hospitals and die there. This situation is further exaggerated in regional areas where there fewer specialist palliative care or hospice services are available. "Art and creative work are a vital human activity" (Shaw 1999) for good life quality, emotional stability, personal enrichment, and self-fulfillment and can offer a diversion from depression or difficulty. According to Hartley et al., if "palliative care is about living life to the full, then that life will include the arts" (Hartley et al. 2008, p. 12). This points to the need for complementary palliative care services including creative arts in both home settings and acute hospitals.

5.2 Patient Confidence

When people join an art group, they may feel self-conscious or apprehensive but group participation, fueled by curiosity for what others create and the range of outcomes from a single medium, usually quickly dissipates any fears. The artwork speaks for itself as an object or image emerges, and enjoyment and confidence grow proportionally. Work by past patients, in all its diversity and variety, can also help overcome a beginner's inertia. Most people delight in the discovery of what they can make.

Our artist collected the following comments from participants in HammondCare's "Art on Prescription" for people receiving cancer rehabilitation, who overcame their initial hesitations:

> "I have never printed before. I never thought I could." — M.
>
> "I don't think I am creative. I have never done it before! Maybe one day I'll give it a go, when I'm not busy. I have things on today: [making excuses] I think a visitor is coming . . . My wife said she might call me . . . No, I think I won't be good at that [trying art]: I'm too awkward, others are better than me. *Then P had a go.*"I love this. I can do this! Can I do more?" — P.

"Look at me! My eyesight is blurry. I have no feeling in my fingers and toes. I am confined to a wheelchair. I have tubes coming out of my neck. And to top it off, I am a banker! . . . Okay: I will give it a go!" — L.

"Art has given me a fun time during a slow recovery." — N.

"You swept away my sadness." — E.

6 Evaluation

Hartley's survey of the *Journal of Medical Humanities* observes that the main focus of arts and humanities evaluation is on how arts in palliative care reflect medical and healthcare experiences. "The contribution of the arts to *treatment* is largely absent" (Hartley et al. 2008, p. 66). An important ideology in palliative care is *holism*; therefore creative expression, self-fulfillment, and other psychosocial objectives are relevant in evaluating arts in palliative care and healthcare needs. Hartley proposes that analysis of trends, observation of behaviors and responses, surveying attitudes toward artwork, comparison with other treatments received, preferences for activities, and perceptible impacts are all relevant hermeneutics. Respondents typically include patients, staff, carers, and family. A number of standardized methods can be applied in the context of arts in palliative care, e.g., the Hospital Anxiety and Depression Scale (HADS), Quality of Death and Dying questionnaire (Downey et al. 2010), spirituality measures, etc. (Hartley et al. 2008, pp. 72–80).

Gilroy and Lee (1995) reviewed the art therapy research in the UK and found it to be focused mainly on issues relating to the professional development of art therapy or to the exploration of clinical practice using case study-based research (Pratt et al. 1998, Loc.372).

Both formative and summative evaluation of programs is important because participatory creative arts will be a new area of application for the majority of palliative care services. An evaluation framework alongside the program not only helps practitioners to learn about the application of the arts in palliative care but also contributes to increasing the knowledge base.

In addition to understanding the efficacy of art making for the patient, evaluation of impact and measurement of effect is important to demonstrate the worth of art interventions to colleagues and funders (see sect. 5). The limited evidence in this field makes it difficult for hospital administrators to justify investment in art programs when faced with resourcing constraints and other "evidence-based" interventions which demand funding.

7 Summary of Key Points

Creative art making offers opportunities to support the person processing a life-changing or terminal diagnosis and receiving palliative care which are not otherwise met through medical care alone. In aiming to provide good whole-person care, there are areas of psychosocial isolation, spiritual or existential anxiety, and deep emotional feelings that may be difficult to express and discover through verbal communication alone or which may seem awkward to voice explicitly. The nonverbal modalities of creative arts allow some of these concerns to be expressed and explored and therein may be relieved, through a variety of art media. The choice of medium can be suited to the interests, frailty, sensory capacity, tactility, and curiosity of the patient.

People find satisfaction in being positively productive and creative, in learning new skills, and in demonstrating abilities to loved ones, staff, and even community engagement through exhibition and leaving a legacy. As artwork is usually more abstract than natural language, sensitive ideas can be veiled or expressed to the degree that a person finds comfortable. For patients who are unable to speak due to physical, medical, cognitive, or other constraints, expressing ideas and emotions through art may provide a way to be heard and a way to express emotions. Illness can affect many aspects of identity and personhood, which may be redeemed to some extent through expression and creativity. Joy and mindful immersion may be experienced through the concentration required in making art. That focus often serves to take attention away from persistent thoughts about

medication, disease, or pain. Pursuing an art form deeply and repetitively is often relaxing.

Through art facilitation in groups, people meet others and even make friends with those who face similar difficulties, finding comfort in not being alone, and also find a safe environment in which they can interact socially and in which their artistic experiments will not be judged. People working into the creative arts in the palliative care space may come from various backgrounds, ranging from professional and community artists working as facilitators, focused on the creative process and artistic fruits, to people from a psychotherapy or art therapy background who use the art-making process to help patients explore their inner world. In the latter scenario, the artifacts often remain confidential and the objective is to reveal psychological concerns, bringing subconscious themes into consciousness for the patient, and to allow them to work through these thoughts with the therapist. Making art can also work in tandem with a cognitive behavior therapy or dialectical behavior therapy model or pastoral care.

Creative arts in palliative care focus on life quality, meaning making, and personal fulfillment in living life fully until the very end.

Abstract

This chapter outlines the role of music in well-being for people near the end of life. Written for the care professional or member of a multidisciplinary team, this chapter assumes that music engagement and a therapeutic approach to music in palliative care is relevant and accessible for all healthcare professionals, not only specialists or music therapy experts. The information provided here looks at the potential impact of music on pain, agitation, and diversion and for supporting emotional and spiritual life quality. Music is especially useful as a relational tool supporting whole-person care and a good end-of-life experience for the patient and their family and friends. This knowledge can be utilized to provide music, to facilitate therapeutic musicians interacting with a patient, and to increase awareness among staff and patients, and patients' families regarding the benefits of music in care, in particular, supporting emotional, psychosocial, spiritual, and physical needs not otherwise supported by medical care. Therapeutic music is presented from a historic, scientific, and holistic perspective, including considerations that will assist in cultural sensitivity.

1 Introduction

Knowledge of the potential application of therapeutic music in palliative care is relevant for the care professional. Firstly, whole-person care is everyone's concern. An appreciation for the evidence-based benefits of music and well-being will help care professionals balance the emotional and psychosocial aspects of well-being that cannot be nourished by medical care, as well as physical symptoms such as pain, loss of appetite, and sleeplessness that can also be improved with appropriate music intervention.

Some of the practical information in this chapter will equip care professionals, irrespective of musical or technological experience, in using or suggesting music as part of palliative care services. In addition, the care professional may need to represent the needs of the patient and advocate for the family when liaising with music therapists, thanatologists (bedside musicians providing a quality end-of-life service), therapeutic musicians, and volunteers involved in music services. In a diverse society, sensitivity to the cultural or spiritual needs of patients and families is core to cultural competency.

It may surprise some people that emotionally impactful music surpasses merely providing joy and relaxation but may also reduce pain and agitation and support appetite, diversion, relational care, and spiritual care.

David Aldridge notes that, "within the past decade music therapists have developed their work with people who have life-threatening illnesses and with those who are dying" (Aldridge 1999). This chapter serves to ensure that medical and care professionals are aware of the advances and scientific corroboration of ideas so that this information reaches patients and their families. Palliative care is also a specialization in which quality of life and meaningful experience supersede the approaches found in other areas of therapy, such as curative, targeted, and physician-directed goal-oriented programs, in favor of patient-initiated choice and focus on inner

psychosocial and spiritual wellness, more than physical goals. Aldridge describes this situation as working collaboratively and creatively: enhancing "the quality of living can help patients make sense of dying . . . [integrating] the physical, psychological, social and spiritual dimensions of their being" (Aldridge 1999).

The contemporary disciplines of music therapy and therapeutic music emerged from a confluence of occupational therapy, general psychology, psychotherapy, special education, music education, anthropology, and medicine, with a variety of goals ranging from artistic, scientific, psychosocial, behavioral, psychotherapeutic to rehabilitative (Wigram et al. 2002, p. 30). To this list may be added the work of pastoral carers and social workers who use music for awareness, insight, spiritual and emotional expression or exploration, facilitation, and "auxiliary" ways (Bruscia 1998). Supportive interventions include intentional distraction and provision of coping skills, and comprehensive resonance therapy includes entrainment and guided imagery with the objective of resolving pain (Wigram et al. 2002, p. 33).

The language of "constructionism" (participant engagement and meaning-making) has found its way into the therapeutic activity of creating "meaningful experiences." These ineffable and ephemeral experiences constructed with music are nonetheless important, especially for friends and family members of the dying person, who will cherish and remember experiences shared and enjoyed together long after the event. In music, there is always the interplay between composer, listener, symbolic language-like rules, and the ambiguous, metaphorical, inexpressible, and spiritual aspects of subjective imagination and active listening.

2 Differentiating Between Music Therapy and Therapeutic Music

The distinction between music therapy and therapeutic or healing music is relevant here. Music therapists have expertise and qualifications in "music therapy." They use goal-oriented therapeutic approaches to music in a variety of settings including aged care, rehabilitation and restorative care, and many related fields. In practice, "*music therapy* is the use of music as a tool in interactive therapy, while *therapeutic music* uses music and music only as the therapy itself" (Riley 2010, p. 108). Professional music therapists often combine music and other disciplines, such as exercise, art, and so on.

In the USA, the National Standards Board for Therapeutic Music (NSBTM) and the American Music Therapy Association (AMTA) distinguish between *music therapy* and *therapeutic music* (which includes the work of Certified Clinical Musicians, Certified Harp Therapists, Certified Healing Musicians, and Certified Bedside Harpists). In Australia and the UK, music therapy requires different training and qualifications from either music performance or therapeutic musicianship.

While music at the bedside of a patient is "prescriptive," it is a *service* (not a performance) – a "compassionate action without agenda" (Riley 2010, p. 109). The appropriate music cannot be anticipated, and the musician usually cannot ask the patient directly about their medical condition and treatment. Instead, the therapeutic musician responds to observed cues, body language, vital signs, monitors, and breathing. The patient is the sole attention of focus, in the moment.

This chapter focuses on therapeutic music in palliative care settings, in which music responds to the patient rather than aims to cure or rehabilitate. The "healing" that occurs concerns wholeness and well-being of mind and soul, as much as of body. If live instrumental playing is utilized, the musician intuitively and spontaneously responds to the patient's status. If recorded music is utilized, it is selected specifically for a patient (e.g., by a friend, relative, or the patient themselves). Music may be used therapeutically by a non-musician to enhance the quality of care, which is undertaken by any member of a multidisciplinary team or combined with pastoral care or relaxation approaches.

Musicians and volunteers (who are not formally trained in music therapy or who are not Certified Clinical Musicians) often adopt a responsive, therapeutic approach, too. Yet others

may volunteer to perform music as entertainment: community groups and children's choirs may visit and sing or perform music in nursing homes, hospices, hospitals, etc. The latter is valuable for its distraction and levity; however it is geared toward entertainment rather than intentional healing intervention and tends to occur in group settings and social spaces.

3 The Link Between Music and Well-Being from Antiquity

Historically, efforts to relate structures in music and the universe and the human body hark back to theories of vibrations, and parallel forms found in the micro- and macrocosmos were already well-established in the antiquarian world of Pythagoras (c. 500 BC). The corresponding connections in periodicity have been associated with revolutions of celestial bodies and planets, the bodily fluids or "humors," somatic disturbances, and consciousness. Before instruments were developed for accurately measuring frequency, theories of relationship could still be calculated by using the ratios of vibration that produce the natural overtone series that echo forms in nature such as resonating cylinders, reeds, strings, etc. (Wigram et al. 2002, pp. 22–23).

From these ideas we retain the concepts of "attunement," "resonance," "sympathy," and "harmonizing" that have both metaphysical and physiological applications. "Attunement" is used not only in contemporary developmental psychology (Stern) but also in Løgstrup's theory of music education.

Therapeutic and healing qualities of music are present in many traditional and ancient indigenous cultures. This includes medicine men, shamans, chanting and meditation traditions, vibrational healing, spiritual and existential music, and pre-Renaissance healing visionaries such as Hildegard von Bingen (musician, visionary, nun, and physician). At the height of Western scientism developed in the Age of Reason, which really harks back to the influence of Classical Epicureanism, we frequently observe a false dichotomy depicted between arts and sciences. It is not surprising that in our reductionist and positivist society of the West, healing with music and the power of "an art" to affect physiological and mental changes is met with skepticism in some circles. Nonetheless, in African, Australian Aboriginal, and various Asian cultures, to name a few, there are millennia of appreciation for the subtle links between inner and outer well-being and arguably a greater appreciation of whole-person wellness that does not depend on a modern clinical model.

Modern psychologists, however, acknowledge the interaction between mind and medicine, seen and unseen, physical and psychological, experiential and conceptual: the phenomenological experience of humanness. Philosophy, too, has largely rejected the Cartesian divide between cognitive and somatic experience. Grand connections, such as music of the spheres, harmony in the universe, and relationships between aesthetics, beauty, nature and art, perfection, and mathematics, date back to the Classical writings of Plato and Aristotle, persisting through the golden ages of fine art in work by multidisciplinarians such as Leonardo da Vinci, Michelangelo, Albrecht Dürer, Johann Sebastian Bach, Palladio, etc. A contemporary medical model clearly emphasizes pharmacology and physiological symptom management over the importance of spiritual and emotional wellness in a patient's overall diagnosis, thus needing adequately integrating whole-person healing in the treatment approach.

Medieval theorists, such as Robert Fludd in his 1617 'Divine Monochord' (James 1995, p.130) and Agrippa von Nettesheim's theory of 1510 (Wigram et al. 2002, p. 25), correlated mind-body-spirit in terms of the physical world, human body, and vibrations in music; language, human mind, and notes and intervals or "grammar" in music; and the cosmos, human spirit, and divine proportions.

Western philosophers ranging from Plato, Aristotle, Augustine, Schopenhauer to Nietzsche consider the theoretical and practical role of music for the individual and health. Arabic (Muslim) physicians were among the first in the world to have used music medicinally as an integrated element of whole-person health as early as the

eleventh and twelfth centuries. Paradoxically, these seemingly antiquated ideas have been revived through quantum physics, in terms of particle energy, rather than merely vibrational waves and the paradoxical relationship of concurrent wave and particle characteristics.

3.1 The Healing Harp in Antiquity

The harp, lyre, and psaltery were interchangeable terms in ancient times – i.e., a plucked chordophone. A 15,000 BC cave painting of a hunting bow shows the possible origin of plucked strings. Early Chinese healers attributed health to the C'hin zither-like instrument. In ancient Egypt, harps were part of the court consort and used in storytelling, songs, and tributes to deities. Harp and lyre were believed to mobilize fertility and usher in births. Sarasvati, the Hindu goddess (wife of Brahma), used "harp" to guide people and gave humans the arts. She is often depicted playing the "vina" arched harp. Ancient Greeks believed the gods communicated with people through harp or lyre music. In the Middle East, lyres had seven strings associated with Pleiades, the constellation, and represented a microcosm of universal order and harmony.

In Scandinavia and Europe, harps were also associated with magic and enchantment in mythology. Symbolic of peace and connection to the "other" world, harps were linked to sleep, to release of tears, and in Ireland 2000 BC, to the Danen people or faeryfolk. Again harp was linked with fertility, agriculture, nature, faery folklore, and the heart of the Gaelic culture. Celtic nobles and Druids held the harp in high esteem – teachers, judges, shaman priests, and holistic healers who used subtle energies, herbs, and bards and musicians/poets were the keepers of knowledge of ancient lore.

The biblical King David soothed King Saul (who was speculated to be depressed) in approximately 1100 BC with music of the *kinore*, an early lyre. Pythagoras of Samos developed the harmonic series overtone scales and Western modes and associated different emotions with different tunings. In 324 BC Alexander the Great's sanity was restored by music of the lyre – recognized for healing and calming. Harp was considered to be a link between worlds and used as a guide through death process. In Mesopotamia in Ur, early lyre instruments have been found. Harpies were harbingers of death, who sometimes heralded fearful times, and the harp ushered the soul to heaven in the Judeo-Christian tradition.

4 A Brief Overview of Music for End-of-Life Care and Dying Well

Thanatology is the scientific study of dying. Music thanatology is live music (often harp or vocal music) at the bedside of dying patients to relieve suffering from physical, emotional, and spiritual pain. It is generally responsive (sometimes called "prescriptive"), the musician interacting with the patient's biomarkers, such as heart rate, breathing rate, mood, anxiety, etc.

Music has had a fundamental place in song and dance in every tribal culture, often quite rhythmically complex. In the Western tradition of healing music, musicians such as Stella Benson have identified harmonic modes with particular healing qualities and theories of specific sounds, modes, and instruments that have universal healing powers:

> The word *Thanatos* comes from the Greek, and refers to the mythological figure who is the twin brother of Sleep (*Hypnos*) and the son of *Nyx* or Night. There are many kinds of thanatologists today – medical, academic, theological, psychological . . . In its sole focus on the physical and spiritual care of the dying with prescriptive music, it is also a pastoral art which takes the words of the [Christian] Gospel seriously, and turns toward the face of suffering without reserve. (The Chalice of Repose 2016)

Since the 1950s, music therapy was recognized as a vocation. The (USA) National Association for Music Therapy and American Association for Music Therapy converged in 1998 to form the current American Music Therapy Association (AMTA). Music therapy according to their definition uses "clinical and evidence-based music interventions to achieve individualised goals"

(Riley 2014, p. 8). The goal of music therapy is to "address a range of physical, emotional, cognitive and social needs of individuals" across a range of settings and needs including hospitals, psychiatric care, community mental health, rehabilitation and day care centers, residential nursing homes, in schools and in private clinics. Music therapy has been effectively utilized in assisting people with physical and cognitive impairments and learning disabilities.

Key figures in the development of therapeutic music include Dr. Ron Price (founder of Healing Harps – who found neurological benefits of playing harp with palsies and dystrophies and other neurological challenges), Therese Schroeder-Sheker (who established The Chalice of Repose music thanatology project to pastorally support peaceful and dignified death), and Sarajane Williams (who established therapeutic harp to help people with psychological conditions including chronic pain, stress, and depression and vibroacoustic harp therapy using the resonance and vibrations of an acoustic instrument to palpably affect the client) (Riley 2014, p. 8). A number of educational programs emerged offering this bedside approach to healing music: the International Harp Therapy Program, International Healing Musician Program, Clinical Musician Certification Program, and the Music for Healing and Transition Program. Thanatology and music vigil are terms specifically used for individually attentive end-of-life settings. "Healing" has the broader meaning of restoration, making peace, improving overall well-being including satiation of emotions and soul, rather than the more specific implication of "cure" that generally pertains to eradicating symptoms of disease.

The use of clear melody or more atmospheric textural sound depends on the situation and the patient. Music composed mostly of chord progressions and non-melodic structures suits those needing deep relaxation and sleep, as well as people in the final moments of life, because melodic lines and metered rhythm in a gentle tempo can help engage the body and "encourage stability of vital signs" (Riley 2014, pp. 22–23). Riley posits that major keys are suited to hospital environments and minor keys may be suited to hospice or palliative care setting, though modal improvisation allows the musician to oscillate from one to the other with ease. As a generalization, a faster tempo should be reserved for situations when the alert patient requests it, and for most situations a slow or moderate tempo is more conducive to calm and relaxation. Other research in the area of dementia care suggests that moderate to slow music evokes a calmer dopamine-induced response, and very fast energetic music is associated with the cortisol (stress hormone) "fight or flight" reaction. The effect on the body should be observed.

4.1 Instruments for Therapeutic Music

The guiding principle is to use instruments that are not loud and intrusive or disruptive; therefore, many acoustic instruments and well-selected keyboard sounds work well. Patient preference should be taken into account. Plucked strings, such as guitar or harp (with nylon or gut strings), are more appropriate than metal-stringed instruments. Bowed instruments can be muted, and wind instruments played gently. Amplified instruments are usually too loud to be relaxing and may affect other patients and staff. While drums are sometimes used in music therapy participatory groups, they are seldom used in therapeutic music at the bedside.

Instrumental register also impacts the effect. "Pleasing" tones of lower and mellow instruments often sound more appropriate than high-pitched potentially annoying sounds or shrill tone. Children can tolerate higher pitch ranges.

4.2 Tailoring Musical Elements to the Patient

Improvisation gives the therapeutic musician the elasticity to adapt to the situation more easily than prepared learned music. Learned music may also be adjusted in register and tempo to suit a certain context.

Rhythmic music, even slowly lilting music, invites involvement and entrainment (synchronizing listening, breathing, and movement to match the beat). This can help a person to breathe at a steady slow rate, for instance, which is linked to relaxation, as understood in meditation. Regular slow rhythm is antithetic to panic and stress.

Nonrhythmic music, more atmospheric and nebulous in character, can be appropriate to the atmosphere of impending death as vital signs are fading, conducive to a peaceful death. Peaceful, nonrhythmic music promotes tranquility and relaxation. Sometimes the musician plays on after the death to hold the meaningful atmosphere with family and friends. Nonrhythmic music can also be fitting for "relieving pain and stress" (Riley 2014, p. 27). Riley suggests that familiarity from early in a person's life is valuable for elderly patients and people with dementia. This requires familiarity with music of, say, the 1920s–1950s, as well as culturally specific knowledge.

4.3 The Chalice of Repose Project

The Chalice of Repose Project is one of the founding therapeutic music organizations (established in 1973 now spanning the USA), calling itself the "voice of music-thanatology" – providing "beauty, intimacy, reverence in end of life palliative and pastoral care" (The Chalice of Repose 2016). Music thanatology derives profound spiritual inspiration and meaning from the Benedictine Cluniac tradition of monastic medicine. The Chalice of Repose Project contemplative curriculum "re-unites medicine, spirituality and music," working "towards the relief of physiological pain and spiritual suffering that may be eclipsing the quality of life at the end of life" (The Chalice of Repose 2016).

Deathbed vigils aim to bring peace, tranquility of silence, and a shift to acceptance. Music thanatology involves intimate concentrated person-to-person connection, entrainment of sound, and breathing. The musician's goal is to support peace-filled, blessed, or conscious dying.

Silence moves (usually) toward synchronization and entrainment, often leading to pain relief, decreased heart rate and pulse, stabilized breathing patterns, change in body temperature, deep restorative sleep; emotional, mental, or spiritual release; and profound relaxation. Sometimes, patients decrease requests for pharmaceuticals.

5 The Relational Facilitation of Music in Care

If progress of disease leads to increasing isolation, the music-therapeutic relationship may provide important interpersonal contact (Aldridge 1999, p. 22). Tenderness is an important quality in loving relationships. Listening to music together, playing music together, or even the instrumentalist and patient bond can legitimize simple holding of hands. That two people are listening to music and exposing their emotions and vulnerability together creates a kind of unspoken intimacy and sensitivity within an acceptable manner of feeling closeness.

The choice of musical engagement, e.g., active creativity such as art therapy or making music in a group, a metaphor for new growth, creativity, and materiality may not suit someone aware of their deteriorating corporeal condition, for whom it may highlight weakness or incapacity, whereas listening in or singing along more calmly might be entirely appropriate. Providing "enabling" experiences or "empowering" experiences that someone can execute gives them freedom and accomplishment. This independence is especially important for a person with high care needs, to maintain their dignity and agency. Usually providing this opportunity through music-making or participation has no clinical disadvantage yet restores some control, decision-making, and expression.

Aldridge says that what patients and friends and families want "is to be fully alive even in the face of impending death" (Aldridge 1999, p. 24) in the presence of relationships, including opportunities for expression and sharing experiences, which may be valuable to ameliorating suffering. Music emphasizes the lived body as sensed, not only as spoken words, i.e., a felt and emotive

response to a palpable and somatic sensory experience that may be difficult to articulate in words.

Music is human contact, even when someone is in a coma. Singing "goodbye" (Aldridge 1999, p. 102) is important so that someone is not alone when dying and dies at peace.

Indications for therapeutic music may include:

- Coping difficulties
- Depression, withdrawal
- Isolation
- Difficulty expressing thoughts, feelings, needs, and desires
- Difficulty exploring spiritual and existential issues
- Distressing physical symptoms (complex pain problems, persistent nausea, anxiety and fear, restlessness, insomnia, dyspnea, disorientation and confusion, and dysphasia
- Cultural language barriers (Aldridge 1999, p. 69)

6 The Neuroscience of Listening to Music

We respond to music physiologically or "viscerally," to the material properties of sound. Medicine refers to this effect as musical "stimulus." The syntactical or organizational level of music imbues it with therapeutic aspects of imprecise description and interpretation. The "semantic" or "message" level of music conveys emotional expression and metaphorical meaning. The "pragmatic" level of music as a social, interactive phenomenon also has a therapeutic purpose in facilitating interaction, connection, communication, and social experience (Wigram et al. 2002, p. 40). Therapeutic musicians work alongside neuropsychologists and psychologists to understand the brain's nonverbal functioning, in areas such as history, identity, and the effects of auditory perception and musical memory; auditory imagery (equivalent to visual imagination), brain processing of musical input, effects of musical abilities, idea formation, and the implications of performance; and participation or active creativity (composition).

Psychoacoustics describes the effect of hearing, such as the physiological characteristics of the ear, on sound perception. Attributes such as the shape of the pinna (external shell-like ear structure), interaural distance (distance between the ears that contributes to spatial understanding of sound in three dimensions around the body, source location, and proximity), loudness, and frequency acuity filter our experience of sound. The phasing and delay of binaural sounds can have interesting psychoacoustic effects on the body that manifest as physical sensations.

Many parts of the brain are involved in the appreciation (and performance) of music. While this means that certain aspects of musical experience will be affected by localized lesions or brain damage, the generalized neurological stimulation that occurs listening music also works to the patient's advantage in that musical appreciation usually outlasts dementia, traumatic brain injury, other cognitive impairment or partial deterioration of senses including hearing. For example, people who have experienced stroke affecting one hemisphere of the brain can often sing better than they can speak with a therapist. More complex musical tasks such as the creative activities of composition or performance involve the cerebral cortex, subcortical motor and sensory nuclei, and the limbic system, combining left-brain dominant structuring and mathematical and organizing functions with right-brain dominated creative, emotional, and "spiritual" elements in a singular activity. Recent brain plasticity research, however, suggests that the hemispheric localization can also change adaptively, and there is currently some controversy about hemispheric localization in music. Despite an abnormally high incidence of blind musicians or blind people pursuing music ably, generally "the auditory system, visual system, somatic motor and sensory systems and memory all play an important role in the appreciation and performance of music" (Wigram et al. 2002). In addition, culture, conditioning, and training affect musical memory.

"Why do songs from your past evoke such vivid memories? Listening to music engages large scale neural networks across the entire brain" (Bergland 2013), ranging from timbral

activations in cognitive areas of the cerebellum, sensory area, and gray matter of cerebral hemispheres to musical pulse and tonality that recruit the cortical and subcortical cognitive, motor, and emotion-related circuits, supporting the idea that music and movement are intertwined. Limbic areas of the brain, associated with emotions, are also involved with rhythm and tonality processing, while the default mode network engaged in timbral interpretation is assumed to be also associated with creativity and imagination. Aimee Baird and Séverine Samson found that: "Music was more efficient at evoking autobiographical memories than verbal prompts of the Autobiographical Memory Interview (AMI) across each life period" (Bergland 2013).

Music can play a helpful role in anesthesia. Spintge's studies especially have found that music (anxioalgolytic music as distinct from merely relaxing music) significantly reduces distress, anxiety, and pain suffered particularly in operations where the patient is conscious and under spinal anesthesia and improved presurgical compliance, thereby reducing the amount of subsequent medication needed for procedures using other than general anesthetic (Spintge 1982). This reduction in anxiety could be translated to intravenous cannulation and other potentially uncomfortable processes in palliative care.

7 Effects of Music on the Mind and Emotions

It would be fair to say that we don't fully understand the emotional effect of music; however, generally music that is more meaningful (and therefore familiar) for a person has greater emotional impact than music that is not meaningful. This is the motivation for attempting to understand the music of relevance and importance to patients in the palliative care setting – i.e., music with associations, memories, and past experiences (good or bad). The human relation to music is a lifelong development, not only linked to the psychology of early development in childhood, for instance. Humanistic psychology related to existential and transactional therapeutic theories have been especially influential in the development of music therapy. While traditional music therapy may look to the supportive, explorative, or regenerative characteristics of a piece of music, the more open approach of therapeutic music in death and dying looks beyond psychotherapeutic potential to experiential, existential, and aesthetic qualities that resonate for the individual. Nonetheless, the steady somewhat predictable, rhythmic, recognizable gestures that lend reassurance reinforce psychotherapeutic principles, such as Pachelbel's *Canon* – a series of melodic variations over a cycling ground bass.

According to Riley, "Studies in mind-body sciences have indicated that memories, experiences and emotions are stored not only in the brain but in the cells of the body as well. There is no boundary between mind and body . . . Emotions that arise may be perceived as positive or negative, but *catharsis is almost always healing*" (Riley 2010, pp. 34–35). Music can draw out unexpressed emotions and help us feel, explore, and express them, including anger, sorrow, and grief. Bill Moyers in *Healing and the Mind*, and Candace Pert in *The Molecules of Emotion*, supports this view that repressed negative emotions are toxic and that appropriate expression has a positive effect on the body (Riley 2010; Pert 1999).

The Guided Imagery and Music method – The Bonny Model – is practiced on North and South America, Oceania, and approximately ten European countries. Its pretext is music-centered investigation of consciousness, where imagery is evoked during music listening – leading to an unfolding of inner experiences "holistic, humanistic, transpersonal and allowing for the emergence of all aspects of human experience: psychological, emotional, physical, social, spiritual and the collective conscience" (Wigram et al. 2002; Bonny 1990).

Various other established music therapy methods, such as the Nordoff-Robins method, or even free improvization therapy, are relatively formulaic and therapist-led in contrast with the paradigm advocated in therapeutic musician certification which focuses on the musician *responding* to the patient, rather than leading or facilitating the interaction. The latter is often well

suited to the context of palliative care when patients may be quite frail, inert, or somewhat cognitively "hazy" due to medication. The horizon for therapeutic music in palliative care is more focused on comfort, relaxation, pain relief, distraction from the medical environment, spiritual and existential reassurance, companionship, and expression of emotions.

Characteristics of potentially **stimulating** (animating, energizing) music:

- Unpredictable changes in tempo
- Unpredictable or sudden changes in:
  - Loudness
  - Rhythm
  - Timbre (tone color)
  - Pitch (register)
  - Harmony (e.g., unexpected dissonance or change of key/modality)
- Wide variety in texture
- Unexpected accents
- Lack of perceptible structure

Overall, these characteristics are united by surprise, unpredictability, dramatic changes, dramatic variety, and inconsistency (Wigram et al. 2002, p. 138).

In contrast, these are characteristics of potentially relaxing music:

- Stable tempo (speed)
- Stable or only gradual changes in:
  - Loudness
  - Rhythm
  - Timbre (tone color)
  - Pitch
  - Harmony
- Consistent texture
- Conventional harmonic modulation
- Cadences, or phrase-endings
- Predictable melodic lines
- Identifiable or inherent structure and form
- Gentle timbre (sonorities)
- Few accents, especially of an irregular nature

Thus, overall, these characteristics involve consistency; reliability; predictability (related to familiarity of music or stylistic tendencies); stability; minimal variation, without surprising/jarring shocking or dramatic changes; and change only through incremental steps (Wigram et al. 2002, pp. 138–139).

These generalizations can be used to transcend genres or styles. It is obvious why it has led to some people generalizing that Baroque music fits well; however that does not take into account the stylistic tastes of the individual that can usually also be met by choosing appropriate music within the kinds of music that is favored, e.g., smooth jazz or lyrical calm popular music, slow sonorous movements of Romantic music, etc. Genres of music whose characteristics tend outside of these guidelines will be the most difficult to satisfy, e.g., finding relaxing rap music, because it is almost always fast tempo with a reliance on syncopation. These characteristics can also guide improvisation by the therapeutic musician, e.g., Stella Benson advocates gently lilting consistent rhythmic music within particular modes for playing harp at the bedside for a person in palliative care or choices of recorded music for the patient. Predictable music offers safety and stability that can meet needs of certain patients.

Auditory pattern recognition is called "active listening." Long periods of overstimulation create fatigue, dizziness, and nausea. "Television addiction" in humans watching fast-cut video is a genuine phenomenon that numbs this response. Auditory overload leads to confusion and fatigue which may, in turn, manifest in frustration, agitation or emotional upset, and problematic behaviors – for animals or humans and especially for people who cannot express themselves verbally (aphasia) – and eventually auditory cognitive overload leads to anxiety. This effect is exaggerated in people with dementia who may have difficulty locating sounds in space and associating a sound source with its purpose or meaning. Attention consumed in active listening is not available for other tasks. Chronic overstimulation invokes the mind-body syndrome of perpetual fight or flight *sympathetic overdrive*. For this reason, careful attention should be given to the intensity and duration of music used therapeutically, especially anyone with dementia or other cognitive impairment that affects sensory overload.

8 Effects of Music on the Body

Vibroacoustic music is a receptive form of therapy in which the patient directly experiences the vibrations of the music through contact with a resonating surface. This can range from a large resonant instrument such as the harp to a developing range of vibrotactile instruments invented in Japan and the USA using extremely low frequencies, for example, pulsed and sinusoidal (sine wave) tones of very low frequency (between 30 and 70 Hz). Vibroacoustic therapy is reportedly effective for pain disorders such as bowel problems, fibromyalgia, migraine, menstrual pain, neck and back pain, and rheumatism. Therapists will adjust the frequencies used according to the pathology (Chesky and Michel 1991).

Riley states that "states of mind do not dictate the body's status, but they do *affect* the body, sometimes profoundly" (Riley 2010, p. 89). Correlates include heart rate, nausea, perspiration and stress, "fear" responses, and physiological responses to the stress hormones, cortisol, and adrenaline. Negative states of mind can also inhibit endorphin production, and reduced serotonin levels may be associated with depression and suppress immune responses. Stressors can be worry, grief, or too much responsibility, for example. Thus, a holistic approach to treatment includes body, mind, and spirit and awareness of this mind and body interaction (Riley 2010, p. 88).

A relaxed state in which pain relief is induced by listening to music is called "audioanalgesia." A related phenomenon is "psychoneuroimmunology" that examines immunologic neuropeptide activity and the body's own capacity to heal when in a relaxed state (Drohan 1999). One of the earliest documentations of the effects of music on humans is Helmholtz's text, *On the Sensation of Tone*, written in 1862 (Helmholtz 2003; Benson 2003).

Anecdotal reports from palliative care are substantiated by empirical evidence including studies by Bailey (1983), Curtis (1986), and Whittall (1989). Bailey found that cancer patients were less tense and anxious and experienced a more positivity and vigor listening to live music than the corresponding recorded music. In her review of 465 cancer patients receiving music therapy, Bailey reported a reduction in pain, mood improvement, and improved communication. Curtis and Whittall's studies corroborate the promotion of pain relief and relaxation, as well as contentment. A decrease in heart rate and respiration rates was measured among a small number of people during intervention of music with guided imagery, deep breathing, and progressive relaxation exercises that suggested a reduction in anxiety (Whittall 1989).

9 Different Formats of Therapeutic Music

There is great diversity to the range of techniques that music therapists and therapeutic musicians use in palliative care to "enhance quality of life . . . and ease suffering: musically supported individual counselling (Munro 1984); improvisation (Delmonte 1993; Salmon 1993); music to facilitate communication between the patients and their significant others (Munro 1984; Salmon 1993); life-review including music (Beggs 1991); music-facilitated pain control and relaxation (Munro 1984); guided imagery and music (Bruscia 1991; Salmon 1993); and group work" (Aldridge 1999, p. 44).

Common themes that emerge in creative musical reflections include self-reflections; compliments; memories; reflections on significant others (including pets); expression of adversity; imagery; prayers; care experiences and experiences of love; gratitude to family members, staff, and God; continuing to remember close people who are deceased; nature imagery and scenes; and the fight with cancer or degenerative disease (Aldridge 1999, p. 55). Staff can assist people by facilitating them choosing their own music for passage and transitioning out of life.

9.1 Different Methods in Music Therapy

Some well-known techniques from music therapy that may be used for therapeutic music in palliative care include:

- Guided imagery and music – the Bonny model
- Analytically oriented music therapy – the Priestly model
- Creative music therapy – the Nordoff-Robins model
- Free improvization therapy – the Alvin model
- Behavioral music therapy

The extent to which patients elect participatory, active, or passive music approaches will depend on how well they are. People in the early course of palliative care may find participatory methods useful for diversion from pain and procedures, whereas weakness and medication may diminish the ability to be creative as the palliative care trajectory advances.

To sound healing may be added techniques including toning, healing with gongs/overtones, body and voice work, drumming, and sound environments or vibrotactile apparatus. Crowe and Scovel (1996) suggest that music therapy and sound healing are different poles on a spectrum. Pragmatism and an open mind are probably useful in the context of palliative care where the objective is maximizing quality of life rather than pursuing a cure.

Hanne Mette Ochsner Ridder (2013) highlights the diversity and non-homogeneity of older adults. Older adults constitute the majority of people in palliative care settings even though it is important to be able to address the needs of people of all ages and experiences (e.g., in 2016, around 90% of HammondCare Greenwich Hospital's palliative care inpatients (in Australia) were senior or elderly, and approximately 91% had cancer). Elderly people may be especially affected by changing relationships to new people, new surroundings, new routines, the disturbing behaviors of other patients, staff who invade their personal space in care situations, and time-poor staff (Wigram et al. 2002, p. 188). Continuity and familiarity of relevant music can be beneficial in this situation to distract from change and disruption, as well as to provide some stability and reassurance. Music in the room or via headphones and a personalized music device can be used as an interactional tool and to ease the institutional setting of a hospital.

9.2 Biomagnetic Fields and Frequency Intervention

Therapeutic musicians can make use of beneficial resonant frequencies and repetition of specific notes that patients can physically feel reverberating through their bodies. Different organs and body structures are associated with different frequencies, though a frequency-related approach should not be formulaic. Riley uses the expression frequency not only to refer to pitch/frequency, measured in Hertz, but also to refer to periodicity of a repeating event. For example, a practitioner may play in a tempo mimicking the heartbeat, to encourage entrainment to that beat.

Example of cyclical body rhythms:

- Adult heart rate averages around 60–80 beats per min.
- Healthy adult respiration averages 12–16 breaths per min.
- The gastric cycle that controls the stomach contracts on average once per 3 min.
- The intestinal cycle contracts in waves approximately once per min.

Brain wave frequencies are described as alpha, beta, delta, and theta frequencies. Normal frequencies are generally:

- Delta (deepest sleep) = 1–3 cps (cycles per second)
- Theta (sleep) = 4–8 cps
- Alpha (light slumber) = 9–16 cps
- Beta (awake) = 17–22 cps (Riley 2010)

Mathematician Barbara Hero and sound healers – Jonathon Goldman and Kay Gardner – have written about the resonant frequencies for each organ and function in the body, with the caveat that bodies are individual and this is not an exact science. Furthermore, some frequencies are multiplied by octave factors in order to be musically presented in the audible range. Some vibrational therapists, such as Bruce Tainio and Gary Young, believe that changes from normal frequency range produce illness.

"Cymatics" is the term given to visible effects of frequency on matter drawing from the work of Ernst Chladni (1756–1827) and, subsequently, Hans Jenny (1904–1972), e.g., the waves, ripples, and formations in different densities of liquids in response to particular frequencies and intervals: visible waveforms, dissonance, and geometric patterns (Jenny 2016). Cymatics uses audible sound frequencies for specific healing stimulation. This approach can be traced back to ancient wisdom traditions (Cymatics Source 2016).

9.3 Toning and Chant

Chant such as repetitive use of words, phrases, or sounds that cause overtones to resonate in the body has long been part of meditation, faith traditions, and ancient wisdom, for example, Medieval Christian chant, Indian Sanskrit mantra, Vedic or Upanishad scripture (Riley 2010, pp. 92–93), Tibetan Buddhist Tantric overtone singing, and in Africa. Such chanting often combines both a rhythmic effect and certain modes or intervals that elicit harmonic overtones. For instance, a close interval will create "difference tones" or a beating sensation relating to the size of the interval, or high overtone harmonics may be heard above extremely low register tones. Certain vocal and throat techniques bring harmonic overtones into audible range. Due to the phenomenological experience of integrated mind state and physiological vibration, chant can be understood as holistic in both the medical and philosophical sense. Generally, this type of chant is more related to meditation than "music" per se. Its psychological effect is of greater importance than melodic features. When a person is actively involved in chanting, not only the palpable sensation of the vibrations and voice but also the long rhythmic periodicity of breath cycles and slowed respiration affects the body. Toning (i.e., chant without the use of words or syllables) has been linked to melatonin production according to Dr. Ranjie Singh and Marc Micozzi, musician Fabien Maman, and several ancient belief systems including Qigong, Taoism, Egyptians, and Zoroastrian rituals and yogic traditions (Riley 2010, p. 91).

9.4 Allopathic (Complementary) Modalities

Many alternate or complementary modalities of therapeutic music and sound have grown up alongside conventional medicine since the 1970s.

Some examples include:

- Drumming
- Harp therapy
- Music thanatology
- Music therapy (interactive/participatory)
- Sound tables
- Chanting and toning
- Vibroacoustic harp therapy

Therapeutic music may be characterized by:

- Intention – always for the good of the patient, whatever that may be, putting aside personal satisfaction
- Taking neither credit nor blame for the effect of genuinely delivered music
- Playing simple rather than complex music for healing, not performance; relief and blessing, not entertainment
- Healing not curing – restitution to wholeness of mind and spirit, not eradication of physical illness or injury – e.g., reducing perception of pain, promoting better sleep, and facilitating relaxation

9.5 Harp Thanatology

Why the propensity to use harp in bedside vigils of people nearing death?

The rationale is not related to heavenly imagery. While monadic or melodic instruments play one note at a time, the harp is able to capture chords, harmony, and resonance – i.e., multiple notes simultaneously. A "travel" or Celtic harp is also relatively portable, allowing the instrument to come to the bedside in a range of settings. The volume of harp allows it to be played softly and calmly in a confined space. The pitch range of the instrument also permits the musician to harness mellow resonant low-frequency notes in

prescriptive music empathetic with relief of pain and suffering. Finally, the *timbre* (tone color) of a well-plucked harp is widely considered to be pleasing and soothing. The anatomy of the harp with its large soundboard and open holes in the back emits the tone with vibroacoustic properties that some believe are healing and certainly viscerally palpable. Some people will sit so that they can rest their back on the harp and literally feel the vibrations permeating their physical body. The polyphonic nature of the harp makes it suitable for encapsulating relevant harmonic modes. Stella Benson's book on *Healing Modes* ascribes different elevating and calming moods and healing purposes to different harmonic modes.

What is so especially healing about the harp?

Sympathetic vibrations are resonances perceived in the body vibrating with string and overtones (harmonics), crossing between the spiritual and physical realm. Others have suggested that the beautiful aesthetics of sound and shape of the harp echo the golden sequence (or Fibonacci series of ratios with "universal" appeal). The ADSR (attack, decay, sustain, and release) of a soundwave determines its timbre (or tone color). The harp has an especially long decay envelope or resonance and energy exchange. Dr. Abraham Kocheril has written about the organizing and calming effects of harp music on chaotic electrophysiology (cardiac arrhythmia), believing that the characteristics of the instrument influence physical symptoms.

10 Music and Pain

"Pain occurs in the physical, emotional, and spiritual realm" (Benson 2003, p. 19). Perception of pain is shaped by many aspects, such as gender, culture, how pain affects the patient's life, stress or anxiety, previous experience with pain, outlook, and other psychological factors. Hence, different individuals will have a different "pain threshold." "Music is known to reduce the sensation of pain, fear, anxiety, need for excess anaesthetic agents . . . recovery rates, mortality rates, hospital stays . . ." and requests for medication. People who are experiencing post-traumatic stress disorder (PTSD), financial or other life instability and stress, or depression, for example, may perceive a greater impact of pain from injury or disease.

Physical pain affects several measurable characteristics, e.g., blood pressure, immunoglobulin levels, and skin temperature (Benson 2003). Other indicators of pain can include moaning, quick or intermittent inhalation/exhalation, holding breath, muscle tension, tight jaw, facial grimaces, fisted hands, knees to chest, moodiness and restlessness, and sensitivity to light.

Music can be used as a noninvasive analgesic. For musicians playing live, Benson suggests slowing down tempo and simplifying melody and harmony, shifting from moving harmony toward a drone, correlating with increased pain. In other words, more spacious, calm music is advocated for people with a high level of pain and more rhythmical, elaborate music for people with a lower level of pain.

Linda Bloom (2016) suggests that pain should be considered as the "fifth vital sign." Bloom criticizes overprescription, especially of addictive narcotics and patient-managed expectations of pain relief in the USA. She believes that "patients are led to expect that they will have 'little or no pain'" and that powerful and addictive pain medicines are automatically provided in response to patient-assessed pain scales, whereas according to Bloom, 73 RCTs on the role of music conducted by Dr. Catherine Meads at Brunel University found that music reduces pain before, during, and after surgery. Meads states that: "This level of relief is comparable to that achieved by a dose of pain-relieving drugs."

According to the International Association for the Study of Pain, pain is an "unpleasant sensory and emotional experience associated with actual or potential tissue damage . . . Pain is both a sensory process felt in the body, and a subjective phenomenon, influenced by the psychological and emotional processes of each given brain" (Bicknell 2011). The brain and nervous system sense and process vibrations. "The spinal cord is composed of nerve bundles carrying different

kinds of sensation; heat and cold; pain, pressure, and vibration" (Thompson 2010). The processing of pain involves both the peripheral and the central nervous system. During musical vibrations, the nerve tracts for vibrational sensing are "preoccupied or "overloaded," effectively disrupting pain sensation. As a pain control feature, musical sound is good and vibratory sound may be even better. Furthermore, the emotional and spiritual effects of music impinge on physiological and psychological responses. The brain has endogenous opioids, and other neuropeptides, such as oxytocin, that may be stimulated and released by hearing music.

With regard to relaxation, the effect of music has been measured on the autonomic nervous system, manifests in a reduction in sympathetic arousal, and increases in parasympathetic activity (Warth et al. 2016).

11 Music and Agitation

Agitation is common among people with dementia, people in the terminal stage of end of life, and as a result of some medications. The so-called agitation is often the expression of an unmet need, especially when someone is unable to communicate verbally. "High levels of agitation are . . . associated with low levels of quality of life" (Samus et al. 2005), and the "use of psychotropic medication is associated with reduced quality of life" (Ballard et al. 2000). Agitation can be linked to stressful triggers or activities such as visitors, grooming, bathing, or mealtimes (Beilharz 2017) and medication "breakthroughs." Music can be a helpful diversion from social triggers, especially if introduced *before* the trigger activity. Music can be helpful getting to sleep or distracting from tense procedures and situations.

"Cognitive impairment lowers the stress threshold so that external stimuli are more likely to cause agitation" (Gerdner 2012). Individualized music intervention "overrides the stressful environmental stimuli that the cognitively impaired person cannot synthesise, and instead evokes remote memory with pleasant associations, decreasing agitation" (Gill and Englert 2013). It has been shown that brain activation in response to a painful heat stimulus is significantly reduced when a person focuses attention on a musical or auditory stimulus instead of focusing on the heat stimulus. Thus distraction is a genuinely effective counter-pain measure (Bushnell et al. 2000).

12 Spiritual Support

What makes a person feel whole? Anthony Storr (1992) refers to the phenomenon of music as "mental furniture," i.e., the music that plays in our head un-summoned. It could be argued that if someone is accustomed to having one's "mental furniture" present and stoked from time to time, then to remove its stimulus is also to lose something stable, familiar, and comforting. For many philosophers, including Schopenhauer, Kant, Hegel, Nietzsche, Freud, and Jung, among others, the metaphysical quality of music permeating inner life (inhabiting spiritual vitality, as it were) also imbues it with power to create *meaning* and passion. Nietzsche went so far as to say that music made life worth living.

12.1 What Is Spirituality?

There are many different definitions of spirituality; however there is consensus that aging, dying, and enduring disease involves a spiritual dimension. It is often a time of life when various changes occur including physical, relationships, dependency and support needs, looking backward and forward through life, assimilating experiences and information differently, emotional needs and feelings, wondering about end of life and legacy, diminishing importance of material riches, and growing emphasis on experiences and relationships.

"The spiritual dimension focuses on meaning of life, hope and purpose, explored through relationships with others, with the natural worlds and with the transcendent" (Mowat and O'Neill 2013). Evidence suggests "genuine and intentional

accompaniment of people on their ageing journey; giving time, presence and listening are the core of good spiritual practice."

Tools in the practice of listening and presence include reminiscence, life-story keeping, creative activities, and meaningful rituals (signifying practices) that help with processing change. Many people receiving palliative care have complex conditions, including pain management and cognitive or psychological issues, which also require spiritual support.

Spirituality often involves the search for meaning in a spectrum from centrality of divine presence at one end and the secular concept of inner life, personal belief, and focus on self at the other end.

To think about the supporting role of music in spirituality, it is helpful to consider various manifestations of spirituality. In secular society, there is a distinction between the terms "spirituality" and "religion," which has become particularly enunciated because many contemporary forms of spirituality do not involve a faith or religion. This clarification has emerged as participation in organized religion has declined and interest in spirituality has ascended, a move from creaturely worship to autonomous subjectivity, a movement from faith in God to faith in self, especially the postmodern sense of self-sufficiency (Swinton and Pattison 2010).

12.2 Music as an Alternative to "Hyper-cognition"

Hyper-cognition refers to the overemphasis on cognitive ability to the detriment of other capacities. Due to its deep emotional connection, arguably transcendent qualities, and relative portability, music provides a way to bring ritual and liturgies (and reminder of community involvement) into the home, hospital, or hospice palliative care.

Music can carry associated feelings of belonging; reassurance; acceptance; hope; forgiveness; acquiescence; compassion; peace; resolution in relationships; purpose, meaning, and context in the vast cosmos; and plane of time.

There is a close link between anxiety or stress and pain. People with post-traumatic stress or depression, for example, may be more sensitized to pain, meaning it is worse for them than it would be otherwise. Conventional chronic and severe pain management, unfortunately, often serves people living with cognitive impairment very poorly. It is estimated that a large group of palliative care patients have cognitive impairment due to confusing medication, metastases in the brain, primary tumors, other disease conditions, or aging and dementia.

A number of alternative methods used for pain management are principally cognitive, such as relaxation and meditation techniques and cognitive behavior therapy (a process of analyzing, abstracting, and objectifying feelings that accentuate anxiety and pain). It is helpful to offer less cognitive and more intuitive ways to relax, appease anxiety, and access meditative or reflective calm for spiritual reasons, because conventional meditation techniques, even breathing exercises or concentration meditation, are not suited to a person with cognitive impairment or pharmacologically impaired concentration.

Music has an important place in spirituality, especially in palliative care. People with cognitive impairment need to be released from the responsibility or expectation of reciting liturgy or prayers, naming requests for forgiveness or meditation. They should be given alternative methods of belonging to their community and finding communion, reconciliation, hope, peace, comfort, and reassurance.

Many older people in palliative care also have dementia. Oliver Sacks in *Musicophilia* (2008), and Cohen and Eisdorfer in *The Loss of Self* (2002), writes about the benefits of music in the context of identity because dementia is most tragically often associated with a disintegration of identity. Music can foster a sense of self and identity that is not contingent on memory but rather on character expressed through musical taste, an embodied response and feelings, stimulation of memories of significant events and associations, and a sense of familiarity and "homeliness."

12.3 Using Music to Support Spiritual Well-Being in the Hospice

Supporting the spiritual well-being of people involves appreciation of these intricacies and looking for opportunities when alternative approaches to spirituality, such as music engagement, can be of value without compromising cultural identity. Ideas should be adapted to the individual's experience and background.

David Vance writes: "Many spiritual and religious activities rely on more *resilient* cognitive features such as procedural memory and limbic system aspects of attachment and motivation" (Vance 2004). By "resilient" Vance means enduring through all stages of cognitive impairment, medication, or dementia. Russell Hilliard reviewed the empirical evidence for music therapy in hospice and palliative care. While he focuses on visits by expert music therapists (as distinct from music engagement more broadly as part of everyday care), the results corroborate the impact of music in supporting comfort and reduced stress toward the end of life. "The primary goal of palliative care is to promote patients' quality of life by alleviating physiological, psychological, social and spiritual distress, and improving comfort … There are several forms of complementary therapy (e.g., massage, art therapy, aromatherapy, reflexology, therapeutic touch) … [and] the emergence of an evidenced-based approach to music therapy in end-of-life care" (Hilliard 2005). There is a rich array of qualitative studies that report music's ability to support end-of-life care and address patient and family needs.

Needs often treated by music therapists in end-of-life care include:

- The social (e.g., isolation, loneliness, boredom)
- Emotional (e.g., depression, anxiety, anger, fear, frustration)
- Cognitive (e.g., neurological impairments, disorientation, confusion)
- Physical (e.g., pain, shortness of breath)
- Spiritual (e.g., lack of spiritual connection, need for spiritually based rituals) (Clements-Cortes 2004; Cunliffe 2003; O'Callaghan 1993)

A considerable concurrence of depression, anxiety, and loneliness may be experienced by people in palliative care due to their social isolation, uncertainty, and feelings of helplessness. In hospice and palliative care, therapeutic musicians treat the many needs of patients *and families* receiving care.

Wlodarczyk investigated the effect of music therapy on the spirituality of people in an inpatient hospice unit. Statistical analyses indicated a significant increase in well-being (using a spiritual well-being scale). His study supports the use of music therapy to increase spiritual well-being for the terminally ill (Wlodarczyk 2003). "The expression and discussion of feelings of loss and grief can be very difficult for terminally ill patients. Expressing their emotions can help… experience a more relaxed and comfortable state" (Clements-Cortes 2004). For people who have very little or no speech, the *only* realistic way for them to express their responses is through emotional expression, and music is one way to feel together, to sing or make music, to harness music that encapsulates a poignant sentiment, or to stimulate volubility so that people can utter and release strong emotions.

12.4 Cultural Sensitivity

Spirituality is an aspect of *cultural competency.* "Cultural competence" refers to: "The process by which individuals and systems respond respectfully and effectively to people of all cultures, languages, classes, races, ethnic backgrounds, religions, and other diverse factors in a manner that recognises, affirms, and values the worth of individuals, families, and communities and protects and preserves the dignity of each" (Jutlla 2016). At least a minimal understanding and of varying attitudes to acceptable music in different faiths (e.g., karma and reincarnation, afterlife, necessary rituals, stigmas, and taboos) is necessary to support the end of life and illness with sensitivity, dignity, and respect using music tailored to the cultural situation.

Christians believe in eternal life after death. Music can be used to reinforce "hope," restoration

of the perfect relationship with God, satiety that does not depend on earthly or material possessions, health, or physical wellness. Music, especially familiar church music, can reinforce a person's sense of belonging and community, fellowship, and sense of being part of a larger entity, the Church. Christians believe that human creatures have intrinsic worth as God's creations, made in His image. This value is not undermined by frailty, illness, or disability. Songs that evoke God's limitless love and grace may provide reassurance and comfort to the believer. Music can be used to mark seasons of life and for faithful contemplation. Apostle Paul suggests that singing and music-making is a collective worship experience: a harmonizing act of inclusion, oneness, community, and communion in the Holy Spirit, embodying the unity of the Church, a corporate act of thanksgiving and praise, and an edifying, unifying imperative (Ephesians 5:18–21).

Hindu religious observance can include prayer, meditation, bathing and cleanliness, dietary needs, and astrological beliefs. The needs of the individual are contextualized in the greater unit of the family, culture, and environment (Coward et al. 2000). Hinduism encourages family members to take a role in care of family members, and selecting and listening to music together can provide a tangible way to be involved in caring. Hindus believe that all living beings possess a soul that passes through successive cycles of birth and rebirth (reincarnation). The great sitar performer, Ravi Shankar, said: "We view music as a kind of spiritual discipline that raises one's inner being to divine peacefulness and bliss … Thus, through music, one can reach God" (Hindu Music 2016). The Indian poet and Nobel Prize winner, Rabindranath Tagore, wrote: "For us Hindus, music always has *a transcendent meaning,* even when its intentions are by no means mystical or religious, but epic and amorous. Above all, music tries to touch the great hidden reasons for happiness in this world" (Hindu Music 2016).

Like Hinduism, Buddhism has the concept of karma (consequences of past actions – in this life or previous incarnations) and reincarnation. The latter means that the way of dying, dying well, and peace and non-agitation at end of life are important for a good reincarnation. Buddhism often uses music as part of spiritual practice, especially in temple practice and many forms of Buddhism practice meditation (by laity as well as monks and nuns). Buddhism takes on local cultural hues wherever it is, such that different manifestations have quite distinctive practices and cultural inflections. Aspects of food, dress, music, humility, and so on adapt within the local environment, from Nepal, India, and Tibet to China, Korea, Japan, India, Thailand, Sri Lana, Cambodia, and Myanmar. Despite this immense variety, most forms of Buddhism have meditation as part of their practice, and in various cultures this is assisted by "music," where music is not "entertainment" but chant, drones, liturgical recitation, and sound vibration as part of the spiritual experience. Music that we might otherwise call soothing or calming is an aid to concentration, immersion, mindfulness, or even working to achieve a "no mind" state of detachment from active thoughts running around in the head. Pain and anxiety can bear all the traits of repetitive, persistent, or obsessive thoughts that detract from quality of life.

Islam provides Muslims with a code of behavior, ethics, and social values, which helps them in tolerating and developing adaptive coping strategies to deal with stressful life events (Sabry and Vohra 2013). There is considerable variety in the attitudes toward music, and so consideration is needed as to when and whether music engagement is an appropriate intervention in care for people of Islamic faith. Drawing from his thorough understanding of Shari'ah, rather than simply quoting the Qur'an or a Hadith, Imam Afroz Ali suggests that it is "important to note that music and singing are essentially two different things … The kinds of singing, which are unequivocally prohibited, are those which contain the celebration of the material world and includes sexual connotation and… inappropriate speaking … [that] remove a person away from the worship and appropriate presence with Allah" (Ali Imam 2016). The kinds of singing that *are* permitted are musical matters that glorify Allah and praise the Prophet. It is also permissible to sing in general

terms about happiness (rather than about Allah specifically). Frivolous instrumental music, without singing, music purely for dance and sensual enjoyment (called *malahi*), is prohibited and abhorred. In a therapeutic or spiritually supportive capacity, great care should be taken to exclude lyrics and instruments that do not fit these criteria. Regarding the concept of whether music is allowed (halal) or forbidden (haram) in Islam, we can find different views from Islamic scholars; however, generally music is not considered forbidden in Islam as long as it is a therapeutic need. A millennium ago, Muslim physicians were considered leaders in medicine and innovative alternative therapies, now considered modern, including music therapy. In the past, Islamic researchers found that music has a great effect as a treatment of depression, insomnia, stress, schizophrenia, dementia, and childhood-related disorders like autism (Hanser and Thompson 1994).

Receptivity toward music in Judaism is similar to Christianity, and there is a rich use of music in Jewish culture, whether celebratory or serious.

13 Implementing Music in Palliative Care

Following are some approaches to implementation, ranging from bringing in expert performers, volunteer musicians, and trained therapists or providing recorded music on portable devices for listening with headphones that can be organized by staff or family and friends.

13.1 Engaging a Musician in Palliative Care

For the musician, a reexamination of values is important preparation for creating music for healing. This includes discarding investment in being right, exclusivity, attachment to past experiences, or expectation. Music for well-being is about an attitude of *sharing* and *encouraging*, and self-acceptance, rather than *showing* or *performing*. Therapeutic settings are frequently challenging. Concurrently, musicians need to deliver nothing less than their best, unselfishly, and with passionate commitment. The therapeutic musician must develop focus and relaxation, and relaxed posture and breathing that coheres with the musical expression, especially in a context when the musician is trying to help a patient relax, rest, or calm anxiety.

13.2 Considerations for Different Settings

The purpose of palliative care is patient comfort, especially pain control for people with medically incurable conditions, and enabling a peaceful and dignified death when appropriate. Not all patients in a palliative care ward or hospice are near to dying but may be there for symptom management. Music can extend to supporting the grieving process.

Acute hospitals typically have more monitoring equipment (O_2 SATS, temp, BP, HR) that often displays vital signs obviously for the therapeutic musician.

It is important to understand the *milieu* and environment (Aasgaard 1999), e.g., tailoring therapeutic music to suit the different settings and expectations of the palliative care ward, general hospital, hospice, or residential care home in which someone receives palliative care or, increasingly, the individual's home and community palliative care. Music ties in with meals, visitors, notions of privacy, and many situational and environmental factors and needs to be sympathetic with creating as relaxed and homelike environment as possible.

Sound in the environment of the home or ward for the person receiving palliative care influences tranquility, privacy, and ability to reflect. Reducing the noise from hospital equipment, alerts and announcements, clattering trolleys and foot traffic, visitors for other people, etc. will improve the experience for the patient and allow them to hear their own therapeutic music more clearly and immersively. Portable music devices and headphones are ideal in this setting rather than loudspeakers to help with occlusion and sound isolation.

13.3 Infection Control

A visiting or volunteering musician may be unfamiliar with requirements of infection control, both to protect the patient and themselves. The health professional may need to provide guidance. This includes sterile equipment, hand-washing protocols, quarantining, avoiding cross-contamination, and precautionary protection of patients and staff. Contagion is a higher risk for immune-compromised individuals who are unwell. Hospitals carry an inflated infection risk (nosocomial infection). Hand-washing and avoiding surface contact are the best strategies for reducing this risk.

13.4 Recorded Music for Individual Listening

Recorded music on portable devices has the several advantages. Firstly, the headphones allow a patient to use music to mask the operational noise of other people and equipment, an immersive environment that occludes or masks noise, chaos, and stress triggers. Secondly, it is not intrusive for others, as compared with small loudspeakers. Thirdly, a simple device, such as an Apple iPod or comparable MP3 player, for example, allows most patients to control the music themselves, thereby being proactively involved in their own music intervention and with the flexibility of being able to listen anywhere and at any time. The latter is very beneficial when music is deliberately used to aid going to sleep or to overcome pain and restlessness, i.e., at any time of the day. Individualized music can also be tailored with a list of music that is both calm and fits into the patient's tastes and interests for the greatest emotional and spiritual impact.

Music can be organized by staff forming part of the whole-person service, or music may be provided by the family and friends as a way to be meaningfully involved in care. If a patient is not able to explain their own interests in music, friends and family are often able to provide this information.

14 Conclusion and Summary

This chapter has looked at the potential impact of therapeutic music in palliative care with special attention to its impact on diversion and minimization of pain perception and calming physiological and emotional effects that can assist in reduction of restlessness, agitation, and anxiety. Further areas of physiological and emotional impacted by music intervention include stimulation of appetite, aiding getting to sleep, reducing agitation, and behaviors triggered by specific events or activities, such as bathing, visitors, and medical procedures. This chapter has outlined the key distinctions between therapeutic music and music therapy: their respective applications and practitioners. The way in which music affects physiology, the brain and mind have been discussed along with a number of approaches in mainstream therapeutic music and some concepts of vibrational therapy from alternative medicine practices. A brief outline of music in relation to health from antiquity to the present, from historical and philosophical perspectives, has been provided for those who are interested in the origins and long cultural background of the healing role of music. A very brief introduction to cultural and faith-related sensitivities points to the importance of cultural competency and sensitivity in multicultural and diverse care delivery.

Most significantly, engagement with music can facilitate relational interaction with family, friends, and care staff and provide companionship, reminiscence, and reinforcement of identity in times of change or isolation. Music has been used therapeutically to help people express emotions and anxieties that are difficult to verbally articulate, and to vent repressed and abstract emotions, especially those associated with dying, resolution of relations, existential issues, and fears. Music engagement provides a complementary modality for supporting emotional, psychosocial, and spiritual needs to balance the physical and medical care that form part of whole-person understanding in palliative care.

Music has a valuable contribution at various stages of palliative care, dying and death, both for the individual in care and for their family and

friends, in coming to terms with emotions and assisting with a calm, dignified environment. Throughout the palliative care trajectory, individualized music provides a flexible and proactive, potentially self-managed intervention that gives the patient some control over their environment, feelings, and pain management as appropriate in a situation where many aspects of their care are not in the patient's own control. Music can be a gentle and subtle way to support spiritual, existential, and deep nonverbalized needs, especially for those who do not identify with a faith community but who, nonetheless, have spiritual and emotional needs that are not addressed by medical care. As a modality, music can often be used in partnership with other therapies to facilitate movement, creativity, creating a legacy, for meditation and reflection, and with pastoral care.

Given its inexpensive nature and lack of side effects, music can provide a very effective, meaningful therapeutic intervention and enhancement to life quality without risk. Music can manifest in a range of presentations ranging from live music at the bedside and vigils by specialist therapeutic musicians to the provision of recorded music on a portable device tailored to individual tastes and needs, supported by any member of the care staff or family and friends, without the need for musical or technological expertise.

Sexuality and Intimacy

Abstract

A primary goal of palliative care is to provide "active total care" and improve quality of life of the person and their family. As sexuality is an integral part of the uniqueness and personality of every human being, failure to acknowledge this aspect of an individual in the palliative care context implies failure to acknowledge personhood. Navigating changes in sexual function and relationships is challenging for all people; however, for people who have a diagnosis of life-limiting illness, there are extra challenges and losses. Despite living in the "shadows of impending death," evidence suggests that the expression of sexuality and the need to connect in an intimate way continues to be an important part of people's

lives, even in the last weeks and days of life. This chapter explores the impact of life-limiting illness on sexual expression and provides some guidance to practitioners in responding to people's needs. The chapter moves beyond the binary division of gender and heterosexual relationships to discuss the needs of people who identify as LGBT and those who experience disenfranchised grief. While sexuality and sexual expression is a positive force in many people's lives, for others, it is a source of trauma and distress, and palliative care practitioners need to be aware of issues, such as sexual trauma and sexual disinhibition, and be in a position to create a safe accepting space, where people feel safe, validated, and supported.

1 Introduction

A primary goal of palliative care is to provide "active total care" and improve quality of life of the person and their family. As sexuality is an integral part of the uniqueness of every person, it follows that practitioners should proactively address this aspect of the person's humanity and human experience. At present, palliative care practitioners are not immune to the wider societal discourse around sexuality that positions sexuality as a taboo and embarrassing subject or frames discussions on sexuality and intimacy within a youth and health orientation. Consequently, the burden of responsibility seems to be on the ill person to initiate discussion. Thus, the challenge for practitioners is to break the cycle of silence and taboo that persists around sexuality and provide person- and family-centered care in a way that reflects and truly acknowledges the person's sense of self.

Navigating changes in sexual function and relationships is challenging for all people; however, for people who have a diagnosis of a life-limiting illness, there may be extra challenges. This chapter explores the impact of life-limiting illnesses, such as cancer, and their treatment on sexuality and sexual expression and provides some guidance to practitioners in responding to people's needs. This chapter moves beyond the binary division of gender and a heterosexual focus to incorporate the needs of people who identify as LGBT. It also discusses issues which receive little attention within the palliative care literature, namely, sexual trauma and sexual disinhibition. These gaps in palliative care literature and the broader dearth of research on sexuality in palliative and end-of-life care are noteworthy, not least because they are in direct conflict with the notion of total care, total pain, and personhood, concepts that are integral to the philosophy of contemporary palliative care.

2 The Complexity of Sexuality

The literature abounds with definitions of sexuality from many different perspectives with no single understanding or clinical definition of sexuality emerging. Taylor (1983 : 54) suggests it is "the constellation of physical and psychological traits that make us male or female," with Wilmoth (2006) being of the view that sexuality, like pain or fatigue, is what the person says it is. While recognizing that sexuality is a very individualized and personal concept, and is best defined by the person, the World Health Organization's (WHO) definition, which is the most common one cited in the literature, is used here to elucidate the various dimensions of sexuality.

The Pan American Health Organisation/World Health Organisation (2000:6) defines sexuality as "...a central aspect of being human throughout life encompasses sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction. Sexuality is experienced and expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviours, practices, roles and relationships. While sexuality can include all of these dimensions, not all of them are always experienced or expressed. Sexuality is influenced by the interaction of biological, psychological, social, economic, political, cultural, legal, historical, religious and spiritual factors."

This broad definition emphasizes the all-encompassing nature of sexuality, which is an integral part of the personality of every human being. Sexuality is a relational experience with oneself, as well as an attraction and connection

with others. While sex is an aspect of sexuality, sexuality is more than sexual activity. Sexuality is also about intimacy and closeness and is as much about fantasies and dreams as it is about desire and erotic sexual pleasure. The PAHO/WHO definition also draws attention to the fact that sexuality encompasses feelings, values, and ideas as they relate to gender identity, sexual orientation, and gender roles and are intimately bound up with one's self-concept, self-esteem, and body image.

The term "sex" is usually used to describe the physical "sexual act," but it is also used to identify a person's designation at birth as male or female based on their anatomy (genitalia/reproductive organs) or biology (sex chromosomes and /or hormones). Although the term "gender" has traditionally been tied to reproductive anatomy (the person's genitals) and framed as a male-female/boy-girl binary, gender goes beyond the binary division of male and female and includes people who identify as transgender, gender fluid, and gender nonbinary. The term "sexual orientation" refers to a person's physical, emotional, or romantic attraction to another person. Although people's sexual orientation does not always appear in definable or fixed categories, traditional constructions of sexual orientation include attraction to the opposite sex (heterosexual), attraction to the same sex (lesbian (L) or gay (G)), attraction to both sexes (bisexual (B)), and attraction to neither.

Finally, the definition highlights that the expression of sexuality involves complex brain or biological processes that are influenced and mediated by wider social, historical, cultural, religious, and political structures. It is also part of our being whether we are partnered, single, sexually active, or celibate; is not limited by age, health status, or functional abilities; and is an aspect of one's being, which exists and changes across the life span.

3 Barriers to Discussing and Expressing Sexuality Within a Palliative Care Context

In a recent systematic review of the literature on patient-provider communication about sexual concerns with cancer patients, Reese et al. (2017) concluded that sexuality needs are unacknowledged and unaddressed for many people, particularly women. Similarly, in the few studies involving palliative care patients, a particular concern was the failure of practitioners to provide a context or space to discuss sexuality or acknowledge the loss and grief they were experiencing as a result of changes to their sexual selves and their intimate relationships (Taylor 2014a). Loss and grief has the potential to contribute to "total pain" and total distress.

Some research about why the topic of sexuality and intimacy remains a taboo in clinical practice settings has been published. Several studies indicate that lack of knowledge, confidence, and skill prevents practitioners from opening a discussion on what they perceive as a deeply personal aspect of life (Reese et al. 2017). Practitioners report feelings of personal discomfort, including fearing that they will offend the person, open up a "Pandora's box" or "can of worms," or transgress some medicolegal or cultural boundary, should they initiate a discussion on sexuality (Hordern and Street 2007; Dyer and das Nair 2013). Health practitioners also report a reluctance to discuss issues as they perceive it inappropriate due to the age, gender, culture, or religion of the person and wonder whether the person would consider sexuality as a legitimate topic for discussion (Dyer and das Nair 2013). The biomedical and pathophysiological approach to care that underpins the practice of some practitioners may result in the ill person being viewed in terms of "diagnosis" and symptom management, resulting in the conversation being "steered" away, albeit unconsciously, from issues of intimacy and relationships (Hordern and Street 2007). In keeping with this approach, practitioners may view the person as asexual or believe that they agree with the emphasis on the disease, are not concerned about sexual issues, have lost interest in that aspect of their life, or are too unwell to discuss sexual intimacy and relationship needs (Hordern and Street 2007; Dyer and das Nair 2013). This may be particularly true in the context of older age and palliative care.

Other factors that maintain the silence around sexuality include structural barriers,

such as: lack of time, lack of privacy within care settings, lack of clear care pathways, and perceiving sexuality issues to be beyond the person's scope of practice, requiring input from some other specialist or discipline (Hordern and Street 2007; Kotronoulas et al. 2009). These fears and concerns may be compounded if the person identifies as LGBT. Although studies that explore palliative care practitioners' responsiveness to the needs of LGBT people are sparse, what is available suggests that practitioners lack knowledge on LGBT issues, presume heterosexuality, and hold ambivalent attitudes toward LGBT people (Harding et al. 2012; Marie Curie 2016).

In many studies practitioners report waiting for the person to seek help. This passive stance, which assumes that patients will seek support and spontaneously open a discussion on their intimate relationships and sexuality, contrasts sharply with the proactive person-centered approach that underpins the philosophy of palliative care and has received attention in the literature with particular reference to suffering and total pain. Total pain as suffering is understood as encompassing physical, psychosocial, and existential distress or struggles, and addressing it remains the most important defining characteristic that distinguishes palliative care from other care provided to patients in hospital. The passive waiting stance of practitioners also ignores the possibility that many people may perceive sexuality as something that they should not openly discuss or indeed they may lack the confidence or skills to open a discussion. If the expression of sexuality is an intrinsic part of our humanity, then its inclusion within a person-centered approach to palliative care is needed.

4 Sexuality and Person-Centeredness

Understanding person-centeredness and holism invites a question on what it means to be human. In her early development of the modern hospice and palliative care movement as we know it, Cicely Saunders was introduced to the writings of Viktor Frankl's *Man's Search for Meaning* and subsequently referred to her copy as "dog-eared and marked almost to extinction" (Saunders 2006: 161). Though few of Frankl's works were translated into English at the time, in *Man's Search for Meaning*, he summarized his understanding of the person and being human (Frankl 1963). This was to have a strong influence on Saunders' theory underpinning palliative care and continues to the present. For Frankl, there are three dimensions to the human being: body (*soma*), mind (*psyche*), and a core, which is spirit (*noös*). These dimensions penetrate one another. The *soma*tic plane includes all things physical; the *psyche* plane is where cognition and emotions reside and so includes emotional states, moods, sensation of drives, instincts, desires, and passions. Also, the *psyche* plane includes intellectual talents, acquired behavior patterns, and social impressions.

The noetic dimension includes that which is uniquely human, the freedom to take a stance, such as against biopsychosocial determinants. This is where values and love reside. A person has a psychophysical overlay but is also spiritual so that "(b)y being centred around the existential personal core, being human is not only individualised but also integrated" (Frankl 2011:34). Wholeness implies the integration of the *soma*, *psyche*, and *noös*. Without spirit, wholeness does not exist. In this, Frankl makes a clear assertion to the proponents of holism (and therefore, palliative care) in healthcare. It is worth noting that Frankl did not agree with the English translation of *noös* to spirit because of the religious connotations. There is much that can and has been said about Frankl's contribution to the philosophy and principles of palliative care. Crucially and for our purposes here, as an integral part of the personality of every human being, sexuality finds expression through all three dimensions: *soma*, *psyche*, and *noös*. Failure to acknowledge this in an individual in the palliative care context implies failure to acknowledge the person and thus, deny their personhood. Understanding the impact of life-limiting illness and its treatment on sexuality is therefore a core aspect of palliative care.

5 Impact of Life-Limiting Illness and Its Treatment on Sexuality

The impact of life-limiting illness on sexuality is well documented within the literature. Numerous studies have been published, including systematic reviews of the research evidence and reviews of the impact of gynecological cancer (Abbott-Anderson and Kwekkeboom 2012; Gilbert et al. 2011), colorectal cancer (Traa et al. 2012), testicular cancer (Nazareth et al. 2001; Carpentier and Fortenberry 2010), penile cancer (Maddineni et al. 2009), vulvar malignancy (Aerts et al. 2012), breast cancer (Gilbert et al. 2010), and prostate cancer (Tucker et al. 2016; Paterson et al. 2015). All of these highlight the impact of cancer on the physical, psychological, and social/relational aspects of sexuality across a range of ages and cultural groups. Although, for ease of presentation, the next section discusses the impact of cancer under three headings, the interrelationships between the physical, psychological, and relational aspects of sexuality as they relate to the wholeness of the person should not be overlooked (see Tables 1 and 2 for overviews of the effects reported within these reviews).

Table 1 Overview of findings from systematic reviews on impact of cancer on men

Men	Physical (Sexual response cycle)	Psychological (Emotional and cognitive responses that influence sexual response)	Relational aspect (Relationship with self and desire for intimacy with others)
Penile cancer Maddineni et al. (2009)	Reduced sexual desire Loss of orgasm Mild-moderate erectile dysfunction Reduced sexual satisfaction	Psychological distress and posttraumatic stress disorder	Not addressed in the review
Prostate cancer Tucker et al. (2016) and Pateerson et al. (2015)	Erectile dysfunction Diminished libido Decreased ability to ejaculate Change to penis shape and size	Feelings of loss and grief at diminishment as a man Guilt at not being able to function as a man Shame, embarrassment, anger	Difficulties relating to partner Doubting ability to sexually satisfy partner Distancing, withdrawal, and avoidance of sexual intimacy Reluctance to have sex in case PSA level would increase
Testicular cancer Nazareth et al. (2001) and Carpentier and Fortenberry (2010)	Ejaculatory dysfunction Erectile dysfunction Reduced or loos of orgasm Decreased sexual drive/ desire	Decrease sense of attractiveness Feel less masculine Desire to look “normal”	Decreased sexual intercourse Self-conscious about missing testicle
Colorectal cancer Traa et al. (2012)	Ejaculatory dysfunction Erectile dysfunction Orgasmic dysfunction Reduced sexual desire	Body image change due to stoma	Having radiotherapy and/or having a stoma predicted less sexual activity

Table 2 Overview of findings from systematic reviews on impact of cancer on women

Women	Physical	Psychological	Relational
Gynecological cancer Abbott-Anderson and Kwekkeboom (2012) and Gilbert et al. (2011)	Dyspareunia Vaginal dryness Vaginal atrophy Reduced vaginal size Difficulty becoming sexually aroused Decreased genital sensation, decreased genital swelling Difficulty or inability to achieve orgasm Decreased sexual satisfaction Postcoital bleeding Fatigue Menopausal symptoms	Altered body image Loss of femininity/ not feeling like a woman Feeling less attractive sexually Lack of feeling or emotion Psychological distress associated with infertility Decreased interest in sexual activity Decreased enjoyment Fear of transmitting cancer to partner Fear of pain with intercourse and fear of reoccurrence of cancer	Reduction in frequency of sexual activity Communication problems with partner and inability to discuss sexual concerns with partner Blaming the sexual relationship or partner for cancer Change in partners interest or loss of interest in sexuality activity Partners becoming emotionally distant Adverse impact on future intimate partner relationships
Vulvar Aerts et al. (2012)	Difficulty with arousal and orgasm Dyspareunia Fatigue	Moderate reduction in sexual desire Dissatisfied with sexual relations Reduced self-confidence Less acceptance of body Loss of self-confidence	Worsening of emotional relationship with their partner Improvement in relationships and an increase in emotional closeness with partner Fear that sexual activity would result in reoccurrence Fear of transmitting cancer to their partner
Breast cancer Gilbert et al. (2010)	Decrease in sexual interest/desire Decrease in sexual arousal Dyspareunia or coital pain Vaginal dryness Numbness if previously sensitive breast Difficulty achieving orgasm Fatigue	Negative body image Feeling sexually unattractive Loss of femininity/ feeling “half a woman” Depression/anxiety Grief at loss of breast Feeling “old”	Withdraw from their partner as feel unattractive Dislike being naked
Colorectal Cancer Traa et al. (2012)	Dyspareunia Vaginal dryness	Feelings of disgust at stoma	Worry about reaction of partner to the stoma Radiotherapy and having a stoma predicted less sexual activity

5.1 Physical Aspect of Sexuality

In relation to the physical aspect of sexuality, numerous studies highlight the impact of surgery, radiotherapy, and chemotherapy on the sexual response cycle. In all the reviews involving people diagnosed with cancer, experiences of decreased sexual desire, sexual arousal, sexual function, orgasm, as well as a decline in sexual activity and sexual satisfaction were reported. While the impact of the treatment is unique to each person, most of the sexual problems experienced resulted from damage to the anatomical or physical structure associated directly or indirectly

with sexual activity, including the autonomic nervous system, endocrine system, and vascular compromise of the genitals. For example, surgery may shorten the upper vagina in women or damage nerves or blood supply to the penis in men. Radiation therapy, particularly to the genital area in women, is associated with decreased vaginal elasticity, difficulty with genital sensations, vaginal atrophy, and vaginal stenosis (Gilbert et al. 2011), and studies involving men report temporary or permanent erectile dysfunction, irritation to the urethra causing pain during ejaculation and maturation, and infertility (Nazareth et al. 2001). In addition to loss of fertility in young women, chemically or surgically induced menopause is associated with difficulty with sexual desire and arousal, loss of pleasurable sexual sensations, vaginal dryness, and decreased intensity of orgasm. Men treated with androgen deprivation therapy report variable degrees of erectile dysfunction, loss of sexual dreams, and feminizing effects, such as hot flashes and an increase in breast tissue (Sountoulides and Rountos 2013). Many of the prescribed medications also impact on sexual function, which may be exacerbated within a palliative care context due to a combination of polypharmacy, multi-morbidity, and decline in health status.

Sex function and sexual behavior also depend on physical energy, mobility, and vitality. As diseases advance, symptoms such as dyspnea, pain, fatigue, and restricted mobility can make the physical expression of sexuality problematic. Studies involving people with a diagnosis of motor neuron disease (amyotrophic lateral sclerosis) highlight the impact of physical weakness, fatigue, and restricted mobility on sexuality (Taylor 2014a, b), with studies involving people with lung disease revealing how dyspnea and the fear of causing dyspnea can impact on sexual function (Lindau et al. 2011). In addition, neutropenia, which predisposes the person to infection, can make sexual contact inadvisable if the partner has an infection. Likewise, thrombocytopenia and the associated risk of bleeding make vigorous genital intercourse or anal intercourse inadvisable (Matzo et al. 2013).

5.2 Psychological Aspects of Sexuality

While the physical changes, such as decline in sexual desire, the frequency of sexual activity, orgasm, and sexual satisfaction, have received greater attention in the literature, several of the reviews highlighted how these effects extend beyond the mechanics of sexual function to impact on the emotional or psychological landscape of the person. The sociocultural discourse that surrounds the body can also have a profound impact on the way the person interprets and gives meaning to the changes experienced. Consequently, disease and treatment can also inflict "invisible assaults" (Gilbert et al. 2011:54) that impact on intimacy and sexual expression.

Altered body image appears to be one of the most challenging issues facing patients. Body image is a product of perceptions, thoughts, and feelings about body size, appearance, attractiveness, competence, and function. Although highly subjective, negative perceptions of body image have been reported in many studies involving men and women. Following surgery, people are often left with mutilating scars or the absence of a body part that was not only an expression of gender, sexuality, and sensuality but an important part of the ideal self and sexual self-concept and expression. The problems reported included dissatisfaction with appearance, perceived loss of body integrity, reluctance to look at oneself naked, feeling less sexually attractive, self-consciousness, and embarrassment about appearance (Abbott-Anderson and Kwekkeboom 2012; Gilbert et al. 2011; Traa et al. 2012; Maddineni et al. 2009; Aerts et al. 2012; Gilbert et al. 2010). The construction and linking of certain body parts with ideals of femininity and masculinity can also have a significant impact. Cancer in organs, such as breast, uterine, or vulva, that have traditionally been constructed as symbols of motherhood and femininity can seriously impact women's sense of identity and well-being. While some women do not report negative changes, the majority of evidence indicates that women who have breast or gynecological cancers experience a range of feelings including decreased feelings of sexual

attractiveness, fear, and insecurity about ability to perform sexually as well as feeling a loss of femininity and "womanliness." In Gilbert et al.'s (2010) review, women who had a mastectomy reported greater body image and sexual attractiveness issues than those who received breast conserving surgery or reconstruction. Similarly, for men psychological distress can occur through a reduced sense of masculinity as a result of cancers that effect testis and penis, all aspects of the body that are imbued with symbolism and social meaning that is highly gendered (Maddineni et al. 2009). A pervasive theme within Tucker et al.'s (2016) meta-synthesis of studies of men following prostate cancer was one of loss and grief, with men reporting a deep sense of being diminished as a man and as a lover because of the treatment.

Cancer does not have to involve organs associated with sexual function to impact on sexual self-esteem and sexual self-concept. Although head and neck cancer does not impact on sexual function, studies indicate that the facial and neck disfigurement associated with these cancers can have a particular negative impact on body image and intimacy (Low et al. 2009). In Traa et al.'s (2012:23) review on colorectal cancer and sexuality, having a stoma was a strong predictor of sexual and intimacy problems, with those who "could not reconcile their own experience of disgust or the potential reaction of the partner to their ostomy" choosing to avoid sexual activity altogether.

5.3 Relational Aspect of Sexuality

Even though there is a distinct lack of research from a relational perspective, what is available suggests mixed outcomes. In some studies participants reported that the burden of disease and treatment negatively impacted on their intimate relationship. Some men and women reported being overwhelmed with worry about their partner's reactions to their body changes, with others reporting a decrease in their partner's sexual interest and emotional intimacy, which they perceived as a negative reaction to their body changes (Abbott-Anderson and Kwekkeboom 2012). Research also suggested that some men and women were so fearful of disappointing their partner sexually that they withdrew and distanced themselves as a protective mechanism (Abbott-Anderson and Kwekkeboom 2012; Tucker et al. 2016). Others avoided intimacy in response to fear of pain and fear that the cancer would return (Abbott-Anderson and Kwekkeboom 2012). Some patients who had radiotherapy particularly to the sexual organs or had cancer in organs associated with sexual function reported fearing that they would damage their partner through intimate sexual contact or feared transmitting the cancer to their partner (Cort et al. 2004). However, others reported engaging in coital sex primarily to satisfy their partners, in case the patner sought sexual pleasure elsewhere (Gilbert et al. 2011; Abbott-Anderson and Kwekkeboom 2012).

Studies that have explored partners and spouses of the ill person suggest that intimacy and sexual contact may diminish for reasons other than the physical and psychological changes that the disease or treatment has on the ill person's body image, sexual desire, and function. For some partners, the shadow of impending death, their partner's failing body, and their partner's inability to respond to their touch were significant barriers to maintain a sexual relationships (Taylor 2014a, b). Similar to the ill person, partners may also have a number of fears and anxieties about initiating a sexual or intimate relationship. Partners may fear dislodging drains and tubes, fear hurting the person, fear that love making would sap the person's energy, and fear that the person might die during love making, while some may experience guilt about feeling desire when their partner was facing a life-limiting illness (Higgins 2012). As the disease progresses and the person becomes more dependent on the partner for care, traditional marital roles change for both individuals; consequently, the intimate and sexual aspect of the relationship may become marginalized as a result of exhaustion, or due to changes in role from intimate partner to career. A balance of cognitive abilities is also a critical element in the maintenance of healthy relationships, and loss of cognitive ability can result in profound changes to a couple's relationship (Wadham et al. 2016).

Partners of people with dementia also have another dilemma in wondering if they are taking advantage of their partner when initiating sex, particularly when it is difficult to determine if it is a consensual act (Wornell 2014).

A key factor associated with many of the relationships where intimacy and sexual relationships diminish is difficulty in communication and silence around sexuality. Indeed, some studies highlight how couples "self-silence" as a way of coping or as a strategy to "protectively buffer" the other person from their distress (Manne and Badr 2010). This self-silencing or guarded communication between the couple made revealing fears and anxieties more challenging, which was often compounded by a lack of information and support by health professionals.

However, for others, despite an overall negative impact of illness, physical intimacy and sexual relationships were ways to convey mutual commitment. Many patients and partners reported improved communication, understanding, and emotional closeness and intimacy with their partner. The quality of the relationship prior to the diagnosis was a strong predictor of whether the couple was able to reframe their sexual identities and successfully incorporate changes into their relationship (Gilbert et al. 2011). There was some evidence that couples who had a broad sexual repertoire prior to diagnosis, were open to exploring alternative sexual activities and those who had an open style of communication were able to renegotiate the meaning of being sexual within the relationship. These couples were more successful in resisting the socially conditioned view of sexuality as penetrative intercourse (Reese et al. 2010; Gilbert et al. 2011; Tucker et al. 2016) and apply what Reese et al. (2010) termed "flexible coping" to learn new ways to appreciate each other's bodies and enact sexual intimacy and pleasure within the relationship. Developing alternative way of sexual expression beyond the "coital imperative" not only buffered both men and women against feelings of failure, but it reaffirmed their relationship, intimacy and sexual self-concept.

While the aforementioned studies included some people who were nearing the end of life, research that has specifically explored sexuality in palliative care contexts clearly indicates that the expression of sexuality continues to be an important part of people's lives, even in the last weeks and days of life (Taylor 2014a, b; Lemieux et al. 2004). For people with advanced life-limiting illnesses and who have complex care needs, there are many barriers to the expression of intimacy and the spontaneity of sexual activity, such as symptoms (dyspnea, pain, fatigue, and limited mobility) and the technologies of care (breathing equipment, catheters, tubes, drains, IV lines, and hospital beds). Nevertheless studies involving patients with motor neuron disease and cancer and their partners poignantly remind us that despite living in the "shadows of impending death," the need to connect in an intimate way remains a significant aspect of some couples' relationships (Taylor 2014a, b; Lemieux et al. 2004). Partners highlighted that despite the pain they experience as they live and cope with the impact of disease on their relationship, physical intimacy was a way to maintain a sense of normalcy and affirm life and was a means of mutual support and renewing of affectional bonds. Although over time connecting was experienced less through erotic sexual relationships and more through kissing, hand holding, and touching, several partners described a pattern of "physical reaching out" or not letting the spouse pass away without being touched in a tender or intimate manner. Affectionate touching helped partners to stay physically close and maintain their deep emotional connection until the end.

6 Addressing Issues of Sexuality in Practice

While the evidence suggests that some men and women restructure and reframe their ideas of sexuality, successfully incorporate body changes into their relationships, and find new and creative ways to express themselves sexually, many others struggle with the physical, psychological, and relationship changes. To move beyond the "safe horizons of medical expertise" (Horden and Streeet 2007:56) and venture into the hazards of a

conversation about love, relationships, loss, sex, and bodies requires the practitioner to view intimacy and sexual expression as a core aspect of identity and relationships and integral to personhood, irrespective of the stage of illness or context of care. In view of the fact that few people will be confident enough to raise their concerns with a member of the healthcare team, practitioners need to proactively legitimize sexuality as an aspect of care and convey a message early in their encounters that sexuality is a permissible subject to talk about. A necessary first step is the inclusion of sexuality as a normal part of care, which may start with a private, one-to-one conversation between the practitioner and the person around the impact of the illness on their lives, relationships, and intimacy needs. An important aspect of this process is to acknowledge that the person may be uncomfortable talking or answering questions about intimacy and relationships. The person will also need to be reassured that there is no pressure on them to answer questions; they may close the door on any line of exploration and are free to return to discuss issues at any time into the future. The use of reflective open-ended questions that allows for freedom of response is far less threatening than closed questions, which limit the person's range of responses and may imply judgments.

Should the person choose to talk, the practitioner's role is about facilitating the person to tell their story, grieve their loss, and talk about their feelings around loss of intimacy and their altered body image. Central to enabling the person to tell their story is the ability to live on the edge of "not knowing," to tolerate the anxiety and feelings of discomfort that are generated, while at the same time creating a context for telling through: embodied listening, "natural curiosity," gentle prompting, reflecting, using emotionally supportive statements, and the asking of interesting questions. Practitioners must also listen for the unasked questions or the often subtle unspoken cues that people may give; for example, the turn of the head away from the wound site, the reluctance to look in the mirror, or the withdrawal from social interactions.

Exploring the meaning of the illness and its impact on the person and their relationships in a compassionate way is central to building the trust and connection necessary to discuss sexuality and intimacy. While the same skills that are used to discuss other issues in palliative care are transferable to this context (e.g., seeking clarification, reflecting back, paraphrasing, and facilitating sensemaking), the caring process needs to be anchored in the principles of "being with," "engaging with," and "caring with" the person. At this stage, listening and bearing witness to the person's story and the meaning they attach to their experience needs to take priority. Practitioners who intervene too soon with premature reassurance or advice may close down the discussion by communicating to the person that their concerns are not permissible to talk about.

For some people sexual intimacy may no longer be desirable or part of their lives, and this needs to be accepted and respected. However, others may want information on symptoms associated with their illness and how to alleviate some of the problems they are experiencing, such as dyspareunia, pain, etc. Providing information and educating the person about alternative positions, touch techniques, or simple suggestions, such as the use of a lubricating gel where vaginal dryness is an issue, can make a major difference to the person's quality of life (see Table 3 for some suggestions). People often need permission to seek new ways of achieving sexual pleasure, to develop a repertoire of the less traditional sexual activities, and to be reassured that there is no right way. It may be helpful to remind people that while some sexual behaviors, such as intercourse, may undergo disruption, other aspects of intimacy and sexual pleasure, such as body caressing, kissing, massaging, mutual pleasuring, and masturbating, need not change. Irrespective of what suggestion is made, eliciting the person's perspective and reaction to the suggestion is central to crafting a plan of care that takes account not only of the physical dimension of sexuality but incorporates the psychological, interpersonal, and relational dimensions.

The interpersonal or relational model of intimacy proposes that ongoing reciprocal disclosures and responses to disclosures between partners is important to the development of

Table 3 Strategies to minimize impact of symptoms on sexual expression

Symptom	Possible strategies to explore
Pain	Explore strategies that may help minimize pain, such as pillows to support limbs, lying side by side, sitting on a chair Timing or temporarily adjusting medication to increase pain control Build in strategies that might help reduce discomfort such as massage, warm shower, and relaxing music
Fatigue	Select a time when less fatigued (morning as opposed to end of day) Provide time to rest before and after sexual intimacy Choose positions to minimize exertion (e.g., side by side)
Dyspnea	Experiment with positions that facilitate increased oxygenation, e.g., sitting up/ raise head of bed Using supplementary oxygen or inhalers before and during sexual activity Taking time and using slower movement to reduce oxygen demand Have partner adopt a position that requires greater physical effort (e.g., going on top)
Nausea	Review antiemetic medication Review timing and triggers that may provoke nausea to see if there is a time when less nausea exists
Mobility restrictions	Review pain control Use position to minimize discomfort Experiment with pillows to support limbs, lying side by side, sitting on a chair
Sore mouth	Identify cause (candidiasis, mucositis, mouth ulcer, cracked lips, coated tongue) and treat Review medication as some may cause dry mouth Refer to dentist if related to dentures or teeth Oral care using a soft toothbrush, fluoride toothpaste and water, after each meal and at bedtime
Dyspareunia	Assess location and type of pain to identify cause, such as infection, vaginal dryness Review medication as some may reduce vaginal lubrication Advise on use of water soluble vaginal lubricants, esthetic gels, or vaginal estrogen creams (VOC); however VOV is contraindicated for women with hormone-positive tumors Consider advice to increase foreplay, massage, and use of vibrator Advise patient to adopt a position where they can control force and pressure of penetration to help reduce pain Even after the original cause is resolved, some women may have difficulty relaxing due to anticipatory pain which may require relaxation techniques If pain persist, explore other ways of mutual pleasuring that does not focus on vaginal penetration
Erectile dysfunction	Medication such as Viagra Advice on other strategies such as vacuum devices or penile injections, although research suggest that many men do not wish to use these devices Explore other ways of

relationship intimacy, with studies supporting the idea that individuals who disclose more of their concerns to their partners experience more relationship intimacy (Manne and Badr 2010). Therefore, engaging in a conversation with the person and their partner, either alone or as a dyad, is important. Those unaccustomed to discussing their sexual and intimacy needs may need help communicating about their individual needs, preferences, and fears. They may also need time and support to explore and understand why each partner may be reacting differently to their changed circumstances. The therapeutic and emancipating value of the couple talking frankly to each other about feelings and experiences should not be underestimated. Providing support to people to open a conversation with their partner may be all that is required to help them to acknowledge their abilities that still exist and explore new ways of expressing love, affection, and pleasure.

While maintaining closeness and intimacy is important in relationships, Cort et al. (2004) remind us that there are also times when couples may need to redefine boundaries and create distance, and couples may need permission to withdraw from their previous physical relationship. Taylor (2014a) also highlights the importance of practitioners being aware of their desire to fix things, as some relationships cannot be repaired., In this context it is important that the practitioner

supports the people to make sense of their experiences and validate feelings of remorse, anger, and loss. If practitioners enable couples to communicate with each other, irrespective of the degree of intimacy within the relationship, not only is there an opportunity to create parting gifts and memories, but there is also an opportunity for couples to discuss feelings and changes in the relationship and resolve any misunderstandings that may have occurred.

The addition of a healthcare practitioner as a third guest into the privacy of a couple's relationship has the potential to create tensions. While the partner may be welcoming and experience great relief from the burden of care responsibilities, practitioners need to be mindful that as they become more involved in the intimate physical and emotional care of the ill person, their involvement may exacerbate ambivalent feelings within the well partner. Their involvement may also accentuate the emotional distancing that may have or be developing between the couple. It is important therefore to be mindful that the role of the practitioner is to facilitate the couple to communicate with each other, and not be drawn into a system, where they become the medium through which couple's communicate.

In a palliative care context, meeting and supporting intimacy and sexuality are not the prerogative of any one discipline, and the person will choose with whom they are most comfortable discussing and disclosing sexuality issues. As no one person within the team will have all the knowledge and skills required to respond to every eventuality, a team approach is required. A team that is not afraid to discuss sexuality in an open and non-hierarchical manner among themselves is also more likely to create and support a culture where sexuality is included in a proactive manner within the horizons of palliative care practice. However, such a team approach is not without its challenges. While a multidisciplinary team brings a range of skills and expertise enabling complex problems to be addressed, there is also the risk that problems become reduced to discrete elements and aligned with a particular discipline. For example, difficulties in maintaining sexual intimacy become viewed only in physical terms and addressed by one discipline through the use technical rational interventions, such as drugs with little acknowledgment of this as a core aspect of identity and relationships, and personhood. Yet, it should be clear from the discussion so far that the impact of a life-limiting illness on sexuality is multidimensional with physical, psychological, relational, and existential dimensions that are interrelated difficult to separate out from one another and greater than the sum of the parts.

7 LGBT Identities

What is interesting about the vast majority of research on sexuality and life-limiting illness is that sexuality is positioned within a heteronormative understanding of sexuality, with the research tools and questions framing sexual expression in the context of vaginal-penis penetration. Consequently, the evidence around the impact of life-limiting illness on LGBT people's expression of sexuality is sparse. Yet there is a growing awareness that, due to oppressive and discriminatory social contexts, people who identify as LGBT engage in more risky lifestyle behaviors, such as smoking and alcohol use, which are associated with higher rates of cancer (Fredriksen-Goldsen et al. 2013). Gay men are also more likely to be exposed to the burden of HIV-related cancers and have higher-risk factors for the development of anal cancers (Quinn et al. 2015). People who identify as LGBT are also more likely to delay accessing healthcare and screening services for fear of discrimination and stigma by health practitioners (Harding et al. 2012). Transgender men and women who have not undergone surgical transition may also find it psychologically difficult to seek help or address health concerns associated with reproductive organs that do not match their current gender (World Health Organisation 2015).

Although the impact of life-limiting illness on the intimacy and sexual needs of people who identify as LGBT is largely under researched, the limited evidence available suggests that they have additional concerns and worries that palliative care practitioners need to understand.

Research into the end-of-life needs of LGBT people suggests that many fear disclosing their sexual orientation or transgender identity and do not feel safe to be "out" within palliative care services, for fear that practitioners will be indifferent or hostile to their sexual orientation or gender identity and directly or indirectly discriminate against them (Marie Curie 2016; Harding et al. 2012; Almack et al. 2010). LGBT people may also have a deep distrust of services and practitioners (e.g., pastoral care worker) who may be perceived as being associated with a religious or church ethos that casts same-sex relationships as deviant, immoral, and sinful. This distrust may result in the person not coming out to the health provider or returning to the "closet" because of the need to rely on church-based services at the end of life. In addition to fears around coming out, those who have a same-sex partner express fears around demonstrating affection toward their partner and worry about receiving negative reactions from staff and other patients and families using the service they attend. People who identify as transgender may fear practitioners undermining and devaluing their identities by calling them by their birth name or by using incorrect pronouns in conversation and documentation. They also have concerns about being supported to live out their lives in their preferred gender and are fearful that, should they be hospitalized or admitted to a palliative care unit, they will be forced to use gender-specific bathrooms or bedrooms that do not align with their preferred gender. Without practitioners being proactive and communicating respect for sexual diversity, people may be reluctant to disclose their sexual orientation or transgender identity. Services, organizations, and care professionals must challenge anti-LGBT bias both within themselves and their service and demonstrate inclusiveness by ensuring that their mission statements, policies, and practices are LGBT affirmative (see Table 4 for LGBT-affirmative practices). At an individual level, practitioners demonstrate respect and acceptance by avoiding heterosexual assumptions and language that privileges heterosexuality. Opening a conversation in a nonjudgmental way and asking about partners and the gender of partners are critical to supporting disclosure. While attitudes toward LGBT people are changing and most people are out to someone about their sexual orientation, there are still some people who identify as LGBT who have not disclosed their orientation or gender preference because of fear or shame. For this small minority being in a palliative care service and feeling acceptance may create a context for this disclosure. On the other hand some people may have no desire to tell and this needs to be respected. LGBT people who are not out to family and friends may fear being inadvertently "outed" by practitioners or be concerned that due to practitioners' lack of knowledge, they will be exposed to intrusive questioning or have to repeatedly come out and/or provide each staff member with education on LGBT issues (Cartwright et al. 2012). Thus, practitioners need to have a conversation with the person on confidentiality, sharing information, and recording information.

LGBT people also worry about a lack of recognition of their relationships and partners during visits, medical decisions and advanced care planning, and decision-making in relation to funeral (Almack et al. 2010; Cartwright et al. 2012). People who identify as transgender have concerns about their wishes being respected after their death; in particular, they may worry that they may not be dressed in keeping with their preferred gender and wishes or fear being buried by their family of origin under their birth name and gender. Engaging in a conversation on living wills, advance care planning, or power of attorney may help avoid or minimize distress and conflict as the person is actively dying and nearing end of life. Such documentation will enable practitioners to give due consideration to the person's wishes, and care preferences should conflict arise. Without this documentation same-sex partners may have limited or no rights, especially if the biological family does not accept the relationship and wishes to exclude the partner (Rawlings 2012).

When it comes to end-of-life care, the research evidence around the needs of LGBT people and their families is sparse; however, in the context of supporting LGBT families, an important aspect is about understanding their differing family structures and relationships. Many LGBT people may

Table 4 LGBT-affirmative practices

Policies and service planning	Service policies make clear statements of inclusiveness of LGBT people and zero tolerance of discriminatory practices by staff and by people who use services Definition of gender within the policies moves beyond the binary division of male and female to include transgender and gender fluid identities Service planning and development informed by research evidence on LGBT issues
Organizational culture	Services display signs that highlight inclusiveness of LGBT people Service and programs (including bereavement services) are developed that address the specific needs of LGBT people All staff act as advocates by challenging heterosexism, homophobia, biphobia, and transphobia within the organization, irrespective of the source
Professional practice and interpersonal communication	Professionals acknowledge the person's sexual orientation and gender identity and promote safe and supportive relationships that are respectful of LGBT identities Care, treatment models, and structural design of services accommodate the realities of the differences between male, female, and transgender people Professionals work within a minority stress framework and recognize the different life experiences of LGBT people, their fears, and challenges in accessing support and being open about LGBT identities Language used is inclusive and affirming of LGBT relationships and reflects the individual's preference and family of choice Documentation and literature are inclusive of LGBT identities and avoids gender stereotyping and heterosexual norms Professionals interrogate their own stereotypes and language and have the confidence to challenge gender stereotyping and language within the team that is exploitative or harmful
Education and research	Professionals are informed and educated on LGBT issues, including LGBT issues as they relate to palliative care A process to address staff attitudes and practices that may be a barrier to LGBT-affirmative care is available Research into LGBT identities and palliative care is ongoing, including the impact of various models of care on outcomes for LGBT people and their families

Adapted from Higgins and Gill (2017)

have experienced rejection when they revealed to parents and siblings their sexual orientation or desire to transition, and consequently, they may be estranged from their biological family or family of origin. As a result of rejection within the biological family, many older LGBT relationships tend to be more friend-based, rather than family-based, and could include current and previous partners, biological or adopted children from relationships, and members of the wider LGBT community. For some LGBT people, the end of life is a time of reconciliation or reunions with estranged family. While some LGBT people may have no desire for a reunion, for others, irrespective of past hurts, reconnecting with, and being accepted by, family continues to be a priority. Practitioners need to be very sensitive and aware of the complex dynamics that such reunions can create, whether they are initiated by the person concerned or by a member of the family that is estranged. Such reunions may magnify the person's feelings of grief and loss, as some families may initiate reconciliation with the person in a way that denies the existence of the same-sex partner/spouse or family of choice (Harding et al. 2012).

8 Sexuality, Sexual Abuse, and Trauma

Sexuality for many is a source of pleasure, comfort, affirmation, connection, and identity; however, for others, sexuality is a site of pain, exploitation, violence, and trauma. Despite

evidence suggesting that sexual abuse (childhood sexual abuse (CSA)/rape/sexual violence (SV)) continues to be a feature of life, with high rates of men and women experiencing some form of sexual abuse in their life, the subject of sexual abuse is relatively nonexistent within the palliative care literature, except for a retrospective review of its prevalence within a palliative care audit (MacPherson 2009) and a paper involving a case study about a woman with a history of CSA and her family (Wygant et al. 2014).

Sexual violence has a lasting impact on a person's emotional, psychological, and social well-being and their quality of life. Evidence suggests that people who have been sexually abused experience low self-esteem, decreased self-worth, shame, stigma, and powerlessness; they have difficulty forming relationships, trusting people in intimate and sexual relationships, and maintaining sexual boundaries. Survivors of abuse frequently develop negative attitudes toward their own sexuality and either avoid all sexual contact or unconsciously enact aspects of early sexual abuse in subsequent sexual relationships. There is also evidence that people who have experienced sexual abuse in childhood are frequently left vulnerable to sexual re-victimization in adulthood. Although SV is both under-reported and under-acknowledged, high rates of sexual trauma have been reported among people who experienced depression, anxiety, self-harm, posttraumatic stress disorder (PTSD), personality disorders, eating disorders, and alcohol problems (Chen et al. 2010). For many these experiences may never have been disclosed because of stigma, self-hatred, shame, self-blame, and a fear that nobody would believe them.

In a paper exploring the intersectionality of terminal illness and unresolved PTSD, Feldman et al. (2014) argue that a diagnosis of a life-limiting illness, such as cancer, and healthcare encounters involving intimate physical examinations can mimic an original trauma, such as CSA. These events can reactivate memories of past CSA or rape, retraumatize the person, or even cause delayed-onset PTSD. As a result, the person may begin to experience hallucination-like flashbacks, intrusive trauma memories, nightmares, difficulty sleeping, dissociation, and hypervigilance with an exaggerated startle response (Feldman et al. 2014). As part of the dying process and preparation for dying, many people conduct life reviews, which may also trigger distress as the person revisits traumatic memories and periods of time.

As the illness advances and the physical body deteriorates, the person's capacity to manage their bodily functions lessens. For people who have experienced sexual trauma, having people violate social norms and conventions around touch, especially around touch of genital areas, can be profoundly distressing for the person, intensifying the suffering associated with the loss of function. In addition, dehumanizing touch and physical contact that treats the person as an "object" of care may trigger intense emotions, such as anger, panic, suspicion, and distrust of authority figures, or lead to the person withdrawing emotionally. Not only does this add to the person's psychological and existential distress, but it can lead to difficult, confrontational, or resistant styles of communication with the MDT team. Practitioners may also experience strong emotional reactions that may hamper the development of a therapeutic relationship, such as anger at the person's behavior or guilt over feeling responsible for the distress. If practitioners do not understand that the behaviors and emotions they are seeing in the patient are protective mechanisms, there is the potential that they label the person as uncooperative or aggressive and respond by avoiding or minimizing contact, thus creating a vicious cycle of avoidance and escalating hostility (Feldman et al. 2014).

While retraumatization can be unintentional, in a trauma-informed palliative care service, all staff (clinical and nonclinical) are mindful of the prevalence of sexual trauma in society and sensitive to the need to constantly work with the person's agenda, promote maximum control over decisions, and have a heightened sensitivity to the potential impact of procedures and touch on the person. They are also mindful of how the gender of the practitioner, power differentials within the relationship, and infantilizing interactions can impact the person.

The recall of sexual abuse can have a significant impact on the person, exacerbate physical symptoms, including pain, overwhelm them with distress close to the end of life, and have a negative impact on the quality of their death. While it is important to acknowledge and validate the significance of the abuse, and create a safe and non-judgmental space where the person feels safe to discuss their experience, both the person's wishes and the stage of the dying process will strongly influence the focus of care. For some people the time available is so limited that to engage in long-term therapeutic interventions is not possible; therefore, the focus of the care is on reducing the person's distress, containing emotions, and creating an environment where they feel safe, validated, and supported. Exploring with the person what coping strategies they found useful in the past may help them to identify their self-comforting skills and reactivate their strengths.

The family context and dynamics can also be highly challenging for practitioners for the following reasons: the abuser may have come from within the family circle or close family network; more than one family member may have been the victim of abuse; the person may have withdrawn from the family as a protective mechanism; the person may not have revealed their sexual abuse experience to the family and may not wish to do so; or the person may have revealed the abuse and was not believed. Therefore, responding to the needs of the person who has experienced sexual trauma whether in childhood or as an adult and the needs of the family requires a multidisciplinary approach, with input from clinicians who have had prior experience of working with trauma survivors and their families.

9 Sexuality and Sexual Disinhibition

Another aspect of sexuality and sexual behavior that has received limited attention in the palliative care literature is the area of sexual disinhibition. Yet it has the potential to cause immense distress to the person and disrupt relationships between the person, and partner, family, and the MDT. Sexualized behaviors and sexual disinhibition may also cause a conflict between the practitioner's ethical and legal responsibilities., Hindering sexual expression may be seen as a violation of the patient's autonomy, whereas failure to prevent sexual disinhibition or sexually inappropriate behaviors can place the patient and others at risk of mental and physical trauma.

As stated earlier in the chapter, the expression of sexuality involves complex brain functions that are influenced and mediated by psychological, cultural, and environmental factors. Altered sexual expression, in the form of sexual disinhibition, can result from damage to certain areas of the brain. Four brain areas or systems are thought to be implicated in the neurobiology of sexually disinhibited behavior, namely: the frontal lobes, the temporal limbic system, the striatum, and the hypothalamus. The frontal lobe of the brain is thought to be important for judgment, impulse control, and the regulation of insight and feedback regarding socially appropriate behaviors, including what might be called "sexual manners" (Higgins et al. 2004). Tumors of the frontal lobes are thought to remove the moral-ethical restraints that control our behavior resulting in decreased impulse inhibition. This may lead to indiscriminate sexual behavior, such as improper sexual remarks or gestures, and other sexual behaviors that may be considered "antisocial" or "inappropriate" to the time, person, or location, such as masturbation in public.

Similarly, dementia, although typically associated with sexual apathy, decline in sexual interest, and the loss of sexual relationships, may be accompanied by sexual disinhibition or "hypersexuality," with studies estimating that between 7 and 25% of patients with dementia exhibit some type of "inappropriate sexual behavior" (Higgins et al. 2004). Black et al. (2005, 156) divide sexually inappropriate behavior in dementia into three groups:

- Sex talk: this is the most common form and involves making sexually suggestive remarks or using foul sexual language that is not in keeping with the patient's premorbid personality.

- Sexual acts: these include acts of touching or grabbing the breasts, buttocks, and genitals of others, exposing genital areas, or masturbating in public areas.
- Implied sexual acts: these include openly reading pornographic material or requesting unnecessary genital care.

Addressing sexual disinhibition requires a team approach where there is an openness to acknowledge the distress and challenges for all concerned, including the person and family members. Exploring and understanding the reasons for, and all possible precursors to, the behavior is the first step in developing a person-centered plan that upholds the dignity and rights of all involved. This includes a systematic assessment of the person's cognitive/health status, their previous personality and sexual behavior, and their response to stress and the environment, including the behavior of staff and other people which might have influenced the person's behavior. Usually the sexual behavior is not confined to one particular relationship and is directed to a number of people. Behavior of people with cognitive impairment may be misconstrued as sexual when in fact it may have an entirely different meaning or purpose. The behavior may be a result of disruption to the neural pathways related to sex drive or may be due to cognitive impairment, where the person has forgotten sexual manners or has confused a person with a much loved partner. Therefore it may be a case of mistaken identity or misinterpretation of environmental cues. In other situations, the behavior may be simply the need for human contact and is the "acting out" of a strong need for intimacy and touch that has been sexualized. Practitioners, therefore, need to be guided by the principle that all human behavior is a form of communication and purposeful; thus key questions to consider is what is the purpose of the behavior and what is the person trying to communicate?

The typical educational, counseling, and behavioral approaches taken to solving these problems with people who do not have a cognitive impairment are not very useful when caring for people who have a continued deterioration in memory and learning ability. In many situations, what is required is a "low-key" approach toward reorientation and limit-setting that takes account of the person's need for human connection (Higgins et al. 2004). Within the literature the pharmacological model of treatment is sometimes advocated, when all possible environmental and psychological causes are assessed and treated. Although recommended, the lack of empirical evidence to support the effectiveness of drugs for sexual disinhibition, coupled with the side-effect profiles, poses professional and ethical challenges for practitioners.

Displays of sexual disinhibition can be very distressing for family members, who do not understand the reason for the behavior and may feel stigmatized, ashamed, and angry or may fear that their relative will be victimized or isolated by practitioners. Family members may also be concerned about the involvement of social or child protection services should the person have contact with children and young people. In an effort to protect the person, especially if they are being cared for at home, family members may restrict people visiting or confine the person to the house, thus isolating the person further (Black et al. 2005). Therefore, family members will need time and space to discuss their concerns, fears, and distress. They will also need education on the possible reasons for the behavior as well as reassurance that staff have seen similar behaviors before and are there to help and support. Involving family members in discussion and inviting them to participate with staff in problem solving are an effective way to build constructive and supportive relationships. This is especially important for partners/spouses who may be too embarrassed to tell practitioners that they are experiencing increasing demands for sex from the person with the cognitive impairment. Without practitioners creating a safe accepting space, and sensitively enquiring about relationships and relationship changes, partners/spouses may be left to cope alone, and feel sexual compliance is their spousal duty or fear that refusing may provoke anger or distress in the person.

10 Disenfranchised Grief and Loss of a Sexual Partner

The loss of a loved one through death is a universal human experience and is considered to be one of the most stressful life events that a human being can encounter. Although the experience of loss is universal, the experience of grief can vary enormously depending on the relationship with the deceased. The literature on grief is rich with information on how to navigate the intense emotional distress following the death of a spouse or partner; however, within this literature there is little reference to what Radosh and Simkin (2016) refer to as "sexual bereavement," the grief as a result of the loss of a sexual relationship. Published narratives and self-help books about the death of a spouse also reinforce this silence as they also fail to mention "sexual bereavement." One exception is Susan Wallbank's (2010) book "*The Empty Bed: Bereavement and the Loss of Love*," which breaks the conspiracy of silence and addresses, with sensitivity and insight, the distress of the loss of a partner with whom to sleep and make love and to physically hold. Within this book Wallbank recounts the stories of the pain of the bereaved person waking to the reality of their loss following vivid dreams of making love to their partner, the distress of being confronted with decisions around ceasing to continue with oral contraception or removing an intrauterine device, and the guilt and shame felt when the bereaved person experiences sexual feelings and desire for a sexual relationship. Despite this, there appears to be a lack of acknowledgment of the grief associated with the loss of a sexual partner by bereavement counselors, with participants in Radosh and Simkin's (2016) study reporting being too embarrassed to share this aspect of their grief experience with professionals. Consequently, practitioners, including bereavement counselors, need to create a context where this aspect of people's grief is spoken about, acknowledged, and validated.

The degree of distress and disenfranchised grief experienced by the person can be further increased if the person is in a same-sex relationship. Bereaved LGBT partners may be particularly vulnerable at this time, as research indicated that many LGBT people experience the pain of "silent mourning," often being deprived of the rituals of "communal sorrow" and other social/psychological supports that are present for heterosexual people. Although Bristowe et al.'s (2016) systematic review found that some LGBT people who had lost a partner were well supported by practitioners, others were not. Those who were in relationships that were not openly acknowledged or "hidden" from family, friends, work colleagues and practitioners were often left to cope and grieve alone. The fragility of biological family relationships or being estranged from the family of origin often meant that traditional sources of support and comfort were absent for some people. In some cases people's grief was exacerbated when they experienced overt exclusion by their partner's family or attended a bereavement support group where they experienced negative attitudes from people within the group.

As with any minority population, there is a need for sensitivity to the social and historical context of the lives of people who identify as LGBT when providing bereavement support. While, in many countries, legal changes have resulted in greater acknowledgment of same-sex relationships, practitioners, however, need to be mindful that many older people lived through a time when their identities were highly stigmatized or indeed illegal, and past experiences may inform their willingness to be open with practitioners. Consequently, practitioners need to be sensitive to the depth and nature of relationships, be mindful of the impact of a heteronormative culture on their assumptions about relationships, and ensure that literature on same-sex grief is openly available to people who use the service. In addition, for those who are out about their relationships, practitioners need to acknowledge the significance of the person's loss, not just as a friend but as a partner and lover, and demonstrate a willingness to develop the communicative space necessary to talk about their loss as well as providing appropriate bereavement support services. For some people this may mean a preference for attending a gay or lesbian bereavement counselor or attending services provided by gay and lesbian support groups.

11 Conclusion

Sexuality is an integral part of being human and being alive to the self that finds expression through body, mind, and spirit. Although sexuality is as unique to the person as their fingerprint, it is intimately bound up with the person's sense of identity, as well as their sense of self within relationships. Regardless of gender or sexual orientation, a life-limiting illness transforms every aspect of the person's life, including sexuality. Life-limiting illnesses can impact on sexuality in a manner that is all pervasive, permeating physical, psychological, relational, and existential dimensions of personhood.

For many people their expression of sexuality is so central to their life and is such a positive force that intimacy and sexual expression can preserve a sense of wholeness and "living well" in the face or shadow of death. For those within a couple relationship, the expression of sexuality can also embody emotional connection and comfort that is beyond language and penetrates the deepest part of their being. However, like a double-edged sword, for others sexuality it is a source of distress and loneliness. This distress may be connected to the loss of intimacy, relationships, and sexual contact that threatens the person sense of wholeness as they face the dying process. At the same time, painful experiences from the past and old traumas that have long been buried may reemerge. Unless the individual practitioner is mindful of sexuality and its complexity, and how the person's fears, embarrassment or self-stigma may impact on their willingness to discuss sexuality issues; "total pain" and suffering may be exacerbated. At the same time, without attention to their own value, judgments, and approach to care, they may desexualize and dehumanize the person adding to the distress experienced.

As person-centeredness or whole person care and "total pain/suffering" remains a defining characteristic that distinguishes palliative care from other care provided to patients in hospital, practitioners need to recognize the shared humanity that exists between themselves and the person, and connect with the person, not as a "patient" who is fighting for survival, but a living breathing sexual human being with a past, present, and future. By incorporating sexuality with the horizon of practice and opening an authentic communicative space that acknowledges the diversity of sexual expression, practitioners not only create an opportunity for the person to make sense of their distress and find meaning in their experience, but they also create opportunities for sexuality and sexual expression to be celebrate as a source of joy and affirmation in the living and dying process.

Abstract

A family-focused care approach in palliative care recognizes the fundamental role of families in contributing to the care of people with life-limiting conditions. It is essential that healthcare providers develop understanding of families' needs and the skills to collaborate effectively with families caring for people at the end of their lives. This chapter introduces the concept and components of family-focused palliative care. It continues with a discussion of what patients and families perceive to be the most important aspects of end-of-life care. This chapter provides information to assist healthcare providers who work with people with life-limiting conditions and their families in providing family-focused care and to identify gaps and challenges to providing such care.

1 Introduction

The increasing reliance on informal family caregivers ("carers") in today's healthcare environment mandates families to be actively involved in patient care and advocate for best practice. The Institute for Patient- and Family-Centered Care defines family-centered care as an approach to planning, delivering, and evaluating healthcare in the context of mutually beneficial partnerships among healthcare providers, patients, and families. It emphasizes collaboration with families who define their own membership and roles in care and decision-making (Johnson et al. 2008). The aim of this chapter is to increase palliative care healthcare providers' awareness of the needs of families to optimize their current and future well-being, including their bereavement outcomes.

After reading this chapter, you will be able to:

- Describe the components of family-focused care
- Discuss patient and family priorities for end-of-life care
- Identify opportunities to strengthen the provision of family-focused palliative care

2 Defining Family

The family is the basic unit of care, yet it comes in all shapes and sizes, compositions, and origins. Contemporary connotations of family extend beyond just people related to one another by blood or marriage. Divorce, same-sex partners, cohabitation, and

workforce globalization have ushered in a new era of family configurations that have superseded traditional nuclear family structures comprised of a husband, wife, and one or more children. Single parent families are increasing, and many children live with a stepparent or grandparent(s) at some point in their lives. In addition to traditionally termed extended family, close friends, companions, and others may all be considered to part of an individual's family. Family members may live in close proximity or at great geographic distances from one another, and as a result of changing work and previous life events, an increasing number of older people live alone. Global mobility and changing demographics mean that many family members may not be physically available to provide care and support in the context of a life-limiting illness and may have limited contact with one another. In this situation, neighbors and friends or distant relatives often step in to fill this void. As a result, who and what constitutes "family" has been evolving. While, some people continue to define family as the group of people they were born into (family of origin), others will define family as the group of close friends chosen to surround themselves with (family of choice) (Lawton et al. 2014). In this chapter, "family" is defined as whomever the patient describes or considers to be family (Torenholt et al. 2014) and/or who they identify as important and who influences their care and well-being (Wright 2007).

3 Family's Needs Throughout the Care Trajectory and Across Life Stages

The World Health Organisation (2018) has long championed the importance of assessing and addressing families' palliative care needs, as reflected in their current definition. This definition centers palliative care on providing relief from pain and distress, normalizing the dying process, providing holistic support using a team approach, and facilitating good quality of life and coping at all stages of the illness for the patient and their family (World Health Organisation 2018). By positioning families alongside patients, this definition highlights the needs of families as recipients of care, particularly in the provision of adjusting, coping, and bereavement support.

A progressive life-limiting illness diagnosis is a life-changing experience, for not only patients but also their families. This type of diagnosis is associated with significant physical, emotional, and social support needs as well as access to timely clinical support and information. Most patients will call upon various family members, often a partner/spouse, to assist them with their decision-making in relationship to treatment preferences, advance care planning, and legal and financial issues. The quality of life of patients with palliative care needs and their families depends on various factors that can change over the course of the illness. These fluctuating needs often occur during the transitions from curative to comfort care as the disease progresses. With each transition, families will have different information needs, and if they are active carers, their contributions to various activities of daily living is likely to increase as the patient's disease progresses, and they become less able to maintain their activity. The care and support that families require may differ according to their varied life stages and relationship to the patient. In some cases, patients are also carers for offspring, siblings, or older parents, which have implications for the family as the patients' own care needs increase. There are also some different implications for the individual and their family depending on whether the patient or carer is of working age (under 65 years old), has young children and/or teenagers, or is post-working age (over 65 years) and living with in-house or more distant family support.

3.1 Diagnosis Affects Families' Needs

Both malignant and nonmalignant diseases pose significant burden at the end of life. Some diseases, especially neurodegenerative conditions and/or primary or metastatic brain cancer, often cause more physical impairment and cognitive/personality changes. These devastating personality changes and disability also affect carers' capacity to manage (Pace et al. 2009; Arber et al. 2010; Gofton et al. 2012) and indicate significant support needs for carers.

Age can play a role in determining the type and level of needs of both patients and their families. For example, younger patients (≤70 years) generally have higher levels of overall unmet needs (McIllmurray et al. 2001), yet middle-aged patients (31–60 years) consistently display greater unmet needs than those age 70 years or older (Sanson-Fisher et al. 2000). These different needs have been attributed to cancer and its treatment having more of a psychosocial impact on younger people and the increased acceptability of younger people disclosing needs as compared to older patients (Sanson-Fisher et al. 2000).

3.2 Needs of Younger Working Age Families

Faced with a premature death during working age (ages 24–65 years) has its own inherent challenges related to life-stage commitments such as family, work, and financial responsibilities. A life-limiting illness has a profound impact on the family life of patients, their partners, and children. Family dynamics are often changed and normal life interrupted, which can be particularly burdensome for any dependent children, as their reality and day-to-day life often changes as the illness of their parent progresses. Families of working age patients have a range of needs at different time points across the illness trajectory (Kochovska et al. 2017), including:

Supportive care needs, which vary according to disease (malignant or nonmalignant) but typically for working-aged families, include assistance to effectively manage the patient's pain and other symptoms and dealing with feelings of loss (anticipatory grief), uncertainty, and fear of the patient and/or children suffering (Kochovska et al. 2017). The partner of working-aged person facing a premature death often have increased input into clinical, household, and financial decision-making and difficulty juggling multiple roles such as parenting, household duties, and family finances. This is all in addition to navigating the healthcare system, transporting the patient to/from hospital and/or appointments, maintaining family schedules, and minimizing the impact on other family members.

Information needs, for families are also significant and include diagnostic and disease information, financial and legal information, as well as end-of-life and spirituality information (Kochovska et al. 2017). This information is required at different stages in the illness trajectory, and healthcare providers should be both aware and prepared to meet families' specific information needs in a timely manner. *Disease and prognosis information* is most often sought at the initiation of treatment and transition from curative to palliative care but least wanted as death approaches. *Financial and legal information* from the time of diagnosis can help to manage anticipated reduced employment capacity for both the patient and carer. Financial advice is least wanted when completing treatment and when returning home from hospital. The need for financial/legal information related to death notification requirements and funerals is greatest immediately after the patient's death. *End-of-life and spirituality information* is most desired during a final hospital or hospice admission and least desired at the commencement of treatment.

Carers needs are significant, as most will need access to support services (such as respite and day care) and practical support (e.g., picking up children, preparing a meal, and other household tasks), especially in rural and remote areas (Kochovska et al. 2017). Balancing these competing demands while trying to maintain normality (especially when children are involved) is challenging, particularly for employed carers and/or those with young children.

Anticipatory grief and bereavement needs are experienced by patients, partners/spouses, and their children at various junctures and require an individualized and empathetic response that recognizes grief as normal but provides timely access to professional help for the minority who need it. Spending quality time with the deteriorating and/or dying person is important and can positively influence bereavement outcomes (Kochovska et al. 2017).

3.3 Maintaining Normality and Balancing Multiple Roles

For both the parent living with the terminal illness and their partner/spouse, maintaining normality is of paramount importance, as it acts as a coping mechanism that limits the adverse effects of the parent's illness on their children. Maintaining this delicate balance is challenging, and most families need practical advice about how best to describe in simple terms the patient's diagnosis, prognosis, and impending death; cope with their partner's/spouse's deterioration; and access practical help and resources, so as to minimize the impact on their children (Kochovska et al. 2017).

The interruption of family dynamics and the need to be able to maintain children's normal routines while managing escalating care demands is a frightening and stressful experience for many families (Kochovska et al. 2017). This is primarily because it requires the healthy parent to assume new roles within the family, deal with uncertainty and feelings of loneliness, balance everyone's needs (including the children, the patient, and themselves), and support their children. Access to specialist palliative care can mitigate many of these challenges and contribute to positive short-term and long-term effects, especially for carers of cancer patients (Kochovska et al. 2017).

Although dealing with a life-limiting illness is a demanding and stressful experience for everyone, there are some positive aspects for both parents with terminal illness and their children, which include strengthening the relationship and shifting perspectives on valuing the family and the important things in life (Kochovska et al. 2017). It is particularly important that children and dying parents remain connected during the terminal illness, and clinical care and support should be tailored to facilitate that (Kochovska et al. 2017).

3.4 Balancing Being Honest with Children, but Not Overburdening Them

Children of parents diagnosed with advanced cancer and/or who are dying need access to timely, age-appropriate information about their parents' disease that is sensitively communicated by people they trust both within and outside of the family (Kochovska et al. 2017). Children with parents living with a life-limiting illness (e.g., advanced cancer) display significant distress but also remarkable awareness and understanding of their parent's illness. While children of dying parents need support, they should not be protected from the truth of the situation, but rather, given accurate information as sensitively as possible (Kochovska et al. 2017).

Adopting a transparent approach helped children to make sense of their parent's impending death in their own way and grow through the experience. They also need an opportunity to spend quality time alone with their parent. While some children may welcome the opportunity to help care for a dying parent, they also need to have opportunities to engage in "normal" activities outside of their caring role both with their family and in contexts where they can temporarily "forget" their home situation (Kochovska et al. 2017).

Where children bear a significant caring responsibility, this may require respite care for the dying parent while the child takes a break. Similarly, adolescents and young adults are often required to assume more household responsibilities and have decreased social activity outside the home (Beale et al. 2004; Kennedy and Lloyd-Williams 2009) which can contribute to increased stress (Huizinga et al. 2003). Older children often take on more practical responsibilities, including picking up their younger siblings from school (Phillips and Lewis 2015). Adolescents also report feeling alone and alienated as family priorities shift and family roles are renegotiated within the family unit (Phillips 2015) and rely on routines to maintain a semblance of normality (Dehlin and Reg 2009). For adolescents, self-management and managing emotions through talking, thinking positively, and creating distractions and social support are also important (Phillips and Lewis 2015). Most adolescents try to maintain a positive attitude and facilitate communication within the family (Phillips and Lewis 2015), viewing the experience as

something that helps them mature and change their way of thinking about life, and reassess their values and relationship with other people (Dehlin and Reg 2009).

There are a growing number of adolescent and young adult carers, so considering their needs is crucial as they often have significantly poor quality of physical health (Hanly et al. 2015) and could be considered to be doubly disadvantaged because their carer role impacts on their educational opportunities and future earning capacity. Australian statistics show that the premature death of a parent can have a detrimental effect on the future wealth and employment of their children as adults (Australian Bureau of Statistics 2010).

4 Defining Family-Focused Care

A family-focused care approach recognizes the fundamental role of families and includes the following core concepts, namely, dignity and respect, information sharing, participation, and collaboration (Johnson et al. 2008). This method of care delivery supports the family in their carer roles and includes them in treatment decision-making. It positions the family as key members of the care team and privileges collaboration as a vehicle that increases trust and promotes more open communication between patients, families, and healthcare providers. When individuals perceive open communication, they are more likely to perceive fair processes, cope, and feel less frustration and confusion. Through collaboration, care provided to patients and families can be tailored to their individual needs, thereby demonstrating recognition of the uniqueness of each patient and family. Furthermore, the family is a valuable source of support for a patient and information on behavior and coping strategies of the individual (Bamm and Rosenbaum 2008). Preferences for communication, degree of involvement in caregiving activities, information provision and education, visiting, and counseling inform the way in which the family is supported and cared for by the palliative care team (Wright 2007).

5 The Most Important Elements of End-of-Life Care from the Family Perspective

Recent work undertaken by Virdun and colleagues (2015, 2017) synthesized 24 studies that described self-reported needs of palliative care patients and families in relation to end-of-life care in the hospital setting, with nearly all of these studies ($n = 21$) including a focus on family participants. This work included a systematic review of the quantitative studies, which included 3117 family members (Virdun et al. 2015) and a meta-synthesis of qualitative studies which examined 278 interview quotes from participating family members ($n = 672$) detailing what families considered the most important aspects of end-of-life care in hospital (Virdun et al. 2017). The 11 resultant themes of these studies structure the remaining sections of this chapter.

5.1 Expert Care (Good Physical Care, Symptom Management, and Integrated Care)

Family-focused care for the domain of expert care centers around concepts of excellent nursing care, excellent symptom assessment and management, holistic care delivered from a multidisciplinary team integrated in their care planning and delivery, and the need for healthcare providers to be knowledgeable about the patient they are caring for. While patients perceived many of these aspects of care provision as highly important for optimal end-of-life care, families specifically noted the importance of the following key aspects of care provision to enable quality end-of-life care:

- Careful attention to the personal hygiene and care needs of the patient both when family are and are not present in the hospital
- Excellence in core nursing as well as the ability to manage specialist patient requirements (e.g., colostomy care)
- Ensuring rapid and comprehensive assessment and management of symptoms with a particular

focus on staff prioritizing the patient's description of their symptoms
- The specific need to manage pain and agitation well
- Multidisciplinary care to support the patient physically, emotionally, and/or spiritually
- Integrated care inclusive of effective discharge planning and ensuring the patient could die in their location of choice
- That healthcare providers were knowledgeable about the specific condition of the patient and that it was clear who was in charge of care (Virdun et al. 2015, 2017)

5.2 Effective Communication and Shared Decision-Making

Family-focused care requires healthcare providers to have effective communication skills to be able to engage multiple members in different aspects of care. The ability to interview or converse with family members together is important to understanding interactions between family members (Denham 2016). Healthcare providers must ensure families understand the medical issues and clarify any technical language used. Plain language materials and providing opportunities for discussion and questions are recommended to address health literacy needs (Wittenberg et al. 2017). Effective communication is necessary to ensure that the patient, family, and healthcare providers have a shared understanding, which is dependent upon the compassionate delivery of understandable and honest information (Virdun et al. 2015, 2017). Being provided with the necessary information is important for families involved in end-of-life decision-making, because they want to understand the medical complexity and the emotional and financial implications of any decisions and be provided with sufficient and timely information to make the decisions that best reflect the patient's preferences (Virdun et al. 2015, 2017). Being actively involved in day-to-day care planning and having regular planned discussions with the healthcare team, including discussions with physicians, are considered by families to be essential for effective communication and shared decision-making (Virdun et al. 2015, 2017).

Families are equally responsible to provide accurate information to healthcare providers including medical and treatment history, patient preferences, and subtle changes in the patient that the provider may not see. Families, likewise, have an important and active role within the healthcare team as they have experience, insights, and knowledge about the patient that can contribute to their overall health and well-being (Johnson et al. 2008). Further, the family, as the unit of care, provides information about group values, supportive interactions, decision-making, relationships, caregiving, and health habits.

The delivery, content, and timing of end-of-life prognostic communication has a significant impact on the quality of life of spousal carers of patients with palliative care needs who have dependent children (Park et al. 2015). Families' preferences for honest and clear information communicated using nonprofessional language and with compassion help to foster a shared understanding of the clinical situation. The provision of adequate information throughout the admission helps support decision-making, decreases the families stress, and minimize surprises (Virdun et al. 2015, 2017).

An important outcome of family-focused care is patient and family coping, which can be facilitated by incorporating elements of family-focused care in practice (Wright 2007), such as:

- **Information Sharing**. The healthcare team communicate comprehensive, accurate, and balanced information for families in a timely, affirming, and useful manner to enable effective participation in both care planning and care provision.
- **Collaboration**. Valued collaboration with families in relation to policy and program design, implementation, and evaluation, the design of health facilities, and professional education and planning and delivery of care.
- **Participation**. Valued and supported participation in care planning and provision, inclusive of decision-making, to the level of the family member's choosing.

DiGiacomo et al. (2013) reported an example of how communication gaps can lead to protracted grief in a qualitative study of recently widowed older women. In the following excerpt, one woman described missed opportunities for healthcare providers to communicate with her regarding her husband's prognosis (refer Box 1). This is further confirmed by data reported by Virdun et al. (2015) where families noted the importance of being able to receive straightforward information about tests, treatments, and prognoses, as well as stating that being sheltered from honest information did not contribute to quality end-of-life care.

Box 1: Unintended Consequence of Ineffective Communication: Julie's Story

Family carer quote:

I definitely would have liked a realistic view. If somebody had said to me, "Julie, the end is nigh," you know? Nobody ever said that. The only thing was the young doctor and only about 3 weeks before he (my husband) died; he (the doctor) was in the room and he was always so lovely, and he said to me, "Julie, have you ever heard of sepsis?" And I said, "Yes, I have." End of conversation. Maybe if I'd answered no, he might have expanded. I remember thinking, "He hasn't got sepsis," but thinking, "Why did he ask me that question?" I thought about that as I drove home that night. I thought, did he know something more than I knew? Maybe I should have followed up on it. At that stage of an illness, I was waiting for them to give me information, not to have to solicit it. That's what I was waiting for. I actually really did think, why wasn't I given more information? All these doctors were coming around and nursing staff, but nobody was telling me anything. To go through the same thing again, I'd be asking a lot, lot more questions. I think I was a bit reticent to ask. I'd keep thinking, they'll tell me if there's something that I should know. I would have liked somebody to have come to me who knew the situation wasn't going to be good and sort of alerting me to what I was going to face. I think that would have been helpful to me...

I was coloured by what happened. I thought, what if I'd said more? I don't know in my case whether it would have altered the outcome, but I think I could have made things a little bit better for him. (Julie, age 71, wife and carer of patient who had cancer and died 12 months prior to interview)

Commentary: These excerpts reflect the interactions and the inner dialogue Julie experienced during her husband's final days in the hospital. Although her carer role had partially acclimated her to her husband's condition, she did not have enough knowledge to understand his illness trajectory. Julie was left ruminating over the experience after her husband's death with feelings of guilt and anger that culminated in a formal complaint to the health service. She had an expectation that information would be provided without necessarily having to seek it out. She wondered whether emphasizing her lack of understanding would have facilitated more and better information provision. This excerpt from an interview with a bereaved spouse depicts an example of the damage inflicted on family caregivers when they perceive that their loved ones have not received adequate care. Self-blame and sorrow for her husband's experience persisted.

5.3 Respectful and Compassionate Care

Families have identified that respectful, compassionate care that preserves the patient's dignity

and supports both the patient and family is vital. Family-focused care enables a welcoming environment where healthcare providers deliver tailored care for the unique needs of each patient and their family unit. Families desire helpful, empathic, affectionate, appreciative, comforting, gentle, considerate, and capable staff. They also spoke of the fact they want to be able to have physical contact with their loved one. Finally, individualized care provision is hugely important in enabling quality care with families noting the need for patients to remain a person and not become a number or illness within the healthcare system (Virdun et al. 2015, 2017).

5.4 Trust and Confidence in Healthcare Providers

Families consistently ranked trust and confidence in their healthcare providers as highly important. Therefore, family-focused care needs to explicitly focus on developing trust and confidence for both patients and families with their treating team. An explicit focus on the principles of person-centered care provision will support this aspect of care (McCormack and McCance 2016) (refer to ► Chap. 33, "Nursing and Palliative Care").

5.5 Adequate Environmental and Organizational Characteristics

Family-focused care respects the integral role of the family in care provision for patients with end-of-life care needs. In doing so, care providers should ensure hospital rules and processes both make sense and support optimal patient care. For example, families have described being asked to move their car while they were visibly distressed, patients not being given symptom relief while waiting formal admission, and visiting hour restrictions for dying patients (Virdun et al. 2017). Families also note the importance of privacy, cleanliness, and quiet within the care environment. Indeed, families noted that lack of privacy led them to feel disconnected from their loved one, unable to talk openly, and like they were simply observing. Family-focused end-of-life care ought to ensure these environmental and organizational characteristics are explicitly reviewed for each patient's care to identify which family members may require alterations to usual care practices. For example, alterations may include changed visiting hour allowances, quarantined time for privacy where staff do not disturb the patient/family member, and innovative thinking for enabling privacy in open-plan environments such as the intensive care unit. Finally, a family-focused care environment will also consider the availability of space to support cultural practices such as congregating family, chanting, or other rituals.

5.6 Recognizing and Supporting the Family Role in Care Including Valuing Their Expert Knowledge of the Patient and Advocating for Patient Needs

Families have outlined the importance of being recognized and respected as having expertise in the care of their loved one. It is essential that healthcare providers understand and respect that many families have been providing expert care to their dying family member long before palliative care is involved, so we need to draw upon their expertise and include them as authentic partners in care. Valuing and honoring families' contribution to care would ensure families were included as equal partners in care planning and provision and would enable their role as patient advocates to succeed. Failing to do this leads to family's feeling they are simply being an observer to care and their contribution is not valued. This challenges healthcare providers to consider approaches to communication and care both within usual care and also at times where care may be distressing with some data showing that removal of family members at times of distress may cause long-term harm into bereavement (Virdun et al. 2015, 2017).

5.7 Financial Affairs

Ensuring that the patients'/families' financial needs are identified and addressed in a timely manner is an often overlooked element of care. Families desire and need healthcare providers to proactively provide them with information about available financial supports, which helps to enhance comfort and decrease stress. They also want healthcare providers to create opportunities for financial issue discussions, at all stages of the patient's illness trajectory, not just during the final days of life (Kochovska et al. 2017). Taking the lead to initiate these conversations is important, as many patients avoid starting these conversations during the early stages of the illness, as they focus on understanding their diagnosis, treatment, and planning their recovery.

For most working-aged patients, an advanced cancer diagnosis is associated with loss of employment and/or their working partner/spouse also having to reduce their working hours. Studies consistently reveal few patients diagnosed with advanced cancer return to work after active treatment and consequently experience significant economic disadvantages, especially in the absence of universal healthcare or health insurance coverage (Kochovska et al. 2017). Cancer-related financial burden has adverse psychological consequences for both patients and their families, increasing the risk of depression, anxiety, and distress (Kochovska et al. 2017). Healthcare costs and out-of-pocket expenses add to financial stress, sometimes forcing families to reduce their discretionary spending and often affecting their medical treatment (Kochovska et al. 2017).

Taking on a caring role adversely impacts employment with many carers having to reduce their work hours and/or having to stop work. In working-aged families, the spouses/partners are often also caring for an aging parent and/or a young family. In this situation, taking on an additional carer role often impacts adversely on child care costs (Kochovska et al. 2017). Patient care cost and limited access to financial assistance are additional concerns of Australian carers, while unexpected costs, bereavement costs, and legal expenses also contribute to the financial burden (Kochovska et al. 2017). As well as imposing a significant financial strain (Gott et al. 2015), a carer role is associated with significant negative impact on quality of life (Williams et al. 2014). Younger patients and those with larger families are at greater risk of financial burden, while those without income seem to have significantly lower quality of physical health (Hanly et al. 2015).

5.8 Maintenance of Patient Safety and Prevention of Harm

Families identified the need for optimal end-of-life care to prevent harm and a feeling of being unsafe within a clinical environment. Aspects of care perceived to lead to a lack of safety included poor communication, lack of person-centered care, lack of identification of unique needs of people at the end-of-life, poor nursing care, lack of timely attention, and families feeling unsure of how to be involved in their loved one's care (Virdun et al. 2017). A recent study articulates that concepts of patient safety for those who are dying, and their family members, continue to focus on correct treatment, timely interventions, and appropriate infection control, just as would be the case for any patient, and therefore, careful attention to this is important for all patients (Collier et al. 2015). However, this same study asserts that patients with palliative care needs and their families also define patient safety quite broadly, inclusive of approaches to care, interpersonal communication, and the sociocultural context of care. Therefore, consideration of patients at the end-of-life and their families within usual patient safety parameters is required (as this patient population is not routinely considered within this forum) as well as consideration of broader contexts of safety, as articulated above. Finally, family-focused care also works to enable support and a feeling of safety for family carers to speak up without repercussions, as required (Virdun et al. 2015, 2017; Kochovska et al. 2017).

5.9 Preparation for Death

Family-focused care ought to ensure optimal communication and, in doing so, ensure families are aware of and prepared for a patient's imminent death so as they are able to say goodbye and assist their bereavement outcomes. Honest communication, delivered compassionately, is imperative as several family members described not understanding the extent of their loved one's illness or that they were imminently dying (Virdun et al. 2017). As healthcare providers, we need to ensure such conversations have been held and understood by families and to plan for and/or facilitate their support throughout this time.

5.10 Duty of Care Extending to the Family After Patient Death

Families have described their need for follow-up after a family member's death so as to avoid their feeling disconnected and rushed away from the hospital at such an important time (Virdun et al. 2017). If the healthcare provider team truly partner with family members in care provision, then it stands to reason that the duty of care would extent to them, following the patient's death. Systems and processes may hinder this aspect of care, and therefore, needs should be considered within a policy and quality improvement framework.

While the majority of palliative care services focus on contacting the decedents' family, usually their documented next of kin, this approach may fail to identify informal caregivers, who, despite their intensive caregiving role are not listed as the patient's next of kin because their relationship falls outside of these parameters. Given the complexities and nuances of modern relationships, an important area of inquiry is to develop the evidence base for palliative care services to systematically determine more broadly the patients' kinship network (Phillips et al. 2018).

Grief is a normal response to loss during a period of bereavement. Spousal bereavement has been associated with increased mortality and longer hospital stays and negative effects on employment (Stephen et al. 2015). Psychological or social support (e.g., talking to family members and friends during the grieving process) and practical support (e.g., with funeral arrangements, legal and financial help) are commonly identified needs of bereaved persons (Stephen et al. 2015). When the bereaved prefers to speak to others or when family networks are dysfunctional, help is sought from professionals closer to the time of death and shortly after (Benkel et al. 2009). Children and teenagers who experienced the death of a parent to cancer have a range of psychosocial anticipatory grief and bereavement needs (Macpherson and Emeleus 2007a, b). These include maintaining contact with the dying parent; being prepared for their death; holding on to meaningful memories; maintaining privacy, normality, and continuity in family and school life; escaping the intensity and stressfulness of the home situation; being understood and supported by others; and better understanding death (Macpherson and Emeleus 2007a, b). Children and teenagers desire support and understanding from others to help them cope with feelings of grief, anger, and depression and need access to information and opportunities to talk with others who have had a similar experience (Patterson and Rangganadhan 2010).

Although grief is a normal response to loss, a subset of bereaved individuals may experience "persistent complex bereavement disorder." It affects approximately 10–20% of bereaved people and causes significant functional impairment and symptoms that last 6 months or longer (Lobb et al. 2010; Shear et al. 2011). Complicated grief requires early intervention (Lobb et al. 2010).

5.11 Enabling Patient Choice at the End of Life

Family-focused care requires healthcare providers to be aware of and follow the patient's advance care directive. Given recent debates about legalized euthanasia for people with advanced and critical illnesses, legal support in relation to enabling patient choice (both in relation to advance care planning/directives and legalized

euthanasia) needs to be understood within each care jurisdiction with global variances notable within this aspect of care. However, the principle of care ought to remain focused on supporting patient choices, within legal parameters, is fundamentally important and forms an important aspect of family-focused end-of-life care.

5.12 Summary

The above domains of care have been consistently reported by families as contributing to optimal end-of-life care for more than 30 years, yet few healthcare systems and services have been able to effectively address these priorities (Virdun et al. 2017). However, services currently lack the ability to measure the quality of such care provision which hinders careful and targeted quality improvement strategies. Strategies focused on education, quality improvement, policy development, and research are required to truly see family-focused care realized for all patients with end-of-life care needs, irrespective of care setting (Virdun et al. 2017).

6 Strategies to Optimize Outcomes for Families

There are a number of important and cost-effective strategies that healthcare providers can implement to optimize palliative care outcomes for families, as detailed below:

6.1 Need for Healthcare Provider Self-Awareness

It is important for healthcare providers to be aware of assumptions they may have about families. Common assumptions may involve the perceived altruistic nature of family members, such that they always have the best interests of the patient at heart, when this may not be the case and/or that the family is close, supportive, and loving. Another assumption is the belief that children, particularly female children, are obliged to care for chronically ill or older family members. We all bring our own assumptions about the structure and function of families, but not all families are the same, and they all bring their experiences from the past. Activities to facilitate self-awareness can help healthcare providers to acknowledge and reflect on their own assumptions and biases to facilitate their ability to provide family-focused care (Acquaviva 2017).

6.2 Interdisciplinary Team

A key strategy underpinning the provision of family-focused interventions is the active engagement of a cohesive team of healthcare providers who are able to respond to the needs of patients and their families during the palliative phase of the patient's illness. It is important to recognize that the focus of care should be on an interdisciplinary approach that enables and supports shared decision-making that includes the family as a core team member. Using this approach, all members of the team are able to contribute and to share their expertise in providing care to the patient's family and in making decisions that are responsive to family issues and concerns (Haugen et al. 2015). The team's focus should be on responding to the family's needs, issues, and care, rather than basing their decisions on the imperatives of healthcare providers (Speck 2006).

6.3 Effectively Engaging and Supporting Families

One of the most important aspects of engaging and supporting families is to respond to them with respect and compassion, in a manner that is non-judgmental and preserves the dignity of their personhood. It is important to recognize the unique qualities of each individual and their unique ways of behaving and responding in the palliative care phase. Chochinov (2007) outlined key elements of preserving dignity for the patient, which could equally be used in the care of families. He emphasized the importance of attitude, behavior, compassion, and dialogue. He describes each element

with examples. Attitude focuses on the healthcare providers' attitudes and assumptions so that they do not adversely affect the rapport that needs to be created and maintained with the patient. Behavior can include the necessity for honest, open, and easily understood communication, with the availability of time to answer questions and clarify information provided. Dialogue encompasses the individuality of a person and seeking to gain an understanding of the person beyond their disease or circumstances. Chochinov poses a key question in relation to the patient:

> "What should I know about you as a person to help me take the best care of you that I can?" (Chochinov 2007)

This same question and the key components of the dignity-preserving model can be equally applied to the family. These principles can provide the foundation for engaging in a relationship with the family to provide effective support during the palliative care phase. Effective engagement of the family using this framework will guide the support that families require. Information about the patient's condition, what to expect at this time, explanations of what a service provides, and the roles of the different healthcare providers are fundamental to families. Information needs to be tailored to the needs, language, and culture of the family. It is important to understand the family's current understanding of the patient's condition and their degree of acceptance or denial of the situation, so that information can be provided in non-threatening and empathic manner. Information that may seem self-evident to healthcare providers concerning dying and death may be totally foreign to a family who has never previously experienced the death of someone (Kristjanson and Aoun 2004).

Acknowledgment of the physical demands and caregiving roles of families is important in providing adequate support. Practical issues such as ensuring that families have access to sustenance can be provided with overnight facilities toward the terminal phase of the patient's illness; gentle reminders to take "time-out" or obtain some relief for their caring roles are also important.

Support for the emotional needs of the family members is also critical. The witnessing of a relative's deterioration, the impending loss, and a sense that they may be relatively alone in confronting this existential challenge require careful assessment and appropriate emotional, psychosocial support, and spiritual support (Cahill et al. 2017). Attending to these needs and preparing the family for the impending loss may alleviate some of the distress of bereavement (Fineberg and Bauer 2011). Engaging the family in preparatory grieving can be ultimately therapeutic for individual family members and the family unit as a whole.

6.4 Undertaking a Family Assessment

A thorough understanding of the patient's family is fundamental to providing family-focused interventions. To ensure that this occurs, a comprehensive assessment of the family should be undertaken (Fineberg and Bauer 2011). This assessment will involve both psychosocial and other healthcare providers on the team. The assessment should include the identification of key family members and any other people considered "family" by the patient. To ascertain the important family member(s) to a patient, a healthcare provider can ask the patient who is important to them or who they consider their family to be and who they want at the bedside or to have present at a meeting about care. The way a healthcare provider asks this question can convey the provider's openness to different family configurations. To normalize this phenomenon of bringing an accompanying person, the healthcare provider can explain that patients often find it helpful to invite one or more people to participate in the meeting with healthcare providers (Acquaviva 2017).

The role of family members in relation to the patient's illness and his/her care should also be delineated, for example, caregiving duties. Identifying all the people who constitute the patient's family ensures that no family member is excluded from the support needed during the palliative care

phase (Kristjanson and Aoun 2004). It is also prudent to obtain information about any estrangements in the family, and to identify family members who are not readily available to the patient, or for the important interactions that need to take place. Documenting the family structure in the form of a genogram may help to ensure that this information is easily accessible to the entire interdisciplinary team. In the course of the patient's care, different family members will often encounter different members of the interdisciplinary team. Recognition by the team of all family member(s) provides a context that is most likely to enhance communication and good relationships between the family and team members. It is also important to gain an understanding of the patient's current illness and its impact on the family as whole and on individual family members (Lethborg and Kissane 2015). Previous significant life events, as well as important events likely to occur in the future (e.g., the birth of a child), should be documented. Particular note should be made of any history of mental illness, substance abuse, or any intra-family abuse (Fineberg and Bauer 2011). In addition, the possible impact of the patient's illness, according to the life stage of individual family members should be considered. Social aspects of the family unit such as culture, language, financial, and employment issues should also be recorded (Lethborg and Kissane 2015). Religious practices and an understanding of spiritual beliefs should be assessed. The particular sources of meaning and purpose for family members will be relevant, given the context of dying and death of their family member.

6.5 Identifying and Understanding Family Patterns of Communication and Cohesiveness

A specific area for family assessment relates to an understanding of how family relationships work, the sources of strength within the family structure, and the family members' preferred communication style(s). Previous ways of relating to each other, and managing challenging family situations, may influence and provide the team with guidance as to how the family might respond and confront the life-limiting illness of their family member (Lethborg and Kissane 2015). Any previous or current issues that have provoked conflict should be identified, particularly those affecting the patient at this final phase of his or her illness. This information and any major concerns articulated by individual family members, or by the family in its entirety, will assist the interdisciplinary team to respond with suitably family-focused interventions (Lethborg and Kissane 2015). The resolution of family conflict may not be possible. However, appropriate family-focused interventions and support may improve family relationships. Such interventions may also foster more open communication and enhance decision-making so that the family's cohesiveness is optimized at this time (King and Quill 2006).

6.6 Engaging Families in Decision-Making

Decision-making in the palliative care context will be influenced by the communication styles of the family and the family's previous ability in making decisions. It may be that the family do not routinely make joint decisions or they may have a preference for one family member to make decisions on their behalf (Wellisch 2000). In addition to understanding previous decision-making patterns, the interdisciplinary team requires an understanding of the degree to which the family unit and individual family members wish to be involved in this process. Some families are content to forego input into decision-making and to allow all decisions to be made by the healthcare team. Alternatively, other families and family members require regular information, consultation, and involvement in decision-making (Isaac and Curtis 2016). It is important to elicit from the family where they are placed on this continuum of decision-making and which decisions are of particular concern to them. For instance, the family may be comfortable for the interdisciplinary team

alone to make decisions about the patient's care. However, they may require the team to consult with them about all decisions that affect both the patient and the family. Families may often have a preference to engage with specific team members in the decision-making process. This preference should be shared with other team members. It is essential to establish and document to what degree family members are surrogate decision-makers for the patient or if one particular family member is the primary spokesperson and surrogate decision-maker (Isaac and Curtis 2016). Patients and families also value the naming of a decision-maker as a contingency plan for situations in which the patient may be unable to make decisions (Cahill et al. 2017). Recognition of these key factors will guide the team to respond effectively and will enable the provision of family-focused care in relation to decision-making.

The processes required for decision-making are likely to involve sharing of information with families and individual family members, in either one-on-one conversations, informal consultations around the patient's bedside or at home, or during a family meeting. Decision-making is likely to be an iterative process and although it is time-consuming, it is integral to family-centered care. In the era of enhanced communication, telephone and electronic devices can facilitate discussions and decision-making when family members are not physically available (Fineberg and Bauer 2011).

Evidence supports the importance of decision-making by family members in the palliative care setting, not only from the family perspective but also for the patient (Cahill et al. 2017). It should be recognized that decision-making may not only focus on clinical issues. Decisions about everyday activities such as going to the hospice garden or having a pet visit may be just as vital for the patient and family. This type of decision-making enables the patient and family to experience some degree of control in their life at a time when this may be limited. It is incumbent on the interdisciplinary team to recognize and support such decision-making to ensure family-centered care (Cahill et al. 2017).

6.7 Undertaking a Family Meeting: Purpose, Roles, and Responsibilities

Cahill et al.'s (2017) systematic review of family meetings highlighted research indicating effective communication is essential to understanding and responding adequately to family needs and concerns. Bringing together patients, family, and interdisciplinary team members for a focused discussion has been advocated as a method to facilitate effective patient-family-team communication in the specialist palliative care setting (Cahill et al. 2017). These formalized conversations are usually referred to as a "family meeting" or a "family conference," and these terms are often used interchangeably in clinical and research settings. In the palliative care context, a family meeting may be defined as a one-off meeting that includes the patient (when possible), family members, and healthcare providers to discuss an issue related to the health and care of the patient and family (Fineberg et al. 2011).

Family meetings can provide a forum for sharing of information concerning the illness experience, goals of care, current treatment, and end-of-life care. The adoption of an open style of communication by the interdisciplinary team members can help build consensus about the goals of care and management plans and promote a shared understanding of the current clinical situation and its uncertainties. These meetings can also increase the patient's and family's involvement in decision-making. Facilitating expression of family concerns, issues, and needs provides the family with a sense that their concerns are being heard and addressed (Cahill et al. 2017). Discussion at these meetings will inevitably include clinical issues; however, psychosocial issues, preparation for death, and other key areas of importance for that patient and family may be paramount and should also be addressed. It will be an important task to establish the best way to communicate with the patient, family, and the clinical team, and with whom, during this phase of the patient's care.

Conflicting perspectives may emerge between the patient and family members, especially when

certain family members are not able to be present. Family participants (or significant others) may also raise contentious issues and unresolved concerns or indicate pre-existing family conflict. In all cases, it is important to address the specific issues (if possible) or to give voice to concerns as expeditiously as possible so that the meeting's focus remains on the patient and the family (Cahill et al. 2017). In some cases, it may be prudent to acknowledge these concerns but to offer an alternative time to deal with them more fully, either with both patient and family present or with the family in the absence of the patient. Significant conflict between the patient and a family member, such as the existence of an abusive relationship, is not conducive to the patient or family member being able to honestly discuss their concerns and issues. In such situations, a family meeting may not be possible or may even be contraindicated.

The practical aspects of arranging, organizing, and convening a family meeting are important if one is to achieve the maximum benefits for all participants in terms of communication, information sharing, and decision-making (Kissane and Hempton 2017). Key components include who will participate and where and how the family meeting will be conducted. The patient and the primary family support person including any additional family members who wish to participate or whom the patient requests to attend. The patient's palliative care consultant and/or registrar and social worker should routinely attend the meeting. Other members of the team, including pastoral care, nursing, and allied health staff attend as required according to the agenda or the specific issues to be discussed. Patients and families may also request the presence of particular team members during the preparation phase of the meeting. Prior to the meeting being convened, one of the attending healthcare providers will be designated to facilitate the meeting based on mutual agreement with other team members. A co-facilitator of the meeting may also be considered (Kissane and Hempton 2017). Ideally, the lead healthcare provider should have had prior experience in facilitating family meetings in the palliative care setting. All participants should be informed in advance of the date, time, and place for the meeting and commit to being present for the entire meeting, with the exception of unanticipated crises. This will ensure that the "flow" of conversation and discussion are not disrupted nor are participants distracted. The meeting focuses on the patient and the family.

Given that the agenda will influence the goals of the meeting, it is important to recognize that the process by which the agenda is set varies considerably in the reported literature. Some authors suggest that healthcare providers set the agenda. However, the Australian Guidelines for Conducting Family Meetings in Palliative Care (Hudson 2004) recommend that the primary family carer should be the one to identify the main issues and concerns; if the patient attends, he/she also should attempt to identify key issues. Whichever method is used, a prearranged agenda shared with all participants is preferable to an ad hoc arrangement.

A private, comfortable space with adequate seating and ventilation is preferred for the meeting. Meetings should not be held in a shared room within inpatient units unless there is no other option physically possible. The space for the meeting should be prepared in advance so that the meeting can commence in a timely and unrushed fashion. The family meeting begins with the facilitator ensuring that all participants introduce themselves and indicate their relationship to the patient and to each other. The participating healthcare providers are reminded of the importance of "open listening" and to refrain from interrupting the patient and family discussion or directing the discussion away from those issues raised by the patient and family members. Occasionally, however, clarification of an issue or point will need to be made to provide information requested by the patient and/or the family. Kissane and Hempton (2017) describe specific details of communication skills required in the context of family meetings.

The agenda should guide the family meeting, although it is likely that the patient and/or their family may raise additional issues or concerns. It is important that the facilitator acknowledges and facilitates discussion about the issues raised.

However, clarification of information about the patient's illness, prognosis, goals of care, and management plans will usually be required (Kissane and Hempton 2017). Patients and family members should be supported when raising anxieties or fears so that these can be heard by all present and addressed in a timely manner (Cahill et al. 2017).

Once the discussion has been completed, the facilitator summarizes the agreed goals of care. Other key points that have been discussed or agreed to, any matters of disagreement, and any actions required to be undertaken following the meeting are confirmed. Endorsement for the decisions made and the actions to be undertaken is sought from the patient, family, and healthcare providers (Hudson et al. 2008; Kissane and Hempton 2017). The facilitator concludes the meeting by emphasizing the positive results from the meeting; acknowledging the patient, family, and clinical contributions to the meeting; and thanking all the participants.

Guidelines for Conducting Family Meetings in Palliative Care were developed in Australia (Hudson et al. 2008) based on available literature, various theoretical models, expert opinion, and the results of focus groups. These consensus guidelines provide a planned approach for preparing, conducting, and documenting the agreed decisions resulting from a family meeting. An evaluation to assess the effectiveness of these *Guidelines* (Hudson et al. 2009) demonstrated a significant increase in families' unmet needs being satisfied as a result of participating in such meetings. Family members also reported that the meetings were useful because they gained a better understanding of the patient's illness and what to expect in the immediate future.

7 Conclusion and Summary

While caring for a family member with a life-limiting condition can be distressing, it can also be a positive and rewarding experience. Carers have reported positive experiences from caregiving to include a strengthened relationship between carer and care recipient, personal growth, increased self-efficacy, and recognition of personal strength through adversity, acceptance, and necessity (Hudson 2004; Wong et al. 2009). However, family-focused care is critical in supporting positive care experiences and more healthy adjustments to grief and bereavement, where possible. Challenges to family-focused care include individual healthcare provider practice that fails to prioritize working in partnership, a lack of policy and infrastructure support with often-exclusive focus on patient needs, and a lack of open, innovative, and creative thinking to facilitate and partner with families caring for people at the end of their lives. Meeting these challenges through education, policy reform, quality improvement initiatives, and research provides enormous opportunity for improved family-focused end-of-life care into the future.

Contents

Abstract

In spite of grief and bereavement being fundamental to high-quality palliative care, grief and bereavement care is often under-resourced and haphazard and fails to reflect contemporary evidence. This chapter will examine a number of approaches to evidence-informed bereavement care and explore some of the seismic shifts that have taken place in our understanding and response to the grieving and bereaved. The chapter will conclude with an examination of complications in bereavement and what might be considered best practice in providing bereavement support in the palliative setting.

1 Introduction

Loss and grief are the ever-present companions along the trajectory from the appearance of symptoms, diagnosis, treatment, palliation, and death. It is important to remember that both death and non-death losses punctuate this journey. These include a loss of physical strength and well-being, independence, role and professional identity, sexual function and intimacy, a sense of control and safety, mental integrity, and life expectancy. The experience of loss may be subtle or overwhelming. These losses may or may not be recognized by family, friends, or health professionals. What matters are the subjective appraisal and experience of these losses.

Loss and grief are fundamental to human life. Grief can be defined as the response to the loss in all of its totality – including its physical, emotional, cognitive, behavioral, and spiritual manifestations – and as a natural and normal reaction to loss. Put simply, grief is the price we pay for love and a natural consequence of forming emotional bonds to people, projects, and possessions. All that we value we will someday lose. Life's most profound losses disconnect us from our sense of who we are and can set in train an effortful process of not only re-learning ourselves but also the world. In recent decades, we have seen a broadening of attention from a traditional focus on emotional consequences, to one that also considers cognitive, social, cultural, and spiritual dimensions to the study of grief. There is also a growing awareness that losses can also provide the possibility of life-enhancing "post-traumatic growth" as one integrates the lessons of loss and resilience. Personal growth following even seismic experiences of loss is common. While loss and grief are fundamental to human life, the course and consequences of bereavement will vary for each individual. For highly resilient individuals, acute grief may be limited to a few weeks, and for most people, their grief subsides over time (Bonanno and Kaltman 2001).

Over the past two decades, the field of grief and bereavement has undergone significant change in terms of how the human experience of loss is understood and how the goals and outcomes of grief therapy are conceptualized. Long-held views about the grief experience have been discarded, with research evidence failing to support popular notions, which construe grief as the navigation of a predictable emotional trajectory, leading from distress to "recovery." We have also witnessed a shift away from the idea that successful grieving requires a "withdrawal of emotional investment" and a "letting go" of the deceased and a shift toward a recognition of the potentially healthy role of retaining continued bonds with the deceased. Recent research evidence has also failed to support popular notions that grieving is necessarily associated with depression, anxiety, and PTSD or that a complex process of "working through" or engagement with "grief work" is critical to recovery. The absence of grief is no longer seen, by definition, as pathological. How we adapt to these deprivations shapes who we become. While recognizing that grief reactions are universal, they are shaped by the reciprocal impact of loss on families, organizations, and broader cultural groups.

While loss and grief are fundamental to human life, the course and consequences of bereavement will vary for each individual. For highly resilient individuals, significant grief may be limited to a few weeks (Bonanno and Kaltman 2001), though a more typical trajectory involves readjustment to life over the course of a few years (Bonanno et al. 2004).

This chapter will explore a number of theoretical approaches to bereavement which has seen a move from simplistic generalizations of these phenomena to more evidence-informed and nuanced descriptive and explanatory frameworks. Attention will be given to some of the current controversies in the field, such as complicated grief as a mental disorder and the management of clients with complex bereavement needs. The chapter will conclude with a consideration of what best-practice bereavement care in the palliative care setting might look like.

2 Theoretical Perspectives

The first major theoretical contribution on grief was provided by Freud in his paper *Mourning and melancholia* (1917/1957) and profoundly shaped

professional intervention for over half a century. For Freud, "grief work" involved a process of breaking the ties that bound the survivor to the deceased. This psychic rearrangement involved three elements: (1) freeing the bereaved from bondage to the deceased, (2) readjustment to new life circumstances without the deceased, and (3) building of new relationships. Freud believed that this separation required the energetic process of acknowledging and expressing painful emotions such as guilt and anger. The view was held that if the bereaved failed to engage with or complete their grief work, the grief process would become complicated and increase the risk of mental and physical illness and compromise recovery. The grief work model stresses the importance of "moving on" as quickly as possible to return to a "normal" level of functioning. It is ironic that Freud maintained that mourning ends within a relatively short time, because, as a bereaved father, he wrote about his strong attachment to his daughter some 30 years after her death. In his private correspondence, he was acutely aware of the long-term nature of grief and a parent's ongoing connection to their dead child (Shapiro 2001).

Several later grief theorists conceptualized grief as proceeding along a series of predictable stages, phases, and tasks (Kübler-Ross 1969; Bowlby 1980; Parkes and Weiss 1983). Perhaps the best-known model is that postulated by Kübler-Ross in her 1969 text *On death and dying*. Based upon her clinical work with the dying, her model was one of anticipatory grief, how an individual responds to a terminal diagnosis. Over time this model transformed into the five stages of grief – (1) shock and denial; (2) anger, resentment, and guilt; (3) bargaining; (4) depression; and (5) acceptance – and was subsequently applied to both the bereavement experience and many other forms of change. The model implied that failure to complete any of these stages would result in a variety of complications. Kübler-Ross's perspective, although capturing the imagination of both lay and professional communities, has been widely criticized for suggesting that individuals must move through these stages and has been empirically rejected.

Stage theories have a certain simplistic appeal – they bring conceptual order to a complex process; however they are incapable of capturing the complexity, diversity, and idiosyncratic quality of the grieving experience. Stage models do not address the multiplicity of physical, psychological, social, and spiritual needs experienced by the bereaved, their families, and intimate networks. Since the birth of these theories, the notion of stages of grief has become deeply ingrained in our cultural and professional beliefs about loss (Stroebe et al. 2017). These models of grieving, albeit without any credible evidence base, have been routinely taught as part of the curriculum in medical and nursing programs (Downe-Wamboldt and Tamlyn 1997).

Prospective studies of spousal bereavement have identified the most common trajectories of adjustment to loss (Bonanno et al. 2002) and made the compelling finding that resilience is the most common pattern and that delayed grief reactions are rare. Five distinct trajectories covered the outcome patterns of most participants: (1) common grief or recovery (11%), (2) stable low distress or resilience (46%), (3) depression followed by improvement (10%), (4) chronic grief (16%), and (5) chronic depression (8%). Bonanno identified, within the depression followed by improvement group, individuals who improved in functioning after the death of their spouse. This was most prevalent in those who experienced relief following a period of considerable caregiver burden or who suffered oppressive relationships (Bonanno et al. 2004).

In Bonanno's research, those who experienced the highest levels of distress tended to exhibit high levels of personal dependency prior to the death of their spouse. For those not depressed prior to the loss, dependency was an important predictor of grief reactions. A lack of expectation or psychological preparation for the loss also contributed strongly to increased distress. The distinction between chronic grief and chronic depression, which this study illuminates, is of critical importance. Relationship conflict was predictive of chronic depression but not chronic grief. Chronic grievers reported greater processing of the loss and searching for meaning

compared to chronically depressed individuals. Both groups evidenced elevated pre-loss dependency. What is clear is that there is no single set of stages or tasks in adapting to loss but instead qualitatively distinct paths through bereavement, which calls for a closer understanding of both patterns of complication and resilience. Further work is required to explore strategies to promote resilience, which includes factors and mechanisms that impact on an individual's level of protection against adversities. Resilience is not only a result of an individual's personal attributes but can be impacted by a variety of community and cultural factors.

The early stage theories of grief became unpopular because they were considered to be too rigid. There are, however, new models that succeed in identifying definite patterns and relations in the complex and idiosyncratic grief experience. Phasal conceptualizations have been enormously influential. Two of the most comprehensive and influential grief theories are the dual process model of Stroebe and Schut (1999) and the task-based model developed by Worden (2008). These models serve both counselors and clients by offering frameworks that guide interventions and enhance clients' self-awareness and self-efficacy.

The dual process model of grief (Stroebe and Schut 1999), developed from a cognitive stress perspective, describes grief as a process of oscillation between two contrasting modes of functioning. In the "loss orientation," the griever engages in emotion-focused coping, exploring, and expressing the range of emotional responses associated with the loss. At other times, in the "restoration orientation," the griever engages with problem-focused coping and is required to focus on the many external adjustments required by the loss, including diversion from it and attention to ongoing life demands. The model suggests that the focus of coping may differ from one moment to another, from one individual to another, and from one cultural group to another.

Worden (2008) suggests that grieving should be considered as an active process that involves engagement with four tasks: (1) to accept the reality of the loss, (2) to process the pain of grief, (3) to adjust to a world without the deceased (including internal, external, and spiritual adjustments), and (4) to find an enduring connection with the deceased in the midst of embarking on a new life.

Worden also identifies seven determining factors that are critical to appreciate in order to understand the client's experience. These include (1) who the person who died was, (2) the nature of the attachment to the deceased, (3) how the person died, (4) historical antecedents, (5) personality variables, (6) social mediators, and (7) concurrent stressors. These determinants include many of the risk and protective factors identified by the research literature and provide an important context for appreciating the idiosyncratic nature of the grief experience. Issues such as the strength and nature of the attachment to the deceased, the survivor's attachment style, and the degree of conflict and ambivalence with the deceased are important considerations. Death-related factors, such as physical proximity, levels of violence or trauma, or a death where a body is not recovered, all can pose significant challenges for the bereaved.

A stigmatizing death, such as that by suicide or AIDS, can "disenfranchise" the griever (Doka 2002) and complicate the bereavement experience. Disenfranchised grief refers to grief that persons experience when they incur a loss that is not or cannot be openly acknowledged, publicly mourned, or socially supported. The concept of disenfranchised grief recognizes that societies have sets of norms – in effect, "grieving rules" – that attempt to specify who, when, where, how, how long, and for whom people should grieve. Disenfranchised grief can be a result of the circumstances of the death but can also extend to the relationship not being socially recognized, the griever being excluded (such as a child), or the way the individual expresses their grief, particularly with regard to the level of emotional distress which is publicly displayed.

Those who help bereaved people must recognize the unique reactions, needs, and challenges as individuals and their families cope with loss.

Subscription to a stage theory can lead to a failure of empathy, where we fail to listen to and address the needs of the bereaved.

3 Continuing Bonds

There has been a paradigm shift from the idea that successful grieving requires "letting go," with writers such as Klass et al. (1996) and Klass and Steffen (2018) offering an alternate approach where they argue that after a death, bonds with the deceased do not necessarily have to be severed and that there is a potentially healthy role for maintaining continuing bonds with the deceased. This idea represents recognition that death ends a life, not necessarily a relationship. Rather than "saying goodbye" or seeking closure, there exists the possibility of the deceased being both present and absent.

The development of this bond is conscious, dynamic, and changing. The expression of this continuing bond can be found in a variety of forms. The deceased may be seen as a role model, and the bereaved may turn to the deceased for guidance or to assist them in clarifying values. The relationship with the deceased may be developed by talking to the deceased or by relocating the deceased in heaven, inside themselves, or joined with others whom they predeceased. The bereaved may experience the deceased in their dreams, by visiting the grave, feeling the presence of the deceased, or through participating in rituals or linking objects. Many people build the connection out of the fabric of daily life. Frequently this continuing bond can be co-created with others. A number of studies have found that approximately half of the bereaved population experience the sense of presence of the deceased (Datson and Marwit 1997) although the true incidence is thought to be much higher, given a great reluctance among the bereaved to disclose its occurrence to clinicians for fear of ridicule or being thought of as "mad or stupid."

Ongoing research is still examining when continuing bonds are helpful and when they are not. Continuing bonds must always be considered within a cultural context, and there needs to be assessment of the ways the bond influences adaptation to the loss. Recent literature has attempted to distinguish the conditions under which it is adaptive from those where it is maladaptive. Field (2006) identified a type of continuing bonds expression that represents failure to integrate the loss due to extreme avoidance in processing the implications of the loss. In keeping with Bowlby's (1980) early work, growing evidence suggests that individuals who experience insecure styles of attachment are more prone to chronic grief trajectories (Bonanno et al. 2004), contributing to maladaptive rather than adaptive forms of continuing bonds with the deceased.

In essence, continuing bonds expressions that are indicative of unresolved loss imply disbelief that the other is dead. An important factor distinguishing adaptive versus maladaptive continuing bonds expression is whether the given expression reflects an attempt to maintain a more concrete tie that entails failure to relinquish the goal to regain physical proximity to the deceased. This can be compared to a more internalized, symbolically based connection, which suggests a greater acceptance of the death.

4 Meaning Reconstruction Following Loss

For many the desire to "make sense" and "find meaning" in the wake of loss is central. Neimeyer and Sands (2011) have emphasized that the reconstruction of meaning represents a critical issue, if not the critical issue in grief. In stark contrast to earlier modernist or positivist views which focus on breaking bonds and universal symptoms and stages of adaptation to loss, the postmodern social constructionist approach views continuing bonds as resources for enriched functioning and the oscillation between avoiding and engaging with grief work as fundamental to grieving (Neimeyer 2001). These later models see grieving as a process of reconstructing a world of meaning that has been challenged by loss. The experience of loss, particularly if it is sudden and unexpected, can interfere with a bereaved

person's ability to rebuild his or her assumptive world, particularly when the death assaults the survivor's notion world that life is predictable or that the universe is benign. A bereaved individual may have no mental constructions to help them with the meaning-making process to incorporate the loss into a new worldview. When people indicated that they could not make sense of the loss, they often indicated that the death seemed unfair, unjust, or random. If the loss is consistent with existing worldviews, then making sense does not appear to represent a significant coping issue.

Across a variety of different losses, a body of research indicates that the failure to find meaning following the loss, especially in terms of "making sense" of the death itself, is associated with higher levels of complicated grief symptoms. An intense and protracted search for meaning is likely to accompany losses that are unexpected and premature, as in the death of a child, and that a ruminative preoccupation with the loss is an indicator of long-term depression, anxiety, anger, and grief. A failure to find spiritual or secular meaning in the loss accounts for nearly all of the heightened symptoms of complicated grief following suicide, homicide, and fatal accident, as opposed to natural anticipated deaths (e.g., cancer) and even natural sudden deaths (e.g., heart attack).

Most definitions of meaning encompass two concepts: (1) making sense of the loss (e.g., the death had been predictable in some way; it was consistent with the caregiver's perspective on life; or religious or spiritual beliefs provide meaning) and (2) finding benefits from the loss (e.g., it led to a growth in character, a gain in perspective, and strengthening of relationships). Data suggests that sensemaking and benefit finding are two distinct processes and represent two distinguishable psychological issues for the bereaved person. It is not so much making sense of the loss that alleviates distress, as it is becoming less interested in the issue. The finding of benefit on the other hand grows stronger with time (Davis et al. 1998). Meaning-making is a highly iterative and interactive process, and the significance of a loss can be affirmed or disconfirmed, congruent or discrepant, and supported or contested within families and other reference groups (Nadeau 1998).

4.1 Complications of Bereavement

A century ago, Freud (1917/1957) wrote:

> Although mourning involves grave departures from the normal attitude toward life, it never occurs to us to regard it as a pathological condition and to refer it to a medical treatment. We rely on its being overcome after a certain lapse of time, and we look upon any interference with it as useless or even harmful. (p. 243)

Research has proved Freud largely correct, although not completely. A small proportion of bereaved individuals experience severe and prolonged grief that has an ongoing and negative impact on their lives.

For a subgroup of individuals, around 10%, the symptoms of distress following the death of a family member or friend are more intense and persistent (Prigerson et al. 1996; Latham and Prigerson 2004). Known variously as complicated grief (Shear et al. 2001) or prolonged grief disorder (Prigerson et al. 1996; Boelen and Prigerson 2007), this condition can be associated with severe mental and physical health problems such as insomnia, substance misuse, depression, depressed immune function, hypertension, cardiac problems, cancer, suicide, and work and social impairment. Bereaved individuals in this cohort report higher use of medical services and more frequent hospitalization than people with similar losses whose grief is less intense and of shorter duration. These effects have been observed for as long as 4–9 years after the death (Neimeyer and Burke 2012).

Neimeyer and Burke (2012), in a summary of the clinical literature on pre-loss risk factors for the development of complicated grief, identified three groups of factors – background factors, death-related factors, and treatment-related factors, which were predictive of adverse outcomes:

1. **Background factors** – these include close kinship to the dying patient, being female,

minority ethnic status, insecure attachment style, high pre-loss marital dependence, religion, and spirituality.

2. **Death-related factors** – these include bereavement overload, low acceptance of pending death, violent death (suicide, homicide, accident), finding or viewing the loved one's body after violent death, death in the hospital (vs. home), and dissatisfaction with death notification.
3. **Treatment-related factors** – these include aggressive medical intervention (e.g., ICU, ventilation, resuscitation), ambivalence regarding treatment, family conflict regarding treatment, economic hardship created by treatment, and caregiver burden.

Most people ultimately adapt well to bereavement, typically regaining their psychological equilibrium after some weeks or months of acute mourning, although they frequently will continue to miss their loved one for a considerably longer period of time (Bonanno et al. 2002). Studies show that for most people grief intensity is fairly low after a period of about 6 months. This does not imply that grief is completed or resolved but rather that it has become better integrated and no longer stands in the way of ongoing life. Acute grief is a normal response to loss, with symptoms that should not be pathologized.

Two main diagnostic criteria for disordered grief have been proposed – complicated grief (Shear et al. 2001) and prolonged grief disorder (Prigerson et al. 2009). Both describe intense distress; a range of cognitive, emotional, and behavioral symptoms; and functional impairments, all persisting for at least 6 months. The American Psychiatric Association (2013) drew from both in proposing persistent complex bereavement disorder, with the criterion that the symptoms must persist for more than 1 year.

Complicated grief (CG) is characterized by a relentless period of profound grieving that continues for at least 6 months beyond the death of the loved one, in which the survivor suffers marked and disruptive separation distress and psychologically disturbing and intrusive thoughts of the deceased. Additionally, CG frequently entails a sense of emptiness and meaninglessness about life and/or the future, trouble accepting the reality of the loss, and difficulty moving forward in making a life without the deceased (Holland et al. 2009; Prigerson and Jacobs 2001). (Stroebe et al. 2007) found that grievers, especially spouses, have an increased risk of early mortality merely as a result of being bereaved, and other investigators have found CG in particular to predict a variety of concerning conditions, including impaired quality of life and social functioning, substance abuse, immune dysfunction, cardiovascular illness, and suicide (Latham and Prigerson 2004; Prigerson et al. 1996, 2009). Clinicians should be alert to these symptoms as they evaluate the longer-term adjustment of clients to the loss of a loved one, as both self-report (Keesee et al. 2008) and neurophysiological (O'Connor et al. 2008) data suggest that time alone does little to diminish CG symptomatology. Once identified, however, prolonged grief is clearly amenable to treatment (Shear et al. 2001).

Population-based studies reveal the clinical threshold for complicated grief to be 2.4% in a Japanese sample (Fujisawa et al. 2010) to 6.7% in a German sample (Kersting et al. 2011). It is now clear that grief, at least for a subset of approximately 10% of the bereaved, can be intense and chronic for many months or years. Individuals bereaved as a result of deaths that are unexpected, violent, or untimely (e.g., the death of a child) tend to be overrepresented in this cohort. This condition, termed complicated grief (CG) or more recently prolonged grief disorder (PGD), has received increasing attention in both the psychiatric and psychological literatures over the past decade. An estimated 7–10% have a complicated grief syndrome – currently called persistent complex grief disorder. More broadly, an estimated 10–20% have some form of complicated response to loss, which includes a full range of mental and/or physical reactions and illnesses. Taken together, 7–20% of all grievers may experience complications which are associated with several mental and physical health problems such as sleep disruption, substance abuse, depression, compromised immune function, hypertension, cardiac problems, cancer, suicide, and work

and social impairment. Bereaved individuals in this cohort report higher utilization of medical services and more frequent hospitalization than people with similar losses whose grief is less profound and extended. These effects have been observed for as long as 4–9 years after the death.

In addition to those who experience complicated grief, a significant proportion of all people caring for someone in palliative care will experience poor psychological, social, financial, spiritual, and physical well-being. When grief is complicated and prolonged, evidence suggests that intervention is both indicated and effective (Currier et al. 2008). Directing scarce resources at the groups that will benefit most from them is critically important. The available evidence suggests that while many bereaved people will benefit from bereavement support, only a minority of people will require and benefit from specialist bereavement interventions.

5 Prolonged Grief Disorder and the DSM-5

In the late 1990s, two research teams independently published a set of diagnostic criteria to assess CG (Horowitz et al. 1997; Prigerson et al. 1999). Recently, these two diagnostic entities were integrated, and the concept of CG was renamed as prolonged grief disorder (PGD). This incapacitating disorder is defined as a combination of separation distress and cognitive, emotional, and behavioral symptoms that can develop after the death of a significant other. The symptoms must last for at least 6 months and cause significant impairment in social, occupational, and other important areas of functioning.

The addition of complicated grief (CG) to the DSM-5 (American Psychiatric Association 2013) received significant support. Findings confirm the proposition that professional assistance is indicated for only a subgroup of the bereaved, namely, those who show CG reactions. CG symptoms have been shown to be different from other symptoms and disorders, such as normal grief reactions, mood disorders, and anxiety disorders including post-traumatic stress disorder.

It is essential that we do not consider bereavement complications simply as a relabeling of conventional psychiatric conditions. Bereavement is a severe stressor that can trigger the onset of both physical and mental disorders such as major depression, post-traumatic stress disorder, anxiety, and sleep disorders. These comorbidities require identification, clinical attention, and treatment. It is noteworthy that antidepressant medication has been found to do little to address the core symptoms of bereavement complication, even when it usefully reduces symptoms of depression (Pasternak et al. 1991).

Although prolonged grief disorder failed to be included in the DSM-5, the most recent edition has included persistent complex bereavement disorder (PCBD) as a condition that merits further study. The criteria for PCBD have been established to encourage future research and are not designed for clinical use.

5.1 Grief Interventions

With the support of friends and family and the mobilization of their own resources, most bereaved individuals adapt well following loss. Unsolicited help based on routine referral and delivered shortly after loss has not been found to be effective. Schut and Stroebe (2005) summarize their review of the literature with the conclusion that:

> Routine intervention for bereavement has not received support from quantitative evaluations of its effectiveness and is therefore not empirically based. Outreach strategies are not advised, and even provision of intervention for those who believe that they need it and who request it should be carefully evaluated. Intervention soon after bereavement may interfere with 'natural' grieving processes. Intervention is more effective for those with more complicated forms of grief. (p. 140)

The general pattern emerging is that the more complicated the grief process, the better the chances of bereavement interventions leading to positive results. When grief is prolonged

or complicated, evidence indicates that interventions are both effective and indicated (Currier et al. 2008). A large body of evidence supports the value of grief counseling as long as clinicians undertake careful assessment and interventions are carefully tailored. Given the idiosyncratic nature of grief, the most effective grief support offers a range of options including psychoeducation, online support, individual counseling, group support, community support, bibliotherapy, and rituals. There are a wide range of publications which provide detailed information on clinical interventions from constructivist (Neimeyer 2001), cognitive (Malkinson 2007), attachment (Kosminsky and Jordan 2016), and family systems perspectives (Nadeau 1998; Kissane and Parnes 2014). Neimeyer (2012) provides comprehensive details on a range of bereavement interventions that are drawn from a range of theoretical perspectives. Fortunately, several research-informed treatments exist, both for use prior to the loss and afterward. The following are examples of grief-specific interventions:

6 Cognitive Behavioral Therapy (CBT) for Complicated Grief

The CBT conceptualization of complicated grief proposes three processes: (a) problems with properly integrating the loss into the bereaved person's existing knowledge about themselves and their relationship with the dead person stored in long-term memory, (b) the presence of unhelpful thinking patterns such as negative global beliefs and misinterpretations of grief reactions, and (c) anxious and depressive avoidance. The CBT approach assumes that these three factors that play a key role in the development of complicated grief, with the first, poor integration, being mainly a disturbance of memory, and that this accounts for the fact that bereaved people can be preoccupied with their loss and, at the same time, continue to feel, think, and act as if the loss is reversible. The second factor, negative cognitions, is primarily a disturbance of thinking, which contributes to yearning and related emotions of sadness, depression, and anxiety. The third process, anxious and depressive avoidance, represents a disturbance in the behaviors of mourners that blocks adjustment as they attempt to deal with the internal demands of their loss (painful feelings and memories) and the external demands (adjusting to a changed situation).

From the perspective of CBT, (a) the loss needs to be integrated with existing knowledge, (b) unhelpful thinking patterns need to be identified and altered, and (c) maladaptive avoidance behaviors need to be replaced by more helpful ones. Various cognitive behavioral interventions can be used to achieve these changes. Imaging techniques, cognitive restructuring, and behavioral activation have been identified as beneficial (Boelen et al. 2006).

7 Family Focused Grief Therapy

Family focused grief therapy (FFGT; Kissane and Bloch 2002) is an approach that has been developed within the palliative care setting. Kissane makes the case for family-centered care, which is based on two premises: families in palliative care can be classified according to the quality of their relational functioning, and this functioning is highly predictive of individual functioning.

Based on the Family Relationships Index (FRI), families are classified as either well-functioning (i.e., supportive, showing a high level of cohesion, or conflict resolving, permitting and accepting each others' differences and dealing with discord constructively) or dysfunctional (hostile, families characterized by high conflict, low cohesion, and poor expressiveness, or sullen, families characterized by poor communication, depression, and muted anger). A final intermediate group shows some impairment in communication and teamwork, although conflict is less intense than in the hostile group (Kissane and Hooghe 2011). Supportive and conflict resolving categories reflect about 53% of families entering palliative care. Those considered sullen and hostile represent about 15–30% of families entering palliative care. Another 20–30% are mid-range, with mixed outcomes if left untreated.

Family focused grief therapy is a brief, focused, and time-limited intervention typically comprising four to eight sessions of 90 minutes' duration, which are arranged flexibly across 9–18 months. The intervention aims to prevent the complications of bereavement by enhancing the functioning of the family, through exploration of its cohesion, communication (of thoughts and feelings), and handling of conflict. The story of illness and related grief is shared in the process. Family focused grief therapy has three phases: (a) assessment (one or two weekly sessions) concentrates on identifying issues and concerns relevant to the specific family and on devising a plan to deal with them, (b) intervention (typically two to four sessions) focuses on the agreed concerns, and (c) termination (one or two sessions) consolidates gains and confronts the end of therapy. The frequency and number of sessions in each phase are modified to meet the needs of each family.

Families that function best under any type of stress tend to be the 3 Cs: communicative, cohesive, and conflict resolving. In clinical practice, one can screen for these characteristics with three simple questions:

> How openly and effectively do you communicate?
> What is your family's teamwork like?
> How do you manage differences of opinion and conflict in your family?

Once a family has been identified as at-risk, members are invited for a family meeting. The goals of FFGT are to increase the three Cs and to promote sharing of grief and mutual support. FFGT deliberately focuses and refocuses the family on:

1. Their strengths and coping skills
2. Transgenerational mapping of patterns of relating and ways of coping with loss
3. Encouraging the family to take responsibility for change

A goal of the therapy is to help the family reconstruct shared meaning. Defining the value and legacy of the dying or deceased person in the family and examining or creating family mottos are also crucial to this meaning-making process. Assessment and treatment typically last six to ten sessions and take place before and after the death of the family member. Outcome studies suggest the FFGT approach (compared to standard care) reduces individual depression and the incidence of complicated grief at 6 months post-death.

8 Complicated Grief Treatment

Complicated grief treatment (CGT; Shear et al. 2005) is an individual treatment protocol which has been specifically designed to identify and resolve complications of grief and to facilitate adaptation to loss. Rigorously tested in three large studies funded by the National Institute of Mental Health (NIMH), the intervention consists of ten modules that include psycho-education about complicated grief as well as a range of techniques derived from interpersonal therapy, motivational interviewing, positive psychology, and cognitive behavioral therapy. The treatment is administered in 16 weekly sessions with introductory, middle, and termination phases. The treatment includes two key areas of focus: restoration (i.e., restoring effective functioning by generating enthusiasm and creating plans for the future) and loss (i.e., helping patients find a way to think about the death that does not evoke intense feelings of anger, guilt, or anxiety). A portion of each of 16 weekly sessions is allotted to each area of focus. Grief monitoring and other weekly activities are assigned at the end of each session. Research indicates that CGT outperformed a more general psychotherapy for carefully diagnosed bereaved people and was particularly helpful for those whose losses were traumatic (Shear 2006).

9 Meaning Reconstruction Approaches to Grief Therapy

Meaning reconstruction refers to a cluster of processes that include sensemaking about the loss (Neimeyer 2000), finding some kind of existential benefit or life lesson in the loss, and then

also reconstructing one's sense of identity as a social being in the wake of that loss. A fundamental tenet of this approach is seeing adaptation to loss as an attempt to rebuild or to reaffirm a world of meaning that has been challenged by the loss experience. Bereavement and loss propel us into unanticipated or unwanted transitions, which we are forced to make sense of both our changed life and identity.

10 Online Support

Internet-based communication has changed the way people communicate and provides an alternative to conventional face-to-face interactions. Online services can overcome some of the restrictions of access posed by geography, disability, and privacy. Studies have found no difference in impact between face-to-face and online interventions (Barak et al. 2008).

While still in its infancy, research is also beginning to investigate the efficacy of online interventions for complicated grief. One study which used a series of tailored writing assignments delivered over the Internet that helped people express and explore their stories of loss significantly reduced symptoms of complicated grief relative to a no-treatment control group (Wagner et al. 2006).

10.1 Palliative Care and Bereavement Support

Although grief and bereavement support is central to palliative care, studies have demonstrated that it is often under-researched, under-resourced, and not systematically applied (Stroebe and Boerner 2015). In the palliative care setting, bereaved persons have frequently undertaken caregiving roles that can have both positive and negative consequences, with caregivers prone to physical and psychological morbidity, financial disadvantage, and social isolation (Hudson et al. 2011). Depression rates of between 12% and 59% (Hudson et al. 2011) and anxiety rates of between 30% and 50% have been reported (Grunfeld et al. 2004; Hudson et al. 2011). Meeting the needs of bereaved persons with complicated grief can be a complex, specialized task requiring input from appropriately trained staff (Guldin et al. 2015), particularly when supporting those from diverse cultural and linguistic backgrounds (Arthur et al. 2011).

In one study (Hudson 2013) almost half of family carers met the criteria for psychological distress when measured at the commencement of palliative care provision. Research indicates that preparing family caregivers for the role of supporting a person with advanced disease has valuable psychological and social sequela including lessening the propensity for distress during bereavement (Hudson et al. 2015). This preparation can include how to support the person with advanced disease, self-care, support services, and considerations for impending death and bereavement. Pre-bereavement levels of psychological distress are predictive of post-bereavement maladjustment (Stroebe and Boerner 2015); pre-existing conditions seem to be most important in explaining the occurrence of complicated grief (Bruinsma et al. 2015).

When grief is complicated, evidence suggests that intervention is both indicated and effective (Currier et al. 2008). However, providing universal bereavement services is unnecessary, and offering therapy to resilient individuals is known to be of limited benefit (Schut and Stroebe 2005; Wittouck et al. 2011).

A tiered or layered approach to bereavement care has been advocated based on meta-analyses of clinical trials (Schut and Stroebe 2005). However, there appears to be a dearth of contemporary practice standards that explicitly articulate what resources palliative care services should allocate, when they should allocate them, how, and by whom. Findings from the USA and Australia indicate that bereavement coordinators and counselors are not available in the majority of hospice or palliative care services, bereavement support is highly variable, and there is insufficient evidence-based guidance (Demmer 2003; Mather et al. 2008). Recent data from Europe also indicates a lack of guidance on bereavement support and a reliance on intuition over evidence

when responding to bereavement care needs in palliative care (Guldin et al. 2015). Alarmingly almost one-fifth of palliative care services provided no bereavement support (Guldin et al. 2015). Furthermore, services may not formally recognize family carers as "clients" consequently bereavement support needs for many may go unmet.

Given the variability in the adaptation to bereavement, it is often difficult to make confident predictions in terms of longer-term functioning of bereaved individuals before a minimum of 6 months post-death. At this point, tools such as the PG-13 (Prigerson and Vanderwerken 2008; Prigerson and Maciejewski 2012) have been found to have effective predictive validity and reliability for identifying a prolonged and complicated grief disorder.

Provision of bereavement support is an essential component of palliative care service delivery and is explicitly acknowledged in several national and international publications (National Institute for Clinical Excellence (NICE) 2004; World Health Organization 2016; National Coalition for Hospice and Palliative Care 2013; De Lima et al. 2012; Hall et al. 2012) that have established recommended standards which are recommended as a minimum level of bereavement support to be provided to primary carers and bereaved individuals by specialist palliative care services. The guiding principles underpinning these standards are:

Standard 1: Access

All primary carers of clients cared for by a specialist palliative care service are eligible to access palliative care bereavement services regardless of age, gender, culture, sexual orientation, socioeconomic status, religious beliefs, and physical or other disabilities or abilities to pay.

Standard 2: Coordination of bereavement services

Bereavement programsin palliative care services should provide coordinated services.

Standard 3: Training and support

All staff in a palliative care service, including administrative staff, will come into contact with bereaved people and will therefore require training and support in dealing with bereaved individuals. Staff and volunteers who have contact with bereaved individuals are required to achieve appropriate competencies in delivering bereavement support.

Standard 4: Screening and assessment

Screening and assessment for the presence of psychosocial and spiritual distress and risk of complicated grief is a continuous process undertaken from the time the client enters the palliative care service to many months after the client's death (where pertinent). These assessments are multidisciplinary and interdisciplinary as clients may disclose different information to different staff at different times.

Pre-death screening and assessment

Several tools are recommended for screening for psychosocial distress such as the Distress Thermometer (National Comprehensive Cancer Network 2013) and the General Health Questionnaire (McCabe et al. 1996; Goldberg et al. 1997). The PG-13 (Prigerson and Vanderwerken 2008; Prigerson and Maciejewski 2012) has been found to have effective predictive validity and reliability for identifying problematic bereavement experiences. Where pertinent the screening should be followed up with a comprehensive holistic assessment and/or referral to a suitably qualified professional. However, there is insufficient empirical evidence to support the validity of one particular tool to screen for risk of complicated bereavement prior to the person's death. For this reason, in addition to the use of a tool, a structured assessment should be undertaken through a conversational exploration of risk factors and strength/resilience factors.

Post-death screening and assessment

Due to the variability in the adaptation to bereavement, it is difficult to make safe predictions in terms of longer-term functioning of bereaved individuals before a minimum of 6 months post-death. There are several different tools available to screen for risk (Sealey et al. 2015); tools such as the PG-13 (Prigerson and

Maciejewski 2012) appear to have predictive validity and reliability for identifying a prolonged and complicated grief disorder.

Standard 5: Bereavement support strategies

The recommended bereavement supports include two types of strategies:

1. Universal strategies that are targeted at all carers and bereaved individuals.
2. Specialist bereavement support strategies targeted at those with elevated risk of developing prolonged or complicated grief or with current psychosocial and/or spiritual distress.

Universal strategies include:

(a) Screening and risk assessment

Screening to identify bereavement support needs does not need to be arduous or overburden already struggling palliative care services. We need to move beyond merely identifying risk factors for CG and toward an understanding of mediating factors. In this way, we can move beyond just identifying those at risk but also minimize the development of grief complications.

(b) Best-practice symptom management of the terminally ill client to reduce the impact of traumatic death on carers as well as the client themselves.

(c) Provision of structured information and support at various points along the grief trajectory including at admission to the palliative care service, when death is imminent, immediately following the death and at regular intervals following the death such as 3, 6, and around 12 months (and beyond if appropriate).

(d) Provision of access to support strategies such as participation in a bereavement information session and opportunities to review and reflect on the experience of loss and activity-based programs such as walking, meditation, and music and art groups.

Specialist bereavement support strategies may include:

Bereavement counseling and psychotherapy using evidence-informed specialist interventions for complicated grief such as:

- Cognitive behavioral therapy (CBT) for complicated grief (Boelen et al. 2006)
- Family focused grief therapy (Kissane and Bloch 2002)
- Complicated grief treatment (Shear et al. 2005)
- Meaning reconstruction approaches to grief therapy (Neimeyer 2000)
- Online support (Wagner et al. 2006)
- Bereavement support groups

In general, the more complicated the grief process, the greater the efficacy of specialist bereavement interventions. The empirical evidence underpinning these interventions should be explored comprehensively prior to implementation.

Standard 6: Clinical handover and referral to specialist services

Where provision of bereavement support falls outside the skills and competencies of palliative care staff, referral to external specialist agencies or practitioners is undertaken.

Standard 7: Community education and health promotion

The importance of promoting community awareness of bereavement issues and acceptance of the bereaved is recognized and acted upon. Information regarding grief and bereavement is available for general practitioners, employers, and other groups.

Standard 8: Privacy, confidentiality, and consent

The palliative care bereavement program ensures the privacy and confidentiality of its bereaved clients.

Standard 9: Integration with the health and support system

The bereavement support program is part of a general health and support system working to promote the health and well-being of bereaved individuals and the wider community.

Standard 10: Resource allocation

One study highlighted that less than 5% of the palliative care budget is directed to bereavement services (Breen and O'Connor 2007). Resources should be allocated in a systematic manner that allows the palliative care service's bereavement program to respond to the changing needs of clients and staff.

A key measure of quality palliative care should be the well-being of family carers in the years after relinquishing the role (Hudson 2013). Accordingly, bereavement support should be targeted, evidence based, and systematically applied. However, the development of bereavement services has lagged behind other palliative care initiatives (Morris and Block 2015), and scientific inquiry into meeting the needs of bereaved family caregivers has received insufficient attention (Stroebe and Boerner 2015).

11 Conclusion

Bereavement support is core to palliative care, yet the rhetoric is not always matched by the reality. Bereavement care is often haphazard and under-resourced and frequently does not reflect contemporary evidence.

Bereavement care is an integral component of palliative care as clinicians sustain continuity of care in assisting the bereaved. Knowledge and competency in assessing grief is essential to enable recognition of the significant minority of the bereaved who can benefit from additional assistance. Routine assessment of the bereaved for risk factors for complicated grief provides a reliable method through which clinicians can intervene preventatively to reduce unnecessary morbidity. Effective therapies are available to assist in the management of complicated grief, and palliative care practitioners should be skilled in their application or understand the circumstances when referral to more specialist practitioners is most appropriate.

Abstract

This chapter aims to tackle end of life issues for patients and their families. It will reflect on the process of disease to understand when "end of life" begins and what this stage entails. It will also address adjusting expectations and treatments, symptom management, and emotional and spiritual care at this stage of the disease. Care for end-of-life patients who are dying and their families will additionally be addressed, as well as the attention that healthcare professionals provide to patients and their families in consideration of different religious perspectives.

1 Introduction

Palliative care also involves caring for people who are nearing death and is referred to as end of life care. End of life care occurs in the last part of a patient's life, but the timeframe can be difficult to predict. Typically, it happens in the last few months, depending on the underlying diagnosis and clinical course. End of life care is an important part of palliative care for people who are nearing death.

End of life care aims to help people live as well as possible and to die with dignity. It is not just about the practical and technical delivery of medical care, but rather also involves supporting and providing available information both to patients and the people who are important to them.

Healthcare professionals should ask about patients' wishes and preferences and take them into account as they work with patients to plan their care.

2 Beneficiaries Of End Of Life Care

People in a variety of situations can benefit from end of life care. Some may have a life expectancy that does not go beyond the next few hours or days. Others receive end of life care over many months. This includes people whose death is imminent, as well as people who (NHS Choices 2015)

- Have an advanced, incurable illness such as cancer, dementia, or motor neuron disease
- Are generally frail and have co-existing conditions whose diagnosis gives them a life expectancy of less than 12 months
- Have existing conditions that make it possible for them to die from a sudden crisis in their condition
- Have a life-threatening, acute condition caused by a sudden, catastrophic event, such as an accident or a stroke

3 Changing The Goals Of Care

End of life care can be provided at home, in care homes, hospices or hospitals, depending on a patient's needs and preferences. The important thing is to have the goals of care clear.

End of life care aims to help people live as well as possible and to die with dignity and to help patients, and the people most important to them, to maintain the best quality of life possible. Holistic assessments of the patient and global care are essential for providing high quality care that prioritizes achieving patients' comfort and wellbeing, as well as that of the people closest to them, until the last days of life.

A number of healthcare professionals can be involved in care at the end of life in order to achieve the goals of care. For example, hospital doctors and nurses, general practitioners, community nurses, psychologists, hospice staff and counselors, as well as social care staff, chaplains (of all faiths or none), physiotherapists, occupational therapists, and complementary therapists, may all be involved. The healthcare professionals involved in a given care plan need to appropriately coordinate and to consider patients and families' previous experiences, including their cultural and spiritual backgrounds.

4 Diagnosis of Impending Death

Predicting the prognosis of advanced diseases can be **complex**. Patients and their families often ask for specific timeframes, which are difficult to set. But when a patient is in his last days of life, several signs help to identify this situation and, in general, healthcare professionals are more precise when the prognosis is shorter rather than longer. Professionals should be alert and prepared to detect these signs and be able to inform the family, the patient and the rest of the team about the impending end. Palliative care professionals must incorporate this responsibility into their work, which is valuable for patients and other professionals (Pontin and Jordan 2013).

4.1 The Importance Of Knowing How To Diagnose Dying

A correct diagnosis allows patients to adjust their expectations and treatment objectives during their last days.

For the family, knowing in time allows them to call upon other family members that may be farther away, to finalize preparations and pending issues, to organize religious rites according to the patient's beliefs and culture, and even to say goodbye.

For the medical team, identifying an impending terminal prognosis helps to focus all care on the patient's comfort, eliminating elements that do not contribute thereto and that may interfere with or tarnish a person's last moments. Healthcare professionals carefully review the patient's surroundings, starting with medical orders and specific and individualized care plans. They change the focus of attention to the patient's comfort in all senses, thus taking care of and accompanying him.

If an impending death is diagnosed in time, the patient can be transferred to the place where she prefers to die if it is suitable, whether that be at home or in hospice. If the situation is not properly identified, a patient may die in a place or under conditions that do not line up with their desires, or they may be on the receiving end of inappropriate or invasive measures during their last days. The task of adapting the care plan is easier for everyone if good prior communication – including a full understanding of the patient's wishes before the crisis (advanced care planning) – was established beforehand.

4.2 How to Diagnose Impending Death

This requires taking into account certain signs that the patient presents (Hui et al. 2014), some measures that can help guide, as well as the team and companions' perceptions. It is a clinical diagnosis that requires an overall view of the patient and his evolution.

4.2.1 The Signs

The most frequent signs include a marked **functional deterioration** and **dysphagia**, with patients gradually losing the ability to swallow liquids, or said task becoming very difficult, although they may still retain the ability to take

small sips. Decreased levels of **consciousness** or, occasionally, terminal delirium may be accompanied by moaning that originates in the vocal cords, including grunting or groaning, which are a sign of neurological changes. **Distal cyanosis** and lividity in the knees or thighs are easily recognizable during physical examination. It may also be impossible to feel the **radial pulse** and coldness in the hands and feet is frequent. In addition, we find changes in breathing, including periods of **apnea**, sometimes a few seconds but sometimes lasting for about a minute, or **Cheyne-Stokes** respiration (growing and decreasing periodically, with intermediate periods of apnea), superficial respiration, noisy or **rattling breathing** with jaw movements or out of breath. One of the most obvious signs is **oligoanuria**, and sometimes edema. All this can be accompanied by tachycardia and a tendency towards hypotension (Hui et al. 2014).

4.2.2 Prognostic Scales

In patients with cancer, the use of prognostic scales can be useful, such as the Palliative Performance Scale (**PPS**), which measures several parameters, including evidence of disease, the ability of patients to walk and care for themselves, and their ingestion and awareness levels. The lower the PPS score, the shorter is the prognosis. A recent study concluded that a PPS of 20% or less associated with **drooping of nasolabial fold** is a reliable predictor of a 3-day life expectancy (Hui et al. 2015). Other scales, such as the Karnofsky index or the PPI (Palliative Prognostic Index), may also be helpful in determining prognosis.

4.2.3 A Global View and Communication

When a patient is thought to be in his last days, and the above points have been reviewed, it is time to share this information with the multidisciplinary team that cares for the patient, thus facilitating adequate coordination and comprehensive care. Doctors tend to overestimate patients' prognosis, while nurses often realize the end is near first (Pontin and Jordan 2013). Sometimes, the patient himself may feel that the end is approaching. If there is a close and preestablished relationship with the patient, it is time to convey this impression and share it with the family.

4.3 How to Respond to Situation of Impending Death

The patient's last hours and care objectives should be recorded in the clinical history.

4.3.1 Emotional, Social, and Spiritual Support

The end of life has a high emotional impact in patients, their relatives, and caregivers. If a medical professional only visits the patient occasionally, it may be more appropriate for their main doctor to talk to them about the situation. The medical professional in question should begin to review and clarify the patient's wishes and their needs, which are physical, social, spiritual, and emotional, in an attempt to find out if the patient has the means and sufficient support to face the diagnosis.

The family should be informed about the signs as they present themselves, including those that will manifest in the future and their meaning and treatment. **Exploring relatives' fears and previous experiences** may help to accompany them in the process. The doctor can delicately tell the family and patient about the availability of spiritual support in accordance with their beliefs.

4.3.2 Review Medical Records

Occasionally, patients with advanced diseases accumulate medications in the last year of life (McNeil et al. 2016).

(a) Necessary treatments should be determined, which include excluding possible treatments that do not contribute to the patient's wellbeing or that could even diminish their level of comfort. This is often easy, for example, with primary prevention guidelines and more difficult with secondary prevention guidelines in patients who have already had problems like ischemic heart disease or seizures. If the patient cannot eat, the risk of hypoglycemia secondary to insulin should be assessed. Treatments that are unanimously

considered superfluous should be taken away first. In general, the **minimum** level of necessary medication should be maintained for symptomatic control to avoid side effects and interactions.

(b) Medical professionals should review how to deliver medication to the patient. If he or she has lost oral functioning, or is expected to lose it in the next few hours, the practitioner should make sure that alternative routes are identified. The intramuscular route is considered the last option, while the intravenous route is an option if already in place; otherwise, the first option is the **subcutaneous** route, which is also safe and accessible outside of the hospital context. The transmucosal or sublingual routes may be damaged by xerostomia. Adult patients and family members react poorly to rectal administration of medication in the presence of viable alternatives.

(c) Other medications should be maintained or prescribed to **prevent** undesirable situations, such as antiepileptic medicine or benzodiazepines in patients at risk for seizures. Certain prescriptions should be left to be administered **according to the nurse's assessment** taking into account that some symptoms may appear when doctors are absent. Indications, dosage, and frequency of administration should be clearly specified.

(d) The benefits and possible disadvantages of artificial **hydration** in each case should be discussed. It is sometimes necessary to relieve symptoms related to dehydration, but it can worsen others such as rales, edema, and dyspnea. Artificial calorie intake does not improve energy, extend survival, or increase comfort in the last days when the patient cannot **feed** him or herself. These issues must be delicately addressed with the patient and family, allowing them to express their opinions and emotions.

4.3.3 Increased Focus on Specific and Individualized Care

(a) Attempts should always be made to include the patient's preferences and the family's participation. Active involvement helps both parties maintain a close relationship and a helpful disposition on the part of family member(s) or loved one(s). Instructing and educating the family in care is one of the essential missions of at-home care.

(b) Special care should be taken of the **skin** by attempting to maintain adequate hydration and preventing ulcers related to pressure. This includes postural changes when the patient can tolerate them. Healthcare professionals should also attempt to maintain the patient's personal **hygiene,** adapting it to the maintenance of general comfort.

(c) Practitioners should ensure adequate care of the **mouth**, which is usually dry and can be painful, seeking to moisturize, moisten, and clean it carefully if the patient tolerates care and it brings him or her relief. For the lips, fatty preparations are better than glycerin, and sprays and swabs soaked or prepared in gel can be used for inside the mouth. **Oral ingestion** should be limited according to the patient's level of consciousness and ability to swallow because of the risk of bronchoaspiration. If feasible, the patient can enjoy cold, thick foods.

(d) If the patient is unable to move to go to the bathroom or has lost all or part of his or her **sphincter control**, practitioners should seek the most appropriate and comfortable way to meet these needs, recognizing the need for privacy and the difficulty of adapting to the loss of autonomy. A bladder catheter can be considered in some cases.

(e) The patient's **surroundings** should be taken care of, respecting natural light, but avoiding sound and excessive stimuli. Practitioners should facilitate the family's presence. The **monitoring** of vital signs will become less frequent in an attempt to respect the patient's need for rest and so as not to alarm those present. Instead, monitoring signs of suffering should be intensified and the practitioner's presence in this sense should be frequent, appropriate, and calming.

5 General Symptoms Near the End of Life

The end of life requires careful and expert management of symptoms, in addition to gentle and humane treatment at all times. Families should receive the message that this is a priority to which effort and resources will be devoted, which may comfort them and encourage them to transmit their concerns or perceptions of suffering (Blinderman and Billings 2015). Family members help healthcare professionals to detect changes in the patient's facial expression and restlessness.

The following includes a description of the most frequent symptoms and their treatment. In the context of the end of life, practitioners should seek to implement the best possible symptom control in accessible and noninvasive ways, taking into account that the patient probably cannot swallow or experiences much difficult doing so, and that a hospital is not the only place where care can occur (Kehl and Kowalkowski 2013; Bartz et al. 2014).

5.1 Pain

Pain is frequent at the end of life; 40% of hospitalized patients present moderate or severe pain in the last 3 days of life. If the patient complained of pain previously and is incapable of expressing it in his or her current state, practitioners should assume that pain medicine is still necessary and treatment should be adjusted accordingly.

Expressions associated with pain should be closely monitored; relatives and other healthcare professionals are to be asked if they detect signs of pain in the patient's movements or gestures. Careful physical examination in search of pain that cannot be verbally expressed is unavoidable; therein, healthcare professionals should look at the patient's facial gestures and his body position, trying to locate suspected pain points with palpation and any skin alterations or deformities that may cause pain.

Pain management should be effective and quick; thus, the administration of opioids is usually necessary. Oral slow release or transdermal administration is not appropriate in this situation because patients tend to eliminate waste less effectively and thus have more side effects from accumulation of metabolites. Rapid and short acting prescriptions should be used, preferably subcutaneously.

Recommended starting doses:

- Subcutaneous Morphine (consult the formulation available in each country and the recommended doses)
- Oxycodone, 2 mg, subcutaneous
- Hydromorphone, 0.4–0.8 mg, intravenous or subcutaneous

The dosage and frequency of administration should be periodically reviewed because the patient's needs may change quickly. Prophylactic doses should be prescribed for procedures known to cause pain.

5.2 Dyspnea

Dyspnea can be accompanied by weakness or anxiety and is stressful for the patient's loved ones. It is easy to recognize if the patient cannot express himself with words. It is not difficult to identify because the patient tries to open his airway as wide as possible by opening the mouth or using auxiliary muscles. Opioid management is similar to pain management, although the required doses are less and morphine is the best choice. The use or maintenance of oxygen therapy should be evaluated individually; if symptomatic hypoxemia presents itself, oxygen administration through the nasal cavity is preferable to a mask because it is tolerated better (Campbell et al. 2013). Other more general measures are effective in relieving the patient and they encourage caregiver participation. Use of a hand or small battery operated fan near the nose and mouth, thus maintaining fresh air, as well as raising the head of the bed, leaving the patient space and trying to convey a sense of tranquility, help the patient to adopt a good breathing posture.

5.3 Delirium

Once reversible causes of delirium have been ruled out, this state is referred to as *terminal delirium* during the end of life. It is often associated with other symptoms and decreases in intensity when treating pain appropriately, for example. The treatment of choice for terminal delirium is haloperidol (0.5–1.5 mg subcutaneous or intravenous), and other atypical or second generation antipsychotics may be used (Boettger et al. 2015). If the patient does not respond to these medicines, it is useful to administer benzodiazepines subcutaneously or intravenously (lorazepam or midazolam). Appropriate prescriptions include the following:

- Haloperidol, 3–6 mg, subcutaneous or intravenous over 24 h
- Olanzapine, 5–10 mg, over 24 h

The patient's surroundings must first be adapted to facilitate his or her bearings and need for rest, avoiding excessive stimuli. Professionals should explain what is happening and the treatment objectives to the family. The main objectives are to ensure calm, to prevent falls or other harm to the patient, and to alleviate the suffering it generates. Sedation is not the primary goal, although it is a frequent side effect of the most frequently used medicines.

5.4 Anxiety

In a patient's last days, it is difficult to distinguish anxiety or anguish from agitation. If healthcare professionals know the patient and have ruled out delirium, anxiety can be treated with benzodiazepines on demand or in perfusion. Doses are lower than those used for other situations and are usually sufficient with 10 mg of midazolam or 1.5 mg of lorazepam over 24 h. These doses, however, may be higher if the patient was previously treated with benzodiazepines for a prolonged period.

5.5 Nausea

As with every stage of illness, healthcare professionals should always think about possible causes to recommend the most successful treatment. At the end of life, there is an additional possibility that respiratory secretions or constipation may rarely cause nausea, although patients do not usually vomit at this stage. At times, in conjunction with postural changes, for example, patients can involuntarily expel secretions or food remains. It is likely that the cause of nausea is not specifically treatable, such that careful symptomatic management should be undertaken. Medication is chosen based on the suspected etiology and sometimes it is necessary to combine two medications to achieve adequate control.

- **Metoclopramide** is the first choice, between 30 and 60 mg over 24 h subcutaneously or intravenously.
- **Haloperidol**, if a central cause is suspected, 1.5–2 mg of haloperidol subcutaneously over 24 h.
- **Dexamethasone**, 4–8 mg subcutaneously or intravenously every 24 h, as adjuvant or in cases with clear cerebral edema or bowel obstruction; if bowel obstruction is clear and established, add Octreotide 300-600mcg over 24 h subcutaneously or intravenously.

5.6 Seizures

For patients with a history of seizures who were already being treated with antiepileptic medicine, an attempt will be made to continue administering the same medication, although the delivery method may change in accordance with the patient's state. There is evidence that supports administering some medicine subcutaneously, like phenobarbital or levetiracetam (Remi et al. 2014). For crises or patients who present seizures for the first time in their last days or hours of life, benzodiazepines are the most appropriate treatment.

5.7 Fever

Some patients have a fever at the end of life. If no obvious infection is present, it is typically associated with oncologic disease or brain damage. If a patient is unable to swallow, intravenous administration of paracetamol is effective, especially if the patient or family wishes to avoid rectal administration. If the only possible means of administration is subcutaneous, ketorolac may be used. Physical interventions help improve levels of comfort.

5.8 Rales or Death Rattle

Noisy breathing (bubbling or rales) is due to the accumulation of bronchial secretions and saliva, usually in the bronchi, trachea, and oropharynx. It may be unpleasant for the family and companions, but it is important to let the family know the person is not "drowning." Practitioners should take into account the impact that these noises have on caregivers and try to treat them when possible.

Some general measures work very well, such as postural changes, raising the head of the bed 30 degrees or the gentle aspiration of secretions if the patient is unconscious.

Depending on the availability and commercialization of some pharmaceuticals, different guidelines are used in different countries. They can cause sedation, worsen dry mouth, and even favor urinary retention. The use of pharmaceuticals that require oral administration is not feasible because patients have usually lost the ability to swallow when they have rales (Kintzel et al. 2009).

There is not enough evidence to show that any intervention is superior to placebo in the treatment of noisy breathing, and there are insufficient data (Wee and Hillier 2008).

The tested pharmacological alternatives include the following:

- **Hyoscine butylbromide (buscopan)**, 60–90 mg every 24 h or more, subcutaneously or intravenously

  It does not cross the blood-brain barrier and is less sedative.

- **Hyoscine hydrobromide (scopolamine)**

  It can be used subcutaneously, transdermally or intravenously and the usual subcutaneous dose is 1.5 mg/24 h.

  It may cause sedation and confusion or worsen delirium.

- **Glycopyrronium bromide.**

  The subcutaneous dose is 0.6–1 mg / 24 h; an oral dose can be used sublingually reducing the dose to 0.4–0.6 mg every 24 h.

  It does not produce sedation or confusion.

  A recent study advocates for the use of **atropine** (in ophthalmic form) administered sublingually (Protus et al. 2013).

  There is not enough evidence about the cardiac effects it can produce (Protus et al. 2013).

6 Holistic Care

As explained in the section above, patients experience physical changes, as well as emotional and spiritual ones, as they approach the end of life. All of these changes are part of the natural way in which the patient prepares himself for this final stage of life. The emotional and spiritual process is individual since each person is unique and needs to do things his or her own way. However, some general considerations of common emotional and spiritual processes are explained in what follows.

6.1 Emotional Care

The following includes an overview of some of the most common emotional reactions at the end of life, aiming to help understand them and to offer some suggestions on how to deal with these reactions. Hope, anger, maintaining control and dignity, and meaning-making will be discussed as part of the process of coping with and adapting to the end of life.

6.1.1 Hope

The concept of hope has been linked with treatments and cure. At initial stages of disease, patients may manifest hope for a cure, but, as the disease worsens and the end of life approaches, patients may feel that all hope is gone. This state of hopelessness can be associated with intensifying depression and a desire to die (Rodin et al. 2009). In a study involving advanced cancer patients, 48% reported at least some sense of hopelessness (Wilson et al. 2004).

Hope is present throughout the illness trajectory and changes accordingly. Palliative care certainly includes hope, though with a slightly different perspective (Nekolaichuk 2005); it identifies other things to hope for that are more achievable and involves hope for the individual. The therapeutic value of hope when it comes to life-threatening illnesses is documented. Hope has been positively linked to effective coping. Living with meaning and hope is one of the six essential elements for psychosocial and spiritual well-being (Lin and Bauer-Wu 2003). Several papers highlight the need to intentionally incorporate hope within end of life care (Sullivan 2003). This can be done by jointly identifying other things to hope for – e.g., good symptom control, staying at home, being with family – and developing realistic plans to achieve them. In addition, some interventions focused on hope for terminally ill patients (e.g., viewing a video on hope and choosing one of three hope activities to work on over a week) could be used given that there is some evidence that hope offers a statistically significant improvement of quality of life for the intervention group versus the control group (Duggleby et al. 2007).

6.1.2 Anger

Anger may arise from fear or feelings of impotence and is a reflection of one's response to the loss of control. During illness, the patient is forced to deal with a series of losses such as the loss of his or her role in life, of functional capacities, of independence and even the awareness of dying. Approaching death leads to another loss that can be expressed with inadequate demands or complaints. Anger can temporarily give a dying person the sense of being in control and block out the emotion of fear. Expressing this anger can be a process towards accepting reality and should be understood as the inability to deal with the situation at hand.

Family members may also become angry because of perceived inadequacies in care and struggles to accept that their loved one is dying.

This feeling is difficult for health professionals and requires a team response. Anger, no matter its cause, can obstruct effective interaction between the patient and the caregiver. If dealt adequately, the patient usually moves on; a painful experience full of fear can become an opportunity for forgiveness and meaning-making.

There are several steps to be taken into account when approaching anger (Philip et al. 2007). The first one involves preparing oneself for the fact that the patient is angry and seeking out an adequate atmosphere that transmits openness and allows for time to discuss. Professionals ought to clearly demonstrate being fully present with eye contact, body language, and verbal response and avoid responding with advice, critique, or reassurance. They should also offer therapeutic validation by identifying the underlying emotions and responding in a way that demonstrates an understanding of them. And they can demonstrate empathy with phrases such as, "I am sorry to hear that." It is important to listen and to engage with the patient in respectful communication, avoiding taking anger personally by remembering that anger can be a coping strategy that contains a different worldview.

In conversation, the angry person can be invited to redirect his or her emotions, encouraging reflection with questions like, "How do you manage to cope?" "What keeps you going even though you have endured so much?" "What do you think you need right now?" "How can I be most helpful to you?"

Anger can be an expression of the patient or the family's suffering. If anger persists, the care team needs to support each other when dealing with them (Philip et al. 2007).

6.1.3 Maintaining Control and Dignity

The experience of living and dying with a terminal illness shocks and shakes aspects that are

otherwise taken for granted. The patient may feel more vulnerable and question his identity, future, worth and even change his perception of dignity. In this situation, the patient is looking to gain some control over his life and death; some patients even express a desire to die in order to demonstrate some measure of control (Monforte-Royo et al. 2012).

One's perception of dignity can also be affected. The dignity of the person has become increasingly relevant in recent years in the healthcare field. A critical review of dignity models in healthcare concludes that all models consider dignity an intrinsic feature of human beings, but at the same time contemplate a subjective dimension that depends on personal experience. This subjective dimension of dignity is influenced by the person's own view of himself, the repercussion that the disease has on this view, the context, and even healthcare professionals' behavior (Errasti-Ibarrondo et al. 2014). These aspects acquire special relevance during terminal illness because the patient may feel more vulnerable. The review points out that Chochinov's Dignity Model is one of the most empirically based models applied to clinical practice (Chochinov 2002) (see ▶ Chap. 42, "Dignity in Palliative Care" for further study). It is important to highlight the concept of care tenor, which refers to the attitudes and behaviors of people who interact with the patient, which is especially applicable to healthcare professionals.

Research points out that relationships and the way in which healthcare professionals care for a terminally ill person make a difference in that patient's experience. Patients convey that authentic relationships with their nurses make them feel valued and dignified and alleviate inner loneliness (Errasti 2015). The way patients perceive of their care echoes dignity-conserving care, which promotes "being there" for the patient and interacting not only according to respective roles, but also as unique persons.

In this framework, clinical interventions have been developed to preserve and promote the patient's perception of dignity, which can be useful at the end of life. To this end, the Patient Dignity Question (Chochinov et al. 2015) stands out. It is a brief intervention to promote the patient's perception of self-value and recognition. The Patient Dignity Question proposes developing a conversation with the following questions:

What should I know about you as a person to help me take care of you?

What are the things that concern you most?

Who else is affected by what's happening with your health?

Who should be here to support you?

This kind of short intervention allows healthcare providers to get to know their patients and incorporate their values and perspectives into the care plan. A review suggests that this novel intervention is useful in approaching and getting to know a patient as a person (Arantzamendi et al. 2016). The TIME questionnaire (Pan et al. 2016) has also been developed and includes a set of questions based on identifying primary themes that emerge from the PDQs qualitative responses in order to elicit personhood and enhance dignity.

6.1.4 The Search for Meaning

The diagnosis of advanced disease and the possibility of dying often involve reprioritizing values and points of views. The patient often "opens his eyes" and sees what is really important in life. This situation leads to rethinking priorities and focusing more on what is really important as the reality of life's finiteness becomes more patent. The patient desires to achieve reprioritized goals and create a bearable or meaningful existence in the face of death.

Forgiveness may be one of these goals and may entail forgiving people who have hurt the patient, as well as asking for forgiveness from the people that the patient wronged. This is a way to diminish negative emotions and to generate well-being and calm (Mickley and Cowles 2001). This process helps re-establish relationships, close pending issues, and achieve a sense of transcendence.

Another goal entails meaning-making, even if this process is sometimes unconscious. Patients draw on their underlying beliefs, personal identities, moral principles, and religious beliefs to make sense of their situation. And, in so doing,

they search for meaning. The meaning left in their lives often corresponds to caring for others, resolving pending matters, and doing what they can to improve the lives of those they leave behind.

Valued relationships become even more important and relationships that were previously taken for granted, often with partners, children, and grandchildren, become more cherished (Sand et al. 2009). This sometimes entails saying goodbye and transmitting gratitude and love to loved ones. In this process, in cases where there are small children, the patient may aim to help them understand the situation and to transmit messages they consider vital. This can be seen as a luxury, since, as one patient said, "*Saying farewell to my children has been hard, but it is a luxury. Yes, yes, I said goodbye to the relatives that matter most to me and my best friends... It was a truly beautiful and fantastic experience that meant a lot to me because I could say goodbye to my wife, my children, my mother, my brothers, my friends ... to all the people that matter to me! I told them that probably not even Onassis or Rockefeller or anyone else had the opportunity I had. And that, to me, is a luxury*" *(Garcia 2017).*

Some people find meaning themselves, while others may benefit from specific interventions such as meaning-centered therapy (Breitbart et al. 2010; Breitbart 2002), dignity therapy (Chochinov et al. 2005; Aoun et al. 2015; Chochinov et al. 2011) (Martinez et al. 2017), or life reviews (Ando et al. 2010) that enhance a sense of meaning, peace, and purpose in their lives as they approach the end of life. Spirituality can be another source of meaning for people at the end of life and indeed constitutes an integral part of human life, which will be explored in what follows.

6.2 Spiritual Care

An acknowledgment of spirituality is necessary at the end of life, as well as throughout the advance of illness (Balboni et al. 2007), and influences decision-making when it comes to care (Silvestri et al. 2003).

From its origins, palliative care has included spiritual care as an essential part of caring for patients (Saunders 2001; Saunders 2003) (see ▶ Chap. 41, "Spirituality in Palliative Care"). It is one of the eight domains of quality palliative care and, as the consensus report developed by 40 health-related Canadian national leaders states, it is crucial (Puchalski et al. 2009).

The term spirituality has different connotations in relation to different backgrounds (e.g., Roman Catholic, Protestant, Eastern religions, or those with no faith at all). Herein, a broad definition is employed. Spirituality is understood as "the dynamic dimension of human life that relates to the way person[s] (individual and community) experience, express and/or seek meaning, purpose and transcendence, and the way they connect to the moment, to self, to others, to nature, to the significant and/or the sacred" (Leget et al. 2014).

Spirituality is a movement of personal searching in three directions: towards the innermost self in search of meaning, towards one's surroundings in search of connection, and towards the beyond in search of transcendence (Gomis et al. 2017). In this movement, many people who are confronted with a life-threatening illness begin to ask themselves "big questions," such as "What did I do wrong?" "Why do I have to suffer?" "Why should I go on living?" "Am I not just a burden to others?" This line of questioning can be called **spiritual** or **existential questions**.

Whether or not a person has expressed spirituality at other moments, the end of life experience will often lead to further exploration of this realm. Many people seek answers from within their life view or religion.

6.2.1 The Natural Course of A Spiritual Process

On life's path, everyone goes through a kind of spiritual process by which the uncertainty of existence is replaced by a kind of purpose or meaning. In this natural process, a number of themes can be distinguished (Leget et al. 2014).

- **Awareness of finiteness**: The moment that disease poses a threat to existence, the patient becomes aware of his or her finiteness. Some

people struggle with it, while others panic. This awareness may also cause the patient profound loneliness as they struggle to deal with and talk about it.

- **Loss of grip on life**: Being aware of one's finiteness causes the patient to feel as if he has lost his grip on life. The constructs of meaning he regularly relied upon no longer suffice for many aspects associated with a threat to existence.
- **Loss of meaning:** When death approaches, a sense of the future is lost. The patient often perceives his experience as unreasonable and meaningless.
- **Bereavement process**: The bereavement process begins when an awareness of all the things one must let go of, such as loved ones and plans, sets in.
- **Experience of connectedness**: This term is used to distinguish it from ways in which the patient previously searched for and found meaning. This experience may be new for the patient and therefore difficult to verbalize.
- **Integration of meaning and the experience of connectedness**: This happens when the search for meaning and the experience of connectedness are again integrated. When finiteness has been integrated into a system of meaning, the patient focuses more on the here and now and usually undergoes a shift in priorities.

6.2.2 Healthcare Professionals and Spiritual Care

During this natural process, the patient is searching and sometimes struggling to find his or her way. Healthcare professionals should be open to considering the spiritual dimension. What should healthcare professionals do specifically?

It is indispensable for healthcare providers to be open, which facilitates an appropriate atmosphere and attitude. Next, healthcare professionals should seek to offer some spiritual accompaniment, understood as the practice of recognizing, welcoming, and giving space to the patient's inner dialogue, such that he himself can give voice to his questions and life to his answers (Gomis et al. 2017). This spiritual accompaniment is part of palliative care's dynamic of interdisciplinary teamwork. It requires detection, exploration, and intervention.

- **Detection** is the responsibility and task of all team members; it consists of using various indicators or "warning signs" to detect the emotional expressions, values, and ethical conflicts, etc., that accompany spiritual experience. One must be attentive to expressions of hopelessness, to phrases like "I do not feel prepared to face the end" or "I think it's time to throw in the towel," and to objects that support a spiritual practice (e.g., certain books the patient is reading or religious icons in the room).
- **Exploration**: Some suggest that the relevance of spirituality for patients should be systematically evaluated. Instruments have been developed to this end, such as FICA (Borneman et al. 2010) or SPIRIT (Taylor 2006).

  From a different perspective, the beginning of spiritual exploration requires establishing a relationship of trust and a therapeutic link to identify suffering and its perceived causes or threats and to try to resolve or neutralize problems that can feasibly be dealt with (Gomis et al. 2017). In this preliminary part, exploration of the experience of suffering as a problem is fundamental, as well as being aware that people define existential suffering differently (Boston et al. 2011). Subsequently, variables in the experience of suffering are seen as a mystery, as an existential condition. In this approach, three levels are involved in spiritual exploration (Gomis et al. 2017).

  The **general level** explores worries, as well as the degree of difficulty in facing them, resources where help can be found, and the patient's expectations about the extent to which healthcare professionals can help. Questions that may be useful are: Is there something that, in this situation, worries you? In your current situation, what is most helpful to you? Is there something more that you think we could do and that could help you? The **intermediate level**

explores the resources and/or concepts that help patients through the process of dying, as well as the existence of certain questions (which express unresolved needs) and the degree to which they influence the patient's process. Some useful questions include other patients in situations similar to yours tell us that, in order to better support illness and everything associated with it, it is very useful to have a certain meaning in life, a way of understanding illness, relationships, your personal story, and so on. Do you have something like that? The s**pecific level** explores more explicitly the spiritual and/or religious realm, its potential benefits, one's desire to deepen therein, and the need to search for another interlocutor. Some questions that may be useful for this exploration include: Do you have any spiritual or religious beliefs? If so, how are they helping you in your situation?

These questions may be useful for exploring spirituality in a natural and nonthreatening way, but should not be used as a questionnaire, thus respecting the patient's personal dynamics. In fact, depending on the patient, third-level questions may appear in the conversation associated with the first level.

- **Intervention:** The mere fact of exploration has a therapeutic element and supposes – in some way – a potential first-level intervention because the patient perceives that someone cares about his person in its entirety. In addition, exploration already has a therapeutic edge because it facilitates a clarification of the internal world (Gomis et al. 2017).

  Specific guidelines have been published addressing the issue of spiritual support or accompaniment (Lo et al. 2002) (Rodin et al. 2009), and interventions have also been developed (Boston et al. 2011), such as a life review, meaning-centered therapy, or dignity therapy, which were mentioned earlier as therapies that promote meaning.

In the process of accompanying a person at the end of life, there may be conversations about death and about how he or she envisions and wants to prepare for it. The patient may appreciate having someone to talk to about this and patients often choose healthcare professionals to have this conversation with. In this type of situation, the practitioner must take a deep breath and stop to really listen to the patient, taking into account that, although death is a universal fact, not everyone faces it in the same way since one's history and culture strongly influence this realm. Listening attentively and responding to concerns, as well as taking about the patient's wishes at the end, are key elements of this conversation (National Institute for Health and Care Excellence 2017).

Reaffirming that the patient will be cared for until the end and that the medical professionals involved will accompany him and help him through the process of death is vital for the patient to feel comforted and recognized as a person. In some situations, various interventions meant to adequately relieve end of life suffering fail and palliative sedation may be considered (see ▶ Chap. 87, "Palliative Sedation: A Medical-Ethical Exploration").

7 Caring for the Family

As mentioned previously, the end of life affects patients, as well as their families. The concept of family is in constant evolution. It has cultural, legal, and sociological definitions – and different cultures define family in a variety of ways. Traditional definitions of family include what is referred to as the nuclear family – including a father, mother, and one or more children – or the extended family that includes grandparents, aunts, uncles, and cousins. Here, family caregiver is broadly defined and refers to any relative, partner, friend, or neighbor who has a significant personal relationship with and provides a broad range of assistance to a person with a chronic or disabling condition (Blum and Sherman 2010).

Palliative care includes caring for the family through the disease process, including at the end of life. The patient's family is like an important ally whose power must be recognized. Family members know the patient better than anyone and can help healthcare professionals do their

jobs. However, the end of life is an emotionally demanding time for the family and they also require the attention of healthcare professionals, taking into account the family's beliefs about health and illness, the culture they belong to, as well as the family's dynamics.

7.1 Preparing the Family for Impeding Death

A loved one's last days has an important emotional impact on the family. Healthcare professionals should consider who they are, as well as their family culture and history (especially religious/spiritual leanings) when caring for the patient and family. Healthcare professionals should consider the following:

- Provide the patient's family with **accurate information** about the prognosis, explaining any uncertainty and how it will be managed and, in so doing, avoiding false optimism (National Institute for Health and Care Excellence 2017). The disease progresses and the patient experiences functional decline. The family perceives that the situation is worsening and that their loved one is becoming weaker, but sometimes is not aware that death is so near. Healthcare professionals can help the family adapt and understand that their loved one is close to death.
- Provide family members an opportunity to talk about their fears and anxieties and to ask questions.
- Provide **information about how to contact healthcare professionals** – especially if the patient is at home – including contact details for relevant after-hours and emergency services.
- Explore the family's fears and previous experiences, since they sometimes make demands that do not line up with the patient's situation based on previous negative experiences.
- Explore whether the patient has prepared a written statement or has verbally stated **preferences about their care during the last days of life** (including any anticipated prescriptive decisions, advance decision to refuse treatment in certain cases, or details about any legal power of attorney for health and welfare).
- Explain that you will continue to care for the patient, prioritizing her comfort and wellbeing. This is an emotionally intense situation for the family, making it advisable to explain that healthcare professionals are on their side and will continue to care for both the patient and the family. In this phase, family members pay close attention to the interactions between healthcare professionals and the patient; it is thus essential to continue providing respectful and quality care that conveys that the patient is truly valued.

7.2 Caring for a Dying Person's Family

Healthcare professionals are supposed to witness and support the family's growing awareness of their loved one's deterioration and medical issues, including what these revelations mean for the family's future. Healthcare professionals have two important roles: to support family-patient interactions and taking care of family members.

The dying process is a roller coaster of emotions for the family too. **Sometimes family members do not know how to interact with a dying person**. Staff should suggest that family members remain themselves as the dying person continues to need intimate, natural, and honest relationships. The family should understand that they do not have to hide their tears, as crying is a way of showing love.

Healthcare professionals should promote discussions with the family about the role they want to play in the patient's care, remembering that it is very important to treat this topic delicately. Some family members may want to be involved in simple activities such as mouth care, while others may not feel comfortable being involved in direct patient care.

Healthcare professionals can encourage the family to think about and **discuss how they want to spend the final weeks and days**, taking advantage of the time that remains with their

loved one. They can decide to spend time together talking, simply being, or recalling old memories. It is important to promote meaningful interaction for the current situation and for future memories.

Healthcare professionals can also explain to relatives the importance of being thoughtful and that the patient feels their love and care. It is important to **show kindness,** as well as convey care and acceptance, thus building trust and enhancing self-esteem. It is helpful for family members to hold the patient's hand, listen to his stories, or just be with him, which will mark the family's future memories. It is not the time to try to change a loved one, but rather a time for full acceptance, support, and comfort.

It is also important to explain to the family the importance of **talking about death** when both parties are ready. While it is difficult to talk about, discussing death can ultimately alleviate fears and foster stronger emotional bonds between the patient and the family. It can help the family reflect on the importance of understanding their loved one's final wishes, so that they can carry them out as fully as possible. Some suggestions for this conversation include the following (Family Care 2016):

- Always use language about death that everyone is comfortable using. Try not to avoid using the word, but feel free to use metaphors or softer words (e.g., "pass away") as long as the fact that death has occurred is clearly explained.
- Do not rush the conversation. Make time for your loved one and realize that you might have to do so on a flexible schedule – predicting when someone will feel comfortable discussing death is often difficult.
- Do not discredit any of the emotions that you, or your loved one, feel. Be sure to acknowledge that these emotions may influence both parties' words and behavior. This will help your loved one to better understand.
- If a loved one brings the topic up and it scares you, do not shut the individual down by saying something like, "don't say that." Instead, even if you are not ready to talk about it, let your loved one discuss his/her feelings. Keep the conversation going by saying things like "really?" or by rephrasing what he or she has already said.
- Finally, talk about your loved one's current condition and his/her hopes or fears for the future.

Saying goodbye is an important part of the patient-family interaction at the end of life. Staff can facilitate it by highlighting its importance and suggesting it as a final gift of love since it contributes to closure and makes the final release possible. It may be helpful to suggest that family members sit close to the patient, take his hand, and say everything they need to say. It may be as simple as saying things like I love you or thank you; or it may involve recounting meaningful shared moments or saying sorry for whatever contributed to any difficulties in the relationship. Tears are a normal, natural part of saying goodbye and should be understood as an expression of love. Healthcare professionals should, in turn, promote an environment that facilitates saying goodbye. This includes adequate symptom control, giving the patient and family privacy by allowing them to be alone and ensuring a pleasant environment.

Healthcare professionals need to address caregivers' needs in a sensitive way, supporting them emotionally. Some suggestions include the following (Centeno et al. 2009):

1. Recognizing the family's suffering and taking an interest in how they are, may be enough for them to open up, improve their attitude toward professionals and share their concerns. It is important to use room visits to assess the family's needs, asking what help they need and how they perceive the patient's state.
2. Be willing and accessible so that the family can express their emotions. Reiterate your offer to help with any of their current needs.
3. Explore with the family the role they wish to have in caring for their loved one. This serves as a manifestation of affection and helps them to feel useful.

4. Explain that you cannot know exactly when the end is near, but do explain the patient's possible course to the family. In particular, it is important to explain, as mentioned previously, possible cognitive changes, the progressive decrease of consciousness, and respiratory difficulties. The impending death of a loved one is always a difficult emotional time, but knowing what to expect can help the family prepare.
5. In the case of families with children, it is important to help children situate themselves and prepare for their loss. The sooner children know what is happening, the better. It is important to reassure children that they did not cause this loss. When adults do not explain things to children, they are faced with drawing their own conclusions, which tend to be much worse than the facts. Ultimately, children are flexible and resilient and can deal with reality.
6. Allow the family to participate in decision-making, ensuring that the family agrees to and understands any changes to the care plan and that said changes are recorded in the clinical record.
7. Offer spiritual support to the family according to their beliefs. Spiritual care as a component of palliative care is also important for those close to the patient since their loved one's impending death can evoke spiritual questions for them as well.
8. Help the family prepare for the death of their loved one, as they may be prepared for the dying process but not for the actual moment of death. It may be helpful to encourage the family to think about and discuss what they want to do at death (i.e., funeral home, prepare the body). They may have talked with their loved one about it or they may know what he or she would like.
9. At the right time, the professionals in charge of the patient's care should discuss with the family the paperwork that needs to be done when the patient dies. Planning a funeral is a complicated process, which is made even more difficult by the emotional stress that accompanies the death of a loved one. Thinking ahead of time about these arrangements decreases the burden on those left behind.
10. Healthcare professionals should support family members who arrive after the patient has lost consciousness or has died, and thus have missed the opportunity for meaningful interaction. They may benefit from information about the patient's state, such as skin temperature and color change, or the jaw being relaxed and the mouth slightly open. Professionals should support them in having private time with the patient should they wish. This might not be an intuitive step for families, and encouragement from staff may be needed.
11. When the patient dies, the family should be supported and, without rushing anything, should be given a few moments of privacy if they wish. After this, the care needed in this situation can be performed, which will be explained later.
12. Help the family with the bereavement process. This can include a phone call to see how the relatives are doing or a condolences letter. There are also a variety of interventions specific to bereavement care, as shown by a systematic review (Forte et al. 2004).

8 Impact of End of Life Care on Healthcare Professionals

Working with patients who have incurable diseases and those in the process of dying exposes professionals to the physical, psychological, and spiritual suffering of patients and their relatives (Hanks 2009). This exposure means that working in palliative care can be challenging, rewarding, and stressful (Bruera et al. 2015). Professionals face a difficult reality that contains different kinds of suffering, a mix of feelings, and questions without answers. This reality may also force professionals to deal with their own mortality, fears, vulnerability, and the meaning they draw from life.

8.1 Definition and Overview of Distressing Experiences

There are a number of distressing experiences that palliative care professionals have to deal with. The most frequently researched are stress, burnout, and compassion fatigue.

8.1.1 Stress

Stress is defined as the body's physical, mental, or emotional response to change (Selye 1980). The European Agency for Safety and Health at Work has defined work-related stress *"in terms of the 'interactions' between employees and (exposure to hazards in) their work environment. Within this model stress can be said to be experienced when the demands from the work environment exceed the employee's ability to cope with them."*

Some studies have found that staff working in palliative care have less stress than other professionals working with patients (Bruera et al. 2015; Berman et al. 2007), but this does not mean that stress does not occur.

8.1.2 Burnout

Burnout is defined as "*the progressive loss of idealism, energy and purpose experienced by people in the helping professions as a result of the conditions of their work*" (Edelwich and Brodsky 1980). In addition, "*The root cause of burnout lies in people's need to believe that their life is meaningful, and that the things they do- and consequently they themselves- are important and significant*" (Pines 1993). It is a response to work-related interpersonal and emotional stressors and has three key dimensions: (1) overwhelming emotional exhaustion (EE), which is the basic individual stress dimension of burnout, (2) feelings of cynicism and detachment from the job, i.e., depersonalization (DP), which is the interpersonal context dimension of burnout, and (3) a sense of ineffectiveness and lack of personal accomplishment (PA), which is the self-evaluation dimension of burnout (Pines 1993). Yet, recent research shows that staff working in palliative care may in fact experience lower levels of burnout than professionals from other disciplines (van Staa et al. 2000; Hospice Friendly Hospitals Programme 2013).

8.1.3 Compassion Fatigue

This fatigue refers to an acute onset of physical and emotional responses in relation to work that culminate in a decrease in compassionate feelings towards others (Sinclair et al. 2017). It is considered a significant stress response in healthcare providers. The signs and symptoms of compassion fatigue can be classified as physical, behavioral, psychological, and spiritual and are thought to have a global impact on healthcare providers wellbeing (Sinclair et al. 2017).

Six occupational areas are associated with the factors that add to distressing experiences, including: (1) workload and intensity of work, (2) lack of autonomy, (3) social climate at work, (4) emotional demands on staff associated with multiple bereavements and grief, as well as exposure to patients and families' distress, and personal discomfort with suffering and death, (5) conflicting values and meanings that arise between the employee and health institution, and (6) working conditions (Bruera et al. 2015).

8.2 Facing Difficulties: Resilience

Resilience is an individual's ability to adjust to adversity, maintain equilibrium, retain some sense of control over one's environment, and continue to move on in a positive manner (Jackson et al. 2007). About resilience nature, Jackson (Jackson et al. 2007) believes that individuals can develop and strengthen personal resilience by developing strategies that reduce their own vulnerability and the personal impact of adversity in the workplace.

8.2.1 Strategies Against Professional Distress

A recent literature review (Hospice Friendly Hospitals Programme 2013) presented five elements that are effective in promoting resilience and avoiding distressing situations: (1) self-care strategies, (2) the creation of support groups, (3) the cultivation of supportive inter-professional relationships, (4) education and skill-building, and (5) meaning-making through ritual or commemoration.

1. ***The four dimensions of self-care***

   Caregivers cannot meet their patients' needs if their own needs are not met (Huggard and Nichols 2011) (Cohen et al. 2001). Self-care is associated with lower levels of stress and burden (Merluzzi et al. 2011) and emphasizes the obligation to take time for self-care (Cohen et al. 2001). This dimension includes maintaining one's health and wellbeing and exploring the feelings derived from being surrounded by difficult situations.
2. ***Inter-professional or specialty-based support groups***

   Inter-professional support groups are based on the idea that supporting the needs of professionals working with incurable disease may improve job satisfaction and prevent compassion fatigue (Hospice Friendly Hospitals Programme 2013) (Huggard 2012) (Wenzel et al. 2011). Several types of support groups are recommended depending on the characteristics of the person in need of support (Huggard and Nichols 2011) (Le Blanc et al. 2007) (van Staa et al. 2000).
3. ***Building supportive teams***

   Teamwork is the central idea of palliative care. This strategy is found in the idea of becoming a supportive team instead of just practicing teamwork. Some studies show improvements as a result of becoming a supportive team (Le Blanc et al. 2007) (Wenzel et al. 2011).
4. ***Education and skill-building***

   There is a need for continuing education focused on developing strategies that enhance professionals' coping skills (Wenzel et al. 2011) so that they can effectively assist in daily patient care. One study argues that end of life care providers "need to be taught a rational concern, which allows the expression of feelings without impairing the ability to make decisions, rather than a detached concern" (Le Blanc et al. 2007).
5. ***Meaning-making.***

   Spending "therapeutic time" with patients can be beneficial for both the patient and the caregiver (Cohen et al. 2001). This can help the professional to consolidate his or her experiences into meaning structures; the individual ability to make or find meaning can transform intensely stressful situations into positive experiences and can serve as a "profound motivational force" that improves quality of life (Desbiens and Fillion 2007).

9 After a Patient's Death

Procedures after death may vary locally so practitioners should be aware of local regulations, considering that they may differ depending on if death occurred at home or in the hospital.

9.1 Tasks to Be Completed After a Patient's Death

In today's hospital environment, it is clear that some relatives do not know what to do after their family member dies, so it is necessary for healthcare professionals to guide the family in the tasks to be completed, including:

(a) Tell the health professional to certify the death.
(b) Contact a funeral service.
(c) Specify the conditions, time, and place of burial/cremation.
(d) Write a notice for dissemination, indicating if a religious funeral will take place and the place of burial/cremation.
(e) Talk to the people close to the deceased and invite them to attend the funeral(s) and burial/cremation.
(f) The deceased's religious creed and his last wishes in this regard must be respected. The funeral chapel and the family and friend gathering' will accommodate the deceased's traditions.
(g) After a few days, it is recommended that relatives respond to the condolences they received.

Although the patient has passed away, healthcare professionals still have other things to deal with, including caring for the family, caring

for other patients who were close to the deceased, as well as caring for the medical team and for the deceased patient (corpse) (Centeno et al. 2009).

9.2 Caring for Family Members

The death of a loved one affects relatives emotionally, which is why the medical team must employ special tact. Family members can react very differently immediately following a loved one's death, and professionals need to know how to understand and respect all of these reactions. Professional must be available and must act naturally, displaying certain closeness. Words may be superfluous at this time and the family is often just grateful for the company (Centeno et al. 2009).

9.3 Caring for the Team

The death of a patient affects caregivers and, when it happens on a daily basis, caregivers' moods can be affected. It is therefore important to develop protective mechanisms for both individuals and for palliative care teams. In this context, it helps to share lived experiences, to review how the patient was cared for, and to recognize the work completed (Centeno et al. 2009).

9.4 Postmortem Care

Once the patient has died, death should be confirmed through available techniques by checking unmistakable signs, usually by means of an electrocardiographic record at the time that the doctor responsible for certifying the death of the patient deems necessary.

Professionals must take into account that sedated patients may have prolonged apnea pauses before dying, so they must rule out any confusion with a situation of apparent death.

After the health professional has verified the patient's death and confirmed it with the family, they should be allowed to remain as long as they need with the deceased, so that they can express their emotions.

Once the family has stayed with the patient as long as they need, they will be invited to move to another unit while health professionals proceed with the postmortem care of the deceased. This care consists in hygiene, withdrawal of clinical devices, and arrangements so that the deceased is in adequate conditions to be seen by relatives who wish to say goodbye. The corpse must be wrapped in a clean sheet or shroud. The deceased's privacy and right to professional secrecy should still be protected.

9.5 Farewell Rituals

A wake involves caring for and accompanying the deceased, and traditionally happened at night. Previously, the wake took place in the deceased's home since people usually died at home. Today, most deaths occur at a hospital, so the deceased is usually transferred to the hospital's mortuary or to the morgue (Centeno et al. 2009).

The deceased's religion and customs determine the relevant funeral rites. Today, different cultures and religions coexist and the rites involved in each case should be respected.

10 Religion and the End of Life

Care for dying patients has always existed in one form or another, but the modern hospice and palliative care movement is intimately associated in its origins with religious orders that cared for those suffering from life threatening illnesses and nearing the end of their lives. In fact, by the middle of the nineteenth century, a number of institutions and hospitals started establishing centers uniquely devoted to care for dying patients (Clark 2016).

Nowadays, even in the most commonly used definitions of palliative care, the spiritual component is included as a key element. The World Health Organization defines palliative care as "an approach that improves the quality of life of patients (adults and children) and their families who are facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification

and correct assessment and treatment of pain and other problems, whether physical, psychosocial or spiritual" (WHO 2017). After all, palliative care supports the person as a whole, which necessarily includes the spiritual dimension.

The importance of religion in palliative care is thus evident, and when reviewing current literature, there is a reasonably large body of research on this topic. Most existing studies have evaluated different religions and their impact on perceptions of palliative care (Steinberg 2011); they commonly note that most palliative care patients have spiritual needs that palliative care providers do not properly address (Richardson 2014). Similarly, in another study, under the assumption that "attending spiritual needs ensures that a dying patient has the chance to find meaning in the midst of suffering," a list of beliefs and traditions from Judaism, Islam, and Christians are presented, along with the way in which they portray dying and mortality (Puchalski et al. 2004). The idea of spirituality being a fundamental element of human experience is deeply established, along with how – viewed in this sense – "spirituality can be a key factor in how people cope with illness, and achieve a sense of coherence" (Puchalski et al. 2004).

Religion is also important during end of life care because it influences ethical (and therefore medical) decisions, which suggests that physicians and nurses should understand religion and spirituality in order to understand people's choices and "to respect their conscience and worldview" (Broeckaert 2011).

The importance and existence of diverse religions suggests the need to better understand them and how they consider issues related to dying since views associated with different religions can be essential knowledge when treating patients. Different religions hold diverse premises that most certainly influence the way a patient should be cared for. There are a few manuals/guides that present information on each religion, focusing on doctrinal elements and beliefs in relation to the concept of illness and death, as well as morality, behavior and commitments, practices and rites, prayers, organization, etc., which are all related to and closely conditioned by the specific religion (Unescocat et al. 2013).

Table 1 presents the most relevant considerations on illness, rituals, and death associated with the world's major religions (Unescocat et al. 2013), but a deeper reading is recommended when

Table 1 Considerations by religion (Unescocat et al. 2013)

	Illness	Rituals before death	Death and other considerations
Catholicism	Pain, disease, and death are all part of life Everyone should care about the sick, seeking to heal them and alleviate their suffering	Anointing of the Sick: The sign of the anointing of the oil gives "a special grace to the Christian experiencing the difficulties inherent to the state of serious illness or old age." The priest prays for the patient's health that he may be granted "strength, peace, encouragement, and the forgiveness of sins"	Death is perceived of differently by thinking of Jesus Christ on the cross and of the difficulties that other saints went through Even though the body ceases to have life, the soul survives and appears before God to be personally judged. The corpse must be treated with respect
Islam	Illness is considered a test of faith and not a punishment. The sick are encouraged to find healing and doctors to thoroughly seek a remedy. But ultimately God allows for healing; doctors and remedies are only means	When death nears, place the patient on his side, with his head facing the Qibla. If that is not possible, then place him lying on his back with his feet towards the Qibla. When suffering becomes intense, people in the room recite the Surah Ya-Sin and recite the profession of faith	Death is the beginning of another phase of existence, the return to God Each person dies at the appointed time and place After death, the eyes are closed and the body is covered. The corpse should be moved with the utmost respect, especially keeping in mind that private parts should remain covered

(*continued*)

Table 1 (continued)

	Illness	Rituals before death	Death and other considerations
Buddhism	Illness is inherent in the nature of living beings. It is the result of negative actions in the past and, at the same time, an opportunity to be free of them	The patient should be in an atmosphere that supports peace of mind. Sometimes, Buddhists give up painkillers to preserve a certain lucidity of conscience before death, which allows them to meditate	Death is the end of current bodily life, but not of individual existence The body must be wrapped in a plain sheet free of symbols. The body must be respected in this state for 72 h
Hinduism	Some consider Western medicine to numb the mind and pollute the body. Thus, they may resist treatment	When death is imminent, the patient is placed with his head facing eastward and the family may request that a lamp be lit near his head, asking those around him to focus on his mantra. The body is left in the foyer or on the floor of the hospital facing south	Death is a natural phenomenon of a life. It is a cyclical transfer from one vital state to another Once dead, the body and the religious objects adorning should not be touched. If you need to touch the body, you should check with the family
Chinese traditions	The rupture of the harmony in human relationships (Confucianism) or of human beings with nature (Taoism) manifests itself in disease since, in Chinese medicine, health is a state of physical and spiritual harmony with nature	Before death, the dying must see each of his relatives. Death is announced in community. The body is bathed in fresh water to make the trip to the next world comfortable. Relatives light an oil lamp at the feet of the body to illuminate their loved one's way to heaven and immortality	Confucianism does not tout the existence of another life after death For Taoism, death is a door to immortality and a release of the body

caring for patients of each religion or a patient of another minority religion.

The implications for medical practice are subsequently based on the fact that spirituality is an essential dimension of integral attention and that death and dying is interpreted depending on specific religious or personal convictions when facing the end of life. Thus, in the end, we aim not only to be respectful of everyone's beliefs, but also to know or at least have material on hand that provides information about the different religions and their associated convictions.

11 Summary

This chapter has explained the context of end of life care and its goals in caring for the patient and family. Palliative care prioritizes comfort, wellbeing, and dignity until the end.

The text additionally highlights the importance of diagnosing impending death such that healthcare providers are able to offer personalized quality care for the patient and the family as the end nears. Recognizing that a patient is nearing death helps professionals adapt physical care and symptom control, in addition to helping them accompany the emotional and spiritual process that facing death involves, whether as the patient or a family member.

Caring for patients and their families at the end of life is challenging, and it is important that healthcare professionals incorporate activities that promote self-care and resilience to avoid falling into burnout or compassion fatigue.

For reflection

The way in which the end of life unfolds leaves an indelible mark on those who

(*continued*)

accompany the dying, thus healthcare professionals have a fundamental role in ensuring that companions' memories are full of peace and, as much as possible, the absence of suffering.

Palliative Care Education: An Overview 49

Lis Latta and Roderick D. MacLeod

Contents

Abstract

Education has been a core function of all practitioners in palliative care since the birth of the modern hospice movement. Much progress has been made since palliative medicine was first recognized as a discrete medical specialty. In order to understand the complexities of education in this area, this chapter provides a broad overview of issues related to palliative care education from undergraduate students to continuing and postgraduate training and to the

needs of family carers and staff who work in residential aged care facilities.

The chapter initially outlines some of the principles of adult education by drawing on the work of several key theorists and then discusses the sociopolitical context of palliative and end-of-life care with due consideration to the changing needs of society. Evidence of progress in undergraduate and continuing education is presented and discussed as well as opportunities for advanced specialty training.

The learning needs of family carers and staff who work in residential aged care facilities are addressed with examples of the types of education and training that is available for these essential providers of palliative care and whose needs are often overlooked in traditional educational settings.

Finally, we provide examples of the many and varied educational methods that are currently in use including simulation, interprofessional education, and learning in the clinical setting.

I never teach my pupils, I only attempt to provide the conditions in which they can learn.
–Albert Einstein

1 Introduction

The development of palliative care as a discrete and recognizable medical specialty in the UK in 1987 presented new challenges to educators in the health professions. Until that time, the main focus of health professional education had been on knowledge and skill acquisition that was focused on cure, which was unsurprising given the advances in medical science and technology that occurred in the first half of the twentieth century. However, this single-minded focus on curative treatment denied many people a peaceful and dignified end to their life and replaced it with aggressive and invasive treatments that carried little if any benefit. The modern hospice movement grew out of an awareness that the care of people who were dying fell far short of what many people in modern society deemed acceptable, and as such, a new dimension to the training of healthcare professionals for the future began with the introduction of teaching in palliative care.

Because of the technological advances in medicine toward the end of the twentieth century, medical education in palliative care tended to focus primarily on techniques for the control or management of symptoms, and there was a real fear by some that palliative medicine would merely become synonymous with symptom management. From an educational point of view that has some attractions, it is far easier to gain knowledge of drugs and how to use them than it is to try and understand the lifeworld of someone close to death. However, symptom management is but one important area of palliative care. It is equally important to learn how to *be with* patients and families who are facing death and how to respond to and relieve suffering in all its guises.

It is impossible to overemphasize the importance of palliative care education, particularly in light of the changing needs of a rapidly aging population with a high prevalence of noncommunicable diseases. In order to be able to provide high-quality care at the end of life and avoid unnecessary suffering, the people who provide that care must be equipped with the necessary knowledge, skills, and experience to be able to do so. Palliative care education must therefore be widely available in the community and accepted as a core component of learning in the health and social care professions. This chapter begins with an overview of relevant adult learning theory before going on to discuss particular issues related to palliative care education and training.

2 Understanding Adult Learning

Once qualified in their chosen speciality, much of health and social care professionals' learning is self-directed, which requires individuals to be reflective, self-aware, and self-motivated learners and practitioners. All of these skills are essential attributes in the provision of high-quality patient care. Self-directed learning can be described as a process in which individuals take

the initiative, with or without the help of others, in diagnosing their learning needs, formulating goals, identifying human and material sources for learning, choosing and implementing appropriate learning strategies, and evaluating learning outcomes.

Self-directed learning takes a variety of forms ranging from informal and unstructured activities to intentional formal educational endeavors based on identified learning needs. Many hospices around the world offer continuing education programs for healthcare professionals with St Christopher's Hospice in London being an outstanding example as the pioneer of the modern hospice movement (www.stchristophers.org.uk/). Conferences, seminars, and workshops also provide a useful avenue for further learning, keeping up to date with recent research, and networking with colleagues who share similar interests. While many countries have excellent national palliative care meetings, notable international palliative care conferences include the International Congress on Palliative Care, the European Association for Palliative Care Conference, and the Asia Pacific Hospice Conference.

There are various types of self-directed learning, all of which are employed by healthcare and social care professionals at various times depending on their learning needs and professional requirements.

2.1 Informal Self-Directed Learning

This is seen as part of the normal day-to-day activity of professional development. There are no specific objectives, but it is rather an attempt to keep abreast of recent developments. The sort of activities included here are journal reading, ad hoc conversations with colleagues or experts (known as educational influentials – professional peers who are deemed to be experts in their field and therefore influential), attendance at regular continuing education meetings (grand rounds, journal clubs, etc.), preparation for lectures, or writing. Often these activities are not documented and are difficult to quantify, evaluate, and assess.

2.2 Semi-structured Self-Directed Learning

These activities are based around specific clinical problems. The clinicians have specific learning needs and objectives that can be related to current clinical problems. Commonly this sort of activity is in the form of discussions with colleagues (educational influentials), literature searches, medical informatics or reading.

2.3 Formal Self-Directed Learning

These are intentional efforts to learn specific topics, usually through a formal course or program, delivered locally or online by distance education and assessed formally with a qualification awarded on successful completion. Additional methods may include learning contracts, formal traineeships, informal traineeships, educational consultants, or specifically tailored plans. These activities are usually self-assessed. Typically, healthcare professionals draw on differing types of educational activities to meet their needs and draw on multiple resources. It is now commonplace in most parts of the world for these activities to be recognized as an essential part of professional development, and many healthcare professions including medicine and nursing are required to undertake continuing education in order to reaccredit for practice.

2.4 The Role of Reflective Practice in Learning

One of the central tenets of professional development is enhanced performance. Perhaps the most relevant work is that of Donald Schön (1987) who used experience as the critical piece of performance to understand how a professional's knowledge changes with what he termed "reflective practice."

Professionals develop a specific knowledge base that informs their work. Experience allows that knowledge base to expand in ways that cannot readily be linked to traditional teaching

methods. Reflective practice proposes that problems are often not clearly identified, and it is through a process of critical reflection that problems can be clarified and solutions or new strategies for future action identified.

Formal interdisciplinary team debriefings following a critical incident and mortality and morbidity meetings are good examples of formal reflective processes that enable individuals to gain an understanding of events from others' perspectives, support one-another, identify issues, and make changes for improved practice.

In Schön's model, learning is directed by performance-related problems, and teaching is seen as guiding or coaching performance rather than the more traditional telling of facts and theory. Learners work on specific professional problems standing alongside a professional as teacher or mentor in that area. Schön also talks of the "right kind of telling" that takes place when students work closely with their teacher or mentor to learn how to frame the questions and to respond in an appropriate manner. By this he means helping learners to see on their own behalf and in their own way what they most need to see and learn about.

It is essential to recognize that individual reflection in, on, and about professional knowledge and practice can be a powerful way of enhancing our understanding of it. Shared reflection with others who understand and can empathize with our experience and life world is especially valuable. This is why mentors, preceptors, professional supervisors, and critical friends (peer mentors) of all sorts are particularly valuable. When nonjudgmental conversations occur between or among collaborative practitioners where experience is reflected upon, it can be a profound and powerful learning experience for all concerned. Finding ways of encouraging and supporting collaborative, interdisciplinary reflection is an important professional development task.

2.5 Motivation in Adult Learning

The ability to make or set goals characterizes much of adult education, which tends to be driven out of curiosity or related to a specific self-identified learning need, otherwise known as intrinsic motivation. On the other hand, extrinsic motivation is an equally common motivator and is driven by external sources such as professional bodies and work-related requirements. Whatever the source, motivation drives learning, and in a modern society with vast resources of ever-changing knowledge, technology and skills, a common goal for educators is to help students become lifelong, self-directed learners in order to respond effectively to the changing needs of the population.

Important educational theories have contributed to our understanding of adult education. Schön (1983) described professionals' self-directed learning as an interaction with the environment in a reflective process which he calls "reflection in action." In this process, the learner becomes aware of a learning need when a "surprise" is encountered (also described as a discrepancy) through a process called "knowing in action." This is thought to be the embedded knowledge that makes up most of the activities of the clinician. Schön makes the point that it is not possible for a professional to work effectively if they do not have this embedded knowledge. In effect, knowing in action represents those activities that are routine and automatic – so deeply learned that they require little reflection or effort. An example of this is the recognition of a diagnosis of a commonly seen problem. This is the level that practice is based on fact and science. The development of a new problem or a doubtful diagnosis produces "surprises." When a surprise occurs, the clinician is caused to pause and reflect on what has happened and on previous actions. This process of reflection may lead to the selection of a solution. This process takes place during the patient-clinician interaction. This may then produce a response that may be appropriate during the patient encounter. The next stage of Schön's model is the "experiment." These experiments reflect the ability of the clinician to reconstruct the information, knowledge, and skills needed to accommodate what it was that was unusual about that encounter. The outcome of that action may then produce the opportunity for "reflection on action." This is when the new learning is

incorporated into the new body of knowledge and becomes part of the new knowing in action. This then is the closing of a loop that brings learning from previous experiences to bear on general procedures and develops new frames of reference for future problems. It is believed that this is one way in which healthcare professionals navigate through the maze of conflict, difference, and uniqueness that characterizes much of their work.

Julian Rotter's work on locus of control (1966) is particularly relevant to educational theory, especially when considering an individual's belief in their ability to effect a positive outcome or achieve learning goals. Individuals with an internal locus of control believe their actions have an effect on the world around them, whereas those with an external locus of control believe outcomes are due to forces outside of their control (e.g., people in authority or fate) and would occur independently of his or her actions (Rotter 1966). In social learning theory, a positive outcome that occurs as a result of an individual's actions reinforces the behavior, which creates an expectation of a similar outcome given similar actions in the future. However, if the outcome is not based on a person's own behavior (i.e., outside of the person's control), there is no such expectation, hence the power of positive reinforcement. On the other hand, a negative outcome or an identified gap between standards and performance has the opposite effect when upon reflection the practitioner learns to avoid certain activities to prevent further negative outcomes. Such experiences often motivate the individual to correct the deficit in their knowledge, skills, or behavior. Albert Bandura's social cognitive theory of the role of self-efficacy in learning and behavior (1977) explains this phenomena as an *outcome expectation* which he describes as "the conviction that one can successfully execute the behaviour required to produce the outcomes" (p.193). Self-efficacy refers to a person's belief in their ability to perform a specific behavior or skill and influences how people think, feel, motivate themselves, and behave and can be positively influenced by education. The greater an individual's self-efficacy, and the more rewarding the outcome expectancy, the more likely they are to be successful in their chosen endeavor (Mason and Ellershaw 2004). Bandura describes efficacy expectations as being based on four main sources of information:

1. Performance accomplishments – opportunities to achieve mastery through practice, e.g., simulation activities and successful clinical encounters
2. Vicarious (observational) experience – opportunities to observe experts in action, e.g., role modeling from senior clinicians and competent peers
3. Verbal persuasion – feedback and encouragement provided by respected clinicians who are knowledgeable and whose opinion can be trusted
4. Emotional arousal – physiological and psychological states that can impair or enhance performance, e.g., negative mood or attitude (e.g., fear and anxiety) may impair performance, whereas positive mood/attitude (energized and enthusiastic about the task) tends to enhance performance (Bandura 1977).

Interestingly, Bandura noted a significant difference between having the required knowledge and skills and the ability to use them in stressful situations. He suggests our ability to perform well in a given situation is determined by our self-efficacy or confidence in our ability to undertake a particular task or activity, which is in turn heavily influenced by the learning process. This confidence is independent of our knowledge and skills, which means that people who have achieved the same level of knowledge and skill tend to perform better or worse depending on their self-efficacy (Bandura 1993). Confidence in our ability to perform well in a given situation suggests we have had opportunities to develop the required skills, which demonstrates a higher level of learning than simply having knowledge of it. For example, knowing the theory of CPR does not mean we can apply it in a cardiac arrest unless we have had opportunities to observe and practice this skill and demonstrate competence in a supervised setting. Such examples suggest that in order for individuals to feel confident in their ability to care for people who are dying, they not only need

knowledge and skills but opportunities to interact with people and families receiving palliative and end-of-life care and critically reflect upon and receive feedback from experienced clinicians about their performance. It follows that if these experiences are lacking, learners may lack confidence and avoid being involved in caring for people who are dying, i.e., an expression of death anxiety. It is therefore important that educators take these factors into consideration when designing curricula and provide opportunities that build self-efficacy. These theories have important implications for undergraduate teaching in the health professions as well as for continuing professional development activities.

Ultimately, all theories require certain personal characteristics for individuals to be effectively motivated to learn. These include:

- The ability for forethought (to perceive a desired outcome)
- The ability to learn from experience (to be reflective practitioners)
- The ability to set goals to achieve the desired outcome
- A sense of curiosity or a perceived gap or need for learning
- A belief in their capability to undertake the required task
- The ability to recall previous success in learning

3 Palliative Care: The Sociopolitical Context

Advances in the management of chronic diseases combined with an aging population have led to an increasing prevalence of people with complex life-limiting conditions and an increasing demand for palliative care. Diseases such as ischemic heart disease, stroke, dementia, chronic respiratory disease, cancer, and diabetes are now the leading causes of death in the 60+ age group accounting for a large majority of deaths in the developed world. This is driven largely by the aging population and behavioral risk factors and is forecast to increase substantially (World Health Organisation 2003). Responding to this need is a global health challenge which requires government-led initiatives to support the provision of palliative care and increase workforce capacity across all healthcare settings.

The World Health Organization defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" (Sepúlveda et al. 2002, p. 94). This definition has been instrumental in guiding the development of palliative care services around the world with increased public awareness and government-led strategies to improve the availability and quality of palliative care.

The 2015 Quality of Death Index (The Economist Intelligence Unit 2015) rates the provision of palliative care across the world with rankings based on income as a predictor of the availability and quality of services. Countries with higher incomes are more likely to have a national palliative care strategy, higher levels of government funding, and palliative care training resources. The UK currently ranks at the top of the scale due to the extensive integration of palliative care into the National Health Service, a comprehensive national strategy that includes undergraduate healthcare education and a strong well-developed hospice movement. Australia and New Zealand come in second and third places, respectively. Other high-income countries such as Ireland, Belgium, Taiwan, Germany, the Netherlands, USA, and France are also listed in the top 10. However, even the highest ranked countries are not able to cater for the palliative care needs of every individual with geographic isolation, late or lack of referral, or an unwillingness to accept palliative care services indicating there is still much work to be done. Barriers to accessing services also exist within the healthcare community where death is often perceived as medical failure, where curative treatment is prioritized over quality of life, and where palliative care tends to be considered the sole domain of hospices for people with cancer in

the last days of life. However, this perception is changing with an increasing recognition that palliative care is relevant in all life-limiting conditions with early integration in the course of illness alongside disease-modifying treatment to improve quality of life. Consequently, palliative care is becoming a more common component of undergraduate education and continuing professional development programs with increasing recognition of the importance of a primary palliative care approach, with support from specialist services for those with complex needs (Gott et al. 2012).

The Quality of Death Index (2015) carries a timely warning that countries without sufficient training resources are likely to face a shortage of specialist staff, while nonspecialists (primary palliative care providers) may lack the skills to provide quality care if adequate educational preparation is not provided.

4 Undergraduate and Continuing Education in Palliative Care

Death and dying is a universal human experience and an inherent part of healthcare. Death occurs in all healthcare settings, and as such, it is difficult for healthcare professionals to avoid. In developed countries where people have access to high-quality healthcare, death is often perceived as an extraordinary event. This is especially true in hospital settings where care is oriented toward providing curative treatment, with palliative care being considered a specialist role. However, caring for people with life-limiting illnesses is part of everyday clinical practice for most health and social care professionals, so it is essential they are well prepared to do so with training beginning in undergraduate programs through into postgraduate and continuing education.

Unfortunately, death and dying have not traditionally been part of undergraduate curricula until relatively recently (Worldwide Palliative Care Alliance 2014; Lloyd-Williams and MacLeod 2004), which reinforces death-denying attitudes. This oversight meant new graduates were left to rely on their colleagues for guidance and support, which was not always readily available and meant that the quality of care depended on graduates' unguided instincts and their colleagues' level of experience and attitudes toward caring for people who are dying. Unsurprisingly, both medical and nursing graduates consistently report feeling inadequately prepared to care for people at the end of life, which not only compromises patient care but may also undermine graduates' self-efficacy at a critical point in their professional development.

A systematic review undertaken by Lloyd-Williams and MacLeod in 2004 reported that despite widespread acknowledgment that learning about palliative care should be included in undergraduate curricula, there was a lack of rigorous research in palliative care education. Teaching had developed in an ad hoc manner, lacked consistency, and coordination and was rarely formally assessed. The authors recommended an integrated approach to teaching palliative care beginning in the preclinical years to reinforce principles and practice across disciplines (Lloyd-Williams and MacLeod 2004). Cultural and institutional factors are common barriers to integrating palliative care into undergraduate education and include issues such as overcrowded curricula, lack of a local champion, and a healthcare system that prioritizes curative treatment over quality of life and the benefits of palliative care (Lloyd-Williams and Field 2002; Ramjan et al. 2010). In recent years, there has been a significant increase in the number of undergraduate programs offering palliative care education, especially in countries where government funding and policy initiatives have been provided to help prepare graduates meet future demand (Brajtman et al. 2007). The UK, Australia, USA, and Germany have seen particularly strong growth in this area, and there is a growing body of research reporting positive results from the evaluation of educational interventions, although there are few that measure the impact on patient care (Walker et al. 2016; Ramjan et al. 2010; Dickinson et al. 2008; Fitzpatrick et al. 2017).

In the UK, USA, Canada, and Germany, palliative care is a required component of undergraduate education, and there has been a recent proliferation of educational initiatives in these countries with legislation being a strong motivator

for educational development. However, even in these countries, the provision of palliative care education is variable, although this is more of a concern in countries where there are no competency requirements specifically related to palliative care. These issues are likely to undermine the quality of care and contribute to a shortage of specialist palliative care providers in the future (The Economist Intelligence Unit 2015).

Countries such as Australia and the USA have invested a great deal in developing national programs aimed at preparing the current and future workforce with essential knowledge and skills in the palliative care approach. In Australia, the National Palliative Care program, funded by the Commonwealth Department of Health and Aging, supports a range of national initiatives to improve access to and support the provision of high-quality palliative care. These programs include Palliative Care 4 Undergraduates (PCC4U) (http://www.pcc4u.org) which uses interactive web-based activities with accompanying resources and facilitator guides as well as workshops. In addition to this, the Programme of Experience in the Palliative Approach (PEPA) (https://pepaeducation.com) provides practicing healthcare professionals with opportunities for workplace training and workshops in palliative care. Both programs are widely available throughout Australia and provide a flexible and highly accessible means of delivery tailored to the needs of various disciplines. Other initiatives supported by the Australian government include CareSearch (https://www.caresearch.com.au) which is an online repository of palliative care information for patients, families, and healthcare professionals. CareSearch also offers online learning in the form of "End of Life Essentials," a series of six palliative care training modules for healthcare professionals working in the acute care setting. Similarly, St Christopher's Hospice in London, UK, provides a comprehensive suite of education packages, one of which is aimed at practicing healthcare professionals, known as QELCA (Quality End of Life Care for All). This program aims to empower health and social care professionals to provide a palliative care approach in all healthcare settings and includes a Train-the-Trainer program to equip teams who wish to lead the development of palliative care in their workplaces (http://www.stchristophers.org.uk/education/course/quality-end-of-life-care-for-all-qelca-train-the-trainers). Initiatives like this provide valuable resources to support continuing education and the provision of quality care at the end of life.

Care assistants who work in residential aged care facilities (RACF) are also important and often neglected; providers of palliative and end-of-life care given that the vast majority of residents in RACFs die there. Aged care facilities are becoming an increasingly common location for end-of-life care as the world's population ages and the prevalence of dementia increases. It is therefore essential that palliative care training for staff working in residential aged care facilities is a mandatory requirement for licensure, with special attention paid to addressing the learning needs of care assistants who provide the majority of hands-on care. Strong links must also be established with local hospices for ongoing liaison and support.

A good example of this model can be found in New Zealand where Hospice New Zealand, the peak body for hospices, has established the "Fundamentals of Palliative Care" course for care assistants employed in residential aged care facilities. This course is available nationwide and is provided by local hospices (MacLeod and Schumacher 2015). Research by Latta and Ross (2010) showed this course to be effective in preparing participants to care for residents who were dying and for validating and empowering care assistants in their work. The New Zealand Ministry of Health also provides funding for hospices to create palliative care liaison positions that work with and support staff working in residential aged care facilities to provide palliative care so residents can be cared for in their own environment, without unnecessary hospital admissions at the end of life.

In the USA, the American Association of Colleges of Nursing (AACM) developed the End of Life Nurse Education Consortium (ELNEC), a national initiative that was introduced in 2000 to improve the provision of palliative care throughout the USA. This course was developed with

support from the Robert Wood Johnson Foundation and uses a train the trainer approach to equip participants with the knowledge and skills required to teach undergraduate and postgraduate educators about palliative care so they can integrate it into their teaching. The ELNEC curriculum consists of eight learning modules that focus on the core competencies of palliative and end-of-life care which reflects the American Association of Colleges of Nursing's 2016 Competencies and Recommendations for Educating Undergraduate Nursing Students. This program has been widely disseminated across America (where it has been attended by 19,500 nurses and other healthcare professionals) and the world including 96 other countries where there is little or no provision of palliative care such as India, South America, and Eastern Europe. The ELNEC program has also been translated into several languages including Albanian, Czech, Romanian, Russian, Spanish, Hindi, Japanese, Korean, Chinese, and German and adapted to speciality areas such as geriatrics, pediatrics, and critical care ensuring an even wider reach (http://www.aacnnursing.org/ELNEC/About). While the ELNEC course has been proved to be effective in improving knowledge and skills (Glover et al. 2017), and is slowly being integrated into undergraduate nursing programs, the Institute of Medicine 2014 report: *Dying in America: Improving Quality and Honouring Individual Preferences near the End of Life* describes current nursing education as lacking adequate emphasis on palliative and end-of-life care.

There is no equivalent of ELNEC for undergraduate medical students in the USA so training varies widely between institutions and is described as being disjointed and sporadic (Horowitz et al. 2014). Palliative care is a required competency for nursing training in the USA, but the same cannot be said for medicine as the Liaison Committee on Medical Education (LCME) does not require medical schools to teach palliative care competencies, and it is not specifically mentioned in its standards. The Association of American Medical Colleges (AAMC) does however include some requirements that are directly related to palliative care, but this has not been translated into medical education in a consistent manner and varies widely between universities from as little as 2 h total teaching through to courses that require weeks of training and clinical experience (Horowitz et al. 2014; DeCoste-Lopez et al. 2015). While a 2014 survey of US medical schools reported 43 out of 51 deans describe palliative care education as being important (Horowitz et al. 2014), there appears to be a mismatch between the perceived importance and the actual delivery of palliative care education in undergraduate medical programs in the USA.

Canada has a longer association with palliative care education and introduced a standardized medical curriculum in 1993. However a 2001 survey by Oneshuk et al. (2004) reported wide variations in time allocated to palliative care, lack of curricula content, and limited availability of teaching staff and associated resources. Similarly, in nursing schools, teaching tends to be threaded throughout the curriculum, but the degree of emphasis is dependent on the level of commitment of teaching staff and the availability of clinical teachers with experience and expertise in this area (Brajtman et al. 2007).

There are many palliative care educational resources available for Canadian physicians such as Learning Essential Approaches to Palliative Care (LEAP) (http://pallium.ca/professional-development/leap-2/) and Ian Anderson Continuing Education Program in End-of-Life Care (https://www.cpd.utoronto.ca/endoflife/default.htm), but these have not necessarily translated into physician training (Downar 2018). Downar suggests that palliative care interventions are undermined by the hidden curriculum and suggests that interventions must be accompanied by continuing education and faculty development to create lasting change in physician behavior.

In the UK, the National Institute for Health and Clinical Excellence (NICE) provides national guidance, advice, and standards based on best evidence to assist in the planning and delivery of healthcare services, including issues related to palliative and end-of-life care. These guidelines have been incorporated into healthcare education to ensure the health workforce is adequately prepared to meet the needs of the population,

including those suffering from life-limiting conditions. A 2006 national survey of all 66 undergraduate nursing programs in the UK (response rate of 79%) reported that palliative care plays a significant role in undergraduate education with an average of 45 teaching hours devoted to this subject (Dickinson et al. 2008). This is a significant improvement on a 2002 study that reported an average of only 12.2 h of palliative care teaching in undergraduate nursing degree programs (Lloyd-Williams and Field 2002), which illustrates the development that has taken place over a relatively short period of time.

In medicine, these issues are addressed by the General Medical Council in "Tomorrow's Doctors" which outlines the outcomes and standards for medical education in the UK (General Medical Council 2009). The Association for Palliative Medicine in Great Britain and Ireland (2014) has since developed an undergraduate curriculum that is mapped to these outcomes and as such provides valuable guidance for medical student education. A recent study published in 2016 by Walker et al. (2016) that surveyed course organizers from all 30 medical schools in the UK reported that all courses provide mandatory teaching on "last days of life, death and bereavement" and offer an average of 36 h of palliative care teaching that is integrated into the curriculum with wide assessment. This can be followed up after graduation by participation in the "Quality End of Life Care for All" (QELCA) program at St Christopher's Hospice, London (Gillet and Bryan 2016). This accommodates practicing physicians experiencing hospice care through a 5-day clinical immersive practice much like the PEPA program in Australia.

In Europe, the European Association for Palliative Care (EAPC) has developed consensus guidelines on the core palliative care competencies for primary palliative care providers of all disciplines (Gamondi et al. 2013). These guidelines provide a useful framework for curriculum development, both in Europe and around the world.

In order to determine the extent of undergraduate palliative care education, an international collaboration of researchers conducted a comprehensive survey of European universities in the World Health Organization European Region with a response rate of 81%. The survey revealed palliative care is being taught in a substantial number of undergraduate medical schools, but there is wide variation between countries. For example, 28 countries (65%) include palliative care in the curriculum of at least one of its universities. In five countries (12%) including Lithuania, Poland, Latvia, Finland, and Spain, palliative care is taught in half of the country's medical schools, and in ten countries palliative care is taught in less than half of medical schools. In 13 countries (30%), palliative care is taught in all medical schools (UK, Israel, Norway, Belgium, France, Malta, Austria, Germany, Ireland, the Republic of Moldova, Hungary, Switzerland and Slovenia); 6 of these countries (those underlined) include palliative care education as a compulsory component of undergraduate training, while 14 mainly Eastern European countries do not include any palliative care teaching at all (Carrasco et al. 2015). Unsurprisingly, these countries rate in the lower half on the 2015 Quality of Death Index (with some not even featuring), which may be a reflection of a lack of government investment in palliative care policy and resources.

Important advances have taken place in Switzerland and Germany since palliative care education became a mandatory component of undergraduate education in 2013, with increases in palliative care content and academic positions to support development (Eychmuller et al. 2015; Weber et al. 2011). However a recent review of international undergraduate medical education cites Ilse et al. (published in German) describing the implementation of this teaching as being uneven and fragmented (Head et al. 2016) with only minimal requirements for nursing education in the legislation.

In Japan, there is increasing acknowledgment of the role of palliative care in healthcare delivery with a national study by Hirakawa et al. (2005) reporting 45% of medical schools and 68.9% of nursing schools that incorporate end-of-life care in their curricula. There is increased emphasis in palliative care in nursing curricula illustrated by 35.5 mean teaching hours which includes clinical learning opportunities and assessment, compared with 7.6 h in medicine.

There is, therefore, an increasing global recognition of the importance of incorporating palliative care into undergraduate curricula in medicine and nursing to prepare graduates to meet the current and predicted future need. The UK and Australia currently lead the world in terms of palliative care education and service delivery (Economist Intelligence Unit 2015) with a steady increase in the number of countries incorporating palliative care into their teaching to improve the provision of a primary palliative care approach in nonspecialist settings. Much of this work has been prompted by legislative requirements and government policy directives and supported by the work of professional bodies such as the European Association for Palliative Care and governing bodies within each country.

Despite increasing availability, palliative care continues to be underrepresented in many areas throughout the world where it competes for space in overcrowded curriculums and is often seen as a "soft subject" (i.e., nonessential). As a result, there is widespread variability and lack of consistency in content, organization, delivery, and curriculum time. Although evaluation studies report improvements in knowledge, skills, and attitudes, graduates continue to report feeling unprepared to provide end-of-life care with anxiety related to this part of their role being a common theme (Walker et al. 2016; Gillan et al. 2014). It is unclear whether this is due to the emotionally challenging nature of the work or because of deficiencies in their education, but it is likely to be a combination of the two. Either way, there are important implications for graduates' ability to care for people who are dying, which may compromise the quality of care and undermine graduates' self-efficacy at a crucial point in their professional development.

Despite the evidence that undergraduate and continuing education in palliative care has increased, the curative model is still predominantly considered the most relevant for medicine. In the jargon of the curative model, patients whose illness cannot be stopped or slowed are termed "untreatable." From a cure-oriented perspective, the care of such patients is still considered by some to be outside the purview of medicine. Medical students learn humanistic skills in their preclinical learning, but this can often be subtly undermined during their clinical attachments through a process of socialization whereby students become enculturated by the attitudes of their senior colleagues which may not be supportive of a palliative approach to patient care.

With that being said, it is important to acknowledge that undergraduate medical education is changing with an increasing emphasis on the importance of applying biomedical knowledge within a bio-psycho-social-spiritual model of care which is consistent with palliative care philosophy and responds to individual patient and family needs. This represents a significant shift in medical culture which has traditionally operated out of a biomedical approach that rewards technical skills over "softer skills" such as communication, which frequently involve emotionally draining encounters at the bedside, thus placing high value on curative interventions as opposed to palliative, whole-person, and family-centered interventions. These latter interventions often appear to encourage greater intimacy with the patient and family as we share in and support them through what is for many the most significant and challenging period in their lives. However, even in the palliative care literature, there is evidence of the danger of the intimacy that can often occur in these end-of-life situations that is associated with the emotional burden of accumulated grief. While intimacy often takes us by surprise and strengthens the therapeutic connection with patients and families, it is often accompanied by the fear that we may be overwhelmed by another's agony, suffering, chaos, and disintegration (Barnard 1995). It is essential therefore that interdisciplinary team members are well supported through comprehensive undergraduate and continuing education as well as opportunities for critical reflection and peer support.

5 Advanced Specialty Training in Palliative Medicine

The Joint Committee on Higher Medical Training in the UK first published a palliative medicine curriculum in 1998 that sets out standards

for trainees in palliative medicine in all areas including clinical, education, and research (JCHMT 1998).

In 2010 the Royal Australasian College of Physicians (RACP) published their curriculum for advanced training in palliative medicine (revised and updated in 2013). The aim of these curricula is "to ensure that specialists in palliative medicine have explored the optimum way to manage patients with active, progressive and far advanced disease for whom the prognosis is limited and the focus of care is on quality of life." The RACP program is built around work-based assessments and learning tools developed from the CanMEDS program developed by the Royal College of Physicians and Surgeons of Canada in the 1990s. Its main purpose was to "define the necessary competencies for all areas of medical practice and provide a comprehensive foundation for medical education and practice in Canada" (http://www.royalcollege.ca/rcsite/canmeds/canmeds-framework-e). Essentially this program for advanced training in palliative medicine identifies and describes the abilities physicians need to effectively meet the healthcare needs of people they serve. These abilities are grouped as Medical Expert, Communicator, Collaborator, Leader, Health Advocate, Scholar, and Professional. Prospective trainees must have completed RACP Basic Training or be a Fellow of a prescribed medical college. At the completion of the Advanced Training Program in Palliative Medicine, as defined by this curriculum, it is expected that a new Fellow will have developed the clinical skills and have acquired the theoretical knowledge for competent palliative medicine practice. It is expected that a new Fellow will be able to:

- Express expert knowledge of the pathophysiology, symptom
- Explain management, psychosocial, and spiritual issues related to life-limiting illness and imminent death
- Understand the experience of disease from the perspective of a patient and the meaning and consequences of illness to a patient and their family
- Make appropriate clinical decisions to provide medical care that is structured around the patients' and families' needs, their understanding and priorities, with the aim of maximizing QoL, relieving suffering, supporting the family, and normalizing their experiences
- Display particular expertise in the management of patients within the home, as well as the hospital and hospice
- Describe the natural history and role of disease-specific treatments in the management of advanced cancer and other progressive life-limiting illnesses
- Practice culturally responsible medicine with understanding of the personal, historical, contextual, legal, cultural, and social influences on both health workers and patients and families
- Provide expert advice as a consultant
- Establish therapeutic and supportive relationships with patients and their families based on understanding, trust, empathy, and confidentiality
- Confidently discuss end-of-life issues with patients and their families
- Sensitively explore patients' concerns across physical, psychological, social, cultural, and spiritual domains
- Communicate effectively with patients, their families, and other health professionals involved in the patients' care
- Manage his/her own time and resources effectively in order to balance patient care, professional development, managerial and administrative duties, learning needs, and personal life
- Work effectively and efficiently in a healthcare organization
- Manage human resource, financial, quality assurance, data management, and administrative aspects of his/her own practice or palliative care service
- Allocate finite healthcare and health education resources effectively (https://www.racp.edu.au/docs/default-source/default-document-library/download-the-advanced-training-in-palliative-medicine-curriculum-(1mb).pdf?sfvrsn=2)

Trainees need to undertake a learning needs analysis, partake in case-based discussions, write up case studies, and are advised to undergo communication skills training, brief clinical examinations, reflection, and research.

In the USA, requirements for aspects of palliative medicine training were first outlined in the mid-1990s, but by 2001 there were still relatively few residency or fellowship requirements to provide any palliative medicine training outside internal medicine, geriatrics, and neurology (Case et al. 2013). Hospital palliative medicine consult teams have increased in number over the last years, and this has encouraged the development of more palliative medicine education. Hospital palliative medicine is now recognized as a specialty, but there are still not enough palliative medicine specialists to meet the wide-ranging needs of the population.

Downar (2018) has provided a helpful overview of the resources for education, training, and mentoring for all physicians providing palliative care which he suggests can serve as a framework to improve palliative care as a whole in Canada.

6 Addressing the Learning Needs of Family Carers

Family carers have significant learning needs if they are to be able to care for their loved one at home. Without the considerable support, sacrifice, and willingness of families to provide care, many patients who would prefer to be at home might otherwise have to be cared for in hospital or a residential care facility. Such caring requires dedication, skill, and a certain amount of knowledge. However, the presence of effective education programs to provide relevant knowledge is fairly limited. One early example was undertaken with the support of the Project Death in America. Patients with advanced cancer and their families were invited to attend a 90-min education program that taught basic problem-solving principles using a cognitive-behavioral framework. The authors surmised that most education programs focused on delivering information rather than problem-solving skills and proposed that one-on-one teaching may provide more effective results (Bucher et al. 2001).

The team at the Centre for Palliative Care in Melbourne have been innovative in their approach to caregiver education. They have undertaken their own work and provided a helpful systematic review of psychosocial interventions for family carers of palliative care patients (Hudson et al. 2010). They noted that interventions included psycho-education, psychosocial support, carer coping, symptom management, sleep promotion, and family meetings. Only three studies in that review were randomized controlled trials which met the criteria for the highest-quality evidence. They conclude that paper by asking:

> *First, how can psychosocial interventions be designed to be effective given the typically short period of time available to intervene?*
>
> *Second, what is the most useful way to determine which family carers need significant psychosocial support?*
>
> *Third, how can health services meet the support needs of the entire family when many may only be resourced to support the primary family carer?*
>
> *And finally what are the priority interventions and methods of delivery that are required for development and testing in the family carer population?* (p. 4)

Answers to these questions are yet to appear consistently in the literature. That group's own intervention demonstrated that a group education program to prepare family caregivers for the role of supporting a dying relative at home was accessible, applicable, and effective. In particular they found a significant positive effect in preparedness for the caring role, caregiving competence, caregiving rewards, and having information needs met (Hudson et al. 2008).

There are clearly many other ways to help to educate carers. One initiative is an open website "The Palliative Care Bridge" www.palliativecarebridge.com that uses recorded materials from experts in the field. There are over 70 short video interviews and presentations on all aspects of palliative care including interviews with patients and family members.

Palliative Care Australia have developed a massive open online course (MOOC) on death, dying and palliative care that is open to anyone

aged 18–100 who has a computer. The 4-week course is presented by the online palliative care resource CareSearch and aims to increase death literacy in the community and engage people in conversations on the topic (http://palliativecare.org.au/new-course-on-death-dying-and-palliative-care).

Many hospices also run courses for family carers which include aspects of the dying process, communication, grief, and bereavement. Macmillan, the leading charity support at the end of life in the UK, runs face to face and online courses for carers of all experiences. A huge selection of resources are available at https://learnzone.org.uk/.

7 Educational Methods

Given the increasing demand for palliative care education, it is important there is a wide range of flexible and accessible educational modalities available to meet the learning needs of all, many of which have already been mentioned.

There is a great deal of variety in approaches to teaching and learning about palliative care from the traditional didactic lecture to simulation, eLearning, small group discussion, and interprofessional education. Ideally, the method should be that which is best suited to the audience and content being delivered. Objectives must be realistically achievable (given the timeframe and participants' level of learning), measurable, and clearly stated. They must also be aligned with prior learning and experience and tailored according to learning needs. Of course, theoretical learning must be partnered with opportunities for practical experience including critical reflection with supervision and feedback from expert clinicians. Undergraduate students should also have opportunities to observe skilled palliative care professionals in action, such as being involved in team discussions about care planning, witnessing high-stakes conversations (about breaking bad news, prognostication, transition to palliative care, and advance care planning), as well as opportunities to be directly involved in caring for people who are dying. These are some of the most valuable, influential and enduring learning experiences a student can have.

The European Association for Palliative Care recommends 10 core competencies that all health and social care professionals should achieve, regardless of the healthcare setting they work in. These competencies provide a useful framework for palliative care education, and while they were developed for a European audience, they are easily transferable to other countries. The White Paper on Palliative Care Education can be accessed through the EAPC website http://www.eapcnet.eu/Themes/Resources/Education/EAPCWhitePaperonEducation.aspx.

Similarly, other countries have specific guidelines and legislative requirements for palliative care education that curriculum developers need to be familiar with to ensure their educational programs align with national priorities.

Relf and Heath (2006) argue that effective teaching in palliative care needs to translate knowledge into behaviors that make a "positive difference to the people we work with, namely our colleagues, patients and all those who care for them." They identify several experiential techniques, as others have done, to provide opportunities for reflection, support, and raising awareness of what influences attitudes, assumptions, and the way we respond. They suggest the use of role-play with reflection and sculpting as useful educational methods to stimulate reflection and self-awareness.

Finally, distance education methods have been shown to be of use to informal caregivers in palliative care in Australia without relying on Internet access or having to travel to group sessions (Forbat et al. 2018). Others have demonstrated the usefulness of classroom-based education for enhancing health and social care professionals' skills for delivering end-of-life care (Pulsford et al. 2011). We now turn our attention to specific educational methods that require focused discussion.

7.1 Simulation

There is growing interest in the use of simulation-based learning experiences (SBLE) in the training

of health and social care professionals in order to prepare students to meet the needs of patients and families who require a palliative approach to care. While there is no substitute for real patient interaction, the unpredictable nature of the clinical setting means that student learning can be highly variable. Simulation is one way of providing consistent learning opportunities to ensure all students can practice core skills in a safe environment with supervision and feedback from experienced clinicians and educators.

Two recent reviews showed that learning activities involving the use of high fidelity mannequins, role-play, and/or simulated patients (actors) appear to be an effective way of enhancing student learning in palliative care, especially when blended with a second modality such as eLearning when used in preparation for the simulation. Skills such as patient assessment, communication (including spiritual and cultural issues), and interprofessional teamwork were all seen as being particularly amenable to simulation, all of which are essential skills in palliative care (Smith et al. 2018; Kirkpatrick et al. 2017; Ellman et al. 2012).

An attractive feature of simulation is that it facilitates critical reflection through the debriefing and feedback process, which allows students to learn from experience (without fear of harming the patient) while developing important clinical and communication skills. Evidence also suggests that palliative simulation activities can improve knowledge and confidence (Pesut and Grieg 2018). However, it is unclear how well learners are able to transfer these skills to the clinical setting with a recent meta-analysis by Selman et al. (2017) showing a smaller effect of communication skills training on interactions with real patients, compared to those demonstrated in a simulated interaction. Personalized feedback on recorded simulated patient interactions however was shown to be helpful in improving clinicians' ability to demonstrate empathy during real patient encounters (Selman et al. 2017).

While simulation holds a great deal of promise as an educational modality, there are important factors that need to be taken into consideration in order for a simulation activity to be successful. These include involving key stakeholders in the design, planning and delivery (especially in interprofessional simulations); clear, achievable, and measurable learning objectives; modality (i.e., high vs low fidelity, actors, role-play, blended methods); authenticity (i.e., as close to reality as possible); and careful debriefing which includes being mindful of safety issues if a student should become distressed by emotionally upsetting content (such as breaking bad news). It is also essential that learners have opportunities to transfer and consolidate the skills learned in a SBLE into the clinical setting through observation of expert clinicians in action and supervised interactions with real patients with personalized feedback from clinicians to improve performance.

In the context of today's high-pressure, high acuity healthcare settings, simulation offers flexible, safe, and consistent opportunities for students to learn and practice essential skills in palliative care.

7.2 Interprofessional Education (IPE)

One of the cornerstones of palliative care is interprofessional teamwork, which is essential in order to be able to respond effectively to the patient and family's physical, psychological, social, and spiritual needs. No one profession is skilled in all these areas, so team members must work collaboratively to meet patient and family needs.

The World Health Organization recommends interprofessional education as a necessary step toward preparing a collaborative practice-ready health workforce that is better prepared to respond to local health needs (WHO & Health Professions Network Nursing and Midwifery Office: Department of Human Resources for Health 2010). A common definition of interprofessional education is that which "occurs when two or more professions learn with, from and about each other to improve collaboration and the quality of care" (Barr 2002 p. 8). The assumption is that health professionals who learn together are more likely to be able to collaborate well in interprofessional teams.

In order to learn these skills, students need to have opportunities to learn with other health and

social care students during their undergraduate training, both in the learning and clinical settings, to prepare them for working in interprofessional teams in the future. Students' observations of effective interprofessional teamwork on clinical placements help students contextualize learning and avoid the risk of education out of context becoming "idealized," thus creating difficulties when it comes to putting into practice the knowledge, skills, and attitudes learned. Furthermore, a lack of interprofessional learning opportunities can lead to clinicians practicing in silos, thus creating rigid professional boundaries and power structures that militate against effective teamwork and the shared care that characterizes communities of practice as described by Étienne Wenger (1998). By this we mean a group of people who share a concern or a passion for something they do (e.g., healthcare) and learn how to do it better as they interact regularly. This reflects the fundamentally social nature of human learning. Hospice and palliative care units provide an ideal setting for learning these skills, especially in the advanced years of undergraduate training.

Formal interprofessional programs require considerable attention to process: letting go of personal and professional biases and assumptions, exploring and defining roles to diminish stereotyping and develop understanding of each other's strengths and abilities; and debriefing to examine system and individual responses. Much of interprofessional learning for palliative care will inevitably take place within small group settings. Small group work benefits from the usual considerations of the learning environment and brings with it additional requirements such as introductions, credentialing, agenda or objective-setting, agreement on ground rules, a modus operandi, and so forth. Whether learning in a theoretical way through cases or problems or reviewing clinical situations, there are certain considerations that can improve effectiveness for this sort of learning (Oandasan and Reeves 2005). For interactive learning to be effective, there is a need to maintain group balance, ensuring that disciplines are not likely to dominate by being overrepresented. The group size must be of an order that facilitates easy communication among the group. Finally, the group is most effective for learning where there is stability with little "turnover" and members can learn together for some time.

In outlining his views of a social theory of learning, Wenger (1998) argues that in order to learn effectively, together we must:

- Discover shared meaning, a way of talking about our abilities and our experiences that can be shared
- Practice a way of talking about our shared histories and social frameworks that mean we can understand each other
- Negotiate identity, a way of talking about how learning changes who we are

To this should perhaps be added that we must also have a willingness to learn and work together, have trust and confidence in each other's abilities, and have a mutual respect of each other's abilities and contributions. How we establish these attitudes and behaviors in the workplace is crucial. Students joining communities of practice that are already functioning more or less effectively (such as clinical teams) are seen to be "on the outside," inexpert, and inexperienced. It is important for their professional development that they are made to feel legitimate members of the team and included as much as possible in team activities. There is some risk for students in this process since they may unknowingly wander from one professional jurisdiction to another. Introductions, orientations, and role definitions all help, but the routine practice of the community is likely to be the greatest determinant of emergent professional identity. In an effectively functioning community of practice, the student is likely to witness negotiations, favors, deals, and trades between professionals conducted in the best interests of the patient – in essence, a team learning with, from, and about each other. These can be transforming experiences in the formation of professional identity and can be the subject of reflective activities. It is also important to recognize that the social dynamics of the community of practice potentially presents students with a variety of role models, a function of which the members may or may not be aware.

In a systematic review of the development of an evidence base for interdisciplinary learning, Cooper et al. (2001) identified many educational interventions from the literature which can be used for interdisciplinary learning. The prominent educational methods used were small group teaching, case studies (real or simulated), and experiential learning. Traditional didactic methods were also used in approximately one third of the interventions. The summary of the main findings of this review showed the largest effects of interdisciplinary learning were on students' knowledge and attitudes, skills, and beliefs and in particular on understanding of professional roles in team working, ideal then for learning in and about palliative care. The smallest effects were for a transfer of learning into students' experiential practice and an effect on students' learning environments.

Pippa Hall (2005) pointed out that physicians traditionally learn independently in a highly competitive academic environment. Nurses learn early in their career to work as a team, collectively working out problems and efficiently exchanging information. She also suggests that the physician-patient relationship tends to be authoritarian, whereas other professions such as social work and nursing have placed more value on patients' self-determination. This variance has led to tensions within interprofessional teams in palliative care where role "blurring" exists. There is the possibility with interprofessional learning of identifying where one role ends and another begins which is clearly an attractive option. Collaboration in the development of effective team work is fundamental, and Norsen et al. (1995) have identified six collaborative skills that are crucial for teamwork that should be addressed in any professional education program and still seem relevant after more than 20 years:

- Cooperation – acknowledging and respecting others' opinions and viewpoints
- Assertiveness – supporting one's own viewpoint with confidence
- Responsibility – accepting and sharing responsibilities and participating in group decision making and planning
- Communication
- Autonomy
- Coordination – efficient organization of group tasks and assignments.

Alternatively, if we identify competencies for palliative care practice in an interprofessional way, we can utilize a format like that is proposed by Hugh Barr (1998) in which "collaborative competencies" are outlined:

- Describe one's roles and responsibilities clearly to other professions
- Recognize and observe the constraints of one's role, responsibilities, and competence, yet perceive the needs of a wider framework
- Recognize and respect the roles, responsibilities, and competencies of other professions in relation to one's own
- Work with other professions to effect change and resolve conflict in the provision of care and treatment
- Work with others to assess, plan, provide, and review care for individual patients
- Tolerate differences, misunderstandings, and shortcomings of other professions
- Facilitate interprofessional case conferences, team meetings, etc.
- Enter into interdependent relationships with other professions

Palliative care is the product of a shared vision of care between the healthcare team, the patient, and their family. The care plan is informed by the patient narrative, which incorporates their values, goals, and priorities with care orientated toward realizing those values, goals, and priorities, including actions and activities that will be instrumental in helping them achieve those goals. The unique course of events and experiences taken by the dying person and their family combined with all the accompanying professional work (i.e., what the healthcare team does using their combined expertise) constitutes the trajectory of dying. In daily practice, there will be many tasks which, in total, constitute care with some degree of complementary overlap between professions. It is therefore essential that students have opportunities to learn how to work effectively as a team

member which is best achieved by learning with, from, and about each other.

Gadoud et al. (2018) have described the perceptions of nonmedical palliative care health professionals (nurses, social workers, and physiotherapists) involved in medical student education in palliative care. Essentially, the staff saw the benefits and value of the experience as providing a different perspective of palliative care delivery, offering a greater understanding of interdisciplinary teams and giving patients a feeling of importance and the opportunity to contribute to student learning. The authors of this study suggest that utilizing such staff "is a practical and rewarding way to achieve undergraduate medical education in both palliative and interprofessional care" (p. 5).

One of the taxing questions for palliative care educators is how and when to introduce the concepts and realities of interprofessional education. While it is clear that there are discipline-specific areas of learning, there is no doubt that in an area of healthcare that relies so heavily on interprofessional working, there is great merit in introducing these concepts at an early stage. To summarize, in the development of an interprofessional educational activity, we must ask:

- What are the goals we are trying to achieve in having students learn together?
- Based on these goals, when should we introduce the learning to students?
- What strategies should be used to accomplish these goals? (Oandasan and Reeves 2005).

7.3 Learning in the Clinical Setting

The clinical setting is critical for applying theoretical knowledge in practice, learning and consolidating new skills both technical and humanistic, learning to work effectively as a member of an interprofessional team, and learning how to care.

The affective quality of work (and learning) is high in the palliative care context as there is often considerable emotional work to do and support required to help patients and families process the losses that occur during illness and upon (and following) the person's death. Consequently, the emotions and values of both patients and professionals must be on the educational agenda. Case studies, recorded patient interviews, and role-plays with small group discussion are good vehicles for the exploration of these issues away from the immediate pressures and demands of the workplace. Briefings, debriefings, and case reviews can serve a similar purpose in the practice setting.

Role modeling is an important and often underestimated part of the informal curriculum that occurs in clinical settings. Observing expert clinicians communicating in difficult situations (such as breaking bad news, discussions about transition to palliative care, and advance care planning) can be a powerful and influential learning experience, especially when followed with discussion, that helps students expand their repertoire of verbal and nonverbal communication skills and provides a point of reference their future practice. Unfortunately, students are often excluded from these conversations out of a well-intentioned desire to protect the patient from unnecessary intrusion at a vulnerable time or the physician's own discomfort in being watched especially if they lack confidence in their ability in such situations. However, if the student has an existing relationship with the patient, it is important for them to have opportunities to observe these interactions (with the patient's consent) as well as opportunities to participate in the care of patients and families with palliative and end-of-life care needs in order to provide the necessary experience to increase their self-efficacy in palliative care.

Aside from formal teaching, much education in palliative care will take place in the clinical setting, and all clinical teachers need to be aware of the learning outcomes students are required to achieve. However, learning in the clinical setting can be messy and unpredictable, and there may be compromises and other negotiations that need to be made to achieve those outcomes which may require further educational work outside the care setting. Value can be added to work experiences through systematic processes of critical reflection

such as using portfolios, logbooks, journals, and/or thought-provoking episode reports to facilitate post-encounter processing and analysis. A helpful example of this might be the Professional Development and Recognition Programme (PDRP) espoused by nursing in New Zealand. The PDRP framework and criteria have been developed cooperatively by District Health Boards and the New Zealand Nurses Organisation to advance professional development in nursing, to support nurses in demonstrating competency to the Nursing Council of New Zealand (2018), and to fulfill obligations negotiated under the nurses' employment agreements. These programs aim to promote and reward nursing expertise and recognize the contribution of nurses to quality patient health outcomes (http://www.nursingcouncil.org.nz/Nurses/PDRPs).

Similar examples of self-reflection have been described. Brady et al. (2002) used narratives to track a group of house staff through 3 years of training to give the authors an understanding of the "interplay among residents' interactions with patients, their own personal issues and their struggles during several discrete stages of their professional development." One goal of the exercise was to encourage the trainees to become self-reflective. The authors felt that residents progressed through a period of "expressing ideal images of themselves as physicians through a bleak, discouraging stage of development and finally entered a stage where they could feel confirmed as professionals by their relationships with patients." By adopting this method, the teachers encouraged deeper and clearer thinking about the young doctors' roles and therefore help them to realize that things they learn about themselves will influence their practice as physicians. Wear (2002) used students' narratives on end-of-life care to illustrate students' worry and concern about end-of-life care and their perceived lack of preparation for such care. The students didn't feel well prepared or supported as they cared for their first dying patients, which continues to be a common theme in the international literature. They did however identify their desire for more support and role modeling from residents and attending physicians.

8 Summary

Increasing demand for palliative care, driven by an aging population and an increasing prevalence of chronic, life-limiting conditions, makes palliative care education an essential requirement for all health and social care professionals in order to prepare them to meet the needs of the world's population into the future. Training in professional programs must begin at undergraduate level and extend into continuing education with increased availability of advanced specialty training to combat the predicted future shortage of palliative care specialists.

The changing emphasis toward more community-oriented care indicates a need for more education and training in these settings to enable people to remain in their own homes and communities for as long as possible and to die there if that is their wish. This includes meeting the educational needs of family carers and health and social care professionals employed in community settings, including staff employed in residential aged care facilities.

This chapter has discussed current issues related to palliative care education and the strategies that can be used to deliver high-quality palliative care for all, at the heart of which is the relief of suffering in all its forms through the power of education.

Abstract

Care at the end of life has developed into a sophisticated specialty, historically modeled around the needs of incurable cancer in terms of complex, rapidly developing symptomatology and psychopathology in a predictable time frame. It is ill-equipped to manage people dying of other conditions, and the aging of the population will see the rise of multimorbidity, frailty, dementia, and organ failure as predominant causes of disability and death. The existing specialized, hospital-focused, and subspecialized health system that currently manages very ill people will not be able to cope with the complexity, multimorbidity, and unpredictability that characterize the future. Generalists, particularly community-based services, will inevitably have a very significant role to play.

This chapter examines the role of primary care, specifically general practice, in managing end-of-life care. It describes the similarities between the aims and objectives of general practice and palliative care, the scope of generalist end-of-life care, the past performance of general practice at the end of life, and models of care that can enhance both GP performance and integration between specialists and generalists. It concludes with initiatives that will facilitate national policy development to promote effective end-of-life care.

1 Introduction

The world has made spectacular advances in overcoming illnesses as diverse as cancer and sepsis. As a result, the average survival rate has increased dramatically, and the improvements in quality of life for most of those years have been impressive. Most of us can be confident that we will be living well into our 80s. While we celebrate "conquering cancer" (and other diseases), what is not discussed much at all is that there is a limit to the length of time we will live. The vast majority of people will die between the ages of 70 and 90 and virtually are all dead by about 100 years of age (World Health Organization 2015). Medical advances have simply delayed the inevitable.

As the population ages rapidly, so the absolute number of deaths per annum will rise. The absolute numbers who will die has to increase faster than the rate at which we are aging. Etkind et al. estimate that the number of people dying per annum in the UK will rise by 25.4% as a result of a higher proportion of older people (from 17.7% $\geq$ 65 in 2014 to 24.2% in 2040) (Etkind et al. 2017). Australian predictions suggest that the picture will continue to escalate beyond 2040. By 2016, the number of deaths was predicted to rise by over 250% from 2011 to 2061 (Australian Bureau of Statistics 2016) (Fig. 1). Moreover, the number whose dying can be anticipated and who will probably benefit from palliative care will escalate from approximately 75% in 2014 to up to 87% in 2040 (Etkind et al. 2017). The need for skilled end-of-life care will escalate.

In addition, the nature of the causes of death is changing. Gill et al. analyzed the cause of death of previously well 70-year-old people and found that the greatest cause of death was frailty (28%), followed by any organ failure (21%), cancer (19%), and dementia (14%) (Gill et al. 2010). Seventy-nine percent of this cohort had a predictable course to death, with the majority of people dying after a prolonged period of disability and ill health. Frailty, the most common cause, is caused by an accumulation of age-related illnesses, impacting on bodies with less capacity to maintain homeostasis. Older people will be taking more medicines than before, with the accompanying risks of expected and unexpected adverse events and drug interactions.

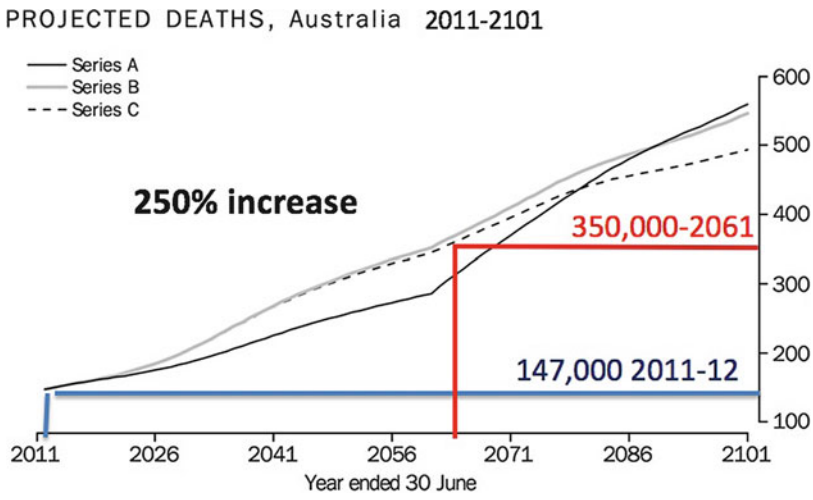

Fig. 1 Annual deaths from 2011 to 2101 in Australia

2 Society's Response: Palliative Care

Society's response to dying has changed dramatically since Cicely Saunders developed a systematic and deliberate response to the problems of distressing deaths from terminal cancer. The sustained study of pain and symptom management and a complete change in approach to death from a perceived medical failure to an expected part of the human experience have had profound effects on modern health care.

Better understanding of pain management and the development the specialized institutions to manage the end of life were the initial response. Better understanding of the management of other symptoms, the psychology of dying, vastly improved communication skills, and better organization of care have put very high quality of care in reach of most people with cancer in developed countries. Indeed, the proportion of people dying of cancer who access palliative care is around 68 percent (Rosenwax and McNamara 2006). Specialist palliative care has largely aligned with cancer care. Palliative care services are often co-located with oncology departments. There may be beds allocated to palliative care services, or the service may be a consultative service to other clinical units.

This model has served these patients well, particularly with timely referral. It is not perfect, particularly when patients are referred too late to have a demonstrable impact on the patient and family's well-being. There are two main reasons the majority of palliative care services manage cancer. The first is historical. The dramatic and tragic course of cancer for many patients makes improvement of the end of life an obvious backdrop for this sort of care. Secondly, with relatively predictable time courses and relatively predictable symptoms, it has been relatively easy to design service delivery to suit end-of-life cancer care.

However, the proportion of people without cancer who die without accessing specialist palliative care is disturbingly high (Rosenwax and McNamara 2006), in spite of the symptom burden of conditions like advanced heart failure being the equivalent of that of advanced lung cancer (Murray et al. 2002). There are several problems in providing specialist palliative care to this group. First, the illness trajectory of these conditions is variable (Fig. 2). A typical organ failure trajectory has multiple relapses and remissions, and the timing of these is unpredictable. Secondly, a person with organ failure may have a prognosis of years before death. The same applies to the person with advanced multimorbidity. They often have substantial care needs relating to mounting disability, but it might take years to recognize that the person is approaching death. Many will have dementia, which in the latter stages limits the ability to undertake more than

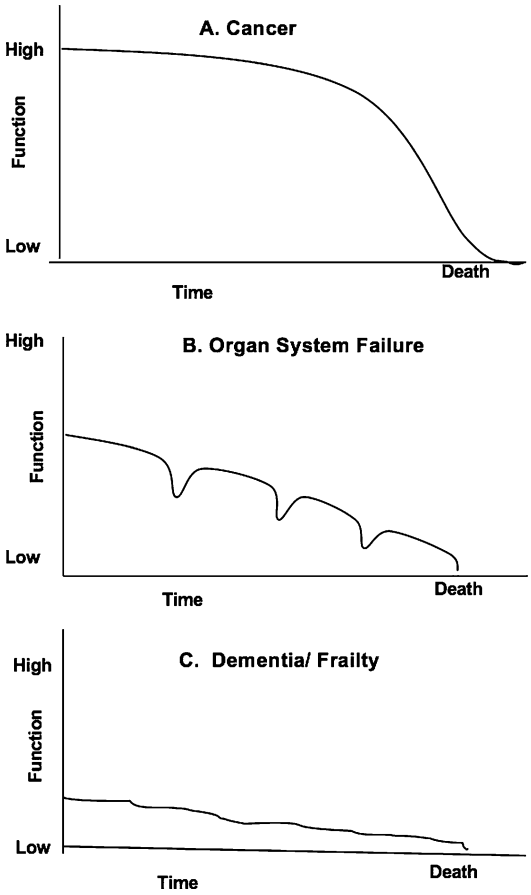

Fig. 2 Trajectories of illness at the end of life

the most basic of activities of daily living. In addition, people with dementia also suffer substantial symptom burden over and above the burden of the underlying condition. For example, approximately half of all people with advanced dementia are reported to suffer pain to some degree (van Kooten et al. 2016).

The end-of-life care model designed for the intense, accelerating need for care seen in cancer palliative patient is not going to work in most people with nonmalignant disease approaching end of life. Currently, about 80% of the patients of specialist palliative care units have a primary diagnosis of cancer (Australian Institute of Health and Welfare 2014). Who looks after the non-cancer deaths? Certainly not specialist palliative care – they are being stretched with the current illness mix. The number of referrals to Australian specialist palliative care services grew by 52% in the decade from 2002 to 2012 (Australian Institute of Health and Welfare 2014), and the services have little ability to take more on. More of the same is not going to work, and urgent attention needs to be paid to alternative models of care.

This chapter aims to describe the place of primary care in the care of people at the end of life, with a particular emphasis on primary care. It examines how ideal primary palliative care could work and the evidence in support of integrating primary care into the management of complex end-of-life conditions. In addition, it demonstrates the performance of general practice as reflected by a systematic review of the literature undertaken to 2014. Finally, it documents some of the major policy initiatives that seek to embed primary palliative care into routine end-of-life care.

3 General Practice, Primary Care and Palliative Care

There are major similarities between the definitions of general practice and of palliative care (Box 1). Both emphasize the importance of treating the whole person. Both emphasize the importance of high-quality assessment and management of people's problems. In addition, family practice emphasizes health promotion and prevention and understanding the context in which the patients live work. End-of-life care is a natural fit for primary care.

Box 1 Definitions of Palliative Care and General Practice

WHO Definition of Palliative Care

Palliative care is an approach that improves the quality of life of patients (adults and children) and their families who are facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and correct assessment and treatment of pain, and other

(*continued*)

Box 1 (continued)
problems, whether physical, psychosocial, or spiritual (World Health Organization 2004).

European Definition of General/ Family Practitioner

General practitioners/family doctors are specialist physicians trained in the principles of the discipline. They are personal doctors, primarily responsible for the provision of comprehensive and continuing care to every individual seeking medical care irrespective of age, sex, and illness. They care for individuals in the context of their family, their community, and their culture, always respecting the autonomy of their patients. They recognize they will also have a professional responsibility to their community. In negotiating management plans with their patients, they integrate physical, psychological, social, cultural, and existential factors, utilizing the knowledge and trust engendered by repeated contacts. General practitioners/family physicians exercise their professional role by promoting health, preventing disease, and providing cure, care, or palliation. This is done either directly or through the services of others according to health needs and the resources available within the community they serve, assisting patients where necessary in accessing these services. They must take the responsibility for developing and maintaining their skills, personal balance, and values as a basis for effective and safe patient care (WONCA Europe 2011).

In fact, as experts in multimorbid care, general practice is where most of end-of-life care should and probably already does take place. It is not clear whether GPs understand that they are already providing end-of-life care as they manage multimorbid and frail older people. There are different perceptions of what palliative care and end-of-life care actually comprise. The classic picture of palliative care involves intense care at the end of life: managing uncontrolled symptoms, rapidly changing and accumulating symptom burden, patient fears, and relatives who are frightened and distressed. And that is what a lot of end-of-life care is like. However, there is another form of end-of-life care which ideally takes place much earlier – months from death is ideal. Here there is a recognition of the inevitability of dying at some stage in the future. Together with the patient, future patient wishes are articulated. Clinicians anticipate future medical and situational problems and start to put into place strategies to manage these when they arise. These are both legitimate forms of end-of-life care but very different (Fig. 3).

4 Multidimensional Care

Murray et al. have gone further to describe the nature of palliative care, calling it a four-dimensional activity. These dimensions are physical, psychological, social, and spiritual dimensions of care (Murray et al. 2007). This framework is very useful in identifying and planning treatment. Different versions of this work have been done. For example, Eychmüller and colleagues (Eychmeuller 2012) have also undertaken work to identify the essential elements of palliative care, developing the SENS structure of palliative care planning and treatment: ***S****ymptoms* both current and anticipated; ***E****nd-of-life decisions* that have to be made; the ***N****etwork of care* required around the patient; and ***S****upport for the family* required to manage the situation. They go on to define the goals of comprehensive care: the so-called 4-S goals, improving ***Self-help*** capacities; promoting ***Self-determination***; ensuring ***Safety***; and assuring ***Support*** for the family.

5 Consumer Expectations of the Role of GPs and Primary Care at the End of Life

A systematic review by Johnson et al. (under review) identified the expectations of patients and their immediate carers of the role of GPs and primary care health professionals at the end of life.

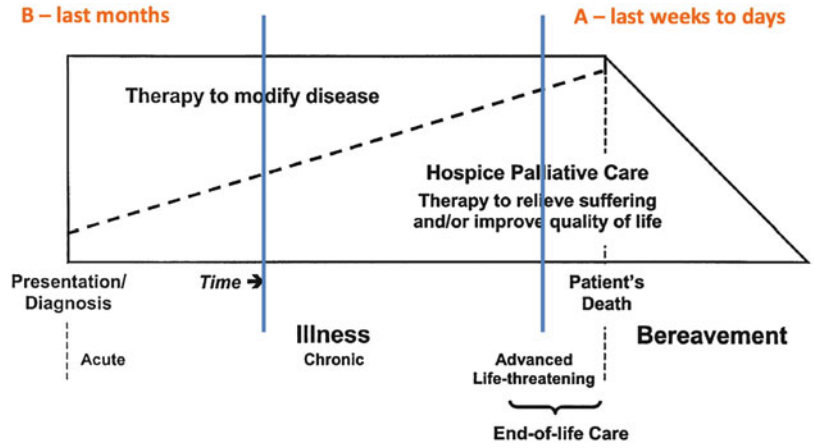

Fig. 3 Different aspects of palliative care dependent on time from death

Continuity of care was considered an important aspect of care (Borgsteede et al. 2006; Neergaard et al. 2008). Different elements were identified in the literature:

1) *Relational continuity of GP care*. Patients and their immediate carers prefer that care is provided by the same known GP (with backup from the same clinic when necessary), rather than different GPs (Borgsteede et al. 2006). Further, patients also preferred to continue their relationship with the GP across different care settings, thus requiring ongoing and close cooperation between the patient's GP and their specialists during the final illness. This relationship should ideally persist with the next of kin, even after the death of the patient.

2) *Informational consistency*. The patient's primary care providers should be the repository of the patients' clinical information. This information should be shared across all health providers to promote consistent care and reduce the need for patients to continually retell their story (Neergaard et al. 2008). Effective means of information sharing is an increasing theme for health care in general. Having a shared clinical record is already a reality in some jurisdictions (e.g., Spain, UK) but not others. Sharing information between specialists and carers is eventually being developed in other places (e.g., Australia). Until that is universal, some means of information sharing should be devised, and primary care practitioners are in a good position to enable that to happen.

3) *Consistency of information provision*. The role of caring is highly stressful, and most carers do not have a health-care background. They are being asked to care for the most unwell people and need good information to do this job. Minor differences in the information provided create anxiety and distress. Consistency of information provision minimizes this problem (Boyd et al. 2004). GPs can be the providers of information or the interpreters of information from others to allay concerns and ensure high-quality care provision.

Interprofessional communication. Patients and carers believe that high-quality interprofessional communication regarding diagnosis, treatment, and prognosis facilitates good end-of-life care (Borgsteede et al. 2006). While patients developed strong rapport and relationships with health professionals in the acute care setting (Aabom and Pfeiffer 2009), they needed to see overt collaboration between those health professionals and other agencies involved in palliative care provision and their GP to feel confident that all health professionals were working together (Neergaard et al. 2008). The GP could be a key carer if the GP-patient relationship was established and effective. Some patients suggested that GPs should be proactive in engaging with health professionals such as oncologists and palliative care services and that oncologists should inform patients of the important role of GPs in end-of-life care (Borgsteede et al. 2006; Neergaard et al. 2008).

Patients believe they benefit from a strong therapeutic relationship with their GP (Slort et al. 2011). Consistently seeing the same GP contributed to a greater knowledge of the personal needs and preferences of the individual, increasing trust and mutual understanding (Michiels et al. 2007). The GP in such a therapeutic relationship would take time to be engaged and "listen carefully," be able to deal with strong emotions, and be able to assist patients with advance care planning to improve patient, carer, and family outcomes (Slort et al. 2011).

Patients observed that they were often the subjects of a health professional-led approach to care, rather than a partnership between health professionals, the patient, and any relevant carers and family members (Boyd et al. 2004). They considered such a partnership a more effective approach, which would empower patients and their carers and facilitate patient-centered care. The limited palliative care experience of some GPs was perceived by some patients and carers to impact on their ability to provide more than basic psychosocial and carer support (Farber et al. 2003).

A ***GP's communication skills*** were particularly valued by both patients and carers (Borgsteede et al. 2006; Neergaard et al. 2008; Grande et al. 2004). Attributes such as trustworthiness, respect, kindness, caring, sympathy, honesty, and sensitivity fostered constructive and collaborative relationships between GPs, patients, and carers (Grande et al. 2004). Patients preferred GPs to be open and initiate discussions about end of life (Slort et al. 2011).

Ready access to and availability of GPs and other health professionals were considered fundamental to good end-of-life care (Borgsteede et al. 2006; Neergaard et al. 2008). Patients needed to be able to see their GP without protracted waiting times for appointments or having to wait for long periods on the day of appointments (Borgsteede et al. 2006). As a patient deteriorated, having a GP who was available out of hours and who conducted home visits was essential if the patient wished to remain at home (Borgsteede et al. 2006; Neergaard et al. 2008; Slort et al. 2011). A GP's lack of time was a barrier to continuity of care.

Patients expect GPs to be competent at diagnosing problems and in the management of their symptoms (Borgsteede et al. 2006), but this was not always the case (Grande et al. 2004). They wanted GPs to be well informed about their condition, how to manage symptoms, and to be aware of the side effects of treatment (Borgsteede et al. 2006; Slort et al. 2011). Patients wanted information about symptoms and their management to be shared with them (Grande et al. 2004).

Patients and carers expect GPs to facilitate or enlist help from other agencies to enhance EOL care. In particular, shared care between GPs, community services, and specialist services was appreciated by them, including engagement with palliative care services when required (Neergaard et al. 2008). Community support services can facilitate access to equipment and supplies.

While some patients and carers identified the importance of the psychological, social, and spiritual support which could be provided by GPs (Grande et al. 2004), others had not considered that they might use the GP for non-biomedical or nontreatment-related issues. They did not want to inconvenience or disturb a busy GP for what they considered "minor matters," despite increasing psychosocial concerns as the disease progressed. Some clinicians described their patient care largely in terms of treating the disease.

6 What Does End of Life Look like in the Community?

End-of-life care in primary care comprises escalating need for care starting months from death and some intense care at the end of life. There are three essential elements to this "early palliative care." First, in order for deliberate planning and management to take place, there has to be a conscious recognition that the end of life is approaching. When that decision is made, then some form of planning should take place. Finally, the health team needs to be ready to enact the plan when the time comes.

7 Essential Steps in Primary Palliative Care

7.1 Identifying Approaching End of Life

Identifying people approaching the end of life seems such a simple proposition, and yet it is not often deliberately done. The identification of patients for palliative care tends to rely on practitioners' subjective judgment (intuition and knowledge), rather than established guidelines (Harrison et al. 2012). Cancer patients had the greatest likelihood of being identified as being in need of palliative care. Patients with non-malignant but advanced and progressive illnesses were less likely to be formally identified for palliative care prior to death (Harrison et al. 2012). This may be because of a perception that palliative care is only the care at the end of life.

Our group has done recent work (under review) that shows that GPs' recognition of approaching end of life is tacit, and they will not often raise it with patients de novo, unless the patient raises the possibility first. If patients raise it, then proceeding to appropriate planning is relatively smooth. If they do not, then the GP is loathe to raise the possibility of impending death. However, the GPs reported that they did subtly, perhaps consciously, shift their care toward comfort care.

Burridge et al. (Burridge et al. 2011) describe "consultation etiquette" – where the patient is too polite to "bother the doctor" with their problems and doctor is too polite to raise issues like this one with the patient. Thus consideration of very important issues like this one is deferred and perhaps never addressed.

7.1.1 Attempts at Systematic Identification of Patients Nearing the End of Life in Primary Care

There have been concerted attempts to systematize the identification of patients approaching the end of life. Keri Thomas of England initiated this movement and developed a sophisticated process of identification through screening of GP patient lists, planning care, and enacting the plan – the so-called Gold Standards Framework (Thomas 2007). There have also been other tools or checklists to assist in the identification of people approaching the end of life. A systematic review has identified four main identification tools and assesses their practicality in the practice setting (Maas et al. 2013). What is clear is that any systematic identification process has to be compatible with the health systems in which they operate. The tools available very clearly illustrate this. Gomez-Batiste in Catalonia, Spain, developed a tool (NECPAL) that could interrogate electronic records and required smaller amounts of input from clinicians (Gomez-Batiste et al. 2013). Spain has a single electronic record that follows the patient through the entire health system. Thomas' Prognostic Indicator Guide (PIG) (Thomas 2011) works in the context of UK's system of capitation payments and rewards for meeting public health targets. This enables practice staff to spend time searching patient records for people suitable for a Palliative Care register and be rewarded for doing so. This will not work in a fee-for-service environment like the Netherlands or Australia, where practitioners only get paid for seeing patients.

Research into the implementation of screening tools has taught several lessons. In the Netherlands, a tool was developed that identified people with advanced cancer and end-stage lung and heart failure, but not those with non-specific frailty or multimorbidity (Thoonsen et al. 2015). The project trained GPs in its use – a good strategy in a fee-for-service environment. However, in an RCT, there was no difference in patient identification when all GPs who were randomized to training in the tool were considered, as half the intervention group did not use it (Thoonsen et al. 2015). However, there were significant improvements in patient identification and multifaceted care when analyzing those GPs who did use the tool (Thoonsen et al. 2015). The Supportive and Palliative Indicator Tool (SPICT) has been the one most used internationally (Highet et al. 2014). It is short (one page) and more inclusive than exclusive of patients through the use of broad categories of disability. It is also constantly being revised and upgraded through web page

(www.spict.org), inviting commentary and registration of its use. It has been translated into several languages as well.

A literature review of the impact of the Gold Standards Framework (Shaw et al. 2010) showed that, in spite of financial incentives to maintain palliative care registers, many people who did die did not appear on the register, as it contained predominantly people with advanced cancer. Why this was the case is yet to be fully determined.

While the concept of screening patient lists is very logical on paper, it appears that converting the idea into practice is another issue. We learn from this literature that GPs recognize deterioration to death with cancer more easily than for end-stage nonmalignant disease. We also learn that relying on GPs to use a tool offered to them is no guarantee of use, even if use does achieve the desired result.

Our group wondered whether there was benefit in using screening tools at all and tested the ability of screening tools to predict death against GP intuition (Mitchell et al. 2018a). We showed that screening tools was more effective than intuition in predicting those who did die but only among those patients that a GP considered were at risk of death. There was no difference between the groups in identifying people who died when whole practice lists of patients over 70 were screened. There was also a very high false-positive rate of identification of risk of death with both techniques. We showed that deliberately screening for likely death was not a useful means of identifying the cohort of people with end-of-life needs, and recognition of escalating needs was a better approach to explore.

Taking identification out of the hands of GPs and making screening an automatic procedure, for example, through electronic records surveillance, may have promise (Mason et al. 2015). The problem will be to have a screening process to identify people at risk, but with appropriately modest false-positive rates. A positive test demands a response, and a high false-positive test will place an unreasonable burden on practitioners if developing a comprehensive care plan is the response. Either a graded response proportional to the level of risk is developed, or a less sensitive and more specific set of search criteria are generated.

Zheng et al. did elegant work in Scottish general practices to see if the problem of end-of-life recognition was the term "palliative" (Zheng et al. 2013). They showed that people with nonmalignant diseases – organ failure and frailty/multimorbidity/dementia – were hardly ever placed on the practice palliative care register as at risk of dying compared with cancer, where three-quarters of cancer patients were identified on the register and in a timely manner. By changing the title of the register to a "supportive needs register," recognition of people who died from nonmalignant was 40% at the time of death, and much earlier recognition occurred.

One issue is that dying in primary care is a low prevalence event in primary care. As the population ages, patient deaths will become more prevalent. However, while patient death will never be a routine event, the incidence of frail and multimorbid patients will rise, all of whom will die. At what point should a doctor "change gears"? Should it be a sudden transition, or a gradual escalation of response to need? The answers to these questions are not yet clear.

In summary, identification of the patient is the essential first step to proactive end-of-life care. While appearing logical, it is in fact highly complex to enact it systematically in the community.

7.2 Planning Care

Once a person is identified as requiring palliative care, ideally some sort of plan needs to be generated. This again is not as easy as it sounds. There are two elements to proactive care planning – advance care planning and clinical care planning (Fig. 4).

7.2.1 Advance Care Planning

Much effort has been made to facilitate advance care decision-making. The rationale is that medical care needs to reflect the individual's goals and aspirations for the remainder of their life, along with preferences for the type of health care they want to have. This is very important in hospital practice, so that care which can be very expensive and which may not produce demonstrable

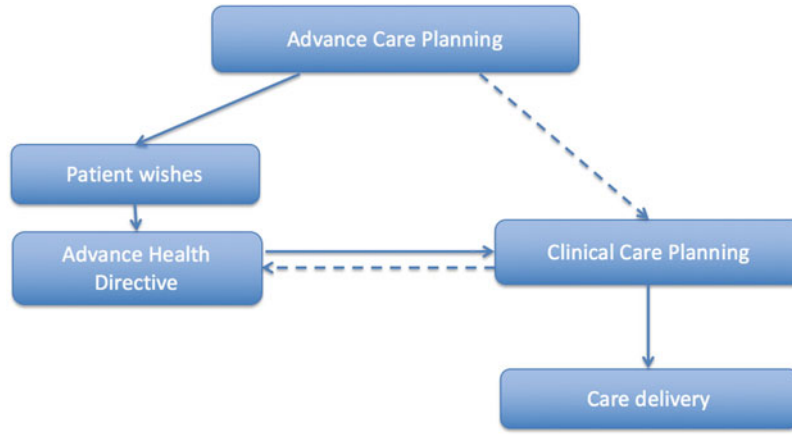

Fig. 4 A concept map of care planning for the end of life (Mitchell. 2014a)

benefits is only offered to those who really want it. The second element of advance care planning is to appoint substitute decision-makers in the event that the person cannot articulate decisions for themselves. These people are usually, but not always, next of kin.

7.2.2 Clinical Care Planning

A second form of care planning is also highly desirable but less considered. This is clinical care planning. Most people with serious illness have predictable complications. For example, a person who has severe heart failure will almost certainly wake up in the middle of the night breathless at some point in the future. What can be done to prevent that? What actions can minimize the breathlessness and facilitate the patient settling without an emergency admission to hospital when it does happen? It should be possible to anticipate these issues and prepare plans that can be enacted when the anticipated problems arise.

7.2.3 Integrating Specialist and Generalist Care

Being ill with multiple conditions can be problematic. Hillman describes a health system where the consequences of lack of integration include a lack of clear decision-making, deferral of critical decisions these often being made by intensive care specialists by default (Hillman and Cardona-Morrell 2015). Gawande describes multiple personal experiences of a loss of focus on the whole person, with decisions being made for reasons far removed from what the patient wants or will provide long-term benefit (Gawande 2014).

General practitioners manage multimorbidity as a matter of course. They are also usually very aware of the personality and social circumstances of the individual, which becomes important in anticipating the needs of people at the end of life.

Management of patients with multimorbid problems is not well coordinated between GP and the specialist team(s). A systematic review of integration programs that deliberately integrated general practitioners with specialists found only 14 such studies (Mitchell et al. 2015). By contrast, there are dozens of studies testing integration in a range of specialist settings. Here integration means integration of different specialist treatment modalities. Actual interventions aimed at bringing medical specialities together are unusual. For example, a Cochrane review of integration in COPD care involved 26 studies, only 2 of which aimed to improve interprofessional integration (Kruis et al. 2013).

Bringing together the contextual knowledge of GPs and the content knowledge of specialists should be of benefit to patients facing the end of life. A number of interventions supporting this form of care have been tested.

The one with the strongest evidence base is case conferences between specialists and GPs.

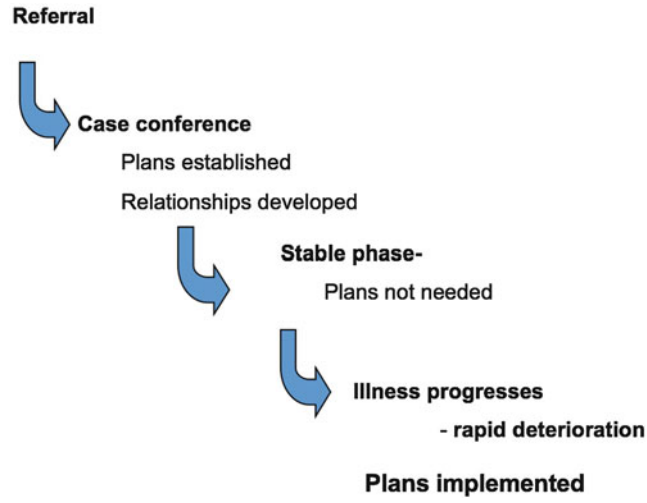

Fig. 5 Mechanism of action of GP specialist case conferences at the end of life

The rationale is that GPs know the context of the patient and their family, while specialist teams have the content expertise. The combination of these two things should be effective in improving patient outcomes. Australian general practice is funded through a blending of fee-for-service and outcomes based funding. In recognition of the importance of integrating GPs into the care of complex and chronic conditions, government rebates for participating in case conferences with other health professionals are available. Both trials used this opportunity to test the above hypothesis. Abernethy et al.'s study (the world's largest randomized controlled trial in palliative care) showed 30% reductions in admissions to hospitals and a mean 10% improvement in maintenance of functional capacity from diagnosis to death (Abernethy et al. 2013). Mitchell et al. showed improvements in the patient's quality of life in the last month of life (Mitchell et al. 2008b).

The assumed mechanism of action for this improvement was that the case conference took place and a joint plan of action was negotiated and the palliative care team members and the GP became acquainted with each other, creating communication channels. This plan was often not enacted immediately because there was often a latent period when the patient was stable. However, when deterioration did occur, the latent communication channels were activated, plans were in place and enacted promptly, and the patient's outcomes were better than those of normal care (Fig. 5).

It appears that a key element of successful GP specialist integration is buy-in from the GPs. Active negotiation of the plan between specialists and GPs appears to work better than passive receipt by a GP of a plan formulated by the specialists – someone else's plan (Mitchell et al. 2008a). Thus the major difference between the program impact was that the GP was an integral part of the planning process – he or she had buy-in – whereas in the geriatrics trial, the primary care practitioner was a passive recipient of someone else's care plan.

7.3 Implementing Care

Once patient and carer needs are identified and care planned, the plan has to be implemented. Recent work (under review) indicates that the GPs' understanding of the patient's willingness to accept their nearness to death determines how overtly a plan to implement end-of-life care is articulated. If the patient can articulate an awareness and acceptance of impending death, then the GP will discuss end-of-life care overtly. If not, then GPs instinctively and subtly changes care goals to include issues of importance at the end of life.

8 What Are the Outcomes for Primary Care-Delivered Palliative Care?

The following sections examine how well GPs perform palliative care from different perspectives. They arise from the series of systematic reviews mentioned in the acknowledgments at the commencement of the chapter.

8.1 Symptoms (Mitchell et al. 2018)

8.1.1 GP-Identified Symptoms

General practitioners (GPs) found symptoms associated with the terminal phase as the most distressing for the patient (Mitchell and Seamark 2016). Of those patients who were cared for at home in the terminal phase of their disease, the main symptom was fatigue, which was a documented symptom in almost all patients (Leemans et al. 2012). Other common symptoms included anorexia, drowsiness, pain, dyspnea, and psychological distress. Pain was perceived as causing less suffering than these in the terminal phase (Mitchell and Seamark 2016).

8.1.2 Did GPs Respond Adequately to Patient Symptoms?

Primary health-care professionals were well placed to recognize symptom issues in palliative care patients. A study comparing agreement on symptom assessments between patients at home with those of nurses and GPs demonstrated high levels of symptom identification (Ewing et al. 2006). Gastrointestinal problems such as nausea, vomiting, and constipation were recognized by GPs more than by the patients themselves. Nonmedical health professionals were more likely to note psychological issues and bestow greater significance to them than patients did themselves. Pain scores were comparable between all groups throughout.

In general, GPs expressed confidence responding to the symptoms identified by their palliative patients (Leemans et al. 2012; Blazekovic-Milakovic et al. 2006; Kuin et al. 2004; Canto et al. 2000). They felt most comfortable in responding to pain. They were least comfortable managing dyspnea, followed by fatigue. However, a study in Spain identified that the majority of GPs felt confident managing pain, dyspnea, and epilepsy by themselves (Canto et al. 2000).

General Psychological Care General practitioners perceived emotional support as being one of the most important aspects of palliative and terminal care they managed (Blazekovic-Milakovic et al. 2006; Ledeboer et al. 2006). They used supportive conversations, assistance with administration procedures, coordination of care, and management of carer and family distress to address patient distress (Canto et al. 2000; Demagny et al. 2009). While GPs felt they were predominantly comfortable providing this care, there were a number of challenges. GPs were often troubled by conversations about death and spirituality (Kelly et al. 2008). In one study, only half of GPs had involved patients in conversations regarding dying, viewing patient stoicism, and the presence of other family members as common barriers. Spirituality was seen as a difficult subject, often viewed by GPs as involving only religious beliefs, and thus rarely discussed. A common theme throughout all such studies was a lack of formal education and experience in this area, with GP eager to participate in further training (Canto et al. 2000).

8.1.3 Effectiveness of GP Symptom Control

(a) ***Pain***. While most general practitioners had adequate knowledge of general pain management, deficits in some GPs' knowledge of treating cancer pain may have resulted in ongoing pain at the end of life (Anquinet et al. 2011). They were also challenged by managing comorbid symptoms, such as neurological symptoms in patients with high-grade gliomas (Sizoo et al. 2010).

There was insufficient evidence available to assess whether GP management provided adequate relief: assessment of suffering, effective cancer pain management (Gott et al. 2010), patients' roles in end-of-life care and advance

care planning, artificial nutrition and hydration, and the understanding of sedation versus euthanasia in relation to pain management (Anquinet et al. 2011).

(b) ***Breathlessness***. GPs were reluctant to prescribe opioids for breathlessness associated with severe COPD, even though they were aware of their proven benefit (Gott et al. 2010; Young et al. 2012). The main reasons for their hesitancy were the lack of education or knowledge of guidelines (Young et al. 2012), perceived scarce evidence supporting expert groups' recommendations for the long-term use of opioids for breathlessness (Young et al. 2012), and the fear of censure (Gott et al. 2010; Young et al. 2012). Some GPs would rather hospitalize patients than prescribe opioids for breathlessness (Gott et al. 2010).

8.1.4 Gastrointestinal Symptoms

One community-based audit showed that 30 of 88 patients were prescribed laxatives (Mitchell and Seamark 2016). Of these 11 were co-prescribed with opioids and 19 for non-opioid-related constipation. Thirty-six patients of the 88 patients had nausea. Most were treated with a single antiemetic, or two antiemetics tried sequentially, while only two had a combination of two antiemetics. In one study, gastrointestinal symptoms were reported as the most frequent symptoms identified by GPs (Borgsteede et al. 2007a). GPs identified nausea and vomiting as more prevalent and more severe than patients reported it, but under-recognized constipation as a problem (Ewing et al. 2006). In a 2002 survey of GPs prescribing an opioid, reported 57.6% would prescribe an antiemetic, only 33% a laxative (Oxenham et al. 2003; Borgsteede et al. 2009), and 20.7% both in the first few days (Barclay et al. 2002).

8.1.5 Depression

GPs experienced difficulties diagnosing and managing depression within the palliative care setting (Warmenhoven et al. 2012). GPs reported relying on clinical judgment, patient context, and the long-standing patient-doctor relationship to identify depression in palliative care patients, rather than making criterion-based diagnoses. The treatment of depression in palliative care was mainly supportive and non-specific, with antidepressants seldom prescribed.

8.1.6 Palliative Sedation

Palliative sedation is a recent phenomenon, performed when standard treatment is not able to control troubling symptoms. By sedating the patient to the point of unconsciousness, it removes awareness of the symptom and alleviates patient distress. The practice is only infrequently required (Donker et al. 2013) and should always be administered after close consultation with the patient and family. Continuous deep sedation until death does not always guarantee the dying process was free from symptoms (Anquinet et al. 2013). There was disagreement among practitioners about which symptoms actually necessitate palliative sedation (Sercu et al. 2014), as well as the potentially life-shortening intentions of sedation (Sercu et al. 2014). Reassuringly, a systematic review has showed palliative sedation does not shorten life expectancy (Beller et al. 2015).

A minority of GPs reported feeling pressure from patients, relatives, or colleagues to commence continuous sedation. This pressure was felt more strongly when patients experienced psychological symptoms (compared to physical symptoms) and when patients had greater estimated life expectancies (Blanker et al. 2012). Such pressure led to GPs seeking advice with respect to therapeutic options and/or specific information (Blanker et al. 2012; van Heest et al. 2009).

8.1.7 Barriers to Good Symptom Control

The need for more formal training in palliative care for GPs at both under- and postgraduate level was well documented (Farber et al. 2004; Hong et al. 2010; Walsh and Regan 2001; Groot et al. 2005). There was a particular need for education in the use of opioids (Hirooka et al. 2014; Gardiner et al. 2012; Todd et al. 2013; Salvato et al. 2003; Higginson and Gao 2012; Hawley et al. 2013) and referral for palliative radiotherapy (Vulto et al. 2009; Olson et al. 2012; Samant et al. 2006).

Another barrier identified by GPs was a lack of access to inpatient beds and home services support – often perceived as the result of bureaucracy – causing delay of essential symptom management or necessitating the patient to travel to hospital for simple procedures that could have been delivered in the home (Walsh and Regan 2001; Groot et al. 2007).

GP confidence in some settings providing palliative care was perceived as being low but increased with experience (Hirooka et al. 2014). The more frequently a GP performed palliative care activities, the more competent they felt (Farber et al. 2004; Gorlen et al. 2012). A death within a GP's population is a low prevalence event, which can exacerbates the GP's sense of inadequacy. However, those physicians who were more interested in palliative care did perform palliative care activities more frequently (Farber et al. 2004).

9 GP Understanding and Use of Opioid Therapy in Pain and Dyspnea Management

GPs were usually familiar with the management of common pain problems, the WHO guidelines on analgesics, and the use of oral opioids (Oxenham et al. 2003; Barclay et al. 2002). However, some gaps were identified: omission of rapid-release opioid use for breakthrough pain (Oxenham et al. 2003; Barclay et al. 2002), not prescribing laxatives and antiemetics when giving opioids (Oxenham et al. 2003; Barclay et al. 2002; Borgsteede et al. 2007b), and difficulty in converting oral opioids to subcutaneous forms (Oxenham et al. 2003; Barclay et al. 2002; Linklater 2008).

Older GPs (Young et al. 2012; Ben Diane et al. 2005), GPs with more experience in the treatment of terminally ill patients (Ben Diane et al. 2005), and those trained in palliative care and pain management (Ben Diane et al. 2005; Mas et al. 2010) were more likely to prescribe strong opioids. They were more comfortable prescribing opioids for cancer patients (Young et al. 2012; Borgsteede et al. 2007b) compared with other conditions and more particularly in the terminal phase (Harrison et al. 2012). Patient factors positively associated with GP opioid prescription included younger age (Harrison et al. 2012; Hirakawa et al. 2007) higher pain levels (higher pain associated with more opioid prescriptions) (Mas et al. 2010), repeated requests for pain medication (Mas et al. 2010), and the presence of relatives caring for the patient.

9.1 Advance Health Directives

9.1.1 Uncertainty about the Timing of ACP

Advance care planning (ACP) is done ad hoc in the terminal phase, is sometimes discussed but not documented, or is not done at all (Evans et al. 2013; Meeussen et al. 2011; Snyder et al. 2013; Vandervoort et al. 2012). Difficulties associated with the unpredictability of the end-of-life trajectory and the absence of a clear beginning of the final stages of non-cancer patient deaths created uncertainty among clinicians about when such a discussion should be initiated (Meeussen et al. 2011; De Vleminck et al. 2014; Evans et al. 2014). Consequently, for non-cancer patients, ACP often occurs in the last week of life (Meeussen et al. 2011; Snyder et al. 2013) despite patients' preference to have a discussion with their GP earlier (Robinson et al. 2012). Discharge from hospital was a common trigger for initiating ACP (Meeussen et al. 2011; Boyd et al. 2010). ACP is more likely to be completed if the patient was in hospital as opposed to the community, as the hospital-treating doctors were more likely to recognize changing clinical status (Boyd et al. 2010).

Several ***factors that influenced the completion of ACP by GPs*** were identified. In terms of provider characteristics, an advance care plan was more likely to be completed if the GP was older and had more clinical experience (Snyder et al. 2013); if the GP was comfortable discussing ACP (Farber et al. 2004; Snyder et al. 2013; Evans et al. 2014); if they had appropriate education and training in ACP (De Vleminck et al. 2014; Robinson et al. 2012; Boyd et al. 2010; Cartwright et al. 2014; Rhee et al. 2013); and if the GP was involved and trained in palliative care (Farber

et al. 2004). There were also issues with the quality of ACP, as studies showed that where end-of-life discussions took place, not all holistic aspects were addressed such as spiritual and existential concerns, social issues, and cultural differences (Farber et al. 2004; Snyder et al. 2013; Evans et al. 2014). Lack of time was also described as a barrier to ACP (Brown 2002).

Patient characteristics and patient interest in ACP also influenced the GP's involvement. If patients lacked awareness of their diagnosis and prognosis or did not initiate such a discussion, ACP was often not raised by the GP (De Vleminck et al. 2014). GPs also found it difficult to introduce ACP to patients who are not already interested or informed about it (Brown 2002). Older patients with non-cancer diseases often had less detailed ACP discussions (Evans et al. 2014). Despite these influences, patients want to discuss ACP with their GP but at a much earlier phase (Robinson et al. 2012).

Other factors that influenced completion or implementation of ACP were identified as concerns about the legal standing (Rhee et al. 2013; Robinson et al. 2013) and currency of ACP documents (Bull and Mash 2012), confusion around the terminologies and systems particularly with substitute decision-making (Cartwright et al. 2014), uncertainty around validity of ACP forms given there are multiple available (Robinson et al. 2013), concerns about making binding decisions about the future given the uncertainties of disease trajectories, and lack of awareness that ACP can be modified (Boyd et al. 2010; Rhee et al. 2013; Robinson et al. 2013).

In addition, organizational and care setting factors were found to influence the completion of an advance care plan. Incorporating ACP as part of standard care and having organizational protocols and systems for ACP, especially in residential care facilities, were found to be important in increasing the use of advance care plans (De Vleminck et al. 2014; Mitchell et al. 2011). ACP was also more likely to be considered in the context of end-of-life care and in the provision of palliative care (Evans et al. 2014; Boyd et al. 2010).

10 Determinants of whether the Completed Advance Care Plans or Directives Are Implemented

These included advance care plan factors such as its availability, currency, and legality of the forms (Rhee et al. 2013; Robinson et al. 2013; Bull and Mash 2012), timing of ACP (Meeussen et al. 2011), patient illness factors (e.g., quality of life of patient, level of functionality, and prognostication), organization and care setting factors (e.g., prioritizing life-sustaining treatments, policies, and protocols to support use of advance care plans), awareness, and attitudes of health professionals and family to ACP (e.g., families' understanding of the disease progression, GPs' desire to avoid family dissent) (Rhee et al. 2013).

10.1 Caring for Carers

Ninety percent of patient care in the final year of life occurs at home (Hinton 1994), with many patients moving to an inpatient setting in the final days of life. Hence, much of the burden of caregiving is managed in the community, with the greatest burden falling on primary caregivers (Aoun 2004). Care may be equivalent to a full-time job, with 20% of caregivers providing full-time or constant care (Aoun 2004).

Caring for a patient with end-of-life needs carries a number of implications. It is often provided by people who are themselves elderly and/or ill, and caregiving may exacerbate the illness burden. Caregivers of patients receiving PC have lower quality of life (QoL-impairment in physical functioning, general health, and vitality) and worse overall physical health than caregivers of patients receiving curative or active treatment (Weitzner et al. 1999). As patients deteriorate physically, caregiver QoL worsens, suggesting a greater need for support at this time (Grunfeld et al. 2004). Furthermore, while many caregivers feel positively about caregiving and derive deep satisfaction in this role, caregivers may also experience a number of physical and psychosocial issues, including reduced social contact, significant financial burden, sadness, anger, or

resentment which may increase the risk of psychiatric morbidity and complicated grief (Aoun et al. 2014). Additionally, caregivers report a number of unmet needs across a variety of areas, including information, communication, and support from services (Aoun et al. 2005). Family members whose own needs are not identified and addressed early have greater needs and less trust and confidence in the health-care system and cope more poorly in the later stages than families who have been informed and supported throughout the course of the illness (Kristjanson and White 2002).

However, despite the shift to include family members and primary caregivers as active participants in PC (Sepulveda et al. 2002), it is still common that the primary focus of the caregiver and of health professionals is on the needs and comfort of the patient, meaning that caregiver needs and distress may be considered secondary to the patient's and may be (Butler et al. 2005). For example, in 2003/2004, the patient was the client in 98.3% of referrals to Home and Community Care services, yet caregivers are a target group of that program. It has also been suggested that caregivers may be reluctant to raise their own needs with their health-care provider, as they do not wish to put their own issues before the patient's or bother the health-care professional (Hudson et al. 2004). On the other hand, health-care professionals are often working under tight time restraints, with the average Australian general practice consultation in lasting only 14.9 minutes (Britt et al. 2016), making it difficult to assess both the patient and caregivers needs in one appointment. Countering this short-time period is the fact that GPs frequently see patients several times to resolve a complex problem.

11 Does Primary Care Involvement Impact on the End-of-Life Outcomes?

Although international literature highlights GPs' variable levels of knowledge about PC and symptom control (Barclay et al. 2003) and their lower perceived levels of competence in these areas compared to specialist PC services, GPs are in an optimal position to evaluate and assess the needs of caregivers. GPs are usually the first point of contact for patients and their caregivers and generally have an established relationship with the patients with palliative care needs as well as having an important contextual knowledge of the family and of the illness. Canadian research indicates that palliative care patients with a regular GP are less likely to seek care from emergency departments (Burge et al. 2003a) and are less likely to die in hospital (Burge et al. 2003b).

Whether the effort of involving the patient in end-of-life care ultimately depends on whether patient and carers are better off with GP involvement. What is the evidence that patients and carers do better with the involvement of their GP, compared with those who have little or no GP involvement?

11.1 Integrated Primary-Secondary Care

We have already presented the controlled trial evidence of the impact of case conferences between GPs and specialist palliative teams managing mainly cancer patients (Abernethy et al. 2013; Mitchell et al. 2008b). An RCT of facilitated family meetings at which GPs were invited to attend for terminal dementia patients in aged care homes showed no group effect on quality of life but improvements in pharmacological and non-pharmacological management of symptoms (Agar et al. 2017).

There is lower level evidence in favor of integrated care specialists and GPs caring for people at the end of life for nonmalignant end-of-life disease as well. Case conferences in end-stage heart failure showed impressive reductions in hospitalization, emergency visits, emergency visits not requiring admission (Mitchell et al. 2014b), and costs (Hollingworth et al. 2016). A uniform pain control pathway reduced palliative patient's pain in rural settings (Tateno and Ishikawa 2012), while half of head and neck cancer patients whose GP used a telephone advice service died at home,

but half also had some level of uncontrolled symptoms (Ledeboer et al. 2006).

It is important to observe that these initiatives were all initiated by specialist services and reached out to general practitioners. It is clear that the primary care and specialist care work in very different ways. GPs tend to react to problems, and their systems are often designed around reaction. By contrast, specialist services are organizations and are more used to working with multidisciplinary teams. They are in a far better situation to initiate collaborative models of care. Active collaboration between them improves outcomes but requires considerable effort to embed such initiatives. Stakeholders need to feel that the outcomes are worth the time and effort.

11.2 Advance Care Planning

There is some evidence that where an advance care plan is in place and implemented, patient preferences and wishes are more likely to be followed (Evans et al. 2013). Other patient outcomes of ACP include anticipated symptoms being identified earlier, greater control with symptom management, (Auerbach and Pantilat 2004) greater patient satisfaction with the GP, (Tierney et al. 2001) and increased support, contact, and visits by GPs in the last week of life (Evans et al. 2013; Meeussen et al. 2011). Moreover, when an advance care plan is completed, patients are more likely to die in their preferred place of death (Vandervoort et al. 2012).

11.3 Caring for Carers

There is one study of GP identification and management of the needs of carers of advanced cancer patients. Using a self-completed needs checklist to identify carer problems, the GP and carer addressed these issues in a carer-focused consultation. This found improvements in outcomes for carers who were anxious or depressed at baseline and who were caring for more ill people and enabled the identification of more needs than the normal care control group (Mitchell et al. 2013).

11.4 Place of Death

There is a significant association between home visits by GPs to patients with advanced cancer with the possibility of dying at home and not hospital (e.g., Burge et al. 2003b; Neergaard et al. 2009). Similar findings on the likelihood of home death were also found for home visits by community nurses to cancer patients (Neergaard et al. 2009).

12 Policy Initiatives

End-of-life care policy has largely focused on specialist palliative care and its role at the very end of life. By and large cancer care is its focus, and the principles and processes of specialist services are well established. Only now is it becoming clear that a far bigger issue is developing – the population is aging, most will die of diseases other than cancer, and the current way of caring for patients is simply not viable to manage massively increased numbers of frail, multimorbid people. In 2014, the World Health Organization passed a resolution declaring end-of-life care of fundamental importance (World Health Organization 2014), thus committing member countries to improving end-of-life care. A core part of this declaration was the central role primary care had to play in providing end-of-life care. Work done by Murray and colleagues through the European Association of Palliative Care Primary Care working group had underpinned that initiative. They developed a set of guidelines based on Stjernsward's work, to allow nations or regions to analyze their end-of-life policy in terms of four high level principles, policy settings, drug availability, education, and implementation (Stjernsward et al. 2007) (Fig. 6), and created a means of evaluating national health systems to show the extent of involvement of primary care in end-of-life care. They evaluated 29 European countries' responses to show a range of facilitators and barriers to primary care end-of-life care (Murray et al. 2015) (Table 1). From that work, national policy to address these issues can arise. The Toolkit has been translated into several languages.

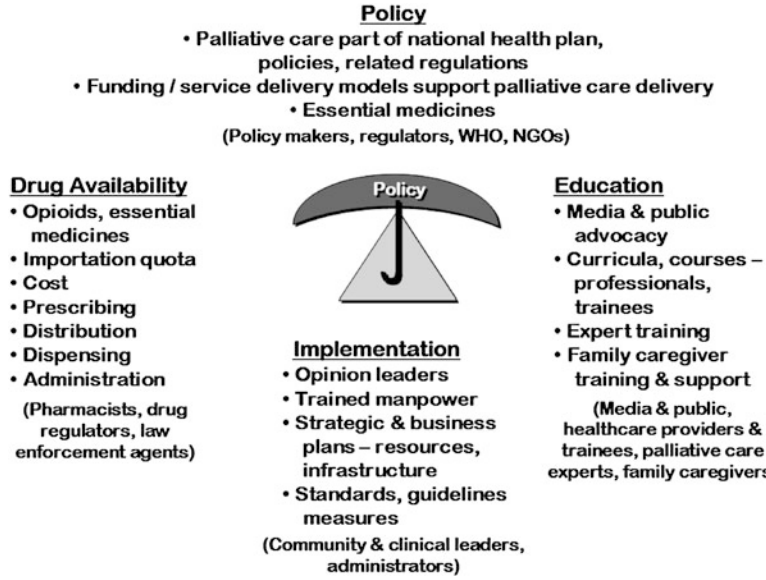

Fig. 6 Policy framework for developing palliative care services (Stjernsward et al. 2007)

Table 1 Barriers and opportunities to facilitate primary care involvement in end-of-life care provision (Murray et al. 2015)

Barriers	Opportunities
Lack of knowledge and skills among GPs and nurses	Training opportunities available in some countries
Financial systems not permitting reimbursements for palliative care	Examples of established primary care infrastructure
Issues hindering opiate prescribing	New national strategies supporting palliative care
Lack of professional or specialist support	Developing clinical networks in many countries
Poor identification of patients requiring palliative care	All patients have access to primary care
Limited public understanding and stigmatization of and palliative care	Increasing political support

Another international initiative has been led by Murray and Mitchell as co-Chairs – the International Primary Palliative Care Collaborative. This group was established in 2005 and has over 300 members from around the world. Its remit is to promote primary palliative care across the world through research, teaching, and local policy development. It has played an important part in developing the considerable momentum that has been evident in the last few years. Excellent work is currently happening in countries across the globe, bringing the critical role of primary care at the end of life to the attention of national governments.

13 Conclusion

Primary care and palliative care share a close affinity through an emphasis on the management of the whole person. In the age of specialist palliative care, a narrow view of end-of-life care has emerged which focuses on the last few weeks of life and largely relating to cancer and some particularly difficult degenerative diseases. The rapid aging of the population will lead to swelling numbers of deaths, with the major contributors being frailty, multimorbidity, organ failure, and dementia. These diseases, with their slowly accumulating needs and unpredictable illness course, are much more difficult to plan for, and a completely new approach to end-of-life care is warranted.

Further, the multidimensional nature of whole person care needs to be acknowledged and care arranged to meet these diverse needs.

Primary care has to take a major role in this. Complex medical problems will demand better

integration of care between patients, carers, primary care practitioners, and specialists. This will be a difficult transition for health systems built on disease and system-focused, subspecialist care, but one that has to commence now.

Palliative Care in Residential Settings 51

Jo Hockley

Contents

Abstract

Many residential care settings for older people have been established on a culture of rehabilitation. However, this is changing. In many Western countries, recent policy is encouraging frail older people to stay longer in their own homes before going into 24-h care. As a result, on admission to these settings, older people are often considerably more dependent and frail than 10 years ago.

The palliative care needs of frail older people with multiple comorbidities admitted to residential care settings are significant. Palliative care is core to their work; such settings are now being compared to the former hospices that founded the hospice movement some 50 years ago. Hospices have an important role to play in reaching out to staff in

residential care settings and the frail older people they care for in order to support and enhance a palliative care approach.

This chapter describes some of the differences between palliative care for people with advanced cancer (often dying in mid-life) and those dying as a frail older person at the end of their lives with multiple comorbidities. It highlights a number of different quality improvement initiatives through which staff in residential care settings can be supported to adopt a greater palliative care approach.

Currently, nearly a quarter of the population in the UK, in Canada, and the USA die in care homes. In other countries, such as The Netherlands and Norway where there is greater on-site healthcare provision including physicians, it is nearer 50% of the country's population.

1 Introduction

This chapter aims to bring: greater awareness to the important place that residential care settings increasingly play in the care of frail older people at the end of life; highlight differences between the populations in these facilities compared to that of hospices; suggest opportunities and initiatives where a palliative care approach might be enhanced; and, finally, use narratives to bring alive important aspects.

For many years, residential care settings have been seen as places for rehabilitation where older people were admitted for companionship and to maintain independence for as long as possible. So much so that, in the UK prior to 2000, while a few frail older people died in the care home they were living in, most residents were admitted to the local hospital to die. Increasingly, however, countries across the world are concerned about how to meet the cost of institutional elderly care and are encouraging the provision of more care for older people in their own homes. Consequently, on admission to a place providing 24-h care, older people are now considerably frailer.

The result of such a policy has meant that there is not only greater frailty in people living in their own homes, which in itself needs to be proactively managed, but the majority of residents living/dying in residential care settings now have advanced, progressive, incurable diseases (IAHPC 2017) – ranging from Parkinson's disease and stroke to a number of different dementias. Gone are the places where the majority of residents would survive more than 3 or 4 years. The average length of stay in UK care homes is now 15 months with the majority of people dying within a year of admission to a care home with on-site nurses (Kinley et al. 2014a). Currently, nearly a quarter of the population in the UK, Canada, and the USA die in care homes; in other countries (i.e., The Netherlands and Norway) where there is greater on-site healthcare provision including physicians, it is nearer 50% of the population.

Staff working in residential care settings are being encouraged to develop their palliative care skills; however, palliative care is still not part of statutory training for residential care settings in many countries. This rise in both the complexity and number of comorbidities of frail older people requiring 24-h care at a later stage demands a higher level of skill and communication within facilities especially facilities where there is no on-site nursing (Handley et al. 2014).

Different terms associated with residential settings globally are now outlined before considering the following: the population of those who live and work in these settings; geriatrics and palliative care and the differing dying trajectories of frail older people; different models and initiatives to enhance palliative care in these settings; components of successful implementation of initiatives and their sustainability; and, innovations for the future.

2 Residential Care Settings Giving 24-H Care to Frail Older People

Froggatt and colleagues undertook a comprehensive mapping and classification of European care homes (with and without nursing) and their palliative care provision collecting data from 29 European countries (Froggatt et al. 2017a).

Their aim was to develop a typology of palliative care activity with respect to the implementation of various palliative care initiatives. They identified three types of facility: Type 1 ("on-site" physicians and nurses and care assistants), Type 2 ("on-site" nurses and care assistants but "off-site" physicians), and Type 3 ("on-site" care assistants with "off-site" physicians and nurses) (Froggatt et al. 2017b). Although the distinction over the years between Type 2 and Type 3 care homes with the regard to the professionals working there remains much the same, the distinction between the people living in these types of facilities is diminishing as the general residential setting population becomes distinctly frailer. Many countries worldwide are now merging the distinction between "low" and "high" care or "residential" and "nursing" care in institutions.

There are different terms used to describe the 24-h residential care given to frail older people and often more than one in the same country (see Table 1). For the purpose of this chapter, residential care settings for people requiring 24-h care will be called "long-term care facilities" (LTCFs) unless talking specifically about a certain country when the name relevant to that country will be used.

Every country has different ways of funding the 24-h care of frail older people. However, there are three broad categories of facilities: independent private ("for profit"), independent charitable foundations ("not for profit"), and government (health/local authority) in most countries. How care is funded for frail older people is gaining increasing attention by researchers and politicians in light of the aging population.

Globally, the development of palliative care services in residential care settings has, in the main, been less well developed than in other settings such as hospitals or hospices with their home care teams. An exception is The Netherlands. Here, in the 1980s, following a 5-year research project at Antonius IJsselmonde, Rotterdam (a 230-bedded nursing home), specific palliative care wards were created in large nursing home organizations in recognition of the needs of frail older people at the end of life (Baar 1999; Baar and van der Kloot Meijburg 2002).

In contrast, in the UK, where palliative care was first developed through hospices and their home care teams, it was not until the turn of the twenty-first century that palliative care services reached out to care homes. Many long-stay geriatric wards were closed down in 1990s, and the money was given to social care who then paid independent care homes to care for older people. While the social care needs of frail older people were considerably advanced, because care homes were now placed outside the NHS, they became isolated from palliative care developments occurring in the NHS and more difficult to reach.

3 The LTCF Population

3.1 Residents and Their Families

Those over 85 years are the fastest growing segment of the population in many western countries. In the UK, this group is projected to more than double by 2039 and is associated with increasing incidence of dementia (ONS 2014). In the UK, those requiring 24-h care in 2030 are projected to increase by 82% with an increasing demand from 400,000 to 630,000 care home places (Jagger et al. 2011).

As has already been mentioned, the LTCF population globally are increasingly frail with multiple comorbidities. In the UK, as many as 80% of residents in care homes have dementia or severe cognitive impairments (Alzheimers Society 2013). It is well documented that people with advanced dementia living in LTCFs can experience "social death" where they are passive recipients or objects of care being robbed of a meaningful interaction in the last months/years of life (Watson 2016). Holistic care and the importance of recognizing that the mind is not separate from the body but intricately made up of mind, body, and soul cannot be over emphasized especially in relation to someone with advanced dementia.

A white paper on the palliative care needs for people with dementia (van der Steen et al. 2014) details complete consensus from experts across 23 European countries in relation to the following:

Table 1 Type of 24-h residential care facility according to country

Country	Name given to facility	Staff employed in facilities	How funded
Australia (type 2 and 3)	Aged Care Facilities (ACFs)	RNs: Registered nurses ENs: Enrolled nurses PCAs: Personal care attendants AHPs: Allied health professionals	Health and social care Privately funded
USA (type 1 and 2)	Skilled Nursing Facilities (SNFs) or Long-term care facilities (LTCFs) or Continuing Care Retirement Communities (CCRCs)	RNs: Registered nurses LVNs: Licensed vocational nurses CNAs: Certified nurse aides CMAs: Certified medication aides APRNs: Advanced practice registered nurses	Medicare Medicaid Private insurance
Canada (type 2 and 3)	Long-term residential care facilities (LTC) or Nursing homes or Homes for the aged	RNs: Registered nurses LPNs: Licensed practical nurses or registered qualified nursing assistants PSW: Personal support worker Type 2 will have the above + physiotherapists + occupational therapists	Variation across the country – currently debating a universal public insurance scheme for long-term care (Grignon and Bernier 2012)
Europe (type 1, 2 and 3) Norway, Finland, Italy, and the Netherlands have elderly care physicians in their nursing homes	Long-term care facilities (LTCFs) or Nursing homes (NHs) or Care homes and care homes with on-site nurses (CHs; CHs-N)	RNs: Registered nurses NAs: Nursing assistants SCW: Social care workers	Different funding models across the different countries – mixture between "health and social care" funding, insurance, privately funded. Care of older people in the Netherlands, for example, is nearly completely covered by a national health insurance plan

Type 1: "On-site" nurses + care assistants + elderly care physicians
Type 2: "On-site" nurses + care assistants; "off-site" physician/s
Type 3: "On-site" care assistants only; "off-site" nurse/s + physician/s
Froggatt et al. (2017b)

- Person-centered care, communication, and shared decision-making
- Optimal treatment of symptoms and providing comfort
- Setting care goals and advance planning
- Continuity of care
- Psychosocial and spiritual support
- Family care and involvement
- Education of the healthcare team
- Societal and ethical issues

The domains provide a framework to guide important aspects of LTCF palliative care development in clinical practice, policy, and research.

3.2 Management and Staffing

Leadership of LTCFs is one of the single most important aspects for high-quality care for frail older people and its continuity in such settings. If staff are valued and supported by management in helping them progress and develop, then this generally cascades down into good care of residents and families. When one sees defensive care and/or poor communication especially in relation to palliative and end-of-life care, then this is often a result of poor leadership and poor role models where staff do not feel supported.

There is a wide variation between countries and even within different LTCF organizations in the same country in relation to staff development. The majority of staff have little healthcare training. Many young people choose to work in these facilities because they want to help frail older people; they come to help dress, feed, and chat to older people. Unfortunately, they are often not prepared with the demands of the work and the fact that many frail older people, who they have got to know very well over the months/year, will die in the LTCF.

In the UK, the majority of formal carers will be encouraged to have some vocational training −50% of staff in a care home should have Level 2 NVQ/SVQ (National/Scottish Vocational Qualification). Such a qualification is based around personal care, moving and handling, nutrition, oral care, etc. for frail older people but does not often include knowledge about different comorbidities and how to communicate about life/death issues. However, despite this, LTC staff are not unskilled. Often they have considerable insight into situations but are not given the opportunity or support to voice their opinions.

In most countries, there are little or no nurses working in LTCFs and no on-site medical support with some exceptions like The Netherlands and Norway. In the UK, only a quarter of care homes have on-site nurses. Where there are nurses, the ratio is in the region of 1 nurse to 30 residents with the rest of the staff being formal care workers. With increasing pressure on workloads and the "risk" that some LTCF staff feel when not having the knowledge and competencies in the care they are being increasingly asked to give, it is not surprising there is a high turnover of staff. In the UK, this has now reached worryingly high proportions. It could be argued that because of the lack of distinction is diminishing between older people residing in the different LTCF/care home settings and because managers are being encouraged not to transfer frail older people in the last months of life, that all LTCFs/care homes should provide "high" care and employ nurses and even care home doctors.

4 Geriatrics and Palliative Care

In 2017, both geriatric and palliative care specialists celebrate important milestones in their development as a speciality – geriatrics celebrate 70 years and palliative care celebrate 50 years. Dame Cicely gained huge insights from well-known physicians in the care of older people to underpin the hospice movement. It was Professor Worcester's seminal work, The Care of the Aged, the Dying and the Dead (1935), which had prominence both in Dame Cicely's writing and on her bookshelf.

In 1989, at the First International Conference on Palliative Care of the Elderly, Balfour Mount (1989, p. 7) also drew interesting analogies between geriatric practice and palliative care:

> Both make the whole person and his or her family the focus of care, while seeking to enhance quality of life and maintain the dignity and autonomy of the individual. Judicious use of investigations are advocated and both eschew unwarranted treatment while providing symptom control and relief of suffering. Both are necessarily multi-disciplinary and both are areas which prompt phobic reactions from society at large. . ..

However, despite the similarities drawn above, there are also differences not only between the settings but also within the care practices (see Table 2).

Respecting the choices of frail older people toward the end of life is extremely important. In 2012, a global initiative called "choosing wisely" was set up to help clinicians and patients engage in conversations about unnecessary tests/treatments and make wise and effective care choices. This initiative now involves professionals from

Table 2 Differences between cancer palliative care and end-of-life care in the elderly dying (Hockley 2002). (Reproduced with kind permission from Open University Press, Buckingham MK18 1XW)

Cancer palliative care	End-of-life care in the elderly dying
Focus in one disease process	Multiple disease processes
Emphasis on dying in mid-age or younger when life is generally seen as being "cut short"	Natural ending of life often understood by both the resident and those caring within the context of care homes
Clearer concept of "prognosis" so terminal care can be planned	Less predictable dying trajectory following a more dependent, lengthier disease process
Professional holistic relationship between patient and staff	Often a much closer/emotional relationship between resident and care home staff as resident becomes "part of the family" and may have lived in the care home months/year
More support from family/friends	Less support from family/friends – often care home staff and other residents seen as family
Both patient and family often want life extended	Elderly, frail people in nursing homes frequently speak about dying and that it would be nice "to go to bed one night and not wake up"
Morphine and other medication frequently used to control symptoms	Pain requiring strong opioids less common
Multidisciplinary model of care	Nurses and care workers having the greatest input of care
Patients more often cognitively intact	Greater percentage of residents in nursing homes are cognitively impaired

across 20 countries. As a result of this initiative, the Long-term Care Medical Directors Association of Canada have come up with six recommendations (see Table 3) that are all evidence-based with their relevant resources (https://choosingwiselycanada.org/long-term-care/). Such recommendations emphasize the importance of palliative care and geriatricians working together for the best care of frail older people.

Table 3 Recommendations from choosing wisely (Jones 2017)

1.	*Don't send the frail resident of a nursing home to the hospital unless their urgent comfort and medical needs cannot be met in their care home.* Transfers to hospital for assessment and treatment of a change in condition have become customary; however, they are of uncertain benefit and may result in increased morbidity
2.	*Don't use antipsychotics as a first choice to treat behavioral and psychological symptoms of dementia.* People with dementia can sometimes be disruptive, behave aggressively, and resist personal care. There is often a reason for this behavior, and identifying and addressing the causes can make drug treatment unnecessary
3.	*Don't do a urine dip or urine culture unless there are clear signs and symptoms of a urinary tract infection (UTI).* Unless there are UTI symptoms, such as urinary discomfort, abdominal/back pain, frequency, urgency, or fever, testing should not be done. Testing often shows bacteria in the urine, with as many as 50% of those tested showing bacteria present in the absence of localizing symptoms to the genitourinary tract
4.	*Don't insert a feeding tube in individuals with advanced dementia. Instead, assist the resident to eat.* Inserting a feeding tube does not prolong or improve quality of life in patients with advanced dementia. If the resident has been declining in health with recurrent and progressive illnesses, they may be nearing the end of their life and will not benefit from feeding tube placement
5.	*Don't continue or add long-term medications unless there is an appropriate indication and a reasonable expectation of benefit in the individual patient.* Long-term medications should be discontinued if they are no longer needed (e.g., heartburn drugs, antihypertensives), as they can reduce the resident's quality of life while having little value for a frail elder with limited life expectancy
6.	*Don't order screening or routine chronic disease testing just because a blood draw is being done.* Unless treatment can be given that would add to quality of life, don't do these tests. What is considered routine testing may lead to harmful overtreatment in frail residents nearing the end of their life

4.1 Different Dying Trajectory

When reaching out to LTCFs with quality improvement initiatives or supporting end-of-life care, it is important not to impose the more familiar model of palliative care developed for

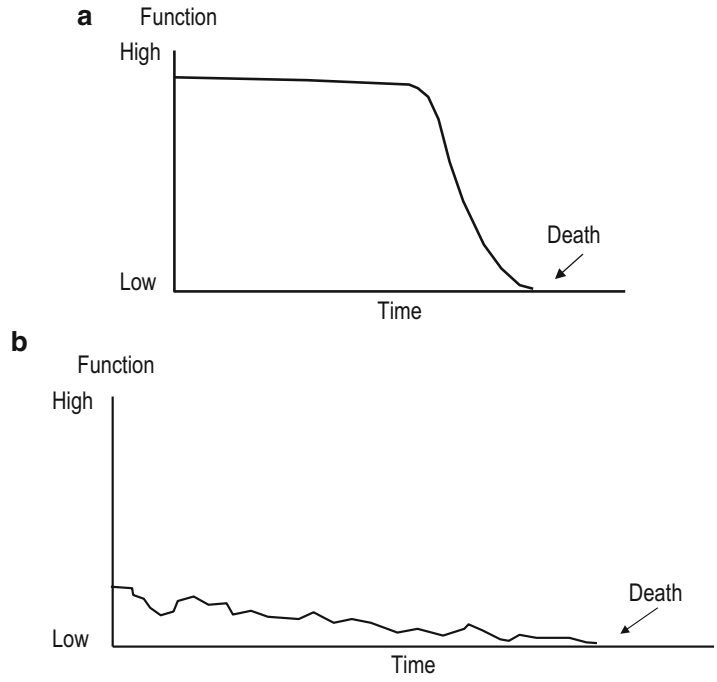

Fig. 1 (**a**) Different dying trajectories – cancer (Lynn and Adamson 2003). (**b**) Dwindling trajectory of frail older people – especially those with advanced dementia (Lynn and Adamson 2003)

people with advanced cancer. There is a difference between palliative care that has been developed for people with advanced cancer, typically from within specialist palliative care and the hospice movement, and palliative care for frail older people dying at the end of life from multiple comorbidities.

The dwindling dying trajectory, so well described by Lynn and Adamson (2003), is very different from the well-known, fairly predictable cancer trajectory – see Fig. 1a, b.

The phrase "bounce back" is an unknown phenomenon when caring for people dying in a hospice or a hospital and is uniquely tied to the dwindling trajectory of frail older people. A frail older person is seen to deteriorate, their medication is reviewed and discontinued, a greater attention to fluid intake is taken, and as a result the person "bounces back."

The danger of imposing a specialist palliative care model in the last days of life, where often opiates and hyoscine are used routinely, onto a frail older person who is dying with advanced dementia is vividly highlighted in the following case study (see Case Study A).

Case Study A: Mrs. A: 89 Years: Advanced Dementia (2012)

The Care Home Project Team at St Christopher's Hospice, London, (https://www.stchristophers.org.uk/education/training-and-research/care-homes/) was involved in development and training in a local care home without on-site nurses. The care home manager had contacted the local community palliative care team to come and review Mrs. A with advanced dementia who was dying. Mrs. A was in her late 80s and had been in the care home for a number of years; with her advancing dementia, she was pleasantly confused. However, she was now very frail and not drinking and clearly had days/week to live.

The community palliative care team were used to putting up syringe drivers when a person at home or in a care home without on-site nurses was dying. Because Mrs. A was slightly agitated, they decided

(*continued*)

to put up a syringe driver with a small dose of diamorphine 10 mg and Buscopan 20 mg/24 h. Within 3 days, Mrs. A had changed from her pleasant confusion to being increasingly agitated, shouting out, and unmanageable.

The Care Home Project Team were contacted and advised the immediate discontinuation of the syringe driver – the opiates had clearly accumulated because of Mrs. A's "old kidneys," and appropriate dehydration at the end-of-life. She was clearly dying but had no pain. It took the administration of s/c fluids and phenobarbitone to help reduce Mrs. A's distress, and she died peacefully 3 days later.

her thoughts – she had worked in the care home sector for many years and had had some training in palliative care. She queried why opiates were being considered when Miss B had no pain. She also queried the use of Buscopan as it would only increase the dryness in Miss B's already dry mouth and suggested: "What about giving a small dose of diazepam rectally to calm her?" Immediately the importance of what the staff nurse was saying was recognized. Following the rectal diazepam, Miss B was still able to take sips of fluid – the care assistants took it in turns to sit with her reading some favorite poetry. Miss B died 12 h later – peacefully and comfortable.

A different scenario (see Case Study B) highlights the benefits of "working alongside" staff in LTCFs – listening to what they would normally do, being open to learn from them in relation to the last day/s of life, and not imposing a specialist palliative care knowledge.

Case Study B: Miss B: 91 Years: Advanced Dementia (2004)

During research into death and dying in care homes with on-site nurses, staff were being supported to implement the "integrated care plan for the last days of life" (Hockley et al. 2005). Miss B, who had worked for many years as pharmacist, was now dying. She had been a "feisty" lady and had lived in the care home several years. If she didn't like your approach when you were helping her with her medication, you were in danger of the tablets being thrown back in your face. However, she now was very frail, reasonably calm, and just able to sip the fluids offered to her. The staff nurse asked for advice, and a typical response from a nurse specialist in palliative care was given: s/c diamorphine 2.5 mg and s/c Buscopan 10 mg. Importantly, the staff nurse offered

As can be seen from Case Study B, the dying process of frail older people is often a natural process requiring little extra medication. William Osler (1849–1919) is well known for saying "pneumonia is the old man's friend," and although written over 150 years ago before the invention of antibiotics, it is as relevant today as it was in the nineteenth century.

Dying itself is not painful (Worcester 1935) – it is only painful in situations where there is unrelieved pain prior to the last days of life. An appropriate assessment of the situation taking into account the frailty, natural dehydration of frail older people, and any specific distressing symptoms must be made and a syringe driver only used if symptoms are severe. Often occasional s/c medication is all that is necessary in frail older people.

A small percentage of deaths in LTCFs can be quite sudden and, despite the person being in their 90s, is seen as "unexpected." An "acute" event like a silent pneumonia can often prompt admission to an acute hospital and sadly the person's dies in unfamiliar surroundings. The dwindling dying trajectory however is the most common type of dying in LTCFs, and generally speaking if properly acknowledged, the death will occur in the LTCF.

5 Different Models and Initiatives to Enhance Palliative Care in LTCFs

It is well documented that palliative care education on its own does not change practice in the often hierarchical structures of LTCFs (Froggatt 2001) that have for many years adopted a rehabilitation culture. However, we know that when education is done alongside implementing a specific tool, for example, advance care planning documentation, there is a greater chance of developing a palliative care approach to care.

Many LTCFs eagerly respond to new initiatives in relation to improving palliative and end-of-life care especially when supported by an outside agency such as a local university or hospice. Effectiveness of a project depends not only on the enthusiasm of the LTCF staff to develop their practice but also the support given by manager/management. Projects benefit when there is both a "top-down" and "bottom-up" approach. However, the current trend of short-term funding of programs is unlikely to bring about long-lasting change unless a funded sustainability initiative has been proposed at the beginning of the project (Hockley and Kinley 2016).

A number of tools, quality improvement initiatives, and models have been developed. These are now described, firstly, from a focus on the implementation of individual aspects of palliative care such as advance care planning or pain assessment in advanced dementia and, secondly, the implementation of a system that addresses multiple aspects of palliative care.

5.1 Individual Tools

If given the task to choose what might be the "key" developments of a palliative care approach in care homes, it would be impossible to list all such initiatives. Nonetheless, there are a number of tools that are gathering evidence of their effectiveness and are described below.

5.1.1 Advance/Anticipatory Care Planning and DNACPR Decisions

Advance/anticipatory care planning (ACP) is reported to decrease inappropriate hospital admissions of frail elderly residents with palliative care needs (Hockley and Kinley 2016). Documentation may take the form of an advance statement of wishes and preferences, an advance decision to refuse treatment (a legal document refusing specific treatment), and/or a surrogate decision-maker in the appointment of a Lasting Power of Attorney for Health and Welfare. These documents are then available to guide care if the individual loses the ability to make decisions or communicate their wishes. However, there are multiple preconditions related to successful ACP in LTCFs which occur at different levels of the organization (Gilissen et al. 2017).

Who in the LTCF Should Undertake These Conversations?

Until recently, the dominant culture in LTCFs has been a "striving to keep alive," and it is not always straightforward for staff to embrace discussions around ACP – especially when they have limited healthcare knowledge.

Most frail older people know they are facing the last year/s of their life. The very fact that they have now been admitted for 24-h care because they can no longer manage to care for themselves at home is every indication to them that this is likely to be their last move; to deny this is to discredit their autonomy and their ability to know their own body. Many residents are very open to discussions in relation to their wishes at the end of life (Stone et al. 2013). However, for many LTCF staff, often young with little healthcare training, conversations about care at the end of life can be extremely daunting.

Learning how to undertake such conversations is really important, and considerable support and education is often required. Learning can be very effective when seeing other people undertaking such a conversation (either through role modeling by an experienced clinician or through watching videos) and/or through role play alongside some communication skills training such as Sage and

Thyme (http://www.sageandthymetraining.org.uk/about). Sitting in with an experienced professional is probably the most useful.

In the UK, discussions about what a resident might want to achieve before becoming very frail, and whether they have thought about who they might want close-by at the end, can be undertaken by experienced social care workers. However, any detailed health-related discussions such as an event that might result in an action like going to hospital must be undertaken by properly qualified healthcare professionals.

With the increasing likelihood that many frail older people are likely to die within months of admission to a LTCF, conversations in relation to wishes toward the end of their life are most important. Such conversations are very individual (often requiring at more than one conversation) and must be documented accordingly.

Relatives are key to these conversations, and while they might like to think they know what their family member wants, sometimes they can be misguided. It is important to include where possible both resident and family in such conversations.

When Should Such Conversations Take Place?

The timing of conversations about the care in the last weeks of life including discussions regarding "do not attempt cardio-resuscitation" (DNACPR) needs to be adopted into routine practice of the facility. Most LTCFs will review residents' care plans on a monthly and 6-month basis; these therefore become the ideal times. For residents who have been in the LTCF a number of months/year/s, then the 6-month review (unless there is a sudden deterioration) is perfectly acceptable opportunity for such a conversation to be added to the end of the general discussion. For someone being admitted to a LTCF, especially if they are frail and ill, the timing is likely to be different.

It is important that the doctor/nurse establishes within a week of admission whether a DNACPR decision is to be signed. More detailed conversations about care at the end of life need to be undertaken once the resident and family have settled into the care home – and likely not to take place until the end of the 1st month in the care home.

There are a considerable number of forms and pamphlets that have been developed and are widely available. However, it is the importance of the conversation that is paramount – and the process should not be a "tick box" exercise. It is really important that such conversations are undertaken by staff who feel competent, having had the opportunity of sitting in with doctors/senior nurses to witness how it is done; such role modeling is very important if care home staff are to become competent.

5.1.2 Monthly Multidisciplinary Meetings

Good coordination of care especially in the last year of life is vital if the needs of frail older people in care homes are to be identified and managed appropriately. Monthly multidisciplinary meetings in the care home bring together all those who not only know the person but also those who have expertise to advise and ensure that care is properly coordinated.

In the UK, the Gold Standards Framework (http://www.goldstandardsframework.org.uk), promoting the development of a palliative care approach both in peoples' own homes and care homes, has advocated the importance of monthly multidisciplinary meetings for over 10 years now.

A simple palliative care register completed at a monthly multidisciplinary meeting in the LTCF prompts staff about different aspects of care, i.e., advance care planning/DNACPR, symptom control issues, and family communication. One of three triggers indicating that a resident is nearing the end of life is the "surprise question" (Thomas 2011):

> would I be surprised if [Mrs B] died in the next. . .three months, six months, year?

This question is asked at the meeting in conjunction with two other triggers: deterioration over the previous month/s and specific clinical

indicators related to certain conditions. As a result of this questioning, the resident is categorized as likely having day/s, week/s, or month/s to live. Importantly, it is often the formal care workers in daily contact with the frail older person who are best able to answer this "surprise" question despite often having little advanced health education. It is important that they are present to discuss their specific residents. Once it is considered likely that the LTCF staff believe the person to be nearing the end of life – even though that might still be month/s away – it is important that there is open communication with the rest of the staff, to the resident (as appropriate), and family.

Such a monthly multidisciplinary meeting not only helps to build teamwork and trust across the different professions as well as good coordination of palliative care. Working with services provided during the day, at night, and at weekends is key to providing seamless quality palliative care in LTCFs.

5.1.3 Pain Assessment/Management Tools

Some diseases and conditions create varying degrees of pain for individuals. Older people often suffer in silence with their pain as they believe arthritis and other musculoskeletal conditions are part of growing old and therefore to be endured. LTCF residents have been found to have considerably more pain compared to the same population living in their own homes (Husebo et al. 2012).

Systematic pain assessment on admission and the use of relevant documentation can contribute to effective pain assessment and management. We know that pain has a combination of physical, emotional, social, and spiritual elements which Dame Cicely Saunders called "total pain." However, with 80% of frail older people in LTCFs having dementia or severe cognitive impairment, pain in these people needs to be assessed differently to that of people with cancer pain. It is often more complex to assess/manage pain in people with advanced dementia than it is in people with cancer (see Case Study C).

Case Study C: Pain Assessment in a Person with Advanced Dementia Unable to Verbalize Her Pain

During a year's study in a particular LTCF, I had got to know the majority of the 40 residents very well indeed. Mrs. C and her husband had been residents for a couple of years – she was a charming but muddled lady in her mid-80s with advanced dementia, while Mr. C had recently been diagnosed with advanced prostate cancer. One day when coming into the LTCF, instead of Mrs. C being up and about dusting the staircase, I noticed her sitting by the front door rubbing her knees. This was a change to Mrs. C's normal activity of walking around the house making sure that everything was spick and span.

At the time, although this was not the focus of the study, I had become interested in the difference between assessing pain in people with advanced dementia and assessing pain in people with advanced cancer in a hospice/community. I had read about the importance of assessing the nonverbal response to pain in people with advanced dementia and in particular the Doloplus2-scale (Lefebvre-Chapiro and the Doloplus Group 2001). The rubbing of the knees was new, and I was interested to find out her level of pain.

The manager happily told me who Mrs. C's carer was, and we proceeded to Mrs. C's room in order to undertake a pain assessment. Using a scale of 0–10, I asked Mrs. C "if '0' is no pain at all and '10' is the most excruciating pain you have ever had in all your life, what score would you give the pain in your knees?" Almost immediately Mrs. C told me 8/10. Ashamedly, because she didn't look as though she was in that much pain, I wondered whether she had become muddled and had really meant 2/10. To confirm my musings, the carer and I

(*continued*)

went away and completed the Doloplus2-scale together.

The Doloplus2-scale pain assessment tool (see Table 4) checks ten reactions at four levels (0–3) divided into three domains: somatic reactions, behavioral reactions, and psychosocial. A total score of 5 or more is likely to represent pain. When the carer added up our scoring of Mrs. C's pain, it came to 15. We realized together that Mrs. C had very real pain. We slowly titrated the analgesics that included starting oral morphine. Gradually over 3 weeks, the morphine was increased until Mrs. C was up and doing her dusting again. She remained stable on MST 30 mg bd alongside paracetamol for a number of months walking around and doing her dusting. She died reasonably suddenly in the LTCF about 4 months later.

There are many different pain assessment scales for use with people with advanced dementia unable to express their pain verbally (Lichtner et al. 2014). There are probably four that have had repeated scrutiny in relation to validity and reliability testing:

- *PAINAD*: This tool (http://geriatrictoolkit.missouri.edu/cog/painad.pdf) has five domains and is a relatively simple tool for nurses/care staff to use (Warden et al. 2003). Tool reliability is good for interrater reliability, but internal consistency is only moderate, and stability has not been demonstrated. http://prc.coh.org/Review%20of%20Tools%20for%20Pain%20Assessment/Review%20of%20Tools%202004/PAINAD/PAINAD_Indepth.pdf
- *ABBEY*: The ABBEY (Abbey et al. 2004) scale is similar to the PAINAD in that it is easy to complete. However, reliability and validity have been shown not to be strong. http://prc.coh.org/PainNOA/ABBEY_D.pdf
- *PACSLAC*: the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (Fuchs-Lacelle and Hadjistavropoulos 2004) has been developed in Canada. It covers four domains: facial expressions × 13, activity/body movement × 20, social/personality/mood × 12, and others × 15. Prospective evaluation has added to the tool's reliability and validity. http://prc.coh.org/PainNOA/PACSLAC_D.pdf
- *Doloplus2-scale*: The Doloplus2-scale (Lefebvre-Chapiro and the Doloplus Group 2001) was specifically developed by geriatricians in France for people with advanced dementia who were no longer able to verbalize their pain. Although more complex to use, its reliability and validity are strong. http://prc.coh.org/PainNOA/Doloplus%202_Tool.pdf (Torvik et al. 2010).

Further studies evaluating the above tools and their efficacy and ease of use in the assessment/management of pain in frail older people with dementia by LTCF staff would be useful.

5.1.4 Documentation for the Last Days of Life

Dame Cicely Saunders (1918–2005) is well known for saying, "How someone dies remains in the memory of those who live on." This is extremely important in LTCF settings where often the majority of staff have little healthcare training. Some sort of documentation to help guide these last days is of vital importance.

Developed and adapted from the Liverpool Care Pathway (Ellershaw and Wilkinson 2003) for specific use in care homes, the *Integrated Care Plan for the Last Days of Life* (Hockley et al. 2005; Watson et al. 2006), further developed to more recent documentation called the *Integrated Personalised Plan for the last days of life* (http://www.stchristophers.org.uk/care-homes/research/ipp) (IPP), has managed to ride the storms of controversy in relation to the Liverpool Care Pathway. A recent audit report outlines the first 50 completed IPPs and the success of its use in care homes in south London (Coleman et al. 2017).

The importance of at least 90% staff in a setting where such documentation is being used was highlighted by Ellershaw and Wilkinson (2003)

Table 4 Doloplus2-scale (http://prc.coh.org/PainNOA/Doloplus%202_Tool.pdf)

DOLOPLUS-2 SCALE — BEHAVIOURAL PAIN ASSESSMENT IN THE ELDERLY

NAME : Christian Name : Unit : DATES

in their original book and has underpinned the work of Coleman et al. (2017). The individual care home setting has managed to be more rigorous in achieving such training than in the acute hospital setting with the myriad of staff to be taught. Training should include the use of a "case scenario" alongside the documentation so that training isn't being taught via a PowerPoint presentation in isolation of real-life situations. It is important to note that any care given is only

as good as the person giving the care, and while "using the IPP does not in itself assure quality of care, the use of such a plan can provide homes with evidence that their care is consistent" (Coleman et al. 2017, p. 41).

5.1.5 Valuing and Supporting Staff Support After Death: Reflective Debriefing Sessions – UK

For many young untrained staff, talking about and caring for people who are dying are frightening and the powerful triggers to any of their own unresolved grief (Holman et al. 2011). With the increasing number of frail older people dying in LTCFs, meaningful support through reflective debriefing sessions has been found to be helpful (Hockley 2014).

Staff often become very close to residents – especially if the resident has been in the LTCF for a number of months or even years. Reflecting on the death in a structured way is a useful support for staff and an innovative way of learning from practice – a tool has been developed (Hockley 2014). The aim of a reflective debriefing sessions is:

- To use the experience of caring for a resident who has died as a basis for learning about end-of-life care
- To be a place where "death and dying" can be safely and openly discussed and where support can be actively shown
- To construct knowledge about end-of-life care of frail older people dying in LTCFs in order to develop a palliative care culture in these settings
- To increase team cohesion between different shifts and across different roles that include not only nurses and carers but different ancillary staff who have known the resident and/or family

Sessions are held monthly with an emphasis on a "no blame" culture. The deaths of residents who have died during the previous weeks are formerly discussed. Such a session lasts about 45 min (a maximum of an hour). If there is no death during the month, then these sessions can be used for informal teaching on any subject that the LTCF manager thinks will be helpful. The essential point is for the sessions to be planned in the diary at a specific point each month of the year so it becomes routine practice and not just something that might happen if there is a significantly bad death. It is important that the LTCF manager be present wherever possible at the reflective debriefing sessions.

The outline of a session is as follows:

- For someone within the group to give a short portrait (no more than a couple of minutes) of the person who has died and the knowledge they had of the family
- What led up to the death – was it sudden or anticipated, etc.
- How did staff fell things went – What went well? What didn't go so well?
- What could have been done differently?
- What needs to change in the LTCF as a result of the reflection?

Each reflection can inform practice and should be used not only as a building block to learning but as a celebration of good practice. Reflection is not a passive contemplation but an active, deliberate process that requires commitment, energy, and a willingness to learn as a team.

5.2 Tools Incorporating Whole System Change to Create a Palliative Care Approach

Not surprisingly, the "individual initiatives" that have been highlighted above do in time promote a palliative care culture to emerge. However, there are initiatives that champion a "whole system" development in one project. Establishing a system which addresses a number of different aspects of palliative/end-of-life care alongside an educational initiative is probably one of the most effective ways to encourage a greater palliative care approach in LTCFs. However, it is sustaining such

initiatives that is of vital importance and will be discussed in Sect. 6.

5.2.1 The Gold Standards Framework for Care Homes: UK/Europe

The most notable whole system change in relation to palliative care/care homes in the UK has been the Gold Standards Framework in Care Homes (GSFCH) (http://www.goldstandardsframework.org.uk/care-homes-training-programme). Professor Keri Thomas, founder of the GSF program, saw the need in the early 2000s for better collaboration and communication in relation to palliative and end-of-life care in the community (Thomas 2003), furthered the vision to encompass a program for care homes (GSFCH) (Badger et al. 2009; Thomas 2016).

The GSFCH program is a 2-year accredited program divided into three parts: a *preparatory phase*, *an implementation phase*, *and a consolidation phase*. The *preparatory phase (6 months)* is extremely important phase encouraging not only the staff, residents, and families to take part but also the local GP/s and specialist palliative care team/s external to the care home.

Care homes from a regional area are encouraged to sign up for the course and as part of the payment will be given all the documentation/folders/videos, etc. Each care home manager appoints GSFCH "champions" who will attend 4 training days during the *implementation period (9–12 months)* and be responsible for disseminating the information to the rest of the care home staff in between each of the 4 days. The number of "champions" is never less than two and will vary depending on the size of the care home. The *consolidation period (6 months)* helps care home staff to work on aspects that they are unsure about and at the same time prepare a portfolio for accreditation. An "after-death analysis" audit is undertaken on a number of residents' deaths before commencing the course and compared to those during/after the completion of the GSFCH program.

The GSFCH provides care home organizations with a number of key aspects of documentation in relation to advance care planning "Thinking Ahead"; prognostic indicator guide; the monthly multidisciplinary supportive care register; the PACA, a summary of resident and carer needs and concerns; the PEPSI COLA Aide Memoire, an holistic assessment tool; and significant event analysis that is completed following a death and helps staff reflect and feel supported.

In 2008, St Christopher's Hospice developed a Care Home Project Team to "reach out" to local care homes (http://www.stchristophers.org.uk/education/training-and-research/care-homes/). It became the first GSFCH regional center in the UK and over a 5-year period reached out to all the 71 care homes with on-site nurses in the area, encouraging them to take part. By the end of 5 years, the percentage of care home residents dying in hospital had reduced from 44% to 22% (Hockley and Kinley 2016).

As a result of GSFCH program, the UK National Health Service developed documentation "Route to Success" to encourage local regions to develop the palliative care needs of their residents in care homes (http://www.nwcscnsenate.nhs.uk/files/7714/3040/1087/Route_To_Success_Care_Homes_updated_Apr2015.pdf?PDFPATHWAY=PDF/). Different localities then developed different tools such as the "Six Steps to Success" and "Steps to Success" programs. While making it locally relevant, some programs have lacked resources when it comes to accreditation, ongoing support, and sustainability.

5.2.2 The PACE Program: Europe

The PACE program (www.eupace.eu) is a randomized controlled trial looking at whole system change in the adoption of a palliative care approach in LTCFs across six European countries (Van den Block et al. 2016; Smets et al. 2018). The PACE program was developed following a number of quality improvement initiatives in care homes and is framed around six steps: advance care planning, mapping changes in a resident's condition, monthly multidisciplinary meetings, pain and symptom assessment, care in the last days of life, and reflective debriefing sessions for staff following a death. The intervention is

complete, and outcomes from the PACE program are awaited.

5.2.3 Palliative Approach Toolkit for Residential Aged Care Facilities: Australia

Deborah Parker and colleagues from Blue Care Research and Development Unit and the University of Queensland developed the "Palliative Approach Toolkit for Residential Aged Care Facilities" – an evidence-based knowledge translation product for staff in aged care facilities in Australia (https://www.caresearch.com.au/caresearch/tabid/3629/Default.aspx). The Toolkit is a set of clinical care, educational and management resources, and a "comprehensive 'how to' guide featuring a step by step approach to implementing a new model of palliative care. It includes policies and procedures, education and training for staff" (Parker 2013). The success of the project was realized when the Australian Government Department of Health funded a national rollout of the Toolkit under the Encouraging Better Practice in Aged Care (EBPAC) initiative between October 2013 and December 2014 (https://www.caresearch.com.au/Caresearch/Portals/0/PA-Tookit/Training%20Support%20Materials/PowerPoint%20Presentation.pdf).

5.2.4 Namaste Care Program: Improving the Quality of Life for Residents with Advanced Dementia: USA and UK

The Namaste Care program was developed by Joyce Simard in the early 2000s in the USA (Simard 2013). Joyce had worked as a social worker in LTCFs and was interested in the importance of meaningful activity to improve the quality of life for people with advanced dementia. She had set up innovative meaningful activity for those with mild to moderate dementia ("The Club") but noticed that many people with advanced dementia just sat on the edges of such activity with little engagements or otherwise didn't attend, remaining alone in their bedrooms.

Namaste is an Indian greeting which means "to honor the spirit within." Namaste Care is a multidimensional program that includes physical, sensory, and emotional elements. The purpose of Namaste is to give comfort and pleasure to people with advanced dementia through sensory stimulation, especially the use of touch. It aims to restructure the care for people with advanced dementia who are often immobile/confined to a wheelchair and incontinent failing in their speech.

Namaste runs for 2-h in the morning and 2-h in the afternoon, 7 days a week, and aims to increase engagement through the five senses (hearing, sight, touch, taste, and smell). It requires no additional staffing. The Namaste Care worker assigned to run the program for that day will work with all those in the facility with advanced dementia as defined above. It is likely that there will be 6–8 such residents within a facility of 60 people. Once they have been helped with breakfast, instead of remaining in their room, these residents are brought to the Namaste Care "space" (whether an adapted dining area or a dedicated space). Here they will be greeted by name, made very welcome and checked for discomfort and pain. The Namaste Care worker will engage with each as appropriate during the next 2 h – doing a hand massage, helping with a drink, combing a resident's hair, applying cream to the face, giving a footbath, and offering cut-up fruit and tasty titbits.

When it is felt a resident would benefit from being part of program, a family meeting is held to understand from them things that will bring pleasure and trigger memories for their family member. This meeting is also an opportunity to acknowledge the resident's deterioration from dementia in the positive context of offering more appropriate care. Finally, the meeting is an opportunity to establish the overarching goal of a peaceful, dignified death in familiar surroundings in the care home.

Namaste Care has now been implemented in LTCFs in a number of countries including the USA, Japan, Australia, and the UK. A toolkit is freely available from the St Christopher's Hospice website (http://www.stchristophers.org.uk/education/resources). There are several core elements of the program (see Table 5).

A recent study evaluating Namaste Care in six care homes found that, where there is strong

Table 5 Core elements of the Namaste Care program (Stacpoole et al. 2016)

1	"Honoring the spirit within"	The guiding principle of Namaste Care is a respectful and compassionate approach to individuals with advanced dementia
2	The presence of others	Namaste residents are brought together as a social group with a dedicated Namaste Care worker, so each resident feels "included" in their community
3	Comfort and pain management	Comfortable seating and pain assessment/management are the essential first step toward enabling Namaste residents to relax, engage, and express how they feel
4	Sensory stimulation	The program incorporates stimulation of the five senses (touch, hearing, sight, smell, taste). Music, color, therapeutic touch and massage, aromatherapy oils, and food treats are all part of the multisensory environment created in the Namaste room
5	Meaningful activity	In Namaste, personal care is provided as a meaningful activity, even though the Namaste residents will usually have had their morning wash. The focus is on pleasure rather than personal hygiene. Hands and face are gently washed with a warm flannel and patted dry with a soft towel. Moisturizing creams are applied, and the Namaste Care worker uses this opportunity to make eye contact and talk affirmatively with the resident. Hand and face washing is part of everyone's life experience and usually results in a sense of well-being. The Namaste Care worker will explore individual wishes and preferences and adapt activities to meet people's needs
6	Life story	Knowledge of the resident's life story is key to adapting the program of activities and interventions so that they are meaningful for each person
7	Food treats and hydration	The Namaste Care worker offers drinks and food throughout the session (being mindful of any swallowing difficulties). This creates extra opportunities to improve hydration and nutrition and contribute to the residents' health and well-being
8	Care worker education	Care workers involved in Namaste require education about dementia and all aspects of the care program. The care workers need support to feel confident
9	Family meetings	Holding a family meeting when a resident is going to start the Namaste Care program creates a further bond between the family/friends and the care staff, opening up the conversation about end-of-life care. Families are encouraged to take part in the Namaste sessions when they visit
10	Care of the dying and after-death care	The care that residents enjoy in the Namaste Care program can be transferred to the bedroom when the person is unwell and when they are dying
11	After-death reflection	Dedicating time to remembering a resident after their death supports the care staff emotionally. Reflecting on what went well, and any difficulties, provides an opportunity for care staff to learn from the experience and improve the care they give to residents when they are dying

leadership, adequate staffing, and good nursing and medical care, the Namaste Care program can improve quality of life for people with advanced dementia in care homes by decreasing behavioral symptoms (Stacpoole et al. 2015).

Implementing such a program actively demonstrates a person-centered relationship-based holistic culture for people with advanced dementia. Those with advanced dementia are not isolated but included in a program that is set to bring them enjoyment through the senses focusing on the palliative care needs including pain and agitation in the end stages of dementia. The Namaste Care worker reports any distress and lack of engagement of those at a session – people cannot engage if they are uncomfortable. The beneficial effect of Namaste Care on the family and staff has also been shown to be significant (Stacpoole et al. 2017).

6 Components of Successful Implementation of Initiatives

Implementing quality improvement initiatives is an interplay of three elements (Kitson et al. 1998, 2008):

- The "context" where the development is to take place (McCormack et al. 2002)

- The quality of the "evidence" that backs up what is being implemented (Rycroft-Malone et al. 2004)
- The level of "facilitation" required based on the "context" and "evidence" (Harvey et al. 2002)

For each of the above elements, different "situations" prevail (Kitson et al. 1998) which makes the element "not so effective" ("low") or "very effective" ("high"). In their model, Kitson and colleagues suggest that for successful implementation of a quality improvement initiative, there has to be a minimum of two "highs" associated with the three elements. For example, in the *context* of many LTCFs, there is no on-site multidisciplinary team, the majority of staff have little healthcare education, and many lack a learning culture. It can therefore be deduced that many LTCFs have a "low" *context* and any LTCF quality improvement initiative therefore needs to have a "high" evidence base + "high" facilitation.

The importance of understanding the multidimensional aspects of implementing quality improvement initiatives in LTCFs cannot be emphasized enough. A recent quality improvement initiative implementing the GSFCH framework ("high" evidence) using "high" facilitation showed four times the number of LTCFs gaining GSFCH accreditation compared to normal facilitation (Kinley et al. 2014b).

The importance of how an initiative is facilitated is often vital to its success. Just giving a LTCF a certain toolkit with little information on how to implement the change will be likely to fail. Where there is no effective facilitation, then any outcome will rely heavily on the care facility ability to "take hold" of the project and its ability to implement it.

Facilitation of 'whole system change' tools discussed in the previous section (such as GSFCH, PACE, Namaste) when supported well by specialist palliative care can be extremely beneficial – not only do colleagues in specialist palliative care increase their understanding of the chronic illness trajectory of frail older people in LTCFs, but such collaboration enables LTCFs to be connected and supported while they develop their own palliative care approach.

6.1 Sustainability When Undertaking Quality Improvement

Evaluations of many quality improvement initiatives in LTCFs have been encouraging. However, the importance of sustaining what has been implemented cannot be emphasized enough especially in light of the current high turnover of staff in LTCFs.

Whether it is just a simple tool or whole systems change, the importance of building in some sustainability initiative into the wider project is extremely important. Sustainability is not without cost but sustainability can be cost effective. Many initiatives, even when LTCF staff and management are keen to develop a palliative care approach, can fail because of lack of sustainability and support of the LTCF once the project is over. This raises a debate about the value of funding short-term initiatives/projects without a long-term vision (Hockley and Kinley 2016).

Little evidence exists regarding sustaining interventions in practice in LTCFs, but where these organizations have contributed financially toward to a sustainability initiative once the implementation has been completed, it has continued to empower, support, and develop staff (Kinley et al. 2017).

7 Future Issues and the Need for Innovation

By 2050 there will be more people in the world over the age of 60 than under the age of 15 years old (UNFPA 2012). It is important to start thinking differently about LTCFs if we are to improve the palliative care needs of frail older people. It is vital that LTCFs are seen as places where frail older people can live out the remaining months/year/s in the knowledge that their end can be in the place where they have got to know and trust the staff.

Increasingly, LTCFs are innovating how they care; whether it is developing a more homely atmosphere for frail older people with advanced dementia (http://hogeweyk.dementiavillage.com/en/) or

encouraging greater emphasis on student involvement and training in order to attract and retain staff (Kirkvold 2008).

Further innovation in relation to palliative care and LTCFs involves technology. Countries, especially those with large rural areas, have developed videoteleconferencing technology (VTC) to support the palliative care needs of LTCF residents' alongside staff training. The need to evaluate such services is important.

Finally, here in Scotland, development is underway to build a teaching/research-based care centre (The Vision for a Teaching/Research-based Care Centre). Based on the "hospice model" of holistic person-centered relationship-based care for people with advanced progressive incurable diseases, it will provide a centre of clinical excellence alongside being a resource for training and coordination of research across the region. With the majority of frail older people requiring 24-h care having a diagnosed dementia or severe cognitive impairment, the emphasis will be on advanced dementia with plans to innovate in relation to proactive respite care and support of families.

It would appear that developing palliative care in LTCFs is now very much on the political agenda. There is a danger however that LTCFs become overwhelmed by all the different education courses, quality improvement initiatives, and research. It is important for there to be a coordinated approach to work with LTCFs in a locality so that they are not inundated with different projects but that a "homely" atmosphere be maintained.

8 Conclusion

William Osler's quote "pneumonia is the old man's friend" was written prior to the considerable developments that have occurred in medicine over the last 70 years within which time geriatrics/gerontology and palliative care have both created their own specialties. The coming together of these specialties in the care of frail older people in residential care facilities is a vital area requiring expansion while recognizing Osler's wise words.

Mutual learning between those passionate with the care of frail older people in residential care settings and those experienced in the palliative care needs of people facing the end of life, while bearing in mind not to impose what has been learned from a cancer "model of palliative care" onto residential care settings, will bring remarkable elegance to the care of frail older people.

This chapter has described a number of initiatives – "stand-alone" as well as "whole system" change initiatives. The emphasis must be on sustainability of such initiatives and the support of staff in residential care settings. An important "white paper" details the areas for practice development and research for people with advanced dementia being cared for in residential care settings. This alone if acted upon will break the isolation that staff caring for the 24-h needs of frail older people often feel.

Competent multidisciplinary working to support the palliative care needs of people in residential care settings will not only reduce inappropriate hospital admissions but is likely to enhance staff support, reduce turnover, respect what really matters to frail older people and their wishes at the end of life, and improve their quality of death.

Abstract

Hospitals are where we find the most seriously ill people in our society. Patients go there to receive lifesaving and life-prolonging treatment, but they are also where many will deteriorate and die. Care for these people and their families is therefore core business for hospitals, and this is being increasingly recognized internationally. Hospitals are also facing the challenge of how best to meet the needs of a population that is becoming ever older and frailer. When in an acute care facility, patients with advanced disease require palliative care in its broadest sense, and when their needs are complex, they deserve reliable and timely access to specialist support.

This chapter will look at the provision of palliative care in the acute setting, from the perspective of a dedicated team, working in a small provincial city in the South Island of New Zealand. It will explore how this service has developed and how it operates and thrives within its unique healthcare setting. A broad range of challenges and opportunities are discussed as well as issues such as information technology, team sustainability, and education provision. Ultimately the aim is to promote a culture change in health that promotes universal access to holistic care at the end of life.

1 Introduction

Specialist palliative care is well recognized internationally as a core component of health service delivery. People with palliative care needs often move from one care setting to another, and the skills and expertise that are provided and supported by those with specialist training need to be readily available. The ideal system is supported and configured to ensure that quality and compassionate care at the end of life is available in a timely way to everyone who needs it, wherever they are located.

The reality is however that in the minds of many (including healthcare professionals, administrators, and funders), palliative care is what happens in hospices and in people's homes, not in acute hospitals. It is often assumed that palliative care is delivered only by nurses who have a calling to provide an alternative option for care when death is inevitable. Grateful and generous communities donate money and provide time as volunteers to supplement government funding. It is viewed as separate and different to the multidisciplinary, quality-driven, holistic, and supportive services that are needed across the wider health system, including in hospitals.

Hospitals are where people who are living with and ultimately dying from chronic progressive illnesses and conditions seek treatment for (usually) short periods during an acute episode or exacerbation (Clark et al. 2014). This is certainly the case in New Zealand, as it is in many other developed countries. Community care has expanded and developed to encompass those who are very unwell and disabled and many acute problems are able to be managed very comprehensively without admission. However, hospitals are where people often look to in times of crisis, and staff should be able to recognize when a person is at risk of dying and respond accordingly. This is achieved best when their department or service recognizes the importance of this issue and is configured appropriately with access to all the necessary resources, policies, and guidelines.

Expectations vary as to what hospitals can provide, but most patients will be hoping that treatment will work and that they will be returned to health. Supporting this belief are the ever-expanding array of specialties and subspecialties which flourish as medicine evolves and more treatment options become available. Hospitals are often where it becomes apparent that cure is not possible, that the person's future is far from certain, and that the priority now is the relief of suffering.

Hospitals are also where a large proportion of our population die. In the period 2000–2013 in New Zealand, 33.9% of all deaths occurred in publicly funded hospitals. This figure is closer to

50% for Australian hospitals (Ireland 2017). The majority of these deaths are able to be anticipated given the progressive nature of the person's medical condition or conditions.

Studies conducted in Australia, the UK, and Belgium have concluded that at any one time, 13–36% of hospital inpatients meet the criteria for palliative care need. A New Zealand estimate from 2013 using the Gold Standards Framework criteria is entirely consistent at 19.8% (Gott et al. 2013). The proportion of in-hospital deaths with a palliative care status identified in hospital databases (from that same Australian study) sits at 44% in 2013–2014 which is up from 37% in 2009–2010. Looking more broadly, it is apparent that the majority of deaths are preceded by a period of deterioration over weeks to months where there was the opportunity to instigate a palliative approach and involve specialist services if required. This issue was cited in a 2008 paper by Project Muse where it was stated that 75–80% of decedents have a dying process that typically occurs over a few weeks to many months (Wilson et al. 2008). Despite these statistics, many are still surprised that such a large proportion of the care provided in hospitals is for patients nearing the end of their lives. Such information should be used to inform end-of-life care policy in hospitals (Clark et al. 2016).

Acceptance of the need for a palliative philosophy in acute care is far from the norm. As far back as 2001, it was stated that "the hospital environment reflects the business of life in society, which still denies the naturalness and inevitability of death. The culture of practice in the acute care setting is inherently related to life supporting and life prolonging activities" (Middlewood et al. 2001). The inclusion of palliative care can be an uneasy fit, but it "has presented an alternative philosophy to guide the care for dying patients... there is a need to integrate palliative care services into the acute care setting to assist the transition of goals from investigative and treatment orientated care to improving quality of life" (Middlewood et al. 2001). This issue of integration has become one of the central functions of palliative care services and will be covered later.

2 Normalizing Death and Dying

The overriding focus for doctors continues to be on returning patients to health using the diagnostic and treatment skills in which they were trained. However, essential to ensuring that palliative care is both available and of high quality is the recognition that dying is inevitable for each and every patient and agreeing that expert and timely care should be delivered with compassion. When it is apparent that a patient is not responding to active treatment or they do not want life-prolonging measures, doctors "step onto the threshold" of a new place, the place of realizing that this person is not improving, not taking the normal path, and perhaps preparing for the end of life and/or even imminent death. Dying brings health professionals face to face with their own mortality. For most this is a frightening landscape. It can be a place of discomfort on many spheres, not just physical. Palliative care operates right on this threshold. Dying often brings everyone into a liminal space, uncharted territory. In hospitals enabling this acceptance to occur is particularly challenging.

The rapid pace of hospital diagnostics and treatments now needs a reduced pace and a slow and listening presence. Assessing where the discomfort is, helping patients and families navigate this landscape and all the uncertainty it brings. Uncovering where the fear lies and transitioning people to a place of understanding and hope, through confident care and management of symptoms, are the essence of the palliative care approach.

The wider nursing and multidisciplinary team in hospitals is strongly influenced by the medical paradigm. This medically oriented hierarchy within hospitals tends to give weight to the narrative set by doctors, and it can be hard for nurses or others to break into this with their own observations and assertions or to give voice to the person's unique concerns and priorities regarding their future care.

The acknowledgement of palliative care brings a fresh perspective to any acutely unwell patient's care. It makes available a different way of

thinking particularly with regard to goals of treatment and the role of the carer and wider family/whānau. (**Whānau**: extended family, family group, or a familiar term of address to a number of people. In the modern context, the term is sometimes used to include friends who may not have any kinship ties to other members (Moorfield 2015) (ISBN 978-0-947491-36-9 (online)).). Hospital palliative care teams can assist with difficult decisions, weighing up the risks and burdens versus benefits of treatment options in real time. They can assist with the transition from active treatment to a palliative approach, uncovering what is most important to the person. This is the unique set of skills that those with specialist training in palliative care and palliative medicine bring to the acute care setting.

In New Zealand, five recurring themes regarding the provision of care to palliative patients in the acute setting have been identified. These are as follows: symptom control and burden, communication with health professionals, decision-making related to patient care and management, inadequate hospital environment, and interpersonal relationships with health professionals (Robinson et al. 2015). These are areas of care provision that can be deliberately addressed by hospital palliative care teams. Ideally, palliative care should be "at the table" when vulnerable patients are discussed. This may go some way to ensuring that a palliative approach is actively considered and that teams are reminded to glean the person's wishes in the light of any clinical concerns or worsening prognosis.

3 New Zealand Context

In New Zealand, hospitals are operated and funded by district health boards who are also responsible for delivering a full range of services in community settings. This is overseen by the New Zealand Ministry of Health (MOH) (Cumming et al. 2013). There is a strong imperative to provide a seamless care experience for consumers, and this is made more achievable given that there is no competition for patient numbers and no conflicting interests across care settings.

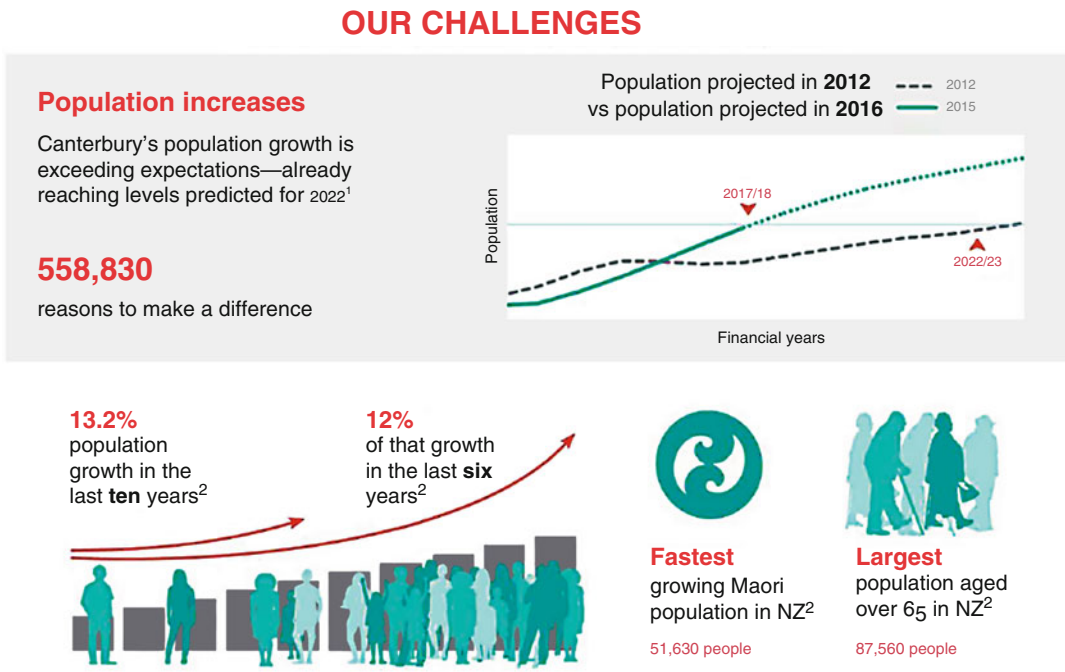

Fig. 1 Challenges of population growth in Canterbury

The insights detailed in this chapter are based on the experience of establishing a hospital palliative care service in Christchurch, Canterbury. Canterbury is located on the east coast of the South Island of New Zealand. The total population of NZ is 4.8 million. The Canterbury District Health Board (CDHB) encompasses one major population group with an overall population of 558,830. The following graphic is taken from the CDHB Annual Report 2016/2017 and illustrates current population challenges, including the high proportion of residents aged over the age of 65 years (http://www.cdhb.health.nz/About-CDHB/corporate-publications/Documents/Canterbury%20DHB%20Annual%20Report%20year%20ended%2030%20June%202017%20%28PDF%2C%202MB%29.pdf).

The Christchurch Hospital is a tertiary-level teaching hospital with approximately 650 beds. There is a second hospital in the north of the city with approximately 300 beds. The hospital palliative care team accepts referrals from both hospitals and consults on a regular basis. There is also a rural hospital with approximately 70 beds in Ashburton in the south of the region. There is a close relationship with the much smaller DHB on the West Coast (WCDHB) which has a highly dispersed mainly rural population of approximately 32,600. A large range of specialist services on the West Coast are provided by the CDHB, and some, including palliative care, are enhanced and supported by the CDHB through agreements and alliances.

Projections of the need for palliative care in all settings in New Zealand were published in 2016 (McLeod 2016). These are based on historic patterns from 2000 to 2013 and demonstrated that palliative care was needed for 73.5% of all deaths in public hospitals. Deaths in acute hospitals are often sudden and unexpected, but there are also a large number where the death can be anticipated and prepared for (Gott et al. 2013). It is anticipated that the South Island will experience an increase in total deaths of 44% over the period 2016–2038, as the population ages and the "baby boomers" begin to reach the end of their lives. As a consequence, it is projected that the need for palliative care will increase by 47% – an increase of 35% in public hospitals and a much bigger increase of 75% in aged residential care.

When considering the need for palliative care services, it is noted that this analysis is done on the basis of place of **death** and not place of **care**. The need for hospital palliative care at older ages is therefore dependent on the extent to which people are hospitalized. It is also a concern that aged residential care facilities will not be expanded as extensively as the predictions suggest, putting additional pressure on home care. Hospitals may also see an increase in admissions for the elderly as a result.

The introduction and sustainability of specialist palliative care in New Zealand hospitals have been very challenging, despite it being a clear recommendation in the palliative care strategy for over 15 years (Minister of Health 2001). In the analysis from 2016 (http://www.cdhb.health.nz/About-CDHB/corporate-publications/Documents/Canterbury%20DHB%20Annual%20Report%20year%20ended%2030%20June%202017%20%28PDF%2C%202MB%29.pdf), the need for palliative care in different settings was assessed, and it is interesting to note that a high proportion of deaths occur outside of hospitals, relative to other countries (Broad et al. 2013). Contributing to this might be the fact that only 25.8% of cancer patients died in public hospitals, in contrast to approximately 56% of cancer patient deaths in England and Wales. It is interesting to note that the largest increase in place of death for cancer patients in New Zealand has been in residential care (Palliative Care Council 2014). In addition to this, an overarching priority of the New Zealand MOH is to provide care "close to home," drawing attention away from acute care as the default option (http://www.health.govt.nz/publication/better-sooner-more-convenient-health-care-community). These factors combined may be contributing to a lack of focus on allocating sufficient resources to hospitals for end-of-life care.

3.1 Definitions

All health systems are complex, and navigating them can be challenging, both as health

professionals and as consumers. Talking about death and dying is also not easy, and confusion can occur when the phrase *palliative care* is used both for the type of care provided to people with a life-limiting or life-threatening condition and for some, **but not all**, of the health professionals tasked with delivering that care. Palliative care organizations are well placed to be involved in developing local models of care and promoting integration across care settings.

Definitions can be confusing, and in order to clarify the situation, the New Zealand Palliative Care Glossary was developed (2nd edition, MOH 2015) to assist with promoting the Framework. Terms such as a "palliative care approach," "primary palliative care," and the "palliative care system" are included, and socializing these concepts has been occurring incrementally.

Palliative Care Approach: an approach to care which embraces the definition of palliative care. It incorporates a positive and open attitude toward death and dying by all service providers working with the person and their family and respects the wishes of the person in relation to their treatment and care.

Primary Palliative Care: is provided by all individuals and organizations who deliver palliative care as a component of their service and who are not part of a specialist palliative care team.

Specialist Palliative Care: palliative care provided by those who have undergone specific training and/or accreditation in palliative care/medicine, working in the context of an expert interdisciplinary team of palliative care health professionals. It may be provided by hospice- or hospital-based palliative care services where people have access to at least medical and nursing palliative care specialists.

Specialist Palliative Care Service: a team or organization whose core work focuses on delivering palliative care, for example, a hospice or hospital palliative care team.

Palliative Care System: comprises specialist palliative care services, primary palliative care providers, and the other factors that enable them to deliver palliative care, such as communication and coordination between providers. It is not simply the existence of primary palliative care providers and palliative care services that comprises the palliative care system; it is the links between them that tie together "a system."

Supporting the delivery of primary palliative care are specialist services. These include

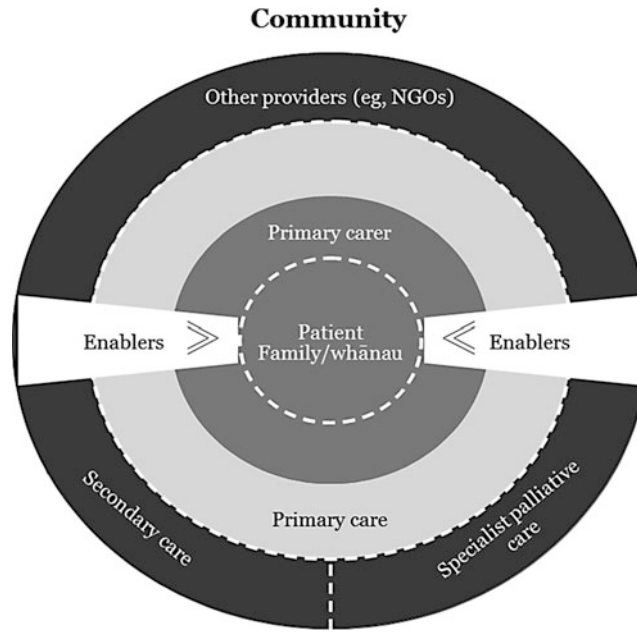

Fig. 2 Support for the patient and family/whanau https://www.health.govt.nz/system/files/documents/publications/resource-capability-framework-adult-palliative-care-services-v2.pdf

hospices and community palliative care teams AND hospital palliative care teams. Hospice inpatient and community services are very well embedded across New Zealand, and they are still considered the face of palliative care in society.

3.2 Models of Care

In 2012, the Resource and Capability Framework for Integrated Adult Palliative Care Services in New Zealand (the Framework) (Ministry of Health 2012) was developed. This outlines a model of care which explicitly recognizes that the majority of palliative care in New Zealand is delivered and coordinated by those without specialist training in palliative care, working outside a hospice or palliative care service/team, i.e., primary palliative care. The current arrangement across both the CDHB and the WCDHB is aligned with this Framework. The following graphic is taken from the Framework document.

The delivery of specialist palliative care in the acute care environment has grown organically in New Zealand, as has been the case around the world. It is contingent on supportive and sympathetic organizational leadership and a shared vision for integration of care across settings. This was fortunate to happen in CDHB leading to the creation of the Christchurch Hospital Palliative Care Service in 1999. The same cannot be said across the country with the establishment of hospital services proving very hard to realize in some DHBs.

The service in Canterbury started with a part-time physician and the recruitment of a full-time specialist nurse a few months later. Now the service employs two physicians, a nurse practitioner, two nurse specialists, registered nursing cover for planned leave, and a full-time registrar training position. The team is located within the Canterbury Regional Cancer and Haematology Service and is funded as a component of the medical and surgical division of the Hospital.

It remains the case that some hospitals in New Zealand still have **no** specialist palliative care presence at all. This is problematic and disappointing and has been allowed to happen because of the lack of a clear MOH directive for DHBs in this regard. Some hospital services are limited to in-reach nurses from hospices, with or without DHB input and often with restricted medical oversight.

Although the interdisciplinary consult liaison team is the usual model of care in hospitals, there are other models utilized in other countries. For example, there are dedicated palliative care units within some hospitals in the UK funded by the National Health Service (NHS). These units have led directly to an increase in home death rate, a reduction in deaths in the acute care hospital setting, and better integration of community, hospital, and palliative care unit team facilitating admissions and discharges and have raised the profile of palliative care within the trust (Grogan et al. 2016). (Trusts are organizations within the National Health Service which serve either a geographical area or a specialized function (such as an ambulance service). In any particular location, there may be several trusts involved in the different aspects of healthcare for a resident.).

Regardless of model, the key aspect of hospital palliative care is providing a higher level of expertise in complex symptom management, psychosocial support, communication, grief, and bereavement. Ideally, this process involves a full multidisciplinary approach and requires negotiation, coordination, communication, and collaboration as well as clinical knowledge and expertise.

The overarching goal is integration across the "whole of system" (Ministry of Health 2017a, b). This is increasingly necessary given the growing burden of chronic conditions. Ensuring that care at the end of life and following bereavement is equitable, of high quality, and available to everyone, **wherever they are located**, can only be achievable by empowering, teaching, and supporting "primary palliative care" providers in all settings, including hospitals. The issue of integration will be covered later in this chapter, but it is worth noting that following the release of the Framework (Ministry of Health 2012), momentum to configure specialist services with improved integration as a focus has indeed increased across New Zealand.

In the South Island, this imperative of integration is led by the South Island Alliance, covering

all five DHBs. Since 2014, palliative care has been represented on the Alliance by the Palliative Care Workstream (https://www.sialliance.health.nz/our-priorities/palliative-care/).

The graphic below illustrates the functions of the SIA with "population health" and "experience of care" being two of its core principles. Of particular relevance to those working in and promoting universal access to palliative care is that "people die with dignity" is one of the eight key priorities (https://www.sialliance.health.nz/UserFiles/SouthIslandAlliance/Image/Outcomes%20Framework_020715.jpg).

4 Hospital Palliative Care Services

As noted earlier, approximately one third of all deaths occur in hospital in New Zealand. Recent trajectories predict this will remain steady over time (http://www.cdhb.health.nz/About-CDHB/corporate-publications/Documents/Canterbury%20DHB%20Annual%20Report%20year%20ended%2030%20June%202017%20%28PDF%2C%202MB%29.pdf; Palliative Care Council 2011). Regardless of whether the risk of dying has been acknowledged, consumers quite rightly expect that alongside active treatment of an advanced progressive condition, attention is paid to pain and any other distressing symptoms and that communication around diagnosis, prognosis, and options for care and treatment is conducted sensitively and with compassion and respect.

While there is an expectation that all health professionals provide supportive and palliative care, it would be fair to say that many do not have sufficient knowledge or understanding to do so effectively, or they feel out of their depth with initiating a palliative approach, particularly in complex situations. Hospital palliative care as a specialist area developed in response to a recognition that many people were dying in acute hospitals without ready access to expert symptom control and a timely referral to palliative care is increasingly recognized as an essential service within the hospital system.

The symptom burden of hospitalized patients is high. "Many patients in hospital with uncontrolled symptoms including pain, nausea, vomiting, constipation, anorexia and dyspnoea" (Jack et al. 2003). The impact of hospital palliative care team has been studied with positive results. "Analysis of the data showed statistically significant improvements in the symptoms of pain, nausea, insomnia, anorexia and constipation following interventions by the team. Discussion regarding diagnosis significantly change the insight of both patients and relatives, and appropriate placement was facilitated. This study has demonstrated the significant contribution that could be made to patient care by a hospital palliative care team" (Ellershaw et al. 1995).

Within hospitals, the primary model of care delivery is the interdisciplinary consultation team (Kelly and Morrison 2015). This is generally referred to as a "consult liaison service." The palliative care team needs to work alongside the treating team and respond to the prevailing discomfort around death and dying, offering clinical support, reassurance, and education. Teams build on the care provided by the primary clinical team to enhance the capability and capacity and quality of the overall service provided while emphasizing the normality of dying. Ideally, teams need not only to be competent but also accessible and nonjudgmental. Within the palliative care team, experience levels and areas of expertise will differ requiring collaboration and support. It is preferable at times for two team members to see an individual patient.

Where hospital services are present, thought needs to be given to two aspects which may extend the "consultation liaison model." The first is "admitting rights" which is the ability to admit patients under a palliative care specialist. The other is about "prescribing rights" which is the acceptance that palliative care team members (doctors or nurse practitioners) can prescribe and amend medications. The situation in the CDHB has not changed since the service was established with the team being able to prescribe freely, in consultation with the treating team, but all patients are admitted under another specialist with

palliative care providing advice and support. This model has served us well but has been challenged a few times over the years.

4.1 Clinical Roles and Functions of Hospital Teams

It is our observation that hospital teams vary considerably in size and personnel depending on available resources. Appendix B of the Framework has outlined the essential composition and clinical functions in the New Zealand context, and teams have used these as a guide and as a vehicle for discussions with funders and managers (Ministry of Health 2012).

The constitution of a hospital-based palliative care team also varies depending on the will and influence of clinical leaders within the individual organization. Many hospital palliative care services began with one nurse or one doctor, sometime in-reaching from a local hospice. One person does not make a team, and successful services depend on their being a team structure for mutual support, sustainability, and professional safety. It is generally recognized that medical and nursing involvement is required **at a minimum**, ideally supported by some administration hours, sufficient to assist the team with the typing, data collection, and general administration.

The hospital team functions are as follows:

- Five days a week on-site service (with after-hours telephone cover)
- Consultation, advice, and liaison with referring multidisciplinary team (MDT)
- Advanced assessment (initial and ongoing) and care planning – medical, nursing, psychosocial, and spiritual
- Liaison – community (primary care) aged care, hospital teams, hospice (inpatient and community services), and pain services
- Input into family meetings
- Input into discharge planning
- Input into advance care planning
- Input into end-of-life care pathway implementation

Nonclinical functions were also included in the framework. These were considered critical to enhance the knowledge and skills of primary palliative care providers and to ensure leadership and strategic direction for palliative care:

- Clinical education – both formal/structured and informal
- Supervision/training (medical and nursing)
- Leadership and strategic planning
- Quality improvement
- Research/audit
- Clinical data collection
- Access to clinical supervision
- Appropriate networks and engagement (local, regional, and national)

An ideal service would be able to offer consultation liaison services 7 days a week and the option of in-person specialist review after-hours for complex or emergency cases. To date this comprehensive coverage has not been possible in any New Zealand hospital, and even providing after-hours telephone cover is proving difficult for most hospital teams. Provision of after-hours telephone advice has been achieved recently in Christchurch and involves the sharing of senior staff across the hospital and the hospice/community services. This arrangement is based on a close working collaboration that has developed over years.

It is apparent that hospital palliative care teams often demonstrate the benefits of a flat hierarchy. This is where the views of the whole team are equally valuable and decisions are made after attending to members' views and ensuring that there has been open and honest dialogue. As a minimum, this requires hospital teams to consist of nurses AND doctors as members and a strong alignment with allied health in the wider hospital to include social, cultural, and spiritual care. Some teams include social worker and/or counselor/psychologist as members of the specialist team, and this can compensate for when there is inexperience in these areas in the wider hospital.

It is important to emphasize that there is a need for hospital teams to operate in a time-constrained

environment which can be challenging. Trust and rapport with patients and families must be established very quickly, in what is a busy and fast-paced environment. The median time from referral to discharge or death for the Christchurch service is 4 days, and this is inclusive of weekends where the team are not on site.

Anecdotally, the case mix for hospital palliative care is somewhat different to hospice and community services, with acute deaths and non-malignant conditions more strongly represented. In Christchurch Hospital, the proportion of new referrals who have a non-cancer diagnosis sits at approximately 40%, a number that has been consistent over the last 5 years. The proportion of new referrals who die during an episode of care has also been stable over time at 25%. Three quarters of referrals therefore are discharged from hospital to community settings, making it an imperative that the process of transfer of care is robust and well-planned (Unpublished data from Christchurch Hospital Palliative Care Database, New Zealand).

Further analysis of the Christchurch data has confirmed the impression that a higher proportion of patients seen by our service die in hospital if they have a nonmalignant condition. Eighteen percent of cancer new referrals to the palliative care team died during that first episode, compared to 49% of non-cancer new referrals. This difference is striking. These patients (and their families) may not be aware of the seriousness of the situation at the time of admission or the possibility that they might be close to death. This raises many issues in regard to community and health system preparedness that is likely to become more important as the general population ages (Unpublished data from Christchurch Hospital Palliative Care Database, New Zealand).

Ward-based referrals are not the only activity undertaken by hospital palliative care teams. Across all disciplines, clinics are a core component of specialist services in acute hospitals. Increasingly these are not led by doctors but by specialist nurses conducting clinics in areas such as oncology, diabetes, wound care, and infectious diseases. Hospital-based palliative care clinics are variably utilized, and this is often a reflection of capacity. It also depends on whether ambulatory care is provided by the local community-based/hospice service. It can be confusing for patients and referrers if there are multiple options for outpatient intervention in palliative care (particularly in a publically funded health system like New Zealand), and it is important not to have unnecessary duplication of resources.

In Christchurch, palliative care services work collaboratively with a number of other specialty areas with clinics and multidisciplinary support processes that complement each other and promote integration. Having combined clinics to address particular areas can work very well and include but are not limited to nephrology (for end-stage kidney disease), motor neurone disease, and heart failure.

Pediatric palliative care is a specialty area on its own, and most adult specialists (medical and nursing) do not feel it is appropriate to be offering advice to their pediatric colleagues. However, the volume of patients in pediatric practice is low, and it takes much longer to accumulate a broad experience base. There is enormous value in some situations for providing collaboration and support. It is an issue that is very worthwhile considering.

Access to bereavement support including formal counseling is ad hoc and often absent. Hospices generally have well-developed services and link very effectively with other community providers. Some hospital-based services such as intensive care and pediatric oncology have policies that include bereavement support, but it is the exception rather than rule. This is the subject of a current project in our DHB.

4.2 Nonclinical Roles

The knowledge and wisdom of individuals within the hospital palliative care team are often utilized by other teams around the hospital to discuss complex patients and debrief over difficult issues, especially in cases where there is particular sensitivity or emotion. This is perhaps because of having expertise in communication skills but also because as a discipline palliative care sits slightly outside the traditional medical model and

therefore brings a different perspective and a sense of neutrality. This listening ear can be highly valued in the stressful environment of acute medical care.

The influence of hospital palliative care extends beyond the patients and the clinical teams caring for them. Ideally the reach should be directly into the realm of quality and patient safety as this is at the heart of what we do. Hospitals receive regular feedback on their services, and criticism is often leveled at issues around poor end-of-life care and communication. Building a profile in the organization where the service is valued for providing guidance and advice is invaluable. This can involve assisting with the processing of complaints in a constructive and meaningful, driving institutional change around policy and priority setting for dying patients.

The requirement for "noncontact time" (the time spent on issues not relating directly to patient care) is specifically identified within the employment contract of doctors in New Zealand. This is very relevant for palliative care where education, service development, research, and continuing professional development must be undertaken. Other staff, most specifically nurses, also require noncontact time for these endeavors. For everyone the ability to prioritize this above clinical work is extremely challenging.

4.3 Staff Training

Advanced medical training to specialist level across Australia and New Zealand is delivered through the Royal Australasian College of Physicians (RACP). New Zealand has a nationally funded program, and palliative medicine registrars work in hospital palliative care for a minimum of 6 months to develop their palliative care skills in an acute setting. This is a mandatory requirement for training. All palliative medicine specialists employed by the CDHB have a role in undergraduate medical student teaching both in the hospital and in the hospice.

Nursing students have little exposure in most undergraduate programs to opportunities to improve generic symptom assessment and treatment skills as well as communication skills. Allied health staff have even less. Palliative care forums worldwide continue to advocate for increased training in all undergraduate programs.

Postgraduate university posts for palliative medicine and palliative care nursing are gradually becoming more common but are still inadequate for the research that is required and for providing sound evidence for clinical decision-making. This is particularly the case in New Zealand. The CDHB is fortunate to have a specialist in post who is also employed as a Senior Clinical Lecturer for the University of Otago.

While numbers are still small, the introduction of nurse practitioners (NP) approximately 15 years ago in New Zealand has assisted in increasing advanced assessment skills and increased pharmacology knowledge among palliative care nurses. This has been valuable in the acute hospital environment as well as rural and community settings and has raised the bar regarding clinical reasoning, knowledge, and prescribing of medications by nurses. The NP role supports the philosophical stance of palliative care in many hospital teams – that nursing, allied health, and doctors consult on the same group of patients. Allowance is made for the clinical experience of the individual practitioner in relation to the complexity of the case, but otherwise there is no differentiation.

Hospital palliative care teams need to prioritize their own ongoing learning which may include journal clubs, hospital grand rounds, complex case management reviews, mortality meetings, cancer multidisciplinary meetings (MDMs), etc. Combined continuing medical education (CME) with other disciplines such as oncology are also highly beneficial and usually easily accessible in the hospital environment. Such meetings also provide opportunity to discuss patients with complex symptoms. Within the hospital system, specific meetings can be set up to review imaging and discuss patients with complex pain issues. This has happened in Christchurch and is proving invaluable in the treatment of patients with pain who require a broader team discussion. Appropriate patients may then be selected for palliative procedures such as cementoplasty/

vertebroplasty, ablation techniques, and nerve blocks as well as palliative surgery and radiotherapy. These meetings provide opportunity for specific ongoing learning as procedures are refined or new innovations become available.

As hospital teams grow, the risk emerges of referring teams getting conflicting advice, depending on who from palliative care responds on each occasion. This needs to be managed proactively as it can erode trust in the wider team. Having agreed symptom management guidelines that the whole team adheres to sets a platform for the main problems that are encountered. Complex cases, where creative thinking may be required, need to come back to the team so that a consensus is developed. Every effort should be made to ensure that each team member does not work independently, with synergy of practice being of paramount importance, while still valuing each other's unique skills and ideas.

Another issue that causes concern is when the advice of palliative care is in conflict with the treatment plan of the referring team. This is not an uncommon situation and requires diplomacy and care to minimize confusion and polarization. Ultimately a consensus is usually reached as long as the needs and preferences of the patient are put at the center. The palliative care perspective is not always correct of course, so mutual respect and humility are very useful attributes.

4.4 Prompt Response to Clinical Need

As hospital palliative care services have been established, so have referral criteria to manage the flow of referrals and to guide referrers. In New Zealand the Framework identifies three main criteria for specialist referral. These are as follows:

1. The patient has active progressive and advanced disease or life-limiting illness.
2. The patient has a level of need that exceeds the resources of the primary palliative care provider. The Framework states that palliative care services "should provide direct management support of patients their families and whānau where more complex palliative care needs exceeds the resources of the primary care provider."

   There has also been agreement that the level of input is "needs based" rather than based on diagnosis or prognosis and in some cases where that level of need becomes extraordinary examples include:

   "Uncontrolled or complicated symptoms, specialised nursing requirements related to mobility functioning or self-care, emotional behavioural difficulties related to the illness such as uncontrolled anxiety or depression."
3. The patient agrees to the referral if competent to do so (or an advocate agrees on their behalf).

On the basis of these criteria, a referral for a specialist palliative care assessment can be activated. The referral is made according to **patient need**. Sometimes patients with a longer or unknown prognosis are referred, and this is entirely consistent with the model of care. It has been recommended that individual service referral criteria in New Zealand are based on the national guidelines. As noted in the Framework, "the subsequent level of involvement/intervention, treatment plan and care package be negotiated with the patient, carer and referring team" (Ministry of Health 2012).

Patients can also be discharged from palliative care services either through patient choice or because their needs have been met and ongoing care can be effectively managed without regular input from specialist services. Discussion with and referral back can be made at any time.

Another recommendation is that teams articulate a target response time for new referrals to be seen once the referral has been received. Not infrequently, referred patients will be in acute pain or close to death. These are sometimes referred to as "late" referrals and to a certain extent are inevitable. Teams should make themselves as approachable as possible to help mitigate this issue, and responding quickly with advice and support is essential. Local policy is that patients are seen the same day if at all possible. While this may not always be achievable, it should be the

ideal as responding to acute need/demand for acutely unwell patients is core business for hospital palliative care. In many cases, the issues affecting the person and/or their family have been present for some time before the referral is generated, so waiting any longer only compounds distress for patients, families, and staff.

Triaging of referrals is a complex and fraught issue. The task of making a referral is often delegated to junior staff who may not appreciate the full picture and struggle to articulate the purpose or urgency. Speaking to the most appropriate member of the referring team (which may be a senior) is often required. To complicate things further, there are often additional concerns that have not been identified by the referring team. Wherever possible, patients should be prepared for a palliative care referral and have agreed for it to occur. The presence of a specific support person may be required. Working alongside referrers on a daily basis is essential to improve their capacity to identify and respond to palliative and end-of-life issues. Over time, referral practices improve and true teamwork emerges.

4.5 Complex Decision-Making and Ethical Challenges

Palliative care skills are generic and required in all locations; however, working in the acute hospital environment allows clinicians to be involved at the coalface for active treatment decisions as they are unfolding during an acute admission. The availability of specialist palliative care support when a patient is in the emergency department or being admitted to intensive care as well as for acute assessment teams such as in general medicine, general surgery, oncology, cardiology, hematology, and older person's health is highly beneficial. Being accepted as part of the wider team requires mutual trust and respect; benefits are significant, and they can work both ways. Palliative care as a specialty needs to stay current with practice trends and developments for the benefit of all patients and also improves interdepartmental communication and collaboration.

Patients with palliative care needs derive many benefits from hospital admissions. Robinson et al. reported that "families felt relieved when they were admitted to hospital. This was seen as relief from the responsibility of decision making associated with caring for someone with a serious illness" (Robinson et al. 2015). Primary teams defer to the hospital palliative care service particularly when patients with complex symptoms or psychosocial issues are admitted when they lack the confidence to manage the case alone (Ireland 2017). Access to specialist palliative care in the hospital environment has a demonstrated effectiveness in reducing the symptom burdens of dying person, whether these be physical or psychosocial (Le and Watt 2010). There are also established benefits for carers (Higginson and Evans 2010). This occurs despite that fact that a member of the hospital palliative care team cannot be at every ward-based multidisciplinary meeting or mortality meeting, just like they cannot be present at every cancer MDM, but the profile of palliative care within the acute hospital should ideally be such that teams can call on a team member to provide a palliative care viewpoint or option in most situations where that is needed.

A regular reason for referral is when ethical challenges arise or where there is conflict between the wishes of the treating team and those of the patient and/or family unit. These cases are distressing for health professionals, and the palliative care team can act as a "sounding board" or "wise ear." This is a form of collegial support which is increasingly important in the acute environment.

It should also be routine that a health professional with advanced knowledge in end-of-life care will assist in the development and socialization of policies and processes linked to complex decision-making. This can be achieved by contributing to initiatives such as the transition from active treatment to a palliative approach, determining and documenting goals/ceiling of care, advance care planning, medical guidance plans for incompetent patients, and policies regarding resuscitation decisions and documentation. It also requires an understanding of how to discuss these delicate issues with consumers.

4.6 Education, Mentoring

The training and education of healthcare professionals who work in acute hospitals are paramount and linked closely to the issues of transitioning patients from active treatment to a palliative approach and end-of-life care. Medical staff trained in the biomedical model with curative intent should be introduced to the basic concepts of palliative care early in their training and be given the opportunity to think about their own mortality and the importance of compassion, empathy, person-centered care, communication, and self-care.

Face-to-face education sessions for ward-based staff are expensive to deliver for resource-constrained hospitals, and this has led an increasing demand for online learning packages. These are also more easily accessible for healthcare professionals working across 24-h shifts, but such programs are time-consuming to produce. Even once implemented, these tools cannot completely eliminate the need for personal contact with experts in the field, especially when teaching sensitive and challenging content that may trigger deeply personal responses that need to be carefully managed.

It is important to maximize informal teaching opportunities and to mentor ward nursing and medical staff and students. This is part of the day-to-day work of hospital palliative care teams. This ongoing requirement can be a heavy workload for inherently numerically small hospital teams but is absolutely necessary.

An excellent opportunity for palliative care education is as part of any communication skills training that happens within the hospital. Teaching and role-playing of breaking bad news/end-of-life care consultations with patients and families are also required. The introduction of advance care planning programs in acute care in recent years has also provided the opportunity for healthcare professionals to improve their communication skills and to encourage them to better acknowledge that people have unique preferences, goals, priorities, and fears when it comes to care at the end of life. Both of these should be taught in the hospital setting, and opportunities for collaboration should be sought with other specialty groups to give weight to the importance of the topic in the eyes of the learners and the organization. Collaborating on teaching also spreads the load which is important for small services with stretched resources.

There is a very high turnover of clinical staff in acute hospitals, not limited to just doctors and nurses, so keeping everyone familiar with the place of palliative care, the role of the service, the availability of resources, and opportunities for education needs to be constantly refreshed. Part of the challenge is to empower staff without de-skilling them. This requires resisting the temptation to do everything ourselves!

New Zealand is an increasingly multicultural society with significant numbers of the registered and unregistered workforce having trained overseas. English may also not be their first language. This may lead to cultural, clinical, and ethical challenges regarding care at the end of life that require targeted education and support.

4.7 Guideline and Pathway Development

Throughout the world, various palliative care guidelines have been developed (e.g., NICE Guidelines in the NHS (https://www.nice.org.uk/guidance/qs13)) to assist in one of the most important purposes of palliative care – the education and support of healthcare professionals. Developing guidelines based on best practice and research is challenging with the relative paucity of robust studies in palliative care. The Christchurch Hospital Palliative Care Guidelines were developed approximately 15 years ago. They were initially only available for hospital-based staff on the intranet, but in more recent times, they have been refined and made available to all health professionals on the CDHB Internet site (http://cdhb.palliativecare.org.nz/). They have been widely accessed and referenced by individuals and services both across NZ and internationally.

Another platform for improving access to localized and relevant information has been HealthPathways (https://www.healthpathwayscommunity.org/About.aspx). In the CDHB there

1. Baseline assessment

A health practitioner undertakes a baseline assessment when they think a person may be entering their last days for life. This change in condition acts as a prompt to ensure conversations occur with the person and with their family/whānau.

If a person in their last days of life has a level of need that exceeds the resources of the primary palliative care provider, that provider should refer them to specialist palliative care.

Table 1: Baseline assessment summary

Te taha tinana: *Physical health*	
1.1	Recognition the person is dying or is approaching the last days of life
1.2	Identification of the lead health practitioner
1.3	Assessment of physical needs
1.4	Review of current management and initiation of prescribing of anticipatory medication
1.7	The person's awareness of their changing condition
1.11	Provision of food and fluids
1.12	Availability of equipment to support the person's care needs
1.13	Consideration of cardiac devices
1.14	Advice to relevant agencies of the person's deterioration
Te taha hinengaro: *Mental health*	
1.5	Assessment of the person's preferences for care
Te taha whānau: *Extended family health*	
1.6	Identification of communication barriers
1.8	The family/whānau's awareness of the person's changing condition
1.9	Discussion of cultural needs
1.15	Provision of information to the family/whānau about support and facilities
Te taha wairua: *Spiritual health*	
1.10	Provision of opportunity for the person and family/whānau to discuss what is important to them

Fig. 3 Baseline assessment at last days of life

is a version for general practice teams and community care and another version for the hospital. HealthPathways have been adopted in many other areas in New Zealand and localized as needed but based on the same principle of a shared platform of information across all settings of care.

A number of location-specific pathways have been developed by the palliative care team. The most notable ones are in the emergency department and the intensive care unit. Both of these areas are highly experienced at dealing with serious life-threatening illness and death but wanted to appreciate and understand the nature and benefits of palliative care in order to improve their services and ensure that transfers were safer and more in line with ward- or community-based care. It has been a mutually beneficial process and is an ongoing work in progress.

New Zealand has also recently released Te Ara Whakapiri: principles and guidance for care at the end of life and the Te Ara Whakapiri Toolkit (April 2017) (Ministry of Health 2017c). The two documents are suitable for all healthcare settings, including acute care, and a process of implementation is currently underway. The program was developed in response to the withdrawal of the Liverpool Care Pathway for the Dying Patient in 2015. The following graphic is taken from the section of the guidance that covers the baseline assessment that is conducted on all people identified as dying, regardless of their location. Te Reo Maori, the language of New Zealand's indigenous peoples, is used throughout the document as a recognition of the need for culurally appropriate care at the end of life.

4.8 Liaison with Community Services

A key aspect of providing seamless palliative care is being able to transfer patients to community-based services upon discharge from hospital. This requires knowledge of what they can provide and

their level of expertise. It also requires close links with specialist palliative care service(s). This interface is improved if there is good sharing of electronic patient data to ensure all information is accurate and up to date and shared in a timely fashion. Ideally this should be inclusive of patients in their own homes, those residents in aged residential care facilities (care homes) as well as any other locations such as supported care homes for those with intellectual disability, and those in prisons or other facilities.

Effective liaison also requires a relationship of trust so that when setting up discharge arrangements from hospital, there is confidence in what follow-up services will be there to for each patient and family. This may be as simple as ascertaining whether the patient can be seen promptly by the community palliative care team and/or district nurse. Hospital teams can act as a "bridge" with the community, and fully understanding the capacity and capability of the local providers is essential to avoid inflated expectations.

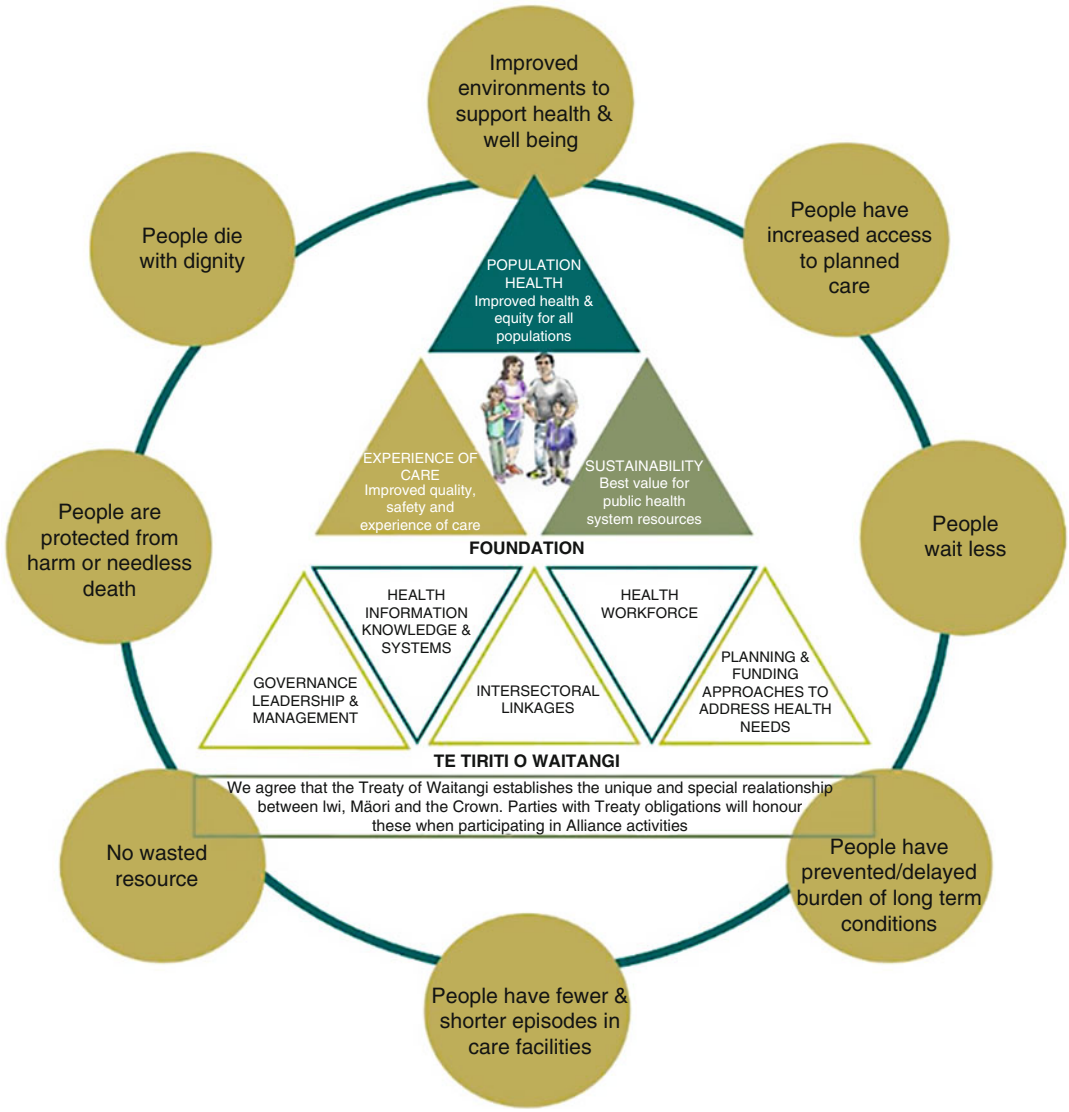

Fig. 4 Best for people, best for system outcomes framework https://www.sialliance.health.nz/system-outcomes-framework-graphic/

Sometimes patients cope better than expected, and sometimes they need to fail in order to understand the extent of their limitations. All of these issues need to be communicated effectively with our community colleagues.

It is imperative in the New Zealand system that the general practice team (also known as the primary healthcare team) is considered at all times. Having a general practitioner (GP) who is supportive is critical to the functioning of the primary palliative care team as the model of care. This is because specialist palliative care in the community is contingent on a collaborative GP relationship.

Models of community care and the organization of palliative care services will vary from country to country and within regions. As part of the model of care in Canterbury, the DHB has an agreement between the hospital and the community (Nurse Maude (https://www.nursemaude.org.nz/)) to work as a single specialist unit – *Canterbury Integrated Palliative Care Services*. Even though the two arms are funded separately, the vision, planning, and operational goals are aligned to eliminate gaps and waste and to enhance the consumer and health professional experience.

Even within a small country such as New Zealand, models of care vary; however, organizations such as the South Island Alliance (SIA) are promoting a more uniform approach. The SIA is funded and supported by the five South Island DHBs which has enabled the region to work collaboratively to develop more innovative and efficient health services than could be achieved independently. The SIA has been a driving factor in improving access, quality, and service development in a wide range of clinical areas.

In order to ensure a connected community of care, access to real-time information such as current medications, results, specialist assessments and letters, acute care plans, advance care plans, goals of care documents, etc. is becoming a universal expectation internationally. Making this happen with diverse IT systems, privacy concerns, and IT logistics is a significant barrier to providing comprehensive integrated palliative care. Improving IT systems and software programs are bridging these gaps; however, having information accessible to all the relevant health professionals in real time is proving to be an ongoing challenge. The SIA is helping spearhead IT integration across the South Island within the limitations of the systems available. Change can be difficult for staff, but benefits are steadily being realized.

4.9 Information Technology

As mentioned above, data sharing and transfer of patient information across healthcare settings is of paramount importance and is an increasingly complex endeavor. Hospital palliative care teams can usually access all the same information as colleagues from other areas within the acute environment, but this does not always translate to the same access for specialist doctors, nurses, and allied health staff working in community settings. This inevitably leads to delays, errors, and frustrations. Working collaboratively with IT services is essential in ensuring that the care of dying patients is seen as just as important as those being treated actively.

In 2013, the Health Information Standards Organisation in NZ developed a suite of national data definitions for specialist palliative care (Health Information Standards Organisation 2013a, b). These have helped drive consistency in hospice services, but as yet there have been no resources available to standardize, measure, and report on activity, demographics, and trends in hospital practice. This issue has been much more proactively addressed in other countries but will not be reported here.

An important way of maximizing productivity for small services is to invest in IT innovations such as Telehealth (videoconferencing). This has been a very successful vehicle in the CDHB especially for rural consultations, for complex case meetings which are conducted regionally, and for staff support.

4.10 Building and Sustaining the Team

New Zealand as well as most other countries has a shortage of skilled palliative care medical

and nursing staff let alone allied health staff. "Growing your own" where possible appears to be the best option available. As mentioned earlier, the RACP has a training program to specialist and diploma level, and these are well utilized. Many New Zealand hospitals are accredited for palliative medicine training, but the number of funded positions is insufficient to meet current and future needs. This issue will no doubt be familiar internationally. In regard to nursing staff, a trust fund is available in New Zealand for two placements per year where a registered nurse can train in palliative care for a 2-year period. Working in the hospital setting is part of the training program, but places and funding are limited, and efforts to improve the situation have not yet been forthcoming.

The recruitment of a "team" is dependent on many factors not least the availability of skilled personnel with appropriate qualifications and experience. Growing the specialty within nursing and succession planning for services is an ongoing challenge. More creative ways to upskill registered nurses in palliative care are required. Working in hospitals is different to hospices, and although many of the necessary skills can be gleaned in hospice or community care, the swift-moving and highly pressured environment in acute care can make it hard for nurses in particular to feel that their input is having any influence.

Leadership in the team is also important to consider and foster. One of the benefits of having a flat structure within hospital teams is being able to share leadership responsibilities, to cover personnel when others are away, and to take collective responsibility for accepting challenging cases. Leadership in any team sets the direction, philosophy, and culture of the service, but the entire team must "share the vision."

Formal orientation to a new position within a hospital team is critical, with clear directions and guidance as to how referrals are managed, how workload is contained, how to seek help, and how to keep skills and knowledge current. Even small teams need orientation packs for new or visiting team members. Teams develop very intricate patterns of behavior that can be mystifying to the outsider; therefore, writing down what your team does helps new personnel to integrate more smoothly and operate effectively.

Maintaining a team in the acute hospital environment requires close professional working relationships and high levels of trust in each other's work as well as the checks and balances of paper ward rounds, patient review meetings, audits, and ongoing research projects. It also requires each individual team member to take responsibility for the emotional, psychological, and spiritual demands inherent in a busy hospital palliative care practice. Reflective professional supervision should be encouraged and funded (as is the case in the CDHB) as well as informal debriefing among the team members as needed. It is a forum where the complexities of the interpersonal interactions that underpin the provision of healthcare can be explored in a supportive and confidential setting (https://www.nzma.org.nz/journal/read-the-journal/all-issues/2010-2019/2016/vol-129-no-1434-6-may-2016/6884). Regular team business meetings can also be helpful and occasional team-building activities. These are essential to create sustainability.

Ideally team members should be supported to utilize their individual strengths and strong enough to tolerate their differences. This is particularly challenging at times of growth and when managing change such as a new manager or leader.

There is no doubt that small teams can fall into the trap of spreading themselves too thinly. An example of this might include the common request for a palliative care physician to be present at every cancer MDM. There are more than 12 individual meetings in the CDHB, each lasting at least an hour and run sometimes every week. Meeting this request is impossible, and each case must be looked at individually to maximize the resource.

Small teams are very vulnerable – both in regard to the myriad of unrealistic expectations placed on them by others but also to the teams' own internal dynamics. Palliative care attracts health professionals with a strong vocation and a desire to venture where others are unable or unwilling to tread, and this can make team members overly sensitive to a fear of failure to meet their own high standards.

It is important to foster relationships with management that are attuned to these pressures, expectations, and dynamics so that they can empower and support hospital teams to develop and thrive, despite the pressure placed upon them. This can make the difference between a team that is able to adapt and change successfully and one that is only able to "tread water" and survive.

5 Raising the Profile and Promoting Culture Change

Having a clear and visible profile within the hospital requires individual commitment and managerial support. Some examples of how this might be achieved include making and taking the opportunity to present at departmental meetings and hospital grand rounds, contributing to hospital newsletters, developing policies and pathways, and participating in strategic projects and hospital-wide meetings. The function of hospital palliative care is not only to provide excellent clinical advice and support but also to be politically astute and active. Being seen to be involved in the workings of the wider hospital system is critically important.

Hospital palliative care teams, when working well, influence and change the culture within the organization around care of the dying. They legitimize dying as being "OK" even within a curative model, and they allow other health professionals to ask for help in both an end-of-life situation and to assist in managing difficult symptom management and complex social needs. They also advocate for patients especially those who are vulnerable. Hospital palliative care teams promote a way of thinking that turns around the notion prevalent in acute care of "what can we do to the patient" to "what is best for the person." Having a palliative care presence in hospitals challenges a model of care that may no longer be appropriate.

There are many examples of patients having more than one team or multiple teams involved in their care and no one team taking the lead. The patient who is left languishing without any direction or plan lost in the complex world of acute hospital care. These are the situations in which patients or family members feel they have little choice other than to lodge complaints against "the system." Added to these are the environmental factors of acute care hospitals. Due to pragmatism and cost, multi-bedded rooms with few, if any, alternative spaces make it extremely difficult for any personal or reflection time let alone private conversations with family members or other healthcare professionals. Discussing spiritual care or fears around dying is extremely challenging in the acute care environment for patients, family, chaplains, pastoral care, and palliative care team members. Therefore, hospital palliative care teams need to use their position within the healthcare system to advocate for patients and to influence change.

6 Palliative Care and Hospital Costs

Despite the fact that death and dying are ubiquitous in hospitals, acceptance of the value of a palliative care presence is far from universal. This may be, in part, due to the reticence of hospices to venture into the acute environment, wishing to preserve the identity and separateness of the hospice philosophy of care. It may also be due to an assumed lack of evidence that they are of benefit. This, however, is not actually the case. Palliative care teams have been shown to improve quality of life for patients with advanced cancer and in a recent study to extend survival (Temel et al. 2010). "Furthermore, palliative care programs can reduce hospital costs by ameliorating pain and other distressing symptoms that increase hospital lengths of stay and cause medical complications; can reduce overuse of unnecessary, ineffective or marginally effective services; and can develop transition plans that result in safe hospital discharges with lower likelihood of readmission" (Morrison et al. 2011).

Cost savings attributable to palliative care services in hospitals have been extensively reported in international studies (Kelly and Morrison 2015; Morrison et al. 2008; Simoens et al. 2010). The paper by Ireland in 2017 examined access to palliative care services during a terminal hospital

admission and concluded that intervention rates and hospital costs were reduced. Involvement from palliative care was associated with significantly lower hospital costs in the order of $5000–8000 (Australian dollars) for all patient groups, but most particularly for those with non-cancer diagnoses. Shorter terminal episodes and greater palliative care-related cost reductions have been identified for patients with diagnoses other than cancer. The paper states that the total costs of these episodes were reduced by 28% for cancer patients and 36% for other patients with much lower rates of ICU admissions and operative procedures being the chief drivers of cost reductions. A prospective multisite cohort study published in 2017 noted that reduced length of stay is the biggest driver of cost saving from early consultation for patients with advanced cancer. Patient- and family-centered discussions on goals of care and transition planning initiated by palliative care consultation teams were felt to be at least as important in driving cost savings as the reduction of unnecessary test and pharmaceuticals identified in other studies (May et al. 2017).

It is worthy to include a note of caution when extrapolating such specific findings to individual situations. "Funding models are a very important consideration and they need to be well understood to ensure best practice and minimise perverse incentives. Before we can conduct cross-national comparisons of costs and impact of palliative care, we need to understand the funding and policy context for palliative care in each country of interest" (Groeneveld et al. 2017).

7 Integrated Palliative Care

Integration is required to ensure that palliative care is available and effective for all who need it. This needs to occur across all settings of care and is dependent on collaboration, trust, respect, and mutual support.

A definition of integration is included in a recent systematic review in Europe. "Integrated palliative care involves bringing together administrative, organisational, clinical and service aspects in order to realise continuity of care between all factors involved in the care network of patients receiving palliative care. It aims to achieve quality of life and a well-supported dying process for the patient and the family in collaboration with all the caregivers, paid and unpaid" (Garralda et al. 2016).

The recommendations from this project are well worth reflecting on, and they address the issue from three levels.

At a policy (macro) level, the focus is on:

1. National policy development
2. Earmarked funding
3. Measurable outcomes
4. Public engagement

At an organizational (meso) level, the following requirements are emphasized:

1. Identify gaps (often communication).
2. Include the multidisciplinary team.
3. Ensure seamless working across systems.
4. Acknowledge that **one size does not fit all.**
5. Promote formal structures specifically targeting integrated care.

At an individual patient/family (micro) level, the report also emphasizes the following;

1. Personalized communication to enable patients to express their preferences for their care, e.g., via formal advance care planning
2. Identification of patients before crises occur, e.g., goals of care
3. Involvement of family/whānau
4. Integration of care across agencies
5. Established communication systems

Many of these points resonate with work that has been occurring in New Zealand, but there is still a long way to go. The work of agencies such as the Health Quality and Safety Commission (https://www.hqsc.govt.nz/our-programmes/patient-deterioration/), the Advance Care Planning Cooperative (http://www.advancecareplanning.org.nz/), the Canterbury Initiative (http://www.canterburyinitiative.org.nz/) (including

HealthInfo and HealthPathways), and the South Island Alliance (https://www.sialliance.health.nz/UserFiles/SouthIslandAlliance/Image/Outcomes%20Framework_020715.jpg) are helping palliative care organizations with promoting integrated care at the end of life and service development.

8 Conclusion

An important indicator of how effectively a health system is operating is how well it cares for the most vulnerable members of society. The dying are extremely vulnerable, and it is pleasing to see that New Zealand features highly in a global context with a ranking of third in the 2010 report by the Economist Intelligence Unit (http://graphics.eiu.com/upload/eb/qualityofdeath.pdf). Despite this, coverage and integration are incomplete, and hospitals remain a major area for improvement.

Within Christchurch Hospital, in addition to medical and nursing partners, it has been beneficial to identify champions in areas such as pharmacy, social work, occupational therapy, acute pain management, counseling, and mental health. These have helped to support the wider interdisciplinary team with their care of routine and complex cases, and collectively they serve to raise the bar in regard to interdisciplinary team commitment to quality palliative and end-of-life care. This is part of creating a shared vision for care of the dying across the whole health system.

Back in 1994, it was recognized that having "palliative care in a hospital. . ..is an issue of justice and equity, and gives structure to compassion" (Lickiss et al. 1994). As indicated throughout this chapter, more recent studies have validated this over and over, providing a clear and welcome message for providers, commissioners, and funders of health services. It is summarized very eloquently in this final paper. "In the intense pressure for health services to do things differently and more cost effectively, specialist palliative care teams may have a central role in delivering better care and outcomes while reducing acute care use in last weeks of life, and should be resourced and commissioned to do so" (Murtagh 2014).

Given the aging population and the ongoing expectation that hospitals will remain central to the delivery of care at the end of life, hospital palliative care must not be forgotten. The relatively poor profile of palliative care in acute settings and in society in general, the observation that high proportions of nonmalignant patients are only being recognized as dying in the final stages, and the vulnerability of small teams are just some of the challenges that need to be faced. Palliative care is not an optional extra. Targeted effort is required to drive improvements in outcomes for patients and families and to ensure that **all** health professions are equipped to look after palliative patients in their care.

Palliative Care in the Intensive Care Unit (ICU)

53

Rebecca A. Aslakson and J. Randall Curtis

Contents

Abstract

Palliative care is a medical specialty and philosophy of care that focuses on reducing suffering among patients with serious illness and their family members, regardless of disease diagnosis or prognosis. As critical illness is often life-threatening and confers significant disease-related symptom burdens, palliative care and palliative care specialists can aid in identifying goals of care, reducing symptom burden, and improving quality of life among intensive care unit (ICU) patients and their

family members. Palliative care in the ICU can be delivered by the ICU team itself, specialist-trained palliative care consultants, or a combination of both. Though initial reports describing end-of-life care practices in the ICU were published in 1976, the modern era of palliative care research in the ICU began in the early 2000s. Since 2010, the Improving Palliative Care in the ICU (IPAL-ICU) Advisory Board has published a series of articles exploring opportunities and barriers to palliative care delivery in the ICU, particularly across different ICU types, ICU providers, and ICU patient populations. Furthermore, initiatives to improve delivery of "family-centered care" in the ICU frequently also correlate with palliative care practices. To date, over 40 palliative care and palliative care-related interventions targeting ICU patients and families have been trialed and published with results showing mixed effectiveness on outcomes such as ICU length of stay, patient and family symptoms, and family member satisfaction; several randomized trials provide important insights into interventions that improve patient and family outcomes as well as those that do not.

1 Introduction

The chapter aim is to discuss the history, delivery models, evidence base, opportunities for, and barriers to palliative care delivery in the intensive care unit.

Critically ill patients often require the most sophisticated technological treatments that modern medicine can offer and are at significant risk of death during or after the intensive care unit (ICU). In addition, ICU patients are at risk for significant morbidity with physical and psychological suffering that can occur both during and after ICU care (Angus et al. 2004; Teno et al. 2013; Wunsch et al. 2010; Cox et al. 2007, 2009; Choi et al. 2014; Puntillo et al. 2010; Herridge et al. 2011; Dowdy et al. 2005; Iwashyna et al. 2010; Davydow et al. 2008, 2009; Nelson et al. 2006a; Needham et al. 2012). Family members and caregivers of ICU patients are also at risk of increased morbidity, especially psychological morbidity (Needham et al. 2012; de Miranda et al. 2011; Swoboda and Lipsett 2002; Van Pelt et al. 2007; Anderson et al. 2008; Siegel et al. 2008; Cameron et al. 2016). The ICU is also a frequent place of patient death, often following a decision to withhold or withdraw life-sustaining treatments when those treatments no longer meet the patient's goals of care as identified by the patient, family member, and/or clinicians (Angus et al. 2004; Teno et al. 2013; Prendergast and Luce 1997). Finally, due to the burdens of critical illness, many ICU patients are unable to make medical decisions (Nelson et al. 2006a; Prendergast and Luce 1997; Silveira et al. 2010). Consequently, family members, caregivers, or other surrogate decision-makers must often work with the ICU team to make complicated, nuanced decisions that ideally attempt to balance a patient's previously expressed wishes with an evolving and often repetitive and cumulative barrage of critical illness-related insults to patient mortality, morbidity, and short- and long-term quality of life (Schenker et al. 2013; Scheunemann et al. 2015; White et al. 2007, 2012; White and Curtis 2006; Zier et al. 2012; Nelson et al. 2017). As critical illness confers significant disease-related symptom burdens, complex values-based decision-making and surrogate decision-making, and nontrivial risk of death, palliative care provided by ICU clinicians and palliative care specialists can aid in reducing symptom burden, facilitating decision-making, and improving quality of life among ICU patients and their family members (Kelley and Morrison 2015; Aslakson et al. 2014a).

2 Recent History of Palliative Care and Ethical Controversies in the ICU

By the late 1960s, the advent of life-supporting technologies – particularly ventilators – and the recognition of a survival benefit conferred through close physiological monitoring and intense nursing for critically ill patients led to the inception of ICUs (Luce 2010). ICUs rapidly

became not only a physical care location but also a nexus for a progressively multidisciplinary team with expertise in selection and delivery of the complex treatments required to optimize patient survival despite severe, life-threatening illness. Indeed, the ICU with its combination of cutting-edge technologies and specialized care teams enabled patient survival through many previously fatal medical conditions. Yet, since inception, ICUs inherently illuminate the boundaries of modern medical care and consequently compel patients, family members, clinicians, and the medical community as a whole to confront and debate if and when aggressive medical treatments are personally, pragmatically, and ethically acceptable.

The advent of ICUs and ICU care has spurred multiple decisional, ethical, and legal conundrums, often involving palliative and end-of-life care-related issues and frequently surrounding the withdrawal or withholding of medical technologies (Luce 2010). By the mid-1960s, ethicists and ICU clinicians began to question the value of sustaining a patient's physiologic life when that patient had sustained a severe, irreversible neurologic insult; by 1968, the Harvard Commission published criteria for brain death and from those criteria evolved treatment pathways for when and how brain dead patients could or should be separated from physiologically supportive technologies, such as ventilators (School, A.H.C.o.t.H.M. 1968). By 1976, a prominent *New England Journal of Medicine* article acknowledged that ICUs are a frequent place of patient death and that ICU clinicians "promulgate and discuss publicly explicit policies about the deliberate withdrawal or non-application of life-prolonging measures" and that it is an "open secret" that "such measures are in fact regularly withheld or withdrawn" (Fried 1976; Optimum care for hopelessly ill patients, 1976). From the 1970s through the early 2000s, life-supporting technologies inherent to the ICU also instigated a series of legal cases in the United States to explore and define whether and when life-supportive technologies could be withdrawn or withheld; the legal cases involving the care of Karen Quinlan and Nancy Cruzan underlie modern ICU practices about if and when life-sustaining treatments can be withheld or withdrawn based on a patient's previously expressed wishes (In re Quinlan 1976; Cruzan v. Director, Missouri Department of Health 1990). Even in modern critical care practice, ethical, legal, and professional debates continue about what ICU-based technologies – such as extracorporeal membranous oxygenation (ECMO) – constitute the boundary of acceptable medical care and in what circumstances those technologies could or should be deployed (Fan et al. 2016).

There has been important regional variation in how decisions have been made regarding withholding and withdrawing life support. For example, a study across Europe conducted in the early 2000s found that much higher proportion of deaths were preceded by withdrawing life support in Northern Europe compared to Southern Europe, while withholding life support was more common in Southern Europe (Sprung et al. 2003). Withdrawal of life support is also less common in many countries in Asia, Africa, and South America. Some of these differences are undoubtedly driven by religious influences (Sprung et al. 2007). However, it is important to note that there is also considerable variability within countries or even among physicians in a single ICU suggesting that lack of consensus and limited education play an important role in this variability (Mark et al. 2015). A recent study suggests that differences are decreasing across Europe, which may be the result of increased consensus and education.

Given these tensions surrounding if and when medical technologies are medically feasible, ethically acceptable, and pragmatically likely to facilitate patient and family medical goals, it is not surprising that early palliative and end-of-life care-related interventions and trials have involved ICUs and ICU patients, family members, and clinicians (Aslakson et al. 2014b). By the late 1980s, a hospital in the state of Michigan in the United States began to evaluate whether a "comprehensive supportive team" for "hopelessly ill" ICU patients, primarily those with hypoxic encephalopathy and advanced dementia, could improve the quality of care and end-of-life care through focused provision of physical comfort,

psychosocial support, and family support (Field et al. 1989; Carlson et al. 1988). Through the early to mid-1990s, further ICU-based, palliative care-related interventions, often led by nurses, trialed whether enhanced communication strategies – informational booklets, daily phone calls to family members, and/or goal-related communication between ICU clinicians and family members – could improve family member-related outcomes such as satisfaction, anxiety, and/or informational awareness. By the late 1990s and early 2000s, the modern era and definitions of palliative care and palliative care practices commenced and consequently spurred a cohort of trials attempting to integrate palliative care principles, and sometimes palliative care specialists providers, into routine ICU care.

3 Defining Palliative Care in the ICU for the Coming Decade

Palliative care is a rapidly growing interprofessional specialty as well as an approach to care by all clinicians who care for patients with serious illness. The key domains of palliative care in the adult ICU, which have been defined by patients and families (Nelson et al. 2010a) as well as by expert consensus (National Consensus Project for Quality Palliative Care 2013; Clarke et al. 2003), include effective management of distress from physical, psychological, and spiritual symptoms; timely and sensitive communication about appropriate goals of intensive care in relation to the patient's condition, prognosis, and values; alignment of treatment with patient values; attention to families' needs and concerns; planning for care transitions; and support for clinicians. Palliative care is often optimally provided together with life-prolonging care, a coordinated approach that has been supported by major societies representing critical care professionals (Lanken et al. 2008; Selecky et al. 2005; Truog et al. 2008; Carlet et al. 2004; Cox et al. 2007, 2009; Choi et al. 2014; Puntillo et al. 2010) and by the World Health Organization (2018) and that is embraced by patients and families (Nelson et al. 2010a). Therefore, palliative care is not a mutually exclusive alternative, nor simply a sequel to failed attempts at life-prolonging care, but rather an integral component of comprehensive care for critically ill patients from the time of ICU admission.

4 Delivery Models of Palliative Care

Palliative care can be in many different clinical settings and can be provided by the following (Nelson et al. 2010b; Quill and Abernethy 2013; Committee on Approaching Death: Addressing Key End of Life Issues; Institute of Medicine 2015):

- Frontline, nonspecialist providers (termed primary or generalist palliative care)
- A specialist, interdisciplinary team with advanced training and skills in symptom management and communication about goals of care, prognosis, and treatment options (termed specialty or consultative palliative care)
- Some combination of both (termed mixed)

This conceptualization is particularly relevant for delivery of palliative care in the ICU (Fig. 1). The ICU team itself is inherently interdisciplinary

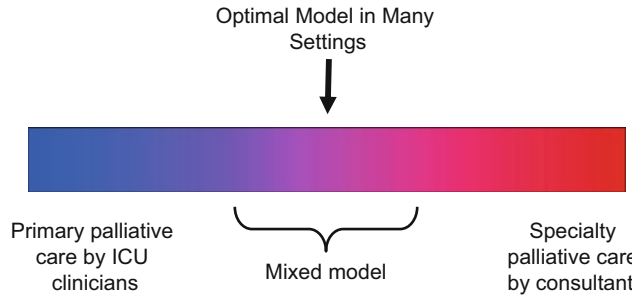

Fig. 1 Conceptualization of palliative care delivery model spectrum – optimal model is based on availability of specialty palliative care and on ICU primary palliative care expertise

and often includes doctors, nurses, social workers, chaplains, respiratory therapists, and pharmacists who are trained and specially skilled to address the unique needs of critically ill patients and their families (Nelson et al. 2010b). In mixed palliative care in the ICU, the primary palliative care provided by this ICU team is further supplemented by care provided by the specialty palliative care interdisciplinary team (Nelson et al. 2010b).

Core elements of palliative care, such as basic symptom management and discussion of goals of care in relation to the patient's prognosis and preferences, should be part of routine critical care practice and within the competency of all ICU clinicians. However, sometimes the optimal care of a critically ill patient may call for more advanced palliative care skills and specialist expert input. Goal setting with a family experiencing unusual distress or internal conflict, symptom management for patients with refractory symptomatology, supporting a bereaved family, or providing continuity of care after the patient is discharged from the ICU are examples of clinical challenges for which a critical care clinician may wish to obtain expert consultation from a palliative care specialist team (Quill and Abernethy 2013). In addition, sometimes a palliative care specialist can serve as a "third party" to help mediate conflict between the ICU team and the patient or family.

After more than a decade of rapid expansion, expert palliative care through a palliative care consultation is now available at the majority of US hospitals, although smaller and/or for-profit hospitals are less likely to have palliative care consult services. Availability of hospital-based palliative care consult services is much more variable in Europe, Asia, and South America although developing in many areas, and where they are developed, they often have less interaction with the ICU than in the United States. Specialty palliative care services have often developed from within oncology, geriatrics, or primary care and may consequently have less experience and integration in the ICU setting. However, as interest in improving palliative care in the ICU increases, this setting can offer an opportunity for palliative care specialists to increase their presence, both in supporting better primary palliative care through ICU clinician education and provision of supportive tools and also in providing specialty palliative care consultation for patients and family members with unmet palliative needs after primary palliative care.

Workforce shortages for palliative care specialists may limit availability of palliative care consultations, at least in the near term (Goldsmith et al. 2008). In addition, excessive reliance on specialty palliative care could fragment care, potentially complicate therapeutic relationships between patients and ICU care clinicians, as well as diminish impetus for ICU clinicians to cultivate and maintain primary palliative care skills (Accreditation Council for Graduate Medical Education 2018). Indeed, a key issue for palliative care in the ICU is to determine how best to utilize existing specialist palliative care resources as well as how to optimally integrate those resources into existing primary palliative care practices and pathways.

Previous palliative care trials in the ICU have frequently used triggers to identify which patients should receive specialist palliative care (Aslakson et al. 2014b). In past trials, triggers have included both diagnoses, such as hypoxic encephalopathy, multiple organ failure for multiple days, or advanced dementia, as well as non-specific assessments such as ICU clinician belief that a patient is "likely to die" and/or intra-ICU team conflicts regarding a patient's likely survival and/or quality of life following critical illness. Ultimately, the provision of primary versus specialist palliative care should be fluid over time, unique to each ICU, and based on multiple factors including unit culture toward palliative and end-of-life care, ICU clinician primary palliative care competence and capacity, the availability of palliative care specialist resources, ICU patient and family desire for specialist palliative care, and/or systematic triggers or goals championed by ICU and/or hospital clinicians and leadership.

When specialty palliative care clinicians are interested in increasing their impact in the ICU setting, either through supporting primary palliative care or providing specialty palliative care consultation, it is very important that the

palliative care clinicians become familiar with the functioning and culture of the ICU. In our experience, two key barriers to effective palliative care consultation in the ICU setting include ICU clinician suspicion that palliative care clinicians will advance an agenda of withholding or withdrawing life support and belief among some ICU clinicians that they already provide high-quality primary palliative care. Understanding such barriers is essential to overcoming them. For example, in the ICU where ICU clinicians are suspicious of the agenda of palliative care clinicians, reassuring ICU clinicians about the lack of such an agenda is essential. However, in the ICU where ICU clinicians believe they provide high-quality primary palliative care, the key to overcoming this barrier is to highlight areas of palliative care that the ICU clinicians are less focused on, such as anticipatory bereavement support and supporting palliative care needs after ICU discharge.

5 Palliative Care Needs Both Within and After the ICU

In this chapter, we focus on studies conducted in adult ICUs in North America and Europe, where existing data demonstrate important opportunities to improve all core components of palliative care in the ICU. For example, multiple studies confirm that symptom distress is prevalent at high levels of severity among critically ill patients (Puntillo et al. 2010, 2014; Puntillo 1990). Communication between clinicians and families is often delayed and fragmented (White et al. 2007; Azoulay et al. 2000; McDonagh et al. 2004). When families meet with ICU physicians, they frequently have insufficient time to share their perspectives on the patient's goals and values or express their own concerns (McDonagh et al. 2004). ICU physicians may miss opportunities for empathic response to emotions, leaving families too distressed to absorb or integrate information they need for surrogate decision-making (Curtis et al. 2005; Selph et al. 2008). Some patients spend their last days in the ICU because planning for care in a more suitable or preferred setting is inadequate. In addition, transitions from one setting to another (e.g., acute care, critical care, long-term care, and home care) are increasingly frequent but often without adequate support for patients and families (Teno et al. 2013). Among those who require prolonged mechanical ventilation, data show that during the year following ICU discharge, patients will make multiple transitions across a variety of facilities, spending an average of 74% of all days in a hospital or post-acute care facility or dependent on a high level of home healthcare (Unroe et al. 2010). Finally, the need to support ICU clinicians more effectively for the emotional strain of ICU practice is evident from the widespread problems of burnout, depression, moral distress, and conflict across disciplines on the critical care team (Azoulay et al. 2009; Studdert et al. 2003a, b; Breen et al. 2001).

The burden of critical illness for patients and family members continues after the ICU. Decreases in hospital mortality from critical illnesses, such as sepsis, acute respiratory distress syndrome (ARDS), and major cardiac or neurologic events, have not diminished the relevance of palliative care in the ICU but rather underscored the importance of anticipating and attending to the palliative care needs of those who survive intensive care as well as those who succumb. As ICU survivors increase in number and investigators examine the experience of these patients and their families more fully, the burdens of survivorship are coming into clearer view (Needham et al. 2012). A broad array of physical and psychological symptoms along with impairments of function and cognition continue to impair the quality of patients' lives (Cox et al. 2009; Choi et al. 2014; Herridge et al. 2003, 2011; Iwashyna et al. 2010; Davydow et al. 2008, 2009; Adhikari et al. 2011; Dowdy et al. 2006; Pandharipande et al. 2013; Boyle et al. 2004). During the 1st year after ICU discharge, ARDS survivors commonly report debilitating insomnia, fatigue, and pain along with emotional lability, depression, and anxiety (Cox et al. 2009). In addition to ongoing functional limitations and decrements in physical quality of life, these survivors have psychological sequelae for as long as 5 years (Herridge et al. 2011). A systematic review of depression in general ICU survivors found that the median point

prevalence of clinically significant depressive symptoms within 14 months of ICU discharge was 28%, and depression in the early post-ICU period predicted longer-term depressive symptoms (Davydow et al. 2009). ICU survivors also struggle with chronic pain that is associated with decrements in health-related quality of life (Boyle et al. 2004). New and clinically significant cognitive impairment follows critical illness for a broad range of survivors (Pandharipande et al. 2013). Some ICU patients surviving acute critical illness remain critically ill on a chronic basis, with protracted or permanent dependence on mechanical ventilation and other intensive care therapies (Nelson et al. 2010c). For this "chronically critically ill" patient group, symptom burden is heavy, functional and cognitive outcomes are very poor, and 1-year mortality is over 50%, exceeding that for many malignancies (Nelson et al. 2004, 2006a; Jubran et al. 2010). Families struggle with their own symptoms and with strains of caregiving (Cox et al. 2009; Needham et al. 2012; de Miranda et al. 2011; Swoboda and Lipsett 2002; Van Pelt et al. 2007; Choi et al. 2011; Pochard et al. 2005). Among family members of critically ill patients, anxiety and depression are common and may persist long after the ICU, along with post-traumatic stress disorder and complicated grief (Anderson et al. 2008; Siegel et al. 2008; Pochard et al. 2005). Thus, a distinctive "postintensive care syndrome" is now recognized not only in patients but also in families (Needham et al. 2012). Effective integration of palliative care during the treatment of acute and chronic critical illness may help patients and families prepare more fully for challenges to come in the days, months, and years after discharge from intensive care.

In addition, the use of intensive care for patients approaching the end of life continues. Approximately one in five deaths in the United States occurs during or shortly after intensive care, with more deaths occurring in the ICU than in any other setting in the hospital (Angus et al. 2004). In the United States, patients over age 65 with severe chronic illness are less likely to die in the hospital and more likely to receive hospice care than they were a decade ago, but ICU treatment during the last month of life has concurrently increased (Teno et al. 2013; Goodman et al. 2011). For patients over age 65 receiving ICU treatment, particularly among those who are mechanically ventilated, the risk of death within 3 years of discharge is nearly three times that of matched controls in the general population (Wunsch et al. 2010). These trends are likely to continue as aggressive medical and surgical treatments are offered to a growing population of older adults with multiple comorbid conditions. For now and the foreseeable future, palliative care will thus remain an essential element of critical care practice, both during and after ICU admission.

6 The Modern Era of Palliative Care in the ICU: Evaluating the Evidence Base

Data for this chapter were drawn from systematic and comprehensive narrative reviews as well as a recent research agenda on palliative care in the ICU (Aslakson et al. 2014a, b, 2017; Khandelwal et al. 2015; Scheunemann et al. 2011). Interventions can be grouped into broad domains based on the intervention target – ICU patient, family members, ICU clinician team, system, and/or multilevel (Table 1) – although some interventions are "bundled" with multiple targets. Interventions can also be organized based on content and goals. It is important for palliative care specialists interested in supporting patients and families in the ICU to understand this evidence base for both primary and specialty palliative care in the ICU.

Structured approaches to communication. Interventional research to date has focused mainly on testing proactive, structured approaches to clinician communication with families, implemented either by the interdisciplinary ICU team or by consultants specializing in palliative care or biomedical ethics (Aslakson et al. 2014b; Curtis et al. 2016; Andereck et al. 2014; Carson et al. 2016). This research has been summarized in several comprehensive reviews (Aslakson et al. 2014b; Khandelwal et al. 2015; Scheunemann et al. 2011). Most studies were conducted in a single center using a pre-post design. In those studies, the communication

Table 1 Examples of ICU-based palliative care interventions and representative studies

Primary target	Examples	Summary of findings	Sample of references
Patient	NONE		
Family	Intervention booklet for family; intensive nurse-, social worker-, or physician-led communication; standardized or structured family meetings; family support coordinator or navigator; family presence during ICU rounds	Mixed – no effect or change in family satisfaction or depression scores, reduced ICU length-of-stay, reduced nonconsensus between ICU clinicians and families; increased DNR and comfort care orders; increased order choosing "aggressive" interventions; improved frequency of communication with ICU providers; decreased ICU costs	Daly et al. 1994; Lilly et al. 2000; Lilly et al. 2003; Azoulay et al. 2002; Burns et al. 2003; Curtis et al. 2016
Clinician team	Education about ethics; education about communication skills; Palliative care team rounds with ICU team	Increased proportion of ICU patients receiving palliative care consultation; reduced ICU length-of-stay	Holloran et al. 1995; Villarreal et al. 2011
System	Palliative care or comfort care order set	No change; increased pastoral care involvement; reduced hospital length-of-stay	Treece et al. 2004; Hall et al. 2004
Multi-level	Palliative care consultation; ethics team consultation; transition of patient out from ICU team to "comprehensive support care team"; ICU clinician education about communication and more frequent and intensive communication with family; clinician education about palliative care communication with designation of local champions and standardized comfort care order sets; communication facilitator	No change; reduced ICU and hospital length-of-stay; reduced treatment intensity; reduced depression, anxiety, and PTSD prevalence among family members; improved nurse quality of death and dying scores; increased frequency of family conferences; increased frequency of prognosis being discussed in family conferences; increased DNR status designation	Carlson et al. 1988; Field et al. 1989; Schneiderman et al. 2000; Campbell and Guzman 2003; Schneiderman et al. 2003; Campbell and Guzman 2004; Lautrette et al. 2007; Norton et al. 2007; Curtis et al. 2008; Curtis et al. 2011

interventions were associated with significant reductions in resource utilization (e.g., shorter ICU length of stay) without increases in mortality, as well as with decreases in discord among decision-makers for ICU patients. However, in one of the largest pre-post studies conducted in five ICUs in two academic medical centers which tested the effect of regular, structured family meetings for patients in the ICU for 5 days or more, there was no significant reduction in ICU length of stay or other utilization outcomes (Daly et al. 2010). Importantly, a multicenter, randomized trial testing a protocol-based strategy for family meetings together with a brochure addressing bereavement found that family members had significant decreases in depression, anxiety, and post-traumatic stress disorder at 3 months after the death of a loved one in the ICU (Cox et al. 2012). Informational brochures have also been independently evaluated and shown in a multicenter, prospective randomized trial to improve family comprehension and satisfaction with information provided by ICU clinicians (Azoulay et al. 2002). These studies suggest that a structured approach to communication with patients and family members in the ICU is one of the most important targets for primary and specialty palliative care interventions.

Support for families and surrogate decision-making. A number of interventions have been

designed to support families of ICU patients through increased involvement of the families or more explicit support for surrogate decision-making (Aslakson et al. 2014b; Scheunemann et al. 2011; Curtis et al. 2016; Carson et al. 2016). Examples include an intervention promoting greater involvement of family members in patient care rounds, a critical care family assistance program, a social worker specifically counseling and supporting ICU families, an ICU family clinic, a communicator facilitator to support ICU families, and a palliative care specialty-trained communicator to convene prognosis-related meetings for family meetings of chronically critically ill patients. Although results vary across studies, these studies suggest such interventions are promising and require further evaluation.

Decision support tools. Several tools have been developed to support surrogate decision-making in the ICU. For example, a short video to support decision-making about resuscitation increased surrogates' knowledge of CPR and the proportion of patients with DNR directives at the time of ICU discharge or death (McCannon et al. 2012). An ICU admission assessment tool to help identify surrogate decision-makers and clarify decision-making standards was associated with shorter LOS and lower total hospital charges for patients requiring mechanical ventilation for 4 days or more (Hatler et al. 2012). A decision aid for surrogates of patients on prolonged mechanical ventilation was associated with less discordance between physicians and surrogates as well as with improved quality of communication as perceived by families and lower hospital costs (Cox et al. 2012). Decision support tools are likely an important area for future research.

ICU diaries, order sets, and "death rounds." Some additional tools have been evaluated to support patients, families, and clinicians. A randomized, controlled multicenter study in Europe evaluated an intervention in which healthcare staff and family contributed to a handwritten diary including photographs that recorded events and experiences on a daily basis during the patient's ICU stay and was provided to the patient 1 month after ICU discharge (Jones et al. 2010). As measured at 3 months after the ICU, this intervention significantly reduced the incidence of new-onset post-traumatic stress disorder among survivors of critical illness when compared to usual care. Another tool included the development of standardized order sets to support clinicians, prepare families, and ensure patient comfort during limitation of life support (Treece et al. 2004). Regular sessions for ICU clinician debriefing after patient deaths have been evaluated for supporting clinicians (Hough et al. 2005). Evidence supports use of these types of tools to support patients, family members, and ICU clinicians.

Multifaceted quality improvement. Multifaceted quality improvement approaches have also been used to improve palliative care in the ICU. The largest and most rigorous study to date was a multicenter, cluster randomized controlled trial that tested a multicomponent intervention comprising education of ICU clinicians, identification of local palliative care "champions" in the ICU, standardization of palliative care order sets, and feedback to ICU clinicians about palliative care-related outcomes. Although this intervention was initially successful at the investigators' own center (Curtis et al. 2008), the multicenter cluster randomized trial found no differences in outcomes including quality of dying as assessed by families or nurses, family satisfaction, ICU length of stay before death, or time from ICU admission to withdrawal of life-sustaining therapies (Curtis et al. 2011). These studies suggest that such interventions may be more successful when generated by and targeted for the needs of each institution.

Tailoring of palliative care interventions for sub-specialty ICUs. A few studies and expert opinion-informed guidelines have addressed further unique palliative care barriers and needs in sub-specialty types of ICUs. Existing data describe cultural tension surrounding palliative and end-of-life care among surgical providers and in surgical intensive care units (Buchman 2010; Buchman et al. 2002, 2003; Cassell et al. 2003a; Olson et al. 2013; Schwarze et al. 2010, 2013). Not surprisingly, studies demonstrate lower utilization of specialist palliative care providers among surgical patient populations (Rodriguez et al. 2015), and a systematic review of palliative care in surgical populations notes

relatively few trials and that most existing trials are small and of low to moderate quality (Lilley et al. 2016). Nonetheless, expert opinion supports thoughtful tailoring of palliative care interventions to surgical intensive care units (Lilley et al. 2017; Mosenthal et al. 2012). In addition, existing data regarding specialist palliative care interventions in surgical intensive care units is promising. A single center, before-after study tested a multifaceted interdisciplinary intervention to integrate palliative care into standard care in a trauma ICU. After the intervention, symptom management and goals of care were discussed more frequently on rounds, and while ICU mortality was unchanged, the intervention was associated with shorter length of stay in the ICU and hospital for patients who died. A similar intervention in the same institution for liver transplant surgical ICU patients was associated with earlier consensus around goals of care, earlier and more frequent use of DNR and withdrawal of life-sustaining treatment order, and shorter surgical ICU length of stay, with unchanged mortality. Further expert statements address tailoring of palliative care in both neurocritical care units and burn critical care units (Frontera et al. 2015; Ray et al. 2017).

7 Opportunities and Challenges for ICU Palliative Care Improvement

Ongoing challenges for optimal integration of palliative care in ICU settings have been identified and it is important that palliative care specialists interested in supporting critically ill patients, family members, and clinicians understand these challenges (Kirchhoff and Beckstrand 2000; Nelson 2006; Fassier et al. 2005). In a survey of a large, nationally representative sample of nurse and physician directors of US adult ICUs, respondents reported on perceived barriers at the level of the patient/family, clinician, and institution (Nelson 2006). Important barriers included unrealistic expectations on the part of patients, families, and clinicians about patient prognosis or effectiveness of ICU treatment, inability of patients to participate in treatment discussions, insufficient training of physicians in relevant communication skills, and competing demands for clinicians' time. Similar perspectives have been articulated by critical care professionals in Europe, along with distinct issues facing these clinicians including cultural variations across different European countries as well as a history of more decision-making by clinicians, and less involvement of families, as compared to North American settings (Fassier et al. 2005).

Special challenges for efforts to integrate palliative care in surgical ICU settings care have been noted. These include surgeons' strong sense of personal responsibility for patient outcomes (Buchman et al. 2002; Cassell et al. 2003b), disparate surgical provider opinions about the adequacy of communication regarding prognosis (Aslakson et al. 2010), and what has been described as a "covenantal" relationship in which the surgeon commits to protect the patient and the patient commits to endure the operation and sequelae (Buchman 2010; Cassell et al. 2003b). In a national survey of surgeons, more than 40% reported conflict with intensive care physicians and nurses with respect to appropriate goals of postoperative care (Olson et al. 2013). In addition, many responding surgeons described difficulties in managing clinical aspects of poor outcomes, communicating with the family and patient about such outcomes, and coping with their own discomfort about these outcomes (Olson et al. 2013).

8 Surrogate Decision-Making

The vast majority of ICU patients are incapacitated and dependent on family or other surrogates for medical decision-making (Nelson et al. 2006a; Prendergast and Luce 1997). Qualitative studies are increasingly illuminating the perspectives, concerns, and needs of these surrogates (Schenker et al. 2013; Boyd 2010; Evans et al. 2009; Apatira et al. 2008; Schenker et al. 2012). Most surrogates favor timely discussion of prognosis by ICU clinicians as necessary for decision-making as well as for emotional and practical preparation for the possibility that the patient could die (Apatira et al.

2008). Surrogates appear to recognize and accept that uncertainty about prognosis is unavoidable yet still wish to discuss expected outcomes (Herridge et al. 2003). At the same time, they experience intrapersonal tensions, acknowledging that information about an unfavorable prognosis may be painful as well as helpful (Schenker et al. 2012, 2013). Surrogate behaviors in response to these tensions include focusing on details rather than the larger picture, relying on personal instincts or beliefs, and, at times, rejecting prognostic information (Schenker et al. 2013; Nelson et al. 2017). Awareness of surrogates' perspectives may help ICU and palliative care clinicians more fully address their concerns and needs, thereby facilitating effective shared decision-making. Palliative care specialists can play an important role in helping ICU clinicians understand and address these concerns and needs.

ICU clinician approaches that maximize family-centered communication, provide support for families, and incorporate active listening are associated with increased family satisfaction, improved surrogate decision-making, and psychological well-being of surrogates (McDonagh et al. 2004; Curtis et al. 2005; West et al. 2005; Stapleton et al. 2006). Palliative care specialists can play a key role in supporting these approaches. Based on qualitative research and expert opinion, clinicians are encouraged to help surrogates "plan for the worst" while "hoping for the best" (Back et al. 2003). Other communication strategies suggested by existing evidence include explicit expression of empathy (Selph et al. 2008; Pollak et al. 2007); affirmative exploration of family concerns and comprehension with adequate time for listening by clinicians (White et al. 2007; Azoulay et al. 2000; McDonagh et al. 2004); assurance that the patient will not be abandoned or allowed to suffer should life-sustaining treatments be withdrawn (West et al. 2005; Stapleton et al. 2006); support for critical decisions made by family members, such as whether the patient would want to limit or continue life-sustaining therapies (Stapleton et al. 2006; Back et al. 2005); and, when possible, advance care planning discussions between surrogates and high-risk patients prior to the need for ICU care or the next episode of critical illness (Majesko et al. 2012).

9 Operationalizing Core Palliative Care Components as Measures of ICU Quality

As interest in value-based care rises, ICU and palliative care clinicians are increasingly working together to implement palliative care quality measures in the ICU. Key domains of ICU palliative care quality have been identified and made operational as specific measures that focus on care processes and outcomes (Mularski et al. 2006; Aslakson and Bridges 2013). Focusing primarily on processes, the "Care and Communication Bundle" was developed and tested as part of a national performance improvement initiative by the Voluntary Hospital Association (VHA), Inc. (Nelson et al. 2006b). The measures in this bundle are triggered by time periods in the ICU, with emphasis on proactive, early performance of key processes (e.g., identify medical decision-maker and resuscitation status before Day 2 in the ICU, offer social work and spiritual care support before Day 4, and conduct an interdisciplinary family meeting no later than Day 5). Specifications are precise (e.g., the family meeting measure defines "interdisciplinary" as including at least the attending physician; a member of another discipline such as a nurse, social worker, or chaplain; and the patient and/or his or her family, as documented in the medical record, and must include discussion of prognosis, goals of care, and the patient's and family's needs and preferences) (Nelson et al. 2006b). Similar Day 1 and Day 3 communication measures were tested in a statewide ICU collaborative project in Rhode Island (Black et al. 2013). Significant increases were seen in compliance with these measures, while improvements in compliance varied across ICU type with less improvement in open, nonteaching, and mixed medical-surgical ICUs. Most patient-specific outcome measures were unchanged, although there was an increase in patients discharged from ICU to inpatient hospice. Additional studies evaluating performance on ICU palliative care quality

measures show wide variation both within and across hospitals and even within individual intensive care units, as well as low performance levels overall on most items and little improvement over recent years (Penrod et al. 2011, 2012; De Cato et al. 2013).

The quality of ICU palliative care should also be evaluated by structure and outcome measures in addition to process measures (Curtis et al. 2006; Pronovost et al. 2001). The relationship of ICU palliative care process measures to desired patient and family outcomes requires further investigation.

10 Resources Available to Support Integrating Palliative Care and Critical Care

Training opportunities for ICU clinicians. Several interventions have focused on training ICU clinicians to deliver palliative care more effectively. Some approaches include communication skills training (Lilly et al. 2000, 2003; Lautrette et al. 2007; Norton et al. 2007) and education on ethics and conflict resolution (Schneiderman et al. 2003; Browning et al. 2007). These training programs are often conducted or supported by palliative care specialists. For intensivists and hospitalists in the United States, the Harvard Medical School Center for Palliative Care offers an annual two-and-half-day course that provides clinicians with information and skills needed to offer high-quality palliative care to critically ill patients and their families. "Critical Care Communication" (C3), another intensive course focusing specifically on communication skills, was offered to physicians training in critical care at the University of Pittsburgh. In workshops for pediatric critical care providers, the "Program to Enhance Relational and Communication Skills" used "parent-actors" to simulate pediatric, values-based, and/or end-of-life conversations (Browning et al. 2007; Meyer et al. 2009). The VitalTalk program offers specific communication training on palliative care and communication skills and also offers a smartphone-based supplemental application. A 1-day workshop was developed specifically to train bedside critical care nurses in skills they need for active and effective participation along with physicians in interdisciplinary meetings with ICU families (Krimshtein et al. 2011). Of nurses receiving this training and surveyed before and after it ($n = 74$), the average proportion self-rating skills as "very good/excellent" rose significantly, and almost all nurses reported that, after training, they had an increased awareness of special contributions they could make and felt more able to initiate interdisciplinary family meetings. The End-of-Life Nursing Education Consortium (ELNEC), an international education initiative to improve palliative care, has developed a critical care-specific course for nurses. A before-after study in three medical and surgical ICUs in a single community hospital tested a 90-min program of interdisciplinary team training to enhance communication with ICU families (Curtis et al. 2013). Along with clinicians' confidence in communication with families, family satisfaction with ICU communication improved significantly. Yet, this randomized trial of a communication skills building workshop for residents and nurse practitioners did not show an improvement in the patient- and family-level outcomes. These studies identify questions and challenges with showing improvements in patient and family outcomes with educational interventions. One-day communication training programs for ICU clinicians have also been offered at some European intensive care congresses over the past decade including the European Society of Intensive Care Medicine, although such training programs seem less common in Europe and other parts of the world than the United States.

Web-based resources. Extensive resources for use in ICU palliative care improvement efforts are readily accessible, and palliative care specialists could consider offering these resources to their ICU colleagues. Many of these are available on the Website of The IPAL-ICU Project, which is sponsored by the National Institutes of Health and the Center to Advance Palliative Care (CAPC). This Website is password-protected and requires an institutional or individual membership to CAPC to be able to access the materials. Yet, once accessed, those materials are extensive and

include a library of relevant references, a variety of practical improvement tools (e.g., family meeting planner and documentation template, data collection instrument for quality monitoring, pocket cards for guidance on symptom management and communication), materials for patients and families (e.g., family meeting brochure), and links to curricula for professional education. In addition, the IPAL-ICU Advisory Board has published an expanding series of articles addressing key issues for efforts to improve palliative care in different types of critical care settings (Nelson et al. 2010b, 2011, 2013, 2015; Puntillo et al. 2014; Mosenthal et al. 2012; Ray et al. 2017; Lustbader et al. 2012).

Professional practice recommendations. Multiple societies representing critical care professionals have published practice recommendations and/or guidelines related to important aspects of ICU palliative care, and these are evidence-based and extensively referenced (Lanken et al. 2008; Selecky et al. 2005; Truog et al. 2008; Carlet et al. 2004; Davidson et al. 2017; Mularski et al. 2013; Mahler et al. 2010; Barr et al. 2013; Yancy et al. 2017; Holloway et al. 2014). Palliative care specialists may be able to use these practice recommendations and guidelines to support improved primary and specialty palliative care in the ICU. For example, the American College of Critical Care Medicine has published consensus recommendations for end-of-life care in the intensive care unit (Truog et al. 2008), as well as clinical practice guidelines for support of the family in the patient-centered intensive care unit (Davidson et al. 2017) and for management of pain, agitation, and delirium (Barr et al. 2013). Similarly, the American Thoracic Society (ATS) published a clinical policy statement on palliative care for patients with respiratory diseases and critical illnesses (Lanken et al. 2008). The American College of Chest Physicians (ACCP) published a position statement on palliative and end-of-life care for patients with cardiopulmonary diseases (Griffin et al. 2007). In addition, both ATS and ACCP have specifically addressed the management of dyspnea (Mularski et al. 2013; Mahler et al. 2010). The American Heart Association (AHA) and American College of Cardiology Foundation included palliative care in their management plan for patients with severe heart failure (Yancy et al. 2017), and the AHA and American Stroke Association have published a statement advocating for palliative care for stroke patients (Holloway et al. 2014). Finally, among five recommendations published as part of the 2014 "Choosing Wisely" campaign, the Critical Care Societies Collaborative recommends that clinicians not "continue life support for patients at high risk for death or severely impaired functional recovery without offering patients and their families the alternative of care focused entirely on comfort" (Halpern et al. 2014). These and other resources can help ICU and palliative care clinicians to strengthen their knowledge and skills and support integration of primary and specialty palliative care as a routine part of critical care practice.

Synergy with family-centered care interventions. Over the past decade, efforts to improve family-centered care in the ICU have burgeoned concurrent to those to improve delivery of palliative care in the ICU (Davidson et al. 2017). Indeed, as psychosocial support of family members is a key component of palliative care, so the two are different facets of the same entity, and interventions to improve family-centered ICU care cannot help but to advance palliative care – often primarily palliative care – content and to improve integration of palliative care practices and providers into ICU care practices.

11 Conclusion and Summary

Palliative care evaluates and treats patient symptoms, provides psychosocial support for patients and families, and identifies and integrates a patient's personal goals into medical treatment. Over the last two decades, intervention studies have explored how to better provide palliative care together with critical care, including incorporating palliative care specialists and supporting critical care clinicians in the delivery of primary palliative care. Moreover, efforts to improve family-centered care in the ICU are synergistic with those to improve palliative care. Evidence supports the benefits of palliative care in the critical

care setting, although the most effective and efficient ways to achieve these benefits are not yet clear. Critical care professional society statements call for delivery of primary palliative care by ICU clinicians as well as provision of specialist palliative care, when needed. Existing educational tools and resources enable ICU clinicians to improve their palliative care knowledge and skills and to help palliative care clinicians identify opportunities to support critically ill patients, their families, and their ICU clinicians. Future research is needed to better determine how best to provide palliative care to critically ill patients and their families both in the ICU and beyond.

Abstract

To ensure the provision of end-of-life care is relevant to individual communities, it must not only reflect the needs of the dying person and their family but also the diverse geography and cultures in which they live. Studies consistently report that rural residents perceive themselves as different to their urban counterparts and clearly hold distinct views on what it means to die well. Currently there is no international consensus on the definition of rurality and remoteness. Rural settings are not homogeneous, and there is considerable individual, cultural, and ethnic diversity both within and between rural locations. Rural communities are close-knit, and known for their social solidarity, community commitment, and loose support networks. While there are many benefits of rural residency, significant challenges exist in the provision of quality end-of-life care. The needs of rural residents are shaped by decreased access and availability of services. While this potentially has a negative influence on outcomes, it is offset by local support networks. Rural palliative care is mostly primary care, with limited access to specialist multidisciplinary palliative care services. Home is the initial preferred place of death for most rural residents; however, when home is not possible, rural hospitals and residential aged care are considered appropriate alternatives, providing they are within ones' community. The universal rural theme is that if rural residents are unable to die at home, then it is essential that their place of death is within their local community.

1 Introduction

To ensure the provision of end-of-life care is relevant to individual communities, it must not only reflect the needs of the dying person and their family but also the diverse geography and cultures in which they live (Bakitas et al. 2015; Cottrell and Duggleby 2016). In general, populations are becoming more urbanized, with the estimated proportion of rural dwellers falling from 70.5% in 1950 to 46% in 2015 (WHO 2014). The highest proportion of rural populations remains in the developing regions, such as sub-Saharan Africa. For example, 84% of Uganda's population is considered rural, compared to 30% in Canada (World Bank 2016). While the size of many individual rural populations is decreasing, they are also aging, often at a faster rate than urban populations. In developed nations, the phenomenon of "sea-change" and "tree-change," adds to the graying of some rural populations, as older urban dwellers leave the cities in search of the more relaxed rural lifestyle (Castleden et al. 2010). Between 2000 and 2030, the growth rate in Australia's population aged 65-years or older is expected to rise by 139%, with a 180% increase anticipated in rural areas (Australian Government Department of Health 2008).

Studies consistently report that rural residents perceive themselves as different to their urban counterparts and clearly hold distinct views on what it means to die well (Wilson et al. 2009a, b; Robinson et al. 2010). In relation to palliative and end-of-life care, rural areas typically have fewer health and social services, as compared to urban areas resulting in substantial differences in the provision of care. As a consequence, some people must move away from their rural community to receive the care required.

Most rural end-of-life research has been focused on healthcare services (intervention studies, needs assessment, program planning and evaluation, education and finances) and professional attitudes, education, and practices (Bakitas et al. 2015). There is also a focus on determining the urban/rural differences, rather than finding ways to explore the unique factors associated with rural

health and in particular rural palliative care (Boarders 2017). Currently, there is a paucity of studies documenting rural end-of-life care experiences and perspectives from the recipients of such care – the patients and their family caregivers (Robinson et al. 2009).

The objective of this chapter is to describe palliative care in rural settings. This is a challenge due to the significant heterogeneity between rural settings. While the rural literature contains a number of excellent rural studies undertaken in sub-Saharan Africa and Asia, overall it is biased toward developed nations, especially Canada, the United Kingdom, Australia, and the United States of America. While attempting to remain inclusive, this chapter is written from the perspective of one Australian rural palliative medicine specialist.

This chapter begins by defining "rural" and exploring the challenges of developing a universal consensus on definition. This is followed by a description of rural residents and the nature of palliative healthcare services in rural settings. The challenges and benefits of receiving and delivering palliative care in rural locations are explored. Place of death in rural settings is described. The chapter concludes with a discussion on the concept of the "good" rural death.

2 The Challenges of Defining "Rural"

Currently, there is no international consensus on rural definition or universal rurality or remoteness index. In the absence of homogeneity within health services and cultural context, it is difficult to compare rural areas, not only between countries but also within countries. "Rural" is a multifaceted concept and can be interpreted in a number of ways. Rural settings encompass large towns with services, smaller towns with limited services, villages, hamlets, and farms of varying degrees of isolation, with some locations metro-adjacent or easily accessible to services, and others isolated by geography or weather; some locations are inland and others coastal. Policy-makers and service providers base definitions on population size, population density or demographics, or distance from urban centers and services. For example, since the early 1990s, four different geographic classifications have been developed in Australia (AIHW 2004): Rural, Remote and Metropolitan Areas classification [RRMA, 1994], in which the index of remoteness is based on the straight line distance to service centers and the distance from other people based on population density; Accessibility/Remoteness Index of Australia [ARIA, 1997], based on the road distance from the closest service center; Australian Standard Geographical Classification [ASGC, 2001], which uses the average distance from each populated locality to the closest service center (population 1000–4999 persons), as well as the larger urban service centers; and Modified Monash Model [MMM, 2015], based on ASGS with the additional subdivision of regional Australia into four categories based on the population size. The classification applied has significant implications on funding, service provision, and financial incentives to attract general practitioners to areas of need.

The definition of rural is complex and cannot be limited to geography based on distances from urban service centers or population densities. The provision of palliative care in rural settings is not only influenced by geographical borders and boundaries. In a rural study conducted by Giesbrecht et al. (2016), formal and informal caregivers in rural Canada identified five forms of borders and boundaries that impact on the delivery, and receiving, of palliative care: political (national/federal and state/provincial borders), jurisdictional (formal borders within states/provinces created by different health authorities), geographical (especially in terms of distances and isolation), professional (boundaries between organizations and specialities that determined specific roles of service providers), and cultural (differences in cultural norms, practices, behaviors, and communications, especially those that distinguished differences between rural and urban dwellers and between Aboriginal and non-Aboriginal peoples).

"Rurality" is a term increasingly used to differentiate rural people as a distinct cultural group consisting of "small human communities,

whose values of mutual aid and shared history still focus on pride and a sense of belonging to a community, a territory, or family. Rural areas are characterised by dynamic and social, cultural and economic practices centred on proximity, conviviality, mutual aid and cooperation" (Ministere des affaires municipales et des regions du Quebec 2007). While urban dwellers may not acknowledge or appreciate rurality as a separate entity, rural people openly state "that there are important differences between dying in a rural community and dying in a large city" (Wilson et al. 2009b, p. 316).

3 The Characteristics of Rural Residents

Despite significant cultural and ethnic diversity between rural communities, rural people are united by the fact they live in rural areas and believe they have some unique perspectives on, and concerns about, dying well and end-of-life care. Rural and urban residents share the desire for autonomy, a pain-free death, and quality end-of-life care; rural residents frequently have an openness and awareness of death and dying (Wilson et al. 2009a) and have been described as "more accepting of death and less likely to intervene to delay death" (Kirby et al. 2016, p. 1).

Some rural residents perceive differences between those living on farms and those residing in rural towns. Those residents living on farms have been described as more independent, resilient, and adept at problem-solving than rural town dwellers. This resilience (flexibility and the capacity to recover quickly from adversity) and self-reliance (the ability to problem solve rather than relying on others) is not necessarily a personality trait but, more out of necessity, born out of personal experiences and expectations with farmers adept to multitasking and finding novel ways to solve multiple problems.

Rural people are also identified by their deep concern for their community and its members (Kirby et al. 2016). Strong relationships and informal community services are important factors that facilitate end-of-life care within rural communities. The high level of community support fosters a strong sense of belonging and attachment to the community (physical, social, and autobiographical). While "country" has special cultural significance for Aboriginal and Indigenous peoples, many rural dwellers prefer to receive care and die in their community as "being at home is like a brick being in the right place: this is my land and these are my people" (Devik et al. 2015, p. 7). While the rural environment can quickly become unsafe and one of isolation, it has the capacity to be a source of great comfort, security, reassurance, and identity, while for many rural people, the urban environment is viewed negatively (e.g., noisy, unfamiliar, and impersonal).

4 Nature of Rural Palliative Healthcare Services

Quality palliative care is considered the right of every dying person, regardless of where they live (WHO 2015). In 2011, 44.6% of all deaths in the United States of America occurred under hospice (palliative) care (NHPCO 2012). In sub-Saharan Africa, the estimated proportion is less than 5% (Grant et al. 2011). The proportion of rural residents receiving specialist palliative care is significantly lower than for urban residents. The palliative care needs of rural and remote residents "are related to context [. . ..] and are shaped by reduced access and availability of services" (Kirby et al. 2016, p. 1). Access to palliative care services differs widely across rural locations – both within countries and between countries, with the commonality being "gaps" in service provision.

As in any location, primary healthcare providers are pivotal to the provision of rural palliative care. While many of the needs of patients and family caregivers are universal, priorities differ between rural and urban dwellers and between developed and developing nations. The nature of service gaps is dependent on context, with many rural areas, especially in developing countries, lacking the basics of healthcare such as trained primary care health workers, basic medicines (such as morphine), and equipment. In Australia,

and other developed countries, increased costs associated with healthcare delivery, decreasing numbers of rural healthcare providers, and centralization of services have all impacted negatively on access to rural and remote healthcare services.

In a number of developed countries, such as Australia, Britain, and Canada, extensive work is being undertaken to address these problems and to ensure palliative care services are provided locally (AIHW 2014).

5 Challenges of Rural Residency

Much of the current rural literature emphasizes the unique challenges associated with rural residency. The obvious challenges relate to isolation and distance from specialist services in major urban centers; however, rural residents face other barriers to receiving quality end-of-life care, as outlined below.

5.1 Distance and Travel

For many rural residents, distance is the greatest negative influence on rural end-of-life care. Many rural patients travel for investigations, diagnosis, and treatment. Commuting can be stressful, exhausting, inconvenient, expensive (Lockie et al. 2010; Pesut et al. 2010; Duggleby et al. 2011; Grant et al. 2011; Devik et al. 2013), and even dangerous or impossible, depending on the weather (Castleden et al. 2010). Despite this, some regard travel for treatment a price for living in a beautiful place, and a compromise they have to make for living at home, that is, "to live in a place that contributes to their overall health" (Wiik 2011, p. 12). While the time taken to reach certain services may be comparable to some urban areas, the actual distances can be considerably more and often at higher speeds. One patient receiving palliative care in rural Australia compared the time taken to travel from her farm to the local hospital, with that of her children who live in the city: "Here you're 20-kilometres but it translates to 15-minutes. In [the city], five-kilometres translates into 15-minutes" (Rainsford 2017, p. 192). While traveling can be acceptable in the early stages of disease, with some residents treating it as "a day out" (Devik et al. 2015), distance and travel become more problematic as patients become more ill and fatigued, when symptoms become more troublesome and when patients enter the terminal phase. Traveling becomes not just an inconvenience but can be associated with physical distress.

Once patients can no longer travel, they often report being disconnected from their specialists (medical, nursing, and allied health), who have been a source of valued support. A time of grieving sometimes follows, for both the patient and their family.

The issues of distance and travel are not just about seeking healthcare support. Distance and travel also impact on family caregivers, regardless of whether they live locally or away. Family caregivers are faced with a number of scenarios while caring for their family member: the out-of-town family having to travel to visit their family member, often leaving their own children and responsibilities for extended periods of time, the local family traveling to the distant tertiary hospital or out-of-region hospice to visit their family member, the anguish of family members trying to decide whether to seek medical help locally or in more distant specialist facilities, and the costs of travel and accommodation when there is no family home to stay in when visiting or supporting family members in hospital or residential aged care. Traveling has been reported to impact negatively on the health of some family caregivers (Lockie et al. 2010).

Most families hope to be present at the time their family member dies. The fear of not being present can be significant and is compounded by the sense of geographical separation (Castleden et al. 2010). When family caregivers have to travel to out-of-region hospitals or hospices to be with their family member, the travel distances become more problematic. While rural family caregivers have a strong desire to be present at the time of death, they have to balance fulfilling their responsibilities at home or the farm with maintaining a bedside vigil away from home.

Traveling out of region, to access services not available locally, increases the risk of fragmented care (Duggleby et al. 2011). Without impeccable clinical handover and coordination of care, the quality of care can be compromised. The greatest support need of many rural patients with a terminal illness, and their family caregivers, especially in developed countries, is informational. Effective communication between healthcare professionals and patients/family caregivers reduces pain and distress, empowers carers to fulfill their responsibilities, facilitates smooth transitions of care, and allows patients and families to prepare for death (Rainsford et al. 2017). When surveyed, most patients and family caregivers report to be satisfied with the standard of communication by rural healthcare professionals (Devik et al. 2013); however, a number of communication difficulties are commonly reported. These include receiving conflicting or untimely information and uncertainty in identifying the lead physician.

However, opinions regarding the effect of distance on the quality of care are divided, with some rural residents seeing it as a major barrier to receiving home-based palliative care, and therefore achieving a home death (Dembinsky 2014), and others not viewing distance and rural residency a disadvantage (Devik et al. 2015). With advanced illness, the patients and family caregivers' sense of solitude (previously seen as an advantage of rural life) can become one of isolation (Duggleby et al. 2011). Geographic isolation can also contribute to the greater unmet emotional needs of rural caregivers, as they often lack the support of others going through similar experiences (Brazil et al. 2014).

5.2 Accessibility to In-Home Services

The availability of rural healthcare professionals to support patients dying at home becomes problematic the greater the travel distance and the more protracted the terminal phase. The most isolated rural locations are the least likely to have access to in-home care and support. Geographical distance limits accessibility to home-based services, especially for patients living outside the home visit boundary. Home visits become less frequent, especially in bad weather, and are often not available at short notice or after hours. Daily home visits to adjust medications, often required during the last days of life, are less likely to be available the further one lives from the service town. Some rural GPs provide on-call medical cover for rural hospitals. As rural generalists, this on-call cover can be in the emergency department, general wards, maternity, anesthetics, and/or operating theatres. In small towns, the on-call doctor is often the only doctor in town after hours and on weekends. While some doctors may be able to leave the hospital briefly to home visit a patient in close proximity to the hospital, they cannot leave town to visit patients living in surrounding villages or farms. In other rural locations, the service provided by GPs is on a part-time basis, with no daily access to medical support.

Mobile phones, computers, and internet access can help reduce the sense of rural isolation by maintaining contact with distant family and improving access to healthcare professionals; however, these technologies are often unreliable or not available in more remote areas (Lockie et al. 2010; Pesut et al. 2010). For some patients, a phone call is not sufficient and does not replace the physical presence of the nurse or doctor (Pesut et al. 2010; Hansen et al. 2012). In an Australian study, one husband living on a farm, felt "unsupported and alone" when the face-to-face presence of "qualified medical advice" was not available the night before his wife died (Rainsford 2017). Robinson et al. (2010) reported that some rural residents familiar with telehealth were not impressed with the service and found it unreliable and expensive. It cannot be presumed that all rural residents have sufficient literacy to use the technology and that phone and internet connections are available in all houses or in all communities.

Consistent with their urban counterparts, rural family caregivers often feel responsible for ensuring the dignity and comfort of their loved ones during their final days and experience distress, guilt, and anger when circumstances prevent them fulfilling this role (Revier et al. 2012).

While rural family caregivers take on the responsibility of providing direct care, many also take on the role of managing and coordinating care while being an advocate for their family member (Pesut et al. 2014); however, "few [are] physically, emotionally, or educationally prepared for the tasks and responsibilities of caregiving" (Revier et al. 2012, p. 5), especially as the illness progresses.

5.3 Lack of Local Specialist Services and Expertise

While travel distances restrict patients from visiting their specialists, the lack of local specialized personnel and facilities offering life-prolonging interventions is often considered a disadvantage of rural residency. However, as patients become more unwell, they and their family caregivers often acknowledge that the need for further complex interventions is no longer necessary, and in fact, helps ensure a better quality of dying. During a bereavement interview, one rural family caregiver commented that "not [being] hooked up to machines" facilitated a more dignified death for his father who achieved a home death on their farm (Rainsford 2017, p. 203).

Unlike metropolitan and some regional areas, most rural and remote locations do not have specialist palliative care services and are reliant on primary healthcare providers. In some locations, GPs and community nurses may be supported by a specialist palliative care nurse. The lack of a specialist service could be viewed as a limitation of the quality of palliative care for rural residents. While GPs often struggle with managing complex issues, such as complex pain and high dose opiates, they do deliver sound and effective palliative care, and rural patients and their family caregivers appreciate the care provided by their primary care professionals (Mitchell 2002). Rural primary care physicians are frequently highly praised for their honesty and presence at the time of death.

The benefits of primary care-led palliative care must not be overlooked. These benefits include increased continuity of care, which often continues when patients are transferred from home to hospital or residential aged care, being cared for by health professionals who have a long standing professional relationship and knowledge of the individual and their family (sometimes intergenerational), and access to continuing care and bereavement support for family members. As a member of the rural community, rural health professionals are also familiar with the broader issues and the unique rural culture within rural communities.

Compared to their urban colleagues, rural primary healthcare professions face additional challenges in providing quality evidenced based end-of-life care. Rural healthcare professionals often find themselves in the dual role of healthcare provider and community member. As members of the community they are not anonymous and are often faced with planning and providing end-of-life care for close friends, neighbors, and colleagues (Beckstrand et al. 2012). Added to this is the difficulty of taking study leave to attend educational programs to up-date knowledge and maintain competencies and skills. Travel distances are compounded by the difficulty of recruiting locums to fill in during periods of absence. Travel distances also limit opportunities for team meetings, which can compound the emotional and physical isolation of independent healthcare professionals. Many rural locations have a single "unofficial" palliative care champion, and in their absence the whole system may stagnate or even disintegrate.

Rural patients are more likely than urban patients to visit their primary care physician (or GP) and the hospital emergency room and less likely to be admitted to an inpatient hospice or make use of respite services (Brazil et al. 2013). For rural patients and their family caregivers, being cared for in their community and by people they know is often more important that receiving specialist care (Veillette et al. 2010).

5.4 Lack of Allied Health Support

A multidisciplinary team is central to the provision of quality palliative care. While medical, nursing, and informal family care are the backbone of rural palliative care, limitations in

accessing allied health support are often cited as a disadvantage of rural residency. In some circumstances, the lack of services and choice of commodities is just an inconvenience, for others the limitations, for example, home nursing, reduce the chance of patients dying at home.

Access to physiotherapy, occupational therapy, social work, counselors, and pastoral care varies depending on location and population. In some rural locations, when these services are available, they are often restricted to inpatient settings in the local rural hospital or are limited by the cost of private fees. Ongoing bereavement counseling is limited in most rural and remote communities. Community pharmacists are valued members of the multidisciplinary team; however, they are not present in all rural locations, and when available, after-hour services are either limited or nonexistent. Specific medications for symptom management are frequently not available at short notice.

6 Benefits of Rural Residency

Despite the challenges faced by rural communities, quality palliative care can be, and is, provided locally. In many ways, the benefits of rural living outweigh the disadvantages. The great sense of community is one benefit of rural living and a major contributor to quality end-of-life care. Another positive of rural living, voiced by many rural residents, is the beauty and tranquility of the rural lifestyle. Despite limited health services, many believe rural living has positive health benefits, and many could not contemplate living in a more urbanized location. Rural residents often speak of feeling "safe" in their isolation; however, when they, and especially those on isolated farms, are diagnosed with a terminal illness, due to the limited availability of medical, nursing and community support, the isolation can contribute to home becoming an unsafe place (Rainsford 2017).

6.1 Personalized Care

Features of care that facilitate quality rural end-of-life care include personalized care (Hansen et al. 2012), "knowing," and "being known" by the healthcare workforce (Pesut et al. 2011), and a willingness of healthcare workers to go beyond their professional duty. The concept of "being known" and "knowing others" is a unique feature of rural communities and extends into rural hospitals and residential aged care. Unlike many large urban institutions, there is often a small turnover of rural staff, within rural institutions, that facilitates personalized care. "Being known" promotes a sense of acceptance, where patients are known for who they are rather than being known for their illness. The workforce within rural community health, hospital, and residential aged care is usually members of the community and known to the patients and their families. This familiarity can assist patients and their families to have confidence in the care provided and can often ease the distress of transferring from home to hospital or residential aged care, for end-of-life care.

However, loss of privacy and anonymity and an expectation that friends will always be available are perceived as barriers (Pesut et al. 2011). Often the quality of care provided is dependent on the personality of the healthcare provider, with difficulties arising if personality conflicts arise, as often no alternative provider is available (Devik et al. 2013). Loss of anonymity can also be problematic if patients are self-conscious of their deteriorating state. Issues of confidentiality can also arise when family caregivers are forced into the dual relationship of family protector and community member. This can result in a spirit of independence as patients and their family caregivers may restrict both formal and informal support in an attempt to keep their personal circumstances private.

6.2 Informal Community Support

The informal support provided by family, friends, neighbors, and the community is significant, with some considering that family is the "most important" factor (Devik et al. 2013, 2015) and essential for culturally congruent care (Mixer et al. 2014). In many rural areas, the profile of informal rural caregivers reflects the social change in

family structure. As previously noted, many rural populations are graying and decreasing in size due to internal migration, as younger family members move to more urbanized areas in search of education and employment. Compared to urban areas, rural caregivers are now more likely to be younger and a non-first-degree relative (Burns et al. 2015).

Rural communities are often described as "very close knit with incredible volunteer bases, and very generous people… who are genuinely concerned about the community" (Castleden et al. 2010, p. 287). Informal community support is highly valued by rural residents and is perceived to be unique to rural communities and a significant advantage of rural residency. It is reported to have a positive influence on rural end-of-life care as it contributes to a sense of solidarity, as people take care of each other (Devik et al. 2015). Community support cannot be taken for granted and is highly reciprocal, with those who have contributed most to their rural community often receiving the highest amount of support from that community (Pesut et al. 2011).

Informal support is mostly direct and practical, such as food, transport, sitting with a patient, and domestic help; however, some support is indirect, with many community members unaware of the significance of a friendly smile or "hello."

There is an assumption that, due to reduced access and availability of services and support, rural caregivers would have higher levels of needs and greater unmet needs than their urban counterparts. However, rural communities are often resourceful when no specialist services are available. Local support networks are created in response to the unspoken responsibility and commitment to care for community members when one identifies as a member of the community. Compared to urban caregivers, rural caregivers perceive the same low level of carer burden and good level of support (Kirby et al. 2016). Rural caregivers are more positive about the caregiving experience than their urban counterparts, with most reporting the experience to be as expected or better than expected. Rural caregivers are also more likely to perceive their deceased family member to have been comfortable during the last 2 weeks of life (Burns et al. 2015). Despite the great sense of community support, the greatest unmet needs identified by rural family caregivers, in both developed and developing countries, remain the tangible or practical needs (Brazil et al. 2013, 2014; Grant et al. 2011).

For some patients receiving treatment in small rural health facilities, a special "subcommunity" can develop, where patients and their family caregivers find mutual support in other patients. For other rural patients and family caregivers, despite the strong sense of community, as disease progresses and patients lose mobility and independence, a sense of isolation can develop as often there is no one in the community who has experienced the same situation, "I am part of my community but I feel alone. Family and friends come to visit me, but I feel isolated as they are unable to understand what is happening to me and my wife" (Duggleby et al. 2011, p. 2).

Despite the perceived willingness to volunteer, it has been suggested that rural community members may volunteer out of obligation, rather than a true desire to be involved. Likewise, formal care providers may also feel pressured to provide services above and beyond that expected of their urban counterparts, because there is often no alternative (Castleden et al. 2010).

6.3 Formal Support

Depending on the locality, formal support can be readily available, limited, or nonexistent. Most rural patients, especially in developed countries, have access to primary palliative care through their general practitioners and community nurses. With the exception of those living in regional towns, most, if not all, rural patients are required to travel to receive specialist care. In contrast to the majority of urban medical practices, most rural GPs and community nurses live in the community where they work, with friendships commonly developing between healthcare professionals and their patients. Healthcare providers' obligations often extend far beyond the professional role with some providers going to extraordinary lengths to be available, and take great "pride in being able to make it work – through responsive,

creative, highly individualized care" (Robinson et al. 2010, p. 81).

In many rural areas, it is not unusual for residents to have their "own" GP. Some rural residents are supported by the same GP and community nurse over a prolonged period, often from the time of diagnosis. The advantages of "being known" and continuity of care enhance the sense of trust in the healthcare providers. The concept of "knowing" also extends to the healthcare providers, who are often known by, and know of, other service providers.

6.4 Convenience of Rural Residency

Despite the travel distances, once in town, there are conveniences often not found in cities. When family caregivers are "time poor," the lack of traffic congestion is a commonly reported benefit of rural residency. Parking at rural hospitals and medical centers is usually free and in close proximity to the front door.

7 Place of Death in Rural Palliative Care

In rural settings, relationships between place and one's self are often stronger than for urban residents, so one would expect that rural people would view dying at home an essential feature of the "good" rural death. Place of death is often considered in terms of geographical location (community) and physical space (home, hospital, residential aged care). Consistent with urban dwellers, surveyed rural residents do indicate that, if faced with a life-limiting illness, home is their preferred place of death, surrounded by family and friends (Veillette et al. 2010), and, in the case of Aboriginal and Indigenous peoples, connected to their land and family (McGrath 2007). However, inconsistencies exist in the current rural literature due to limited and small studies, heterogeneous rural definitions, and rural data embedded in mixed geographical studies (Rainsford et al. 2016a). Also, most rural studies are either population surveys reporting hypothetical preferences of healthy people or retrospective bereavement interviews/questionnaires of families and carers. Few studies report preferences directly from patients, i.e., those facing an end-of-life situation. Therefore, rural preferences for place of death are not clearly understood.

In contemporary rural studies, more than half of rural participants expressed a preference for dying at home; however, this is not a universal finding. Locations with stronger traditional cultures and values exhibit the strongest preferences for, and the highest numbers of, home deaths; however, these locations often have less access to hospitals, hospices, and residential aged care (Rainsford et al. 2016a). Rural residents are often considered disadvantaged by the lack of rural inpatient hospice facilities, with rural hospitals and residential aged care acting as substitutes for inpatient hospice (Menec et al. 2010). While wishing to remain home, studies indicate that many rural residents and their family caregivers accept the need to alternate between home and hospital, providing the length of hospital stay is kept to the minimum.

Currently, there is great variation in the rate of home deaths between rural settings. Rates range from just over 10% to 80%, with a large cluster around 25% (Rainsford et al. 2016a). Compared to urban residents, the chance of dying at home in rural areas is often dependent on the specific rural setting and cause of death. Rural residents who die of cancer in South Australia have been reported to have a greater chance of dying at home than urban residents (Hunt et al. 2001). Likewise, people living in rural England with COPD (Higginson et al. 2017) and living in parts of rural Europe with cancer (Cohen et al. 2010) are less likely to die in hospital than patients residing in urban locations. However, a Canadian study by Lavergne et al. (2015) reported no significant difference in the odds of dying in hospital for urban and rural residents with a terminal illness, organ failure, or frailty.

The most frequently cited reasons for leaving home are symptom control and carer distress. Factors influencing place of care/place of death in rural settings are not clearly identified in the literature but, when reported, include patients' functional status and clinical condition, carer and social networks, and health-system facilities. With

limited medical and nursing support at home to respond to changes in patients' conditions, the influence of rural residency has the potential to render rural homes, especially farms and outliers, more susceptible to become unsafe, earlier, and more frequently than most urban homes.

Deciding on place of death is a complex process, in which wishes and preferences are not necessarily the same. Rural patients change their preferences as illness progresses, with most accepting that a home death may not be possible. For many rural patients, hospital becomes their preference, and an acceptable alternative to home, especially in the last 48-hours and providing they are located within the patients' community (Robinson et al. 2010). Rural hospitals are often a substitute for inpatient hospice care.

Rural hospitals could be perceived as less safe than urban hospitals, due to the lack of specialist palliative care and expertise; however, this is often not the perception of rural patients. The familiarity and personal attention provided by rural hospitals, and the benefit of being known, creates a safe place within rural hospitals. At end of life, the inability of small rural hospitals to provide aggressive and often futile interventions is often perceived as an enabler to maintaining dignity. However, this experience is not universal. When local hospitals are perceived as unsafe, or under-resourced for "active" treatment, some rural residents choose to move away from their community, to specialist palliative care facilities or larger hospitals. Safety is not simply following procedures and policies. Safety is aligned with trust. Trust is based on prior knowledge of the hospital, and dependent on the moment-to-moment experience of care, not only for the patient but also their family. The biggest barriers to using hospital-based palliative care services for Indigenous peoples are the lack of cultural awareness by healthcare professionals and not being able to die "in country" (Kelly et al. 2009; Grant et al. 2011; Dembinsky 2014).

When available, residential aged care is a significant provider of rural palliative and end-of-life care for those aged 65 years and older; however, this option is not available in all rural regions. Availability of residential aged care varies significantly, not only within countries but between countries. In some Australian rural locations, it is not uncommon for patients who are unable to return home from hospital to be transferred to residential aged care for end-of-life care. Consistent with urban residential aged care, current workloads and staff shortages create challenges for registered nurses to be available, in a timely fashion, to attend to the acute palliative care needs of residents.

The congruence between preferred and actual place of care and place of death has been mooted as a quality outcome for palliative care, with health policies aimed at enabling people to die in their preferred place. Based on the current literature, the assumption is that for most people, the preferred place of care and place of death is home, being in a familiar place, surrounded by family and/or friends. With limited studies reporting the actual and preferred place of death, there is currently insufficient data to draw any conclusions as to the degree of congruence within rural settings.

Robinson et al. (2010) suggest that a death at home is not necessarily the most appropriate or desirable place in rural settings, due to often limited palliative care resources, especially after hours. The significant burden and cost (financial, physical, and emotional) to family caregivers, caring for a family member at home, is often overlooked. Patients may only be able to die well and have a "good death" if they leave their home or farm to die in the rural hospital. Therefore, it remains unclear if the "push" to increase the rate of home deaths in rural settings is justified.

If rural residents are unable to die at home, then most consider it important that they die within their community. Many rural residents will sacrifice access to specialist palliative care to ensure they are not displaced from their rural community. Dying within community is one factor contributing to the "good" rural death.

8 The Concept of the "Good" Rural Death

The "good death" is a difficult concept to define and is dependent on individual interpretations, perspectives, and priorities formulated by cultural, religious, and political values and beliefs.

There is significant overlap between urban and rural views, highlighting that all people, regardless of where they live, have some common needs and desire a "good death." The elements considered essential for a "good" rural death go beyond culture and ethnicity; however, the context and priority placed on each factor differ from the urban perspective (Kirby et al. 2016). The essential elements include those that maintain quality of life for the patient and their family and address the physical, emotional, social, spiritual, and cultural needs of the dying person and their family caregivers.

The dominant theme, from both developed and developing countries, is that a rural "good death" is one that is peaceful, free of pain, and without suffering (Rainsford et al. 2016b). The themes describing the "good" rural death parallel the urban view and include a "controlled" death, with control over symptoms, place of death, decision-making, manner of death, and independence (Wilson et al. 2009a, b; Veillette et al. 2010); a "timely" death, which is a death coming "naturally and after a long and well-spent life" (van der Geest 2004, p. 899) after having had opportunity to say goodbye to family; a "dignified" death by maintaining identity, self-worth, integrity, and control (Wilson et al. 2009a; Devik et al. 2013); a "social" death, such as to die within the community with family present (Wilson et al. 2009a, b); and a "noble" death such as through enduring the situation (Grant et al. 2003; Devik et al. 2013).

Rural residents consider family and community important, especially at end of life, because "the togetherness of the family members makes you feel they love you and are not abandoning you" (Grant et al. 2003, p. 163). In some cultures, the family and community play an important role after the death of a family member, by ensuring specific rituals are carried out.

The strong connection to one's rural/remote community means that dying within one's rural locality is frequently identified as a critical element in achieving a "good death." If it is not possible to die at home surrounded by family, then it is important to die within the rural community, as "home or home community… [is] the only place where the dying person [can] be close to the many people who have meaning for them" (Wilson et al. 2009b, p. 316). In Ghana, dying away from home is considered "bad" and disgraceful; however, partial restoration can be achieved by "bringing the dead body home" (van der Geest 2004, p. 909).

8.1 Physical Support (Pain and Symptom Management)

Good pain and symptom control is the overriding factor reported to ensure a "good death." Pain relief is central to maintaining quality of life through the dying journey, not just for the patient but also the family caregiver. Most dying people and families fear pain. While inadequate pain control is reported in developed countries, moderate to severe pain often dominates the lives of patients in rural sub-Saharan Africa, due to the shortage or absence of pain medication and healthcare workers (Grant et al. 2011). Anticipating medication requirements, when commuting long distances, is an important consideration for some rural patients (Pesut et al. 2010; Lockie et al. 2010).

8.2 Emotional Support

Strong emotional support is a facilitator of quality rural end-of-life care. Faith and hope are central to emotional well-being. Hope is often maintained through connection with family, friends, and being linked to something outside the illness. The serenity and peacefulness of many rural settings are an advantage of rural residency.

8.3 Social Support

As previously indicated, rural communities provide significant social support (both formally and informally) for patients and family caregivers. This support is an enabler of the "good death" and is dependent on good communication, information, the presence of healthcare professionals, and the support of other patients. The solidarity of

rural communities and mutual support of neighbors is unique to rural settings (Wilson et al. 2009a; Robinson et al. 2010).

8.4 Spiritual Support

Spiritual connection and faith foster hope, with faith seen as an enabler to persevering in life as death draws near. Faith is fundamental to rural Appalachians and their transition through end-of-life care (Mixer et al. 2014). In many rural communities, church support is not limited to spiritual issues, as congregations often also provide physical and financial support.

8.5 Cultural Influences on the "Good" Rural Death

In addition to the influence of rural residency, cultural beliefs and values influence how individuals view end-of-life care and preferences for management, interventions, conversations, and place of care and death. This chapter is written mostly from a western point of view, where there is an emphasis on individualism, autonomy, quality of life, privacy, science, and the nuclear family. Other cultures may place greater emphasis on interdependence, extended family, village community, and respect for elders and traditional healers. In more traditional rural settings, for example, Kenya, "powerful cultural traditions [make] it difficult for social needs to be met" (Grant et al. 2003, p. 163). In many developing countries, while Christianity has influenced the concept of the "good" and "bad" death, it has not replaced, but instead has been interpreted and applied to, traditional beliefs. These beliefs can significantly impact on the health and well-being of the community, descendants, and ancestors (Grant et al. 2003, 2011). The "good death" is often regarded as one that does not disrupt the life and health of the community (van der Geest 2004). In contrast, rural residents in developed countries often view the "good death" in light of a biomedical model, placing greater emphasis on autonomy, the process of dying, and minimizing any sense of struggle. Stoicism and the culture of "not complaining" are a feature of rural residents in both developed (Devik et al. 2013) and developing countries (Grant et al. 2003).

9 Summary

Regardless of place of residency, all people desire a "good death." The goal of palliative care is to ensure the dying person and their family is free of suffering and distress. However, the provision of palliative care in rural settings is variable and dependent on the degree of rurality. Currently there is no international consensus on the definition of rurality and remoteness. There is considerable individual, cultural, and ethnic diversity with regard to preferences for end-of-life care. Rural culture is distinct from urban culture, with rural residents holding unique perspectives on what it means to die well. Rural communities are close-knit and known for their social solidarity, community commitment, and loose support networks. While there are many benefits of rural residency, significant challenges exist. The needs of rural residents are shaped by decreased access and availability of services. While this potentially has a negative influence on outcomes, it is offset by local support networks. Rural palliative care is mostly primary care, with limited access to specialist multidisciplinary palliative care services. Home is the preferred place of death for most rural residents; however, when home is not possible, rural hospitals and residential aged care are considered appropriate alternatives, providing they are within ones' community.

10 Conclusion

To ensure palliative care is relevant to individual communities, it must reflect the needs of the dying person and their family, and the diverse geography and cultures of the community in which they live. While there are many similarities between urban and rural end-of-life care, there are many significant differences. Rural settings are not homogeneous. While studies indicate that rural

residents are mostly satisfied with the level of palliative care provided, there are huge, and often unacceptable, variations, especially in remote and developing regions. The universal rural theme is that if rural residents are unable to die at home, then it is essential that their place of death is within their local community.

Contents

Abstract

This chapter considers the importance of informal carers in enabling patients to remain at home towards the end of life, providing extensive hours of care and covering a range of caregiving tasks, including physical, emotional, and social care and monitoring. It highlights the considerable impact that caregiving has mainly on carers' psychological health, but also their general wellbeing, and it reviews the evidence on factors that predict worse impact, key elements of which are carers' own appraisal of their situation and their preparedness. The chapter describes how carers occupy two main roles: that of a co-worker and of being a client themselves, and the main areas with which they need support to enable them to support the patient as co-workers, and to look after their own health

and wellbeing as clients. It reviews the limited success interventions for carers have had to date, some of the challenges that need to be overcome, the importance of individualized, person-centered interventions, and some of the assessment tools that may help facilitate tailored support. It also highlights that assessment in itself is unlikely to be of benefit without clear procedures for discussion of and response to identified problems. Finally, it considers factors required for implementation of carer support within palliative care practice, including procedures for identifying carers, recording carer data and for intervention delivery, as well as organizational level support to sustain implementation including leadership, staff training, protected time, and carer champions. However, fundamental to achieving consistent carer support is the question of whether carers are true clients of palliative care services.

1 Introduction: The Importance of Carers

Informal carers make a substantial contribution to patient care. In the UK, it is estimated that informal carers of people of all conditions provide care to the value of £132 billion per year, close to the annual healthcare spending of £134 billion (Buckner and Yeandle 2015). In Australia, the cost of replacing the hours of informal caregiving with formal care would be equivalent to 60% of the spending on the health and social care work industry (Carers Australia 2015), while in Canada carers have been estimated to provide 80–90% of home care (Romanow 2002).

The size of the contribution of informal carers in palliative and end of life care is less clear. Caregiving hours are in this situation likely to be considerably higher compared to caregiving in general, thus representing a sizable input, but input from formal services is also likely to increase. A recent study from England found that informal caregiving amounted to more than twice the cost of formal healthcare among patients with advanced chronic disease and refractory breathlessness (Dzingina et al. 2017). Conversely, an Irish study found that informal caregiving accounted for 22% of total costs in the last year of life among patients receiving specialist palliative care (Brick et al. 2017). These estimates will depend on the caregiving context and what tasks are considered. Formal care input is likely to have been different in the two above studies. Further, Brick et al. (2017) only focused on carers' assistance with activities of daily living and out of pocket expenditure. Dzingina et al. (2017) considered hours "on call" in addition to more practical or physical caregiving tasks. Arguably, to gain a true picture of the value of caregiving (and impact on the carer), we need to consider caregiving in the broader sense, not just practical and physical elements but also their constant vigilance: a lot of carer time at home involves monitoring of the patient's condition and being on call. This in one sense mirrors the situation in inpatient care, where monitoring and being able to call on assistance when needed is an important aspect of care. Time spent looking after patients' psychological and social needs is also important in maintaining patients' psychological wellbeing and personhood, which arguably are important elements of holistic care.

Not surprisingly, the efforts of informal carers are crucial in enabling care to take place at home towards the end of life. The vast majority of patients prefer to be looked after at home towards the end of life, and although the percentage who actually wants to die at home may be smaller, these may still form the majority (Gomes et al. 2013a). Studies consistently show that the availability of carers is a major and consistent predictor of likelihood of dying at home: patients who have a primary carer, are married, live with relatives, have an extended family or carer network are more likely to achieve a home death than their counterparts (Gomes and Higginson 2006; Grande and Ewing 2008; Burns et al. 2013). Similarly, a substantial proportion of "inappropriate" hospital admissions may be carer initiated or due to carers' inability to cope (Reyniers et al. 2017; Gott et al. 2013, respectively).

Current healthcare policies often promote care in the community over inpatient care towards

end of life based on patient preferences and costs, where hospital inpatient care accounts for the majority of healthcare costs (Gardiner et al. 2017). However, sustaining care in the community is heavily dependent on carers' efforts, and this policy normally does not take into account the impact on carers and the size and economic value of their contribution (Gardiner et al. 2017). For instance, The National End of Life Care Programme (NEoLCP 2012) in England estimated that end of life community care was likely to be cheaper than acute hospital care, but this calculation only considered the costs of health and social care provision, not the costs of carers' contribution. Literature reviews indicate that the costs of palliative care is lower than standard care, but economic evaluations consistently fail to consider carers' time and out-of-pocket costs (Smith et al. 2013; Gomes et al. 2013b; Penders et al. 2017). Support for carers was explicitly excluded from the NHS Palliative Care Tariff recommended by the Palliative Care Funding Review (DH 2011) for England, despite the PCFR's emphasis on enabling patient death at home.

Proper recognition of carers' input, consideration of the impact on carers, and how we support them will be of increasing importance in the future. In the UK, the number of carers in the population increased by 16.5% from 2001 to 2015. More importantly, there was an increase of nearly 43% in carers providing 20–49 h and 33% in those providing >50 h per week (Buckner and Yeandle 2015). Our reliance on carers is likely to continue to increase in years to come, particularly for end of life care. Projections in the UK indicate there will be increases in people over 85, those with life limiting illness (Buckner and Yeandle 2015), in dependency in the final years of life (Kingston et al. 2017) and in the number deaths (ONS 2013). These demographic changes are likely to be mirrored at least across the developed world. Health and social care services are likely to struggle to meet these future demands, and carers are likely to have to make up much of the shortfall.

This chapter will give an overview of who carers are, what they do, what impact caregiving has on them and who may be worst affected, what support they need, what may help carers in terms of interventions, and how we embed carer support within palliative care.

2 Who Are the Carers?

Carers have been defined as "lay people in a close supportive role who share in the illness experience of the patient and who undertake vital care work and emotion management" (NICE 2004). They are usually first degree relatives, most often a spouse or adult child of the patient (Abernethy et al. 2009), but can also be more distant relatives, friends, or neighbors. In fact, the wider network of carers may have a more prominent role than is often realized. For instance, a population based study in Australia by Burns et al. (2013) found that of those reported providing "hands on care" for someone at end of life, only 44% were first degree relatives (a spouse, child, parent, or sibling) and 56% were extended family, friends, and others. Nevertheless, first degree relatives were more likely to do daily care and to care for a longer period. Therefore, the main burden of care is still likely to fall on the closest relatives.

Other characteristics are likely to define those who provide the most care. Abernethy et al. (2009) found that carers who provided more frequent care (daily or several times a week) were more likely to be women. Those providing more intermittent care compared to daily care were more likely to be younger (<60 years), have higher education, be in paid work and to be wealthier, as well as being more likely to be children, parents, other relatives, or friends of the patient.

3 What Do Carers Do?

Carers in general provide substantial hours of care per week. National data from England indicate that the majority of carers (62%) provide up to 19 h per week, although 24% provide 50 h or more (Buckner and Yeandle 2015). Carers of people with cancer have been estimated to provide

15–24.5 h per week (Van Houtven et al. 2010; Round et al. 2015, respectively). However, this is unlikely to reflect the intensity of caregiving towards the end of life.

To gain an overview of carer hours and tasks in the patient's final months of life, we conducted a national census post-bereavement survey of everyone who had reported the death of a relative from cancer in England during a two-week period in 2015 (Rowland et al. 2017). Respondents were asked to estimate how many hours they spent on a range of caregiving tasks in a typical week during the patient's last 3 months of life. A total of 1504 (28.5%) of 5270 relatives completed the survey and 91% provided information on hours of care. These carers reported spending a median of 69 h and 30 min on caregiving per week (interquartile range 28:37–115:15 h). Carers of people with cancer may therefore on average spend nearly 10 h per day 7 days per week on caregiving during the patient's final months. This may still not provide the full picture of informal care contributions: 60% of respondents reported receiving additional informal help in the patient's last 3 months, mostly from family, but also friends and neighbors, and the extent of this help was a median of 20 h per week (Interquartile range 7.3–50 h). While we do not have similar data for carers of people dying from other conditions, their contribution is also likely to be substantial.

Carers carried out a broad range of support tasks within their caregiving hours (Rowland et al. 2017). Most spent time on social and emotional support for the patient (83%), followed by shopping (79%), cleaning, preparing food/drink, general administration, organizing/attending appointments and helping with symptoms (all between 70–73%), personal care (64%), travelling with the patient (58%), and maintenance/miscellaneous jobs (55%).

Carers can also have considerable out of pocket expenditure in relation to caregiving. In a study of 13 European countries, Penders et al. (2017) found such expenditure in the last year of life to amount to 2–25% of median household income. In our national survey for England (Rowland et al. 2017), carers were asked to report total out of pocket expenditure during the deceased person's last 3 months. Seventy one percent reported such expenditure, with a median total expenditure of £370 among those reporting figures, including spending on travel, meals, medical equipment, and care supplies. Additionally, 17% reported "one off" expenses during the total time of caregiving with a median expense of £2000, including mobility equipment, furniture, or house adaptations. These expenditures relate to a country with public health service coverage and are likely to be considerably higher where people pay for private medical and nursing care.

4 Impact of Caregiving on Carers

Caregiving has considerable impact on carers' own psychological and physical health (Stajduhar et al. 2010). Studies have found carers to have worse psychological health compared with the general population (Dumont et al. 2006; Grov et al. 2005; Gotze et al. 2014; Kenny et al. 2010; Zapart et al. 2007), although some studies show them to have similar or better physical health than the norm (Grov et al. 2005; Zapart et al. 2007; Kenny et al. 2010). Compared with carers of people with non-terminal conditions, carers of palliative and end of life patients have worse emotional health and physical health (Williams et al. 2014; Wolff et al. 2007). They have even been found to have greater prevalence of anxiety and depression than patients themselves (Braun et al. 2007; Gotze et al. 2014; Grunfeld et al. 2004). In general, research seems to show that caregiving has the greatest and most consistent impact on carers' psychological health, and patterns seem to be similar at least across English-speaking countries and Europe (Dumont et al. 2006; Stajduhar et al. 2010; Wolff et al. 2007; Williams et al. 2014; Grov et al. 2005; Zapart et al. 2007; Kenny et al. 2010; Gotze et al. 2014).

The level of impact on the mental health among carers of palliative and end of life patients gives cause for concern. Studies using standard measures that enable identification of clinically significant levels of distress have found a prevalence of anxiety ranging from 34% to 47% among these carers during caregiving (Grov et al. 2005; Gotze et al. 2014; Grunfeld et al. 2004; Rumpold et al. 2016) and a prevalence of depression of 39%

(Braun et al. 2007). However, results may not be fully generalizable. These studies mainly have recruited carers for oncology/tertiary care (Grov et al. 2005; Grunfeld et al. 2004; Braun et al. 2007; Rumpold et al. 2016) or palliative care services (Zapart et al. 2007; Kenny et al. 2010; Gotze et al. 2014), and specialist services may produce better outcomes than generalist services. Conversely, patients referred to these services may also have more complex needs. Only Dumont et al. (2006) recruited carers both through generalist and specialist care, and found significant levels psychological morbidity to be between 41% and 62%. Only two studies have considered population data (Wolff et al. 2007; Williams et al. 2014). However, these used single item, non-standard scales of emotional impact which do not allow us to ascertain levels of clinical significance. Furthermore, most studies have included large proportions of carers of patients who are not yet in the final months of life and who may still be relatively well (Wolff et al. 2007; Grov et al. 2005; Zapart et al. 2007; Kenny et al. 2010; Gotze et al. 2014; Grunfeld et al. 2004; Braun et al. 2007; Rumpold et al. 2016), thus not indicating the full impact of caregiving on carers during the course of the patients' illness.

To gain insights into psychological morbidity and general health during end of life caregiving for a broader population of carers we investigated psychological and general health in our 2015 national census post-bereavement survey of carers of people who died from cancer in England (Grande et al. 2018). We asked for carers' retrospective reports of how they felt during the patient's last 3 months of life using the GHQ-12, a standard measure of psychological morbidity, and the EQ-VAS, an established single item scale for general health. We compared carers' reports with scores from the general population using the Health Survey for England 2014. Survey responses indicated that 83% of carers had clinically significant psychological morbidity compared with 15% in the general population, and their psychological morbidity scores were 5–7 times higher than population scores across all age groups. Carers also overall had worse general health than the general population, but differences were less marked than for psychological morbidity, and carer and population scores converged towards older age with carers age 75 and over in fact scoring better than the population. Given that these are retrospective carer reports, we have to treat the absolute scores with some caution. However, carers were surveyed 4 months post-bereavement to enhance accuracy of recall. Further, the GHQ-12 mainly focuses on psychological functioning, e.g., ability to concentrate or to make decisions, rather than more subjective general feelings. We can therefore probably conclude with some certainty that levels of psychological morbidity among carers during end of life care are very high relative to the general population.

However, it is important to recognize that many carers also can see caregiving as positive and rewarding alongside the challenges and problems experienced. We therefore must understand these positive aspects and how we can help preserve these, while seeking to ameliorate some of the negative impacts from caregiving. Reviews of caregiving (Funk et al. 2010; Li and Loke 2013) report that positive aspects of caregiving include gaining a sense of reward, personal growth, growing closer to the patient and demonstrating love, gaining a feeling of self-esteem and accomplishment, and finding life enriching and meaningful features within the experience. However, the Funk et al. (2010) review notes that these findings may reflect carer coping processes that use positive interpretation and identification of rewards as part of meaning-based ways of coping. Nevertheless, this should not invalidate these processes in any way or indicate that we should not seek to support these ways of coping.

5 When Are Carers More Likely to Suffer Negative Impacts from Caregiving?

Not surprisingly, the patient's disease burden (i.e., level of functioning and symptoms) appears to have negative impact on carers' psychological health, quality of life, and perceived burden (Stajduhar et al. 2010; Hirdes et al. 2012; Lee et al. 2013; Tang et al. 2013). Similarly carers have greater psychological morbidity (Burridge

et al. 2009; Tang et al. 2013; Grant et al. 2013; Hirdes et al. 2012) and worse health (Lee et al. 2013) as patients' approach death, where closeness to death is again likely to be associated with greater patient disease burden.

Hours of caregiving may also matter. A national survey of carers in general (Hirst 2005) found that increased hours were related to worse carer psychological health. Results are less clear for palliative care, however. Whilst some studies have found that longer hours of caregiving are associated with worse carer psychological health (Hirdes et al. 2012) and physical health (Kenny et al. 2010; Yoon et al. 2014), other hospice care studies have found no relationship (Washington et al. 2015).

Several demographic and contextual variables also affect impact of caregiving. A closer relationship with the patient may relate to more negative impact. Research indicates that spouses and/or (adult) children suffer greater psychological morbidity (Gotze et al. 2014; Hirdes et al. 2012; Tang et al. 2013) than less close relations. Spouses also report worse physical health (Park et al. 2012; Yoon et al. 2014) than other carers, but spouses may often also be older carers and therefore have worse physical health due to age. Good social network support is associated with reduced carer psychological morbidity (Gotze et al. 2014; Tang et al. 2013), health problems (Park et al. 2012), and perceived burden (Lee et al. 2013). Conversely, competing carer commitments may make caregiving more demanding. Stajduhar (2013) highlights that a growing number of carers, termed the "sandwich" generation, may be juggling caregiving for older parents with care for younger children and work which may be detrimental to their own health. However, more research is probably required into how the sum total of carers' commitments impact on carer health. Women generally report greater psychological morbidity during caregiving than men (Burridge et al. 2009; Stajduhar et al. 2010) and may also have worse physical health than male carers (Kenny et al. 2010; Park et al. 2012; Washington et al. 2015). Younger carers may suffer more psychological impact than older carers (Stajduhar et al. 2010), although Given et al. (2004) found middle aged carers to be more affected than younger and older carers, possibly representing the "sandwich generation." In contrast, older carers report worse physical health than younger carers (Kenny et al. 2010; Park et al. 2012; Yoon et al. 2014), but this may simply reflect the link between physical health and age. Carers with lower education on the whole seem to have worse psychological and physical health (Stadjuhar et al. 2010; Park et al. 2012) compared with those with higher education. Financial burden may be related to worse carer psychological morbidity (Gotze et al. 2014), and higher income or better financial support to better physical health and less perceived carer burden (Lee et al. 2013; Park et al. 2012; Yoon et al. 2014).

However, carers' own personal reactions and subjective appraisals of burden are probably more important in determining the impact of caregiving on their health and wellbeing than the actual, "objective" demands of caregiving or demographic and contextual variables. Review of the quantitative literature indicates that better outcomes are, for instance, associated with carers' perception of benefits of caregiving, as well as better preparation for caregiving and lower difficulty with tasks, a greater sense of meaning and comfort with caregiving tasks; and the feeling of greater role esteem, self-efficacy, and confidence in relation to caregiving (Stajduhar et al. 2010; Li and Loke 2013). "Reframing" coping strategies, including acceptance and redefinition, and positive religious coping also relate to better outcomes (Stajduhar et al. 2010; Li and Loke 2013). Reviews of the qualitative literature also indicates that carers often lack preparation, knowledge, and ability for caregiving and that lack of preparedness is associated with negative psychological outcomes (Funk et al. 2010). This clearly provides pointers for interventions with carers.

6 What Do Carers Say They Need Help with?

Given that carers' own appraisal of their caregiving situation is likely to be of prime importance in determining the impact of caregiving on them, it is crucial to understand how individual

carers appraise their situation, what they struggle to manage, and where they feel they need additional support. To help with this, we investigated what carers normally need support with when looking after someone during palliative or end of life care, in order to help improve individualized carer assessment and support and highlight what areas we may generally need to address to support them. We conducted a large-scale qualitative study involving 75 bereaved carers in focus groups and interviews (Ewing and Grande 2013). Participants were carers of patients who had been referred to one of five hospice home care services across the UK.

Findings showed that carers' support needs fell into two broad groups: carers needed support to enable them to support the patient in their role as a key "co-worker." They also needed support to look after their own wellbeing in their role as a "client" in their own right. Responses indicated that carers felt a deep sense of responsibility for the patient's care and may be more willing to talk about their needs as "co-workers," and more reluctant to talk about their own needs (see Sect. 8). However, we have to recognize that to fully support carers, we must address their support needs both in their roles as co-worker and client. Within each role, carers' needs for support encompassed seven broad domains (see Box 1).

Box 1 Support needs of carers as co-workers or clients during end of life caregiving

Enabling carers to care (co-worker role)	Direct support for carers (client role)
Knowing who to contact when concerned	Own physical health concerns
Understanding the patient's illness	Dealing with their own feelings and worries
Knowing what to expect in the future	Beliefs or spiritual concerns
Managing symptoms and giving medicine	Practical help in the home
Talking to the patient about their illness	Financial, legal, or work issues
Equipment to help care for the patient	Having time for themselves in the day
Providing personal care for the patient	Overnight break from caring

The 14 domains were incorporated into a Carer Support Needs Assessment Tool (CSNAT). To ensure the 14 domains captured, the support needed by carers during palliative and end of life care, we conducted a validation study with 225 carers who were currently supporting a patient who had been referred to one of six UK hospice home care services (Ewing et al. 2013). Carers completed a postal survey indicating if they needed more support with any of the 14 support need domains or with "anything else," and completed standard measures of strain, distress, preparedness, global health, and positive appraisals of caregiving. Survey results showed that all the 14 domains were used by somebody to indicate further need for support. Further, only five of 225 carers wrote that they needed help with "anything else" that was not already fully covered by the existing domains, and what they added was nevertheless very closely related to existing domains, e.g., information on services available in the area. Need for further support with the domains was significantly correlated with increased carer strain and distress, worse global health, and reduced preparedness for caregiving, but not to positive appraisals (Ewing et al. 2013). Further linear regression analysis showed that a need for more support explained the greatest variance in strain (47%), followed by global health (35%), distress (29%), and preparedness (27%), but explained very little variance in positive appraisals (9%) (Grande et al. 2012). In terms of direction of these relationships, it is probably more likely that insufficient support predicts worse carer health and wellbeing, and that a lack of carer preparedness predicts a need for more support, but the nature of these relationships requires further investigation.

The validation study results indicate that the 14 domains were both comprehensive and sufficient in capturing carers' support needs and that they related to important measures of health and wellbeing. This study and subsequent research (Aoun et al. 2015a) show that the main domain carers need more support with are "knowing what to expect in the future," "dealing with your feelings and worries," "having time for

yourself in the day" and "understanding your relative's illness." However, carers' support needs will differ and all the domains will be important to someone.

It is furthermore important to recognize that carers will differ in the individual support needs they have within any given domain and correspondingly the supportive input that they will require to meet those needs (Ewing and Grande 2013). Needing more support with symptom and medication management, for instance, will encompass a range of different support needs. These may include a need to understand the medicine regimen; what side effects to expect; being involved in discussions about symptom control; knowing at what point there is cause for alarm so that further help should be sought; or something else specific to the individual. Each of these scenarios requires different input and only the carer can define what supportive input is helpful in their case. While the 14 domains therefore comprehensively capture the broad areas that need to be considered when supporting carers, it is important that carers have the opportunity to express their individual support needs and to define what input would actually help with these needs.

7 How Well Have We Done in Supporting Carers to Date?

There is limited evidence to date that interventions have been effective in improving carer outcomes. An early systematic review by Lorenz et al. (2008) found that in general there was moderate evidence that palliative, supportive, and end of life care interventions increased carer satisfaction, but only weak evidence that such care actually improved carer outcomes This review did, however, find moderate evidence that interventions for carers of people with dementia were beneficial, but these may not necessarily be relevant to other palliative and end of life carers (e.g., they may focus on dealing with behavior problems or personality change). A Cochrane review (Candy et al. 2011) of supportive interventions, mainly to improve the psychological health of carers of patients in the terminal phase of their illness, found that interventions reduced carer distress short-term, but the effect was small (effect size $d = 0.15$). Further, there were no significant improvements in coping and quality of life. A more recent Cochrane review of home palliative care interventions by Gomes et al. (2013b) concluded that the overall evidence for improvement was nonsignificant, inconclusive, or conflicting with only some individual studies indicating shorter term improvement in burden, sense of reward, or reduced distress.

Part of the problem in assessing the effect of palliative and end of life interventions on carers is the wide range of interventions considered, so that it is difficult to draw clear and consistent conclusions and establish the "active components" of an intervention that may make a difference. Lorenz et al.'s (2008) review included regular palliative care and enhanced palliative care, group interventions and individual interventions. Gomes et al. (2013b) considered both regular and enhanced home palliative care, which again comes in many forms. Candy et al.'s (2011) review was more focused but still encompassed a considerable range of supportive interventions. Another problem is that many of the above interventions were mainly aimed at the patient, e.g., home palliative care, so it is perhaps unsurprising that they did not show a clear impact on carers, although there was a hope that carers would benefit. Further, even when interventions are targeted at carers, there may be a lack of effect because the intervention that is offered does not fit with what carers actually need (Buck et al. 2013; Levesque et al. 2010). Conclusions from Lorenz et al.'s review (2008) were that interventions were more likely to be effective when they were individually targeted and when they had multiple components (not just focused on one aspect).

To achieve meaningful improvements in carer outcomes, we therefore probably need to design interventions that are specifically focused on carers, more responsive to their individual needs and that address the range of needs or problems they may have. This means we need to understand the perspective of carers themselves; look at the whole individual; and let carers define what

they need and let that drive the intervention. This comes back to asking carers themselves what it is they need support with, and sits squarely within the person-centered, holistic approach to support and care which is normally seen as core to palliative and end of life care.

8 Fitting Interventions to Carers' Considerations, Situation, and Individual Needs

There are several challenges that have to be overcome to ensure a fit between intervention (or support offered) and carers: negotiating carers' dual role and ambivalence at receiving help; restraints of location, time, and energy; and ensuring support fits the needs of individual carers.

As we have seen, carers have a dual role as both co-worker and client. Norms and expectations (held by carers themselves, but also sometimes by patients, family, and services) mean that carers often do not see themselves as legitimate care recipients and are ambivalent about receiving help or taking a break from caregiving. Carers may only accept support if they feel this will help them care and does not take resources and attention away from the patient (Harding and Higginson 2001). To provide effective support, we need to recognize these dynamics, help legitimize the expression of need for help and support, and ensure that help is on carers' own terms. This is likely to require a proactive approach as carers themselves are often reluctant to express what they themselves need help with, may not know what aspects of support are available or what it is legitimate to ask for support with. While volunteering that they need help is often difficult for carers, being asked about needs and/or offered help as part of an established, formal process may help overcome barriers. It may also help if this is done in such a way that carers do not have to express their needs in front of the patient (Ewing and Grande 2018).

Any standardized interventions need to be sensitive to the dilemmas and constraints of the carer role. They need to recognize the potential conflict between carers' desire to sustain caregiving and looking after their own needs. Respite may for instance be easier for carers to accept in the form of briefer daytime breaks or overnight sitting, rather than inpatient admission. Help with the patient's personal care may be more acceptable if the carer can still be present and involved. In each case, it is important to know what carers want; some may want a complete break from caregiving, but for others this can be hard to accept, although they need a rest and some support. Interventions that depend on carers leaving the patient, e.g., to attend group activities or therapies, are often also practically difficult for carers, unless formal care for the patient forms part of the intervention, and even then carers need to feel this is an acceptable solution for the patient. Carer interventions that can be delivered at home or during delivery of day care, outpatient or inpatient care for the patient may therefore prove more feasible. Joint patient/carer interventions may provide a solution and be desirable where the aim of the intervention for instance is to foster communication or joint problem solving. However, this may inhibit expression of carers' own needs and concerns. Interventions that to some extent can be tailored are also likely to be of more use to carers who will have limited time and energy. For instance, one can hypothesize that access to bitesize, individualized information is likely to be more helpful than bigger, standardized chunks. Any standard intervention needs to be developed from carers' perspective to ensure they actually fit carers' situation and address what they need. It is therefore essential that we engage carers in the design of general interventions or support services for carers.

If we are to provide more individualized support, however, this normally requires individual assessment of need for support. There are two broad approaches that can be taken to assessing carers' need for support: assessment of adverse effects of caregiving or more direct assessment of the problems that carers need support with.

Assessment of adverse effects of caregiving enables identification of carers that are suffering particularly high impacts from caregiving, which enables us to focus intervention resources on

those most in need of help and most likely to benefit from intervention. Numerous tools exist that may be used for assessment of adverse effects during caregiving (Hudson et al. 2010). The main groups of adverse outcomes that have been considered include psychological morbidity, subjective burden, and quality of life. Measures of psychological morbidity have not been developed specifically for carers, but general measures have successfully been used with the carer population. These include the Hospital Anxiety and Depression Scale (HADS), the Beck Depression Inventory (BDI) (Hudson et al. 2010), and the General Health Questionnaire (GHQ-12) (Grande et al. 2018), all of which are relatively short (12–21 items) with good reliability. The single item Distress Thermometer has also been used as a brief screening tool for anxiety and depression in carers to identify those who may require further follow up (Zwahlen et al. 2008). Measures of subjective burden, or strain, have been specifically developed for carers to capture burdens related to the caregiver situation. These include the Zarit Burden Interview (ZBI), the Caregiver's Burden Scale in End-of-Life Care (CBS-EOLC), and the Caregiver Strain Index (CSI) (Hudson et al. 2010). Again these are relatively short (13–22 items) with good reliability. The Family Appraisal of Caregiving Questionnaire for Palliative Care (FACQ-PC; 25 items) seeks to capture both strain and distress, as well as positive appraisals (Hudson et al. 2010). Questionnaires that have been used to measure carers' quality of life include both generic questionnaires and questionnaires specifically developed or adapted for carers. The former include the SF-36 and the Quality of Life Scale (QOLS) (16 items). The latter include the Quality of Life in Life-Threatening Illness – Family carer version (QOLTTI-F) and the Caregiver Quality of Life Index – Cancer (CQOLC) scale (Hudson et al. 2010) with 16 and 35 items, respectively, all again with good reliability.

These measures can give an indication that a carer is experiencing adverse effects from caregiving likely to need further intervention. However, these measures still require us to then identify the individual areas of difficulty or needs the carer has as well as appropriate courses of action to help ameliorate the psychological morbidity, burden or poor Quality of Life. Appropriate action may for instance be to target carers' psychological appraisals of caregiving burden and improve coping, resilience, and capabilities, or more direct intervention with the day to day problems they experience with caregiving. In any case, actions should involve discussion with carers regarding what may help. Further, one would ideally want to try to intervene before burden, psychological morbidity and deteriorating quality of life reach critical levels, where possible.

Here more direct assessment of the issues that carers need support with or that give rise to distress can help by providing practical pointers for meaningful action or earlier intervention to prevent adverse impacts reaching critical levels. Tools that may help with this include The Needs Assessment Tool – Caregivers (NAT-C), Carer Support Needs Assessment Tool (CSNAT), Carers' Alert Thermometer (CAT), and The Family Inventory of Needs (FIN). The NAT-C (Mitchell et al. 2010) is a 32 item tool developed from the literature and 25 interviews with practitioners and carers. It can be self-completed by carers or together with a practitioner and enables carers to indicate their levels of concern on a range of issues including physical and psychological wellbeing, spiritual, existential, social, financial and legal concerns, and whether they would like to discuss them with their GP or other practitioner. The CSNAT (Ewing and Grande 2013), as previously noted, contains 14 items or domains and was developed from focus groups with 75 bereaved carers. It is intended to be self-completed by carers and enables them to indicate whether they need more support with looking after the patient or with preserving their own wellbeing (Box 1). The Carers' Alert Thermometer (CAT) (Knighting et al. 2016) contains 10 items about the carers' caring situation and their health and wellbeing. It is designed for practitioners to complete to identify any alerts that require further intervention. The Family Inventory of Needs (FIN) (Kristjanson et al. 1995) identifies areas of importance to the carer where services "fall short." Its

20 items represent a range of needs, mainly in relation to information including having questions answered honestly, knowing what treatment the patient is receiving, and what to do for the patient. It enables carers to rate how important each item is to them and indicate the extent to which these are met by practitioners.

However, assessment tools in and of themselves are unlikely to improve carer outcomes. If used as a questionnaire or form without subsequent discussion of, and response to, identified problems, none of these tools are likely to have beneficial impact on carer outcomes. Both the NAT-C and CSNAT are examples of tools that have been designed to be used as part of a defined intervention process, and whose impact has subsequently been tested through trials. In the NAT-C intervention, the completion of the tool by the carer is intended to be followed by a discussion of the NAT-C with their GP or other practitioner. As part of the process, the GP is supported by resource folder outlining potential carer problems and suggested resources and strategies that may help (Mitchell et al. 2010). A randomized controlled trial of this intervention with GPs indicated that for carers with clinical anxiety at baseline, the intervention improved mental wellbeing, and for those with clinical depression at baseline, the intervention slowed the worsening of depression (Mitchell et al. 2013).

The CSNAT is explicitly designed be part of a person-centered process that is led by the carer, although facilitated by practitioners. Early CSNAT feasibility work with practitioners highlighted the important features of this process to ensure it has meaningful impact and represents a truly person-centered comprehensive approach (the CSNAT Approach; Ewing et al. 2015). The CSNAT Approach is encapsulated in five stages, which also have relevance for other assessments: (1) Introduction: It is important to ensure the carer understands that the tool is part of a process of assessment that gives them the opportunity to consider their own support needs as distinct from the patient not just another leaflet or form. (2) Carer consideration of needs: The carer needs time to consider what areas they need support with, in privacy if required. Whatever time they require, carers need to know they will then have opportunity to discuss identified support needs with a practitioner. (3) Assessment conversation: In completing the CSNAT, the carer will have highlighted domains where they need more support and then prioritized those most pressing for them at the moment. The focus of the conversation is on the carers' individual needs within the domain(s) they have prioritized, to establish the particular issue they need help with and what supportive input they feel would help in relation to this. As highlighted earlier, carers will differ in the supportive input that they need within each domain, so it is important not to work from set assumptions by the practitioner as to the problem and its solution. (4) Shared action plan: Supportive input is based on the assessment conversation; it summarizes and documents actions put in place. This can take different forms: actions carers themselves take to access support (self-help or help from family); support directly delivered by practitioners such as "active listening," reassurance, advice giving, provision of information (which may be accomplished within the visit/contact); signposting the carer to other sources of support or referral to other agencies. Not all support needs have to be met by the practitioner or their organization. (5) Shared review: Carers' support needs change and so review of their situation needs to be ongoing. The prompt for a review can come from either the carer or the practitioner. It is important that carers are aware that they may raise their support needs at any time.

Further feasibility studies and trials showed that use of the CSNAT to support carers was seen as valuable both by practitioners and carers. Practitioners felt that use of such an assessment tool opened up different conversations with carers, challenged their assumptions regarding what carers needed help with, and improved expression, visibility and "legitimacy" of support needs (Ewing et al. 2016). The carers themselves felt that this helped them identify and express support needs that would otherwise not be possible; that it enabled necessary reflection, although this could at times be challenging; and that it provided them with validation, reassurance, and empowerment (Aoun et al. 2015b). Cluster

trials of the impact of the CSNAT intervention on carer outcomes found that the intervention group had significantly lower levels of strain during caregiving from baseline to follow up (effect size, d = 0.35) (Aoun et al. 2015a) and that they had significantly lower early grief and better psychological and physical health post-bereavement (Grande et al. 2017).

9 How Do We Implement Carer Support in Practice?

Successful development and trialing of interventions will not be of broader benefit unless evidence-based practice can be implemented and integrated into mainstream care. This normally entails a change in practice, which requires change not only at the level of individual practitioners but also at organization level to provide the structures and processes needed to support implementation and sustain it longer term, beyond a research project or practice initiative. The challenges of implementing change can be overlooked within policy, practice, and research. The MORECare Guidance for palliative care research recommends that implementation should be considered from the outset, within development, piloting and testing stages (Higginson et al. 2013).

In England, the Government's strategy for palliative care has for a long time highlighted that there should be assessment and support for carers as well as patients (DH End of Life Care (EOLC) Strategy 2008; NPEoLP Ambitions for Palliative and End of life Care 2015). Yet within this strategy, there has been no consideration of how this will be implemented in practice for carers. It was largely in response to this gap in the Government's 2008 strategy that the CSNAT was developed. However, our feasibility testing, trial, and implementation work with the CSNAT intervention helped us begin to identify the factors that need to be in place for successful implementation of change in practice in general and the assessment and support for carers in particular.

These lessons were consolidated and extended in a UK project to develop key recommendations for implementation of comprehensive, person-centered carer assessment, and support in end of life care. The project involved research review and stakeholder consultation through three interlinked stages: (1) secondary analysis of rich data from pragmatic implementation of person-centered carer assessment and support within 36 palliative care services using the CSNAT intervention; (2) new focus groups with hospice practitioners/leads, and (3) wide consultation with stakeholders from hospice, hospital, community, policy, and academia as well as carer groups to confirm and validate the set of recommendations. Box 2 lists the resulting ten recommendations, all of which were identified as key issues for implementation of carer assessment and support in practice and not consistently met by current provision in end of life care. Broadly, the first four recommendations indicate what needs to be

Box 2 Ten recommendations for achieving organizational change to enable provision of comprehensive, person-centered assessment and support for family carers towards the end of life

1. Consistent identification of carers within the care setting.
2. Demographic and contextual data on who the carer is and their situation.
3. A protocol for assessing carers and responding to the assessment.
4. A recording system for carer information, separate from patient data.
5. A process for training practitioners about carer assessment and support.
6. Available time/workload capacity for carer assessment and support.
7. Support from senior managers for carer assessment and support.
8. Role models/champions for carer assessment and support.
9. Pathways for communication about carer assessment and support.
10. Procedures for monitoring/auditing processes and outcomes of carer assessment and support.

embedded in organizations to provide person-centered support for carers and the remaining six are the structures and processes needed to successfully implement and sustain this approach in practice. Together they illustrate the whole-systems approach that need to be taken to implementation (Ewing and Grande 2018).

While developed for carer assessment and support, these principles are likely to have general applicability for implementation of interventions to support carers. The context for each recommendation is described in more detail below.

Underpinning any carer interventions is the need to know who the patient's main carer or carers are. Current practice of carer identification can be quite ad hoc, allowing many carers to slip through the net. A more systematic and proactive approach is necessary for **Consistent identification of carers within the care setting** as many carers do not self-identify and can miss out on much needed support. This is particularly the case where they see themselves in relationship terms, as a wife/husband or son/daughter of the patient and do not recognize themselves as a "carer." In these circumstances, a questions such as "who provides the patient with most support" (who is not a healthcare professional) can be helpful in carer identification.

Closely linked to carer identification is the recommendation for **Demographic and contextual data on who the carer is and their situation**, to aid communication with carers and awareness of their circumstances. Even where carers are known to palliative care services, there can be a lack of documentation about them. Our project found this was particularly the case in hospital settings where the primary focus is on the patient but was also true in hospices. There was a lack of basic information such as number of carers known to the organization, and even for identified carers contact information and basic details about their situation or needs were often not recorded. This again makes it difficult to sustain meaningful intervention.

The project's third recommendation – **A protocol for assessing carers and responding to the assessment** is a principle that translates to implementation in general, in that there has to be a clear protocol for how any new intervention is to be delivered in practice. In terms of delivering consistent carer assessment and support, this normally represents a considerable practice change: identification of carers' needs may currently be missed altogether, and when it does take place, is often an informal, practitioner-led approach conducted as part of the patient assessment or takes the form of "doorstep conversations" (Ewing et al. 2015) when carers don't want to talk in front of the patient. Further, solutions are often based on practitioners' assumptions rather than identified by carers. A clear protocol is a prerequisite for implementing consistent, comprehensive, person-centered carer assessment and support. This puts carers on a more equal footing to patients and helps legitimize their support in palliative and end of life care.

A recording system for carer information, separate from patient data, is to ensure that information on carers is recorded in a defined location for record keeping and future reference. This is an issue linked to consistent carer identification and data gathering. If this information cannot be easily accessed and utilized, it is unlikely to aid effective interventions. Current health record systems focus on patients: any information that is recorded about carers is usually done within the patient record, often under family support. However, a systems change in recording processes is needed if carers are to be consistently identified and supported. Flexibility to develop separate carer records will vary across settings with particular challenges for hospital-based palliative care teams, but many hospices are already developing separate carer record systems.

Fundamental to achieving consistency in practice with carers is putting in place **a process for training practitioners about carer assessment and support**. Training is core to ensure everyone is on board with the purpose and procedures of the

intervention and how it is different from existing practice, otherwise what may be a beneficial intervention at conception, may change to become ineffective or even detrimental in its implementation (Neuberger et al. 2013). It is, for instance, important to identify the differences between a comprehensive, person-centered approach and current practice for those already working to support carers in everyday practice. Training about carer assessment and support also has resonance across all settings and at all stages: from broader carer awareness raising early in nurse education to understand the key role of carers in end of life care; to assist more junior frontline staff who are unfamiliar with identifying carer needs; through to more experienced practitioners who feel they "already do" carer assessment and support, providing an opportunity to "up their game."

Available time/workload capacity for carer assessment and support: For implementation of any intervention, organizations need to consider how to make sufficient time to plan, implement, and sustain a change in practice. For carer assessment and support the leadership in organizations needs to decide whether this is part of their "core" business, rather than an "add-on" to patient care, only when time allows. If core, organizations need to consider how to make sufficient time for meaningful implementation. Investment of time on carers in the short-term can achieve longer-term gains in averting crises. However achieving capacity at practitioner level for this new way of working not only requires a mind-shift away from a focus solely on patients but also time and resources for its practical implementation by frontline staff.

Support from senior managers for carer assessment and support: This is crucial to provide a wider strategic overview and the authority for implementation of new interventions across all settings. This includes (1) initiating the change from current practice and (2) driving forward the new way of working through facilitating training and ensuring workforce capacity for implementation. Input from senior managers is vital to sustaining the change to comprehensive, person-centered assessment and support in the longer term, through review, improving processes and providing evidence to commissioners to support palliative care delivery for carers, not just patients.

Role models/champions for carer assessment and support: This highlights the need for organizational support at several levels for implementation. Rather than managers, champions need to be credible practitioners committed to the new intervention and able to promote its implementation in practice. Champions provide essential facilitation through creating a positive culture around the new way of working, cascading training and support to practitioners working with carers as well as acting as a source of advice. Organizational investment in the role is crucial to ensure champions are supported and have the necessary resources but also that the role continues even if the original post-holder moved on.

Pathways for communication about carer assessment and support: Different communication processes are important to embed and sustain new ways of working. This needs to operate both between and within different organizational levels. Two-way processes are required: (top down) from service leads and champions to communicate what is expected of practitioners and to provide help and advice, but also (bottom up) feedback by practitioners who are implementing a new intervention about what is helping or hindering its use in practice. Putting in place peer discussions for problem solving and sharing of good practice provides further opportunities to support a different way of working.

Procedures for monitoring/auditing processes and outcomes of carer assessment and support: This is not always well done within palliative care services; yet these are key organizational activities for internal purposes to measure progress towards targets and review work done by the services in supporting carers. Crucially, these processes can communicate impact of service delivery on carer outcomes, demonstrating achievements in carer assessment and support to external agencies such as commissioners of palliative care services and other funding bodies.

Overall, achieving comprehensive, person-centered assessment and support for carers is not without challenges for palliative care delivery. The first main challenge is that this way of working with carers is not commonplace: It represents a substantial change in practice for end of life care, not just for practitioners directly supporting carers but for organizations in terms of the structures and process that need to be in place. The ten recommendations identify the building blocks to achieving the necessary organizational changes. There is, however, a second and perhaps more difficult challenge of addressing the question of where carers "fit" within palliative care provision. Since its beginnings, palliative care has had an ethos of services being there for the carer and family, not just the patient. While this is a strong philosophy, its translation into practice is hindered by the many issues underpinning the ten recommendations. If carers are to be identified, assessed, and supported in end of life care, the fundamental question of whether or not they are to be viewed as true clients of services (and therefore their care and support can become legitimized through commissioning and funding processes) has to be addressed.

10 Conclusion and Summary

This chapter has shown that family carers provide vital support for patients towards the end of life. Formal services clearly have an essential part to play, but resource constraints mean that the time and support they can provide will always remain limited. Family carers therefore undertake the main bulk of patient care and support and make care at home viable. Our dependence on carers is likely to increase in light of a projected increase in the older population and number of deaths.

Carers suffer adverse consequences from caregiving, particularly in terms of their mental health. The prevalence of clinically significant psychological morbidity among carers during end of life care may indeed be so high that it can be deemed a public health problem. However, there is considerable individual variation in who is most affected. While the patient's disease burden and hours of caregiving have some impact on carers' health, impact also depends on carers' demographic characteristics and context, and in particular on carers' own subjective appraisals and preparedness for caregiving. This indicates that there is considerable scope for intervention.

In terms of what may help, carers support needs fall into two broad areas: firstly, they need support to enable them to support the patient, in their role as "co-workers"; secondly, they need support to look after their own health and wellbeing, as "clients" in their own right. Both areas need to be addressed if we are to fully support carers. It is important to realize that the type of supportive input carers need in each case varies greatly from individual to individual, and that "one size does not fit all." This implies that it is important to take an individualized approach to carer support and to ensure that the assessment of carers' support needs and identification of what supportive input would help, is carer-led.

Reviews indicate that interventions to support carers so far have had fairly limited success. Part of the problem may be that interventions have not been specifically designed to support carers or that what is provided has not matched what carers actually need. Again more individualized interventions that encompass a broader range of needs appear to be more successful. Further, any intervention should be designed with carers' situation and concerns in mind and include meaningful carer involvement in its development.

Individualized, tailored intervention is difficult to achieve without some form of assessment of need. This may be in the form of assessing which carers are suffering critically high levels of adverse impact on their health and wellbeing and focusing efforts on these carers. However, this still requires identification of what intervention is appropriate. Assessment may also be in the form of directly assessing what carers say they need more support with, to enable more direct and potentially more preventative interventions with carers. However, assessment in itself is not likely to be beneficial without subsequent discussion and follow up.

If we are to implement carer support within mainstream palliative care practice, this is likely to require a considerable change in practice which entails a whole-systems approach to implementation. Such a whole-system implementation would need to encompass organizational procedures for identifying carers and recording carer information, as well as protocols for how to support carers. To implement and sustain such a change, wider organizational support is also required in terms of leadership, staff training, champions for driving change forward, protected time for supporting carers, communication pathways, and procedures for auditing and monitoring change.

However, the fundamental, underlying question that needs to be addressed if we are to provide consistent, meaningful carer support within palliative care is where carers fit within palliative care provision. We have to decide whether supporting carers is simply an add-on which only is covered on a more intermittent basis or whether it is part of "core" business which is consequently funded and has protected time.

Abstract

Volunteers are key members of the hospice and palliative care team. In some countries, they are the only source of care provision for a person at a palliative stage of a disease. This chapter highlights both the importance of volunteers in these settings and the impact their contribution makes to care. The chapter covers the definitions of volunteering, the historical development of volunteering in hospice and palliative care, as well as research evaluation to document volunteer practice, an understanding of their distinct role in patient and family care, and assessment of their impact on patients and their families experience. The chapter also provides five case studies from volunteers across the world on their experiences in volunteering.

1 Introduction and Aim of the Chapter

Like the concepts of hospice and palliative care, volunteering can be described variously. For volunteering what is distinctive and important in these settings is that volunteering is inextricably linked to the development of the modern hospice and palliative care movement. Volunteering is also distinctive and important in hospice and palliative care because of the breadth and depth of volunteer involvement not only in directly supporting the provision of care but in leading some services, in administrative roles, in fundraising, and in influencing organization and the care it provides. Volunteers may also have a special and unique role in direct patient and family care. This has been described as "being there," which may involve a social or quiet presence, and a link between the patient and their family and health professionals. Reliance in hospice and palliative care on the work of volunteers is likely to increase with the aging global population and increased recognition of the need to provide access to hospice and palliative care to all irrespective of disease.

Research evaluation in hospice and palliative care is needed to both evaluate what interventions work and what work best and where. Evaluation is also needed to help understand how an intervention may work. Such research evaluation includes the contribution of volunteers. With finite resources in hospice and palliative care and a growing demand for these services, it is important to know how best to involve and support volunteers, to recognize their distinct contribution, and to sustain the large contribution they make in these settings.

The aim of this chapter is to provide an overview of both the importance of and evidence on understanding the role and impact of the contribution of volunteers in hospice and palliative care.

2 What Do We Mean by Volunteering in Hospice and Palliative Care?

Before focusing on volunteering in hospice and palliative care, it is worth considering volunteering more generally in order to gain an

understanding of its breadth, diversity, and complexity. Volunteering means many things to many people. For some, it can be seen as a force for good in making a difference, yet for others it can be a reminder of difficult times, for example, under some communist regimes, where volunteering was compulsory for children and adults. As a result, volunteering is often less prevalent in former communist countries. The word "volunteering" in reality encapsulates a diverse range of people of all ages, motivations, skills, activities, and contexts. We will, therefore, explore a number of volunteering constructs before narrowing these down to be clear about what we mean by volunteering in hospice and palliative care in this chapter. The United Nations (UN) describes volunteering as happening at all levels: individual, community, national, and global (United Nations 2015). They consider that volunteering encompasses "traditional forms of mutual aid and self-help, as well as formal service delivery" in addition to "enabling and promoting participation and engaging through advocacy, campaigning and or activism" (p. xiv). The UN defines volunteering as "activities ... undertaken of free will, for the general public good and where monetary reward is not the principal motivating factor" (United Nations 2015, p. xiv). In seeking to apply more generic volunteering definitions to hospice and palliative care, the European Association of Palliative Care (EAPC) Task Force on Volunteering in Hospice and Palliative Care arrived at a specific definition following consultation across a number of countries. They propose the following definition in their EAPC White Paper "...the time freely given by individuals, with no expectation of financial gain, within some form of organised structure other than the already existing social relations or familial ties, with the intention of improving the quality of life of adults and children with life-limiting conditions and those close to them (family and others)" (Goossensen et al. 2016).

Within such a broad definition, there are necessarily many different volunteering models and structures ranging from informal to formal. Informal volunteering may be defined as individuals giving help without payment to others outwith their family (Rochester et al. 2016). This type of volunteering often operates outwith any recognized organization and often within local communities (United Nations 2015). One example of this might be the person motivated by the plight of refugees who travels overseas to provide help as an independent individual, unrelated to any organization. In contrast, Rochester et al. (2010) describe formal volunteering as help for which no remuneration is given, which benefits people or the environment and is undertaken through organizations (Rochester et al. 2016). An example of this would be the person who offers specific help regularly on a voluntary basis within an statutory, not-for-profit, or private organization.

Volunteering in hospice and palliative care is often only understood solely in terms of formal volunteering traditionally seen in many well-resourced countries, and that is provided within a dedicated hospice, at home, or in specialist units within a general hospital. This is typified by a hierarchical structure within which volunteers are managed by paid staff, work regularly in specified roles within limited and boundaried activities. This structure, however, does not include all possible ways of volunteering in hospice and palliative care in different countries. For instance, the community (and volunteer) led approach to volunteering in hospice and palliative care as seen in countries such as India or Africa and the "almost-at-home-houses" well established within the Netherlands (Kiange 2018) in addition to those within the UK such as Hospice Neighbours and Compassionate Neighbours. In reality, therefore, within hospice and palliative care volunteering in the same way as in the wider context of volunteering, there is a spectrum of volunteering.

What we mean by volunteering in this chapter, therefore, draws upon the definition from the EAPC Task Force on Volunteering White Paper, recognizing that hospice and palliative care volunteering encompasses a broad spectrum of activities and structures ranging from more informal volunteer-led approaches to formal service delivery models (Goossensen et al. 2016). Having arrived at a working definition, the next section

will now go on to consider some of the origins of hospice and palliative care volunteering.

3 History of Hospice and Palliative Care Volunteering

Hospice and palliative care has evolved in diverse ways in different countries, often influenced by culture, society, and available resources (Morris et al. 2013). This can also be seen in the development of volunteering. It is beyond the scope of this chapter to consider this in detail, and so this section will give a brief overview giving examples from a number of countries.

In many countries throughout the world, volunteering is inextricably linked to the development of hospice and palliative care services and the support that the services offer to patients and families. Scott (2015) suggests that volunteers were instrumental in establishing many palliative care services particularly hospices (Scott 2015), while Radbruch and Payne (2010) describe the development of hospice care in general as "a civil rights movement based on volunteering" (Radbruch and Payne 2010) (p. 26). The work of Dame Cicely Saunders, considered by many to be the founder of the modern hospice movement, has been influential in the development of palliative care in many countries. Having worked as a volunteer herself, she was committed to the involvement of volunteers as a fundamental part of St Christopher's Hospice in London, UK, from its inception in 1967 (Howlett and Scott 2018).

A Volunteer in Australia Describes Her Experiences

My journey volunteering began in 2013 when I decided to apply to Concord Palliative Care Unit. I went to the orientation with no idea of what was actually involved but just knew that I wanted to "put back" something into the community. I was excited to be part of the team in palliative care that could make just the smallest amount of difference at a time when both the patients and family were under duress. For 12 months, I did the weekend "jolly trolley," taking around an array of sweets and beverages. It was almost like the naughty trolley and many of the patients loved the fact that even though they were desperately ill, they could sort of cheat a bit and eat and drink things perceived "not allowed." Many times they just loved to chat and pass some time before loved ones arrived. Others shared intimate life experiences and confided their most inner thoughts and frailties. I felt so privileged to not only get a firsthand account of their lives but also to feel like I was in the inner circle. To them they reached out to a stranger and for just a small amount of time felt connected to the outside world, not the new world they had become accustomed to, and had some sort of normality. In turn, each week I would walk away knowing that in some shape or form I had given them just a little respite from their stresses and made them feel like they were important and valued. Many did not have family and friends, and even though it saddened me to think that they were going it alone, they weren't totally alone, because as a volunteer I was there to ensure that they had a helping hand and I was there to listen and also support them in the little time they had. I felt like I was part of one of the most important, intimate part of a patients' life, and it humbled me.

In Austria and Poland, it was volunteers in conjunction with catholic and protestant churches who were influential in establishing hospice and palliative care services (Krakowiak and Pawłowski 2018; Pelttari and Pissarek 2018). In Poland, it is interesting to note that this development took place in the face of significant political opposition (Krakowiak and Pawłowski 2018). In Germany, hospice and palliative care volunteering developed "in parallel" with palliative medicine. Hesse and Radbruch (2018)

describe this as a "citizen's movement" motivated by poor societal attitudes to death and dying (Hesse and Radbruch 2018) (ibid.). Volunteering emerged somewhat differently in Australia where UK hospice models (involving dedicated hospice units within the community) were less common with palliative care considered as a clinical rather than community issue (Huntir 2018). Volunteers, therefore, became involved in hospitals and community health centers or separate not-for-profit organizations with close links to hospital networks (ibid.). In the Netherlands, having considered the UK hospice model, there was a move toward more community-led hospice care (Goossensen and Somsen 2018). While in many countries hospice and palliative care development was a reaction to poor care of the dying, in Africa, the involvement of volunteers was in response to the overwhelming challenge of communicable diseases such as HIV and TB (Kiange 2018).

So far the focus has been on adult services, and it is worth taking a moment to consider what is known about volunteers within pediatric hospice and palliative care. Children's services developed at a later date than adult, when the first children's hospice, Helen House opened in Oxford in the UK in 1982. In the UK, however, the children's hospice and palliative care sector was slower to embrace volunteering than their adult equivalents. Burbeck et al. (2013) suggest this may be due to stakeholder anxiety about the complexity of the children's conditions and the number of professionals already involved in the lives of families caring for a child with a life-threatening and life-limiting condition and issues involved in safeguarding children and young people (Burbeck et al. 2013). Volunteering in this sector has evolved to a stage where currently in the UK most not-for-profit children's hospices and some voluntary and statutory community pediatric palliative care teams now involve volunteers. Likewise in Austria, volunteers often take care of siblings, and there is a special curriculum for volunteers in pediatric hospice and palliative care.

What seems to emerge from this history is the strong influence that people from local communities can have in responding to the palliative and end of life care needs of others.

4 Influences of and on Volunteering in Palliative Care

As we have seen in the last section, volunteers made a significant contribution to the development of hospice and palliative care in many countries. The involvement of volunteers, however, necessarily has significant influence on organizations. As members of the local community offering their time and skills with no expectation of financial reward, volunteers bring a wide range of skills, individual values, and perspectives that affects organizational culture and values. Indeed Scott (2013) identifies a number of key organizational areas which are influenced by volunteers including (1) diversification of available skills, such as professionals providing their skills as volunteers, and service quality, (2) leadership and governance, (3) financial sustainability, and (4) support of local communities and general public (Scott 2013).

This section, therefore, focuses briefly on the role of volunteers (discussed in more depth in further sections) in order to explore how different volunteering activities influence both the care of patients and families and the organization more widely. It is important to recognize that volunteering in turn is also affected by a range of external factors, and this section also explores the ways in which volunteering can be affected by societal and demographic factors.

In considering the diversity of volunteering roles in hospice and palliative care, the EAPC Task Force in Volunteering White paper, as earlier mentioned groups these under three distinct headings: (1) volunteers from local communities who provide direct practical or social support to patients and their families, or who provide other skills to the organization which may include fundraising, administration, catering, and gardening; (2) governance volunteers, trustees, and board members of hospices and other not-for-profit services; and (3) professionals using their professional skills in a voluntary capacity, for example, doctors, nurses, and chaplains (Goossensen et al. 2016). These roles may take place in many different settings including inpatient hospices, day hospices, in the

community in patients' homes, hospitals, specialized units and elsewhere, and care homes (Goossensen et al. 2016).

Volunteers enable hospice and palliative care services to increase the range and enhance the quality of services offered (Scott 2015). A brief scoping of the research literature indicates that volunteers can have a beneficial influence on the care of patients and families; this includes that they can help to make care more person centered and less medicalized (Morris et al. 2015; Claxton-Oldfield 2015a; Block et al. 2010; Wilson et al. 2005; Pesut et al. 2014), while Luijkx and Schols (2009) highlight that volunteers make life less stressful for families caring for a loved one at end of life (Luijkx and Schols 2009). Indeed Herbst-Damm and Kulik's (2005) study found that volunteer support can extend survival time in terminally ill patients (Herbst-Damm and Kulik 2005). A more in-depth discussion of the research evidence on the impact of volunteers in hospice and palliative care can be found in Sect. 6 of this chapter.

The role of volunteers in the leadership and governance of not-for-profit organizations is often little recognized. As trustees (or non-executive board directors), these volunteers carry strategic and legal accountability for ensuring that organizations in particular hospices are effectively run and meet regulatory requirements. Volunteer trustees, therefore, have significant influence on the culture, leadership, and future direction of hospice and palliative care services. It is somewhat perplexing, however, that this voluntary strategic leadership is often responsible for the restrictions and boundaries imposed on other volunteering roles, influencing the activities that volunteers can and cannot undertake.

Morris et al. (2015) suggest that volunteers play a key role in bringing the local community into hospices and in extending the reach of the hospice and palliative care services in supporting patients and families at home (Morris et al. 2015). McKee et al. (2010) suggest that volunteers "inhabit a unique third culture of care" (p. 103) and play a vital role within community networks that enable high-quality hospice and palliative care (McKee et al. 2010). These themes are further explored in Sect. 5.3.

The influence of volunteers extends as already documented beyond patient care, and in some countries, volunteers are also involved in raising awareness of hospice and palliative care and in generating income to support the delivery of services (Scott 2015). Wilson et al. (2005), while recognizing a lack of evidence, suggest that volunteers may be important to the viability of organizations (Wilson et al. 2005). A later research study by Scott (2015) in the UK supports this hypothesis and found that volunteers were essential to the sustainability of not-for-profit hospices, with a number of respondents indicating that without volunteer support, their services would close (Scott 2015).

It is possible, however, that the influence of volunteers may be felt beyond hospice and palliative care organizations. Scott (2015) highlights the role of volunteers in educating the public about hospice and palliative care and including to "dispel myths and taboos" (p. 81) (Scott 2015). For example, in Austria, in common with a number of other countries, this includes hospice and palliative care volunteers going in to schools to talk to children about death, dying, and hospice and palliative care. The Council of Europe (2003) suggests that the role of volunteers in hospice and palliative care "is often underestimated" and contends that volunteers help to normalize dying and contextualize death as a societal rather than solely a medical issue (Council of Europe 2003) (ibid. p. 67).

While volunteering may influence a number of aspects of hospice and palliative care, there are a number of external influences which can impact on volunteering itself including culture, society, politics, legislation, or regulation. Culture affects not only how volunteering is perceived but can also encourage or inhibit the development of volunteering. As noted earlier, the level of volunteering may be affected by political influences, but this is not always the case. Globisch (2005) suggests that there is little tradition in Denmark of volunteering in healthcare settings (Globisch 2005). The reasons cited are the high level of female employment (who at least traditionally volunteered more than their male

counterparts) and resistance from staff in the hospice and palliative care sector (ibid.).

Changes in volunteering are also evident in a number of countries as a result of societal changes. Howlett and Scott (2018) highlight that volunteers in many countries today have less time available and want their time to be utilized wisely (Howlett and Scott 2018). Today's hospice and palliative care volunteers may demand more from their experience than earlier generations. They may be motivated by personal and professional development, seeking responsibility and meaningful activities (ibid.). This poses challenges for hospice and other palliative care organizations which may see the increased involvement of the community as volunteers as key in helping to address the current and future growing demand as populations age.

In the light of these changes in and effects on volunteering, there is perhaps one further influence that is worth considering before leaving this section. The EAPC launched "Voice for Volunteering," the EAPC Madrid Charter on Volunteering in Hospice and Palliative Care in May 2017 (European Association of Palliative Care 2017). The purpose of this Charter is to emphasize the importance of and embed volunteering within hospice and palliative care. The aims of the Charter are:

- Promote the successful development of volunteering for the benefit of patients, families and the wider hospice and palliative care community.
- Recognise volunteering as a third resource alongside professional care and family care, with its own identity, position and value.
- Promote research and best practice models in the recruitment, management, support, integration, training and resourcing of volunteers. (ibid.)

The Charter calls for organizations to recognize the role of volunteers in direct patient care as one of "being there" which is described as focusing on the "human connection on 'being with' the person, that is the basis for sensing what kind of support the volunteer can provide to this particular person at this particular time." Actions outlined in the Charter are targeted at individual, organizational, local, and national levels and encompass areas such as recognizing the role of volunteers, effective management, training, and support, and identify volunteering as a key area for evaluation and research (ibid.).

5 Using Research to Understanding the Volunteers Role in Hospice and Palliative Care

5.1 Why Use Research to Understand the Volunteers Role in Hospice and Palliative Care?

The previous sections have highlighted many aspects of the volunteering in the context of hospice and palliative care such as definitions and the development of the modern hospice movement. They have also raised discussions about the complexity of the volunteering role and the many influences which mold this role, both on a personal (e.g., expectations) and on a wider societal and organizational level. At the same time, little is currently known from a population viewpoint about how volunteers deliver care in hospice and palliative care, in particular the level of activities provided within hospice and palliative care and in what settings do these activities occur? What are volunteers' own experiences? Are they overall good or bad? How do volunteers perceive their role and do they feel adequately prepared to perform it?

It is obviously important to understand these issues. Volunteers are as already stated often a vital resource in the delivery of care. To ensure that they continue to play an active role and do not suffer from burnt-out, research is needed to inform best practice. Although volunteers work has historically been linked closely to the development of the hospice movement (Goossensen et al. 2016), it is important to ensure that volunteers help provide good quality care, especially in an age where there is a growing emphasis on accountability. Within this context and to help plan services for the future at a population, it is necessary to quantify the types of care delivered

by volunteers and in what settings. To help answer these questions robustly, research provides a range of tools.

Firstly, to recap what is research? It is the systematic and rigorous progress of inquiry that aims to describe processes and develop explanatory concepts in order to contribute to the scientific body of knowledge. Conducting good quality research facilitates the production of reliable and valid data from which effective and acceptable decisions can be applied to the broadest set of phenomena. This chapter section explores the research looking at volunteers in patient- and family-facing roles in hospice and palliative care to:

1. Quantify the activities of volunteers
2. Explore the role of volunteers
3. Discuss limitations in current research and to explore potential ways forward in future research

There are, as discussed earlier in this chapter, Sect. 2, different types of roles and settings that volunteers may work in within hospice and palliative care. These differences can be grouped in various ways: (1) community volunteering both in direct patient and family care-facing contact and in indirect facilitative roles, (2) voluntary board membership, and (3) professionals working within their discipline without receiving payment (Goossensen et al. 2016). The focus in this chapter section (and subsequent sections on research) is on research evidence in regard to patient- and family care-facing volunteers in hospice and palliative care settings. This focus is chosen as it is important to understand in what way volunteers have a direct impact on patient and family experience. At the same time, volunteers have unique concerns and challenges that exist in the role of providing care to patients and family in these settings. These include involvement in caring for very vulnerable patients of persons with non-professional training. Research evaluating their role in such care could also help combat any element of resistance and difficulty volunteers may suffer in establishing a link with some paid staff within the palliative care sector. The focus on research in this area is also needed as the number of volunteers is likely to increase greatly due to insufficient numbers of available professional staff to care for the growing demand for hospice and palliative care. Moreover there is now increasingly global interest in understanding the extent and best practice of volunteer involvement in providing this support (Morris et al. 2013) as demonstrated by the EAPC charter for volunteering in hospice and palliative care (see Sect. 4).

It is important to highlight that the focus of this section and subsequent research sections in this chapter aims to provide an international context to research looking at volunteers in hospice and palliative care. However, we acknowledge that most of the studies conducted in these settings have been conducted in Europe, North America, and Australia and may not be relevant to all volunteer hospice and palliative care services in other areas of the world.

5.2 What Activities Do Volunteers in Hospice and Palliative Care Engage in?

Previous studies have grouped the main roles of volunteers in hospice and palliative care in patient- and family-facing roles into five areas: emotional, social, practical, informational, and spiritual (Wilson et al. 2005; Claxton-Oldfield 2015b). Large surveys, e.g., national or international, are important tools in helping to illuminate the broader picture and quantify the breadth and depth of the role of volunteer involvement in patient- and family-facing care, as they illustrate both the settings where volunteers work within hospice and palliative care and the types of activities they engage in within these settings. Several large national surveys have been conducted across different European countries such as the UK, Poland, and Belgium or the various countries involved in the recent EAPC Taskforce initiative on volunteers. These surveys have both confirmed and quantified that most volunteers are involved in a wide range of patient-facing roles, meeting and greeting patients (Burbeck et al. 2014a),

providing emotional support/psychosocial care to patients (Burbeck et al. 2013, 2014a; Pabst et al. 2017; Pawłowski et al. 2016; Vanderstichelen et al. 2017) and bereavement support, feeding patients or cleaning rooms (Burbeck et al. 2013; Pawłowski et al. 2016), and providing a range of complementary and diversional therapies, pastoral/faith-based services, and beauty/hairdressing (Burbeck et al. 2014a).

Two published surveys have looked at where volunteers work by care setting. One within the Flemish healthcare system found that volunteers based in palliative care units were more likely to be involved in direct patient care compared with those based in medical oncology unit. These volunteers were also more likely to be providing psychological, spiritual, and existential care (Vanderstichelen et al. 2017). The other, a UK-based survey of volunteers in adult hospice and palliative care services, found that volunteers were more likely to be involved in day care, bereavement services, and with in-patients, but less likely to be involved in home care (Burbeck et al. 2014a). In looking at volunteer involvement in patient and family-facing care delivery, those working in the voluntary sector (when compared to those working in the statutory sector) were more likely to be involved in the range of specific activities such as creative/diversional therapies, complementary/alternative therapies, counseling, pastoral/faith-based activities, and hair dressing/beauty, and where in many cases, volunteers were entirely responsible for the running of these services (Burbeck et al. 2014a).

A Volunteer in India Describes His Experiences

I head the creative wing to improve the ambience of Institute of Palliative Medicine. Late one evening, while walking to my room passing by the patients' wards, I saw her sitting by the window waving at me with a bright smile. Rishna was suffering from brain tumor. A bright chirpy 12-year-old girl with a sparkle in her eyes who was interested in Art. I had told Rishna that I'd get her art supplies the last time she was here. Now that she was back. I had the art supplies in my room and planned to give it to her on the way back. Something came up and it was too late to visit her. So I kept the supplies in my bag and decided to visit her first thing in the morning.

Next morning I went by her room but she was sleeping. Little did I know that her condition was bad and she was on heavy medication. I went by her room later that afternoon, she was still sleeping. My heart sank a little, but I hoped that next morning she would be better and I would be able to keep my word. Things just got from bad to worse and soon she was terminal. A few days later, she deteriorated progressively never recovering to her former state. I knew that with her condition, there was no coming back, but I never thought, the day I walked past her room would be the last time I would see her smile – her death posed a lot of questions to me – why didn't I give her the art supplies at the moment itself? Why did I put it off? How granted did I take that moment, thinking I would get a chance the next day – that incident taught me the value of a moment – the moment I had lost. It was a learning lesson for me to cherish every moment then on. In our daily life, there are those little moments we take for granted but only realize the value of that moment once it's gone. Later that week I got a call from my friend saying another girl has been admitted in the same room as Rishna was and she is interested in coloring. I went back with coloring supplies!

Most surveys have investigated the involvement of volunteers in adult services, but it is important not to forget the role of the volunteer in hospice and palliative pediatric care where additional potential ethical issues exist in how volunteers are involved given the relatively young age of the population and societal attitudes to caring for this group. Moreover, there are often

general structural differences between children's and adult hospice and palliative care services. For example, in the UK, this care may be delivered to an individual child over a number of years, which in many cases may additionally involve the provision of education and play. Despite the complexities of providing pediatric palliative care, surveys in this area though are extremely limited, with only one study looking specifically at the involvement of volunteers in the delivery of pediatric palliative care (Burbeck et al. 2013). Although this study was conducted in the UK, some limited comparisons can be made with countries which have a similar service provision. In comparing the activities of volunteers between adult and children services, there were common aspects in their roles. In both cases, volunteers' most common activities included greeting visitors to the service, serving meals and drinks in the hospice, and assisting with social activities. In both settings, many of their services provided by the hospices, such as complementary therapies and pastoral care services, were dependent on volunteers running these services. Nevertheless, clear differences existed between volunteers in both settings. The number of volunteers in this UK survey in pediatric services (median 25 volunteers per service such as a dedicated hospice) is small compared to a UK survey in adult services (median 85 volunteers per service) (Burbeck et al. 2014a). Volunteers in pediatric hospice and palliative care were also found to be less likely to have direct patient care contact with children, but more likely to be involved in music and arts-based activities, befriending, and complementary therapies provision for the whole family. They were also not involved in any aspect of home care (Burbeck et al. 2013). In addition to structural differences with adult service, these findings may reflect that pediatric hospice and palliative care is compared to adult care a relatively recent development with potentially few beds available and a volunteer's role which is less well-defined. However, it should be noted that this survey in pediatric services was undertaken over 5 years ago and services have evolved since then. For instance, some community teams in the UK now involve volunteers.

There are difficulties underlying the current published literature in this area. There are as demonstrated few published surveys. The focus of the research questions of some of these surveys do not specifically address the role of volunteers per se but have their focus on topics such as specific training issues for volunteers (Pawłowski et al. 2016) or the role of motivation in volunteers (Pabst et al. 2017). Some surveys are "in progress," published in abstract only thereby lack sufficient detail (Vanderstichelen et al. 2017). Another difficulty, in generalizing these findings on how volunteers deliver patient-facing care in hospice and palliative care, is that different countries have different structural systems and cultural values in how they run their hospice and palliative care services and what is permissible for volunteers to do. It is also important to highlight that the focus in this section is on surveys published in peer-reviewed journals. There will be other surveys documented elsewhere such as "in-house" yearly service surveys. Only surveys published in peer-reviewed journals were discussed in this section because such papers are in general (across all types of research) likely to be of higher quality or reliability than non-peer reviewed as they are published based on approval of a board of professional experts. There may also be other surveys not noted in this section published in peer-reviewed journals, this is as they were not published in English. These restrictions may have limited the findings in this section.

5.3 What Volunteers in Patient- and Family-Facing Roles Within Hospice and Palliative Care Settings Understand About Their Role

The previous section explored the role of volunteers in the context of the activities that they performed in different settings within hospice and palliative care. It is equally important to understand how volunteers see their role. In this section, the perspectives of volunteers in patient- and family-facing roles in hospice and palliative care are explored using the findings of qualitative

designed studies. Although we acknowledge that quantitative designed studies (those that predominantly provide numerical data), particularly large surveys, may be useful in identifying general trends, qualitative research are more valuable in exploring a phenomenon from the perspective of the individuals experiencing it, in this case what volunteers understand about their role, and there are now numerous qualitative studies available exploring this.

In the first part of this current section, the review of qualitative studies by Burbeck et al. (2014b) is critiqued and presented on how volunteers perceive their role and also how other key stakeholders (such as patient and their families and professional staff) perceive the role of the volunteer in hospice and palliative care. In the second part, the results of this review are compared with qualitative studies published since the review.

The Burbeck et al. review uses a qualitative evidence synthesis approach in its interpretation of how volunteers understand their role. The synthesis explores the qualitative analysis from all known qualitative studies (Burbeck et al. 2014b). It takes a thematic approach in the synthesis of the individual studies analysis; in doing so it considers connections, similarities, and differences between the findings of each study. This may identify "higher-order" key themes not identified in any study but only apparent in the pooling of their findings. This can produce a deeper and potentially new understanding of what the volunteers may understand of their role. This review identified 12 studies, mainly from North America (7/12) or Europe (4/12), but with 1 study originating from Uganda. The total sample comprises of 294 participants who were mostly volunteers but also other stakeholders relevant to understanding the role of the volunteer including a patient and their family and hospice and palliative care staff. Most participants were female.

The review identified three theme clusters in the studies. Theme 1 highlights the *distinctness of the volunteers' role*, in which the volunteer saw their role as having an identity separate from paid staff. This distinct role was often described in terms of recognized work boundaries. Volunteers felt they were not restricted in either the tasks or the time they could offer to patients or families in the same way that paid staff were. Volunteers saw their roles characterized by two factors: independence in that the task that they would perform would not be done by a paid member of staff and surrogacy which was possible due to the blurred relationship between volunteers and patients. Within these role characterizations, volunteers act either as "go-between" between the patients and their family and members of staff or as advocates for patients and families in representing the interests of these people. These roles highlight the surrogate nature of the volunteer role, where volunteers potentially become an "additional" members of the family due the person time at the hospice.

Theme 2: characteristics of the role. This theme highlights *the social nature of the volunteer role*, as opposed to being task-orientated. This aspect of the volunteers' role is further illustrated by the value that volunteers feel that they provide patients and family in terms of social support, notably in providing emotional support and "being there" for them. The perceived social aspect was seen as a motivating factor for volunteering in a hospice setting.

Theme 3: volunteers experience of the role, defined in terms of its ambiguity, flexibility, and informality and their relationship with paid members of staff. The synthesis identified *ambiguity in how volunteers understood the role*. Volunteers viewed the flexibility and informality of their role positively, but at the same time, they found it stressful when there was uncertainty around the tasks that they should be doing. The relationship between volunteers and paid staff was central in shaping the volunteers' experience of their role, in particular the way that staff controlled their role by restricting the availability of patient information or treating volunteers as subordinates. The synthesis highlighted tensions between the perceptions of informality of the volunteers' role with the growing formalization of their roles, through the need to be increasingly professionalized, often due to the increased need to work within a legal framework.

This review provides a distinct understanding of how volunteers perceive their role in patient and family-facing settings. It also highlights many issues that planners and managers of hospice and palliative care services may need to be aware of to facilitate the best of volunteers' contributions, namely, that it can be perceived as social in nature and it may also be about dealing with the ambiguous nature of the volunteers' role. This review by including 12 studies of different populations of volunteers, as well as some other key stakeholders such as family members, enabled the role of the volunteer to be constructed from a range of different perspectives. The studies reviewed came from a variety of North American and European countries, which increased the generalizability of the findings to a wide range of healthcare settings. Furthermore, the review explored differences in care settings, with volunteers working in inpatients services adopting a quasi-professional approach to their role while those volunteering in home-based care tended to act more as surrogate family members. Nevertheless, there are some methodological issues that need to be considered when interpreting the findings from this review, in particular the range of questions asked by the researchers from the 12 studies in collecting their primary data where not all directly asking about the role of the volunteer.

Since the publication of the Burbeck et al. (2014) review (Burbeck et al. 2014b), four relevant qualitative studies on volunteers perspectives in hospice and palliative care have been published (Brighton et al. 2017; Dean and Willis 2017; Gale 2015; Söderhamn et al. 2017). The studies are European, three from the UK and one from Norway. Unlike the studies analyzed in the Burbeck review where the volunteers were all from dedicated hospices and palliative care units, the volunteers from two of these studies came from community palliative care (Gale 2015; Söderhamn et al. 2017). These studies have explored the volunteer experience to varying degrees. One study focused on the impact of how working with patients near the end of life influenced volunteers own experience and attitudes toward death and dying (Gale 2015). The second looks at how the experience of volunteers are affected by the training and support provided by a palliative care coordinator (Söderhamn et al. 2017). The remaining two have used the volunteer experience as a means of identifying how to improve training for volunteers working with people with palliative care needs (Brighton et al. 2017; Dean and Willis 2017).

The main findings from these studies chime closely with the three themes identified from the Burbeck et al. review. These include dilemmas around the development of close relationships, friendships, between volunteers and patients (Gale 2015; Söderhamn et al. 2017) and doing tasks not performed by health care professionals (Brighton et al. 2017), "being there" (Söderhamn et al. 2017), and providing emotional and social support to family members (Söderhamn et al. 2017). Nevertheless, the theme of increasingly professionalism and regulation (Gale 2015; Söderhamn et al. 2017) is reflected in the later studies, particularly the importance of volunteers having a clarified role and provided with sufficient knowledge to carry out the task (Söderhamn et al. 2017). Likewise, it is equally important for health professionals to be aware of the volunteers' role (Söderhamn et al. 2017).

A Volunteer in Canada Describes Her Experiences

On a practical level, I have, over the years, been involved with fundraising, for example, the Christmas "Angel's Remembered" campaign, the annual "Hike for Hospice," and giving presentations in the community to bring awareness to the topic and services available. I also teach the "communication with the dying and their loved ones" component of the volunteer training program for a local hospice organization once every year or so. However, mostly I have offered emotional, social, and practical support to patients/clients, for example, accompanying people to medical appointments, taking them for drives, and walking them around

(*continued*)

hospital grounds or their own gardens or homes. I have given hand massages and sometimes used a relaxation technique known as Reiki when requested. I have spent time with the dying person's loved ones listening and talking and listening again to their stories, fears, and concerns for their loved ones and sometimes their concerns for their own future when thinking about their inevitable and impending aloneness. And, last but not least and, by far what I mostly enjoy is the countless hours I have spent just sitting with or at the bedside of the dying person – many of those hours were spent in silence as they lay sleeping or were semicomatose/comatose due to the disease (or more often, due to the drugs used for symptom control of the disease). On these occasions, I will often just touch a hand or a shoulder periodically to remind them that they are not alone. If it is expected to be a long stretch of time with someone who is unconscious, I will take a book with me and during breaks from reading I often find myself watching the breathing patterns and will imagine the person in their life before they entered the final stages. Since we don't currently have any freestanding hospices in our area, I visit people in their homes and the hospitals.

My role as a hospice palliative care volunteer over the last 25 plus years has offered me the opportunity to meet some wonderful people that I likely otherwise would not have met, at a time in their life when they were often the most vulnerable – whether they were the patient/client or the loved one (s). Front-line volunteering has, at times, offered me experiences that have stretched me out of my comfort zone whether through dealing with uncomfortable situations due to stressful family dynamics or because sometimes witnessing the suffering of an individual is just simply almost too much to bare. Then there have been the times when I have felt a bit like a fraud because I've been sure that I have been getting more out of the relationship than I was giving. No matter the situation, every person I have met has taught me something about myself and about life. It has always been a great privilege to be involved – as cliché as that sounds, it's the truth, as anyone who has journeyed with a dying person will tell you. Volunteering in this field has had a profound impact in shaping my life – for the better!

In palliative care, feeling unprepared to perform certain tasks related to their role is a challenge facing many volunteers in direct contact with patients and their families; this includes dealing with imminently dying patients or subsequent bereavement issues with family members (Dean and Willis 2017). Likewise, similar challenges also apply to volunteers working in hospital settings, who, through their roles of acting as hospital guides, chaplain volunteers, and ward visitors and assisting with patient discharge to home, work with patients with palliative and end of life care needs, involving difficult and emotionally intensive encounters (Brighton et al. 2017). These studies emphasize the importance of providing good support to its volunteers (Gale 2015), potentially through a mentor (Söderhamn et al. 2017). There is recognition that tailor-made training is an important element to support volunteers carry out their role (Brighton et al. 2017; Dean and Willis 2017).

5.4 Limitations of Research on the Volunteers' Role in Patient and Family-Facing Support in Hospice and Palliative Care

Studies in this area confirm the broad range of activities that volunteers are involved in and have provided a greater understanding of how volunteers understand their role and how they experience it. Nevertheless, current studies, particularly

looking at the volunteer experience, are limited. The majority of studies have originated from North America, Australia, or Europe (mainly the UK or the Scandinavian countries), with the main findings limited in their generalizability. More studies need to be conducted and published from other European countries and from countries outside North America and Europe. The samples used in these studies have mainly been volunteers, apart from three studies from the Burbeck et al. (2014) review (Burbeck et al. 2014b) which identified three studies exploring either the patient or family members' perspectives of the volunteer role. Although these studies provide a relevant basis to understanding the experience of volunteers, it is equally important to understand the perspectives of all stakeholders, including those who receive care from these volunteers, namely, the patients or their family members as well as those who work closely with volunteers such as nurses. More studies are needed to explore the perspectives of these groups as findings from these groups will enable us to see how they compare with those from volunteer only studies and so build up a wider picture about the role of volunteers in hospice and palliative care. Such an approach has been used in a qualitative study looking at the collaboration between volunteers and staff in a pediatric palliative care unit, which identified communication, particularly good information flow as a key factor in successful collaboration between volunteers and staff (Meyer et al. 2018).

The qualitative studies identified have all used interviews or focus groups to collect their data. While these methods can allow a wide range of topics to be discussed, there are several limitations. Although the interviewees have some flexibility in responding to interviewers' questions, the interviewers/researchers exert control in determining what topics are covered during the interviews or focus groups and how they are discussed. There is also an assumption in conducting interviews and focus groups that what participants say is what they actually do, but this may not be the case in many situations. Interviews and focus groups, by their very nature, do not look at the interaction between how participants interact with their social environment. Within the field of volunteer research, other alternative methods may be more appropriate in teasing out the social interactions between volunteers and other potential stakeholders such as patients, family members, and health professionals working in hospice and palliative care institutions. One such method is ethnography, where the researcher participates openly in the field they are studying and immerses themselves in that social environment, observing the interactions of the topic being explored and recording detailed field notes. This methodology is useful in examining health beliefs and the organization of health care. Although time-consuming, such studies would provide a deeper and richer understanding of how volunteers in hospice and palliative care interact with other agencies.

6 Using Research to Understand the Impact of Patient- and Family-Facing Volunteers in Hospice and Palliative Care

In this section, the focus is on research to assess the impact of patient- and family-facing volunteers in hospice and palliative care settings. The section opens with a discussion on what is the value of evaluating volunteers' involvement in patient care within hospice and palliative care settings. By this, what is meant is on whether the contribution of the volunteer has an influence on the patient or their family, such as in their well-being or care satisfaction. This is followed with an outline on how we may evaluate impact. Presentation and a critique are then made of the findings of studies that have evaluated the impact of patient- and family-facing volunteers in hospice and palliative care. Considering the limitations in this evidence base, the next subsection highlights the challenges in evaluation. The section concludes with discussion on the way forward in assessing impact.

A Volunteer in Austria Describes Her Experiences

Here we are, sitting in a small cafe in the 16th district of Vienna. Mrs. M. sits in her wheelchair, drinks a black coffee, and smokes a cigarette. She starts talking about her uncle's suicide. "You know, he had colon cancer, just like I do. He couldn't bear the pain, the physical limitations and the fear anymore. He had two children and he was Catholic, very religious. I don't know how he could possibly. . .". Tears are flooding her eyes. It's been a year now that I am with her and her family, and it's the first time this strong, brave, and self-reflective woman is crying in my presence. When saying goodbye this day, she shakes my hand longer and more firmly than she usually does. "Thank you," she says, looking deeply into my eyes. This moment makes me realize that I am where I'm supposed to be, doing what matters to me.

During my work as a hospice volunteer, I am honored to experience many situations like this. I feel blessed how much trust, openness, and gratefulness I receive and that I can be there for someone, simply by listening with an open mind and heart. These intimate encounters also allow me to experience myself in a unique way: Being fully present and compassionate, I feel very connected to others, and my experiences and relationships seem more meaningful.

Some other day, I am sitting with Mrs. M. and her husband in their living room. They hardly ever talk about her illness and the impact it has on their lives. During the conversation, Mr. M. looks at me and speaks about how he admires his wife and her strength, what a loving mother she is and how proud he is to be her husband. Mrs. M. sits right next to him and tries to establish eye contact with him. He doesn't react and keeps looking at me, as if he couldn't look at her while saying those words. It feels like magic and I wonder if my presence made this possible. And I am overwhelmingly grateful to witness it.

6.1 Do We Need to Evaluate the Impact of Patient- and Family-Facing Hospice and Palliative Care Volunteers?

In answer to the question on why do we need to evaluate the impact of hospice and palliative care volunteers, let us first take this as a health or social care intervention that involves the contribution of volunteers. If we look broadly at health and social care evaluations, we find that many, be they drug treatments, non-drug, or services, in hospice and palliative care and elsewhere have been implemented without rigorous research to assess their impact. This includes the exploration on the barriers and facilitators to the best implementation in practice of an intervention. In other words, there are interventions that lack sufficient evidence to either recommend or not recommend. In hospice and palliative care because of historic underfunding in research, and because of the complexities in undertaking research in these settings, under-evaluation may be more extensive than in many other areas of healthcare. On the other hand, it may seem intuitive that many healthcare, palliative or otherwise, interventions help and indeed for some evaluation are unnecessary, inappropriate, or even unethical. Many of the most effective treatments have not been the subject of evaluation by controlled trial, including external defibrillation, which is used to start a stopped heart (Howick 2011). In hospice and palliative care, there are clear ethical issues to consider in conducting research that involves withholding from a proportion of the study participants (those in the control or comparison arm of a trial) additional care, which while not of established benefit may be unlikely to cause harm (Casarett 2009). However, without rigorous evaluation, the impact

of interventions on important outcomes is not fully known nor is it known what is the better approach to care. This is not to challenge the value of clinical experience in the provision of good quality healthcare. In the evaluation of care interventions though, clinical judgment does not provide an adequate basis for detecting at population level modest beneficial or adverse effects (Howick 2011). For instance, a review of all published trials on a particular drug or of a new supportive therapy or service perhaps involving a volunteer or a nurse may find a higher rate of adverse events in patients taking the drug or having the supportive therapy compared to those receiving usual care. Unaided by comparative studies, a clinician (who is likely to have seen fewer patients needing the drug or supportive therapy than those participating in trial evaluations) will be less likely to detect this.

The provision of hospice and palliative care varies across countries as does, as demonstrated earlier in this chapter, the role of the volunteer. However, what is consistent is the extensive depth and breadth of volunteer involvement in these settings particularly in the community, in home care, and in dedicated hospice and palliative care facilities. In many countries, the volunteers' contribution was critical to the development and to the sustainability of hospice and palliative care services. In other countries, volunteering is the workforce providing hospice and palliative care. Moreover, alongside the growing global number of older people, there is growing demand for hospice and palliative care. There are insufficient numbers of professional staff to respond to this need, and there may need to be an even greater reliance in many countries on volunteers to help provide care and support. In recognition of this, some governments have endorsed policies that may directly or indirectly promote informal caregivers like volunteers to assume a greater share of care provision at the end of life (Alcock 2010). In parallel, a recent development within hospice and palliative care has been called to adopt the principles of public health to further promote community volunteering to fill the growing gaps in professional support services (Abel and Kellehear 2016). Thereby to identify and accelerate best practice, there has never been a more pressing time for the need to have robust and relevant evaluation of the impact of volunteers in hospice and palliative care.

6.2 How Do We Evaluate the Impact of Patient- and Family-Facing Volunteers in Hospice and Palliative Care?

In answer to the how do we evaluate, firstly we should consider what we should evaluate. A starting point is to consider why patient- and family-facing volunteers are needed in hospice and palliative care. The reasons include as noted earlier, but are not limited to, to enable services to be provided, to allow finite resources to go further, to involve the community, and to provide more holistic care. It is also worth considering to whom patient- and family-facing volunteers make a difference. This could be as already noted the difference made to patients and their families experience. It could also be the difference made to volunteers, the difference made to the local community, and difference made to the organization (e.g., organizational capacity, staff able to focus on specialist roles, reaching more people, and in providing a wider range of services). Exploring all these points though is beyond the scope of this chapter. They are noted here to highlight some of the broad scope of what could be evaluated.

There are various study designs that can be used to measure volunteers' impact on patient and family experience. Randomized controlled trials (RCTs) are considered the gold standard to evaluate the effects of an intervention. This study design more than any other reduces the risk of biased results. However, for various reasons including ethical, there are limited numbers of RCTs in hospice and palliative care. These reasons will be discussed further later in this section. There are though other designed studies that allow, although to a lesser extent, the evaluation of the impact of an intervention to be measured. This is by comparing, like a RCT, one group that experienced the intervention of interest, here

volunteers, with another group who do not experience the "volunteer intervention." These include a range of different designed studies such as quasi-randomized controlled trials, controlled before-and-after studies, and interrupted time series.

The work of Methods Of Researching End of life Care (MORECARE) project aimed to provide evidence-based guidance on research methods in end of life and palliative care (Higginson et al. 2013). One of their recommendations, it is important to note here, is for the use of research exploring patient and family experience in intervention development. These experiences can be gathered via qualitative research methods which are extremely useful in understanding the mechanisms behind what any intervention may achieve.

6.3 Differences Made to Patients and Families in Hospice and Palliative Care: Choice of Outcomes

Comparative studies, such as trials, can tell us a lot about a whether a treatment works, whether it is cost-effective, and whether it causes no serious harm. What such a study can tell is dependent on the outcomes selected. The impact assessment of many care interventions in hospice and palliative settings is characterized as involving a range of different measures. For instance, in a Cochrane systematic review on the effectiveness of home palliative care services, there were eight items of interest in regard to whether the service made a difference to the patient and their family. These items were satisfaction with care, symptom controlled, physical functioning, quality of life, time spent at home, death at home, and caregiver pre- and post-bereavement outcomes (Gomes et al. 2009). Multiple outcome assessments may be undertaken in a study in part as it may be unclear what outcomes an intervention may impact on. It is also because in hospice and palliative care, the impact of many interventions is known to be broad, and one outcome measure is insufficient to assess this. Take, for instance, how palliative care is defined by the World Health Organization (WHO). This is as an "approach that improves the quality of life (QOL) of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" (World Health Organization 2018). Since it is a goal of palliative care, it would seem appropriate that a key outcome to evaluate the impact of the involvement of patient- and family-facing volunteer is patient and family QOL. But assessment may also include other measures to assess prevention and relief of suffering on varied domains (e.g., pain, other symptoms, emotional, social, and spiritual). This broadness, though, is not the only thing that is not straightforward in hospice and palliative care research. Outcome assessments are complex because of the changing nature of the patients' condition and its impact on symptoms and physical, emotional, social, and spiritual needs. Moreover, in hospice and palliative care where a person's health is deteriorating, in regard to the assessment of QOL, for example, you may not necessarily be focusing in measuring whether the intervention leads to an improvement or not. Evaluation of an intervention may be on measuring whether it limits decline or halts decline in QOL.

The role of a patient and family-facing volunteer can be considered, as discussed in Sect. 5, as distinct from those of healthcare professionals and families role in caring and support. If we follow an overarching theme in the qualitative literature of "being there," then perhaps we have another way we should evaluate the impact of volunteers, namely, on outcomes relating to the social nature of the role of the volunteer. Another complementary way to identify relevant outcomes to assess what the benefit of patient- and family-facing volunteers in hospice and palliative care is what patients and families value in the involvement of volunteers? However, there a few qualitative studies specifically exploring the experiences of patients and their families on receiving support from a volunteer. One qualitative study conducted individual interviews with ten bereaved women

(Weeks et al. 2008). The overarching theme that emerged in their analysis was that volunteers had a unique social role in care:

> And I think, for [my husband], the fact of having somebody from outside, not just staff, is important. I think the staff that deal with you all the time, there is some humiliation in your situation that staff has to deal with at another level, his physical needs, so this is strictly someone to talk and be there, a friendly face, a kind face. (Bereaved wife Weeks et al. 2008)

6.4 What Is the Best Evidence on the Impact of Volunteers in Hospice and Palliative Care?

There are few comparative studies that have evaluated the impact of patient- and family-facing volunteers in hospice and palliative care (Candy et al. 2015). Of these, there is only one known RCT (Walshe et al. 2016). Other comparative studies include retrospective studies of datasets (Block et al. 2010; Herbst-Damm and Kulik 2005). In two of these three studies, the volunteers who delivered the intervention provided weekly social home visits, of up to 3 h (Block et al. 2010; Walshe et al. 2016). In the other, it is not reported what volunteers did or how often they provided support (Herbst-Damm and Kulik 2005).

The ELSA study was a UK-based pragmatic RCT, a prospective wait-list trial that assessed the impact of volunteer-delivered support services at the end of life (Walshe et al. 2016). The intervention involved volunteers providing tailored face-to-face support to people who were anticipated to be in their last year of life. Support was deemed to be supplementary to usual forms of health and social care. It commonly involved befriending weekly visits of between 1 and 3 h, but it could also involve signposting the recipient to relevant services. The setting was in the community, most commonly this was the patient's home. The intervention was compared to usual care. The primary outcome of interest was the impact on change in QOL at 4 weeks after the start of the intervention. Other outcomes assessed were whether the intervention reduced loneliness, affected the perception of social support, or impacted on the use of health and social care services. The study enrolled 196 patients. It was found that there was no statistically significant difference in impact on change in QOL between volunteer-provided support and those in the treatment as usual trial arm. Overall the trial authors noted that "there were trends in the data in favour of the intervention, but the effect is small, and related to reducing the rate of decline rather than improving outcomes." However, the study was underpowered, and the authors had questions about their choice of outcome measures, in that the one they used may not have addressed QOL appropriately within the context of end of life. Therefore, they concluded the effectiveness of these volunteer services remains unknown.

The Herbst-Damm and Kilik (2005) comparative study undertook secondary analysis of a dataset of survival rates of 290 US hospice patients comparing those who received volunteer home visits with those who did not. Volunteers who provided the home visits were trained to listen, to provide conversation, and to provide if requested personal grooming needs such as trimming nails or combing hair. They found that those who received volunteers' visits ($n = 94$) lived longer than those who did not, on average of an 80-day increase in survival. Specifically, and controlling in their survival analysis for patients' physical status (Karnofsky score at study entry), they demonstrated (using Cox's proportional Hazard Model) that neither marital status nor gender independently predicted survival, but the survival rate for those receiving visits was almost three times that of those who were not visited by a volunteer (likelihood ratio, 2.9; p value <0.001).

The third comparative study was by Block and colleagues. It compared satisfaction with care of (United Nations 2015) families whose relative received care from hospices that involved greater volunteer involvement in direct care with (Goossensen et al. 2016) those who received care in hospices with less volunteer involvement (Block et al. 2010). The study using the US National Hospice and Palliative Care Organization National Data Set (NDS) undertook a secondary analysis of hospice programs using the number of direct patient care volunteer hours.

These programs provide support in the home, freestanding hospices, hospitals, nursing homes, and other long-term facilities. The data did not provide detail on what the volunteer involvement in care entailed. Obtained using information from 57,353 individuals from 32% ($n = 305$) of hospice organizations that provided data for the NDS were families' perception of the quality of care. They analyzed "excellent" ratings of care by the number of volunteer hours reported by hospices using a multivariate analysis model that adjusted for hospice characteristics, such as the number of care staff (full-time equivalents) and patient characteristics (diagnosis and hospice length of stay). They found statistically significantly more relatives rated care as "excellent" in those hospices reporting the highest number of volunteer hours per patient week (3.3 h), compared with those reporting the lowest number of hours (0.245 h); coefficient, 6%; and 95% confidence interval, 4–9%.

In conclusion while the RCT found limited evidence of benefit, the other two studies of weaker design report statistically significant positive outcomes in the involvement of patient- and family-facing volunteers in hospice and palliative care. There are limited conclusions to be drawn as the evidence base to date is of low quality. This is as the studies were few, the studies differed in setting and evaluation, and for two the research design was at a higher risk of biased results. While there remains as there is for volunteer-delivered service elsewhere limited evidence on their efficacy (Jenkinson et al. 2013), there are some relevant comparative studies underway. This includes, for instance, in Ireland a pilot randomized trial of a volunteer-led community social and practical support intervention for adults with life-limiting illness.

6.5 Challenges and Way Forward in Evaluation of the Impact of Volunteers in Hospice and Palliative Care

There is a paucity of well-designed evaluations on the impact of hospice and palliative care, not just in services involving volunteers in these settings. There are many methodological and ethical challenges in evaluation in hospice and palliative care (Krouse et al. 2004). The ethical issues, while not unique to these settings, may be more compounded in these settings. The population is vulnerable, and for which inviting and seeking consent to be part of research is complicated because of emotional distress, potential decline in mental capacity, invasiveness of treatment, and physical and mental burden of taking part in an evaluation. In trials, there is also the issue of the "no treatment arm." This is the risk that those allocated to this arm of the trial will receive suboptimal support and care. Although one could argue the other way around, those in the intervention may receive suboptimal support and care. There are other methodological issues that while may not be unique to hospice and palliative care, they may be more extensive in these settings. This includes heterogeneity in population; patients may be dying from a broad range of diseases which have different rates of progression. This if not considered in planning and analysis may lead to bias results. In a trial, for example, this is when in one arm there are a higher proportion of the participants despite randomization have a disease with a shorter prognosis (Hoerger 2017). Results are also at a risk of biases as in these settings as there are often high attrition rates due to declining physical or mental incapacity or death. Other issues include the need for surrogate respondents and difficulty as already noted in selection of outcomes.

This is not to suggest there are no trials. For instance, although disappointingly, a recent systematic review on the association of palliative care and patient and family caregiver outcomes was unable to draw strong conclusions on impact even though it included many trials (Kavalieratos et al. 2016). It included several combined analyses (meta-analyses) of data from up to 13 RCTs. Its conclusion was limited because of issues in the trial evidence including heterogeneity of outcome measures and poorly conducted trials.

So are these challenges insurmountable for research on impact of patient- and family-facing volunteers in hospice and palliative care? It is

worth remembering that hospice and palliative care research is a relatively new endeavor, but at the same time, there is a growing body of researchers and hospice and palliative care research groups around the world who are successful in attracting competitive research funding (Johnson et al. 2017). While there is a need for more focused research attention to better understand how to maximize their contribution while providing better support for volunteers' (Pesut et al. 2014), there are groups exploring how to improve research methods in palliative care (Higginson et al. 2013). This includes the authors of the one RCT of a volunteer intervention in palliative care, they highlight the use of wait-list controls to overcome issues of withholding a potentially beneficial intervention to people who have shorten lives, and they also recommend to enhance completion and reduce attrition and ease of ethical approval short and easy to complete measures (Walshe et al. 2016).

7 Training of Volunteers in Hospice Palliative Care

This section focuses on the training of volunteers in hospice and palliative care. It begins with a discursive section which poses questions on the need to train volunteers. This is followed by a brief exploration of the tensions that exist between training volunteers to be effective in their roles while nurturing the humanity and freedom that characterizes volunteering. This section concludes by examining the limited evidence base on volunteer training in hospice and palliative care and considers the way forward.

7.1 Why Do We Need to Train Volunteers in Hospice and Palliative Care?

There is limited research evidence in the field of hospice and palliative care on the effectiveness and value of volunteer training (Dean and Willis 2017; Horey et al. 2015). Despite this, it is accepted in many countries that training volunteers in hospice and palliative care is good practice, and it is likely that there are few instances where volunteers receive no preparation or training whatsoever. At a minimum, volunteers are likely to receive an introduction to the organization and guidance on the boundaries of their role (Brighton et al. 2017; Dean and Willis 2017). So why is it that training volunteers seems to be so embedded in practice? Is it to enable volunteers to be effective and have confidence in their role; to enable paid staff, patients, and families to trust that volunteers have the right skills; or to satisfy legislative or regulatory requirements? Does the training take a theoretical approach or is the focus on helping volunteers to reflect on and develop their natural skills in responding to the needs those they support? In taking a theoretical approach, do we risk volunteers becoming more like professionals and losing their unique role as community "friend" or "neighbor"; what is the role that we need them to play?

In reality, it may be a mixture of some or all of these reasons and approaches to training depending on the volunteer activity, the organizational philosophy and wider influences as outlined in Sect. 4. The Council of Europe (2003) states that volunteers in hospice and palliative care must receive appropriate training and that "willingness to help not enough" (Council of Europe 2003) (p. 67). Radbruch and Payne (2010) take this a step further stating that such volunteers should receive "an accredited instruction course" and receive ongoing training along with supervision and support (Radbruch and Payne 2010). As highlighted in Sect. 5, training has an important role to play in supporting volunteers to carry out their role (Brighton et al. 2017; Dean and Willis 2017), in which effective training programs are important in mitigating stress for volunteers (Claxton-Oldfield 2015b). Volunteers sought flexibility in deciding what topics they wanted to be trained on, according to their interest and need at the time. Volunteers wanted to be taught by highly respected staff working in the field, which was particularly important for those volunteers working in acute hospitals (Brighton et al. 2017). Volunteers did not think online teaching would be suitable as part of their training (Brighton

et al. 2017; Dean and Willis 2017). As part of their training package, volunteers benefitted from shadowing "experienced" volunteers (Dean and Willis 2017) or being followed up by a highly skilled mentor on a regular basis, who would be able to monitor the volunteer's progress or clarify their role (Söderhamn et al. 2017).

The EAPC Madrid Charter on Volunteering in Hospice and Palliative Care considers that the aim of training is to prepare volunteers for the hospice and palliative care environment and to help them to develop their own natural human ability to reach out others (European Association of Palliative Care 2017).

Before moving on to explore volunteer training in different countries, there remains a question about training for the volunteer professional who offers their skill as a doctor, nurse, chaplain, or complementary therapist without payment. What training do these volunteers require? Are there limits to their role enforced either by their professional body legislation/regulation or by the organization? Does the professional need to learn to become a volunteer?

7.2 What Is Happening Across Countries?

In considering some of these questions, it is helpful to explore what is happening in different countries. A study undertaken in Belgium found that 91% of hospice and palliative care volunteers received training, with only 33% of organizations providing mandatory training (Vanderstichelen et al. 2017). Austria, the Netherlands, and Germany have national curricula for volunteering. In Austria, for example, the required basic volunteer training is 120 h, comprising 80 h of theory and 40 h of practice (Pelttari and Pissarek 2018). All volunteers must undertake the basic training with additional training of 80 h (40 theory and 40 practice) for children's palliative care volunteers. Bereavement volunteers must undertake a separate training of 110 h or may add an additional 80 h to the basic training. In the Netherlands, volunteer training is provided over seven sessions and includes online learning (ibid) (Goossensen and Somsen 2018). In Germany, 100–120 h of training is proposed, and funding for volunteer coordinator roles is dependent on volunteers being trained (Hesse and Radbruch 2018).

Canada has a national volunteer training program of approximately 30 h available to hospice and palliative services. Claxton-Oldfield suggests that a typical hospice volunteer training program would include an overview of hospice palliative care, the roles of the multidisciplinary team, volunteer roles, multicultural faith and spiritual perspectives, clinical care, death, dying and bereavement, and communication and coping skills in addition to volunteer policies and procedures (Claxton-Oldfield 2015b).

A Volunteer in Scotland Describes Her Experiences

I have been a volunteer massage therapist within a Marie Curie Hospice for 3 years now. In an earlier life, I was a career civil servant working for the Scottish Government. At age 54, I was given the opportunity of early retirement and that is when my second, and more satisfying, working life began. A few years previously, I had studied in my spare time for a Diploma in Swedish Massage so I decided to build on this by qualifying in sports and remedial massage therapy. I was fortunate to be offered two part-time jobs, one in a private swimming club and the other in a health clinic which is where I gained real experience and honed my skills. For reasons I will explain, I had wanted to be able to offer treatments to patients coping with a cancer diagnosis, and, when I felt I had sufficient basic skills, I was lucky enough to study massage for people living with cancer. I now volunteer 1 day a week at the Edinburgh hospice and treat inpatients, day patients, outpatients, and also carers and bereaved carers.

The first time I had personal experience of the beneficial effects of massage was, sadly, 20 years ago when my late husband

(*continued*)

was receiving palliative care in hospital. His back was often uncomfortable and I used to climb up behind him in his hospital bed and, with no training – and questionable skills! – would knead his muscles and stroke his back to give him relief. In the latter stages of his illness, he loved me gently massaging his feet. When you are in despair and would do anything to help ease your loved one's pain, being able to do even these small personal things for him helped me cope too. I think, even then, I had made up my mind that this was something I'd like to do for others although it was many years before I felt emotionally able to do so. Although my husband had no hospice care, members of my family and two close friends did, and I had seen firsthand how wonderfully caring the whole environment is and, particularly, how special the staff are who work there. When I got the opportunity to join them, I was delighted. I had not expected it to be easy, but, initially, I struggled quite badly with my sadness for both the patients and their loved ones and my mind and dreams were full of some of these people for days after my weekly session and sometimes longer. Fortunately, I was well supported by both staff within Marie Curie and fellow therapists and began to realize that these were common emotions and that being able to discuss coping mechanisms with others was invaluable. As time passed, while still very moved by particular people and their situations, I found myself able to put my emotions in perspective and just feeling glad that I can help in some small way. Being invited into patients' lives at this poignant stage and knowing that the gentle touch massage gives some pleasure and relief from pain and discomfort in their final days feels such a privilege.

I have also found that my role extends beyond that of massage therapist particularly when treating carers and people who have been bereaved. It may be the safe, warm, and welcoming environment in which we see people or just that they feel able to talk freely to someone outwith their family, but I find that a significant part of my job is listening to their troubles and fears and empathizing and supporting them where I can. I love working with the patients at Marie Curie. There are some tears but lots of laughter and lightheartedness too, and I gain so much more from being there than I give.

Without a national volunteer education program in the UK, it falls to individual hospice and palliative care organizations develop their own training courses for volunteers. However, anecdotal evidence suggests that training topics are common to many organizations and are very similar to those delivered in Canada as outlined above. In addition organizations may require volunteers to undertake some core mandatory training relevant to their role such as infection control, health and safety, moving and handling, and food safety. Resources have recently been launched for community children's palliative care volunteering in the UK entitled "Together We Can"; these online materials from Together for Short Lives include a six-module training program of approximately 21–24 h.

Australia offers a Palliative Care Training Resource Kit in addition to a handbook for Palliative Care Volunteers. The length of training is determined by the needs of the service and varies from 2 to 8 days in length (Huntir 2018). The context in the USA is somewhat different as volunteers are a mandatory part of hospice and palliative care for any hospice that receives payment from Medicare (Brock and Herndon 2017). Under this provision, the training of volunteers is required but not prescribed. However, a 16 h training program is suggested by the National Hospice and Palliative Care Organization. They suggest that this should include hospice ethos, services and aims, confidentiality, protecting the rights of patients and families,

family dynamics, understanding the impact of dying, death and bereavement, and coping strategies. In addition, volunteers should be clear about their role, accountability and reporting structure.

It might be considered, therefore, that the training is firmly embedded within the concept of hospice and palliative care volunteering. It is interesting to note that this extends to community-driven hospice and palliative care services. For example in Neighbourhood Network in Palliative Care in Kerala in India those interested in helping receive 16 h of training (Kumar and Numpeli 2005).

7.3 What Do We Know About the Impact of Training

A review published in 2005 sought to describe the dominant topics in research literature on volunteering in hospice and palliative care. The review focused on publication years 1988–2004 (Wilson et al. 2005). Of the three overarching themes identified in the literature, one was on descriptions of volunteer training programs and training needs. Ten years later, a Cochrane systematic review sought to evaluate the effect of training programs for volunteers in patient- and family-facing roles in hospice and palliative care (Horey et al. 2015). This review focused on comparative prospective studies, such as RCTs. They sought evaluations of training programs according to any stated or implied purpose: of whether the program was intended to build skills for the volunteer's role, to enhance volunteers coping, or to maintain service standards. No relevant well-designed studies were identified. In their conclusions, they highlight that they excluded some comparative prospective trials on volunteer training in this setting (this is because of limitations in the trial design prevented meaningful comparison between those who received volunteer training and those who did not). This they suggest indicates that rigorous research in this area is possible. Although since this publication to our knowledge there have been no new trials published.

8 Conclusion

This chapter has explored volunteering from both practice and research perspectives in both adult and children's hospice and palliative care. While countries and cultures may approach hospice and palliative care differently, there is a surprising similarity in the roles and involvement of volunteers. Research suggests that their roles are distinct from those of paid staff; they are perceived by volunteers as less task oriented and more social in nature. Their activities are diverse, and volunteer presence in hospice and palliative care spans many different contexts in which care is delivered. Volunteering is not without its challenges, however. Research shows that volunteers themselves sometimes feel unprepared for what they face highlighting the importance of good support and training. There is much anecdotal evidence but a paucity of empirical evidence on the impact of volunteering in hospice and palliative care and of the content and effectiveness of training. This chapter has also explored the ethical and research challenges of identifying and measuring outcomes for volunteering and concluded that these are not insurmountable.

Clearly embedded in the history and development of hospice and palliative care across many countries, volunteering plays an essential role in contributing to leadership, fundraising and governance, patient and family experience, and public education. Volunteers, as community members, play an important part in helping to normalize death and dying as a social issue. If we are serious about delivering truly holistic hospice and palliative care to patients and families, we need to recognize and address the vital role played by volunteers.

Abstract

There is a growing trend in oncology, both in research and in clinical practice, toward the early integration of palliative care into regular oncology treatment, from diagnosis of advanced cancer onward. This new care approach has been developed to tackle two major problems insufficiently addressed by traditional methods which seriously affect the quality of life of advanced cancer patients – the undertreatment of symptoms

and the overtreatment of the cancer itself. Although these problems can also be observed in other life-threatening diseases such as heart failure and dementia, the early integration of palliative care is gaining ground particularly in oncology, as the specific, more recognizable symptoms of advanced cancer and the relative predictability of time of death make it more suitable for early palliative care.

Recently, several models of the early integration of palliative care into regular oncological health services have been developed. In some of these models, the oncologists themselves are responsible for the palliative care of the patient during the illness trajectory, and in others specialist palliative care teams are integrated into regular oncology care. There is accumulating evidence that supports the value of early integration of specialist palliative care teams both in outpatient and inpatient settings. However, despite this evidence, palliative care is still largely seen, and applied, only in the later stages. In this chapter, several barriers to the early integration of palliative care related to healthcare professionals, to patients and family, and to the healthcare system itself are identified and discussed.

1 Introduction

There is a growing trend in oncology, both in research and in clinical practice, toward the early integration of palliative care into regular oncology treatment, from diagnosis of advanced cancer onward. This trend is in accordance with the 2002 definition of palliative care by the World Health Organization (WHO) which clearly states that palliative care is applicable early in the course of a life-threatening illness, in conjunction with disease-modifying and life-prolonging therapies, and is not limited to end of life or terminal care when death is likely to occur within a few days or weeks (WHO 2002). According to the WHO, the goals of palliative care, such as improving quality of life through comprehensive symptom management and patient and family support, are ideally applied throughout the trajectory of a serious illness like an advanced cancer. More recently, in 2016, on the basis of accumulating evidence, the American Society of Clinical Oncology (ASCO) issued an official guideline stating that inpatients and outpatients with advanced cancer should receive dedicated palliative care services, early in the disease course, concurrent with active treatment (Ferrell et al. 2017). With this, an important step has been taken toward actual integration into clinical practice.

Figure 1 describes the new model of early integrated palliative care; this differs from the old but still much used model in which palliative care is seen as an attachment to the curative and life-extending phase. This figure is an adaptation of the figure that was developed by Lynne and Adamson in 2003 (with permission of RAND Health) (Lynn and Adamson 2003). In the old model, palliative care is only initiated when there are no options left. In the new model, palliative care starts at diagnosis by evaluating whether the patient has palliative care needs. As the disease progresses, palliative care becomes increasingly important, though in a varying way, according to the patient's needs; additionally, it also focuses on those close to the person who is dying, both before and after death.

This chapter discusses (1) which problems in traditional oncology care have led to the development of this new approach, (2) what models of early integration of palliative care in oncology are being developed and proposed, (3) why the integration of palliative care is gaining ground particularly in oncology rather than in other diseases such as heart disease and dementia, (4) what the research evidence says about the early integration of palliative care into oncology, and (5) what the current state of affairs is with regard to the actual integration of palliative care into clinical practice and which barriers have to be overcome in order to improve it.

2 Problems Insufficiently Addressed by Traditional Oncology Care

There are several problems that seriously affect the quality of life of people with advanced cancer which are insufficiently addressed by traditional

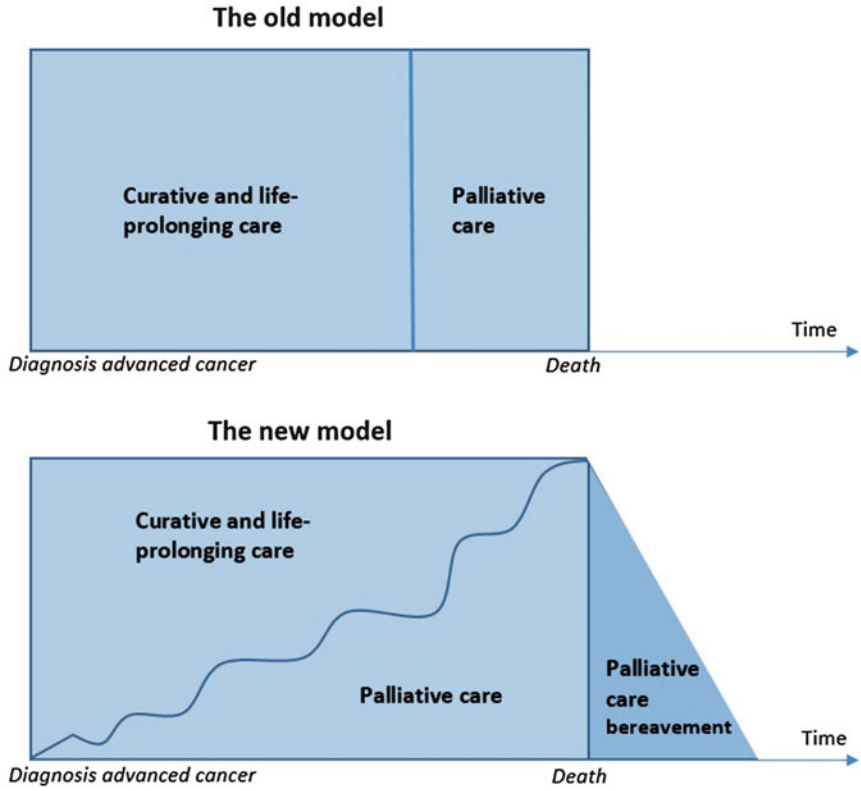

Fig. 1 The old and new model of early integrated palliative care in oncology care

oncology care, a situation that has led to the development of the new approach of early integration of palliative care into oncology care. Perhaps the most obvious of these is that people with advanced cancer with limited life expectancy often suffer from multiple symptoms – on the physical, psychological, social, and existential levels – that appear to be undertreated. A recent study of pain from the USA, one of the most frequent and debilitating of symptoms, shows that of 3123 ambulatory patients with invasive breast, gastrointestinal, or lung cancer, 33% of those who were suffering from pain were receiving inadequate analgesic prescribing, a problem that persisted even after a 1-month follow-up (Fisch et al. 2012). A study in a teaching hospital in Australia examined the treatment of nausea in hospitalized cancer patients and concluded that nausea is often inadequately treated, with more than one third of nauseated patients either not being prescribed an antiemetic or not having taken prescribed medication (Greaves et al. 2009). Studies with regard to other common symptoms in advanced cancer, such as dyspnea, constipation, loss of appetite, and depression, show similar results.

One of the reasons for undertreatment of symptoms is their underdiagnosis; according to a European multicenter study, healthcare providers underestimate symptom intensity in one out of ten patients, with variations between cancer diagnoses (Laugsand et al. 2010). Other related reasons include the strong orientation of healthcare providers toward cure or life prolongation rather than quality of life, a lack of expert knowledge of symptom management, and limited time to spend with patients.

A second problem is that people with advanced and incurable cancer run the risk of overtreatment, of receiving continued burdensome treatment with only marginal positive effect, if any, but with many adverse effects. This has been

demonstrated in several studies; a population-based retrospective study in Ontario, Canada, for instance, used administrative data to examine aggressiveness of end-of-life cancer care. The care was deemed aggressive if there was at least one of the following indicators: the last dose of chemotherapy received within 14 days of death, more than one emergency department visit within 30 days of death, more than one hospitalization within 30 days of death, or at least one intensive care unit admission within 30 days of death. It was observed that almost 25% of patients experienced at least one occurrence of potentially aggressive end-of-life care, and this was most likely in breast, lung, or hematological malignancies (Ho et al. 2011). The researchers also remarked that chemotherapy and intensive care unit utilization was higher in the USA than in Ontario.

This tendency to overtreat can be ascribed to oncologists whose orientation is naturally toward cure and life prolongation, but it might also be related to the wishes of the person who is dying, who may prefer to receive aggressive treatment for as long as possible. However, research shows that the treatment approach has often not been thoroughly discussed with the patient and thus does not always correspond with their fully informed preferences. There is ample empirical evidence that most patients with serious life-threatening illness prefer to avoid hospitalizations and aggressive care when their illness is advanced.

Both problems, the undertreatment of the symptoms and the overtreatment of the cancer, can be tackled by the early integration of palliative care into regular oncological care. The WHO defines palliative care as an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual (WHO 2002). In palliative care the expertise exists to diagnose and treat the many symptoms that advanced cancer patients experience. The focus of palliative care on the quality rather than quantity of life acts as a good counterbalance to the use of possibly futile aggressive treatments. The integration of the two care systems, i.e., oncology with its focus on disease-oriented treatment and palliative care with its focus on symptom reduction and quality of life, can ensure that people who are dying and those close to them receive the best possible care, tailored to their wishes and their needs.

3 Early Palliative Care Is Gaining Ground More in Oncology than in Other Medical Specialties

The early integration of the palliative care model is gaining ground in oncology more than in other medical specialties. This is unexpected because the problems of cancer patients that, as described above, originally led to integrated palliative care do not only affect oncology patients but also others with life-limiting diseases such as heart failure and dementia. Considering heart failure, for instance, a US study compared the symptom burden, depression, and lack of existential well-being of heart failure patients with that of advanced cancer patients and found that both groups had a similar number of physical symptoms, depression scores, and scores for spiritual well-being, after adjustment for age, gender, marital status, education, and income. The authors concluded that heart failure patients, particularly those with more severe heart failure, need the option of palliative care just as much as advanced cancer patients do (Bekelman et al. 2009). Another study in Belgium, Europe, interviewed people with cancer, chronic obstructive lung disease, heart failure, or dementia at different phases of the illness trajectory. They were asked how they experienced the care needs related to their disease from diagnosis onward. The results revealed that various problems and care needs, i.e., physical, practical, psychological, social, existential, and financial, as well as needs for information and communication, were present in every disease group (Beernaert et al. 2016). The needs occurred both in the earlier phases, from diagnosis onward, and in the later phases in the illness trajectory of every disease group.

One explanation for the leading role of oncology in the early integration of palliative care can be found in the specific disease pathway of cancer

compared with other diseases such as heart failure and dementia (Lynn and Adamson 2003). The cancer pathway is characterized by the presence of various symptoms that are highly recognizable and by a relatively predictable time of death. As a result, the match with palliative care is possibly much greater than it is with other diseases. Heart failure usually results in a slow deterioration of the state of health, interspersed with more acute phases of deterioration. Any of these acute phases can result in a more or less "sudden" death. In such patients, there is much less clarity about the imminence of death. The third pathway, dementia, is characterized by a steady period of decline in functional and mental capacity; death itself is usually the result of the occurrence of an acute infection.

The different pathways of cancer, heart failure, and dementia are described in Fig. 2 (with

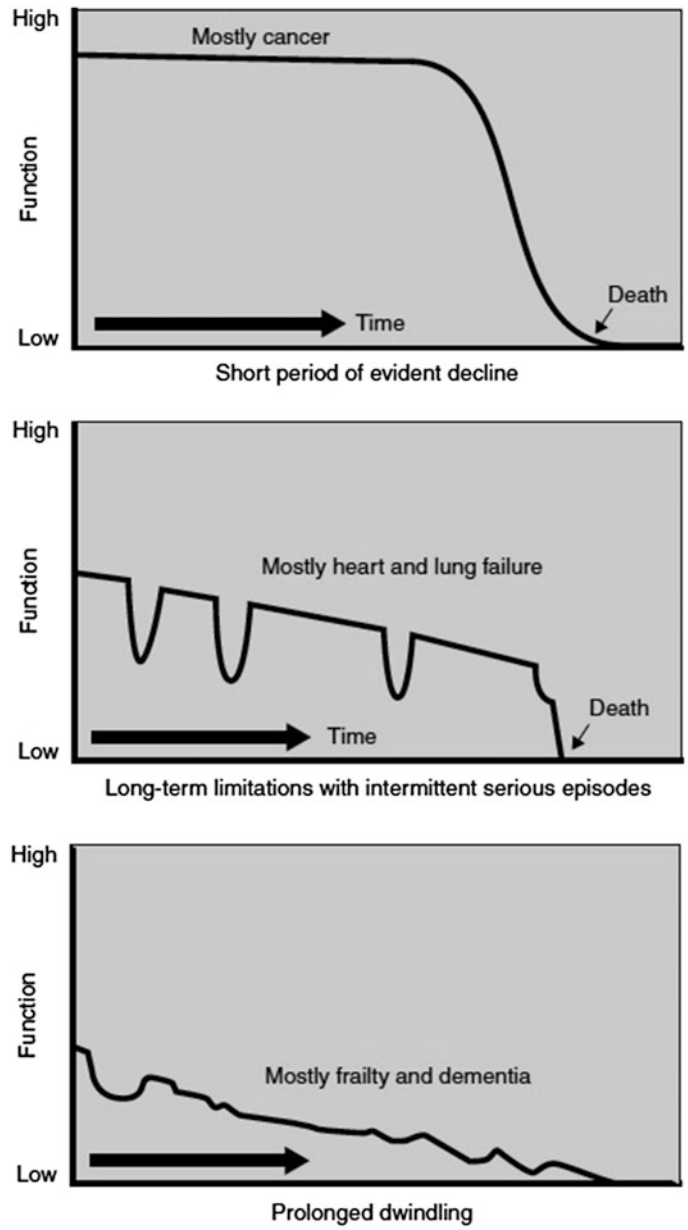

Fig. 2 The typical disease pathway of cancer, heart failure, and dementia

permission of RAND Health). It has to be noted that these disease pathways describe an overall trajectory that is not always applicable to individual patients. This means that even in cancer patients the disease trajectory cannot always be predicted, even with the best prognostic tools and skills. The predictability of the disease trajectory can also depend on the specific cancer diagnosis. The pathway of hematological cancer, for example, is characterized by acute exacerbations and a rapid dying trajectory, resulting in difficulties for hematologists in assessing the right time to refer to palliative care. For some cancer types such as breast and colorectal cancers, there is an evolution toward chronic disease, and the differences with nonmalignant disease have become less. Moreover, the development of new immunotherapies that are effective for some people can add years to a life, further complicating the prognostic estimations of physicians. However, the limited predictability of life-threatening diseases, whether cancer or other conditions, does not need to be a barrier to the early integration of palliative care. Palliative care is in its essence a holistic approach that is focused on the person and not on the disease. This means that it is important in palliative care to evaluate every person separately to assess whether they have palliative care needs and to offer palliative care if indicated, rather than to start from a specific diagnosis.

4 Models of Early Integration of Palliative Care into Oncological Care

Models of early integration of palliative care within regular oncological health services have only recently begun to be developed. Bruera et al., for instance, described three possible models and levels of integration of palliative care services within oncology care: a solo practice model, a congress practice model, and a fully integrated palliative care model (Bruera and Hui 2012). The first, the solo practice model, requires the oncologist to manage all aspects of cancer care, i.e., the treatment of the cancer as well as supportive and palliative care. To be able to achieve this, the oncologist has to fully integrate palliative care knowledge and skills into their daily practice. The second, the "congress" practice model, is one in which the oncologist does not provide palliative care but refers patients to multiple consultants for the management of pain, distress, fatigue, and other symptoms. This requires some knowledge and skills in palliative care by the oncologist as it is important to be able to diagnose the palliative care symptoms of the patient and to assess the need for professional help with these symptoms. The third, the fully integrated palliative care model, is one in which the oncologist focuses on cancer-specific treatments while the palliative care team systematically attends to the patient's physical symptoms and psychosocial concerns. In this model, the oncologist and palliative care physicians comanage care in a complementary manner, thereby reducing the need for the extensive use of outside consultants.

These three models each have their advantages and disadvantages. The solo practice model, for example, has the advantage that both medical disease-oriented care and palliative care are provided by one person, requiring fewer visits for the patient and less coordination between specialists. The disadvantage is that oncologists are often not trained in palliative care and may not always have the time to take on this task. The congress practice model has the advantage that the oncologist can refer to experts and does not need to have all the expertise, but the disadvantage is that there is often limited communication and coordination of care. On the other hand, good coordination and close cooperation are possible in the fully integrated care model, but this coordination can only be effective if good care pathways or protocols are established and followed.

Bruera's three models, however, conceal something that is often mentioned in the literature – the distinction between general and specialist palliative care (Quill and Abernethy 2013). General palliative care is care that is provided by regular healthcare professionals who have basic palliative care knowledge and skills.

In concrete terms, general palliative care would mean that the oncologist engages in systematic basic symptom assessment and management, in discussions about prognosis and goals of care, in shared decision-making, and in timely care planning.

Specialist palliative care involves the separate discipline of palliative care as provided by multidisciplinary teams in hospitals, in outpatient clinics, and in palliative home care. In this case, the palliative care is provided by physicians, nurses, and other specialists who have received special training and whose main activity is to provide palliative care. This form of palliative care is what most people understand as palliative care. Specialized palliative care has become increasingly available in recent years. Researchers at the University of Lancaster, UK, for instance, have identified the existence of 16,000 hospices and/or palliative care units worldwide – standalone units or those attached to a hospital – that treat patients in the final phase of life through the provision of adequate symptom relief (Lynch et al. 2013). The countries in the top category for such provision are Austria, Australia, Belgium, Canada, France, Germany, Hong Kong, Iceland, Ireland, Italy, Japan, Norway, Poland, Romania, Singapore, Uganda, and the UK. According to this WHO-recognized classification, these countries have developed a critical mass in the field of palliative care, spread across various locations within the country. This means there is a complete range of various forms of palliative care from multiple service providers. In these countries both professional caregivers and society and government as a whole are aware of the need and importance of palliative care; there is widespread though heavily regulated availability of morphine and other analgesics. In addition, the specialist healthcare providers are organized into one or more palliative care associations (WPCA and WHO 2014). Unfortunately, there is still a large group of countries, 75 in total, where no center for palliative care exists. These are mainly countries with a low gross national income.

The question arises of which model of early integration of palliative care into oncology is preferable. Much research has been undertaken looking at the third model of full and early integration of specialist palliative care in oncology care, and strong evidence for the effectiveness of this model has been found. However, one clear disadvantage of this model is that it is time intensive and expensive, which raises the question of whether the full integration of specialist palliative care is actually feasible in times of increased aging and increased numbers of chronically ill people. For this reason it has been suggested and argued that the support of a fully integrated model throughout the disease course is not necessary but is only required when the patient develops complex palliative care needs. At other times general palliative care, i.e., that provided by an oncologist who has had a basic training in palliative care, will suffice. In other words, in this scenario the best overall model would be one in which integrated specialist palliative care is being interchanged with general palliative care provided by the oncologist, depending on the complexity and the severity of the palliative care needs of the patient.

5 Research Evidence for the Value of Early Integration of Palliative Care into Oncology

There is accumulating scientific evidence that demonstrates the added value of models of early integration of specialist palliative care provided by an interdisciplinary palliative care team both in outpatient and inpatient settings. Other models of early palliative care in oncology, such as the model of general palliative care in oncology, have not been studied thoroughly, and therefore no definitive statements can be made regarding their effectiveness.

The randomized controlled trial (RCT) studies that have tested the early and fully integrated specialist palliative care model are discussed below. These trials were strongly based on others that studied palliative care in the home or hospital setting but have the specific feature that the palliative care was provided early in the disease trajectory to maximize the beneficial effects on quality of life and symptom burden of the person who is dying and those close to them.

5.1 Temel et al. (USA): Study 1

Temel et al. undertook an RCT with 151 outpatients with metastatic non-small cell lung cancer (NSCLC) who were treated in the thoracic oncology clinic of Massachusetts General Hospital in the USA (Temel et al. 2010). They compared early specialist palliative care integrated into standard oncology care versus standard oncology care alone with no palliative care provision or care provided only late in the disease course. The researchers chose to study newly diagnosed metastatic lung cancer patients because they have a median life expectancy of less than 1 year and experience a high symptom burden.

The early palliative care intervention consisted of consultations with the patient by a member of the hospital palliative care team shortly after diagnosis and at least monthly thereafter. The palliative care team of the hospital consisted of six palliative care physicians and an advanced practice nurse. The consultations were guided by newly developed palliative care guidelines that differed from the existing guidelines for standard palliative care in that the clinicians were specifically encouraged to assess physical and psychosocial symptoms throughout the disease trajectory, to establish goals of care and to assist with treatment decision-making and coordination of care. Table 1 gives an overview of the early palliative care guidelines.

Table 1 Ambulatory palliative care guidelines in the study of Temel et al.

1. Illness understanding/education
Inquire about illness and prognostic understanding
Offer clarification of treatment goals
2. Symptom management – inquire about uncontrolled symptoms with a focus on:
Pain
Pulmonary symptoms (cough, dyspnea)
Fatigue and sleep disturbance
Mood (depression and anxiety)
Gastrointestinal (anorexia and weight loss, nausea and vomiting, constipation)
3. Decision-making
Inquire about mode of decision-making
Assist with treatment decision-making, if necessary
4. Coping with life-threatening illness
Patient
Family/family caregivers
5. Referrals/prescriptions
Identify care plan for future appointments
Indicate referrals to other care providers
Note new medications prescribed

The researchers found that the people in the early palliative care group had a significantly higher quality of life compared with those in the standard care group alone at 12 weeks after baseline. The percentage of patients with depression at 12 weeks was significantly lower in the palliative care group than in the standard care group, but there was no difference between groups in scores for symptoms of anxiety. With regard to end-of-life care, 33% of those who were assigned to early palliative care compared with 54% of the standard oncology group had received aggressive end-of-life care. Another important finding that drew the attention of the medical community was that patients receiving early palliative care had a longer median survival rate than those in the standard care group (11.6 versus 8.9 months since diagnosis). It is not yet clear what precisely causes the increased survival time in the early palliative care group. The researchers concluded that early integration of palliative care for patients with metastatic non-small cell lung cancer is a clinically meaningful and feasible care model that has effects on quality of life and survival that are similar to the effects of first-line chemotherapy.

5.2 Temel et al. (USA): Study 2

Temel et al. then conducted a further RCT with 350 patients with newly diagnosed incurable lung cancer (NSCLC, small cell, or mesothelioma) or non-colorectal gastrointestinal cancer (pancreatic, esophageal, gastric, or hepatobiliary) recruited from the Massachusetts General Hospital (Temel et al. 2017). Patients were randomly assigned to the intervention group providing at least monthly consultations with a palliative care clinician plus usual care or the control group providing usual care alone.

There was no significant improvement in quality of life in the early integration group at

12 weeks after baseline, but there was at the 24-week time point. People in the intervention group also had lower depression at week 24, controlling for baseline scores. At 24 weeks there were also significantly more in the intervention group who had discussed their end-of-life wishes with their oncologist than in the control group. Exploratory analyses of the study outcomes by cancer type revealed important differences in both cancer groups. Lung cancer patients in the intervention group improved in quality of life from baseline to 12 weeks, while those lung cancer patients in the control group reported worsened quality of life. On the other hand, the non-colorectal gastrointestinal cancer patients improved in quality of life in both groups with no differences between groups. Thus, there seems to be a difference in the effect of the intervention depending on cancer type.

5.3 Bakitas et al. (USA): Study 1

Bakitas et al. studied 322 patients with different types of newly diagnosed advanced cancer in a rural comprehensive cancer center, affiliated outreach clinics, and a Veterans Affairs Medical Center (USA). In this study, people were randomly assigned to early palliative care and usual care (intervention group) versus usual care alone (control group) (Bakitas et al. 2009). The intervention consisted of a multicomponent psycho-educational intervention (the ENABLE study: Educate, Nurture, Advise, Before Life Ends) that was given shortly after diagnosis of advanced or recurrent cancer. Trained palliative care advanced practice nurses undertook four weekly educational sessions with the patient and monthly telephone sessions thereafter for follow-up. The sessions focused on patient activation, empowerment, and self-management; patients learned important palliative care principles and crisis prevention through the practice of problem solving, symptom management, communication, and advance care planning. The nurses also had a referring role to other healthcare professionals when this was indicated in order to improve quality of life. Patient-reported outcomes were measured on baseline, at 1 month and every 3 months until death or study completion.

Patients in the palliative care group had significant higher quality of life scores compared with control group patients, better mood, a trend toward lower symptom intensity, but no different resource use (i.e., days in hospital, days in intensive care unit, number of emergency department visits). The survival time in the intervention group was not significantly higher compared with the control group.

5.4 Bakitas et al. (USA): Study 2

Bakitas et al. conducted another RCT later on in the same centers with a similar intervention to determine at what time in the illness trajectory it is best to begin early palliative care; they compared two early palliative care groups, one in which palliative care was begun after enrollment, within 30–60 days (early palliative oncology care), and one in which palliative care was started 3 months after enrollment (still early but delayed palliative oncology care compared with the other group) (Bakitas et al. 2015). The researchers found no significant differences in the patient-reported outcomes of quality of life and symptom impact at 3, 6, and 12 months after enrollment. However at 1 year, a 15% survival advantage was found in the early palliative oncology care group. The precise mechanism of the prolonged survival is not clear yet and can have many possible causes according to the researchers.

5.5 Zimmerman et al. (Canada)

Zimmerman et al. undertook a cluster RCT in the Princess Margaret Cancer Centre in Toronto, Canada, in which 24 medical oncology clinics were randomized to early palliative care integrated in standard cancer care or standard cancer care alone (Zimmermann et al. 2014). A total of 461 advanced cancer patients with solid tumors with a clinical prognosis of 6–24 months participated. The core intervention of early palliative care comprised a consultation and follow-up in

Table 2 Components of the intervention of early palliative care in the study of Zimmerman et al.

1. Within 1 month of recruitment: a multidisciplinary assessment of symptoms, psychological distress, and social support. The duration of this consultation was approximately 60–90 min
2. One week after the first consultation and thereafter as needed: routine telephone contact from a palliative care nurse
3. On a monthly basis: outpatient palliative care follow-up. The duration of these follow-up consultations was 20–50 min
4. 24/7: an on-call service for telephone management of urgent issues

the oncology palliative care clinic by a palliative care physician and nurse. The components of the intervention are described in more detail in Table 2.

The results of the study showed that there was no significant improvement in the early palliative care group compared with the control group at 3 months after enrollment, but there was at 4 months. Their satisfaction with care was significantly better both at 3 and 4 months, and the symptom scores were significantly better at 4 months. There were no significant differences in the specific problems of patients in their interactions with nurses and doctors. Looking at the effects of early palliative care on the caregivers, a significant improvement in their satisfaction with care was observed, while the results regarding their quality of life were inconclusive (McDonald et al. 2017).

5.6 Maltoni et al. (Italy)

Maltoni et al. conducted a multicenter RCT study in Italy of 207 outpatients with metastatic or locally advanced inoperable pancreatic cancer (Maltoni et al. 2016b). The goal was to compare the impact of standard cancer care with systematic early palliative care on the one hand with that of standard cancer care with on-demand palliative care on the other hand. The difference between the two groups was that in the first group all participants received palliative care as a standard, whereas in the second group it was only provided if there was an explicit request from a doctor or patient.

The intervention and trial were very similar to Temel's study. Patients in the intervention arm were given an appointment with a palliative care specialist who used a checklist of topics that were the same as those used by Temel. They were seen every 2–4 weeks until death by a member of the palliative care team. Palliative care appointments and interventions initiated by the palliative care specialist were shared with the oncologist.

Systematic early palliative care significantly improved quality of life 3 months after baseline compared with on-demand palliative care. There were fewer people with depression and anxiety in the intervention group, but the difference was not significant. There was no difference in overall survival between the two groups. With regard to the aggressiveness of end-of-life care, there were differences in favor of the intervention group on some indicators, in particular the use of hospice services and chemotherapy provided in the last 30 days of life (Maltoni et al. 2016a).

5.7 Overall Assessment of Research

When we compare the six trials, there are a number of similarities and differences. Looking at the intervention that was being evaluated, in all studies it involved early integration of specialist palliative care into standard oncological care and consisted of at least monthly patient consultations by a member of the specialist palliative care team. In the studies of Bakitas et al., the first consultations were highly educational, which was not the case in the other studies, and the subsequent monthly consultations were conducted by telephone because of the rural setting in which the study took place. The palliative care guidelines on which the consultations were based were most clearly described in Temel and Maltoni's study. According to these guidelines, the following topics were required to be discussed in the consultations with the person and those close to them: illness perception, symptom management, medical decision-making, coping with the illness, and referral to other healthcare professionals. In the study of Zimmerman et al., the description of the intervention explicitly mentioned – besides the

monthly consultations – the possibility of telephone contact with a palliative care nurse if needed and 24/7 on-call service for the telephone management of urgent issues.

Different patient populations were studied in the six studies. The first study of Temel and the study of Maltoni examined one type of cancer, i.e., non-small cell lung cancer and pancreatic cancer, respectively, both being very deadly cancers with a high symptom burden. In the second study of Temel, two types of cancers were studied, incurable lung cancer and non-colorectal gastrointestinal cancer. In the studies of Zimmerman and Bakitas, a heterogeneous group of patients with different types of advanced cancer were studied. In all studies, quality of life was the primary factor investigated, and an effect was found in all studies. However, this effect was not observed in Temel's second study and in Zimmerman's study at the intended 3 months after baseline, but only at 6 and 4 months after baseline, respectively. It seems that the palliative care intervention may require longer than 3 months before having a noticeable effect on quality of life. The other outcomes that were often investigated in the studies were depression, anxiety, symptom burden, use of resources, and survival time. These outcome measures were sometimes significantly improved in the intervention group compared with the control group, and sometimes they were not, depending on the study. Increased survival time in the intervention group was only significant in the first study of Temel and in the second study of Bakitas.

6 Actual Integration into Clinical Practice: Barriers to Overcome

Despite the established principle of early integration of palliative care in oncology and evidence of its benefits, research evaluating the use and timing of both general and specialist palliative care shows that, overall, it is still both seen and applied as terminal care (Quill and Abernethy 2013; Beernaert et al. 2013; Van den Block et al. 2008). A survey to determine the availability and degree of integration of palliative care services in the USA showed that the median duration from referral to specialist palliative care was 90 days before death for outpatient clinics, 7 days for inpatient consultation teams, and 7 days for palliative care units (Hui et al. 2010). A study on referral practices of oncologists to specialized palliative care conducted in Canada also showed that referral was late in the disease trajectory for patients with uncontrolled symptoms (Wentlandt et al. 2012). In Belgium, about 60% of patients who did not die suddenly of cancer were referred to a palliative care service, and for about half of those, this was less than 20 days before death (Beernaert et al. 2013).

Using specialist palliative care does not, of course, necessarily reflect whether or not palliative care was being provided, as regular care could also have been aimed at improving the quality of life of patients and those close to them by addressing their palliative care needs. There are however several studies that indicate that this is not the case. Mortality follow-back studies in Belgium, for instance, have looked at the type of care delivered in the final 3 months of life and demonstrated that, in a majority of cases, the aim of care shifted to comfort or palliation only in the final weeks of life (Beernaert et al. 2013; Van den Block et al. 2008).

Several studies have been done to examine why palliative care is often offered only very late in the disease trajectory when death is imminent, if at all. Three types of barriers have been identified that play a role in the lack of early integration of palliative care in oncology – barriers related to the healthcare professionals, barriers related to the person who is dying and those close to them, and barriers related to the healthcare system.

6.1 Barriers Relating to Healthcare Providers

At the level of healthcare providers, one of the main barriers is the fact that many oncologists still have the idea that palliative care equals terminal care and that palliative care thus only needs to be initiated at the end of life. In order to address this barrier, it is important that healthcare providers become well-informed about the benefits of early

palliative care, both through scientific literature and textbooks such as this one and through their own professional organizations. A good and important step was taken by the American Society of Clinical Oncology (ASCO), which established a provisional clinical opinion in 2012 based on the first RCT study of Temel stating that patients with metastatic NSCLC should be offered concurrent palliative care and standard oncologic care at initial diagnosis (Smith et al. 2012). By 2016, ASCO updated this provisional clinical opinion reflecting changes in evidence since the Temel study and recommending that all patients with advanced cancer should receive palliative care early in the disease course, concurrent with active treatment (Ferrell et al. 2017).

Even if oncologists are convinced of the benefits of early palliative care, they are still sometimes hesitant to discuss and initiate it because of fear that the use of the term palliative care will take away hope from their patient. Research has indeed shown that oncologists tend to avoid discussing more difficult topics such as prognosis, life expectancy, and palliative care, even if the patient wants this information (Pardon et al. 2011). Some investigators have suggested using the term supportive care instead of palliative care, in order to address this problem. There are studies that have demonstrated that renaming palliative care as supportive care effectively led to more referrals to palliative care. A study by the MD Anderson Cancer Center in Texas, for example, observed a 41% increase in palliative care consultations and a quicker referral to palliative care after a name change (Dalal et al. 2011).

Another barrier at the level of oncologists is that very often they have not received any training at all in palliative care and thus lack basic palliative care knowledge, skills, and attitudes (Aldridge et al. 2016). A basic training in palliative care is fundamental in enabling oncologists and other regular health professionals to recognize palliative care needs. It would also facilitate oncologists in providing general palliative care themselves whenever necessary and in referring to and working with specialist palliative care teams in the case of complex problems. Training in palliative care is also important because it may contribute to the elimination of other barriers such as the idea that it is the duty of the oncologist to provide palliative care themselves or the negative image of palliative care they may have as a result of negative experiences in their clinical practice. For the integration of palliative care in oncology, it is additionally important that oncologists have specific knowledge of how palliative care is organized in their country, to what degree palliative care services are accessible and available, and what the legal and financial framework is for the cooperation between oncology and palliative care.

Besides barriers at the level of the oncologist, there are also barriers at the level of palliative care professionals. One barrier is that early integration of palliative care into oncology leads to a greater workload for palliative care specialists, who are already underrepresented and often overburdened (Kain and Eisenhauer 2016). Another barrier for successful integration might be that the palliative care experts are insufficiently informed about the therapies the patient is receiving from diagnosis on, the side effects of these therapies, and the overall expertise and modus operandi of oncologists in relation to their patients.

6.2 Barriers Relating to the Person Who Is Dying and Those Close to Them

One barrier relating to the person who is dying and those close to them is that they often think of palliative care as terminal care, as many regular healthcare professionals do, although terminal care is only part of what palliative care provides. Patients who participated in the RCT of Zimmerman were asked after the study how they had viewed palliative care before the study had started (CAPC 2015; Zimmermann et al. 2016). In their answers it became clear that most patients associated palliative care with death, dependence, and end-of-life comfort care in inpatient settings. This perception changed for those who received the intervention of early palliative care, even though they still thought that the term itself was very much associated with stigma and that it needed to be better explained by healthcare

professionals. An important step toward eliminating this barrier is to educate the public about palliative care through awareness campaigns and through more accurate information provision by healthcare professionals. Another way is to change the name as discussed above.

6.3 Barriers Relating to the Healthcare System

The early integration of palliative care into oncology is challenging because it questions the adequacy and efficacy of the current structure and organization of the healthcare system as it exists in many countries. The current healthcare system is primarily organization-centered, with limited communication and cooperation between the different specialties that are involved in care and between the different healthcare settings (hospital, nursing home, home). The aim of the integration of services however is to enhance cooperation and communication and organize healthcare around the person who is dying and his or her needs. To be able to let healthcare services cooperate more and to make the patient central is another way of working that is not financially and structurally endorsed in the current system. In many countries, for instance, the financing of healthcare is such that technical performance may be rewarded, while the quality of care and the time spent on communication and coordination is less highly regarded.

The current system thus needs to a certain extent to be changed from an organization-centered to a patient-centered system, and one way of doing this is to develop pathways or protocols (Kaasa et al. 2017). These are structured, multidisciplinary care plans that clearly identify who is responsible for care in the various disciplines and how communication will be achieved. Care pathways also make clear what resources are needed to make optimal integrated care possible during the disease trajectory. Researchers have stressed the importance of such care pathways and have clarified that they should reflect different needs, different goals, and different forms of expertise and that therefore different pathways need to be developed for different subgroups of patients. Information and communication technology (ICT) can be very helpful in developing integrated palliative care models. ICT can, for example, facilitate communication between healthcare providers, carers, and the patient through shared digital medical records, interdisciplinary meetings using video communication, and digital educational or informational programs for the patient, helping them to understand and to cope with their condition. ICT can also be used to enable systematic and automatic monitoring of symptoms, allowing professional and informal carers and the patient to respond rapidly to clinical changes, symptoms, and other care needs in a population where time is of the essence. However in order for care pathways and ICT to be successful, the input and support of all stakeholders – e.g., healthcare professionals, patients, hospital administrators, and health policymakers – in the development, evaluation, and implementation of these tools is of crucial importance.

The WHO captures the use of protocols, care pathways, and ICT to improve the care of patients with chronic or life-threatening disease under the heading "Health Technology" which it defines as "the application of organized knowledge and skills in the form of devices, medicines/vaccines, procedures and systems developed to solve a health problem and improve quality of lives" (WHO 2007). Although health technology is a fast-moving field that offers huge possibilities, it has yet to be developed and evaluated thoroughly in the domain of the early integration of palliative care in oncology.

Another barrier on the level of the healthcare system that hinders the widespread integration of palliative care in oncology is that of costs. Palliative care services in most countries are too understaffed to be able to take on the extra workload of the early integration of palliative care and thus require new investment and incentives. In the USA, for instance, a study found that there is only one palliative medicine physician for every 1200 people with a life-threatening disease. In comparison, for every 141 newly diagnosed cancer patients, there is one oncologist (CAPC 2015). Several studies point out that investing in

palliative care has a cost neutral or even a cost-saving effect. Palliative care interventions, for instance, limit the number of hospitalizations at the end of life, and such hospitalizations make up 5% of the healthcare costs of a dying patient. Two studies in US hospitals revealed that the implementation of specific palliative care consultation programs helped to bring down overall healthcare costs in the last months of life (Ciemins et al. 2007; Penrod et al. 2006). The early integration of palliative care might typically involve the withholding and withdrawal of expensive surgery as well as of life-prolonging therapies such as chemotherapy, hormone therapy, or radiotherapy, which can compensate for the costs of the new palliative care interventions.

7 Conclusion and Summary

The severity and multiplicity of symptoms of advanced cancer warrant a comprehensive care approach, integrating adequate oncology treatment with general and specialist palliative care options. Evidence for the benefits of the early integration of palliative care into oncological care is very promising but has not yet been widely translated into implementation in clinical practice. For this to happen in the future, it will be necessary to disseminate information about the beneficial effects of the early integration of palliative care into oncology and confront the misapprehension that palliative care is only terminal care. Moreover, organizational and structural changes in healthcare systems will be necessary in order to support the efforts of healthcare professionals to collaborate intensively and effectively with each other and with the person who is dying and those close to them, for the benefit of all involved.

Abstract

Neurological disease is a major cause of disability and death across the world. There is increasing evidence that palliative care is effective in managing symptoms, maintaining and improving quality of life, and helping patients

and families cope with the deterioration. As the disease progression varies, both between diseases and for individuals, palliative care may be involved for varying periods of time, and may need to be involved episodically throughout the disease progression. Careful assessment of all the issues – physical, psychosocial, and spiritual – will allow appropriate management and support for patients and families. Carer support is very important as families face all the issues of coping with a progressive disease. Recognition of the later stages of life is helpful in enabling patients, families, and professionals to be able to prepare for the dying phase and manage all the issues appropriately.

1 Introduction

1.1 Extent of the Problem

Neurological disease is a major cause of ill health, disability, and death across the world. In 2015 it was estimated that 12% of all deaths worldwide were due to neurological disease – this included progressive disease, stroke (10% of all deaths), and infections (WHO 2006). These disease groups vary greatly, and there is individuality for each patient – as the symptoms, progression, and prognosis can vary from person to person.

The commonest causes of death from neurological disease are cerebrovascular disease (10.2%), dementias (0.81%), epilepsy (0.21%), Parkinson's disease (PD) (0.20%), and multiple sclerosis (MS) (0.03%) (OFNS 2012). Infections are common – with tetanus and meningitis causing 0.4% of deaths worldwide. The distribution varies greatly across the world, and neurological disease accounts for a higher percentage of deaths (16.8%) in lower middle-income countries, compared to 13.2% in high-income and 8.2% in low-income countries (WHO 2006). There is the expectation that these figures will increase over the coming decades, as the majority of neurological diseases develop with increasing age, and by 2030 it has been estimated that 12.22% of all deaths will be due to neurological disease (WHO 2006).

Palliative care may be appropriate for many of these disease groups. In some instances, there may be a sudden deterioration and death may be unexpected – such as in epilepsy or cerebrovascular disease. The principles of holistic care within palliative care may be appropriate for all these people as they face a sudden deterioration in their functional state and quality of life. However with many progressive diseases, there is a slow and gradual progression, and there is no curative treatment, with the best that treatment can offer being the slowing of progression or the management of symptoms.

Although progressive neurological diseases are relatively rare individually, as a group they do cause both morbidity and mortality. The common progressive diseases are motor neurone disease/amyotrophic lateral sclerosis (MND/ALS) with a prevalence of 7/100,000, Parkinson's disease (PD) 180/100,000 but with a prevalence of 1750/100,000 for people over 80 years, dementias 700/100,000, multiple systems atrophy 5/100,000, progressive supranuclear palsy 7/100,000, Huntington's disease 6/100,000, and multiple sclerosis 80–140/100,000 but with higher rates in higher-income and northerly areas compared to lower-income or lower-latitude countries (WHO 2006; OFNS 2012; Alzheimer's Society 2015).

Thus neurological disease does lead to morbidity, disability, and death, and with the aging of the population on many countries, there will be increasing numbers of people affected and increasing palliative care needs.

2 Role of Palliative Care

Palliative care may be seen as appropriate for many neurological diseases which have no curative treatment and progress over time – such as MND/ALS, PD, MS, MSA, PSP, HD – and the World Health Organization definition of palliative care defines palliative care as helpful for "life-threatening illness" (WHO 2002). Moreover for other diseases which may have a more sudden onset, such as cerebrovascular disease (stroke), there may be an uncertainty of the prognosis and future progression with many people left with

severe disability and/or the risk of further deterioration and death.

Even for the progressive diseases, the prognosis and progression can be very variable, and patients have to cope with uncertainty of the future – both in terms of quality of life and prognosis. The prognosis of MND/ALS is usually 2–3 years from diagnosis, which may only be made after a year of symptoms, but 25% of people are alive at 5 years from diagnosis and 5–10% at 10 years (Shaw et al. 2014). PD has an average prognosis of 14 years but many people live 20–30 years, and as they are elderly there may be only a small reduction in life expectancy.

Palliative care has been increasingly recommended for neurological disease, and a consensus document from the European Association for Palliative Care (EAPC) and the European Academy of Neurology (EAN) has recommended that "palliative care should be considered early in the disease trajectory, depending on the underlying prognosis" (Oliver et al. 2016). Moreover there have been many guidelines recommending palliative care for different diseases, such as MND/ALS (Andersen et al. 2012) and PD (NICE 2006), and for neurology in general (Boersma et al. 2014).

However it is often considered that palliative care is only appropriate at the end of life, and referral for care may be very late in the disease progression. Within cancer there has been increased awareness of the effectiveness of early palliative care involvement, and a study of lung cancer patients showed that not only did early palliative care involvement improve quality of life and reduce depressive symptoms, but the prognosis was extended from 8.9 months to 11.6 months (Temel et al. 2010). Other studies have suggested early integration of palliative care within oncological services, so that patients' problems can be identified and managed appropriately (Gaertner et al. 2011).

As the prognosis of progressive neurological diseases varies – average prognoses are MND/ALS 2–3 years, PD 14 years, MSA 9 years, PSP 7 years, MS 30 years, and Alzheimer's disease 8–10 years – the involvement of early palliative care can be complex. However earlier involvement, according to the person's particular needs, can be very helpful in improving quality of life and managing symptoms, and also establishing a relationship with a multidisciplinary team so that the care can be easily accessed and accepted as the disease progresses (Oliver 2014). This approach, considering all aspects of care – physical, psychosocial, and spiritual – and considering family as well as patient, is the basis of palliative care. Although this approach may be helpful over a long period of time, the involvement of palliative care may be episodic, responding to particular issues (Bede et al. 2009). For instance, for a person with ALS, there may be particular concerns and issues at diagnosis, consideration of a gastrostomy, development of respiratory problems, and consideration of ventilatory support as the person deteriorates at the end of life (Oliver 2014).

3 Palliative Care in Neurological Disease: Evidence of Effectiveness

From the WHO definition of palliative care, it is clear that the measurement of the effectiveness of palliative care should be focused on the improvement of the individual quality of life (IQoL) of both patients and families and on the other physical, psychosocial, and spiritual issues that can be caused by the advanced disease.

Effectiveness can also be gauged by the evaluation of the complex services provided by palliative care, considering the wide range of these facilities. These vary in different countries and health services, and palliative care can be considered as a "simple approach" adopted by any health-care provider to severely ill patients or provided by primary medicine operators for patients with a low burden of palliative care needs (often known as generalist palliative care) or the specialist palliative care, provided by multidisciplinary services, with training and ongoing involvement in the care of people with complex needs in specific settings like hospice inpatient facilities, home specialist palliative care, or hospital teams.

The role of palliative care services in terms of impact of care, outcome measurement, and effectiveness has been increasingly studied. In 2003 the first study reporting the positive impact of palliative care was released (Higginson et al. 2003). A later review showed that the evidence for benefit from specialized palliative care is sparse and limited by methodological shortcomings (Zimmermann et al. 2008). More recently other researchers highlighted how palliative care can have a moderate positive effect on the main palliative care outcome (IQoL) (Catania et al. 2015), the integration of early palliative care can improve QoL and mood (Bakitas et al. 2009), and, even though not being a primary outcome, survival increased in patients with advanced lung cancer (Temel et al. 2010). Palliative care has been shown to have cost savings (Smith and Wasner 2014).

In patients affected by long-term neurodegenerative conditions, palliative care provision and integration with neurological services remains heterogeneous. There is a need for an improved model of integration that should be rigorously tested for effectiveness. Nevertheless the impact of palliative care services on the specific outcomes of patients severely affected by neurological disorders was studied for the first time by the King's College London palliative and supportive group for people with multiple sclerosis (MS) (Higginson et al. 2008). A phase 2 randomized controlled study was performed comparing a fast track group of patients who received immediately the palliative care service versus a control group who had a waiting list of 3 months before being cared for. This study showed how the involvement with the palliative care service appeared to positively affect some key symptoms and reduced informal caregiver burden and is cost effective (Higginson et al. 2009; Edmonds et al. 2010).

Using the same methodology, a similar RCT was repeated widening the service to a mix of neurological disorders (ALS, MS, PD, and related disorders). Fifty patients were randomized to receive immediate specialist palliative care (SPC) versus standard care (SC). This study showed how patients who received SPC input reported a significant clinical and statistical improvement in IQoL and in important physical symptoms like pain, dyspnea, quality of sleep, and bowel symptoms versus those who had SC (Veronese et al. 2015). Patients in the fast track group received home care multidisciplinary visits and were seen by palliative care physicians, nurses, physiotherapist, and psychologist if required. The team was in contact with the neurological service if specific issues emerged. On average, patients received weekly visits for all the duration of the study (16 weeks), and the service was not discontinued at the end of the follow-up.

An Italian multicenter, phase 3 RCT studied the impact of a home based palliative care approach (HPA) on the needs of patients with severe MS and their informal carers (Solari et al. 2015). The preliminary findings indicate that HPA reduced symptom burden, but there was no evidence of HPA efficacy on patient QoL or secondary patient and carer outcomes. The difference in the intensity of the service provision may explain the lack of effectiveness as the team were less experienced, and it may show that a specialist palliative care approach is necessary to really affect patient experience.

This available evidence shows that there is strong interest in elucidating the appropriate role of palliative care for people with neurological conditions. At present there is data showing a positive impact of palliative care on patients and their carers, even though the intensity of care or specific service that is ideal for such a heterogeneous group of disorders is not exactly clear. The model suggested by Bede (Bede et al. 2009) and adopted in a NHS document in the UK (NELCP 2010) represents the optimal option for the challenge of providing the correct amount of care at the right times during the disease trajectory. This approach creates useful links with the specialist palliative care services for significant moments where palliative care issues emerge and to better identify the end-of-life phase which is obviously inherent to palliative care.

4 Physical Symptom Management

Patients affected by advanced neurological conditions suffer a high burden of physical symptoms, often not adequately assessed and treated (Veronese et al. 2017). In the consensus review on the development of palliative care for patients with chronic and progressive neurological disease (Oliver et al. 2016), three recommendations focus on the importance of assessing and treating physical symptoms:

- Proactive assessment of physical and psychosocial issues is recommended to reduce the intensity, frequency, and need for crisis intervention.
- Physical symptoms require thorough differential diagnosis, pharmacological and non-pharmacological management, and regular review.
- The principles of symptom management, as part of the wider palliative care assessment, should be applied to neurological care.

Studies showed that many symptoms in people severely affected by multiple sclerosis (MS) are as highly prevalent and severe as those experienced by patients with advanced cancer and that increased disability is associated with increased severity for some symptoms (Higginson et al. 2006). Patients with late-stage PD, MSA, and PSP experience a complex mix of non-motor and motor symptoms. In a 1-year follow-up, symptoms are not resolved and half of the patients deteriorate. Palliative problems are predictive of future symptoms, suggesting that an early palliative assessment might help screen for those in need of earlier intervention (van Vliet et al. 2016). In ALS the impact of unmet physical issues is also very high (O'Brien et al. 1992), and the fear of choking to death, related to the shortness of breath, can be a leading cause for requests of hastening death (Veldink et al. 2002).

4.1 Motor Symptoms

In general, advanced neurological conditions cause motor complications and physical disability that impact deeply in the IQoL of patients and cause high burden of care to the informal carers (Veronese et al. 2015). Clinically, motor impairment can appear as muscular flaccidity, typical when the second motor neurone is involved such as in traumatic paralysis, in some forms of ALS, or in spinal cord metastasis. In other conditions, the patient can suffer from muscular rigidity or spasticity, like in stroke, MS, movement disorders, and ALS forms with prevalent first motor neurone involvement. Other muscular symptoms can be spasms, cramps, fasciculation, or myoclonus.

Some of these symptoms can be treated by modulating the specific drugs for the primary disorder; for example, in IPD rigidity can be improved by increasing L-DOPA or dopaminergic drugs. Since most of these conditions do not respond to specific treatments, in the advanced stages motor symptoms are treated with a symptomatic approach. A combination of physical therapy and muscle relaxant and muscle relaxant drugs can be used for stiffness and rigidity, for example, in advanced MS or ALS. Even in the very advanced stages, when the patient is restricted to a wheelchair or bedbound, adequate stretching programs can be adopted and useful to control the pain related to stiffness, maintain joint elasticity, and prevent bedsores. Occupational therapists play a role in prescribing aids to compensate for the disability and can be useful for transferring, writing, and other activities of daily living. The use of medications like baclofen, tizanidine, or dantrolene can be effective as muscle relaxant, but doses must be individually titrated and re-evaluated on regular bases. Benzodiazepines have also a role in treating stiffness, taking into account the possible central side effects. Botulinum toxin injections are used for those patients whose rigidity does not respond to symptomatic treatments. This option can help in hygienic procedures like allowing the movement of thighs in MS of very rigid patients and facilitating personal care. In specific cases advanced treatments can be effective for motor symptoms and complications. Intrathecal continuous injection of baclofen is used in advanced MS for general rigidity, using a

pump often positioned in the patients' abdomen (Otero-Romero et al. 2016). In IPD, selected patients' motor symptoms can be approached with specific options like apomorphine subcutaneous infusion, deep brain stimulation, and continuous intrajejunal infusion of levodopa-carbidopa intestinal gel (Worth 2013).

In most cases, however, motor complications cannot be effectively resolved, and patients and carers are exposed to the restless progression of disability. A role of palliative care is to help their assisted patient to accept the condition trying to enhance resilience and adaptation strategies. Disability is challenging, but feeling abandoned can be worse. One of the most touching quotes from the founder of modern palliative care, Dame Cicely Saunders, says: "You matter because you are you, and you matter to the end of your life. We will do all we can not only to help you die peacefully, but also to live until you die." According to this mandate, palliative care must face patients even when they cannot solve their problems, but continue providing help and promoting the residual quality of life.

Pain is a common and often unrecognized symptom in patients affected by neurodegenerative conditions (see Table 1).

Table 1 Prevalence of pain in neurologic conditions

Neurological disorder	Prevalence of pain	References
Parkinson's disease	40–86%	(Simuni and Sethi 2008)
Multisystem atrophy – MSA	88%	(Higginson 2012)
Progressive supranuclear palsy – PSP	60%	(Higginson 2012)
Multiple sclerosis	50–86%	(O'Connor et al. 2008; Bermejo et al. 2010)
ALS/MND	40–73%	(Miller et al. 1999)
Alzheimer's disease	57%	(Pautex et al. 2006)
Post stroke	14–85%	(Kumar et al. 2009; (Klit et al. 2009)
Spinal cord injury	64.9%	(Modirian et al. 2010)
Guillain-Barré syndrome	89%	(Moulin et al. 1997)

Chronic pain in patients with neurologic disorders has some challenging features to be considered. Chronic pain causes significant changes in function, anatomy, and chemistry of the brain (Borsook 2012); these changes are "brain-wide" including areas like the cerebellum, not normally involved in the pain system (Moulton et al. 2010). For many diseases the pathophysiology of pain remains unclear, but patients can suffer more than one pain at a time, and the symptom can be related or not related to the underlying disorder, in the latter case being due to comorbidity, but always painful (Lee et al. 2007). Finally the association of pain with depression and mood disorders is very common. This dangerous loop can worsen the intensity and the impact of both symptoms and makes difficult to understand and treat both. Furthermore, it is known how depression, hopelessness, and pain can drive the request for hastened death (Breitbart et al. 2000).

There are peculiar painful syndromes in different neurological conditions that should be tackled with specific approaches. In PDs and related disorders, pain can be musculoskeletal 70%, dystonic 40%, radicular neuropathic 20%, or central neuropathic 10% (Lee et al. 2007; Borsook 2012). Pain can increase and decrease with dopaminergic fluctuations or may be related to a central dopaminergic deficit and in both cases can be alleviated by adjusting L-DOPA medications (dystonic and central pain). Botulinum toxin may help involuntary muscular contractions related to dystonia, and neuropathic pain can benefit from anticonvulsants and other drugs used for this type of pain. NSAIDs may reduce local irritation and work on musculoskeletal pains, and opioids modulate pain pathways and can be useful in all pain syndromes.

4.2 Respiratory Symptoms

Patients affected by advanced neurodegenerative disorders frequently experience respiratory distress including dyspnea, weak cough, trouble in management of secretions, respiratory infections, neurogenic pulmonary edema, and noisy secretions at the end of life (death rattle).

Respiratory complications represent a frequent cause of death in advanced neurological patients since the muscular impairment can lead to dysfunction like choking, ineffective cough, and susceptibility to atelectasis and aspiration pneumonia (Aboussouan 2005).

In neuromuscular disorders, the main cause of respiratory symptoms is the muscular impairment directly caused by the neurological disease. In ALS respiratory impairment is caused by the lack of innervation, caused by the death of the motor neurones, and the following development of respiratory insufficiency with hypoventilation on the basis of diaphragmatic and intercostal muscle weakness (Mangera et al. 2012). In MS the nervous denervation and spasticity above all of the expiratory muscles can lead to the development of voluntary or autonomic respiration, diaphragmatic paralysis, paroxysmal hyperventilation, apneustic breathing, and neurogenic edema; the pattern depends on the location of the lesions in the brain, which follows both axonal and neuronal death. Muscular weakness and lack of coordination, worsening with the course of the disease, are involved in PD. In other disorders like HD or Alzheimer's disease, a combination of neurologic damage in the brain is responsible for the respiratory impairment and consequent symptoms.

Shortness of breath (dyspnea) is a personal unpleasant experience that can cause the fear of choking to death. It has been defined as "a subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity." This experience is the combined effect of multiple physiological, psychological, social, and environmental factors and can itself induce both physiological and behavioral reactions. It can be associated to an objective respiratory insufficiency or just being a subjective feeling. It is strongly related to anxiety and often it creates a dangerous loop in which both symptoms are enhanced and worsened. The prevalence of breathlessness and respiratory distress varies with the disease: Dementia 12–52%, PD 22–35%, ALS 81–88%, and MS 26% (Moens 2014; Lee et al. 2007).

Symptoms of respiratory insufficiency in ALS include dyspnea on exertion, supine dyspnea, marked fatigue, disturbed sleep (frequent nocturnal awakenings, excessive daytime sleepiness), cough, and morning headaches (Miller et al. 2009). Weak coughing may be tolerable for patients who have an intact swallowing mechanism and minimal airway secretions, but the onset of complications like acute bronchitis or bulbar dysfunction may precipitate a life-threatening crisis.

Patients with neurological disorders should be monitored in the course of the disease for the possible onset of respiratory problems. In ALS specific guidelines provide indications on the timing and the clinical decisions to be undertaken. In other conditions, however, the pulmonary function should be assessed since its earlier detection can lead to the improvement of patients' outcome (Aboussouan 2005).

Treatment of respiratory symptoms should start from the recognition and treatment of possible underlying causes (e.g., respiratory infections), toward a more palliative approach when there is not a treatable cause. In the latter case, both pharmacological and non-pharmacological options can be effective, often combined. Physical therapy can help in correct positioning of the patients, and help in clearing secretions with techniques including manually assisted coughing, and others such as oscillation or percussion use of aids such as the assisted cough machine. Speech and language therapy can help when there are problems of coordination or vocal cord adduction. Noninvasive ventilation (NIV) via external mask is often effective for the support of inspiratory muscle function (Aboussouan 2005), though it may be contraindicated in some patients such as ALS with bulbar impairment or patients with cognitive decline or agitation. It can improve QoL of patients and data suggest an increase in survival in ALS (Radunovic 2013).

Invasive ventilation (IV) via tracheostomy remains a debated issue. There are differences in the adoption of this treatment in different countries. Although IV may increase survival, the disease continues to progress to the extent that the person becomes "locked in," with no form of communication, or it becomes a burdensome therapy. There are also ethical issues as it is an expensive treatment and may lead to the request of withdrawal from the ventilator, which will usually

lead to the person's death within a short time. There is strong consensus that NIV should be preferred to IV for many reasons, including ease of administration, less strain on caregivers, lower cost, greater portability, fewer infections, the virtual elimination of airway complications, and reduced need for hospitalization (Radunovic 2013). The impact on survival of ALS patients is not very clear since the literature shows a range of life protraction from less than 1 year to more than 40 months after tracheostomy. The role of family carers is very important in the constant care (24 h/7 days) required by patients in need of frequent tracheal aspiration. There are studies showing that the carers' QoL can be seriously affected by these tasks (Kaub-Wittemer et al. 2003).

Palliative and hospice care represent an alternative choice which can effectively impact on respiratory symptoms (Veronese et al. 2015), through the accurate use of drugs, like opioids, found useful in respiratory distress (Jennings et al. 2001) and recommended in specific guidelines and consensus reviews (Andersen et al. 2012; Miller et al. 2009).

4.3 Dysphagia and Swallowing Problems

Difficulties in coordination of the processes of contraction and relaxation of the various muscles involved in mastication, deglutition, and the progression of the bolus toward the stomach are common in neurodegenerative disorders causing difficulty with swallowing food, liquid, or saliva. The characteristics of the swallowing disorder can vary according to the neurological condition, the severity of the neurological disease, and other comorbidities. Dysphagia is considered as a general indicator of decline in any neurological disorder having a negative impact on survival above all if associated to weight loss (Thomas and Armstrong Wilson 2016). In late-stage PD, it occurs in up to 95% of patients and is associated with aspiration pneumonia. It is also very common in Parkinson's plus syndromes, and studies show that its onset has a negative prognostic meaning (Walshe 2014).

In advanced MS dysphagia affects 33% to 50% of patients, possibly because of uncoordinated respiration during swallowing.

Many people with ALS will experience problems with dysphagia (swallowing problems), which can make eating and drinking difficult. Dysphagia is reported to be prevalent in 30–100% of individuals depending on the type of ALS and the stage of disease affecting all individuals in the later stages of the disease. This can cause anxiety for people with ALS and their carers/family, who may have concerns about choking on food and liquids.

Dysphagia in advanced stages of dementia is associated with malnutrition and aspiration pneumonia which is a significant cause of death in this population. It is also prevalent in Huntington's disease and Prion diseases.

Managing swallowing issues can be really challenging for both patients and carers. Food and liquids are essential for living and are often associated to ethical and existential aspects. Help can be provided by an accurate assessment of the cause of dysphagia, treatment of underlying secondary causes, and advice on dietary modifications. Intervention can be focused on compensatory (changes in posture, modification of food and/or fluid, and adaptation of methods of eating and drinking) or rehabilitation techniques depending on the specific disorder.

Some treatments showed benefits for dysphagia in selected populations. Electrical stimulation and botulinum toxin treatment have been shown to be helpful in reducing the swallowing impairment in MS. In PD, speech and language therapy and dopaminergic drug adjustment are suggested to improve deglutition. Rotigotine patches can play a role in advanced PD when swallowing is impaired, but deep brain stimulation (DBS) did not show positive effects on dysphagia.

When swallowing becomes very difficult, distressing, very slow, or impossible, the tube feeding option can be considered. This is very often offered to ALS patients, even earlier stages, when first signs of swallowing impairment appear. This is due to the positive impact on QoL with improved dietary intake, and the patient may be able to continue to eat and taste his or her favorite food in

small amounts. Furthermore, PEG placement should be done before a decrease in pulmonary function becomes clinically significant, to avoid surgical and postsurgical risks of respiratory complication. In terminal dementia or in other neurological diseases with significant cognitive impairment, there is no evidence of positive effect of tube feeding in terms of QoL, survival, or other patients' outcomes, and the placement and later care may cause distress and even mortality (Sampson et al. 2009).

Even when clinically appropriate, patients can refuse tube feeding for many personal reasons – for instance, they may not want any further treatment to prolong their life. In this case the decision should be respected, and the involvement of palliative and end-of-life care becomes very important. Advance care planning should involve these decisions that are to be reassessed frequently, because as problems progress, they may change their mind.

5 Psychosocial/Spiritual Care

Facing a neurological disease may lead to many psychological and emotional issues. These may depend on the physical issues that affect the person; for instance, a person with PD who has severe mobility issues may become more anxious and concerned about how they cope with day-to-day activities and become disturbed. The response will also be affected by the previous experiences and issues faced by the person and their family – for instance, if there have been difficulties within a relationship, these may be heightened when there are stresses associated with a progressive disabling illness. Moreover changes in cognition and communication may also affect the person's coping mechanisms and lead to increased distress.

There are many psychological issues that may be faced:

- Concerns about the diagnosis – this may be a disease which is unknown to the person, or they may have experience, such as someone with HD who often has memories and experiences from a family member who has suffered and died of HD.
- Concerns about increasing disability and dependency.
- Feelings of depression or anxiety as they face the various symptoms and disability due to the disease progression.
- Fears of the process of dying. Many neurological diseases are associated with a distressing death, which may have been highlighted in discussions and debates about dying or assisted dying. For instance, people with MND/ALS have talked publically of their fears when discussing and advocating assisted dying, talking of choking to death and their fears of distress.
- Fears of losing control, especially as they may fear losing mobility, communication, and cognition. These are possibilities for many neurological diseases and needed to be discussed and ways of minimizing the effects on the person and their family considered (Goldstein 2014).

There may be no easy answers for these fears and concerns, but it is important to allow patients and their families to discuss and express their feelings. An openness of professional carers allows this, and this again emphasizes the need for longer-term involvement with teams, so that trust is engendered and discussions can more easily occur.

Most people are part of a wider family or caring network and those close to them may have similar issues. They may have the same fears about deterioration, dependency, disability, dying, and death, and depending on the previous relationship, they may or may not be able to discuss these openly with the person. If communication and discussion is limited, this may in turn lead to more difficulties as trust is lost, and the issues increase for both parties if there is not the opportunity to discuss and resolve these issues. Moreover if the spouse or carers are elderly, they may be facing their own illnesses and comorbidities, including psychological or cognitive change, and they will thus find the issues very difficult to cope with (Smith and Wasner 2014). If the person has cognitive change or dementia, there may be great stresses within a household, and it may become increasingly difficult to cope at home,

or extra care may be needed that further disrupts the previous normality.

There may be very practical issues faced by someone with a neurological disease as they become more disabled that may lead to fear, anxiety, and family conflicts – the roles within a family may become disrupted as the person becomes more disabled and is unable to perform their normal roles within the family and conflicts may arise; care within the housing may become more difficult, and consideration of changing the housing such as the installation of lifts or planning to move to more suitable accommodation may be needed, with ensuing stress and the potential for conflict.

There may also be spiritual issues faced by both the person and family. The experiences, beliefs, and values of any person will affect how they cope and manage with illness and disability. This may be particularly so for a person with a neurological disease who is facing increasing deterioration and dependency and death. These issues may be very important for their family as well. The beliefs may be manifested in a religious belief or practice, and the involvement of others from their religious group, such as a faith leader, may be helpful. However many people do not espouse such belief but still search for meaning and value in their life – their own individual spiritual values. All may find coping with these deeper questions, such as the meaning of life and death, very difficult. These issues may not have any easy answers but should be heard and acknowledged (Lambert 2014).

With all these areas of care, there is the need for listening and awareness of the possibility of concerns by all the professional carers involved. Sharing of concerns and encouraging families to share their concerns together are often helpful. Specialized counselling may be helpful for some, and access to this service is essential if we are to help patients cope with their disease.

6 Communication Issues

The need for careful communication with both the patient and family has been emphasized in the EAPC/EAN consensus document (Oliver et al. 2016) and may be especially important in neurological disease, due to the complexity and variability of the disease progression and the risks of both communication ability and the cognitive ability of the patients as the disease progresses (Oliver et al. 2016). The areas that may need particular attention are the following.

6.1 Diagnosis

The giving of the diagnosis of a progressive neurological disease will set the agenda for future care, and may influence the patient and their family's response and coping with the disease as it progresses. There is evidence from the telling of the diagnosis in cancer that the use of a protocol, such as the SPIKES protocol, allows an open and clear discussion and aids in the telling of bad news (Baile et al. 2000). Such a protocol suggests that consideration is given to **S**etting up the interview, with preparing the setting and ensuring all the information is available; assessing the patient's **P**erception by asking for their thoughts and views; obtaining the patient's **I**nvitation by ascertaining their wishes on the information they would wish; giving **K**nowledge and information, by giving clear information in small chunks and without bluntness or over negative views; addressing the patient's **E**motions with empathic responses; and setting a **S**trategy and **S**ummary at the end of the discussion so that the patient has a clear plan of the next steps to be taken (Baile et al. 2000).

It has been shown that the SPIKES protocol can be helpful in enabling neurologists to tell the diagnosis of MND/ALS. In Australia it was found that 36% of patients were dissatisfied with the telling of the diagnosis and patients were more satisfied if the neurologists spent longer time, responded empathetically, shared information and suggested realistic goals, explored the expectations of patient and family, and made a clear plan with follow-up (Aoun et al. 2015). Moreover 70% of neurologists in this same study found telling the diagnosis somewhat to very difficult, and 65% were stressed and anxious when delivering this news (Aoun et al. 2015, 2016). Families also were concerned when communication was

not satisfactory and commented on long-term emotional stress in these circumstances (Aoun 2017). There is evidence that these skills can be acquired through training in a specific program (Lienard et al. 2010).

Throughout the disease progression, there is the need for good communication and discussion of the disease, its effects, and the future prognosis. This may need to be repeated many times, and patients and families may take this information on board in different ways at different times. Time is needed to ensure that they have the information they wish and to facilitate communication within families, so that they are able to be open together. It has also been suggested that two appointments allow patients and families more time to understand and discuss the news and then ask more questions at the second appointment (Seeber et al. 2016).

However there may be family situations when communication is not open and conflicts arise. The aim should be to allow the patient to discuss what they wish, within their abilities of communication and understanding. Families may need extra support, as they are facing the issues of loss and change in the same way as the patient, but with their own particular concerns and experiences that may color their reactions. This may be compounded when there are communication issues, due to dysarthria or dysphasia and cognitive change – as one family described: "He received a death sentence and it felt like I had received a life sentence."

6.2 Advance Care Planning

As communication and cognition may deteriorate with disease progression, knowing the wishes of the patient while they are able to communicate with them is important. Advance care planning (ACP) is "a voluntary process of discussion and review to help an individual who has capacity to anticipate how their condition may affect them in the future and, if they wish, set on record choices or decisions relating to their care and treatment so that these can be referred to by their carers – whether professional or family – in the event that they lose capacity to decide once their illness progresses" (Chapman 2012). It is a voluntary act, without coercion, and should be offered appropriately and over time and may need to be repeated and reviewed (Chapman 2012).

A person can give their wishes for many aspects of care and treatment including the place of care and death, foods they may like/dislike, how they would like to be cared for, their values, and the treatment options they may wish/may not wish to receive. They may be able, according to the country's legislation, to refuse certain treatments if they define these clearly and show that they realize that these decisions could lead to their death (Chapman 2012).

ACP may be as:

- An advance directive – where the patient defines treatments they do not wish to receive – such as admission to hospital, cardiopulmonary resuscitation, tracheostomy ventilation, antibiotics for a urinary or chest infection.
- Appointment of a proxy to make decisions when they are not able to do so – this proxy would be asked by the professional team for a decision in the same way as they would have asked the patient, if he had been able to make the decision.
- An expression of their general views on care and treatment – in the UK this is known as an advance statement and is not legally binding, but should be taken into consideration in the decision-making.

In the care of neurological patients, ACP has been found to be helpful (Voltz et al. 1998), and it has been shown that patients do wish their ACP to be adhered to (Jox et al. 2008). Moreover patients with MS did want to express their views, and if doctors avoided these discussions, patients felt that they were less empathetic (Buecken et al. 2012).

Thus ACP is helpful and should be considered for patients, particularly when loss of communication or cognition is a possibility. However this may not be easy as patients and families often do not want to consider the future, due to fears of what may happen and concerns that these considerations may precipitate a decline. Professionals may also be reluctant to discuss the issues, as they

find it difficult and stressful and time consuming. Thus careful discussion early in the disease progression may be necessary if the patient is able to express their wishes easily, and ACP may need to be discussed on several occasions – the completion of ACP is "a process" over time, and careful explanation of the benefits for the person and their family needs to be stressed.

6.3 Wish for Hastened Death

There is evidence that people with neurological disease and their families may wish to discuss hastened death – euthanasia and assisted suicide (Stutzki et al. 2014) – even if this is not an option within the specific country. There is a debate as to whether hastened death is part of palliative care, and in Belgium the services often work together (Bernheim and Raus 2017), but the European Association for Palliative Care White Paper on euthanasia has stated clearly that there is a clear separation and palliative care does not include hastened death (Radbruch et al. 2015).

However there is a need to allow patients and their families to discuss these issues. The request may come from the fear of symptoms, and a distressing death, of dependency, or of maintaining control over their life and death. For instance, although many patients with ALS fear a distressing death, there is increasing evidence that with good palliative care, this is unlikely and choking to death, a common fear, is rare (Neudert et al. 2001). These issues should be discussed, and with clear explanation, planning for possible crises, and ACP, the wish may lessen. There will be a number of patients who will still wish to retain control, and in areas without any legislation, there will need to be ongoing support for the patient, their family, and all the professional teams involved (Ganzini et al. 1998).

6.4 Communication Issues

Communication may become complex for people with neurological disease because of loss of speech and/or cognition. Speech may be affected due to bulbar changes (affecting the mouth, tongue, and lips), the respiratory muscles/diaphragm (causing weakness of respiration and reducing the ability to articulate), the central neurological control of speech or damage to the speech centers of the brain. Careful assessment is necessary, involving speech and language therapy, to help patients communicate. This may involve relatively low-tech equipment, such as pad and paper or a communication board, to high-tech computer-based systems, and even systems based on eye gaze or electroencephalograms. Extra time is often necessary to allow the person to communicate, as even the most sophisticated computer communication system is much slower than normal speech. It is essential to allow people to communicate their wishes and allow them to complete the communication (Scott and McPhee 2014).

There may also be a loss of cognition, which may be complex and not immediately obvious. Subtle changes in understanding or language may not be understood by families or carers but cause distress to all as communication becomes confusing and the behavior affected. For instance, frontal lobe changes, which may be found in up to 50% of people with ALS, may affect decision-making, cause subtle language difficulties including word and sentence comprehension and word finding, increase distractibility, lead to impulsivity, and lead to difficulty in planning activities, forgetfulness, difficulty in judging the emotions of others, and loss of empathy (Goldstein 2014). These changes may be subtle but may affect the person's ability to function and carers, both family and professional, need to be aware of the possibility of needing to provide extra support in helping the person with decisions or activities. Reduction of the "cognitive load" when making decisions can be helpful, so that the information provided is limited and the decision is reduced to a small number of options, which may be possible for the person to understand (Goldstein 2014). Awareness of the possibility of cognitive change is essential when communicating with people with neurological disease so that they can be involved in discussions and decisions, within the limits of their abilities.

7 Support of Carers

Family or informal carers are persons who take care of patients affected by chronic illnesses, disability, or other care need, outside a professional or formal employment framework. They are considered as beneficiaries of palliative care according to the WHO definition (WHO 2002), but, above all in a home setting, they are often viewed as a co-worker or even a member of the caring team but as such may not be identified as having care needs in their own right (Grande and Ewing 2009). They are the ones who spend most of their time with patients and, therefore, can provide essential information on minimal changes in needs and health status. Family carers should be educated and trained in medication management and symptom control (Bede et al. 2009).

Early education on the practical, technical, and emotional aspects of providing end-of-life care may be required for those caring for people with nonmalignant disease when the trajectory of dying is more uncertain (Funk et al. 2010). Professionals need to "think family" and consider how support for family carers can affect the care of the patient, above all when they tend to have problems related to aging. Understanding the complexities of end-of-life care in the home and the support needs for family carers can improve services, and among the main areas of need identified by lay carers are social and psychological support, financial concerns, and the need for choice and information (McIlfatrick 2007). Assessment of carers of patients with severe MS has shown a need for qualified personnel and care coordination in day-to-day home care, in particular identifying personal hygiene, a supportive network, and the preservation of patient/carer roles within the family and community (Borreani et al. 2014).

As many family or lay carers have never seen a person deteriorate or die, they can be worried about the future: uncertainty about the disease progression; physical dependency; mental deterioration; and the need to take decisions on behalf of their loved ones can cause anxiety and have a negative impact on their daily life.

Considering informal carers of people affected by neurological disorders, some aspects are to be taken into account:

- Carers, as well as patients, are often very frightened of the dying process and may be more fearful of the process of dying than of death itself.
- Appropriate information on further support is essential as well as opportunities to share their concerns and fears.
- Some carers (e.g., those caring for MS patients) will have been told that their condition is not one people die from and therefore may be unprepared, especially where there has been a slow and severe progression and death occurs suddenly.
- Carers could be the first to recognize and interpret subtle changes in reduced energy, engagement, and mood as the neurological condition worsens. They may experience patients' acute crises that may require hospital admission (infections, trauma, agitation).
- They need information about significant changes in care management, for example, in oral feeding and hydration.
- They may feel they have already "lost" the person and experience episodes of grieving during the care management.
- They may need specialist palliative care for unmet needs requiring psychosocial or spiritual input from the services to prevent severe psychiatric illness and even suicide among carers.
- Cultural and religious differences around the end of life deserve respect.
- Support for carers should continue into bereavement.

The needs of carers should be assessed on a regular basis, and the support of carers – before and after death – is an indispensable part of palliative care, reducing complicated bereavement and improve patients' quality of life (Oliver et al. 2016).

The care needs of carers of patients with neurodegenerative conditions are extensive and when unmet may be related to negative changes in their quality of life. Issues can range from significant

anxiety and insomnia, related to their role, to depression related to caregiver burden and social dysfunction. Family suffering increases when the neurological disorder reaches advanced stages, and also financial problems are to be taken into account (Whetten-Goldstein et al. 2000). As the disease progresses and end of life approaches, the primary caregivers and also the wider family of persons with progressive neurological conditions need more supportive interaction and information.

8 End-of-Life Care

The General Medical Council in the UK defines end of life (EoL) as patients who are "approaching the end of life" when they are likely to die within the next 12 months. This includes those patients whose death is expected within hours or days; those who have advanced, progressive incurable conditions; those with general frailty and coexisting conditions that mean they are expected to die within 12 months; those at risk of dying from a sudden acute crisis in an existing condition; and those with life-threatening acute conditions caused by sudden catastrophic events. The term "approaching the end of life" can also apply to extremely premature neonates whose prospects for survival are known to be very poor, and patients who are diagnosed as being in a persistent vegetative state (PVS) for whom a decision to withdraw treatment and care may lead to their death. The "end stage" of life may be considered as the final period or phase in the course of a progressive disease leading to a patient's death (GMC 2017).

The identification of when someone with an advanced neurological condition may be approaching the EoL phase of their illness is important, because it enables the appropriate action to be taken. The consensus review on the development of palliative care for patients with chronic and progressive neurological disease states that the recognition of deterioration in disease progression near the end of life is essential in enabling the provision of appropriate care and support for patients and their families. Once recognized it must be considered how a regular reassessment is important, with careful continued discussion to enable the changes to be recognized (Oliver et al. 2016).

Unfortunately there are challenges in recognizing EoL in many neurological disorders because of many factors:

- The long duration of disease with the involvement of complex multidisciplinary care (e.g., MS).
- Sudden death (e.g., ALS, MSA).
- The lack of a predictable or fluctuating course (e.g., PD).
- The involvement of specialist treatments (e.g., deep brain stimulation, continuous intrajejunal infusion of levodopa-carbidopa, or continuous apomorphine subcutaneous infusion).
- Neuropsychiatric problems (e.g., behavioral and cognitive changes) can appear throughout the course of the disease creating confusion between terminal delirium and treatable complications.

Rapidly progressive diseases may need palliative care early on in the disease trajectory, in some conditions even from diagnosis (Oliver 2014). The role of comorbidities needs to be considered as many people (in particular the elderly) die with, but not from, their neurological condition. Nevertheless the neurological disease may play a role in the dying process, often causing difficulties in medical decisions and the priorities of care.

Palliative care can play a role at different times in the progression of a neurological disease. Figure 1 shows how this has changed over the decades – in the past palliative care was often only considered at the end of life, and more recently there has been a gradual transition with both neurological and palliative care services collaborating in care. However palliative care may have a role throughout the disease progression and in an episodic way, according to the patient and family's needs. Early involvement will enable a relationship to be developed between the patient and family and the multidisciplinary team which will facilitate care and may also make it easier for professionals to recognize the deterioration at the end of life.

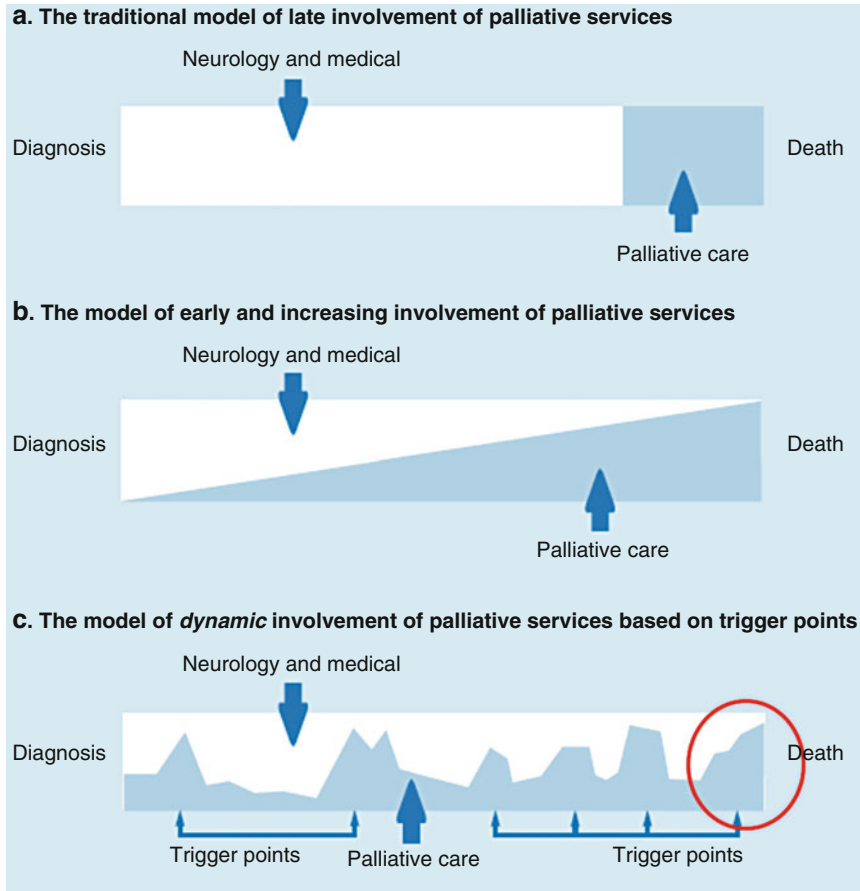

Fig. 1 Possible model of palliative care involvement in neurological disorders (Adapted from Bede et al.)

There are various instruments that can guide the clinician in the process of identification of an EoL trajectory. The Gold Standard Framework provides a multi-step decisional approach to identify patients approaching EoL Proactive Identification Guidance 2016 (GSF 2017). This toolkit is aimed at helping the primary medicine professional to screen the patients that they see and enter into the palliative care register those who are at risk of death and starts from the surprise question: "Would you be surprised if this patient were to die in the next 6–12 months?". If the answer is no, then the patient with advanced disease is further investigated in order to understand the desired choices of care and the presence and intensity of special need of supportive/palliative care. There is also the assessment of specific clinical indicators related to the main diagnosis that can indicate that the disorder is end stage. These indicators are also listed for neurological conditions like ALS, MS, PDs, stroke, and dementia. This approach helps to identify, assess, and plan for living well and dying well.

General triggers for EoL in neurological disorders were found to be rapid physical decline; significant complex symptoms, including pain; infection in combination with cognitive impairment; and risk of aspiration (NEOLCP 2010). Research has shown that the number of triggers increases as death approaches and the terminal phase was recognized for 72.6% of patients (Hussain et al. 2014).

The Supportive & Palliative Care Indicators Tool (SPICT™) is used to help identify people

at risk of deteriorating and dying with one or multiple advanced illnesses for holistic, palliative care needs assessment and care planning (http://www.spict.org.uk/).

In the care planning of patients at the EoL, it is essential to assess important issues:

- The preferred place of care
  Including the desirability and feasibility of care for this person at home.
- The preferred place of death
  The person may feel better in his/her home or may feel more secure better in a more protective environment (such as a hospice or a nursing home).
- The family coping systems to deal with a death in their house
- The presence of other frail people at home who may need some protection – children, other seriously disabled family members, drug abuser, or alcohol addicted

In order to achieve a good quality of death, physical symptoms and psychosocial and spiritual issues are to be accurately addressed and reviewed any time the phase of illness changes, and the care plan has to be adapted.

Patients with ALS fear choking to death, even though there is good evidence that for those receiving good palliative care, most deaths are peaceful (Neudert et al. 2001). However, if they are not addressed, these worries can lead to desperation, and some patients are more likely to wish hastened death (Albert et al. 2005). The provision of appropriate medication "in case of need" may be appropriate – the Breathing Space Programme in the UK suggests the provision of morphine, midazolam, and glycopyrronium bromide injections in case of a sudden deterioration or distressing symptoms (Oliver 1996). For other conditions prevention of possible crises and careful planning of the EoL can be possible. The adopting of the principles of symptom management, as part of the wider palliative care assessment, should be applied to neurological care, allowing open discussion about the dying process and explanation that most patients will die peacefully with appropriate care.

9 Education

There is a need for information for all involved in the care of a person with a neurological disease. The diseases are relatively rare and may not have been encountered at all by patients and families and may be rarely seen by health and social care professionals. Thus there is the need for information to be available if the person is to attain the best quality of life and activity.

9.1 Patient and Family

At the time of diagnosis, patients and families may have limited information about what they face. However with some disease, which has a genetic component, they may be only too aware, having seen family members with the disease, such as in Huntington's disease. All need good and reliable information, but how this is provided is often difficult as some people may want limited information, whereas others feel let down if they develop new problems and feel that they have not been prepared beforehand. There is evidence that patients may seek information in different ways – "active seekers" who look for information, "selective seekers" who often rely on family members or friends to prescreen information and pass it on if they feel it is suitable, and "avoiders" who would rely on others to "buffer" and check any information (O'Brien 2004). Care is needed in allowing these people to receive information in the most effective way for them.

There are also issues if people look for information on the Internet, for although there are many excellent sites, often provided by specialist support societies, there are many misleading and erroneous sites and some which try to extort money for "cures" which are unsubstantiated or completely dishonest.

In the provision of information, awareness of the understanding of those involved is essential – many people may not be able to use written information due to literacy or language issues, and cultural differences may affect how information is perceived. However good information from reliable sources can be very positive, providing

support and understanding and enabling care – for instance, awareness of behavioral changes in ALS when there is cognitive change enables family to understand why the person is acting in different ways and develop ways of coping and minimizing the difficult behavior (Goldstein 2014).

Specialist support groups and associations are very helpful in providing reliable information for people. They are able to provide specialist information for patients/families and professionals. They also help to facilitate general awareness of the issues facing people with the particular illness and help to raise funds for further research.

9.2 Professionals

There is increasing awareness of the need for professionals to be more aware of the needs of both patients with neurological disease and their carers/families. This may be for increased awareness of the role of palliative care for neurological/rehabilitation services and for increased knowledge of neurological disease for palliative care services (Creutzfelt et al. 2016). This is part of the ongoing development of health-care professionals in awareness of holistic care and the need for improved communication skills (Aoun et al. 2016).

10 Conclusions

The care of people with neurological disease can be complex and involves a wide multidisciplinary approach. There is a need for careful assessment and care needs to be individualized for every patient and family. This complexity is a challenge for palliative care services, as there is variable involvement over a variable period of time and collaboration and interaction with other professional teams. However with a careful collaborative approach, much can be done to improve the quality of life of this patient group.

To improve care further, it is hoped that there will be increased awareness of palliative care within neurology – including within guidelines on care. This will enable patients and families to receive the care they need. The numbers will increase over the coming years and decades as the population ages and all professionals will need to become more familiar with the palliative care of this population, who may also have multiple comorbidities.

The education of all professionals in the principles of palliative care will enable the approach to become more usual with a clearer understanding of the aims of management – often to minimize symptoms and allow people to live their lives as effectively as possible. As Dame Cicely Saunders, founder of St Christopher's Hospice where neurological patients were cared for from the opening in 1967, our aim should be "to help people live, live until they die."

Abstract

An optimal approach to palliative care for people with dementia has been defined by the European Association for Palliative Care with 11 domains including applicability of palliative care; person-centered care, communication, and shared decision-making; and setting care goals and advance care planning. Not all people with dementia will require specialist palliative care, and all involved in dementia care should be able to provide palliative care focusing on care and treatment which aims to increase the comfort and quality of life of the individual and supporting their family. There are many complications and symptoms which may arise for someone with dementia including increased infections, shortness of breath, swallowing difficulties, and pain which the individual may not be able to clearly express. These complications can lead to difficult decisions which need to be made by not only practitioners but also family caregivers as proxy. There should be a shared decision-making approach to these complications and symptoms, with advance care planning performed where possible. Caring for someone with dementia is one of the most difficult caring roles; support for family caregivers as part of a palliative approach is essential. Each person with dementia is different, and needs should be assessed on an individual basis, adopting a person-centered approach to care.

1 Introduction

With aging populations across the world, the numbers of people with dementia continuing to increase and with no known disease-modifying treatment, the delivery of high-quality palliative care is becoming a high priority for health and social care services. Dementia is often not recognized or understood as a terminal illness which will ultimately lead to death; however, research over the last decade has increased, and attention paid to palliative care for people with dementia continues to be recognized. Through the use of a case study/vignette (Mrs. S) in this chapter, we provide a definition of optimal palliative care for older people with dementia through the domains of the European Association for Palliative Care (EAPC) (van der Steen et al. 2014b). Drawing on a case study, we discuss common issues and symptoms for those with dementia including

symptoms which may be experienced in the dying phase, and their associated treatments, considering the controversy of some of these treatments, such as artificial nutrition. The chapter considers the role of family caregivers in decision-making and the difficult decisions which are often left to them to make as proxy. The importance of family caregivers in dementia palliative care is highlighted including their health and psychological needs. Throughout this chapter we highlight the person-centered approach which should be adopted and needs and support should be considered on an individual basis.

2 Defining Palliative Care for People with Dementia

Palliative care has a great deal to offer for people with dementia. The trajectory of dementia usually involves multiple changes in condition and in the situation of people with dementia. What is needed is a care approach that is highly responsive to such changes, and which therefore explicitly incorporates and anticipates the future, to promote a feeling of being in control in a situation where people often feel loss of control. This does not mean that all people with dementia need specialist palliative care. Rather, with no cure of the disease available, the palliative approach may help as a reminder to focus care and treatment on maintaining or improving quality of life of the patient and supporting the family caregiver in changing and often difficult roles. As the course of the disease is much less predictable than, for example, with cancer, it is more problematic to limit palliative care in dementia to the end of life: when should that be? In order to integrate a palliative approach in dementia care, and for specialist palliative care to appreciate what is specific about dementia, a common understanding of what is needed from palliative care in dementia is needed.

A single sentence to define palliative care in dementia would not suffice. Therefore, in a Delphi study based on evidence and consensus among palliative care and dementia care experts, the European Association for Palliative Care (EAPC) sought to identify the important domains in palliative care in dementia to serve as a framework for development of practice, policy, and research (van der Steen et al. 2014b). This Delphi study focused on older people with dementia, as little is known about the specific issues of young-onset dementia at the end of life. Within each domain, the most important recommendations were provided to optimize palliative care in dementia, backed up by an explanation and evidence where available.

Box 1. Domains of Palliative Care in Older People with Dementia European Association for Palliative Care (EAPC) (van der Steen et al. 2014b)

1. Applicability of palliative care
2. Person-centered care, communication, and shared decision-making
3. Setting care goals and advance care planning
4. Continuity of care
5. Prognostication and timely recognition of dying
6. Avoiding overly aggressive, burdensome, or futile treatment
7. Optimal treatment of symptoms and providing comfort
8. Psychosocial and spiritual support
9. Family care and involvement
10. Education of the health-care team
11. Societal and ethical issues

The first domain is applicability of palliative care, because dementia is not always considered a terminal disease. It does shorten life expectancy (Rait et al. 2010), but perhaps more important is that dementia is a progressive disease and there needs to be continuous assessment of the needs of the individual, whether resulting in death with or from the dementia. Palliative care asserts that knowledge of and acceptance of the course of a disease, with no cure, is essential, even though this may be an emotionally charged area. In dementia there are indications that (on average) people die more comfortably and with better quality care when family and professional caregivers

recognize dementia as a terminal disease before the dying phase (van der Steen et al. 2013). Also physicians perceived that patients suffered more in the final hours of life if their physician felt unprepared with an unexpected death (van der Steen et al. 2017a). Studies of advance care planning also speak to a general benefit of conceptualizing dementia as a terminal disease and preparation for declining health.

The important question then arises when palliative care should begin. In principle, when diagnosed with a terminal illness, one may wish to start and prepare. However, and especially with an early diagnosis, the end of life may still be far away. The exclusive focus on advance dementia seen in research suggests that moderate dementia is not yet a terminal disease (Mitchell et al. 2009). This is, however, difficult to maintain if half of people with dementia die before ever reaching the advanced stage, and after having experiencing a number of complications, with pneumonia and dehydration of cachexia occurring in moderate dementia as well (Hendriks et al. 2016). Moreover, people with advanced dementia may survive for many years (Gill et al. 2010), often referred to as dwindling; with good care, they may even form a selected subgroup of "survivors." The domain of prognostication and timely recognition of dying (Box 1) acknowledges difficulties in prognostication and is therefore typical for palliative care in dementia, where it is not usually a domain in itself in palliative care more generally or for other diseases.

The EAPC work also acknowledges that it is not possible to state a uniform and good starting point for palliative care for all people with dementia. Instead, palliative care is conceptualized as most compatible with two of three major care goals: maintenance of function and maximization of comfort (Fig. 1), which both relate strongly to quality of life. There may be a mixture of care goals, which can shift over time, with progressive dementia. Also, because this is a model, how exactly care goals may shift differs between individuals. In principle, however, palliative care can start at diagnosis (such as with naming of a proxy decision-maker; see advance care planning discussion Sect. 3 in this chapter), even though the care goal that overwhelmingly takes priority at that point may be life prolongation (Fig. 1).

Understanding the applicability and mainstays of palliative care in dementia is not only important for practice but also for policy making, given the benefits and slow uptake in, for example, national dementia strategies where, if included, palliative care is often regarded as care for the dying. Two other domains are relevant especially for policy makers, which are the final two domains (education of the health-care team and societal and ethical issues); however, these are beyond the scope of this chapter and as such not discussed.

The most important of the 11 domains (Box 1) of palliative care in people with dementia according to the experts – and perhaps for all patients with no dementia or palliative care needs – are optimal

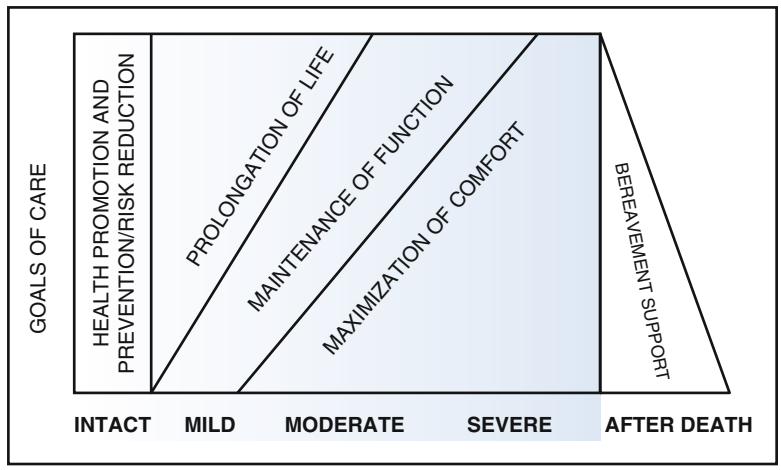

Fig. 1 Dementia progression and suggested prioritizing of care goals. The goals of maintenance of function and maximization of comfort are compatible with palliative care which aims to improve quality of life (van der Steen et al. 2014b. Copyright © 2014 by the Authors. Reprinted by permission of SAGE Publications, Ltd.)

treatment of symptoms and providing comfort and person-centered care, communication, and shared decision-making. Nevertheless, how this is being achieved is different with dementia than with several other terminal diseases; this is discussed in Sects. 4, 6, and 7. Several of the domains listed in Box 1 are emphasized more in palliative care in dementia than with palliative care in other diseases. These are the domains of setting care goals and advance care planning, because of missed opportunities when waiting for the patient to decline in cognitive functioning, and family care and involvement because of the great burden placed on families through both the physical and cognitive decline of the person with dementia. It may be argued that in advanced dementia or at the end of life, continuity of care, avoiding transfer and change or adding of new staff in the last phase, is also of special importance in people with dementia. The same may be true for the two domains that relate to a historical development of palliative care in response to an overly aggressive unilateral medical approach until (almost) dying: avoiding overly aggressive, burdensome, or futile treatment and psychosocial and spiritual support. Explicit attending to needs for spiritual care may fill a gap in dementia care practice, as spiritual care is nearly absent in most dementia guidelines and national dementia strategies (Durepos et al. 2017; Nakanishi et al. 2015).

Palliative care issues, however, may not be raised at all in the absence of a timely diagnosis of dementia which is shown in the case below.

Patient Case/Vignette Part 1 Mrs. S is an 82-year-old lady who lives at home. She has two children, a daughter and a son; her husband died 6 years ago. Her daughter visits her at home as much as possible. Her son lives abroad.

She has a history of a hypertension and has had a hysterectomy. She visits the GP regularly to check her blood pressure. Over the past year, she has visited her GP a few more times due to two urinary tract infections. She calls her daughter and son a couple of times a day and never remembers she has just called. Her daughter often finds moldy food in the fridge, and Mrs. S has got lost on her way home several times.

One day Mrs. S does not answer the phone; her daughter is worried and goes over to her mother. Mrs. S is lying next to the toilet; she does not know how long she has been on the floor. She can't use her right leg because she is in too much pain. Her daughter calls an ambulance, and in the hospital, a hip fracture is diagnosed.

During her stay in the hospital, Mrs. S gets very disoriented and hallucinates and is diagnosed with delirium. The possibility of dementia is mentioned, but at this point, it is not possible to run tests. Mrs. S's daughter agrees that her mother cannot go back home, and they decide to transfer Mrs. S to a rehabilitation unit.

3 Advance Care Planning

As can be seen in the case of Mrs. S, there has been little planning for her future care or treatment as her cognitive decline progresses and as her ability and capacity to make her own health, care, and welfare (including financial) diminishes. This stresses the importance of advance care planning.

3.1 Definition

Advance care planning (ACP) has been defined as "process of discussion that usually takes place in anticipation of a future deterioration of a person's condition, between that person and a care worker" (Henry and Seymour 2007). Advance care planning can include advance statements about wishes to inform subsequent treatment, for example, how one's religious beliefs should be reflected in care, or an advance decision to refuse treatment such as antibiotics to treat an infection. Included in the advance care plan are nonmedical decisions such as decisions about who should manage the individual's finances. An advance decision may sometimes be referred to as a living will, advance directive, advance policy making, or advance physician orders. It is important to highlight that ACP is a process of communication. It does not necessarily lead to a living will or nomination of a proxy decision-maker, it may also simply be conversations which are not documented; however, this is not recommended

and documentation of decisions should be made when possible.

3.2 Why Is ACP Important in Dementia?

A timely diagnosis of dementia can be vital to encourage the process of ACP. As discussed above as cognitive decline progresses, an individual's ability to consider their own health and care needs deteriorates, along with their ability to make informed decisions. At this point many decisions are left to families to make in a shared decision-making process with practitioners, leaving families often unsure about their status and feeling guilty. ACP has demonstrated improved outcomes for both people with dementia and their caregivers (Dixon and Knapp 2018), including reduced depression, stress, and anxiety in family caregivers (Dixon and Knapp 2018). As is in the case of Mrs. S in patient case/vignette part 5, ongoing discussions around the future and complications may have reduced the surprise for the family when she deteriorated. There is little evidence, however, if there are subgroups of people who benefit more or less than others – for example, if there are people who would rather benefit from support in living one day at a time.

Patient Case/Vignette Part 2 Mrs. S in the rehabilitation unit is dependent on nurses' care, and she becomes more disoriented in time and place as her cognitive decline progresses. She has more difficulty finding words to express herself. After a while Mrs. S is diagnosed with dementia of Alzheimer type. Her children and the multidisciplinary team do not think Mrs. S can go back home, and they want to transfer her to a nursing home with a special dementia care unit. Her children feel quite guilty about this even more so since Mrs. S wants to go home.

3.3 What Should They Discuss and the Approaches: Who, How, and When?

The EAPC recommendations on optimal palliative care for people with dementia recognize ACP as a core domain (Box 1, domain 3) (van der Steen et al. 2014b). According to the EAPC, ACP should be considered early in the disease process shortly after diagnosis, continually reviewed as an ongoing process with the patient and family on a regular basis and following any significant change in health condition. As can be seen in Fig. 1, the care goals will change, and priorities may alter over time from life prolongation and maintenance of function in early dementia through to maximizing comfort in the severe/advanced stages of dementia.

However, there is ambiguity about when to start advance care planning. Starting shortly after diagnosis may not be appropriate for everyone and is currently not necessarily a common practice in many countries. In recognition that the optimal timing of initiating the process is highly individual, the EAPC recommends a minimum as to what should be done at diagnosis, which is to name a (future) substitute decision-maker. The health-care team may also just "plant the seed." Introducing planning and decision-making as early as possible is encouraged in many countries. Decisions about when to start ACP should be considered on an individual patient by patient level and should include both the person with dementia and those close to them.

There are many national guidelines across many countries which provide example templates for ACP, including how to begin discussions and what the discussions should include. Initial discussions may include identifying the wishes and preferences of an individual, including preference of where they would like to be cared for (e.g., hospital, nursing home, or at home), but this often depends on the care that is needed and how they may like their religious and spiritual beliefs incorporated in their care. Although an individual with dementia may express their preference of place of care throughout their dementia, for example, in the case of Mrs. S in patient case/vignette part 2. Often people with dementia want to remain at home, being a familiar environment and close to their relatives. Often, like in the case of Mrs. S, people are admitted to a hospital and are

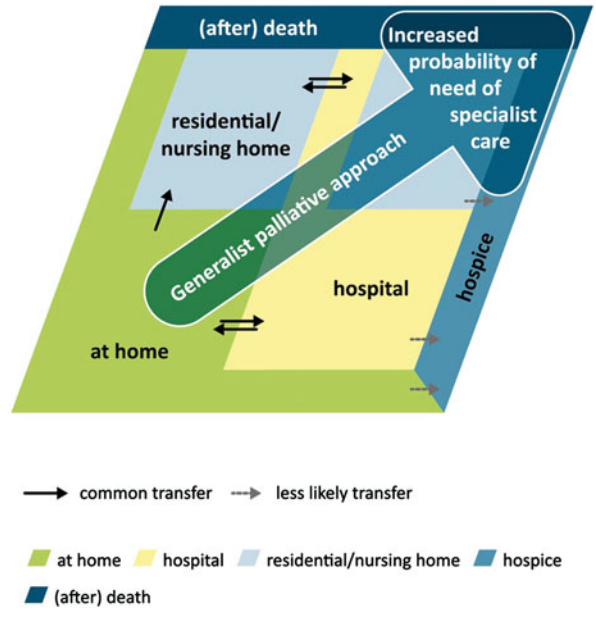

Fig. 2 Possible journey for person with dementia and health-care service transitions (Published with kind permission of © JT van der Steen, MS Klapwijk and N Davies 2018. All Rights Reserved)

afterward transferred to a nursing home because they need more care and staying at home is not safe anymore or the partner or relatives can't deliver the amount of care or guidance that is needed.

Figure 2 shows the different journeys for people with dementia; many live at home, but with the increase in care dependency, people are transferred to a hospital or a nursing home. Sometimes people are also admitted from home to a hospice or from a hospital or nursing home to a hospice. The discussions may then gradually move on to consider more specific decisions, such as treatment and scenarios of future health. These may include treatment such as artificial nutrition and hydration, the use of antibiotics for recurrent infections, and cardiopulmonary resuscitation. As with patients and families, physicians also differ in whether they feel comfortable with discussing future scenarios or rather focus on care goals and values with specific decisions postponed to when the situation occurs (van Soest-Poortvliet et al. 2015). There is a growing amount of literature surrounding planning with some placing high importance on what they regard as the necessity for people with dementia to complete advance care plans (Dixon and Knapp 2018).

3.4 Barriers

Despite many efforts internationally to encourage ACP for people with dementia, they are often not consulted about their wishes. ACP is less well developed across Europe, with much more work in Australia, Canada, and the USA. Several studies have identified a number of barriers why ACP does not occur including a lack of knowledge of ACP, difficulty of talking about such sensitive topics, fear of facing one's own mortality, organizational context, discontinuity of care, lack of a relationship with practitioners as well as within families, lack of time, as well as being made more complex in dementia by it often not being acknowledged as a terminal illness (van der Steen et al. 2014c). Many health and social care professionals are reported to lack the confidence, feel inexperienced, and need additional training and support in this area (Sampson et al. 2012). Health and social care staff in some countries believe that if they do not call emergency services in a crisis, there will be repercussions for them (Harrison Dening et al. 2012). This issue highlights the legal ambiguity that is often seen across countries of ACP (Jones et al. 2016). For example, in the UK, the legal document as part of ACP is the advance decision. The advance decision,

however, is only legally binding if it complies with the Mental Capacity Act (2005), is valid (e.g., it is signed by the individual and a witness, and it specifies clearly the treatments the individual wishes to refuse), and applies to the situation. It is important to check the legal framework of decisions at the end of life in your country or region as this does differ.

3.5 Facilitators and Benefits

ACP potentially gives patients and families an opportunity to think about what is important for them and plan to try to ensure these wishes are met. However, it may not always be possible for the individual's wishes to be met, for example, as in the case of Mrs. S's wish to go home in patient case/vignette part 2. To facilitate ACP, practitioners should be available to educate families, and in particular, there should be a dedicated key facilitator to educate both practitioner and family. ACP can lead to reduced hospital admissions, unnecessary interventions, reduced costs (Robinson et al. 2012), and even reduced stress among family caregivers as discussed in Sect. 8.2 of this chapter.

Patient Case/Vignette Part 3 Finally Mrs. S has been moved from the rehabilitation unit to a unit (wing) for people with dementia in a nursing home. At first she seems to experience problems with her new environment; later she seems to feel better in her new rhythm of the unit.

At one point she starts to frown sometimes and to behave in an agitated manner. She cannot verbally express what she is feeling at those moments. At first nothing is found which could explain this. One day a nurse hears Mrs. S moaning and sees her frowning. Physical examination and a urine test lead to a diagnosis of a urinary tract infection, which is then treated with antibiotics.

4 Symptom Management

At the beginning of the disease, people with dementia live at home and are often still capable of expressing their feelings, for instance, pain. But with the progression of the disease, people often lose this ability to communicate verbally due to neuropathological changes. This is also reflected in functional and physical impairment and behavioral and psychological symptoms, for which people often have to be admitted to a nursing home. As the dementia progresses, the need for help rises, and the last year of living with dementia is known for a high level of disability with a high need for assistance in activities for daily living. Symptoms that are often described in studies of people with dementia include pain, shortness of breath, and agitation or other neuropsychiatric symptoms.

The clinical course of dementia shows that family or medical staff working with people with dementia should pay particular attention for symptoms of pain, shortness of breath, or anxiety (Hendriks et al. 2015; Hendriks et al. 2016). Often with the progression of the disease, people get urinary incontinence and later bowel incontinence and are at high risk for swallowing problems and aspiration, weight loss, pressure ulcers, infections (pneumonia and urinary tract infections), and febrile episodes, as can be seen in the case of Mrs. S (patient case/vignette part 3) (Mitchell et al. 2009).

4.1 Pain

The gold standard for the assessment of pain is self-report. This is often not possible in a later stage of dementia when people are often not capable of verbally expressing the experience of pain or lose the capacity of pain memory. Pain can result in behavior that challenges, for example, agitation or aggression if left untreated. In the case of Mrs. S, she can be seen to frown at times, and this is often coupled with agitation; this may be an indication that she is in pain. Pain can be experienced differently in people with different kinds of dementia or at different stages, related to the different neuropathological changes. Pain is however very common, 12–76%, in people with dementia, in all stages (van der Steen 2010).

Previous studies had suggested that people with dementia in nursing homes receive less pain

medication compared to people without dementia; however, newer evidence suggests that there is no difference in people with or without dementia (Haasum et al. 2011) or it is even higher among people with dementia in some studies (Lövheim et al. 2008). Studies have also expressed concern about the overuse of opioids in people with dementia. It is therefore vital to ensure pain is a central component of continual assessment with a person with dementia, and an approach to maximizing comfort and quality of life is taken.

There are a number of instruments (pain scales) which can be used to assist staff identify pain in people with dementia if they are not able to verbally express this pain, such as the case with Mrs. S The team is alerted by the moaning and frowning suggesting she is in pain. The involvement of family and caregivers may be a very good way of assessing the patient, especially at home or just after admission in a nursing home, as they are familiar with changes in behavior or expression that may indicate distress. There are a large number of available instruments which have shown different reliability and validity, currently over 30, but for clinical practice, the Pain Assessment in Advanced Dementia (PAINAD) and Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC) are often recommended (Ellis-Smith et al. 2016). Research continues to look for an instrument that is reliable and valid and which can identify expressions specifically indicative for pain. In clinical settings it is important to evaluate the possibility of pain regularly and sometimes try the effect of analgesics, as well as assessment of current pain medication being received; is it still adequate and is it still necessary?

4.2 Shortness of Breath

Shortness of breath is often reported in studies of people with dementia with a range of 16–26% (Hendriks et al. 2015; Mitchell et al. 2009). Shortness of breath can be caused by different problems; common causes include pulmonary infection such as pneumonia or cardiac problems. Pneumonia may also be related to aspiration. Angina and pulmonary embolism are very difficult to recognize in people with dementia in cases where there are difficulties verbally expressing pain (chest) or shortness of breath.

4.3 Unmet Need/Challenging Behavior

Many feelings, for instance, pain as mentioned above, are the result of a sensation that is unpleasant, and they can lead to a change in the individual's behavior, which may be considered challenging. Many neuropsychiatric symptoms are seen in people with dementia and can have a great impact on the quality of life of that person and those surrounding them: family and caregivers.

Neuropsychiatric symptoms (NPS) (or behavioral and psychological symptoms of dementia (BPSD)) include delusions, hallucinations, depressive mood, anxiety, irritability/lability, apathy, euphoria, disinhibition, agitation/aggression, aberrant motor activity, and sleep or appetite changes (Cerejeira et al. 2012). The range of NPS prevalence in community-dwelling people with dementia is generally more than half of people (Borsje et al. 2015). These different types of behavior, often called challenging behavior, can also be frequently seen in nursing homes. Family or a regular staff member that know the person with dementia can often provide extra information on the cause of the behavior or have useful information on how to diminish this.

Infections such as a urinary tract infection are known to be a frequent cause of challenging behavior or even cause an episode of delirium; this is often the cause of admission to hospital for many people with dementia. The prevalence and incidence of delirium can be high in people with dementia, ranging from 8% in nursing homes to 89% in hospital and community populations (Boorsma et al. 2012; Fick et al. 2002). Many tools have been developed to assess delirium, including tools that are also used for people with dementia to ensure early recognition (Morandi et al. 2012), including the Richmond Agitation and Sedation Scale (RASS) and modified-RASS (m-RASS) (Morandi et al. 2016).

Agitation is often reported as one of the biggest behavioral challenges in people with dementia, and numbers ranging from 57% to 71% were found (Hendriks et al. 2015). However, for many, families are more concerned with pain, breathing problems, and memory problems than agitation (Shega et al. 2008). Pain and agitation are often reported simultaneously but a strong association was not found (van Dalen-Kok et al. 2015). Anxiety is also frequently reported in people with dementia, but this is also complex and difficult to test, due to an overlap with depression (Seignourel et al. 2008).

As can be seen in the case of Mrs. S, these symptoms and challenges often result in family caregivers acting as proxy, making decisions about the person with dementia's care when there is no advance care plan or in case of an advance care plan to check if the decision is in accordance with the ideas/wishes of the person with dementia. These are very difficult decisions for families as discussed in Sect. 6. One of the most difficult decisions is whether to move the person with dementia into a nursing home; in the case of Mrs. S, the family believe this is in the best interest of Mrs. S; however, they feel guilty about this decision as Mrs. S would like to return home (patient case/vignette part 2).

Patient Case/Vignette Part 4 After a few months in the nursing home, Mrs. S gets a fever, is short of breath, and coughs, and the amounts of fluids and food she takes are less than normal according to the nursing staff. The visiting physician diagnoses pneumonia and wants to talk to the family to discuss if Mrs. S should be sent to a hospital or not.

Mrs. S recovers from pneumonia, but she eats and drinks less every week. She can still walk but she is less stable and has a high risk of falling. She sometimes coughs during the meals. Her son asks if his mother should receive artificial hydration and feeding.

5 Treatment Options of Common Complications

In this section we refer to pharmacological and non-pharmacological treatment options for a variety of complications/symptoms which may arise before the person with dementia is in the dying phase. Later in this chapter (Sect. 9.2), we will discuss treatment in the dying phase.

5.1 Non-pharmacological Treatment Options (Including Spiritual Care)

In recent years person-centered care has been introduced in the care for people with dementia, and more evidence is showing the benefits of nondrug treatment, particularly for behavioral and psychological symptoms in relation to pain. Person-centered care is discussed in more detail later in this chapter in Sect. 7. The care for people with dementia should be multidisciplinary and include spiritual care. Studies show an effect of therapies like music therapy, massage, and aromatherapy, and these should be considered and need to be prioritized in clinical and research settings (Winblad et al. 2016). For example, music therapy has shown a reduction in the short term of depressive symptoms following at least five sessions, but there was little to no effect on agitation or aggression, and the long-term effects are yet to be studied (van der Steen et al. 2017b).

Every time when behavior changes, one has to pay attention to the possibility of medical conditions causing this change, for instance, infections, constipation, bladder retention, pressure sores, pressure sores or infections in the mouth, and side effects of medication, but also, for instance, changes in environment. Regular evaluation in a multidisciplinary team including the nursing staff, psychologist, physiotherapist, social care practitioner, occupational therapist, spiritual care counselor, dietitian, and a physician with evaluation on, among others, behavior, pain, medication, mobility, swallowing, weight change, and incontinence can help improve the quality of care for a person with dementia.

There are several environmental factors which should be considered when caring for someone with dementia. These may range from consideration about the aesthetics of the individuals' room and environment through to consistency of staff. In the home or nursing home, small alterations

may help with orientation such as using different colored doors or pictures to help identify different rooms. It is important to ensure continuity of care when delivering palliative care for someone with dementia (van der Steen et al. 2014b). Continuity encompasses, ensuring the individual is able to remain in their preferred place of care with minimal disruption and minimizing the need for transfers between settings, continuity of the provision of care even if there is a transfer, and continuity of staff caring for the individual.

5.2 Pharmacological Treatment Options

Infections in persons with dementia are usually treated following national or regional antibiotic guidelines, like Mrs. S in the patient case/vignette part 3. As the dementia progresses, there should be a process of ongoing discussions as to what to expect from treatment (this may be part of ACP), for instance, antibiotics, and the likelihood of response to treatment. In some cases, a patient may not respond to treatment when they are too sick and are not capable of drinking and eating anymore. The use of antibiotics should be discussed with the family or advocate including the person with dementia if possible; it is viewed differently in different countries. In some countries the families have more influence on treatment decisions, and the practitioner may simply provide choices, whereas in others this may be a medical decision, in discussion with the wider multidisciplinary team and family. Antibiotics can prolong life but sometimes just for several days (van der Steen et al. 2012). See Sect. 6 on controversies and decision-making in this chapter.

When people with dementia are transferred to a hospital, they often receive intravenous treatment with antibiotics or fluid or even tube feeding. This treatment increases at the end of life but practice in different countries varies (Klapwijk et al. 2014; Mitchell et al. 2009), and they also vary over time; for example, there is a decline in feeding tubes used in the USA (Mitchell et al. 2016).

As pain medication, acetaminophen (paracetamol) is often used as a first-line treatment (Hendriks et al. 2015; Sandvik et al. 2016a), followed by the use of opioids to treat more severe pain which is nonreactive to acetaminophen (commonly used, up to 24%) (Hendriks et al. 2015; Pieper et al. 2017; Sandvik et al. 2016a; Griffioen et al. 2017). Antipsychotic drugs are frequently used to treat challenging behavior in dementia, often with no positive result and many adverse effects, like extrapyramidal symptoms, stroke, or death. Research and the EAPC white paper recommend that non-pharmacological treatment (see above) should be tried first for behavior which challenges (van der Steen et al. 2014b). Several other types of medication besides (typical and atypical) antipsychotic drugs are also used to treat neuropsychiatric symptoms: anxiolytics, sedatives, antidepressants, and anti-dementia drugs. More research is needed to gain a better understanding of how and when to start and stop these pharmacological treatments to optimize prescription in people with dementia, including for cases of delirium (Agar et al. 2017). Bronchodilators are often used in the treatment of shortness of breath; studies show different prevalence, ranging from 29% to 67% (Hendriks et al. 2015).

6 Controversies and Decisions

6.1 End-of-Life Decisions

The decisions which need to be made toward the end of life are often medically focused, relating to the complex symptoms which pose a dilemma for practitioners. However, many other nonmedical factors are also important and need to be considered, for example, spiritual care. As discussed in the previous section, difficult decisions both medical and nonmedical can include spiritual care, place of care, cardiopulmonary resuscitation, treatment of infections, management of eating and drinking problems, pain, shortness of breath, behavioral problems and hospitalization, as well as any comorbid conditions. In the case of Mrs. S, as she begins to eat and drink less, the son wishes to discuss the potential use of artificial hydration and feeding (patient case/vignette part 4).

In some countries, many are raising the option of euthanasia for people with dementia. This is legal in a small number of countries including the Netherlands when strict criteria are met, but many physicians are reluctant to fulfill such a preference in the absence of clear communication with the patient.

6.2 Who Should Make the Decisions?

Ultimately, health- and care-based decisions should be made by the individual/patient themselves. However, in many cases, by the time dilemmas such as difficulty with eating and swallowing arise, it is not possible due to a diminished capacity. Hence, the individual does not have the ability to make informed decisions. Despite efforts to increase advance care planning (ACP) with people with dementia, many people reach the end of life without one (see Sect. 3 earlier in this chapter). Some are not ready to have conversations about death and face their own mortality, and decision-making is left to families (Davies et al. 2014). Practitioners rely on families to know the wishes of the individual and to relay these with confidence and accuracy when making end-of-life decisions. However, caution should be taken by practitioners as family caregivers/proxies have been shown to have a low to moderate agreement with the person with dementia about preferences for end-of-life treatments (Harrison Dening et al. 2016). Practitioners should engage closely with families to understand the individuals' previous wishes and work with the family through a shared decision-making process.

6.3 What Gets in the Way of Making Decisions?

Many barriers have been identified by family caregivers/proxies which prevent them from making decisions about end-of-life care, including a lack of information, poor communication, difficult dynamics/conflict within families, limited emotional and practical support, and dynamic care systems (Davies et al. 2014; Lamahewa et al. 2018). Practitioners should provide clear information which is communicated in a sensitive and supportive manner, helping to facilitate the decision-making process. Social care practitioners can also act as mediators in family conflict to encourage supportive family relationships and aid decision-making.

It is not just family caregivers/proxies who have difficulties in making decisions; many practitioners lack the confidence to hold such difficult conversations and shy away from these discussions (Davies et al. 2013; Lamahewa et al. 2018). These difficult conversations require a high level of skill and a vast amount of experience to be conducted sensitively; many practitioners, and even experienced practitioners, dread such conversations. This leaves family caregivers often not knowing how to approach such conversations, being left to make difficult decisions and care plans, with many feeling doubts about their status.

6.4 Approaching Challenging Decisions/Dilemmas

There are relatively few professional guidelines which address end-of-life care for people with dementia. Until recently, many palliative care guidelines have focused on cancer such as the National Institute for Health and Care Excellence (NICE) (England and Wales). Practitioners should consult their national guidelines for both dementia and palliative care (see EAPC Atlas of Palliative Care in Europe), Alzheimer Europe, and consult the EAPC white paper on optimal palliative care for people with dementia (van der Steen et al. 2014b) as discussed in the symptom management, Sect. 4.

A recent practical toolkit for making decisions specific for end-of-life care of people with dementia used in conjunction with available guidance (Davies et al. 2016) consists of a series of heuristics (schematic patterns that can be applied in complex situations and function as prompts to initiate thinking and action) which offer a

clinically familiar approach, are brief, are easy to remember, and lead to action. The toolkit covers key decisions including eating and swallowing difficulties, agitation/restlessness, reviewing treatment and interventions at the end of life (e.g., routine medication), and providing routine care at the end of life (e.g., changing dry bedsheets in the final days to hours of life). Examples of the heuristics are given in Figs. 3 and 4 and are discussed below with reference to common dilemmas and controversies.

6.5 Common Decision-Making Dilemmas and Controversies

A number of challenges and controversies around providing end-of-life care for people with dementia have been identified.

6.5.1 Hospitalization

In the process of attempting to manage symptoms and maintain quality of life, many people at the end of life often experience what are termed as avoidable hospital admissions (van der Steen 2010). This description of "avoidable" may be for a number of reasons including the nature and consequences of the condition, such as an infection (van der Steen 2010). These admissions often cause more pain and distress to both the individual and their family than remaining in their normal place of care. It is important, as in the example of Mrs. S (patient case/vignette part 4), to discuss the possibility of hospitalization with the relatives, discuss expectations, and make this decision together. Individuals can go to hospitals which have a focus on cure as opposed to care and may receive what is described as unnecessary tests or aggressive and invasive procedures. Cardiopulmonary resuscitation should be avoided in people with dementia, as it is less likely to be successful in people with dementia compared to those without. CPR can be very distressing for all those involved including both the person with dementia and the families, with those who are successfully resuscitated often being transferred to intensive care and dying a short while later.

6.5.2 Artificial Nutrition and Hydration

A common medical decision toward the end of life (like in the patient case/vignette part 4) is the introduction of artificial feeding when the individual is no longer able to swallow food, liquid, or medication. Many people, families and

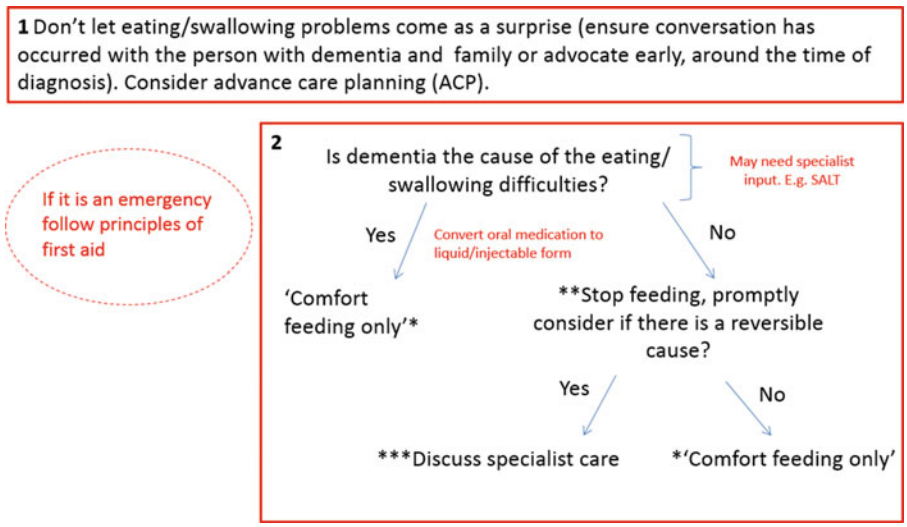

Fig. 3 Heuristic for eating/swallowing difficulties. *Comfort feeding may carry associated risks of aspiration; **Closely observe all intake particularly if changes to swallow function are suspected; ***Consider appropriateness on individual basis (Published with kind permission of © Nathan Davies and Steve Iliffe 2016. All Rights Reserved)

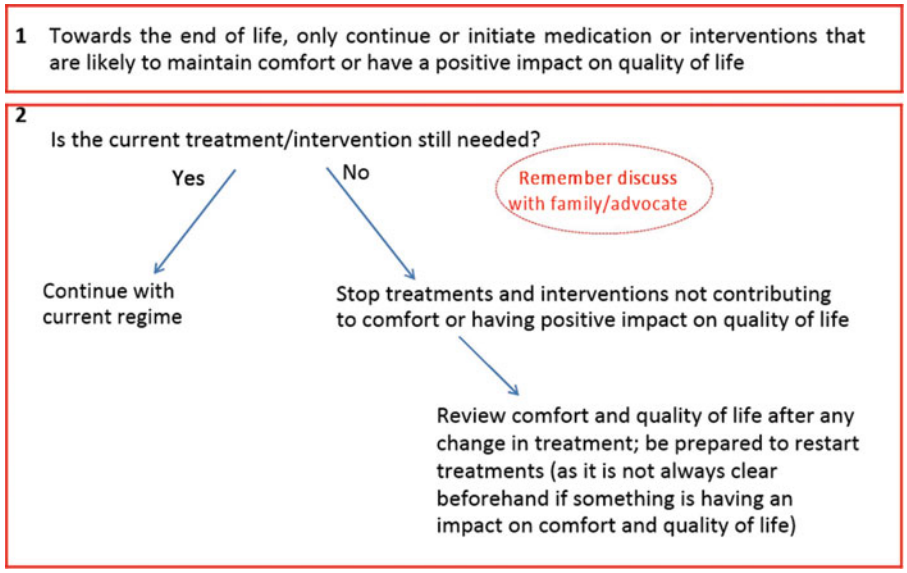

Fig. 4 Heuristic for initiating medication and interventions (Published with kind permission of © Nathan Davies and Steve Iliffe 2016. All Rights Reserved)

professional caring teams, believe that they cannot allow the individual to "starve to death," and they feel that the use of artificial feeding will extend life and prevent discomfort or further complications such as aspiration, potentially leading to an improvement in quality of life (Mitchell and Lawson 1999). In the UK, the Netherlands, and many other countries, the adoption of artificial nutrition and hydration has been a controversial topic for some time and remains so. The EAPC recommends that hydration (preferably subcutaneous) should only be provided if appropriate in the management of potentially reversible causes, such as infection, but should not be used in the dying phase when an individual loses their ability to swallow (van der Steen et al. 2014b). However, the EAPC white paper was unable to reach a consensus on this topic with the professionals they consulted, acting only to further highlight the controversy within this topic. It is unclear if rehydration therapy affects discomfort or indeed survival. A study of Italian nursing home patients with advanced dementia demonstrated that for almost all patients treated with intravenous rehydration therapy, the goal of treatment was to reduce symptoms and suffering. Despite this goal, discomfort was high overall, but symptom relief may be improved (van der Steen et al. 2018). More work to explore the effects of rehydration therapy and discomfort is needed.

The EAPC also recommends that permanent artificial feeding, using a gastrostomy or a nasogastric tube, should be avoided (van der Steen et al. 2014b). Careful and skillful hand feeding or comfort feeding should be provided. Comfort feeding refers to the process of eating for pleasure, providing small amounts of food, even though there may be associated risks such as aspiration. Practitioners together with families must balance the risks of feeding with the potential comfort and pleasure that eating may provide for the individual – Fig. 3 illustrates a heuristic which conveys a practical approach to how these decisions can be considered in the case of Mrs. S.

Currently there are no studies which show an association that artificial feeding offers benefits to the individual. On the contrary some studies have demonstrated they increase the chance of infection, aspiration, further complications (Palecek et al. 2010), and potentially mortality (Ticinesi et al. 2016). As with the limited understanding of pain in dementia, we similarly have a limited understanding around feelings of hunger and thirst in

people with dementia. Data in the USA indicates a reduction in the use of feeding tubes in people with dementia (Mitchell et al. 2016).

6.5.3 Medication: Antimicrobial Treatment

The ability of antimicrobial treatment for recurrent infections in people with dementia to extend life or improve comfort is not well understood; however, some studies have demonstrated increased survival following antimicrobial treatment compared to no treatment or a palliative approach (van der Steen et al. 2012). The use of antimicrobials including oral, intramuscular, and intravenous for pneumonia has increased survival but was also associated with more symptoms reported in retrospect in the period from before to after the pneumonia in a nursing home population with advanced dementia (Givens et al. 2010). However, this was in the USA, where people with dementia and pneumonia with fewer symptoms were more likely not to be treated with antibiotics (van der Steen 2011). Another study used discomfort observed by independent, blinded observers measured with validated tools after antibiotic treatment, and discomfort levels were lower after antibiotic treatment (van der Steen 2011). A more recent study with the same strong methods showed that, with more symptom-relieving treatment provided, antibiotics were no longer associated with discomfort (van der Maaden et al. 2016). Antimicrobial use might be more beneficial for people in the earlier stages of dementia compared to the later stages, with no difference in mortality at in more advanced dementia between those receiving antimicrobial treatment and palliation and those not (Fabiszewski et al. 1990). Some studies have shown that increased survival after antibiotic treatment, but this may only last for a few days in some cases (van der Steen et al. 2012), which may be simply prolonging the dying process (van der Steen et al. 2012). Antimicrobial treatment is associated with renal failure, diarrhea, the use of intravenous lines, and skin rashes. After nearly 25 years of research investigating the effectiveness of antimicrobial treatment for people with dementia, the effects (benefits and adverse effects) are still unclear.

It is important to identify the source of the infection which may be causing symptoms such as fever and balance the benefits of treatment with the potential side effects and consequences. The EAPC recommends that antibiotics are appropriate for treating infections which have a goal of increasing comfort, but life-prolonging effects should be considered carefully (van der Steen et al. 2014b). This can be demonstrated through the heuristic in Fig. 4.

6.5.4 Other Medications

Treatments with other medications for preventive or symptomatic use can cause dilemmas too. Acetylcholinesterase inhibitors, HMG-CoA reductase inhibitors (statins), antihypertensive drugs, antihyperglycemic drugs, and anticoagulants are prescribed often in people with advanced dementia, but many medical guidelines provide an understanding of initiating such treatments but often do not include when and how to stop them. Discontinuation should be considered, but it can be difficult to determine what the effect can be and if stopping will contribute to a better quality of life (see Fig. 4); however, it can reduce the risks of side effects and drug interaction. Multidisciplinary meetings, medication review, and educational programs can help to improve appropriate medication use for people with advanced dementia in nursing homes.

7 Person-Centered Care

For many, being viewed as a person and treated with respect and dignity is, in addition to good symptom management, fundamental to a good death. This is consistent with what experts regard as the most important domains in palliative care with dementia: optimal treatment of symptoms and providing comfort and person-centered care, communication, and shared decision-making (van der Steen et al. 2014b). It can be argued that person-centered care is always important, but it may help to emphasize its importance in patients at risk of not being seen as a person anymore, which is the case with advanced dementia or when patients are not very responsive due to

illness or at the end of life. Indeed, with admission to a nursing home, for example, as is the case with Mrs. S, family caregivers may be concerned that staff do not know the patient well enough to provide person-centered care, and as they live in a nursing home, they continue to lose their identity and may struggle to maintain this identity which is so important to person-centered care (Davies et al. 2017).

8 Family Caregivers of People with Dementia

8.1 Importance of Family Caregivers

An estimated 46.8 million people are living with dementia worldwide (Alzheimer's Disease International 2015), many of whom will be cared for by family caregivers and can be referred to as lay carers, untrained carers, informal carers, caregivers, or proxies. In the UK the Alzheimer's Society has insisted that without the help and support of family caregivers, the formal care system would collapse. Traditionally there are distinct boundaries between caregivers and the cared for. Caring in palliative care however may differ from caring for someone with a nonterminal physical or intellectual impairment. The boundary between the "caregiver" and the "cared for" is said to be somewhat blurred, because of the increasing need for support for the individual from the caregiver in palliative care. The caregiving career involves a variety of tasks in addition to meeting the physical and mental needs of the person with dementia. These include interaction with health and social care professionals, doing daily household chores, and escorting the person with dementia to various medical, dental, optical, and hairdressing appointments.

8.2 Effects of Caring for Someone with Dementia

It is well known that caring in general can be a stressful role and that the burden placed on the individual caregiver is often great, with limited opportunity to have breaks, socialize, and have whatever one may classify as a "normal" life. However, caring for an older person or a relative with dementia is thought to be one of the most stressful and difficult forms of caring. Caregivers as described in the portraits by Sanders and colleagues face the difficulty of coming to terms with the diagnosis and the loss of the person they once knew (Sanders et al. 2009). They may find difficulties with the individual's behavioral and cognitive decline, the loss of their own "normal" life, the role of caring, and finally the eventual death of the person. Uncertainty of death and the treatment options for people with dementia can lead to feelings of guilt among family caregivers; this is illustrated in patient case/vignette part 2. Caregivers of people with dementia have higher rates of various health problems, both physical and psychological, including depression and cardiovascular problems, resulting in increased doctor visits and an economical burden on health-care services, with a higher risk of mortality (Brodaty and Donkin 2009).

8.3 Supporting Caregivers

The lack of definitive split between the person with dementia and the caregiver can be conceptualized as what Twigg termed as carers as co-clients (Twigg 1989). Despite caregivers being seen as having a caring "career," the experience is not the same for all. Something which is often forgotten or not considered is that not all caregivers are loved by their relatives and conversely can be mistakenly labeled as "loved ones." The caregiver may endure a trajectory of caring from the encounter stage, where they are coming to terms with both the diagnosis of dementia and also their new role, moving onto an enduring stage at which point the caring intensity increases, through to the exit stage where they face the death of the individual and adapting to their new life (Lindgren 1993). As we discussed in Sect. 2 of this chapter, palliative care may cover all stages of this "caregiving career," and each individual caregiver may require more or less support at various stages

(Davies et al. 2014). A thorough caregiver's assessment should be completed with the family caregiver of the person with dementia, to identify their needs and levels of support required. This should be a holistic assessment considering medical as well as psychosocial aspects of care and support.

8.4 Grief, Loss, and Bereavement

Grief and loss when someone dies is to be expected with most people and is considered a normal response to death. Grief has been defined as "the reaction to the perception of loss with symptoms including yearning, sadness, anger, guilt, regret, anxiety, loneliness, fatigue, shock, numbness, positive feelings and a variety of physical symptoms unique to the individual" (Rando 2000).

Throughout the course of dementia, family caregivers may be experiencing a series of multiple losses, for example, loss of intimacy, companionship, control, personal freedom, and well-being among them (Chan et al. 2013). These losses can be described as part of anticipatory grief, that is, grief which occurs before the death of the individual (Rando 2000). Anticipatory grief occurs in 47–71% of family caregivers of people with dementia (Chan et al. 2013). The sometimes long projected course of dementia means that anticipating the death of the individual and ambiguity of what the future holds can be common among family caregivers. Anticipatory grief has been shown to have an association with depression, and depression is increased with anticipatory grief (Sanders and Adams 2005). However, some studies have suggested that what appears as clinical depression may actually be a grief reaction (Sanders and Adams 2005). Other factors which appear positively associated with increasing anticipatory grief include burden, non-English primary language in English-speaking countries, living with the person with dementia prior to being placed in a care home, and less satisfaction with care (Chan et al. 2013).

Grief appears to be more severe during the moderate to severe stages of dementia (Chan et al. 2013). However, as suggested, the needs of individual caregivers may differ, and this may also relate to their response to grief and loss. Individual caregivers may experience grief at different stages, and this should be carefully considered when supporting family caregivers. In particular, there may be a marked difference between spouses and adult children responding differently at different stages. Adult children appear to experience minimal grief in the early stages of dementia, most intense at the moderate stage, and the grief lessens toward the advanced stages with feelings of relief when the individual moves into a nursing home, for example. For spouses, grief appears to reflect a linear pattern increasing as dementia progresses; however, another work has suggested grief remains stable in advanced dementia and therefore may not continue to increase for all (Givens et al. 2011). It is important to reassure caregivers that relief after death is common and they should not feel guilty about this feeling; it can be part of the post-death grieving process (Chan et al. 2013). For some, grief may continue for some time after death, termed complicated grief if more than 6 months; this is termed as *persistent complex bereavement disorder* in the DSM-5, marked by an individual "incapacitated" by grief affecting their daily life.

Particular consideration and attention may be needed toward male caregivers who can find it difficult to openly accept their feelings of grief, strain, and distress (Sanders et al. 2003). Grief in some may be expressed in different ways or using different language, for example, portraying emotional dissociation from the person with dementia (Sanders et al. 2003). Males often have less stable social support networks and are less likely to seek assistance in dealing with their grief than females. This may be particularly pertinent in spouse male caregivers, who may be older and for whom grief may be particularly challenging, as they come to deal with the emotions associated with being alone at a time when their own social networks will be dwindling (Sanders et al. 2003).

In addition to regular caregiver assessments and reviews as mentioned, post-bereavement support should be offered to families (van der Steen et al. 2014b), including helping them adjust to a life of post-caring when much of this previous world

will have disappeared. This may include as in the case of Mrs. S patient case/vignette part 5 a meeting at the nursing home with the family after their relative has died. Practitioners should identify caregivers who are at increased risk of grief (anticipatory, normal, and complicated grief), such as those with high levels of burden and depression, offering caregiver support at an early stage.

8.5 What Do Caregivers Want from Care?

The individuality of caregivers is not only reflected in the needs of them as a caregiver but also in their views of how palliative and end-of-life care should be provided for someone with dementia. Caregivers' views regarding the appropriate treatment in particular referring to the dilemmas discussed in Sect. 6 of this chapter lie on a spectrum of beliefs from provision of care purely aimed at comfort by relieving symptoms through to active/invasive/aggressive treatment which is aimed at "cure" (Davies et al. 2014). It is important to reflect on the stage of the dementia and provide information and education to family caregivers as to the progression of dementia (see Fig. 1) and appropriate treatment options (van der Steen et al. 2014b). However, it is also important to acknowledge that there is a great deal of diversity when families want to receive the information (individual and between countries). When considering families' views, there should be a recognition that they may not have the complex medical knowledge that many practitioners have and this may be their first experience caring for someone who is dying. Caregivers may focus on the psychosocial aspects of care as their main priorities (Davies et al. 2017). This is important to emphasize as we discussed previously that not all decisions are medically focused.

Patient Case/Vignette Part 5 Mrs. S gets weaker and is not able to walk anymore. She has lost a lot of weight in the past few months. She gets another case of pneumonia, is in bed all day, and doesn't eat or drink anything anymore; the nurses think that Mrs. S is going to die this time. For the daughter of Mrs. S, this comes as a surprise. The physician and the nursing staff make all sorts of arrangements, for example, on pain relief, treatment in case of shortness of breath, and prevention of pressure ulcers and constipation. A spiritual counselor is asked by the nursing home to visit Mrs. S. Mrs. S's daughter stays with her mother all the time. She frequently asks when her mother is going to die. After 3 days and nights, Mrs. S dies in the presence of her daughter.

A few weeks after the death of Mrs. S, the family is invited to attend a meeting with the nursing staff and the physician. They talk about the stay of their mother in the nursing home and the final days to death.

9 Dying with Dementia

A prognosis is very difficult to provide to a person with dementia (Brown et al. 2013). With the disease comes a decline in cognitive functioning, but it is very difficult to predict if a person with dementia is in the last months of life, whereas with cancer patients, end of life seems more predictable. People do not always reach the last phase of dementia, and about half of people with dementia may die before the advanced stages (Hendriks et al. 2016). In people with cancer and dementia, a high number of symptoms are found while dying in various settings, such as a hospice and nursing home. In the USA hospice generally refers to hospice care as a service. In many other countries across the world, such as the UK, a hospice is a physical building which delivers palliative care (see Fig. 2); however, few people with dementia will receive care here (Reyniers et al. 2015).

The 6-month mortality rate in nursing homes is high and often higher than anticipated (van der Steen et al. 2007). The most frequent causes of death are respiratory infections or cardiovascular disorders, and in later stages, people are often more dehydrated and cachectic due to eating/swallowing difficulties like Mrs. S in the patient case/vignette part 5 (Hendriks et al. 2014). Also in the earlier stages of dementia, there is an association between eating and drinking less and mortality (Hendriks et al. 2016).

Many people with dementia die in a nursing home, but the numbers differ between countries related to the available system of care for people with dementia. In some countries a large proportion of people will still die in a hospital (Reyniers et al. 2015). The different journeys from home to sometimes hospital, nursing home or hospice to death, and the increased need for palliative specialist care are shown in Fig. 2.

Prognosis for someone with dementia is difficult; however, the prediction of short-term mortality, for example, 1 week, is much more accurate (Casarett et al. 2012; Klapwijk et al. 2014). Even when death is expected within days, it is not possible to predict when exactly someone is going to die such as in the case of Mrs. S (patient case/vignette part 5).

Many studies on the last days of life of dementia show often burdensome symptoms like pain or shortness of breath, and this is also indicated by relatives, who in many cases experience death as a struggle. Only 50% of the relatives perceive death as peaceful in a Dutch study (De Roo et al. 2014).

In the literature a minority of nursing home residents with advanced dementia enter or are transferred to a hospice (Reyniers et al. 2015), but this also depends on available care system and the care that is required; not all people with dementia will require a hospice placement (see Fig. 2). Hospice care is often more for symptomatic treatment, often scheduled treatment of pain and shortness of breath. All people with dementia should get good quality of care at the end of life, not only in a hospice.

9.1 Symptoms in the Dying Phase

Several studies on the last days of life with dementia show high percentages of pain in the days before death, ranging from 15% to 78%; however, there are differences among studies, possibly also due to different measurement scales or methods (Hendriks et al. 2014, 2015; Klapwijk et al. 2014; Sandvik et al. 2016b). There is a high prevalence of shortness of breath in people with dementia increasing in the period to death sometimes even to 80% of people (Hendriks et al. 2015; Klapwijk et al. 2014; van der Steen 2010). Different behaviors are seen in the days before death. People are often in bed and can be unconscious. Restless behavior, anxiety, and agitation are seen in several studies, and also delirium has been reported (Hendriks et al. 2014, 2015; Vandervoort et al. 2013; Mitchell et al. 2009).

9.2 Treatment Options

9.2.1 Non-pharmacological Treatment Options (Including Spiritual Care)

Many of the non-pharmacological treatment options as described in Sect. 5.2 can also be used in the last days before death. The Namaste Care program, offering meaningful activities by a trained nursing assistant in nursing homes for people with advanced dementia, specifically describes the use of the program for the dying phase (Volicer and Simard 2015).

When a person with dementia reaches the dying phase, nursing staff and medical team should pay close attention to prevent constipation, bladder retention, and pressure sores. Regular mouth care should be started. People should be offered drinks and food, but it should not be forced upon them. The medication should be evaluated, and if oral medication can't be swallowed, it should be stopped. Regular evaluation of pain, shortness of breath, or discomfort is needed; observational instruments for pain or discomfort can be used in this phase, for example, the Discomfort Scale-Dementia of Alzheimer Type (DS-DAT) (Hurley et al. 1992). The presence of a pacemaker or implantable cardioverter defibrillator (ICD) should be checked, and in case one of these is present, it should be explained what to do to nursing staff and family.

It is important to highlight the needs of people are individual and some people have personal needs and may want spiritual counseling. Spiritual counseling is often overlooked; a study from a UK hospital showed that the religious beliefs of people with dementia were documented less than those without dementia (Sampson et al. 2006). Spiritual care has been associated with an improved perception of

quality of care from families at the end of life (Daaleman et al. 2008) and families' satisfaction with physicians' communication shortly after admission to a nursing home (van der Steen et al. 2014a).

It is very important for the nursing staff and medical team to explain the course of symptoms and possible treatment options to the family (including the presence of Cheyne-Stokes respiration, rattle, and time of death) and to make a clear description of medication with explanation what to give when and also if necessary extra medication which can be given. It is vital to include families as much as possible and to ask for the wishes of the family, when the team should contact the family and who. An end-of-life care plan can help to improve communication and care in the last days of life (Detering et al. 2010).

9.2.2 Pharmacological Treatment Options

Pain and shortness of breath are often treated with opioids; a high percentage of people use opioids on the last day before death, often requiring an increase on the last day (Hendriks et al. 2014, 2015; Klapwijk et al. 2014; Sandvik et al. 2016b). Agitation is treated with anxiolytics, but also palliative sedation may be initiated, with a Dutch study demonstrating palliative sedation was started in around 21% of cases (Hendriks et al. 2014, 2015).

Response to opioids should be closely monitored when prescribed for pain or shortness of breath to ensure effective response without excessive side effects. Special caution should be taken when prescribing for patients with renal failure as there is a risk of accumulation of renally excreted opioids.

Death rattle is sometimes treated with hyoscine (also known as scopolamine) subcutaneously; however, evidence is limited with a lack of consensus on the best approach (van der Maaden et al. 2015).

10 Conclusion

As this chapter demonstrates, palliative care for people with dementia shows similarities to palliative care for people with other conditions such as cancer in particular with relation to symptoms. However, there are also differences which make palliative care for people with dementia unique, including communication difficulties with the individual, recognition of dementia as a terminal illness, and large elements of uncertainty in several areas including patient wishes and prognosis. Advance care planning is important for people with dementia. Person-centered care should be adopted throughout the care journey, but in this chapter, we have also highlighted the importance of family caregivers. Families should be involved in care decisions and processes, but also we highlight their need for care themselves, as such palliative care for people with dementia is not a dyad relationship of health and care team and the person with dementia but a triad of the person with dementia, family, and the health and care team.

Abstract

There have been significant advances in the prevention and management of stroke over the last few decades. Despite these important developments, stroke, both in the acute and chronic phases, remains a major cause of morbidity and mortality. The value of integrating palliative care principles and practices into stroke care management is being increasingly recognized across a range of domains including symptom management, assistance with complex decision-making, discharge planning, and end-of-life care. This chapter will explore the logistics, benefits, complexities, and challenges associated with the evolving relationship between stroke and palliative care services.

1 Introduction

There have been significant advances in the acute treatment and rehabilitation of stroke over the last few decades. Contributing factors include improved early detection/recognition, timely hospital presentation, the use of thrombolytic and endovascular therapies, early initiation of rehabilitation, and the introduction of organized stroke care. Ongoing improvements in stroke prevention, treatment, and rehabilitation are crucial as stroke prevalence is expected to increase with the aging population. The lifetime risk of having a stroke has been reported to be approximately one in five for females and one in six for males (Mozaffarian et al. 2015) although this figure was calculated from a predominantly Caucasian cohort within the United States and may therefore not be easily generalizable. Stroke incidence varies between countries and is influenced by a range of health, cultural, geopolitical, and socioeconomic factors. Globally the burden of stroke is increasing as measured by the absolute number of people affected, stroke survivors, and disability-adjusted life years lost (Feigin et al. 2014). Much of this burden is seen in low- to middle-income countries.

Strokes constitute a heterogeneous group of conditions which can be described by mechanism and/or location of injury. Approximately 80–85% of strokes are ischemic in nature, with the remainder being either intracerebral hemorrhage (ICH) or subarachnoid hemorrhage (SAH). ICH generally occurs following arterial wall rupture in vessels weakened by chronic hypertension while SAH typically follows aneurysmal rupture within the circle of Willis or trauma (Simmons and Parks 2008). Ischemic subtypes include thrombotic strokes due to occlusive arterial atherosclerotic disease, embolic strokes which are typically cardiac in origin, and lacunar infarcts which occur following the occlusion of the small arteries that supply deep brain structures. Broadly speaking the extent of injury or damage associated with a stroke will depend upon the blood vessels involved and the areas and extent of brain affected.

The most important factor in the initial management of acute stroke is time. The sooner a stroke is recognized and treatment commenced, the better the outcome is likely to be. Another key factor in optimizing chance of recovery is venue of care. There is clear evidence that patients who are managed in a designated stroke center or unit with a specialist multidisciplinary team do better than patients managed elsewhere. In a Cochrane review of 28 trials and 5855 participants which compared stroke care unit (SCU) care with alternative care, SCU was associated with significant reductions in the odds of death, dependency, and/or institutionalized care (Stroke Unit Trialists' Collaboration 2013). The benefits of management within a SCU have been demonstrated for all subtypes of ischemic strokes (Smith et al. 2010a) as well as for ICH (Langhorne et al. 2013).

After initial cardiorespiratory stabilization, immediate stroke management is individualized according to a range of factors including type and severity of stroke, presence of contraindications, medical comorbidities, and patient and family wishes. Following an ischemic stroke in appropriate patients who do not have contraindications, the initial goal is to provide intravenous (IV) thrombolytic therapy as quickly as possible. The provision of a single dose of IV recombinant tissue plasminogen activator (IV rt-PA) within 4.5 h of the commencement of symptoms has been associated with a substantially improved chance of independent function at 3 months post stroke (Maldonado et al. 2014). The use of endovascular therapies following ischemic stroke is an area of ongoing research and development. Therapies under this umbrella include endovascular thrombolysis, thrombectomy, and stent retriever technology. It has been suggested that these approaches may provide superior recanalization in situations such as proximal vessel occlusion when systemic thrombolysis may be less efficacious although until recently results from randomized trials were mixed. Two recently published trials however, both of which were stopped early due to efficacy, have shown significant improvements in functional outcome (Campbell et al. 2015; Goyal et al. 2015) as well as mortality (Goyal et al. 2015) for the combination of endovascular thrombectomy and IV rt-PA compared to IV rt-PA alone, in ischemic stroke with proximal cerebral arterial occlusion.

The management of ICH involves acute stabilization including management of blood glucose and temperature, careful blood pressure control, quality nursing care, prevention of complications, early rehabilitation, and prevention of recurrent hemorrhage (Hemphill et al. 2015). Time is again crucial as it is common for deterioration to occur in the period soon after an ICH. While the benefits of surgical removal of hemorrhage for most supratentorial ICH have not been proven, prompt surgical management is recommended for patients with a cerebellar ICH who are deteriorating neurologically or have brain stem compression (Simmons and Parks 2008; Hemphill et al. 2015). Emergent therapies under investigation in ICH include minimally invasive surgical techniques and the use of biological neuroprotective agents.

Despite advances in prevention, acute treatment, and rehabilitation, stroke remains a prominent cause of morbidity and mortality worldwide. It is a major cause of disability in the United States where up to a third of patients require admission to a long-term care facility following stroke (Mozaffarian et al. 2015). A range of psychological and physical sequelae have been reported by stroke survivors including anxiety and depression, pain syndromes, and communication difficulties. Not surprisingly high levels of distress and caregiver burden are also common among relatives and loved ones. The ideal model for managing the important physical and psychosocial needs of stroke survivors and their families is yet to be established, and it is not clear where palliative care services sit in this paradigm.

While mortality rates vary internationally and have decreased over the last 20 years (Feigin et al. 2014), stroke remains the second commonest cause of death worldwide (World Health Organization 2014). A range of important and diverse needs have been reported by dying patients and their families including symptom management, psychosocial support and assistance with prognostication, treatment decision-making, and future planning. The utilization of palliative care principles and practices would seem appropriate in meeting these needs, and there is increasing recognition, including from international guidelines, of the importance of integrating palliative care into stroke care (National Stroke Foundation 2010; Holloway et al. 2014; Casaubon et al. 2016; Intercollegiate Stroke Working Group 2016). However a range of challenges to effective integration have also been identified from both a stroke and palliative care perspective. The aim of this chapter is to explore the relationship between stroke services and palliative care in both the acute and longer-term setting. The current level of involvement and proposed models of integration will be discussed as well as some of the common palliative care needs and issues identified by patients, families, and health professionals. It is hoped this will provide a contemporaneous overview of the current situation and highlight some important areas for future thought, research, and investment.

2 Palliative Care and Acute Stroke

There is growing recognition that some patients and families following an acute stroke have needs that will be best met by integrating palliative care philosophies and practices into their stroke management.

2.1 Palliative Care Recognition Within International Stroke Guidelines

There is increasing recognition of the relevance of palliative care principles for some patients following a stroke within published international stroke guidelines. While the depth and breadth of information varies across guidelines, there is general agreement concerning the importance of high-quality end-of-life care within stroke services and some support for palliative care throughout the stroke care trajectory.

In a comprehensive scientific statement from the American Heart Association/American Stroke Association, Holloway and colleagues explored the dynamics, logistics, and complexities associated with palliative and end-of-life care in stroke (Holloway et al. 2014). The authors advocate for

the availability of palliative care for all patients and their families following a severe or life-threatening stroke, throughout the disease course. In their proposed model, the management of most palliative care problems would be carried out by the stroke service multidisciplinary team with specialist palliative care services available for secondary consultation in situations of heightened complexity. Importantly, the authors provide evidence-based recommendations and guidance to aid implementation, including practical education regarding communication skills, goal setting, and symptom assessment and management.

The Canadian Stroke Best Practice Recommendations emphasize the importance of fostering palliative care expertise within stroke centers (Casaubon et al. 2016). The guidelines make a distinction between palliative care and end-of-life care noting that palliative care can occur in combination with life-prolonging therapies and is not reserved only for those who are imminently dying. A palliative approach is suggested in the setting of catastrophic stroke or multiple comorbidities in order to support both patient and family. Replicating the recommendations of Holloway and colleagues (2014), the guidelines make clear that the stroke service multidisciplinary team should have the appropriate palliative care skills to support dying stroke patients but also that there be access to specialist expertise. Specific indications for specialist palliative care referral include the management of unstable symptoms and assistance with decision-making and with managing complex family and psycho-social dynamics. Recommendations are also made in relation to Advance Care Planning (ACP), specifically that stroke survivors, their families, and caregivers should be supported to participate in it.

In Australia, the 2010 Clinical Guidelines for Stroke Management recommend that all patients dying following a stroke have access to care that is aligned with palliative care principles and practices (National Stroke Foundation 2010). This includes consideration of physical, psychosocial, spiritual, and cultural needs as well as guidance with prognostication and the diagnosis of dying in deteriorating patients or those following a severe stroke. The guidelines note that in many less complex situations, this care will be provided by stroke service staff, and these staff will require ongoing education and support in relation to end-of-life care. The importance of clear and timely communication between stroke services, patients, and families is stressed, and family meetings are suggested as an appropriate forum for these discussions.

The 2016 fifth edition of the UK National Clinical Guideline for Stroke include, among their key recommendations, the proposition that multidisciplinary stroke teams should consider high-quality end-of-life care as a core component of their work (Intercollegiate Stroke Working Group 2016). The need for enhanced education and support for stroke service staff in palliative care principles is emphasized, as is access to specialist palliative care and the opportunity for timely transfer to home if this is the desirable outcome. Among changes from the previous iteration, the 2016 guidelines caution against imposing burdensome restrictions upon patients dying from stroke with particular mention made about the pragmatic management of impaired swallowing and oral intake at end of life. The guidelines acknowledge the range of physical and psychological stressors that can occur following a large stroke and propose that the appropriate management of these problems can help ameliorate distress for patients and their families at end of life.

When considered together, a number of common themes are evident across the guidelines. These include:

- General support for palliative care principles as key components of stroke care.
- Recognition of the presence of multidimensional symptom issues for many patients and their families following a large stroke.
- The importance of clear and ongoing communication between stroke services, patients, and families particularly in relation to issues such as prognostication, goals of care, and management.
- Support for a service model in which the multidisciplinary stroke team provides the majority of palliative and end-of-life care with secondary support available from specialist palliative care services.

2.2 Integration of Stroke and Palliative Care

Although integrating palliative care and acute stroke services is considered important for patients, families, and health professionals alike, how this integration might actually take place is under-researched and not without its challenges. Establishing the palliative care needs of stroke patients and their families is a crucial first step in an integrated approach; however data addressing this question are limited and little is known about how these needs might change over time (Stevens et al. 2007).

Potential methods to assess palliative care needs might include triggers built into existing stroke care pathways – simple bedside prompts or more formal targeted needs assessment tools. Creutzfeldt and colleagues (2015) showed that the use of a simple four-question "palliative care needs checklist" during neurology ward rounds was an effective prompt for recognizing and meeting patient and family needs. Questions in the checklist addressed the presence of distressing symptoms, how the patient and family were coping, and whether the goals of care or treatment approach needed to be modified. Burton and colleagues (2010) used the Sheffield Profile for Assessment and Referral for Care (SPARC) tool to identify high levels of palliative care needs in a prospective study of 191 consecutive stroke admissions to two UK hospitals. The SPARC was developed to screen patients with a range of advanced diseases for specialist palliative care (SPC) referral and incorporates five domains covering physical, psychosocial, spiritual, and functional issues. The authors concluded that the use of the SPARC tool particularly in more disabled stroke patients provided a valuable trigger for staff to consider a range of palliative care issues.

In some ways acute stroke and palliative care might not be considered particularly compatible. The acute stroke environment is one of high-intensity neuro-restorative care with an emphasis on survival, while palliative care is commonly considered more meditative in approach with less concern placed upon survival and more on quality of life. Challenges in introducing palliative care into general stroke management are highlighted by qualitative studies in which stroke unit staff have questioned the juxtaposition of a simultaneous curative focused and palliative approach (Gardiner et al. 2013) and have viewed palliative care as being predominantly about end-of-life care and representative of failure of stroke management (Burton and Payne 2012). Beyond the acute stroke phase, categorizing a patient as "palliative" has been identified as a barrier to combining rehabilitation and palliative care (Burton and Payne 2012).

Traditional palliative care models developed predominantly for patients with malignant diseases may not be easily transferrable to stroke. With its typically sudden onset and decidedly unpredictable clinical course, stroke may behave differently to many cancers or other chronic non-malignant conditions in which palliative care is commonly involved. Such differences were highlighted by a study of 544 patients admitted to a tertiary SCU that found more than 50% of the 87 patients who died had been completely independent and well immediately prior to their stroke (Eastman et al. 2013). Caregivers of stroke survivors have also been noted to have different needs when compared to those of patients with cancer. They are typically older and frailer and as a result may lack important support and social networks (Stevens et al. 2007).

Despite a current lack of clarity concerning the characteristics and function of palliative care within acute stroke services (Burton and Payne 2012), there does appear to be general acceptance of a pragmatic service model in which the multidisciplinary stroke team provides the majority of palliative and end-of-life care with secondary support available from SPC (Holloway et al. 2014; Creutzfeldt et al. 2015; Casaubon et al. 2016). SPC services are also ideally placed to provide the necessary education, training, and support to enable the provision of high-quality nonspecialist palliative care. Importantly, for any model to be applicable to patients throughout the disease course as has been suggested (Holloway et al. 2014; Creutzfeldt et al. 2015), recognition will

be required from stroke services that palliative care principles can be positive adjuncts to disease-modifying therapies rather than simply applying to end-of-life care. Additionally a model combining stroke and palliative care will need to consider important system issues such as avoiding overburdening already-stretched palliative care services and not deskilling stroke unit staff (Stevens et al. 2007).

Using qualitative data obtained from patients, families, and stroke service staff, Burton and Payne (2012) constructed a theoretical framework on how the integration of stroke services and palliative care might occur. They proposed that integration was underpinned by six key mechanisms, namely, *clinical legitimacy*, *capacity*, *family engagement*, *early integration*, *recognition of complexity*, and *recognition of dying*. These mechanisms could themselves be influenced by a range of clinical and organizational factors which vary according to the existing structures and processes within individual healthcare settings. Burton and Payne (2012) propose that analysis of the relationships and interactions influencing these six key mechanisms will facilitate service development and improve the care of patients and families following stroke.

Overall the development and optimization of integrative models will depend not only on the willingness of the stroke and palliative care sectors to embrace the process but also organizational and governmental support to ensure adequate funding and support. Underpinning the whole process is the requirement for ongoing collaborative quantitative and qualitative research focusing not just on outcomes but also factors such as needs assessment, appropriate patient stratification, timing and indication for SPC referral, cost/benefit analysis, and patient, family, and health professional experiences.

2.3 Specialist Palliative Care Utilization in Acute Stroke: A Review of the Current Literature

Data quantifying the level of SPC involvement in stroke are limited and predominantly focused on inpatient consultation services. While variability is seen between health organizations internationally, there is evidence to suggest that the overall uptake of palliative care services for patients following an acute stroke is increasing. In a large cross-sectional study investigating palliative care utilization in nontraumatic intracerebral hemorrhage (ICH), Murthy and colleagues (2016) analyzed admissions to over 1000 American hospitals using the National Inpatient Sample, the largest inpatient health database in the United States. Of the 311,217 included admissions, 32,159 (10.3%) received palliative care, with a substantial annual increase in palliative care involvement seen (4.3% in 2007 to 16.2% in 2011). In an analysis of administrative data of 4894 patients who died within 30 days of an ischemic stroke, 23% of all patients were enrolled in hospice for end-of-life care, a threefold increase from previously reported rates (duPreez et al. 2008).

A small amount of research has explored predictors for SPC involvement in patients following stroke as well as differences between referred and non-referred patients. The influence of both sociodemographic and clinical factors on referral patterns has been reported with data typically obtained from either large administrative dataset analyses or retrospective cohort studies.

In an analysis of palliative care involvement for patients following nontraumatic ICH (Murthy et al. 2016), significant predictors for palliative care involvement included ICH severity, associated comorbidities, female gender, advanced age, hospital location, and ethnicity. Several of these factors were also predictors for hospice utilization in 4894 patients who died within 30 days of an ischemic stroke (duPreez et al. 2008). Predictors which increased the likelihood of hospice utilization included older age, female gender, dementia, Caucasian descent, and hospital length of stay greater than 3 days. Mechanical ventilation, gastrostomy, and uncomplicated diabetes mellitus as a comorbidity correlated with decreased hospice enrolment.

Holloway and colleagues (2010) reviewed all patients referred to an inpatient palliative care consultation service within a large US teaching hospital over a 3-year period. Compared to

patients with cancer or common nonmalignant diagnoses including chronic obstructive pulmonary disease (COPD), stroke patients tended to be more functionally impaired, less likely to have decision-making capacity, and were more likely to die in the hospital. For the 1551 stroke patients analyzed during the study period, 6.5% received palliative care consultation. Stroke patients seen by the palliative care service were older, stayed longer in the hospital, and were more likely to be discharged to hospice. However, the majority of stroke patients who died or were discharged to hospice were not seen by SPC.

In an Australian review of 544 admissions over a single year to a metropolitan, tertiary SCU, just over 11% of patients were referred to SPC (Eastman et al. 2013). The predominant reason for referral was end-of-life care, and a number of predictors for referral were identified. These included female gender, older age, increased disability pre stroke, ICH, and living alone or in a residential aged care facility prior to stroke. Sixteen per cent of all SCU admissions died during the review period with just over half seen by the palliative care team. This is approximately double the rate reported from both Swiss and Irish stroke services where only 26% and 24%, respectively, of decreased stroke patients received palliative care consultation (Mazzocato et al. 2010; Ntlholang et al. 2016). Stroke patients referred to the Australian SPC who died during the admission were older, more disabled, and had a significantly longer length of stay than those not referred. In contrast to the total SCU population, the proportion of patients with an ICH was higher in deceased stroke patients who did not receive palliative care consultation (50% vs. 37%). This in combination with the significantly shorter median survival of non-referred patients (2.5 days vs. 6 days) supports previous observations that stroke service staff are generally comfortable managing clearly terminal patients (Rogers and Addington-Hall 2005).

In a retrospective review of 54 consecutive deaths on an Irish teaching hospital stroke service over a 2-year period, several differences were found between patients referred and not referred to SPC (Ntlholang et al. 2016). Those patients whose cause of death was judged to be unrelated to their stroke were more likely to be seen by the SPC team. These patients also had a longer median time between stroke and death, again supporting the notion that stroke unit staff are more comfortable managing the palliative care needs of patients who die soon after a severe stroke, and less so in those who survive longer.

Taken together these data suggest that referrals to SPC, particularly to inpatient consultation services, following acute stroke are increasing. This may reflect increased recognition of the benefits associated with palliative care in areas such as symptom management, complex end-of-life decision-making, and communication. Referral to SPC is influenced by a range of clinical, sociodemographic, and health service factors, but not surprisingly stroke patients referred to palliative care tended to be older, frailer, and sicker. Importantly the majority of stroke patients, including those who were severely disabled or died, were not referred to SPC. While epidemiological data regarding referral rates and predictors are useful for service provision and planning, they do not answer important questions such as whether all patients with complex needs who would benefit from SPC input are currently being referred or whether non-referred "less complex" stroke patients are receiving timely and appropriate non-specialist palliative care (Stevens et al. 2007). This represents an area for ongoing research.

2.4 Shared Stroke and Palliative Care Issues in the Acute Setting

2.4.1 Prognostication

The prediction and communication of prognosis is an important but inherently difficult part of stroke care. Given the majority of patients will survive a stroke, prognostication is relevant to all stages of stroke care from initial acute presentation to post-acute recovery and finally to rehabilitation and/or discharge. Accurate prognostication provides a road map to guide treatment decision-making and allows patients and families to plan for the future. Inaccurate prognostication runs the risk of depriving some patients of the best chance of

recovery while exposing others to burdensome treatments that may only prolong suffering. In essence prognostication attempts to provide some degree of certainty while being at the same time inherently uncertain. In a qualitative study that examined patient and family members' perspectives of acute stroke care, honest discussions around prognosis despite uncertainty were valued by relatives even when it was predicted that prognosis might be poor (Payne et al. 2010).

Studies investigating prognosis following stroke have tended to focus on mortality more than functional outcome or recovery. Numerous clinical, sociodemographic, and institutional predictors for mortality have been identified, with stroke severity and older age generally reported to have the strongest associations (Smith et al. 2010b). The National Institutes of Health Stroke Scale (NIHSS) provides a quantification of stroke severity and is a highly reliable predictor of mortality after stroke both on its own and in combination with other variables (Smith et al. 2010b; Frontera et al. 2015). It is a 15-item validated bedside assessment tool which incorporates testing of consciousness, language, sensation, and motor function.

Stroke type itself is also a strong predictor of mortality. This is illustrated by a Danish study of 39,484 hospitalized stroke patients in which intracerebral hemorrhage (ICH) was associated with a fourfold increased risk of dying compared to ischemic events in the immediate post-stroke period (Andersen et al. 2009). Interestingly the difference in mortality between the two stroke types progressively decreased over time until at 3 months, stroke type no longer correlated with mortality. Temporal differences in the factors associated with mortality have also been reported after ischemic stroke. In a Canadian study of 3631 patients following ischemic strokes, stroke severity was found to be a significant predictor of mortality at all time points, while clinician experience was only significant at seven and 30 days and age and medical comorbidities only significantly associated with 30-day and 1-year mortality (Saposnik et al. 2008).

Numerous multivariate prediction models for outcome and mortality following stroke are available although the quality and clinical utility of these models varies (Holloway et al. 2014). Examples include the Hunt-Hess scale for subarachnoid hemorrhage and the ICH score which incorporates Glasgow Coma Scale, ICH volume, intraventricular hemorrhage, age, and site of ICH origin. ICH scores of three or greater have been reported to have a sensitivity and specificity approaching 80% and 90%, respectively, for mortality following ICH (Simmons and Parks 2008).

The applicability of prognostic models to the real world is related in part to the commonality of the variables included and also by the sample from which the data are drawn. Prediction models, for example, generated using data from cohorts with high numbers of clinical trial participants or only patients managed in specialized stroke centers may not be easily applicable to a broader, community-based stroke population. Similarly models that include clinical information from imaging modalities that are not widely available may also lack generalizability.

One particular concern raised by a number of stroke researchers when considering mortality prediction models is the concept of "withdrawal bias." It is argued that because current models have incorporated patients who either never commenced or had life-sustaining therapies withdrawn, there is a potential bias toward mortality (or treatment withdrawal) as well as difficulty in establishing the true effect (positive or otherwise) of these therapies following severe stroke. This is likely to be particularly relevant for stroke types with poor prognosis such as ICH. Given this the importance for clinicians to understand the strengths and limitations of these models, when using them to establish and communicate prognosis to patients and families, has been highlighted (Holloway et al. 2014; Frontera et al. 2015). This may be particularly the case when considering instigating or transitioning to end-of-life care.

Prognostication based upon clinician experience and expertise is an alternative to a model-based approach. Unlike fixed mathematically generated models, clinicians have the advantage of being able to consider an individualized range of factors and adjust their estimations in real time. Clinician-based estimates however may vary

considerably between individuals and be influenced by both optimistic and pessimistic judgements (Holloway et al. 2014; Frontera et al. 2015). The involvement of the multidisciplinary team and utilization of a second opinion (including from SPC) have been suggested as ways to overcome some of the issues with clinician-based estimates.

Despite the inherent difficulties associated with prognostication, the importance of providing patients and their families with a sense of the future cannot be underestimated. This is likely to be best achieved using a combination of clinician acumen and evidence-based estimation models individualized to each patient and their unique characteristics.

2.4.2 Limitations of Treatment

The majority of deaths after stroke follow either the limitation, cessation, or foregoing of potentially life-prolonging therapies (Kelly et al. 2012; Holloway et al. 2014; Creutzfeldt et al. 2015; Alonso et al. 2016). In the United States, up to 60% of all stroke deaths follow the removal of mechanical ventilation (Holloway et al. 2014) although this rate is likely to be different in other countries. Decision-making regarding limitations of treatment in acute stroke is complex as it needs to incorporate a range of patient, sociocultural, and clinical factors including autonomy, patient and family wishes, and prognostication. Additionally in the acute phase when uncertainty is high, management decisions need to be made quickly so as to maximize the chances of injury reversal and potential recovery. The acute stroke setting has been described as a "fast-paced, chaotic environment wrought with hope and disappointment, relief and anxiety" (Creutzfeldt et al. 2015), and therefore it is hardly surprising that decision-making in this setting is challenging. Complicating the situation further, many patients have impaired communication as a consequence of their stroke, meaning the responsibility for these complex and often life-and-death decisions will involve family and loved ones.

Treatment limitations can take numerous forms and may alter over time. In the acute setting, they may include decisions regarding thrombolytic and/or endovascular therapy or aggressive resuscitative approaches such as cardiorespiratory resuscitation or mechanical ventilation. In some patients, particularly the more elderly, frail, or those following a severe stroke, the decision to take a palliative approach with an emphasis on comfort might be taken at the outset. This might involve, among other things, the foregoing or withdrawal of antibiotic therapy, hydration, or supplementary feeding. In the majority of circumstances, these discussions and decisions will not involve SPC but be undertaken by members of the stroke team or emergency department. Relatives of stroke patients have reported experiencing discomfort when they felt excluded from the decision-making process, overly responsible for the decisions made (Cowey et al. 2015), or when participating in discussions if they knew do-not-resuscitate (DNR) orders had already been made by the medical team (Payne et al. 2010). This highlights the importance of mutual, shared decision-making between clinicians, patients, and families. The importance of good communication skills underpinned by an awareness of palliative care practice and philosophy has been advocated as a valuable component of both neurology practice and training (Holloway et al. 2014; Creutzfeldt et al. 2015).

The impact of treatment limitations on acute stroke outcomes has been fairly extensively studied with particular interest in the effect of early DNR orders (and other limitations) on stroke mortality. A number of papers have shown an association between DNR orders and increased mortality in both ICH and ischemic stroke independent of other established mortality predictors (Zahuranec et al. 2007; Holloway et al. 2014; Parry-Jones et al. 2016). In a study of 270 non-traumatic ICH, the presence of early treatment limitations (defined as DNR orders alone or in combination with early withdrawal and/or early deferral of other life-sustaining therapies) was associated with a twofold increase in mortality independent of a range of established predictors including age, Glasgow Coma Scale score, and ICH volume (Zahuranec et al. 2007). It has been suggested that the association between DNR orders and early mortality following stroke (and

ICH in particular) represents a "self-fulfilling prophecy" whereby the prediction of poor prognosis leads to limitations of care which ultimately produce a poor prognosis. Accordingly, and in the absence of clear advance care directives, caution is advised about making early treatment limitations decisions in the immediate post-stroke period.

Following the acute stroke phase, ongoing consideration of treatment goals is influenced by the evolving clinical picture, patient and family wishes, and expectations in relation to recovery. This can be a time of significant uncertainty for patients, families, and clinicians and one in which decision-making can be become more complex with emphasis on factors such as prognosis, potential withdrawal of life-prolonging therapies, and discharge planning (Rogers et al. 2005; Eastman et al. 2013). Decisions around the withdrawal of hydration and nutrition can be particularly challenging and were recorded as a source of conflict in nearly half of all interactions between family members and staff in a study of 104 patients who died in a Canadian SCU (Blacquiere et al. 2009). Assistance with this complex decision-making and communication is a common reason for SPC involvement following stroke and is valued by other health professionals. In one study, stroke staff noted that the benefits of access to SPC in these complex scenarios included "reassurance" and "support for decision-making" (Burton and Payne 2012).

For relatives of patients who have had a severe stroke, acting as a surrogate decision-maker can be a two-edged sword. On the one hand, feeling sufficiently involved in decision-making is a predictor of high satisfaction with end-of-life care for bereaved relatives of stroke patients (Young et al. 2009). On the other, when relatives have reflected upon their experiences as surrogates for patients who had suffered severe strokes, a number of conflicts and struggles were described (de Boer et al. 2015). These include the strain of making decisions under time pressure, feeling unprepared or underqualified to speak for their relative, and dealing with uncertainty and change. Despite differences in the experiences reported between interviewees, there was an overall tendency for surrogates to follow medical advice, highlighting again the importance of patient- and family-centered communication in this setting.

Longer-term positive and negative consequences have been reported for surrogates involved in making treatment decisions for others (not specific to stroke). In a systematic review (Wendler and Rid 2011) which included 2854 surrogates across 40 quantitative and qualitative studies, nine papers found that being involved in decision-making had beneficial effects for some surrogates. Importantly however up to a third of surrogates reported negative emotional consequences associated with making decisions for their loved one including stress, guilt, and doubt about whether they had done the right thing. These negative emotions were typically sustained for months and sometimes years which has important implications for bereavement services. Feeling confident they were following a treatment plan consistent with patient preferences seemed to mitigate some of the emotional burden on surrogates, perhaps highlighting the value of Advance Care Directives as a way of planning for future health care.

2.4.3 Symptom Burden Following Acute Stroke

The recognition and appropriate management of both physical and psychological symptoms has been highlighted as an unmet need for patients and their families following acute stroke (Addington-Hall et al. 1995; Stevens et al. 2007; Burton and Payne 2012). While published literature is limited, symptom burden has been reported in between 65% and 98% of dying stroke patients. A broad range of physical symptoms have been reported with varying frequency in patients following an acute stroke including fatigue, nausea, restlessness, and issues with urination and defecation. Pain has been variably described with reported prevalence rates of between 30% and 70% (Addington-Hall et al. 1995; Mazzocato et al. 2010; Ntlholang et al. 2016; Eriksson et al. 2016).

There is evidence that psychological distress is common in patients following an acute stroke, although differences in prevalence are noted in the limited available published literature. Psychological distress, including anxiety, dysthymia, and

loneliness, was found to be present in almost half of 191 consecutive stroke admissions in one UK study (Burton et al. 2010) and in 25% of dying stroke patients referred to a Swiss palliative care consultation service (Mazzocato et al. 2010). By contrast, in a separate review of 54 consecutive deaths in an Irish specialist stroke service, psychological distress was reported in only one patient (Ntlholang et al. 2016). Investigating the palliative care needs of patients following an acute stroke, Burton and colleagues (2010) found that while spiritual or religious concerns were low, up to a 25% of patients were worried about death and dying. Additionally, many were concerned about ongoing dependence and disability and the impact this might have on their loved ones. About a quarter felt that their care needs would exceed the capabilities of their families creating the potential for additional distress and even disharmony in an already emotionally fraught time.

The importance of considering the psychological impact of stroke upon patients and families was highlighted in a study investigating bereaved family members' satisfaction with the care provided to patients palliated after ischemic stroke (Blacquiere et al. 2013). While overall satisfaction with palliative care was high, lower satisfaction rates were reported for treatment of anxiety and depression and for the level of emotional support provided to families. The impact of stroke upon loved ones and families is frequently profound, in large part due to the abrupt change in function and cognition often associated with stroke. In the longer term, a number of adverse outcomes have been identified in stroke caregivers including mental health issues, worsening physical health, and financial burden (van Heugten et al. 2006; Carod-Artal and Egido 2009). This potential for longer-term adverse sequelae adds further weight to the importance of considering the psychosocial needs of stroke patients and their families in the acute phase.

While variability in symptom burden following acute stroke has been reported, respiratory symptoms including dyspnea and secretions appear to be particularly prevalent. This is likely to be due, at least in part, to their demonstrability when compared to less visibly obvious symptoms such as pain and anxiety. In one prospective cohort study of 22 patients admitted to a SCU and felt likely to die within 3 months of admission, all of the 20 patients who subsequently died experienced respiratory symptoms during their last hours of life (Rogers and Addington-Hall 2005). Respiratory secretions or "death rattle" were recorded in just over 60% of 1626 dying stroke patients in a Swedish database review (Eriksson et al. 2016), and dyspnea was the commonest recorded symptom in 54 consecutive patients who died in an Irish hospital stroke service (Ntlholang et al. 2016) and in 81% of stroke patients referred to a Swiss palliative care consultation team (Mazzocato et al. 2010). The potential difficulty of managing dyspnea in dying patients was highlighted in this study as only 48% of patients were felt to be free from dyspnea during their last 48 h of life (compared to 81% who were assessed as being free from pain).

Using data from the Swedish Register of Palliative Care, Eriksson and colleagues (2016) compared the prevalence of six symptoms (pain, "death rattle," dyspnea, anxiety, confusion, and nausea) between 1626 patients who died following a stroke and 1626 patients dying from cancer. Interesting differences in symptom prevalence, awareness, and management were noted between the groups. While all symptoms were present in the stroke group (nausea 7.6%, confusion 7.9%, dyspnea 16.3%, anxiety 18.9%, pain 42.7%, and "death rattles" 60.7%) when compared with their matched counterparts with cancer, stroke patients were significantly more likely to experience "death rattles" but less likely to experience any of the other five symptoms. Importantly however, staff caring for stroke patients were significantly less likely to know whether a patient suffered from any of the target symptoms compared to staff caring for patients with malignant disease. It might be anticipated that this difference was related to higher rates of reduced consciousness in dying stroke patients; however this does not seem to have been the case as the ability to self-determine until the last days of life was equivalent between groups (73.3% of stroke patients, 74.3% in cancer). In keeping with the differences seen in symptom prevalence and staff awareness of

symptoms, stroke patients were significantly more likely to have as-required medications charted for "death rattle" but less likely to have them for pain, nausea, or anxiety. Overall this study highlights the potential differences in palliative care needs between dying stroke and cancer patients and lends support to individualized approaches rather than assuming that one model of care will fit all. Crucially it also reinforces the importance of stroke service staff being appropriately educated and supported in the provision of general palliative care.

The considerable variability in symptom prevalence seen in the published literature is likely due to a range of factors including communication and consciousness impairment and inconsistent symptom assessment. Additionally accurate quantification of symptom burden for patients following an acute stroke is hampered at least in part by the fact that most studies addressing the question have been retrospective reviews of precollected data. Further prospective longitudinal research is required to expand the currently limited dataset addressing this question and to guide the development of appropriate interventions and approaches to meet the important needs of patients and their families.

2.4.4 End-of-Life Care and Dying Following Acute Stroke

The recognition or diagnosis of dying is complicated and largely arbitrary. Difficulties identifying the time point at which end-of-life care (EOLC) might be initiated are commonly reported by stroke care staff (Burton and Payne 2012; Gardiner et al. 2013; Cowey et al. 2015) leading to potential under- or overtreatment and delay in providing palliative and end-of-life care. A large contributor to this difficulty is the commonality between many of the features associated with dying and those seen in patients following a severe stroke who may subsequently recover. A range of factors have been used to identify dying stroke patients including stroke characteristics (including subtype and severity), clinical course (in particular the lack of meaningful recovery or ongoing deterioration), and physiological parameters (such as altered breathing patterns) (Cowey et al. 2015). In a study of patients who died in a stroke unit, disturbed consciousness, early dysphagia, and large supratentorial strokes were indications for initiation of EOLC (Alonso et al. 2016). In a separate mixed-methods study involving 23 Scottish stroke unit health professionals, over a quarter reported using intuition (at least in part) to recognize dying (Cowey et al. 2015).

The responsibility for decision-making regarding commencement of EOLC for hospitalized stroke patients has generally rested with the SCU medical team, although the importance of input and insight from other members of the multidisciplinary team cannot be underestimated. As we have seen due to the nature of stroke presentation and management, SPC services are infrequently and reactively involved in this process typically at times of increased complexity or significant uncertainty. Involvement of family members in decision-making around end-of-life care is important but not without its problems particularly if there is discordance between relatives and healthcare professionals (Rogers and Addington-Hall 2005). Feeding patients after a severe stroke has been highlighted as an area where motivations and opinions may differ between family members and staff. Rogers and Addington-Hall (2005) noted that while relatives and stroke unit staff shared the common motivation of wanting to avoid prolongation of suffering, stroke unit staff were also concerned about the patient starving or having their chance of recovery impinged due to lack of nutrition. Despite these difficulties family involvement allows a unique perspective on the patient and their place in the world and has been shown to be a predictor of high satisfaction with EOLC. As for all other areas of stroke care, the importance of clear, unambiguous, empathic, and effective communication cannot be overstated.

Two distinct patterns of dying following an acute stroke have been described, namely, a rapid, sudden death or prolonged dying. A prolonged dying phase can be particularly difficult for family members, and this is likely to be exacerbated if there was expectation of a quick death, they had not been informed of the possibility of prolonged dying, and in the setting of severe

dysphagia (Cowey et al. 2015). Not surprisingly the transition from recovery-focused care to EOLC can be challenging for family members with feelings of isolation and abandonment reported (Payne et al. 2010). However when death is considered likely, the most important things identified by relatives and stroke unit staff alike are the avoidance of distress and the maintenance of comfort and dignity (Rogers and Addington-Hall 2005; Payne et al. 2010).

End-of-life care (EOLC) pathways have been used to guide and optimize multidisciplinary, holistic care for dying patients and their families including following stroke. In this setting EOLC pathways aim to cover not only physical symptoms but also psychological, spiritual, and cultural considerations, desired place of care, and after-death management. The Liverpool Care Pathway (LCP) is an example of an EOLC pathway which has been used worldwide in both malignant and nonmalignant conditions. Recently the LCP has attracted considerable media attention and controversy in part due to concerns about its perceived overapplication at times, the inappropriate denial of nutrition and hydration in some cases, and deficits in communication with patients and families about its use. A subsequent UK government-commissioned independent review, while acknowledging the principles underpinning the LCP, expressed among a range of concerns that it was too frequently used as a "tick-box" exercise and recommended that it be progressively phased out and replaced by individualized care plans (Neuberger et al. 2013).

There is limited evidence addressing the use of EOLC pathways following severe stroke with available data seeming to be generally supportive of their use. The Australian Clinical Guidelines for Stroke Management in a small section devoted to palliative care include a recommendation that pathways for stroke palliative care can be used to improve the care of people dying following a stroke but acknowledge that evidence to support this recommendation is weak (National Stroke Foundation 2010). Very little is known about the quantitative impact of EOLC pathways on care parameters following severe stroke although improvements in both documentation and clinical practice were observed in a small retrospective audit pre- and post the implementation of the LCP on a 12-bed stroke unit (Jack et al. 2004). Examples of the changes in clinical practice seen included increases in the discontinuation of inappropriate medications (from 40% to 100%), in the charting of subcutaneous medications (from 20% to 85%), and in the assessment of religious needs. While these results appear promising, they need to be interpreted cautiously given the retrospective study design and small sample size.

Two qualitative studies have addressed the perceptions of healthcare professionals regarding the use of the LCP in English and Scottish stroke units (Gardiner et al. 2013; Cowey et al. 2015). In general satisfaction has been reported with its use, with staff in one study suggesting that the LCP was a core element of high-quality palliative care (Gardiner et al. 2013). Surveyed family members were also generally satisfied with LCP-based care although tended to be more concerned with adequate control of problems rather than whether an EOLC pathway was used (Cowey et al. 2015). Importantly family members were able to influence EOLC including when the LCP was used. This meant that management plans, including components such as the ongoing provision of parenteral hydration, were adapted to incorporate their wishes. This negotiated mutual pragmatism is perhaps what Neuberger and colleagues (2013) were envisaging when they recommended the replacement of the LCP with individualized care plans. Interestingly while both of these studies undertook their qualitative data collection prior to the 2013 independent LCP review, the paper by Cowey and colleagues (2015) was published subsequent to it. In their conclusions, the authors acknowledged the withdrawal of the LCP in the UK but noted that it continued to be used worldwide. They reiterated that in their study, family members were more concerned with distressing stroke-related problems than the LCP. In a succinct summary encapsulating the complexity of EOLC following stroke, they concluded that "such problems are enduring in nature and remain as clinical challenges whether end-of-life care pathways are used or not."

3 Palliative Care in the Post-Stroke Phase

The last couple of decades have seen emerging recognition of the role palliative care can play beyond end of life. Earlier involvement in advanced malignant disease, for example, has been demonstrated to lead to improvements in symptom burden, quality of life, and psychological well-being. Increased awareness of the substantive symptom burden and distress associated with a range of noncancer conditions, including chronic respiratory, renal, and neurological disorders, has highlighted the benefits of multidisciplinary palliative care in symptom management, complex decision-making, and care facilitation. In stroke while there is a developing evidence base for palliative care in the acute phase, the picture is much less clear for the post-stroke period. This is worthy of further consideration because as previously discussed the majority of patients will ultimately survive an acute stroke.

For those people who survive their initial stroke, the focus of most clinical programs and the literature has understandably been on secondary prevention and stroke rehabilitation. Accordingly there is comparatively little published data evaluating the involvement or potential role of palliative care services in post-stroke care. While data examining palliative care in this setting are limited, there is evidence of a range of often under-recognized symptoms and morbidity in patients, families, and caregivers following stroke.

The symptoms and issues experienced by patients and their caregivers in the chronic post-stroke phase will be familiar to many palliative care clinicians. They can include pain, depression, functional disability, seizures, bladder and bowel dysfunction, and caregiver stress/fatigue. While these symptoms are likely to share similarities with those seen in patients with cancer, end-organ failure, and/or neurological degenerative disorders, they may also display features unique to stroke. For example, the immediate onset of profound change in physical and cognitive function that often accompanies acute stroke contrasts with the subacute development of illness and disability in other malignant and nonmalignant conditions. Additionally the management of symptom burden in an environment where patient survival might be measured in years rather than weeks or months is outside the traditional skill set of many palliative care clinicians.

In some ways the chronic post-stroke period might be considered analogous to cancer survivorship as both may share features of ongoing symptoms in the context of likely long-term survival. The role of palliative care in cancer survivorship, while variable worldwide, remains relatively undefined, debatably appropriate, and influenced by a broad range of clinical and structural factors including limitations in clinician experience, workforce issues, and funding models. It seems likely that involvement in the post-stroke phase will provide palliative care, at both a clinician and organizational level, with similar challenges regarding clinical appropriateness and service provision.

3.1 Pain Syndromes

The most common types of pain reported in stroke survivors are central post-stroke pain, hemiplegic shoulder pain, painful spasticity, musculoskeletal pain, and tension-type headache (Creutzfeldt et al. 2012). Accurate pain assessment following stroke can be challenging due to the consequent communication deficits that may include dysphasia and dysarthria and/or changes in consciousness that occur in some stroke survivors.

3.1.1 Central Post-Stroke Pain

Central post-stroke pain (CPSP) is a neuropathic pain syndrome that is both highly distressing and frequently refractory to treatment. Sometimes referred to as Dejerine-Roussy syndrome, it was first described in 1906 (Vartiainen et al. 2016). There is variability in the reported rates of CPSP development among stroke survivors as well as concerns that it may be under-recognized. In an Italian population-based study which included 1494 post-stroke patients, symptoms and sensory changes consistent with CPSP were present in 11% of stroke survivors (Raffaeli et al. 2013). Other authors have reported prevalence rates of

between 3% and 8% when all stroke survivors are considered (Vartiainen et al. 2016) and up to 35% in those with specific thalamic lesions. While the pathogenesis of CPSP is not well established, postulated mechanisms for development include hyperexcitability of injured sensory networks, changes in central inhibitory mechanisms, or central nervous system neurotransmitter imbalances. The varying incidence and prevalence of CPSP is explained by the unclear etiology of this pain syndrome as well as the lack of universally accepted diagnostic criteria. The diagnosis of CPSP requires the exclusion of pain caused by joint contracture, peripheral nerve disorders, and spasticity.

The pain of CPSP may be spontaneous or evoked. Spontaneous pain can occur either continuously or intermittently, while evoked pain is typically precipitated by stimuli such as touch, movement, stress, or temperature change (Creutzfeldt et al. 2012; Vartiainen et al. 2016). Sensory abnormalities such as allodynia, dysesthesia, paresthesia, and hyperalgesia are common features (Creutzfeldt et al. 2012; Raffaeli et al. 2013). The pain is typically experienced within the area of sensory impairment and usually at the point of maximal deficit. Spinothalamic abnormalities such as temperature-sensory abnormality are frequently described. CPSP may develop at any time from immediately to years after a stroke; however onset most commonly occurs at 3–6 months (Raffaeli et al. 2013).

Management of CPSP is challenging as there is a paucity of evidence to guide practice. Optimal management is likely to be best achieved by utilizing a combination of pharmacological and non-pharmacological treatment approaches. A range of pharmacological agents have been trialed in the management of CPSP with a particular focus on antidepressants and anticonvulsants. The efficacy and tolerability of these agents has varied across trials. Amitriptyline at a final dose of 75 mg daily was associated with significant improvements in pain when compared to placebo in a small double-blind, placebo-controlled crossover study conducted in 15 nondepressed patients (Leigon and Boivie 1989). Importantly there was little in the way of adverse effect associated with amitriptyline. No statistically significant benefit was seen for carbamazepine (at doses of up to 800 mg/day) in the same study.

In terms of other agents, there is some evidence of benefit from both case series and a controlled trial for lamotrigine; however, there is limited evidence for gabapentin and none for opioids (Frese et al. 2006). The efficacy and safety of pregabalin in the management of CPSP was assessed in a double-blind, placebo-controlled randomized trial in 219 patients. The mean dose of pregabalin received was 356.8 mg, and after 13 weeks, pain had improved in both treatment arms (pregabalin baseline pain score 6.5, end-point pain score 4.9; placebo baseline pain score 6.3, end-point pain score 5.0); however there was no significant difference between the groups. Pregabalin was associated with improvements in sleep and anxiety in the study; however, more than 50% of patients in the pregabalin group reported some adverse effects (compared to 23% in the placebo group), with dizziness and somnolence being most common (Kim et al. 2011).

Non-pharmacological therapies including cognitive behavioral therapy and stimulation therapies including transcutaneous electrical nerve stimulation and acupuncture have been described in small case series; however, controlled trial evidence is lacking. Surgical pain therapies such as rhizotomy, sympathectomy, cordotomy, and deep brain stimulation have not been formally evaluated for the treatment of CPSP and should be considered only in the context of approved clinical trials.

3.1.2 Hemiplegic Shoulder Pain

Hemiplegic shoulder pain (HSP) is the most common post-stroke pain, occurring in 11–83% of patients (Creutzfeldt et al. 2012). The prevalence of HSP increases with worsening motor impairment. HSP occurs as a consequence of joint subluxation and sensory and motor deficits. Careful attention to joint positioning in hemiplegic patients and physical therapies are the mainstay of treatment, with some emerging data for intra-articular steroid injections and intramuscular injections of botulinum toxin-A. Analgesia with anti-inflammatory medications, paracetamol, and topical heat or ice and soft-tissue massage can also assist with initial pain management.

3.1.3 Spasticity and Musculoskeletal Pain

Pain due to contractures, pressure areas, and spasticity are best prevented through the use of physical and rehabilitative therapies, body positioning, and range of motion exercises. Baclofen and dantrolene are used for post-stroke spasticity; however, their side effects including sedation, confusion, and dizziness can limit their use. Botulinum toxin can be used, particularly in upper-limb spasticity, to improve functional outcome (Creutzfeldt et al. 2012).

3.2 Post-Stroke Depression

Depression is part of a constellation of neuropsychiatric disorders that are recognized to be associated with stroke. Estimates of the frequency of post-stroke depression (PSD) vary due to the heterogeneity of assessment and reporting approaches; however, a recent meta-analysis which included 61 studies and over 25,000 people found a frequency for PSD of 31% out to 5 years post stroke (Hackett and Pickles 2014). PSD onset can occur at any time following a stroke, with a prospective, longitudinal study of over 200 patients, observing rates of PSD to be relatively stable across a range of time points from 1 month to 18 months post stroke (De Ryck et al. 2014). Stroke severity and the resultant degree of physical and functional disability are the strongest predictors of post-stroke depression, with other recognized predictors including cognitive impairment, dysphasia and aphasia, apraxia, and premorbid history of depression or anxiety (De Ryck et al. 2014; Robinson and Jorge 2016). Evidence for the impact of social support and stroke lesion location upon PSD is conflicting; however, there are reports of association between left frontal and left basal ganglia lesions and PSD (Robinson and Jorge 2016).

Post-stroke depression is associated with increased mortality, poorer engagement in rehabilitation, decreased quality of life, and social isolation (Creutzfeldt et al. 2012; De Ryck et al. 2014; Robinson and Jorge 2016). An independent and direct association exists between depression severity and functional impairment although this relationship is likely to be reciprocal in many cases. The increased mortality associated with PSD has been reported to be due to greater cardiovascular mortality, with PSD associated disruptions in autonomic nervous system function postulated as a potential explanatory mechanism (Robinson and Jorge 2016).

A number of double-blind, placebo-controlled treatment trials for PSD have been undertaken using both tricyclic antidepressants and selective-serotonin uptake inhibitors (SSRI) since 1984 (Robinson and Jorge 2016). Although sample numbers were generally small across the trials, most reported improvements in depression scores when compared to placebo. A meta-analysis that included 17 trials (13 using pharmacological agents and 4 psychotherapy) and 1655 patients (Hackett et al. 2008) found that pharmacotherapy conferred a small but significant benefit in treating depression and reducing depressive symptoms; however, this was coupled with an increase in adverse effects. No evidence of benefit was demonstrated for psychotherapy; however, other studies have reported positive outcomes for brief psychosocial interventions (including psychoeducation and family support) when combined with antidepressants (Robinson and Jorge 2016). The impacts of antidepressant medications on physical and functional outcomes are less well described (Creutzfeldt et al. 2012); however, improvements in motor, cognitive, and functional capacity have been demonstrated (Robinson and Jorge 2016). There is emerging evidence that pharmacotherapy (in particular SSRIs) may have a preventative role in PSD as well as interesting data, suggesting antidepressants might improve stroke survival independent of either successful depression treatment or the presence of depression in the first place (Robinson and Jorge 2016).

3.3 Quality of Life

Of patients who survive 30 days following acute stroke, half will die within 5 years, and of the survivors, approximately 30% will remain disabled, with 14% requiring institutional care

(Hankey et al. 2002). Quality of life (QOL) while difficult to define and inherently subjective in nature is generally considered to be a multidimensional construct incorporating multiple broad domains including physical, social, and mental. Recognition of the potential impact of stroke upon QOL has seen the development of a number of stroke-specific health-related QOL scales in recent years. These scales include specific factors relevant to stroke patients including vision and language impairments, with examples being the Stroke Impact Scale and the Burden of Stroke Scale (Carod-Artal and Egido 2009).

A wide range of factors have been shown to impair QOL following stroke including dependency in activities of daily living (ADL), motor dysfunction, aphasia, presence of depression, CPSP, sexual dysfunction, and limited social supports (Carod-Artal et al. 2000; Choi-Kwon et al. 2006; Carod-Artal and Egido 2009). Reductions in QOL have been described by stroke survivors with differing levels of functional impairment from the profoundly disabled to those who regained independence in ADL function but did not get back to premorbid functional levels and in others who were not able to return to work. A Korean study that examined influences on QOL in 151 first-time stroke patients found that ADL dependency, CPSP, depression, and lower socioeconomic status were all important explanatory factors for lower QOL 3 years post stroke (Choi-Kwon et al. 2006). Although variation exists in the literature stroke type, lesion location, age, and gender have not consistently been associated with lower QOL (Choi-Kwon et al. 2006) although there is some evidence to suggest females have lower QOL following stroke than men (Carod-Artal et al. 2000; Carod-Artal and Egido 2009).

Importantly recognition of the negative influence of a broad range of factors upon QOL highlights the need for close attention to be paid to these things in the post-stroke period. In particular, vigilance when it comes to the assessment and treatment of depression and pain and rehabilitative efforts focused on maximizing functional outcomes and independence are crucial components in the preservation of QOL for patients following a stroke.

3.4 Caregiver Issues

While patients after stroke confront a myriad of issues, caregivers are also confronted with a new and often devastatingly different world. This is often exacerbated by the sudden onset of change which necessitates the rapid acquisition of new knowledge, skills, and acceptance of changed circumstances. This contrasts other more chronic illnesses where disease progression is typically gradual and predictable, allowing caregivers greater opportunity for adjustment and adaptation. Cognitive deficits including perceptual and language change along with motor deficits and functional dependency add additional complexity to the caregiver role. Additionally many caregivers are themselves elderly with their own health problems and often contracting social and support networks.

Worsening physical health, lower QOL, high levels of stress and mood disorder, social isolation, and financial burden have all been reported by stroke caregivers (van Heugten et al. 2006; Carod-Artal and Egido 2009). Anxiety and depression are common with rates of depression estimated to be upward of 25%. Given the recognized high levels of burden among stroke caregivers and the crucial role they play in supporting patients at home, increasing attention is being paid to assessing and managing stroke caregiver needs. Importantly despite the clear challenges that the caregiver role can bring, evidence suggests that many stroke caregivers still experience increased appreciation of life and role fulfillment.

A lack of attention to caregivers in established stroke guidelines prompted the development of evidence-based clinical practice guidelines specific to stroke caregivers in the Netherlands in the mid-2000s (van Heugten et al. 2006). These guidelines cover a range of topics including risk factors for caregiver burden, approaches to assessing burden, and possible caregiver interventions. Factors identified as predictive of increased caregiver burden include both patient characteristics (particularly limited functional capacity and significant cognitive impairment) and caregiver factors including preexisting psychological ill-health.

The impact of interventions upon stroke caregivers has been evaluated across a number of

studies with varying degrees of benefit reported. Interventions identified to provide at least some improvement in caregiver wellbeing include the provision of information, social and practical supports, training in the caregiver role, attention to mental health issues, and counseling (Kalra et al. 2004; van Heugten et al. 2006). Clinicians have a key role to play in preparing caregivers for their role. In retrospective surveys of bereaved caregivers, satisfaction with care following a stroke is positively correlated with involvement of doctors and nurses who are knowledgeable about stroke, clinicians being open to discussing fears and concerns, and caregivers being involving in decision-making processes (Young et al. 2009).

While after-stroke care largely focuses on secondary prevention and rehabilitation, it is clear that symptoms and complex care needs including pain syndromes, depression, impaired quality of life, functional impairment, and caregiver issues are highly prevalent following stroke. These are all things familiar to multidisciplinary palliative care clinicians, who accordingly are conceivably well positioned to address them utilizing expertise and experience drawn from other chronic diseases, as well as collaboration with colleagues from stroke and rehabilitation teams.

4 Conclusions/Summary

Despite significant advances in prevention, recognition, and treatment, stroke remains a major cause of morbidity and mortality worldwide. The value of integrating palliative care principles and practices into stroke management is being increasingly recognized particularly in relation to issues such as symptom management, complex decision-making, and establishment of goals of care. Ongoing research is required addressing not only these important patient and family needs but also the theoretical basis, clinical requirements, and departmental structures required for successful integration. In the acute phase, the majority of palliative care is currently and likely to continue to be undertaken by members of the stroke team with secondary support available from specialist palliative care services on an as-needed basis. Additionally specialist palliative care is ideally placed to provide the necessary education and guidance to ensure the provision of high-quality care.

The role of palliative care in the more chronic post-stroke phase is less clear with little published data addressing the question. There is clear evidence of significant symptom burden, reduced quality of life, and caregiver distress for patients and their families in this period, and these are all things familiar to multidisciplinary palliative care teams. In many ways palliative care clinicians are well placed to take a lead role in the management of many of these problems although their chronicity is likely to impose clinical, organizational, and workforce challenges upon the profession.

The ongoing success of the integration of palliative care and stroke services will be contingent on a number of factors, not least of which being buy-in from both specialties. For palliative care this will perhaps require a conscious shift away from the cancer-related models and ideologies of the past and an acknowledgement that adaption, conciliation, and collaboration will be crucial in moving forward. This is relevant not just for stroke but also other nonmalignant diseases and the ever-changing cancer landscape. In essence this is the challenge for modern palliative care and the next generation of specialists.

Contents

Abstract

Heart failure is a life limiting cardiovascular condition, frequently encountered in the increasingly aged population. People affected endure a symptomatic burden and mortality risk at least equivalent to those associated with common cancers. However, the clinical scenario is usually more complicated in that heart

failure tends to occur in multimorbid older individuals who exhibit an unpredictable disease trajectory. In most patients, cardiac function tends to decline inexorably, with a mortality of about 50% in the 5 years following diagnosis. An ever more complex evidence-based therapy, which likely materially benefits less than half of those with this clinical diagnosis, involves polypharmacy, implanted cardiac devices, and consideration for surgical intervention including cardiac transplantation. Acknowledging its prognostic ambiguity, the capricious nature of the heart failure state, and the relatively onerous treatment protocol may undermine care coordination, patient autonomy, and ultimately conflict with patients' and families' preferences for care along a progressively declining clinical course to the end of life. This chapter describes the challenges and opportunities in providing palliative care to this burgeoning clinical population.

1 Introduction

Heart failure is a common clinical and public health problem which occurs in epidemic proportions. Currently, about 38 million people suffer with heart failure worldwide, of whom approximately 6.5 million are affected in the United States, where there is an anticipated 46% increase in prevalence by 2030 (Roger 2013; Braunwald 2015; Benjamin et al. 2017). Heart failure accounts for a significant proportion of healthcare expenditure, and for 2012, the global economic burden of heart failure was estimated at nearly US$108 billion in direct and indirect costs (Cook et al. 2014). From the age of 45 years through to 95 years, the lifetime risk of heart failure is high, ranging from 20% to 45% depending on a spectrum of demographic, lifestyle, and cardiovascular risk factors (Huffman et al. 2013). Heart failure tends to occur in older individuals, being diagnosed in 1–2% of the general population, but rising to about 8% in people aged 80 years or more (Guha and McDonagh 2013). For males, the incidence of heart failure doubles for each decade between 65 and 85 years, while for females the incidence trebles over the same periods (Benjamin et al. 2017). Given the changing demography with a trend towards an aging population, the incidence of heart failure is now similar to that of breast, bowel, prostate, and lung cancers combined (Conrad et al. 2017). Despite our best efforts to address the needs of this increasingly dependent clinical cohort, heart failure remains a generally progressive condition and affected individuals are subject to a symptom burden, a poor quality of life, and a mortality risk at least equivalent to those resulting from the above cancers. Recognition of the comparable palliative care needs and the resulting literature base accruing over the past 20 years, it is evident that heart failure has been in the vanguard of the expansion of palliative care beyond its founding association with oncologic care. A suite of consensus documents and guidelines have been produced, but delivery of palliative care to the increasingly complex population diagnosed with this unpredictable clinical condition remains problematic (Goodlin et al. 2004: Jaarsma et al. 2009; McKelvie et al. 2011; Braun et al. 2016).

2 The Nature of Heart Failure

Forty years ago, Dr. Dean Mason, then chief of cardiovascular medicine at the University of California, Davis, penned a classic description of heart failure as "*the abnormal condition in which disturbed cardiac performance is primarily responsible for the inability of the heart to pump blood at a rate commensurate with systemic metabolic requirements at rest and during normal activity*" (Mason 1976). It is important to note that heart failure is not a disease per se but rather a group of acute and chronic syndromes arising from abnormalities of cardiac structure and function, representing the outcome of a diverse range of acquired or inherited cardiovascular diseases (Ponikowski et al. 2016). Given that these various etiologies result in a spectrum of disordered left ventricular physiology and remodeling, it is unsurprising that the clinical features of heart failure occur in the setting of both systolic and diastolic dysfunction.
