Foreword by Luc Deliens

We recently commemorated the 100th birth anniversary of Cicely Saunders, born in 1918. She began her education by studying philosophy, politics, and economics at the University of Oxford and then qualified as a nurse during the Second World War in the Nightingale Home and Training School in London; as a medical social worker, again at Oxford; and then as a medical doctor in the 1950s at King's College London. Her multidisciplinary educational background, combined with her personal experience (she twice fell in love with dying patients, both Polish refugees) which included a period of what she called "pathological grieving" after a series of bereavements, will have had an impact on her thinking and the development of the concept of palliative care, but also on her activism and her decades-long campaign against the terminal neglect of those who are dying and the medicalization of death. She wrote her first medical paper on care for dying people in 1957, and by the summer of 1967, she had initiated palliative care as an interdisciplinary concept at St. Christopher's Hospice in London, in the establishment of which she was involved. She is now acknowledged worldwide as one of the founders of the palliative care and hospice movement. Ever since, the field of palliative care has grown rapidly across the world, and the scientific evidence for its effectiveness is steadily growing, as is the list of countries with a national palliative care policy. The number of scientific journals covering death, dying, supportive care, palliative care, and end-of-life care is also rapidly growing, and about 20 of these have an impact factor indexed by the Web of Science, with around 5 being classified in the upper quartile of their domain. Hence, this textbook is timely and one of the indicators that palliative care as a clinical as well as a scientific domain has come to full growth.

"Palliative care" can be understood in several ways. It can be understood as a clinical specialism for medical doctors, as it is now recognized by the Royal College of Physicians as a specialty within the UK; it can also be understood as a specialist palliative care service, e.g., an inpatient hospice or palliative care unit, in which a multidisciplinary team delivers the care of people with serious illnesses, or, as a concept of care, a holistic philosophy of care taking into account more than just medical problems such as the burden of physical symptoms. This is reflected in the holistic definition of palliative care by the World Health Organization in which (apart from the medical aspects), nursing, social, psychological, and existential aspects are covered, or ideally should be covered. The latter suggests that there is a difference between what palliative

care is in the real world and what it should be in the reality of our health-care systems; in most countries, the quality of palliative care in most care settings or contexts is suboptimal or can potentially be improved and further developed. This textbook can help clinicians, students, health-care providers, managers, researchers, and also policy-makers to improve their knowledge and skill in palliative care.

This textbook presents 101 chapters in 11 different parts: Palliative Care: Definitions, Development, Policies; Symptom Assessment and Management; Palliative Care Professionals and Provision; Organization of Palliative Care in Different Settings; Palliative Care in Specific Disease Groups; Palliative Care in Specific Populations; Palliative Care Emergencies; Ethics of Palliative Care and End-of-Life Decision-Making; Research in Palliative Care; Public Health Approach in Palliative and End-of-Life Care; and Financial Aspects and Cost-Effectiveness in Palliative Care. It offers a synthesis of the practice and knowledge base that has grown over the last 50 years. Since Cicely Saunders developed the concept of palliative care, focusing on preventing harm to people who are dying and promoting their quality of life, the field has evolved professionally and now covers a complex and wide range of aspects of care for all people with a serious illness, involving informal or family carers and volunteers as well as health-care professionals. Palliative care promotes life until death and should be understood as different from the narrow concept of terminal care. In order to challenge this narrow understanding, palliative care should also embrace the knowledge and skills of the disciplines of health promotion and public health, the latest developments of which are well covered in this textbook.

Cicely Saunders' multidisciplinary background is well reflected by the contents of the *Textbook of Palliative Care* and by its editors, a palliative care doctor, Professor Rod MacLeod from New Zealand, and a social scientist and clinical psychologist, Professor Lieve Van den Block from Belgium. The textbook, with over 100 chapters, covers the breadth of the domain, including clinical, health services, and public health-related aspects of palliative care. The editors should be congratulated on this impressive academic achievement and, more specifically because they have consulted a wide range of clinicians, far more social scientists, and public health experts than any other textbook on palliative care. I hope that this book, available online as well as in print, soon finds its way into the classrooms, universities, and vocational schools of all involved in the care of those who are dying or those with serious illness.

Professor of Palliative Care Research at Ghent University, Ghent, and VUB University
Brussels, Belgium

Luc Deliens

Foreword by Sheila Payne

Palliative care has come of age. No longer can we claim, or make excuses, that palliative care is a young or novice discipline. This impressive *Textbook of Palliative Care* with over 100 chapters offers convincing evidence that palliative care is now a mature discipline. The textbook provides a comprehensive overview of numerous topics that form the core and substance of the discipline. The global reach of the chapter contributors and the distinguished section editors and the overall guidance from two remarkable editors have produced an outstanding testament to not only palliative care's place within medicine but also, importantly, within society.

However, let me caution you from any feelings of complacency and premature celebration. There are still many challenges ahead. We know from the work of the Lancet Commission on pain relief and palliative care that on a global scale, there remain very poor access to palliative care and woefully insufficient affordable and accessible pain relief (Knaul et al. 2017). According to the authors, in 20 health conditions where there were identifiable palliative care needs, 84% account for deaths in adults and 60% in children. Global projections indicate that between 40 and 80 million patients with advanced disease need access to palliative care, with 78–95% of them living in low- and middle-income countries (Knaul et al. 2017). Shockingly, infants and children have even less access to pain relief and palliative care than adults (Knaul et al. 2017).

One way forward is to ensure that the key principles of palliative care are taught as a fundamental part of all basic and post-basic health and social care education programmes. Let me draw a comparison here with the recognition of communication skills as a core element of all courses. When I trained as a nurse in the early 1970s in a well-respected London teaching hospital, my only communication skills education was the well-worn advice for nurses working in hospital wards, which was to *draw the curtains and reassure the patient*. Quite how I might provide that 'reassurance', when the poor patient was likely to be facing an uncomfortable, painful and/or embarrassing procedure, was never revealed. Fortunately, communication skills education is now a core topic in virtually all medical, nursing and other health professional programmes. In some countries, it is even mandatory. In my view, likewise, palliative care core competencies also need to be embedded in all health and social care programmes as essential aspects of professional education (Gamondi et al. 2013).

So what will be the future challenges facing palliative care? We need to be prepared to 'give it away' so that basic palliative care practices and knowledge move beyond the restricted domains of certain places such as specialist palliative care units, or disease groups such as those with cancer, or age groups, or professional disciplinary boundaries. I am not arguing that there is no future for specialist palliative care, as the people working in these settings, and with this expertise, are essential to drive the education of others; improve the quality of care, through research and reflective practice; and provide leadership. However, to ensure universal coverage and access to basic palliative care, more energy, resource and leadership need to be devoted to spreading the political and policy message that palliative care is not a luxury for the few but a fundamental human right.

Universal access to high-quality palliative care may not be quite within our grasp yet but should be a goal for everyone. Suffering, especially avoidable suffering, blights the lives of millions of people, creating a lasting impact on their families in terms of financial burden and emotional distress. Addressing the challenges of responding compassionately, while drawing on the best scientific evidence, to ameliorate suffering for those with complex, advanced and life-limiting conditions lies at the heart of palliative care. This textbook is a good example of this commitment to improve care for all in need.

This textbook is truly outstanding. I am not going to highlight specific chapters, as I am sure that all contributors will have fulfilled their brief under the guidance of the editorial team. It is a textbook to dip into, relishing the quality of the information contained in these pages. You, dear reader, will make your choices, but let me urge you to venture into new areas, perhaps reading those chapters that are outside your normal interest zone. Become a critical consumer of the material and resources presented in this textbook. How does it compare to your practice? What does it challenge you to think about in a new and different way? What do you agree with? This textbook, developed by an international team of experts, offers guidance on the development and establishment of all aspects of palliative care services, and it wonderfully captures the flourishing of a mature discipline.

Emeritus Professor
International Observatory on End of Life Care

Preface

Nothing in life is to be feared, it is only to be understood.

Attributed to Marie Curie. *On ne doit rien craindre dans la vie—il suffit de comprendre* in Université Laval, Faculté de médecine, Société medicale des hôpitaux universitaires de Québec, Laval médical (1951), 16, 569

Palliative care has been identified as a discrete part of healthcare for over 50 years, and yet we still find ourselves having to explain the nature and practice of palliative care to many of our professional colleagues and to the public in general. Healthcare education and training has been slow to recognize the vital importance of ensuring that *all* practitioners have a good understanding of what is involved in the care of people with serious or advanced illnesses and their families. Because of this limited exposure, many laypeople and professionals still have understandable fear and anxiety about death and dying.

However, the science of palliative care is advancing, and our understanding of the evidence concerning many aspects of palliative care is developing rapidly. There are now excellent research teams and facilities around the world exploring different characteristics of this essential aspect of healthcare from a wide range of disciplines.

There have been many authoritative books on various facets of palliative care produced over the last years. In planning this *Textbook of Palliative Care,* we hoped to produce a comprehensive, clinically relevant, and state-of-the-art book, aimed at advancing palliative care, as a science, a clinical practice, and an art.

For this major reference work, we have been able to draw on our own collective experience and the goodwill of many fine people from around the world. We have endeavored to produce a *Textbook* that showcases the multi- and interdisciplinarity of palliative care and is unique in bringing together authors from all fields of palliative care – physical, psychological, social, and existential or spiritual. The majority of them are internationally recognized experts in their chosen discipline. We have been helped by dozens of authors and the committed section editors, who have given their time, expertise, and wisdom to ensure that this work can be disseminated around the globe to assist in the understanding of all aspects of illness and disease near the end of life as

well as death, dying, and into bereavement. Our authors have drawn not only on the evidence available but also on their own phronesis or practical wisdom. They have summarized and extended the state of the art in their field and challenge the reader with new insights, challenges, opportunities, and potential future evolutions. We are deeply indebted to all those who have been involved in the preparation, writing, and editing of this work. They all undertook their work with enthusiasm and commitment.

We expect this *textbook* will be of value to practitioners in all disciplines and professions where the care of people approaching death is important, specialists as well as nonspecialists, in any setting where people with serious advanced illnesses reside. It can also be an important resource for researchers, policy-makers, and decision-makers – national or regional – as well as for laypersons, patients, and/or families, seeking to learn more about palliative care. Neither the science nor the art of palliative care will stand still, so we hope to be able to keep this *textbook* updated as the authors find new evidence and approaches to care.

Our special appreciation goes to Vasowati Shome and Tina Shelton of Springer who have guided us expertly through the process of creating this reference work – we are deeply indebted to them.

About the Editors

Roderick Duncan MacLeod is a Palliative Medicine Specialist at Harbour Hospice in Auckland, New Zealand, and Consultant to HammondCare in Sydney where he is also Honorary Professor in the University of Sydney School of Medicine.

He gained his primary medical degrees from the University of Dundee in 1976 and went on to train for general practice. He was a Principal in general practice for almost 10 years before moving to the discipline of palliative care. He was first appointed as Medical Director of the Dorothy House Foundation in Bath, England, in 1989 after having completed a period of prolonged study leave exploring palliative care in the community. In 1994, he was appointed Medical Director and subsequently Director of Palliative Care at the Mary Potter Hospice in Wellington, New Zealand. He was made a Fellow of the Royal College of General Practitioners (UK) in 1999. He was a Foundation Fellow of the Royal Australasian College of Physicians, Australasian Chapter of Palliative Medicine, in 2000. He received his Ph.D. in 2001 from the University of Glamorgan (Prifysgol De Cymru) for his work and publications on "Changing the Way that Doctors Learn to Care for People Who Are Dying."

In 2003, he was appointed to New Zealand's first Chair in Palliative Care as the inaugural South Link Health Professor in Palliative Care at the University of Otago Dunedin School of Medicine and in 2013 was appointed Conjoint Professor in Palliative Care at the University of Sydney and worked clinically as Senior Staff Specialist in Palliative Care for HammondCare in Sydney. He has been a Member of the Australasian Chapter of Palliative Medicine

Education Committee, the NZ National Health Committee – Working Party on Care of People Who Are Dying, the NZ Palliative Care Expert Working Group, and the Council of the Asia Pacific Hospice Network. He was appointed to the Expert Advisory Group (Physician Education) and the Chapter of Palliative Medicine Committee of the Royal Australasian College of Physicians and the NZ Ministry of Health Palliative Care Advisory Group. He has also held a number of roles within Hospice NZ.

He has published over 130 peer-reviewed articles in the field of palliative care in national and international journals and has written over 20 chapters for palliative care texts. In addition, he has been on editorial boards of international peer-reviewed journals in the field of palliative care and has reviewed manuscripts for over 25 different academic journals. He has also published two anthologies of poetry, exploring what it might be like to approach death and experience bereavement and loss.

He is one of the authors of *The Palliative Care Handbook*, which has become a freely available standard text for healthcare professionals in New Zealand and parts of Australia.

He was appointed a Member of the New Zealand Order of Merit by Her Majesty Queen Elizabeth II in the Queen's birthday honors in 2015.

Lieve Van den Block is Professor of Ageing and Palliative Care at the Vrije Universiteit Brussel (VUB) and Chair of the Ageing and Palliative Care Research Programme at the End-of-Life Care Research Group of the VUB and Ghent University in Belgium. She holds a Ph.D. in Medical Social Sciences and a master's in Clinical Psychology. Professor Van den Block has been involved in palliative care research for over 15 years, focusing on national and international public health and interventional research aimed at monitoring and improving palliative and end-of-life care. She has received several scientific awards for her work, including the 2014 Early Researcher Award of the European Association for Palliative Care. She has published over 100 peer-reviewed articles on palliative care and is editor and author of several books and chapters. Her work has been supported by grants from the European Commission, national fundamental and applied research foundations, and leading medical and health charities.

Palliative Care: Definitions, Development, Policies

Approach and Nature of Palliative Care

1

Roderick D. MacLeod

Contents

Abstract

Caring for people who are near the end of life has a relatively short timeframe as a specialist health care activity. In this chapter, the history of palliative care is briefly outlined along with a description of who might provide such care. An introduction to aspects of learning in palliative care is followed by an emphasis on the importance of psychosocial-spiritual assessment and care; some of the universal needs of people who are dying is outlined. It is important to recognize the significance of understanding the social, emotional, psychological, cultural, sexual, and spiritual context of each

clinical situation and to view these within our own and our institution's and perhaps our society's ethical framework. By doing so, we can begin to understand how best to understand the nature of palliative care and how best we might approach this most significant aspect of care in people's lives.

Caring for people who are dying is clearly not new but has been seen as a special form of care for centuries. In the first millennium, the Christian church was closely involved with this activity, and the original hospices were set up as resting places for travelers. Religious orders advanced the notion of care for people who were dying in the nineteenth century, and perhaps the first of its kind, St Joseph's Hospice, was founded in London in 1905. It was however as a response to the perceived inadequacies of medical care that what has become known as the modern hospice movement was born (Clark 2002). The pioneering work of hospices such as St Christopher's Hospice, which opened in Sydenham, London, in 1967, demonstrated that the principles of hospice care (good clinical practice, whatever the patient's illness, wherever the patient is under care, whatever his/her social status, creed, culture or education, http://hospicecare.com/about-iahpc/publications/manuals-guidelines-books/getting-started/6-principles-of-palliative-care) could be applied in a variety of settings.

Dame Cicely Saunders introduced the concept of whole person care in that institution and developed the model of "total pain" which highlighted not only the physical aspects of a person's pain but also psychological, social, and spiritual dimensions of their distress (Saunders and Sykes 1993). The term "palliative care" was coined in Canada in 1974 by Balfour Mount, a pioneering surgeon who had worked in London with Saunders and wanted to take the concept back to Canada where there could have been confusion among the French-speaking population about the term hospice. Using the term palliation to reflect the non-curative nature of care was not new – it had been used in the seventeenth century. This terminology was subsequently adopted in many countries, and a new medical specialty was proposed – that of palliative medicine. The discipline received recognition by the Royal College of Physicians, London, in 1987 as a specialty within medicine in the United Kingdom (UK). Since that time other countries have adopted that approach, and palliative medicine and palliative care are practiced around the world in over 100 countries. A universally agreed definition of palliative care was disseminated by the World Health Organization (WHO) in 1986, followed by a revision in 1990. A revised and updated definition of palliative care was accepted by the WHO in 2002 (Sepúlveda et al. 2002).

Palliative care is an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual.

Palliative care:

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten or postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help the family cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counselling, if indicated
- Will enhance quality of life and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications

Definitions are helpful in gaining consensus about the limits of a specialty, but what does it mean in practice? Generally speaking, people

with advancing disease need to be supported and cared for by clinicians with excellent skills.

1 Who Provides Palliative Care?

Palliative care is provided by two distinct categories of health and social care professionals:

- Generalist palliative care is provided by those working to provide day-to-day care to patients, families, and carers in their homes and in hospitals:
  - They should be able to assess the care needs of each patient and their families across the domains of physical, psychological, social, and spiritual needs.
  - Meet those needs within the limits of their knowledge, skills, and competence in palliative care, and know when to seek advice from or refer to specialist palliative care services.
- Specialist palliative care is provided by professionals with additional training in the discipline and who only work in palliative care (e.g., consultants in palliative medicine and clinical nurse specialists in palliative care).

2 Specialist Palliative Care Services

These services are provided by specialist interdisciplinary teams and include:

- Assessment, advice, and care for patients and families in any or all care settings, including hospitals and care homes, also known as palliative care consultation
- Specialist inpatient facilities (in hospices or hospitals) for patients and families who benefit from the continuous support and care of those specialist teams
- Intensive coordinated home support for patients with complex needs who wish to stay at home (this may involve the specialist palliative care service working with the patient's own doctor and community nurse to enable someone to stay in their own home).
  - Many teams also now provide extended specialist palliative nursing, medical, social, and emotional support and care in the patient's home, often known as "hospice at home."
- Outpatient clinic appointments and day-care facilities that offer a range of opportunities for assessment and review of patients' needs and enable the provision of physical, psychological, and social interventions within a context of social interaction, support, and friendship. Many also offer creative and complementary therapies.
- Advice and support to all the people involved in a patient's care.
- Bereavement support services which provide support for the people involved in a patient's care before and following the patient's death.
- Education and training (and for many, research) in palliative care.

The specialist teams should include palliative medicine and palliative care nurse specialists together with a range of expertise provided by physiotherapists, occupational therapists, art and music therapists, dieticians, pharmacists, social workers, and those able to give spiritual and psychological support.

3 Who Should Receive Palliative Care?

Anyone with a life-limiting disease should be able to have access to palliative care services. Historically modern palliative care services were primarily involved with providing care for people with cancer and some neurological disorders such as motor neuron disease or other degenerative disorders of the nervous system.

The other major group of people who should receive palliative care are those with failure of one of the major organs of the body such as the lungs, heart, kidneys, liver, or brain. In these situations, people often have a prolonged period of time to adjust to the understanding that the body is failing. One problem though can be that medical science has become so adept at propping up failing bodies that the realization that death is approaching may not be so apparent. This can produce problems for families and carers as death approaches.

It has been suggested that the clinical course of people who do not die suddenly tends to follow one of three trajectories (Dy and Lynn 2007). The first is the maintenance of relatively good function until a predicted decline a few weeks or short months before death. The second is the course of chronic organ failure which shows a slow decline with exacerbations that may end in sudden death. The third trajectory is one where there is poor functional status over a long time with a slow but relentless decline; frail elderly people with many comorbidities fit into this group. It is important therefore that services are developed for people who are dying in any of these ways. There are a number of models available – for example, the Gold Standards Framework in the UK which incorporates resources and end-of-life tools into primary care, hoping to enable people to have real choice about where they wish to die (Thomas 2003; King et al. 2007).

Of course, the majority of people who are dying would prefer to do so at home being cared for by their primary healthcare professionals. Primary care shares common values with specialist palliative care – holistic, patient centered, and delivered in the context of their families – but too often it becomes difficult for a number of reasons for people to be cared for in their own homes (Murray et al. 2004). Developing primary palliative care is essential if people are to exercise their right to die in the bed of their choice.

Twenty years ago, David Field, an expert in the sociology of death and dying, identified two important differences between patients with cancer and those with nonmalignant conditions (Field 1998). Perhaps not much has changed over those 20 years? First, differences in disease progression mean there is a continuing benefit from curative/restorative interventions and treatments for the latter category. Second, there was greater uncertainty about the fact and likely time of death with non-cancer patients. Field identifies the latter as appearing to be the key obstruction to extending specialist palliative care services to non-cancer patients. This is because they will not be seen as suitable candidates for palliative care until they have been defined as terminally ill. One of the reasons that this may occur is because of the difficulty many clinicians have in dealing with uncertainty in general. In medicine, and possibly in other disciplines as well, uncertainty stimulates and propels activity (Hall 2002) – doctors have a "propensity to resolve uncertainty and ambiguity by action rather than inaction" (Katz 1984). Increasing diagnostic uncertainty leads to a reluctance to withdraw from "active" interventions, leaving patients and families in a similar situation of ambiguity and doubt about the future (Christakis and Asch 1993). This relates to a tendency for the continuation of what might be deemed futile treatment in the face of relentlessly advancing disease. Taken out of context (i.e., without considering the person as a whole), almost any disease may be deemed "treatable" – such are the advances in medical science and technology. This confidence in the advancement of medical science is relayed not only to the medical and nursing professions but to the lay public as well, with a consequent sense of expectation that is unfortunately not wholly realized. This situation is compounded with the advancing age of people being treated. Many elderly patients have multiple clinical diagnoses involving multi-system pathology, and the diagnosis of dying is often made only by exclusion. Communication may be more difficult due to a combination of a higher incidence of confusion in elderly patients with nonmalignant disease than in younger people with cancer, and reduced social networks in the elderly may potentially lead to reduced care and support from family and friends. The incidence, duration, intensity, and type of symptoms follow a different pattern in cancer compared to other illnesses. People with nonmalignant disease also tend to be older. People aged 75 and over who do not die from cancer are more likely to have outlived their spouses, brothers and sisters, and even their children. They are predominantly women, and many live alone or in residential care and therefore present differing challenges for the provision of social support.

The scope of palliative care therefore extends beyond people with a diagnosis of cancer to include patients with other chronic life-threatening diseases.

Perhaps one of the greatest challenges for palliative care services is the provision of care for people with dementia – an area which until recently modern palliative care avoided (https://www.nhpco.org/hospice-statistics-research-pressroom/facts-hospice-and-palliative-care). The annual incidence of dementia in North Americans, for example, doubles nearly every 5 years from 7 in 1000 (65–69 years of age) to 118 in 1000 (86–89 years of age) (Hanrahan et al. 2001). The European Association for Palliative Care (EAPC) published a white paper which helpfully defines optimum palliative care for people with dementia and provides a set of 57 recommendations for practice, policy, and research (van der Steen et al. 2014). Further, the white paper provides a model of dementia progression and suggested prioritizing of care goals and a recommendation of further research into how to give shape to palliative care in dementia across dementia stages.

4 How Should Learning in Palliative Care Be Approached?

Clearly much of what is taught and what is learned is of a technical and knowledge-based nature. This is fundamental in any healthcare practice and particularly relevant in a specialty where so many patients have such a wide range of clinical problems. It would be seductive to imagine that the essence of palliative care lies within these technical and knowledge-based areas, but it is essential that those responsible for teaching and learning in this area maintain a focus on those aspects of the discipline that are less easily quantified and identified. In any domain of professional practice, it is important to identify the true nature of that practice. Professional practice involves not only professional content but also professional process, and it is in the untangling of these two elements that we can discern something of the difficulty facing those responsible for the training of palliative care clinicians for the future. Palliative care cannot be seen solely in terms of skills and knowledge – it must include those processes that can be identified as metacognitive and reflective as well (MacLeod 2000).

The care of seriously ill and dying people necessitates a philosophical and ethical basis. Palliative care must be based on a philosophy that acknowledges the inherent worth and dignity of each person. The ethic of care must include respect for autonomy, justice, non-maleficence, and beneficence. The context of death exerts a powerful influence over what is said, received, and interpreted, and professionals must relinquish control, share decision-making, and treat patients and families as partners.

Caring can be thought of in terms of behavior or as a motivation. As behavior, it is often thought to mean "looking after people and seeing to their needs." As a motivation it can refer to being fond of someone, feeling sympathy or empathy for that person, being concerned for their well-being, or having a professional commitment to them. It could be argued that the best caring professionals show both of these aspects of care. If we care about anything or if we care for someone, it is because deep caring is part of the very nature of our being (van Hooft 1996).

Empathy is an essential component of the way that care is provided and can be an elusive concept in medicine. Empathy helps us to know who we are and what we feel. Empathy requires living and knowing – it requires the ability to put oneself imaginatively in the place of another. The aspect of empathy that is crucial for clinical practice is that of genuine attention to the individual's concerns and the acceptance of those concerns. Empathy can be thought of as a mode of caring. Specifically, it involves caring for the fate of another human being – the concept of empathy is relevant to the care of people who are dying because more than anything they are people in need. Empathy is an understanding of how a disease or its treatment is likely to affect how patients actually live and hope to live their lives. It is an openness to, and respect for, the individuality of another human being.

Francis Peabody (1927) emphasized the importance of getting to know the patient as a major part of the art of medicine. By writing that the art of medicine and the science of medicine were not antagonistic but supplementary to one another, he was essentially saying that empathy is

a prerequisite for the effective care of any patient. It was perhaps particularly poignant that Peabody was terminally ill when he wrote the article.

Sir William Osler (1904) wrote "it is a safe rule… to have no teaching without a patient for text and the best teaching is taught by the patient himself." This was written in 1904 in an attempt to encourage students to learn at the bedside rather than through books alone. This assertion encourages students to pay heed to the patients' stories and the themes that flow from them. Empathic listening is a most powerful means of understanding a person and the things in their life that are of significance for them at that time. Until the start of the nineteenth century, the science of medicine was taught as an apprenticeship – not based on scientific principles but on clinical observation and narrative. Such stories were once the primary source of medical knowledge and the science of medicine developed through the collection of anecdotes. The case presentation is the narrative center of medicine as a discipline – the care of the patient begins with such a story, and the clinician translates those stories in a way that helps the patient understand their ill-health. Without the experience of such stories, the education of healthcare practitioners is incomplete. It is also possible though to encounter stories in other forms; literature, poetry, art, film, and music can all give indications of the human condition and can help us better understand the meaning of care.

Over the last 50 years, since the birth of the modern hospice movement, great progress has been made toward the alleviation of many symptoms that accompany the end of life – particularly in those who have malignant disease, so enabling the maintenance of the highest possible quality of life. Such progress has been made in clinical practice that in many minds the "mainstreaming" of palliative medicine into all healthcare is a given. Alongside this mainstreaming is a desire to see palliative care practiced with the same evidence-based approach that other specialties and subspecialties are adopting. This is clearly a laudable sentiment. However, there is a danger that in adopting such an approach much of what is unique about care at the end of life may be lost. If we are to focus on purely practicing from an evidence base, we will surely lose aspects of the art of clinical care as we become more and more seduced by the science of what we have been led to believe is predominantly a scientific discipline. For example, the doctor's role as technician, guided by standard empiricism, does not exclude their adopting other roles as a consoler, healer, or even friend. The evidence that is built from the "gold standard" double-blind, randomized, controlled clinical trial has been a powerful instrument in furthering medical knowledge, but it is often not enough in recommending a form of management or treatment for a particular individual. Medicine is an art that is especially concerned with human beings as individual and unique creations, but it provides us with a context that shows us that our bodies are fragile and that ultimately they will fail us. The good that medicine in particular and healthcare in general is purported to achieve is not just the maintenance of organic functioning. It is also to maintain a spiritual, emotional, and social well-being that enables each individual to function to some degree within the society in which we live. If we focus too strongly on the achievement of biomedical good, there is a danger that the shortcomings of modern healthcare will be exposed. Evidence-based practice and the strong beliefs of standard empiricism offer a structure for analyzing clinical decision-making but are not sufficient to describe the more tacit processes of expert clinical judgment. It is not possible to find or provide evidence for all aspects of clinical competence. There is a generally widely held belief that medicine has become so powerful that it enables us to overcome not only the bodily ills that we may all experience but also some of life's other misfortunes, not only physical pain but human suffering as well. Part of the difficulty with developments in the academic aspects of medical and nursing sciences is that they tend to have a narrow focus on what constitutes knowledge (and therefore the "evidence base"). It is the application of the knowledge base that becomes problematic in health sciences. It is not sufficient to address only the technical approaches to disease management; there must also be a realistic context for social definition. Those who work with people at the end of life

soon realize that we often face the limits of medicine and the temporal and physical limits of being human. When we acknowledge that all our efforts are for the "good of the patient," we also are confronted with the limits of our clinical expertise and face the reality that ultimately what we offer people is not our role as doctor or nurse but as human being. The challenge for clinicians is to identify not only the evidence base for the practice of palliative care but also the features of sound clinical judgment and the character of those clinicians who make those judgments. It is in this aspect that we must identify the role of wisdom in palliative care. Professional practices are refined by science and corrected by wisdom (Cogan 1953). Wisdom is a form of understanding that combines the practicalities of knowledge with a reflective approach to the utilization of that knowledge over time. There are certain aspects of wisdom that can be readily identified. Practical wisdom is that habit of mind that enables one to choose well, not only with respect to a particular domain of human action but in the whole of one's life. It is the "intellectual virtue that orders human practice in order to attain truth for the sake of action as opposed to truth for its own sake" (Pellegrino and Thomasma 1993).

So, understanding the nature of care, the importance of empathy, and the utilization of wisdom are all essential in our approach to the care of people who are dying. There are some specific dimensions of care that we need to address, and these are identified below.

5 Psychosocial Care

Psychosocial care (a better term might be psychosociospiritual care) has been defined as that which is "concerned with the psychological and emotional well-being of the patient and their family/carers, including issues of self-esteem, insight into an adaptation to the illness and its consequences, communication, social functioning and relationships" (National Council for Hospice and Specialist Palliative Care Services 1997).

Psychosocial care addresses the psychological experiences of loss and facing death for the patient and their impact on those close to them. It involves the spiritual beliefs, culture, and values of those concerned and the social factors, which influence the experience. Psychosocial care includes the practical aspects of care such as financial, housing, and aids to daily living and overlaps with spiritual care. Spiritual care is less easy to define and is often subjective, arbitrary, and personal. It is generally assumed to include an individual's beliefs, values, sense of meaning and purpose, identity, and for some people religion. It may also encompass the emotional benefits of informal support from relatives, friends, religious groups, and more formal pastoral care. For many, existential questions about the human condition can be ignored during many phases of life but are brought into acuity at the end of life (Williams 2006).

Psychosocial care also includes the professional carers who are inevitably affected by their experiences and who thus require support.

Thus, psychosocial care encompasses psychological approaches, which are concerned with enabling patients and those close to them to express thoughts feelings and concerns relating to illness. It also incorporates interventions to improve the psychological and emotional well-being of the patient and their family/carers.

In the past there has been a greater emphasis on psychological needs than social needs – the National Council for Hospice and Specialist Palliative Care Services (NCHSPCS 1997) have emphasized the importance of social care to patients:

> The social fabric of their lives is central to how they make sense of their illness experiences, the meanings they draw upon to understand these and the range of resources they can call upon to help them manage them.

In practice, the social aspects of palliative care are often limited to a focus upon the patient's family, ignoring community influences.

6 Psychosocial Assessment

Patients and families face a range of issues which are not only related to illness and approaching death. Healthcare professionals need to assess

individual strengths and coping styles, experience, and stress and attend to previous losses.

The initial assessment of a patient is carried out by a member of the specialist palliative care team and will include a detailed assessment of the patient's and family's/carers' needs. The time invested in this initial assessment is essential in creating a framework for the provision of future care, a partnership between patient and professionals. The initial assessment may indicate the need for more formal psychological, social, or spiritual assessment. This will for many include the need to maintain autonomy which includes respect for dignity and the opportunity to exercise choice.

In order to identify caregivers at risk of poor psychosocial functioning, self-reported anxiety and competence rating is suggested as an aid to care provision (Hudson et al. 2006). A small group of caregivers (35) was studied. Using a screening tool, these researchers identified the possibility of low-level psychosocial functioning as a potential determinant for family caregivers at risk of psychosocial distress.

There are however a multitude of assessment tools and techniques that will illuminate elements of psychosocial well-being and identify psychological and social needs of patients and caregivers.

The psychosocial aspects of care of the dying person whatever their diagnosis include the need for:

- Understanding – of symptoms and the nature of disease and of the process of dying
- Acceptance – regardless of mood, sociability, and appearance
- Self-esteem – involvement in decision-making
- Safety – a feeling of security
- Belonging – a wish to feel needed and not to feel a burden
- Love – expressions of affection and human contact (touch)
- Spirituality – an explanation of meaning and purpose, both religious and nonreligious
- Hope – for an improvement in any aspect of their life or of their living

In the provision of psychosocial care for people at the end of life, each of these needs must be identified and addressed.

7 Social Context

Social elements of care are often influenced by the disease that is ending a life. Dying from a nonmalignant disease, in many ways, creates a different social structure or standing than dying from cancer. The language that we use is quite different – for example, people who die from cancer are often referred to as "brave" in their "battle" with cancer. They often talk of "beating" the disease or "fighting" it. Nonmalignant disease does not seem to have that same social cachet. Death from end-organ failure is often silent and slow – in many ways relentless in its nature. Without heroic medical interventions to replace organs or use artificial means to support ailing bodies, many of these people would die earlier and perhaps more suddenly. In identifying social or psychological care for these people, it is important to recognize this significant difference in perception of disease that is possible to have originated both from the individual and from society.

For many people with cancer, there are well-recognized social networks or programs that may provide both psychological and social support. Social supports for people with nonmalignant diseases should emerge from people in similar situations, family, and friends and from the wider community. With the exception of some of the neuromuscular degenerative diseases, many of the current support systems for people with nonmalignant disease are focused on raising awareness and funding for curative interventions rather than supporting people in the last stages of their disease. The professions, while openly supporting cancer networks and programs, have been slower to acknowledge the need for similar systems for people with incurable nonmalignant disease.

8 Emotional Context

Some feelings and emotions are almost universally experienced near the end of life.

- Fear of being left alone or having to leave loved ones, of breaking down or losing control

– of the situation they are currently in, getting worse.
- A sense of helplessness in which physical and psychological crises show up human powerlessness. Alongside this is the knowledge of physical and emotional strength gradually deteriorating – loss of physical ability bringing with it attendant psychological and social helplessness.
- Feelings of sadness for what is not to be and for the loss to come.
- A sense of longing for all that has gone before and all that is not going to be, in the future.
- Feelings of guilt for being better off than others or regret for things that have been done or not done.
- A sense of shame for having been exposed as helpless, emotional, and of needing others or for not having reacted, as one would have wished.
- Anger at what has happened, at whatever caused it or allowed it to happen, that the treatment hasn't worked, at the injustice and senselessness of it all and the shame and indignity and at the lack of proper understanding by others.

These feelings and emotions may also be influenced by memories of feelings or loss or of love for other people in their lives who have been injured or died, perhaps let down by doctors, by the system or society, or by the family.

9 Psychological Context

The fundamental clinical skill of medicine is acquiring the history of the illness from the patient, and providing the patient with the opportunity to identify their concerns is mandatory. Specific questions need to be asked to elucidate psychological distress; in particular, they should include questions concerning fatigue, hallucinations, and suicide risk (Macleod 2011).

Examples of psychological interventions include psychosocial support and psychotherapy, behavioral-cognitive therapies, and educational therapies.

Initially it is helpful to look for indicators of pathological levels of psychological disturbance such as clinical depression or other mood disturbance or personality disorder. These lend themselves well to specific psychological interventions. Variables suggesting that the patient or family is at serious risk of psychological disorder or distress may be identified (e.g., social isolation or a history of psychiatric hospitalizations). All members of the healthcare team may observe and subjectively report distress that they feel is psychological in nature (fear or anger) or psychologically mediated (pain or breathlessness) but may not meet the criteria of a discrete psychological disorder. The team should also look for the potential for preventative interventions that may forestall, minimize, or bolster resources for predictable areas or times of vulnerability and hardship (similar patterns of ill-health, pre-bereavement work, or anniversary calls to the bereaved).

Specific psychoeducational interventions that may enhance coping skills, psychological insights, and quality of life should be employed, regardless of the presence or absence of clinical levels of psychological distress. (For an extensive review of psychiatric syndromes and interventions, see Macleod (2011).)

People with neuromuscular degenerative disorders such as motor neuron disease, multiple sclerosis, muscular dystrophies, and less frequently seen disorders like Creutzfeldt-Jakob disease may have particular psychological needs associated with their care. Such disorders bring with them potentially challenging communication issues. For example, some patients may not be able to communicate verbally but retain effective cognitive functioning. It is important to help families to differentiate between behavioral disturbances associated with cognitive impairment from other communication difficulties. Cognitive impairment, depressive symptoms, emotional incontinence, or lability all need expert assessment and careful explanation and management. All or any of these may significantly impact on coping ability, psychological adjustment, and communication both of the patient and family (Macleod 2001).

10 Cultural Context

In palliative care, the cornerstone of practice is the holistic approach to care that is exemplified by the management of "total" pain. As stated earlier, this

classically includes physical, psychological, social, and spiritual pain. Cultural pain or distress can be expressed through any of these dimensions. Often closely allied to culture is spiritual and religious beliefs that have a bearing on how people approach and understand their disease. In many societies people define themselves by their religious, cultural, or tribal grouping, even when their faith or immersion in religion or culture is limited. There are wide variations between people of differing faiths, ethnic backgrounds and national origins, and their approach to the end of life. Although documented evidence is sparse, there is anecdotal evidence to suggest that there is a difference in approach to dealing with malignant and non-malignant disease. In order to understand these differences, it is important to understand the culture from the perspective of the patient and family.

In caring from people of a different culture to our own, it is imperative that we understand the expectations of that culture in order that we act appropriately. For example, the notion of individual autonomy is essentially a western one – many peoples live together and make decisions together in extended families. Many people in China, Japan, and the Pacific Islands as well as many Māori in New Zealand, for example, consider the family as the fundamental unit of society and will expect the family to make medical decisions. Without the accurate and honest provision of information in the right form, at the right time, and in the right place, there can be little hope of an understanding being reached about the situation the patient and family is facing and the goals of care that are being formulated. Without asking, we cannot know what individuals need to make a difference to the end of their life. That asking must include an acknowledgment of difference – difference in culture, in religious beliefs, in understanding of the nature of disease, in expectations in a particular situation, and in perceptions for hope at the end of life.

11 Sexual Context

Sexuality is an element of being that is often easily sidelined or overlooked when caring for people at the end of life, particularly if those people are elderly. It is too often assumed that because people approaching death are weak and tired that their sexual identity or needs are minimized, this fails to recognize the many ways in which human beings can express their sexuality. Staff often view people's sexual interests as "behavioral problems" rather than natural occurrences or expressions of needs for loving contact (Steinke 1997; McPherson et al. 2001). Many people approaching the end of life with a non-malignant disease have had a relentless decrease in their physical being for some time. Much of their time may have been spent in repeated hospital admissions and the physical isolation that encourages. Many treatments, as well as the diseases themselves, can affect sexual function, and of course sexual activity will most often not be at the forefront of people's minds as they approach death. Acknowledging that all people are sexual beings is a starting point in helping people address their sexual needs and wishes – it is in no way different to acknowledging that they are physical or emotional beings as well. This is one aspect of their functional health that can contribute to their sense of self-worth or self-esteem. Changes in physical appearance, size, skin color, and texture as well as increasing fatigue often decrease an individual's sense of self-worth or attractiveness. Identifying psychological elements of their functional health may help to reverse this decrease. Providing information and advice on ways of expressing sexuality other than through sexual intercourse may help to restore an individual's sense of worth in this aspect of themselves.

12 Spiritual Needs

Understanding spiritual needs is essential in the care of people who are dying as these needs are intertwined with an individual's meaning of life, hope, transcendence, and beliefs as they arise from social relationships. Near the end of life, for example, pain can present that defies the efforts of clinicians to manage it. Increasingly clinicians, researchers, and educators have acknowledged the importance of spirituality in the end of life. The

presence of spiritual pain, especially in people who are dying, can be recognized in terminal agitation or restlessness in the absence of other obvious factors. This can manifest as a pre-death event that indicates physical, psychological, and/or spiritual discomfort or distress.

A particularly helpful definition of spirituality that has been articulated by Puchalski et al. (2009) was arrived at by consensus in a conference of invited expert practitioners. This definition states: "Spirituality is the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and to the significant or sacred."

Meaning as related to life purpose is aptly described as "having a sense that one's life has meaning, or involves the conviction that one is fulfilling a unique role and purpose in a life that is a gift" according to Frankl (cited in Chochinov and Cann 2005, pS107). Palliative care aims to recognize and facilitate resolution of spiritual, social, emotional, and physical issues to enable dying well. Clinicians need to be able help people to identify any sources of spiritual unrest and to contemplate their contextual meaning and importance so assisting in the alleviation of spiritual suffering at the end of life.

13 Ethical Context

In all of our care for people near the end of life, one of our goals is to help people to do what they want in the way that they want. In many ways that is what has become known as autonomy. People's choices at the end of life are often different to those they may make earlier in their life. Patients' authority to choose what interventions they have and even to refuse interventions is seen as one way of protecting dignity and autonomy. Being in charge is better than having control taken away (Carter et al. 2004). That idea of being in charge though will be different for people from different ethnic groups. Professional carers need to ensure that they understand the nature of communication and decision-making that is the norm for each person and family they encounter. Assessment of family dynamics from a different culture may help ensure that their ethical constructs are not overridden.

The ethics of the provision of palliative care are really no different to those required for any form of healthcare; however, in providing care for the most vulnerable, there are particular issues to address. Palliative care must be based on a philosophy that acknowledges the inherent worth and dignity of each person and in order to understand that worth and dignity every facet of their being should be explored – not just the physical. This philosophy must be based on an ethical framework – this is most commonly represented by the "four principles" postulated by Tom Beauchamp and James Childress in their textbook *Principles of biomedical ethics* – autonomy, beneficence, non-maleficence, and justice (Gillon 1994). These principles encourage a sharing of decision-making between carer and cared for but also create the right environment for promoting patient well-being. In addition to this framework, virtue-based ethics may give some indicators for the way in which we could practice our professions. Virtues are often thought to be "old-fashioned," but they are particularly relevant to end-of-life care.

Integrity and trust are perhaps the cornerstones of the caring relationship. Development of these can be gained by attending to the psychosocial and spiritual as well as the physical wants and needs of individuals and families. Trust is essential in any human relationship but in one where one party is so vulnerable then perhaps it is even more important. In all of our dealings with patients and their families, we must be truthful and honest. People who are dying have lost so many elements of their being that it is essential that they can maintain trust in their professional attendants.

Compassion, a further virtue required in all our dealings with patients and their families, could be described as suffering together *with* another or participation *in* suffering. Suffering is clearly not only related to the physical elements of our being, and in order to understand suffering in its broadest sense, we must address social, psychological, and spiritual elements as well.

Phronesis is a virtue rarely mentioned in modern practice, but it is essentially prudent. Nowadays this can be regarded as timidity, undue self-interest, or unwillingness to take risks, but it might also be considered to be discretion or common sense. In history, phronesis was thought to be practical wisdom – the link between the intellectual and moral life. Phronesis urges us to look for the right way of acting.

In modern healthcare practice, working from an effective evidence base, where randomized controlled trials are sought for as many interventions as possible to guide us, it is often forgotten that practical wisdom, phronesis, can guide us where there is no concrete evidence to do so.

The virtue of justice or fairness requires that people are not put down or labelled in any way. Such labels can determine how people are cared for in the future, and they may often have arisen from isolated encounters. So often, labels can imply intolerance – this in turn can lead to an expectation that there is a particular "right" way to live or a right way to die.

Integrity defines the nature of the individual, and it also integrates all the virtues.

A person with integrity is someone who can judge the relative importance in each situation of principles, rules, guidelines, and other virtues in reaching a decision. It implies honesty and righteousness. The integrity of a person is shown in the right ordering of the parts in relation to the whole, the balance, and the harmony between the various dimensions of human existence necessary for the healthy functioning of the whole organism (Pellegrino and Thomasma 1993). It is a balanced relationship between the physical, psychosocial, and intellectual elements of their lives. This could be a definition of what palliative care should be about.

The doctor/patient relationship relies on integrity and trust. Neither party must impose their values on the other. Overriding another person's values is an assault on their humanity and their person.

Using these principles and virtues enables carers to address some of the challenging moral or ethical issues near the end of life. Aspects such as people asking for or insisting on futile treatments, balancing ordinary and extraordinary treatment, the doctrine of double effect, and the relationship between killing and letting die have attracted much discussion and comment over the last four decades, and the debate has been considerably better informed by research, investigation, and dialogue between those in the palliative care community and their colleagues in the field of medical bioethics.

The developments in the provision and understanding of palliative care have enabled a more informed discussion of these topics, but resolution for many in our broader society is still a long way off. However, by attending to people as whole people within the context of their family whoever that may be, we stand a much better chance of meeting their needs – not just their physical needs but their psychological, their social, and their spiritual needs as well.

One aim of palliative care then is to care for people in a way that facilitates dying well. This notion is dependent on many variables that encompass the holistic dimensions of our existence. Dying well is likely to be different for everyone, and seeking a universal definition of what it means may be futile. Dying is, to a greater or lesser extent, a social event (Kellehear 2008), and denying the psychological, social, and spiritual aspects of the dying person leads to a less than optimal dying experience. Understanding the many dimensions of the approaches to and the nature of care then is a prerequisite to starting to get that way of caring right for each person and their family that we encounter as they approach the end of life.

Quality of Life

2

Lukas Radbruch and Birgit Jaspers

Contents

Abstract

Improving the quality of life is considered a central goal of palliative care, together with the prevention and relief of suffering. However, there is no broadly accepted definition of palliative care. Quality of life may be defined as the gap between expectations, hopes, and ambitions and the present experiences (Calman gap). With progression of the underlying disease, and deterioration of physical and cognitive performance status, patients may still report good quality of life, if they reduce their expectations or shift the focus to other areas to find quality of life (response shift). However, patients experiencing rapid progression of severe illness may be overwhelmed with the

next steps of deterioration, and may not be able to adapt their expectations quickly. Using quality of life measures as a primary outcome parameter for palliative care may be difficult, as there are so many things that affect it that have nothing to do with the provision of palliative care.

A large number of assessment instruments have been published for quality of life. The Short Form Survey of the Medical Outcome Study (SF-36) and its even shorter forms SF-12 and SF-8 are most prominent for health-related quality of life. The Functional Assessment of Chronic Illness Therapy (FACIT) and the European Organization for Research and Treatment of Cancer (EORTC) family of tools are used extensively for disease-related quality of life. The Schedule for the Evaluation of the Individual Quality of Life (SEIQoL) is a prominent example for the assessment of the individual quality of life.

However, many palliative care patients can only complete short and simple assessment instruments. The EQ-5D uses only six items, but also single-items have been tested.

A number of concepts overlap to some degree with quality of life, such as overall happiness, meaning in life, sense of coherence, or quality of dying and death. However, with all these concepts, some components of the quality of end-of-life care and the quality of dying may be difficult or even impossible to measure.

1 Quality of Life: A Central Goal of Palliative Care

Following the definition of palliative care of the World Health Organization from 2002, quality of life is central to the concept of palliative care: *palliative care is an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual* (Sepulveda et al. 2002).

This has been confirmed in a discourse analysis of a broad range of English and German definitions of palliative care (Pastrana et al. 2008), which found a striking agreement that prevention and relief of suffering and improvement of quality of life are considered as central goals of palliative care.

As improvement or at least maintaining the best possible quality of life for patients and families is per definition the main goal of palliative care, this merits a close look at the concept, and more specifically, how to define quality of life and how to operationalize and assess it.

However, this may not be easy, as the lack of a satisfactory definition of quality of life has been highlighted by Randall and Downie in their critical review of the philosophy of palliative care, though they note that *judging by volume of literature on the topic, the search for one has not been abandoned* (Randell and Downie 2006).

The strong focus on quality of life is not unique for palliative care, as other areas of medicine, especially those that deal with chronic (incurable) disease such as Endocrinology, Genetics, or Neurology – share this goal (Strawson 2014).

Palliative care is not restricted to the terminal phase, and indeed early integration of palliative care in the disease trajectory of severely ill patients is an emerging focus. However, many patients are facing death, or at least the sudden impact of a short prognosis, and are grappling with a drastic reduction of the remaining lifespan. For these patients, the question arises whether they can experience any quality of life at all, or how there can be any improvement of quality of life when facing death.

However, clinical experience shows that palliative care patients are able to experience good quality of life. In some patients, quality of life is astonishingly high. Relief of suffering with adequate symptom control can increase quality of life, but also other factors may be essential to maintain or even increase quality of life in spite of the prognosis, e.g., a feeling of connectedness.

Even though patients would not often use the term quality of life, they have a clear understanding how to fill the concept for themselves.

2 Quality of Life Concepts

There is considerable agreement that quality of life is a multidimensional construct integrating a broad spectrum of indicators of personal well-being (Felce and Perry 1995). In general, quality of life will be influenced by the degree that the needs of the individual are met. These needs will vary widely depending on the setting.

In the resource pool setting, quality of life will depend largely on regular, if possible daily, access to clean water, food, shelter and heating, and if possible money. In richer settings, coverage of these basic needs is taken for granted, and quality of life will depend more on the pursuit of professional and personal ambitions.

Maslow has described this in the hierarchy of needs (Maslow 1943, 1954), which starts from the basic needs of living and ends with the need for personnel growth (Fig. 1). The first four levels are deficiency needs, which motivate people when they are unmet. These needs will become stronger when they are not met: the longer you lack access to water, the more thirsty will you become. When a needs deficit on one level has been satisfied, motivation will be directed toward the next level of needs.

In contrast to the first four levels of deficiency needs, the top level represents a growth or being need. Self-actualization includes realizing personal potential, self-fulfillment, seeking personal growth, and peak experiences. This is not a deficiency that can be fulfilled, and most often growth needs will even become stronger when they are being tackled by the individual, with higher goals for self-fulfillment and peak experiences.

The hierarchy of needs does not mean that higher levels of needs are correlated with higher quality of life. An increase in the standard of living, either by economic progress in general or by climbing up the social ladder for the individual, does not necessarily result in an increase in quality of life.

The General Social Survey (GSS) in the US is performed since 1972 (gss.norc.org). It does not ask about quality of life, but includes some questions about happiness. General happiness is assessed as: "Taken all together, how would you say things are these days, would you say that you are very happy, pretty happy, or not too happy?" Happiness has been promoted as a stand-alone indicator of well-being, as overall happiness was related to longer lives (Lawrence et al. 2015).

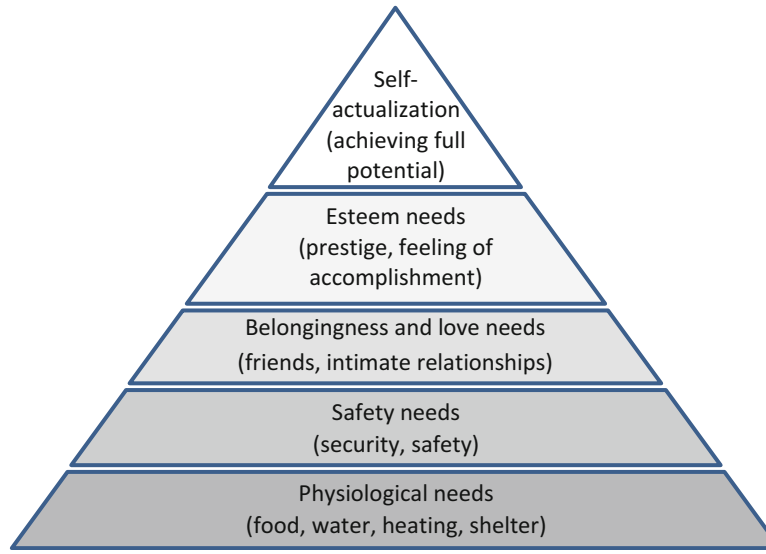

Fig. 1 Hierarchy of needs (Maslow 1943, 1954)

However, in spite of increased standards of living, due to technical advances and economic progress, the percentage of respondents rating themselves as very happy has remained roughly the same since 1972, with the 2014 level near the 1972–2014 average at 33% (Smith et al. 2015). Similar results have been reported for Great Britain (Blanchflower and Oswald 2004).

2.1 Health-Specific Quality of Life

For health care discussion, there is a high desire to assess and measure quality of life. For this purpose, the broad overall concept of quality of life had to be narrowed down to health-related quality of life. The World Health Organization has defined health not merely as the absence of disease, but rather as a state of complete physical, mental, and social well-being (World Health Organization 1948). In consequence, assessment instruments for health-related quality of life try to integrate these dimensions. The 36-item Short Form Health Survey (SF-36) developed in the Medical Outcomes Study is a prominent example of such an instrument (Ware and Sherbourne 1992).

2.2 Disease-Specific Quality of Life

With illnesses with a prolonged disease trajectory such as cancer, quality of life may be influenced by a number of disease- or treatment-related factors. Assessment of disease-specific quality of life, e.g., with the questionnaire of the European Organization for Research and Treatment of Cancer (EORTC) or the Functional Assessment of Chronic Illness Therapy (FACIT). Both instruments have a core questionnaire that assesses the main dimensions of quality of life, and a vast range of add-on modules for assessment of specific symptoms or common problems with specific diagnoses.

2.3 Individual Quality of Life

The standardized items of health- or disease-related quality of life questionnaires allow for the calculation of total and subscale scores. However, with the selection of items, there is also an inherent bias, as the patient's quality of life will only be captured when it is defined by the items in the questionnaire. If the patient finds that activities or experiences outside of these items make up part of his quality of life, this will not be included in the assessment.

This produces a dilemma for assessment: either a validated and highly standardized questionnaire is used, with calculated scores that allow easy comparison, but does assess only that part of quality of life that is represented by the items in the questionnaire, or a broader assessment is used, with a higher chance to capture all factors that contribute to the patient's quality of life, but does not allow for easy calculation of scores. This is Heisenberg's principle of uncertainty as applied to palliative care. This principle has been described in particle physics. Heisenberg stated that it is impossible to measure the position and the velocity of a particle at the same time. Either the position is assessed, but this invariably will cause a change of velocity, or the velocity is determined, but then this would involve a change in position. Similarly, assessment of quality of life will either allow assessment of the nature of well-being or of the extent of quality of life, but not both at the same time.

However, an attempt to capture the individual quality of life has been made with the Schedule for the Evaluation of the Individual Quality of Life (SEIQoL) (O'Boyle et al. 1995). This instrument first asks the patient which are the favorite domains that contribute to his quality of life, then assesses the contribution and the degree of impairment in each of these domains. A sum score can be calculated from this information. As the disease progresses along its trajectory, some of the favorite domains may change, but the scores still can be calculated and compared with previous quality of life scores.

3 Quality of Life Assessment

A large number of assessment instruments have been published for quality of life. A systematic review on outcome assessment instruments in

palliative care identified 80 instruments for assessment of quality of life, the most frequent domain in outcome assessment (Stiel et al. 2012). QOL assessment can be used in a number of ways, e.g., for outcome measurement, for cost effectiveness calculations, and as accountability measurement. However, quality of life assessment as an accountability measure has some disadvantage, as quality of life is influenced by so many factors such as adaptation to illness and functional disability that have nothing to do with the provision of palliative care. Quality of life assessment can also be useful in clinical care and care planning.

3.1 SF-36

The SF-36 is the best-known example for the assessment of health-related quality of life. It includes items assessing health-related limitations in eight dimensions: physical functioning, social functioning, physical role, emotional role, emotional well-being, pain, energy/fatigue, and general health perceptions. Evaluation requires a complex algorithm, as the resulting scores are converted in standardized scores with a range of 0–100, where the general US population would reach mean scores of 50 with a standard deviation of 10. In addition to the subscores on eight dimensions, two main scores can be calculated for the physical and mental well-being. The SF-36 has been extensively investigated in in a broad range of settings and languages (Gandek et al. 1998; Ware et al. 1998).

A shorter version has been developed with 12 items, which covers the same dimensions but results only in summary scores for physical and mental health (Ware et al. 1996). More recently, the SF-8 has been developed with eight single items assessing the same dimensions (Ware et al. 2001). Whereas the SF-12 is an exerpt of the SF-36, the SF-8 has similar, but not identical items compared to SF-36 and SF-12.

The SF-36 questionnaire may be too complicated for many patients with advanced disease requiring palliative care, and some questions may deemed inappropriate by the patients. For example, in our own experience, the question "Compared to one year ago, how would your rate your health in general now?" has been perceived as distressing by patients with advanced cancer and rapid deterioration in the last year.

3.2 FACIT

The Functional Assessment of Cancer Therapy (FACT-G) questionnaire aims at collecting data on the quality of life of cancer patients with 27 items in four domains: physical, social, emotional, and functional well-being. All items are rated on a 5-point Likert scale (0 = not at all, 1 = a little bit, 2 = somewhat, 3 = quite a bit, 4 = very much). All questions refer to the time frame of the last week. A general quality of life score is calculated as well as five subscores on physical, functional, social, sexual, and mental-emotional well-being (Cella et al. 1993). Higher scores represent lower QoL and higher impairment ("0 = best possible" to "108 = worst possible").

The questionnaire has also been useful in other patient groups and has been renamed Functional Assessment of Chronic Illness Treatment (FACIT). The core questionnaire can be augmented with add-on modules for cancer- (or other diseases-) specific, treatment-specific or symptom-specific problems (e.g., for bone pain or fatigue). The FACIT website lists information on modules and language availability (www.facit.org).

An add-on module is available for palliative care (FACIT-PAL), which adds 19 items to the core questionnaire, resulting in a total of 46 items (Lien et al. 2011; Siegert et al. 2014). As this taxes the capacity of patients with advanced disease and cognitive and physical impairments, a shorter version with 14 items in total has been designed, the FACIT-PAL14. This short version provides a sum score, but no subscores (range 0–56, higher scores = better quality of life) (Zeng et al. 2013).

3.3 EORTC

The European Organization for Research and Treatment of Cancer has developed the core questionnaire for quality of life EORTC-QLQ-C30 (Aaronson et al. 1993). The questionnaire includes

30 items on the general condition of the last 7 days, except for the questions about the physical well-being which refers only to the current situation. Five subscales on the physical, role, cognitive, emotional, and social functioning are summarized with 2–5 items each. Nine additional symptom scores on fatigue, nausea and vomiting, pain, dyspnoea, insomnia, loss of appetite, obstipation, diarrhea, and financial problems are calculated from 1–3 items each. All items are rated on a 4-point Likert scale (1 = not at all, 2 = a little, 3 = quite a bit, 4 = very much). Additionally, a global health and QoL index is calculated from two items on a 7-point Likert scale reaching from 1 = very bad until 7 = excellent. For the five functional subscores and for the global health index, higher scores represent higher quality of life, whereas higher scores in the symptom scales indicate higher symptom intensity, resulting in lower quality of life.

An algorithm for the calculation of a summary score has been introduced only recently (Giesinger et al. 2016). The questionnaire has been used and validated in a range of settings and languages.

As with the FACIT, a large number of additional modules are available, mostly on different cancer entities, but also on other topics such as fatigue or information (http://groups.eortc.be/qol/eortc-qlq-c30).

A shorter version with 15 items has been developed as a core questionnaire for palliative care patients, the EORTC-QLQ-C15-PAL (Groenvold et al. 2005). This questionnaire includes the symptom scales for pain, dypsnea, insomnia, appetite loss, and constipation, as well as abbreviated subscales for physical and emotional functioning, nausea, vomiting, and fatigue, and one of the two questions on general health. The EORTC-QLQ-C15-PAL has been promoted as the new standard for quality of life assessment in advanced cancer (Groenvold et al. 2006) and has even been found useful as a prognostic indicator in patients with advanced cancer (Lee et al. 2014).

3.4 SEIQoL DW

SEIQoL: This tool assesses five domains of the patient's individual quality of life with a structured interview (O'Boyle et al. 1992; Waldron et al. 1999). The patient is asked to name five domains of his life that he finds most important right now. He then is asked to rate his level of satisfaction with each of these domains, by drawing bars in a 100-mm box (0 = worst possible satisfaction and 100 = best possible satisfaction). In the original SEIQoL, the weight that each domain has for the patient's quality of life would be elicited in the interview. However, this process takes time, and most patients prefer a shorter assessment. The direct weighting version (SEIQoL-DW) uses a disk with five movable colored segments (O'Boyle et al. 1995; Hickey et al. 1996). The patient adjusts the segments according to the relevance (weight) he attributes to each domain. The cumulative products of level of satisfaction and weight represent the quality of life score, in a range between 0% and 100%, with higher scores representing higher QoL.

The most frequent domains named by patients with advanced cancer in the validation paper were family, health, social life, spiritual life, friendship/relationships, contentment/happiness, work, finances, marriage, mobility, and pain relief (Waldron et al. 1999). Other studies using the SEIQoL have confirmed the predominance of family and social relationships in other patient groups such as elderly patients or patients with amyotrophic lateral sclerosis or with congenital heart disease, with health issues only coming second (Neudert et al. 2004; Moons et al. 2005; Hall et al. 2011; Hamidou et al. 2017).

As the disease progresses, some domains that the patient has used for the SEIQoL rating may not be feasible or important for him anymore, e.g., work and career advancement may drop from the screen disease-related disability, or sport activities may become impossible because of physical impairment. However, other domains will then become more important. Allowing for changing domains in the quality of life assessment corresponds with the real life experience in palliative care, where patients sometimes explain that with progression of the disease lost abilities and chances are balanced by gaining a new focus on what they find really important in life.

However, completing the SEIQoL requires the ability to concentrate and the capacity for abstraction. It seems doubtful whether the majority of palliative patients are able to use this instrument as their physical and cognitive status and general condition often are rapidly declining. Use of the SEIQoL may be too time-intensive and not practicable in clinical palliative care routine.

3.5 Short Assessment Tools

Assessment tools that are well established in other settings often are not practicable in palliative care because of the limited physical, cognitive, or psychological status of patients. Assessment tools have to be short and simple to reduce the burden on the patient. Comprehensive questionnaires are feasible only for a minority of patients in the clinical setting of a palliative care unit (Stiel et al. 2011).

The EuroQoL consortium has produced a concise instrument, the EQ-5D. Five items cover one dimension each: mobility, self-care, usual activities, pain/discomfort, anxiety/depression. Two version are available, one with three response options (no problems/some or moderate problems/extreme problems), the other with five options (no problems/slight problems/moderate problems/severe problems/extreme problems). In addition, a thermometer scale is used for rating overall health (0 = worst health that can be imagined, 100 = best health that can be imagined).

3.6 Specific Palliative Care QOL Instruments

A number of specific tools for quality of life assessment have been developed, including the McGill Quality of Life Index, the Missoula-VITAS Quality of Life Index (MVQOLI), the Needs at the End-of-life Screening Tool (NEST), and the Quality of Life at the End of Life (QUAL-E) (more information at http://www.npcrc.org/content/25/Measurement-and-Evaluation-Tools.aspx). However, these instruments have been used less frequently and are available in fewer languages other than English compared to the more general quality-of-life questionnaires discussed above. The McGill index includes 20 items, the QUAL-E 26 items. The NEST questionnaire uses only 13 items, but with additional items, if the cut-off scores of any items are exceeded, so that the total length of the questionnaire can be extended up to 65 items. The MVQOLI uses three questions on five domains, one each on subjective assessment, function, and importance of the domain.

Patients at the end of life with reduced physical and cognitive function often need help for the completion of these questionnaires. Ideally for the palliative care setting, assessment of quality of life would be done with a single question. This approach has been recommended for specific area in palliative care, e.g., depression (Chochinov et al. 1997) or fatigue (Radbruch et al. 2008). However, using the single item "How do you feel today?" we found only moderate correlations with the global scores of EORTC-QLQ-C30 and FACIT-G (Stiel et al. 2011). Highest correlations were found with physical and functional subscales of the comprehensive instruments. Most patients seem to understand the single item as a medical question addressing these physical-functional aspects in the clinical routine.

Ongoing research in our department has investigated two alternative single items. The single item "How would you rate your overall quality of life during the past few weeks?" was taken from the EORTC QLQ-C30 quality of life questionnaire, but correlations of other instruments with this single item were inadequate as well. However, the second single item "How satisfied are you currently with your physical and emotional well-being?" correlated well with the total score and with the physical, emotional and functional subscales and moderately with the social well-being subscale of the FACIT. This single item seems suitable as a short screening instrument for quality of life in palliative care.

4 Quality of Life as a Static or Dynamic Concept

Measuring health-related or disease-related quality of life with standardized instruments fosters the attitude that quality of life is a static construct,

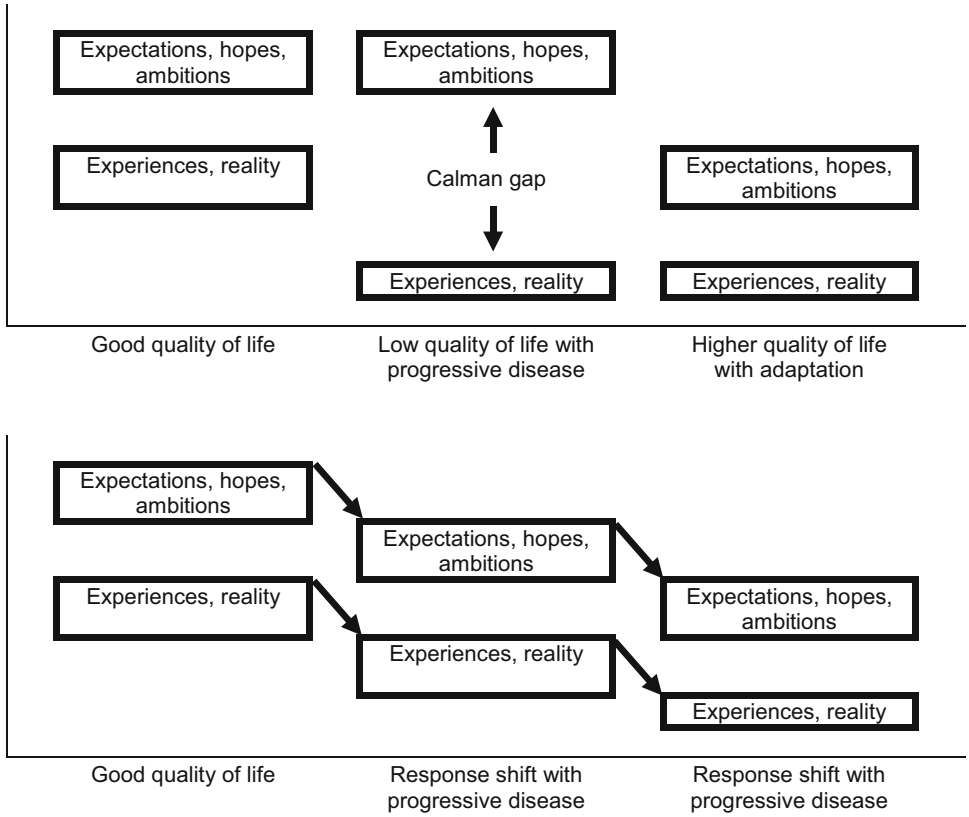

Fig. 2 Calman Gap and response shift

influenced predominantly by factors such as physical or cognitive performance status, physical symptoms, or social relationships. These contributing factors are to a large degree outside the influence of the patient. The patient's quality of life remains unchanged, if there are no aggravating factors (e.g., disease progression) or alleviating factors (e.g., effective symptom control).

However, this is contrary to the experience in clinical practice that quality of life depends to a major degree on the patient's needs, preferences, and expectations. In an influential approach, Calman proposed quality of life as the difference between the hopes and expectations of an individual and the individual's present experiences (Calman 1984). This difference has also been described as the Calman gap, and support a dynamic construct of quality of life.

In consequence, patients with severe cognitive or physical impairments may report high quality of life, if they have had time to adapt their hopes and expectations to the present situation (Fig. 2). This is similar to patients with chronic disabilities, who also quite often report normal or even high quality of life.

With progressive disease, patients often will reduce their hopes and expectations as they feel the deterioration. As the gap between experiences and expectations does not widen with the lower levels of expectations, patients will report no change in overall quality of life, even though their present experiences have become much worse. This is known as the response shift (Fig. 2).

However, adaptation takes time, and even experienced palliative care staff often underestimates the amount of time patients and caregivers need to adapt to a new situation. Patients experiencing rapid progression of severe illness may be overwhelmed with the next steps of deterioration, and may not be able to adapt their expectations quickly.

Defining quality of life as the difference between patient's expectations and present experience also means that quality of life can be improved in two ways, either by improving the experiences (e.g., with effective symptom control) or by lowering the expectations. This poses an inherent danger in palliative care, as lowering the expectations may be easier. Facilitating adequate adaptation of expectations to the deterioration with progressive disease may be perceived as very helpful by patients, but this should not be carried too far, as the patient and his caregivers also have a right to keep up their hopes and ambitions, even if they are clearly unrealistic in the face of the progressive disease.

Several studies have demonstrated the effect of response shift in patients with advanced cancer over time (Hagedoorn et al. 2002; Ahmed et al. 2004; Echteld et al. 2005) or compared to healthy controls (Stiefel et al. 2008; Fegg et al. 2010b). Response shift has also been discussed as a major confounder for the outcome evaluation in clinical trials (Ring et al. 2005; Verdam et al. 2015), and an expert panel recently recommended more research on response shift (Preston et al. 2013).

5 Concepts Related to Quality of Life

As there is no broad consensus on the definition of quality of life, it is not surprising that a number of concepts overlap to some degree with quality of life. Overall happiness (included in the General Social Survey) has already been discussed above.

Quality of life seems closely related to the search for meaning, as expressed in Viktor Frankl's famous quote "Those who have a 'why' to live, can bear with almost any 'how'" (Frankl 1962). A German workgroup has developed a Schedule for Meaning in Life Evaluation (SMiLE) that has been used in different palliative care settings (Fegg et al. 2008, 2010a). The evaluation uses a similar method as the SEIQoL, but patients are asked to name the major domains that contribute to the meaning they find in life. However, the domains that are selected by the patients closely overlap with those selected in the SEIQoL, with a predominance of family and social relationships. This raises the question whether there is a meaningful separation between quality of life and meaning in life, or whether the two concepts are correlated so closely that only quality of life needs to be assessed.

Making meaning is also an integral part of the sense of coherence concept, together with understanding and being able to influence the environments or events happening. The Sense of Coherence Scale (SOC) includes 29 items or 13 items in a short version (Antonovsky 1993), but a number of other versions has been used as well (Eriksson and Lindstrom 2005). Subscales for the three dimensions manageability, comprehensibility, and meaningfulness have been calculated, though Antonovky suggested to use only the total score of the instrument. A systematic review found a strong relationship between sense of coherence and quality of life: the stronger the sense of coherence, the better the quality of life (Eriksson and Lindstrom 2007). In addition, sense of coherence seemed to be a good predictor for good quality of life in longitudinal studies.

A quality of death index has been developed to describe the quality of life until the very end (Economist Intelligence Unit 2015). However, this is a macroeconomic indicator, compiling information on palliative care and healthcare environment, human resources, affordability of care, quality of care, and community engagement to compare the quality of palliative care available to adults in 80 countries. This does not provide information on individual patients.

On an individual level, the Quality of Dying and Death (QODD) questionnaire is used to interview family members after the death of the patient to evaluate the quality of care in the final stage of life (Curtis et al. 2002). The QODD includes 31 items assessing symptoms, patient preferences, and satisfaction with care. The total score ranges from 0 to 100 with higher scores indicating better quality of dying and death.

Other instruments have been developed for evaluation of the quality of dying, but a systematic review found only the QODD has been well validated and widely used (Hales et al. 2010). Shortcomings of the instrument have been critically

discussed, challenging that some components of the quality of end-of-life care and the quality of dying may be difficult or even impossible to measure (Curtis et al. 2013).

6 Conclusions and Summary

Quality of life assessment can be used in a number of ways, e.g., for outcome measurement, for cost effectiveness calculations, and as accountability measurement. Improving the quality of life is considered a central goal of palliative care, together with the prevention and relief of suffering. However, there is some variety in the definition and indeed the understanding of the concept of quality of life, and in consequence a range of assessment instruments have been developed.

The Short Form Survey of the Medical Outcome Study (SF-36) and its even shorter forms SF-12 and SF-8 are most prominent for health-related quality of life. The Functional Assessment of Chronic Illness Therapy (FACIT) and the European Organization for Research and Treatment of Cancer (EORTC) family of tools are used extensively for disease-related quality of life. The Schedule for the Evaluation of the Individual Quality of Life (SEIQoL) is a prominent example for the assessment of the individual quality of life.

However, many palliative care patients can only complete short and simple assessment instruments. With the limitations on assessment, the number of other factors influencing quality of life such as adaptation to illness and functional disability and the overlap of quality of life with other concepts such as meaning in life or sense of coherence some components of the quality of end-of-life care and the quality of dying may be elusive or even impossible to measure.

Global Aspects of Palliative Care

3

Stephen R. Connor

Contents

Abstract

In this chapter we will look at the growth of modern palliative care globally from its humble beginnings to finally becoming part of mainstream health care; major developments and milestones in global development, including involvement of the World Health Organization (WHO), the HIV/AIDS Pandemic, the rise of non-communicable diseases, the millennium goals, and now the sustainable development goals; and the World Health Assembly resolution on palliative care. We will explore the current status of palliative care globally and look at future directions and challenges for palliative care to reach its goal of full access to those in need.

1 Introduction

What was once a small movement confined to high-income countries is slowly becoming an essential part of any modern health-care system. Hospice palliative care is part of the solution to what ails the current health-care system. Consistently, palliative care leads to effective symptom control (Shu-Yu et al. 2016), improved quality of life (Temel et al. 2010), less unnecessary hospitalization (Morrison et al. 2008), realization of dignity (Chochinov et al. 2011), and reduced cost both for patients and families as well as providers (Smith et al. 2014).

Yet palliative care still remains on the fringes of mainstream health care and many myths persist resulting in too few patients able to access any care or are referred on the brink of death. Eighty percent of the need for palliative care is in low- and middle-income countries, while 80% of the current palliative care that is available is confined to only 20 high-income countries that have managed to achieve advanced levels of integration into mainstream health care.

Persisting myths include that hospice or palliative care is a building where you are sent to die, that patients are given morphine and no longer communicate or become addicts, that having hospice and palliative care will cause you to give up and die sooner, that palliative care is just for people with cancer, and that palliative care is just for old people. In the United States, the median length of service is less than 3 weeks. There are still many people that fear the idea of hospice or palliative care simply because of an association with dying.

2 History of Modern Palliative Care Development Globally

Modern hospice care began in 1967 with the opening of St. Christopher's Hospice outside London. Dame Cicely Saunders, founder of St. Christopher's, had a vision for a place where those facing the end of life could be cared for with the principles of pain and symptom control and whole-person compassionate care, using an interdisciplinary team approach for both the ill person and their family. She pioneered the field of hospice care and became a beacon for all countries worldwide to learn this new approach to care. An education and training center was established at St. Christopher's where people from dozens of countries came to learn hospice care and then return to their home country to transplant this new approach to caring for the dying in their own setting and culture.

The term palliative care was introduced by Dr. Balfour Mount at the Royal Victoria Hospital in Montreal, Quebec, in 1974. The word *hospice* in French is understood to mean "home for the destitute" and was seen as an unacceptable term in Francophone Quebec. The word *palliate* originates from the Greek and translates as "to cloak," meaning that when we care for the dying, our interventions are meant to cloak or to prevent from seeing or experiencing pain or other suffering. Palliative care is the term generally used to refer to the practice of hospice and palliative care globally and encompasses hospice care. It also signifies the transfer of hospice principles into the wider health-care system including hospitals, long-term care facilities, clinics, primary care settings, and personal residences.

The hospice movement has grown slowly in the past 50 years but has mainly been confined to high-income countries.

3 Major Developments Globally

3.1 World Health Organization

Several significant developments have occurred in recent decades that have spurred the development of global palliative care. The World Health Organization (WHO) published the first monograph *Cancer Pain Relief* guidance on the assessment and treatment of cancer pain in 1986 that included a new WHO pain relief ladder. The ladder identified three simple steps for treating mild, moderate, and severe pain. This monograph was revised in 1996 with a guide to opioid availability. Also in 1990 WHO published the first definition of palliative care emphasizing symptom

management and pain control in a wider approach. This was followed in 2000 with the publication of an expanded definition of palliative care emphasizing treatment for all life-threatening illnesses from the time of diagnosis.

WHO's support for palliative care was crucial in its early development but was centered in the cancer department, giving the impression that palliative care was only for cancer though the WHO definition was much broader and referenced any life-threatening illness. There was also considerable attention to the palliative care needs of those with HIV/AIDS, especially before the advent of highly active anti-retroviral treatments. WHO has shifted its emphasis from communicable disease to the major cause of death being from noncommunicable diseases.

3.2 Noncommunicable Diseases (NCDs)

WHO's realignment around noncommunicable diseases is an opportunity for palliative care to be vocal about the necessity of its inclusion in all aspects of policy, program development, and service delivery. Following criticism that WHO was too focused on HIV and TB treatment while 66% of all deaths from all causes were due to NCDs, WHO has shifted its focus to put a major emphasis on NCDs.

A global UN dialogue on NCDs has continued since 2012, informed by the Global Action Plan for the Prevention and Control of NCDs 2013–2020. A Global Coordination Mechanism on NCDs continues this dialogue, and a Global Monitoring Framework for NCDs has been developed. Palliative care advocates were successful in getting an indicator for palliative care at the country level that measures opioid consumption against total cancer deaths. This is one of 25 WHO-approved indicators that countries can use to measure progress.

NCDs kill 38 million people each year, almost three quarters in low- and middle-income countries. Sixteen million of these deaths are considered premature in those before the age of 70. There were 17.5 million cardiovascular deaths, 8.2 million cancer deaths, 4 million deaths from respiratory diseases, and 1.5 million from diabetes, these four accounting for 82% of all NCD deaths. All of these conditions are appropriate for palliative care.

3.3 Sustainable Development Goals and Universal Health Coverage (SDG/UHC)

The SDGs are a UN initiative officially known as "Transforming our world: the 2030 Agenda for Sustainable Development." There are 17 aspirational goals with 169 targets. One of the goals (#3) is to "Ensure healthy lives and promote well-being for all at all ages." One of the targets under SDG3 is to "Achieve universal health coverage, including financial risk protection, access to quality essential health care services and access to safe, effective, quality and affordable essential medicines and vaccines for all."

Palliative care advocates were able to include palliative care in the description of the continuum of services under UHC. The continuum is Promotion – Prevention – Treatment – Rehabilitation – Palliation. This was a major achievement and allows palliative care to claim its place in the SDGs. Without palliation, UHC cannot be achieved. Unfortunately, despite several attempts, palliative care advocates have not yet been able to get WHO approval for a palliative care indicator to hold countries to account for palliative care development.

3.4 World Health Assembly (WHA) Resolution on Palliative Care

Perhaps the greatest achievement for global palliative care to date is the unanimous passage of WHA resolution 69.17 (World Health Assembly 2014) "Strengthening of palliative care as a component of comprehensive care throughout the life course." The WHA is the governing body of the WHO and is made up of all UN countries. It took 3 years of sustained advocacy to get this resolution on the WHA agenda. The WHO staff

then prepared a report to inform the resolution that used data from the WHPCA/WHO Global Atlas of Palliative Care at the End of Life (Connor and Sepulveda 2014). The Atlas describes the need for palliative care, the current status of palliative care delivery, the barriers to access, the limited resources devoted to palliative care, and recommendations for improving access to care.

The resolution calls for a series of actions by all countries and by the WHO itself to ensure that palliative care is part of every country's healthcare system with an emphasis on community-based primary health care. Specifically, countries are called upon to:

- Develop and strengthen policies to integrate palliative care into health systems
- Ensure adequate domestic funding and human resources
- Support families, volunteers, and caregivers
- Integrate palliative care in health professional curricula at all levels
- Assess domestic palliative care needs including for essential medicines
- Review and revise drug control legislation and regulation and add palliative care medicines to national essential medicine lists
- Support partnerships between governments and civil society
- Integrate palliative care into plans for management and control of noncommunicable diseases

The resolution further calls on WHO to:

- Ensure palliative care is integrated into all heath system plans
- Update or develop guidelines and tools on palliation in health system and across disease groups and levels of care, addressing ethical issues
- Support countries in reviewing and improving drug legislation and policy to ensure balance
- Explore ways to increase availability and accessibility of essential palliative care medicines
- Work with the International Narcotics Control Board and the UN Office on Drugs and Crime to promote availability of controlled substances for pain and symptom management and support accurate estimates for opioids
- Collaborate with UNICEF to promote pediatric palliative care
- Monitor global situation of palliative care to evaluate progress
- Encourage countries to adequately fund PC programs and research on palliative care models in low- and middle-income countries
- Report back on implementation of resolution

4 Current Status of Global Palliative Care

To date progress on meeting all these recommendations from the WHA resolution is occurring slowly. Some technical assistance documents have been published, six countries have been identified to host official WHO demonstration projects, and work has begun on revision of the original WHO cancer pain guidelines. However, access to opioids is still overly restricted in 75% of the world; there is no measure of how many professional schools have added palliative care curricula or audit of policies that have been changed to include palliative care. Funding for palliative care implementation has if anything decreased. A new audit of levels of development in palliative care is planned for completion in 2018, and it is hoped that the 42% of countries lacking any palliative care last measured in 2011 will be decreased.

Findings from the most recent assessment of the state of palliative care globally can be found in the *Global Atlas of Palliative Care at the End of Life (Connor & Sepulveda, 2014)*. The purpose of the Atlas was to paint a picture of palliative care globally by answering the following questions:

- What is palliative care?
- Why is palliative care a human rights issue?
- What are the main diseases requiring palliative care?
- What is the need for palliative care?
- What are the barriers to palliative care?
- Where is palliative care currently available?

- What are the models of palliative care worldwide?
- What resources are devoted to palliative care?
- What is the way forward?

The WHO's **2002 definition of palliative care** both for adults and children (World Health Organization 2017a) was used along with a definition of hospice. Some limitations in the definition are noted including lack of clarity on four points: first that palliative care is needed in chronic as well as life-threatening/limiting conditions, second that there should be no time or prognostic limit on the delivery of palliative care, third that palliative care is needed at all levels of care including primary and secondary as well as tertiary care, and fourth that palliative care is needed in all settings of care.

Palliative care has begun to be accepted as a **human right** in health care. There are a number of precedents for this belief including reference to the 1966 International Human Right to Health from the UN International Covenant of Economic, Social and Cultural Rights (Committee on Economic, Social and Cultural Rights (CESCR) General Comment 14 para.12), which calls for the right of everyone to the enjoyment of the highest attainable standard of physical and mental health. Further the UN Special Rapporteur on torture has said that denying access to pain relief can amount to inhumane and degrading treatment. It is governments that do not allow access to essential medicines such as opioids that are responsible, rather than clinicians. There are many other statements in support of this right.

In order to identify the main **diseases that require palliative care** and the number of these patients, the *Atlas* used WHO's most recent mortality data (2011). There were over 54.5 million deaths worldwide that year, most (66%) due to noncommunicable diseases. At minimum over 20 million of these were identified as needing palliative care. The primary diseases for adults included cardiovascular, cancer, pulmonary, HIV/AIDS, kidney, liver, dementias, multi-drug resistant TB, Parkinson's, rheumatoid arthritis, and multiple sclerosis. For children the major diseases included congenital anomalies, neonatal conditions, protein energy malnutrition, meningitis, HIV/AIDS, cardiovascular, endocrine-blood-immune disorders, cancer, neurological conditions, and kidney and liver diseases.

This was the first time that WHO acknowledged that all these conditions required palliative care. Prior to this publication, WHO only provided guidance on palliative care for cancer and HIV. Further the *Atlas* looked at the distribution of need for palliative care and found that almost 80% of the need is in low- and middle-income countries. The majority of those needing palliative care are adults 60 years or older (69%) with 25% aged 15–59 and 6% being children from birth to 14 years. While the number of over 20 million refers to those at the end of life needing palliative care, we effectively doubled that number to 40 million to account for all those needing palliative care prior to the end of or last year of life. Add several family members to this need and you have well over 100 million people annually that need palliative care services.

When assessing the **barriers to palliative care development**, we use the WHO public health model. The model has four components: (1) policy, (2) education, (3) medication availability, and (4) implementation of services. For palliative care to develop in an individual country, it is often best to use a simultaneous bottom-up and top-down approach. A country champion is needed to advocate for palliative care within the country and to eventually develop a prototype palliative care delivery program. However, this is difficult to do if there is no recognition of palliative care in government policies and regulations. Therefore, the lack of government policies is often a barrier that must be overcome initially.

Conducting a national needs assessment can be a helpful starting point to educate officials as to the scope of the need for palliative care and to demonstrate the gap in lack of services. Examples of comprehensive national needs assessments and other key policy documents can be found at http://www.thewhpca.org/resources/category/country-reports-and-needs-assessments. Other key policy documents that should be developed include:

- National standards for program operation
- Clinical guidelines for palliative care provision

- Inclusion of palliative care in national policies on NCDs, HIV, TB, cancer, and health-care priority setting documents
- Legal recognition of palliative care in health-care law and regulation including licensing
- Recognition of palliative care as an area of health-care specialization
- Regulation of access to controlled substances
- National strategy for implementation of services

Controlled substances, especially opioids, are either unavailable or so tightly controlled in 75% of the world that they are not available for palliative care (International Narcotics Control Board 2015). It is essential that unnecessary and overly burdensome regulations are removed or modified so that they can be used for palliative care. The WHO has a model list of essential palliative care medicines (World Health Organization 2017b) that should be available in all countries. This is often a long and difficult process that involves multiple ministries to approve including ministry of health, drug control authorities, police and internal affairs, and ultimately the legislative and executive bodies in the country.

Gaining access to medicines, especially oral morphine, is critical to successful palliative care development and has to go hand in hand with provision of **education** for health professionals. The World Health Assembly resolution on palliative care (2017) calls on all governments to ensure that palliative care education is provided at all levels of health professional training including undergraduate, graduate, postgraduate, and specialization training. Practically this means that basic palliative care curricula should be included in medical and nursing schools, additional courses and practicums should be provided during residency and internships, continuing education should include palliative care, and a pathway for specialty or sub-specialty qualification should exist. Further, palliative care content should be included in social work, psychology, and chaplaincy education.

In addition to health professional education, it is equally important for the public to be informed and sensitized to the need and availability of palliative care. Most people, particularly in limited resource settings, may assume that advance illnesses such as cancer inevitably result in unrelieved pain and suffering when we know that symptom relief and quality of life are possible and should be available to all citizens. Families faced with the need to care for seriously ill relatives also need practical hands-on training in caregiving to make it possible for loved ones to remain in the place they call home.

All of this should lead to the formation and growth of palliative care services **implemented** throughout a health-care system. While many initial hospice or palliative care programs begin as standalone programs effectively outside the mainstream health delivery system, the challenge to reach the majority of persons needing palliative care is to effectively integrate palliative care into all levels of health care including primary, intermediate, and tertiary levels in both the public and private health-care systems (Gomez-Batiste and Connor 2017).

5 Future Directions for Global Palliative Care

5.1 Low- and Middle-Income Countries (LMIC)

The future of palliative care depends on how successful we are in developing palliative care in limited resource settings. Since almost 80% of the need for palliative care is in LMICs, it is imperative that palliative care is successfully implemented there. There are a number of good models that have been described (Connor and Sepulveda 2014) that may be replicated, and there is a lot of work being done to develop, test, and implement models that are viable and sustainable in LMIC settings. Notably, WHO plans demonstration projects in six countries (Belarus, Jamaica, Oman, Malaysia, Thailand, and Zimbabwe) and the Worldwide Hospice Palliative Care Alliance another six (Bangladesh, Ethiopia, Jordan, Panama, Philippines, and Ukraine) that will hopefully develop and disseminate new models. The challenges are great, but it is critical that progress be made since less than 20% of current palliative care delivery is available in LMICs.

5.2 Community-Based Palliative Care

One of the critical factors in developing palliative care in limited resource settings is the degree to which palliative care is owned by the community. This is also critical in high-income settings but more so in LMICs. When resources are limited, there is a general tendency for people to take care of each other more readily and family connections are often closer. This is a strength, but so often without the support and training that palliative care provides, caregivers are left to helplessly witness unrelieved suffering. With modest investments in palliative care that support community care giving, community based palliative care can become mainly self-sufficient.

5.3 Medication and Education

In 75% of the current world, access to effective pain medication is so severely restricted (International Narcotics Control Board 2015) that it is essentially impossible to achieve pain relief and comfort for dying patients. This is the world's biggest drug problem. Notable efforts are beginning to change this severe imbalance, but a lot more work is needed to correct this situation. Fear of misuse of opioids has resulted in major interference in the practice of medicine throughout the world. Effective safeguards against misuse need to be in place, but the situation is so out of balance in most of the world that palliative care cannot be practiced effectively.

On top of this, education in palliative care and pain relief is still in its infancy worldwide. It is useless to train physicians and nurses in palliative care if essential palliative care medicines are unavailable. This includes not only opioids and other analgesics but other psychotropic medication including anti-anxiety and anti-depressant medication, anti-seizure, anti-emetic, and anti-psychotic medication. What is taught is forgotten in situations where relief of suffering is not possible. Most importantly bedside teaching, where real learning occurs, is not realistic if these medications are unavailable.

5.4 Funding

The ultimate test of whether palliative care is effectively implemented in a country is the willingness of governments to reallocate funding to palliative care, especially in non-hospital settings. In all countries most health-related funding flows to hospital care. What has been seen over and over is that hospice and palliative care reduce the need for unnecessary hospital care in favor of care in the community. The net result is usually a reduction in expense to the health-care system. The difficult part practically and politically is to shift funds now going to inpatient care to home care services. This requires evidence and political will. Corruption and self-interest often stand in the way, but this can and has been done in many countries.

6 Integration

Ultimately the future of palliative care is in its integration into the mainstream health-care system in every country. Palliative care will not succeed as a specialized form of care outside the mainstream of existing health-care delivery. Forty years ago many of us thought the need for hospice and palliative care would disappear in 20 years as we improved the care of dying patients. That has not occurred and the need for specialist palliative care is now well established worldwide. However, the majority of patients needing palliative care should be able to be effectively cared for by their primary health caregivers. This is where new development is occurring globally. Organizations like the International Primary Palliative Care Network and the European Association for Palliative Care's primary care task force have made great strides in promotion of palliative care as a core competency in family medicine, and oncology associations have called for early integration of palliative care in oncology practice. Still there are literally millions of health-care professionals that have never received training in palliative care and will need to do so.

7 Conclusion and Summary

The international hospice palliative care movement, now 50 years old, remains underdeveloped. Less than 10% of the global need for palliative care throughout the course of life-limiting illness is being met. The greatest need is in low- and middle-income countries where palliative care is available the least. Great strides have been made in identifying this need and getting the United Nations and international bodies to call for integration of palliative care throughout the life course. However, translating this progress to the ground is a long way off. It will require major improvements at the individual country level in setting policies that promote palliative care, education in palliative care for literally millions of health-care workers, removal of excessive restrictions on essential palliative care medicines, and resources and political will to implement both primary and specialized services. Further it will require major changes in the attitudes and beliefs of both the public and the health professions. Acceptance of palliative care at some level requires an acknowledgment that death and dying are essential parts of life and that care of those with life-limiting conditions and illnesses is an essential part of every health-care system. As the global population ages and confronts these realities, there is every hope that palliative care will grow and thrive in the future.

Abstract

Palliative care has developed rapidly and heterogeneously in the past decade around the globe. In this chapter, we present an overview of palliative care development in different regions of the world with a pair of case studies of models of palliative care delivery within each region. The textbook is divided into subsections based on the following regions: Europe, North America, Latin America, Africa, Asia-Pacific, and Middle East. Regions were decided based on existing palliative care networks, where available. Information regarding palliative care development in each region is organized based on the World Health Organization's Public Health Strategy for Palliative Care: (1) policies, (2) medicine availability, (3) education, and (4) implementation of services plus (5) vitality (professional activity). This chapter is intended for the reader to gain a high-level view of the state of palliative care development in regions of the world and the challenges and successes within each region. Two case models per region give the reader a quick view into the diversity of palliative care services offered in different regions of the world and give the reader insight into regional-specific delivery models.

1 Introduction

The aim of this chapter is to provide an overview of palliative care development globally with supplementary case studies to describe an array of existing models of palliative care delivery.

Outside of Europe, North America, and Australia, generally, access to quality palliative care services is rare (WHPCA and WHO 2014). However, palliative care has seen a remarkable growth in the past few years. In 2011, 58% of the world's countries had at least one palliative care service, a 9% increase since 2006, with the greatest gains in Africa (Lynch et al. 2013). Still, only 8.5% of countries have achieved advanced integration of palliative care into service provision (Lynch et al. 2013).

This chapter outlines the development of palliative care in different regions of the world, organized by the facets of the World Health Organization's Public Health Strategy for Palliative Care, which include (1) policies, (2) medicine availability, (3) education, and (4) implementation of services (Stjernsward et al. 2007). In addition, due to the fact that the growth in palliative care has often been due to advocates in various countries, we include information on a fifth category: vitality (Centeno et al. 2007, 2016; Woitha et al. 2016b). Each subsection is divided into different geographical regions: Europe,

North America, Latin America, Africa, Asia-Pacific, and Middle East. The regions were mostly based on existence of regional palliative care networks, which often provide much needed information on palliative care development in their respective regions. Each region also contains two case studies of two models of hospice and palliative care service delivery, recommended by experts, for the reader to gain a deeper insight into the different types of models available in palliative care delivery globally. The case studies, therefore, do not necessarily represent the most developed palliative care service in the region, but are available to show the richness in different types of palliative care service delivery throughout the world.

In this chapter, palliative care is defined as "care given to improve the quality of life of patients who have a serious or life-threatening disease, such as cancer" (National Cancer Institute 2010). With its goal to "prevent or treat, as early as possible, the symptoms and side effects of the disease and its treatment, in addition to the related psychological, social, and spiritual problems" (National Cancer Institute 2010). Hospice care has the same principles but palliative care is offered earlier in the disease process, and hospice care is a form of palliative care and is usually limited to a terminal diagnosis (usually defined as having a life expectancy of 6 months or less) (National Cancer Institute 2010).

It is important to note that, in different regions of the world, the concept of palliative care versus hospice care may manifest itself in different ways. In the United States, patients are enrolled in a hospice when a physician estimates a life expectancy of 6 months or less, whereas a hospice in Uganda may, in practice, be providing palliative care, not limiting its patient population to a particular life expectancy.

2 Europe

A total of 32 countries which are part of the European Association for Palliative Care were included in this section (Fig. 1). We thank Mr. Eduardo Garralda (University of Navarra) for reviewing and providing guidance on this section.

2.1 Implementation of Services

According to the European Atlas of Palliative Care, in 2013, the UK had 308 palliative care hospital support teams, 189 inpatient hospices, and 272 day hospice/day care centers (Centeno et al. 2013b). In addition, it leads pediatric palliative care services with 46 pediatric home palliative care support teams, 241 pediatric palliative care units in tertiary hospitals, 42 pediatric inpatient hospices, and 31 pediatric day care services (Centeno et al. 2013b). There is much greater variation in Central and Eastern Europe, where certain countries have no known palliative care capacity (such as Uzbekistan), while others have advanced integration of services (Poland) (Lynch et al. 2013).

Specialized palliative care services in Europe have increased greatly from 1,449 to 5,000 over a period from 2005 to 2012 (Centeno et al. 2016). However, most of the service growth has been in Western Europe, with minimal growth in Central and Eastern Europe (Centeno et al. 2016). In 2012, there were 2,063 home-care teams, 1,879 inpatient palliative care services, and 1,088 hospital support teams in Europe (Centeno et al. 2016) (Fig. 2). Generalist palliative care provision remains an issue and there is a lack of valid, feasible, and measurable indicators to compare generalist palliative care services in Europe (Centeno and Garralda 2016).

The UK has consistently been identified as among the highest performing countries in palliative care according to the Quality of Death Index (The Economist Intelligence Unit 2015), and Western European countries generally show a high level of service provision, with most of the countries falling under levels 4a/4b (preliminary/advanced integration of services) according to the world map (Lynch et al. 2013).

2.2 Policies

Since the development of Recommendation (2003) 24, a national palliative care policy framework, by the Council of Europe (2003), many European countries have adopted laws or frameworks on palliative care. A recent study showed

Fig. 1 Member countries of the European Association for Palliative Care

that out of the 46 countries that took part in the survey in 2013, 12 European Union (EU) and 6 non-EU countries had national palliative care plans (Woitha et al. 2016a). Sixty-three percentage of European countries had a national law where PC provisions were identified, and 52% had national documents with standards and/or norms regarding palliative care provision (Woitha et al. 2016a). Sixty-seven percentage of countries had specific responsibilities for palliative care delivery within the Ministries of Health; some countries delegate the responsibility to one person (e.g., Latvia, Bulgaria), while others have a national office supervising palliative care provision (e.g., Italy). Figure 3 outlines a map of national palliative care plans/strategies and laws by country in Europe.

With regard to the financial resources for palliative care provision, 32 countries (out of 45) provide palliative care free of charge, and 19 countries provide free medications (Woitha et al. 2016a). Full payment was only required in Bulgaria, whereas the majority of the countries had some type of subsidized system for consultation costs and medications (Woitha et al. 2016a). However, national palliative care leaders report that major barriers to palliative care development in Europe include lack of a national plan, lack of adequate regulatory frameworks, and insufficient funding. Particularly, lack of funding allocated specifically for palliative care was seen as the greatest issue in 19 countries (Centeno and Garralda 2016).

2.3 Education in Palliative Care

Twenty-eight European countries (65% of responding countries) have palliative medicine in the curriculum of at least one medical

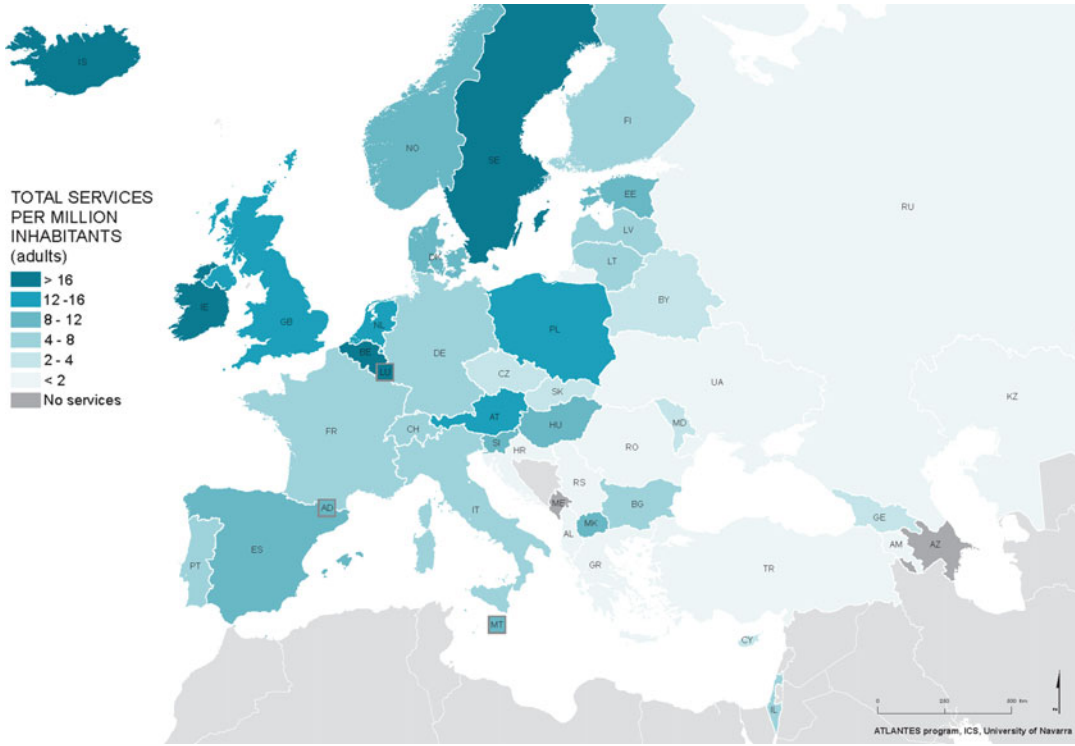

Fig. 2 Density of palliative care services in Europe. (Reproduced with permissions from authors) (Centeno et al. 2013a)

university, and in 13 countries, it is taught in all medical schools (Carrasco et al. 2015). Fourteen countries did not have palliative medicine in their undergraduate medical curriculum (Carrasco et al. 2015). In the United Kingdom (UK), Norway, Belgium, France, and Malta, palliative medicine is a required course in all medical schools. Seventeen countries reported having full professors of palliative medicine on faculty (Carrasco et al. 2015).

According to an expert committee on education convened by the European Association of Palliative Care, Norway, UK, Belgium, and France were rated highest in terms of undergraduate palliative medicine education (Carrasco et al. 2015). Another European study identified that 18 of 53 European countries had accredited specialization in palliative medicine, including Czech Republic, Denmark, Finland, France, Georgia, Germany, Hungary, Ireland, Israel, Italy, Latvia, Malta, Norway, Poland, Portugal, Romania, Slovakia, and the UK (Centeno et al. 2015).

2.4 Medicine Availability

There is a large difference in opioid availability and consumption between Western and Eastern Europe. In most Western European countries, opioids are available to cancer patients for no cost or subsidized >75% (Cherny et al. 2010). Though there are many Eastern European countries that also provide opioids for no cost or subsidized >75% (Czech Republic, Croatia, Latvia, Rumania, the Slovak Republic, Hungary, Estonia, and Serbia), there are also a large number of countries that lack essential medicines (Lithuania, Tajikistan, Belarus, Albania, Georgia, and Ukraine) (Cherny et al. 2010).

However, as availability does not necessarily equate to accessibility, accessibility remains an issue in many countries. Many Eastern European countries and Greece require special permits or physicians from only certain specialties to prescribe opioids (Cherny et al. 2010). In general, countries with the greatest number of regulatory

Fig. 3 National palliative care plans, strategies, and laws across Europe. (Reproduced with permissions from authors) (Centeno et al. 2013a)

barriers to accessibility also tended to have the most limited opioid formularies (Cherny et al. 2010).

2.5 Vitality and Advocacy

The European Association for Palliative Care (EAPC) was founded in 1988 with 42 founding members (EAPC 2016). It has grown significantly since its inception with members from 48 countries around the world and 57 National Associations from 32 European countries (EAPC 2016). Figure 1 shows a map of all the member countries of the EAPC.

The EAPC has been active internationally, partnering with national and international organizations, such as the International Association for Hospice and Palliative Care (IAHPC) and Worldwide Hospice Palliative Care Alliance (WHPCA) in different policy initiatives and petitions, and organizing annual palliative care congresses. In 2007, it led the Budapest Commitments, which aided national palliative care associations in defining clear goals, frameworks, and commitments in developing palliative care in their respective countries (Radbruch et al. 2007). And it partnered with IAHPC, WHPCA, and Human Rights Watch in creating the Prague Charter in 2013, urging governments to ensure the right to palliative care (Cleary et al. 2013d).

The EAPC has two official journals, the European Journal of Palliative Care and Palliative Medicine, and Palliative Medicine currently ranks the highest in terms of impact factor among other palliative care-related journals (EAPC 2016).

Across Europe, 37 countries have at least one National Association for Palliative Care (with some countries having more than one), 21 have published directories of palliative care services, 19 countries hold national palliative care congresses, 15 have a dedicated palliative care journal, and another 15 have palliative care research centers (Centeno et al. 2013b).

Palliative Care Model #1: PAL24, Madrid, Spain (Harding et al. 2013; Merino 2016; Plan Estratégico de Cuidados Paliativos de la Comunidad de Madrid 2010)

Palliative care in Madrid was started in the 1990s due to the tireless work of a few pioneers in palliative care. The first palliative care unit was opened at the Hospital General Universitario Gregorio Marañón and the first home-based service at Hospital Clínico San Carlos. Initially, palliative care was not available in all districts of Madrid, but following the Regional Palliative Care Plan in 2005, it was extended into all. Through the Regional Plan, palliative care and support teams were implemented in many new hospitals, and new beds and units were expanded in hospitals with already existing palliative care services. A pediatric palliative care unit was started in 2008 at the Hospital Infantil Universitario Niño Jesús de Madrid. Of note, the Spanish Healthcare System is publicly financed, and covers palliative care.

PAL24 (Platform Specific Palliative Care 24 Hours), a continuity of care model implemented in Madrid, is an innovative program that centralizes and coordinates palliative care resources in Madrid. The program is operational 24 h a day, 365 days a year, and its goals are to support caregivers at home and avoid unnecessary emergency visits to hospitals, support professionals taking care of patients at any level of care, and manage palliative care resources available throughout Madrid. The program is composed of six palliative care units, each with a doctor and a nurse, and services are provided through telemedicine (phone), advising professionals, and home-visits, when necessary. It uses INFOPAL, a system that allows for tracking of patients across hospitals and hospices, allowing for coordination and continuity of care. More than 500 professionals across

Palliative Care Model #1: PAL24, Madrid, Spain (Harding et al. 2013; Merino 2016; Plan Estratégico de Cuidados Paliativos de la Comunidad de Madrid 2010) (continued)

Madrid, including 11 home-care teams, 12 hospital-based teams, 289 palliative care beds, 6 teams from the Spanish Association Against Cancer, and a pediatric team, are working in coordination with the PAL24 team to deliver and coordinate services.

The service is housed and financed through SUMMA112, which is the Emergency Medical Service of Madrid. In 2015 alone, more than 22,000 contacts were made with PAL24, servicing over 86,000 patients.

Palliative Care Model #2: Hospice Casa Sperantei, Brasov, Romania (Hospice Casa Sperantei 2016)

Hospice Casa Sperantei was started in 1992 in Brasov and was the first charity providing care for end-of-life patients in Romania. Since its start, it has grown to be an important provider of palliative care services for the region, with over 100 staff members. In addition to its home-care program, which includes two rural teams in Fagaras and Zarnesti, the Hospice runs a 20-bed inpatient unit for adults and children.

The Hospice, furthermore, provides education on hospice and palliative care, not only in Romania but also to the Southeastern region of Europe. In 1997, it opened the Princess Diana Education Centre in Brasov, providing resources and training courses for medical and social care professionals, and in 2004, it opened the Nicholas Edeleanu Institute and Teaching Centre in Bucharest, offering resources and training for those interested in hospice and palliative

(*continued*)

Palliative Care Model #2: Hospice Casa Sperantei, Brasov, Romania (Hospice Casa Sperantei 2016) (continued)

care. Through both teaching centers, the Hospice has trained more than 15,000 individuals, and it offers Master's and Certificate-level programs for healthcare providers.

The Hospice provides services free of charge, and most of its operating budget is supported through international and national grants, and also through Local Authorities and taxpayers, who can direct part of their income tax to the Hospice. The Hospice was supported by 400 volunteers in 2015, amounting to 18,000 volunteer hours donated (Image 1).

3 North America

For North America, the focus will be on the United States and Canada, since no information was available for Greenland. Figure 4 shows a map of the countries included in this subsection (three countries). We thank Dr. Diane Meier (Center to Advance Palliative Care, USA) and Dr. Jose Pereira (Pallium Canada, Canada) for reviewing and providing guidance on this section.

3.1 Implementation of Services

In North America, Canada and the United States (US) have advanced integration of palliative care in to the health system, but Greenland had no identifiable palliative care activity (Lynch et al. 2013). The US had a ratio of 1:48,000 of hospice/palliative care services to population and Canada had a ratio of 1:67,000 (Lynch et al. 2013). According to the Economist Intelligence Unit, the US and Canada were ranked 9 and 11, respectively, in the Quality of Death Index overall scores (The Economist Intelligence Unit 2015).

In USA, about 67% of hospitals have palliative care programs, with 90% having palliative care programs if the hospital had 300 beds or more (Dumanovsky et al. 2016). However, there is regional variation with New England having 88% and east south central part of the United States having only 42% of hospitals with palliative care programs (Dumanovsky et al. 2016). Hospitals owned by a for-profit entity, those in the South of the United States, and hospitals with fewer than 50 beds are least likely to report palliative care services (Dumanovsky et al. 2016).

Fig. 4 Countries included in North America

The first hospice opened in the US in 1973, and since then, has grown to 6,100 in 2014, with a majority (59.1%) being free-standing/independent hospices (National Hospice and Palliative Care Organization 2015b). There are about 4,400 board-certified palliative care physicians, but research shows that there is an estimated shortage of at least 6,000–10,000 palliative care physicians based just on current palliative care need in the US (Lupu and American Academy of Hospice and Palliative Medicine Workforce Task Force 2010). Considering the rapid growth in the population over age 65, the workforce needs have been grossly underestimated.

3.2 Policies

In the United States (US), the Medicare Hospice Benefit (passed by Congress in 1982) is the major source of hospice payment and reimbursement in the country, paying for 85.5% of hospice patients in 2014 (National Hospice and Palliative Care Organization 2015b). In 1993, under President Clinton's healthcare reform, hospice was included as a nationally guaranteed benefit (National Hospice and Palliative Care Organization 2015a). The passage of the Patient Protection and Affordable Care Act in the US in 2010 provided many additional opportunities for palliative care growth, by shifting healthcare delivery models from volume to value, which promotes the palliative care model of team-based approaches. However, patients are only eligible for reimbursements for non-hospice forms of home care if they have "skilled needs," i.e., they require a nurse or physical therapist (The Economist Intelligence Unit 2015). The passage of the Act required state Medicaid programs to allow children with life-limiting illnesses to concurrently receive both hospice care and curative treatment (National Hospice and Palliative Care Organization 2015a). Less than a fraction of 1% of the National Institutes of

Health's research budget is dedicated to palliative care, placing significant limits on the adequacy of the evidence base supporting palliative care clinical delivery (Gelfman et al. 2013).

In Canada, the Canadian Health Act (CHA), enacted in 1984, is the most important law that governs the provision of health care in general, though there is no law that specifically governs hospice and palliative care (Williams et al. 2010). Health care service delivery, with a few exceptions, is the responsibility of the Provinces and Territories in this highly-federalized system. Therefore, there has evolved significant variation in how palliative care services are organized and delivered across the country as it is dependent on regional and provincial/territorial policymakers and funders (Williams et al. 2010). A patchwork has evolved in which there are centers and regions of excellence in terms of high levels of access to various hospice and palliative care services in some jurisdictions, and other regions in which some components are either not available or not fully integrated in the regional or provincial jurisdictions (Williams et al. 2010).

There is currently no national policy or strategy related to the provision of hospice palliative care services in Canada. National guidelines have instead been developed by national and provincial palliative care organizations (Williams et al. 2010). However, there is currently a national planning strategy underway in Canada, and in November 2016, a Consensus Statement of the Palliative Care Lay Panel made recommendations that will be vital to the development of policy options and implementation plans for Canada in the spring of 2017 (Covenant Health 2017).

3.3 Education in Palliative Care

The US does not have a mandatory palliative care curriculum for medical schools. In fact, one large review of the literature found that US medical students had little to no mandatory training in palliative care (Aldridge et al. 2016), and in 2015, only 20% of schools had a separate course in palliative care, most of which are elective (Dickinson 2016).

In 2006, the American Board of Medical Specialties approved hospice and palliative care as a medical specialty (National Hospice and Palliative Care Organization 2015a). Currently, palliative care is an accredited postgraduate fellowship program by the Accreditation Council for Graduate Medical Education (Connor 2007). Furthermore, the Hospice and Palliative Care Nurse Association offers certification for advanced practice nurses, registered nurses, and nursing assistants (Connor 2007).

In Canada, there has been significant work done over the last two decades related to integrating palliative care education across the learning continuum, from undergraduate and postgraduate curricula, to continuing professional development (CPD) for health professionals already in practice. Pallium Canada has been the most active national organization with respect to CPD (Pallium Canada 2017). It has been developing and implementing CPD-level education programs across the country since 2001 (Pallium Canada 2017). Their Learning Essentials Approaches to Palliative Care (LEAP) courses are interprofessional and bilingual (English and French) and various versions cover many different healthcare settings (Pallium Canada 2017). The materials are also used in undergraduate and postgraduate curricula (Pallium Canada 2017). More advanced, intermediate courses for professionals wanting to develop more in-depth skills is also offered by Victoria Hospice and McMaster University (Williams et al. 2010). The Educating Future Physicians in Palliative and End-of-Life Care (EFPPEC) project, which ran from 2004 to 2009, implemented a palliative care education team and program in each of Canada's 17 medical schools, though there has been variable update across schools (TAFMC).

For over a decade, there has been a specialized-level palliative care nursing certificate program offered by the Canadian Nursing Association and a 1-year added competency residency program accredited at several medical schools by the College of Family Physicians of Canada (CFPC) and the Royal College of Physicians (RCPSC). In 2015, both the CFPC and the RCPSC granted palliative care formal subspecialty status and will be

accrediting 1- and 2-year palliative care residency programs (CHPCA 2016).

3.4 Medicine Availability

According to data from the International Narcotics Control Board (INCB), which includes both North and South America in their regional reporting of the Americas, from 1980 to 2006, the Americas had a steady increase in total morphine equivalents consumption (Gilson et al. 2013). Canada and the United States drive morphine consumption trends in this region (Gilson et al. 2013). As opposed to Asia or Africa, substance use disorder, in the form of illegal drugs and diversion of prescription drugs, has remained a major problem in Canada and the US (International Narcotics Control Board 2015). It is important to note that in Canada, the majority of opioid prescriptions (about nine out of ten) are related to chronic pain prescriptions for patients who do not have a concurrent serious illness. Total morphine equivalents in Canada in 2014 in mg per person was 967 and 733 without including methadone (Pain and Policy Studies Group 2014a).

In the US, the Centers for Disease Control, in 2016, released guidelines for prescribing opioids for chronic pain (Dowell et al. 2016) to try to address the exponentially increasing sale of prescription opioid and opioid-use related deaths. Opioid overdoses have quadrupled between 1999 and 2015 even though there has not been an overall change in the amount of pain Americans report (Centers for Disease Control and Prevention 2016). In fact, opioids, both prescription and illicit, are the main driver of drug overdose deaths in the US (Centers for Disease Control and Prevention 2016).

3.5 Vitality and Advocacy

The National Hospice Organization was founded in the US as early as 1978 as a professional membership organization, and in 2000, changed its name to the National Hospice and Palliative Care Organization (NHPCO 2015a). The National Coalition for Hospice and Palliative Care was founded in 2001 (NCHPC 2017); it leads advocacy efforts in the US through its member organizations and started the National Consensus Project for Quality Palliative Care in 2002, a task force to "further define and underscore the value of palliative care and to improve upon the delivery of palliative care in the United States" (NCHPC 2017). It has been involved in developing and disseminating versions of the *Clinical Practice Guidelines for Quality Palliative Care* in 2004, 2009, and 2013 (NCHPC 2017). In addition, in 2013, the Patient Quality of Life Coalition was formed, working to improve quality of care for patients and families with serious illnesses by promoting policies to expand access to high-quality palliative care (Patient Quality of Life Coalition 2017).

The National Palliative Care Research Center (NPCRC) coordinates research in palliative care across the US, as most medical schools do not yet have departments or divisions in palliative care (National Palliative Care Research Center 2013). The Center to Advance Palliative Care, which partners closely with the NPCRC, provides tools, training, technical assistance, and metrics to help implement and integrate palliative care into healthcare organizations (CAPC 2017).

In Canada, the Canadian Palliative Care Association, now known as the Canadian Hospice Palliative Care Association (CHPCA), was established in 1991 (CHPCA 2016) and the Canadian Society of Palliative Care Physicians (CSPCP) in 1993 (CSPCP 2014). The CHPCA has been important in acting as a national voice in policy, awareness, and education; it has developed a model to guide to hospice and palliative care in 2002, and it represents more than 500 programs and services and more than 30,000 members (Williams et al. 2010).

Palliative Care Matters has also been important in Canada in bringing together experts and organizations nationally and internationally to help develop a national palliative care strategy and to ensure that palliative care becomes a part of Canada's universal healthcare model (Covenant Health 2017).

Palliative Care Model #1: ProHEALTH Care Support, New York, USA (Lustbader et al. 2016)

ProHEALTH Care is a large multispecialty practice with multiple locations throughout the New York metropolitan area, and employing 900 providers. Within ProHEALTH Care is ProHEALTH Care Support, a home-based palliative care program that provides care in the context of a Medicare Shared Savings Program Accountable Care Organization (ACO).

The palliative care team is comprised of six registered nurses, two social workers, two doctors, one data analyst, and three administrative staff. The team also has 12 volunteers, who visit patients at their homes. Each nurse makes about five home visits and five phone calls per day and is responsible for about 90 patients, working in concert with a social worker and physician. Most patients are seen at their home at least once a month with two telephone calls per month, with additional visits as needed.

One interesting aspect of this model is the importance of telepalliative care, where patients and/or their caregivers may have a virtual visit with any team member through a smart phone or laptop. The nurses also report support from physicians via telemedicine when visiting a patient's home. Patients have 24/7 access by telephone or telemedicine, and about 20% of patients utilize the service. Patients with advanced heart failure, chronic obstructive pulmonary disease on home oxygen, metastatic cancer, or severe dementia qualify for the program, identified through an algorithm developed by the ACO using claims data.

This model is unique in its use of telemedicine with specialty-level palliative care and 24/7 coverage for patients. Comparing patients receiving this home-based care model to those receiving usual care, cost per patient for Medicare parts A, B, and D was $10,435 lower than the cost per patient receiving usual care, and $12,000 lower in the last 3 months of life. Furthermore, hospital admissions were 34% lower in the final months of life than those receiving usual care, and had 35% greater hospice utilization rate as compared to usual care recipients.

This innovative model of palliative care may provide significant savings for healthcare systems while still providing excellent care to patients by providing 24/7 access and meeting patient desires at end of life by with a majority (87%) dying at home rather than in the hospital (Image 2).

Palliative Care Model #2: Edmonton Regional Palliative Care Program, Canada (Canadian Medical Association 2015; Bruera et al. 1999; Fainsinger et al. 2007)

The Edmonton Regional Palliative Care Program was established in 1995 with the goal of increasing access to care for terminal patients with cancer to palliative care services. The Program initially consisted of a tertiary palliative care unit and a weekly multidisciplinary palliative care clinic in the local cancer center and has since expanded to include home care, hospice care, hospital care, and additional outpatient clinics.

The Regional Program's Administrative Office coordinates delivery of care, ensuring standards are met, and coordinating funding, program development, education, and research. The Family Physicians and Home Care are able to offer 24-h care to patients and with the Alberta Health Care Insurance Plan, able to bill for visits with palliative care patients. Hospices provide an important part of the Program, especially

(*continued*)

Image 2 ProHEALTH Care Support Palliative Care Team. (Photo provided by Dana Lustbader)

Palliative Care Model #2: Edmonton Regional Palliative Care Program, Canada (Canadian Medical Association 2015; Bruera et al. 1999; Fainsinger et al. 2007) (continued)

when patients may not have the resources or may not want to die at home. The Tertiary Palliative Care Unit allows for care for patients with symptoms that are difficult to manage. The Palliative Care Consulting Service was also formed in order to provide consultations to acute care facilities and the community, providing consultation services for home care, long-term care, and community hospitals, with 24-h coverage throughout the year.

Palliative care services are provided through family doctors and nurses and are supported by a multidisciplinary team of dieticians, occupational therapists, homemakers, chaplains, pharmacists, physiotherapists, recreational therapists, rehabilitation therapists and assistants, social workers, volunteers, and palliative care consultants.

One unique aspect of the program is its research base and a model for providing standardized care through tools developed either at Edmonton or adopted for the interdisciplinary teams such as the Edmonton

Palliative Care Model #2: Edmonton Regional Palliative Care Program, Canada (Canadian Medical Association 2015; Bruera et al. 1999; Fainsinger et al. 2007) (continued)

Symptom Assessment System, the Mini-Mental State Questionnaire, the CAGE Questionnaire, The Palliative Performance Scale, Mean Equivalent Daily Dose of Parenteral Morphine, and the Edmonton Staging System for Cancer Pain. This allows for standardization and coordination of transfers of care, allowing ease of communication across different institutions within the Edmonton Region, supported by research and evidence. A regional database was developed to allow for generation of reports and continuous process improvement, including evaluating aspects of the program. The databases have allowed for research demonstrating decreases in death in acute care facilities and cost-savings for the region. The program's strength in research and evidence has allowed it to continue developing programs, including an educational curriculum in the undergraduate medical school and a Palliative Medicine Residency Program and incorporation of PhD personnel into research programs.

4 Latin America and the Caribean

A total of 18 countries were included in this section (Fig. 5). We thank Ms. Liliana de Lima (International Association for Hospice and Palliative Care) for reviewing and providing guidance on this section.

4.1 Implementation of Services

In 2012, there were 922 palliative care services across Latin America, with ratios ranging from 16.06 services per one million persons in Costa Rica to 0.24 services per one million persons in Honduras (Pastrana et al. 2012). The services offered are often concentrated in the most highly developed countries in terms of palliative care development. Argentina, Mexico, and Chile had the highest number of services in the region, with 151, 119, and 277 total services, respectively (Pastrana et al. 2012). According to the World Map of Palliative Care, there were no Latin American countries in the highest level (advanced integration of palliative care into the healthcare system), but Costa Rica, Chile, and Uruguay were categorized into the second highest category of preliminary integration (Lynch et al. 2013). There are 44 day care centers across all of Latin America, with the highest concentration in Costa Rica (1.63 day care centers per one million persons) (Pastrana et al. 2012).

There are 600 specialists in palliative care in the region, with the majority (70%) practicing in the three most developed countries in terms of palliative care (Chile, Mexico, and Argentina) (Pastrana et al. 2012) .

Fig. 5 Countries included under the umbrella of the Latin American Association for Palliative Care

4.2 Policies

National palliative care programs exist in many Latin American countries. However, one SWOT (strengths, weaknesses, opportunities, threats) analysis of palliative care development in Latin America showed that in eight countries, health policies were a significant barrier to palliative care development (Pastrana et al. 2015). National palliative care programs/plans exist in Brazil, Chile, Cuba, Mexico, Panama, Peru, and Venezuela (Pastrana et al. 2012).

According to the Atlas of Palliative Care in Latin America, published in 2012 by the Latin American Association for Palliative Care (ALCP for its Spanish acronym), three countries had national palliative care laws (Mexico, Colombia, and Chile), and all countries mentioned palliative care in the national HIV/AIDS Program and national primary care program (Pastrana et al. 2012). However, three countries did not mention palliative care in their corresponding national cancer control plan (Bolivia, Guatemala, and Paraguay) (Pastrana et al. 2012). Only five countries had a monitoring/auditing program in place (Chile, Costa Rica, Cuba, Panama, and Venezuela) (Pastrana et al. 2012).

4.3 Education in Palliative Care

There is uneven offering of education in palliative care across the region. Four countries in Latin America have an official palliative care specialty or subspecialty (Brazil, Venezuela, Costa Rica, and Colombia), with the first accreditation in Colombia in 1998. In six countries, palliative care training can be obtained via a course or diploma (Argentina, Chile, Cuba, Mexico, Panama, and Uruguay) (Pastrana et al. 2012). Postgraduate training in palliative care is offered in ten countries (Argentina, Brazil, Colombia, Costa Rica, Cuba, Guatemala, Mexico, Paraguay, Uruguay, and Venezuela) (Pastrana et al. 2012).

In many countries, including Bolivia, El Salvador, Honduras, and Nicaragua, there is no mention of palliative care in medical school training, while, on the other hand, Cuba and Uruguay have palliative care offerings throughout their medical schools either as a separate offering or part of another course (Pastrana et al. 2012).

4.4 Medicine Availability

According to the Global Opioid Policy Initiative, Chile and Argentina have the highest opioid consumption in the region (which included Latin America and the Caribbean), though consumption even in those two countries is considered moderate when compared to international levels (Cleary et al. 2013a). Morphine consumption was higher than the global mean (6.24 mg/capita) only in Argentina in 2014, according to the Pain and Policy Studies Group (2014c). All countries except Anguilla had injectable morphine, and six countries (Dominican Republic, Ecuador, El Salvador, Honduras, Paraguay, and Trinidad and Tobago) did not have immediate release morphine available (Cleary et al. 2013a).

Jamaica, Anguilla, and St. Lucia allow nurse prescription with special permit or authorization, and Uruguay allows nurse prescribing in emergencies (Cleary et al. 2013a). All countries allow oncologists to prescribe opioids, although six countries required special permits (Argentina, Bolivia, Brazil, Ecuador, Honduras, and Mexico) (Cleary et al. 2013a), and family doctors and surgeons are also allowed to prescribe, but more countries required special permits (and Anguilla allows surgeons to prescribe only in emergency situations) (Cleary et al. 2013a).

4.5 Vitality and Advocacy

Palliative care in Latin America began in the 1980s with support from local leaders and international experts (Bruera 1993). In addition to publishing the Atlas of Palliative Care in Latin America, the ALCP has been implementing a regional palliative care congress every 2 years which has had a positive influence in the development and advancement of the field in the Region. In addition, the ALCP serves as a source

of information and dissemination for news, updates, and networking (Pastrana et al. 2012). The countries with the highest number of members in the ALCP are Brazil and Argentina (Pastrana et al. 2012). Figure 5 shows a map of the countries included under the umbrella of the ALCP.

In addition to the regional association, 11 countries have at least 1 national palliative care association, with some having more than 1 (Brazil, Costa Rica, and Mexico) (Pastrana et al. 2012). Chile has the greatest number of research teams in palliative care (27 teams), and nine countries had identifiable palliative care research teams (Pastrana et al. 2015). Only Brazil has a national journal covering palliative care topics, and 13 countries have national conference on palliative care (only Bolivia, Guatemala, Honduras, Nicaragua, Dominican Republic, and Venezuela did not have national conferences) (Pastrana et al. 2012). Mexico and Argentina were the most active in terms of projects or agreements with organizations in other countries (Pastrana et al. 2012).

Latin American national palliative care leaders report international cooperation in research and training initiatives as important components for the region in terms of vitality, especially with institutions from the UK, Spain, Canada, and United States, and with countries in the region like Mexico or Argentina (Pastrana et al. 2012).

Palliative Care Model #1: Palliative Care Unit, Hospital Universitario Austral, Buenos Aires, Argentina (Mutto 2016)

Information for this case model was provided by Dr. Eduardo Mario Mutto, Hospital Universitario Austral.

The Hospital Universitario Austral (HUA), accredited by Joint Commission International, is located 50 km from Buenos Aires. Its Palliative Care Unit (PCU) began in March 2013 and consists of three doctors, two nurses, a psychologist, three volunteers and two chaplains. The PCU has morphine (oral/parenteral), methadone (oral), oxycodone (oral) and fentanyl (parenteral/transdermal) available.

Patients are cared for in the inpatient unit, outpatient clinic, the emergency service, and, in some cases, at home. All patients also receive weekly phone calls. Most patients reside in districts near HUA (within a radius of 50 km) and belong to the middle class and have some form of private medical coverage, though some patients come from neighboring countries and from throughout Argentina.

Since its establishment, 600 patients have been treated, referred by the following hospital services: Medical Clinic 34%; Oncology 23%; Emergency 14%; Spontaneous 10%; Hepatology 4%; Other 15%. An average of 15 first-time consultations and 60 active follow-up patients are treated monthly. About 50.5% of patients die in the hospital; 26.5% at home and 23.4% at another hospital.

The team prioritizes research and teaching medicine and nursing students at the university. The team tracks four patient care indicators: Place of death; integrated care; contact with primary caregiver; evaluation of symptoms using the Edmonton Symptom Assessment System. Students receive theoretical classes with a practical component in the PCU, and students can take a Palliative Medicine elective in their fifth year and are able to complete a senior thesis in palliative care. In 2017, a postgraduate course in palliative care will be available for doctors and nurses.

There is a close relationship between the PCU and Hospice Buen Samaritano (HBS), located 3.5 km from HUA, providing palliative care to patients in difficult financial situations. In 2015, an agreement was made between the HUA and the HBS for a joint training fellowship in palliative care (Image 3).

Image 3 Hospital Universitario Austral in Argentina Palliative Care Team. (Photo provided by Eduardo Mutto)

Palliative Care Model #2: Palliative Care Clinic, El Salvador (López Saca 2016)

Information for this case model was provided by Dr. José Mario López Saca, Clínica de Cuidados Paliativos.

There is one hospice in El Salvador and six pain and palliative care units in public hospitals providing free care but with few physicians with formal training and with limited access to opioids. In 2013, an internal medicine physician with 2 years of palliative care training from La Clínica Universidad de Navarra, Spain, started a private palliative care clinic in the capital with an oncologist, an oncology-trained nurse, and a psychologist with experience working with hospice patients.

Previously, palliative care units did not exist in the country, and therefore, the team took steps to gain approval from the National Council of Public Health, which authorized the clinic through the Medical and Nursing Surveillance Board. Requirements were created that provide the basis for similar initiatives.

Thus, the Palliative Care Clinic started with the aim of providing support and

Palliative Care Model #2: Palliative Care Clinic, El Salvador (López Saca 2016) (continued)

control of symptoms for patients with both advanced cancer and noncancer patients through outpatient consultation, day clinic, and home care. In the outpatient clinic, patients with higher functional capacity are managed where pain is usually the main symptom. At the day clinic, patients receive medications, including palliative chemotherapy or intravenous antibiotics. The largest proportion of patients is cared for at home. The clinic, although private, provides free care for patients who cannot pay. In the past 4 years, the number of patients has been increasing, and currently, the team manages about six patients per month at home.

Due to the growing number of patients, the multidisciplinary team has also grown; currently, there are two palliative doctors, two outpatient nurses, one part-time psychologist, and ten home-care nurses.

The team has a continuous training plan in place; two Saturdays a month, there is a

(*continued*)

Palliative Care Model #2: Palliative Care Clinic, El Salvador (López Saca 2016) (continued)

team session, and once a month, there is an online session with teams abroad (Spain, Guatemala, Argentina and Chile). One semester per year, a basic palliative care course is given to the nurses who provide home care. The team also runs a palliative medicine course that has been taught from 2013 at the medical school as an elective in the fifth year of medicine. Interest has grown exponentially, and starting from 2017, the course will be mandatory for sixth year students.

The unit has a strong relationship with the General Directorate of Medicines, the institution responsible for the supervision of opioids in the country, and there are currently two or three pharmacies in San Salvador that have extended-release morphine, liquid morphine, methadone tablets, extended- and immediate-release oxycodone tablets, fentanyl patches, and liquid fentanyl. The mechanism for obtaining the opioid at home is now faster, but there are still barriers to certain opioids in El Salvador (Image 4).

5 Africa

Africa differs from much of the rest of the world in its delivery in palliative care and level of burden of specific diseases such as HIV/AIDS, which predominates in Africa, even over malignant diseases, and tuberculosis (WHPCA and WHO 2014). Furthermore, due to the fact that Africa hosts the majority of children, globally, in need of palliative care (49%), the balance in need of various different types of palliative care service provision differ from the rest of the world (WHPCA and WHO 2014). A total of 54 countries (Fig. 6) were included in this section. We thank Dr. Emmanuel Luyirika (African Palliative Care Association) for reviewing and providing guidance on this section.

5.1 Implementation of Services

Uganda, South Africa, and Kenya have the highest number of hospice and specialized palliative care services (Rhee et al. 2017). The first hospice in Africa was started in Zimbabwe in 1979 (Di Sorbo et al. 2010). Since then, there has been a large growth in palliative care in Africa, accounting for most of the growth in palliative care globally from 2006 to 2011 (Lynch et al. 2013). According to the global update of the

Fig. 6 Countries included under the umbrella of the African Palliative Care Association

world mapping project in palliative care, Africa was the most prominent region for progress of countries from Group 3 to 4 (isolated/generalized provision to initial/advanced integration into the health system) (Lynch et al. 2013). However, no palliative care services were identified in 28 countries, and countries, like Zimbabwe, have moved dramatically between different levels of palliative care service provision based on political volatility (Lynch et al. 2013). Ratio of hospice palliative care services to population ranges from 1:237,000 in Swaziland to 1:41,412,000 in Ethiopia (Lynch et al. 2013).

Radiotherapy is particularly important for palliation in the African context. Although there were 277 machines in the continent in 2010, 60% of these machines were housed in two countries (South Africa and Egypt) (Abdel-Wahab et al. 2013). Furthermore, 29 countries, at the time of the study, had no radiotherapy machines, and 7 countries had only 1 radiotherapy machine (Abdel-Wahab et al. 2013). There is need to advocate for African countries to invest in radiotherapy as a palliative care treatment modality in order to improve the quality of life for patients with cancer and in need of palliation.

5.2 Policies

In 2002, the first African declaration at Cape Town was passed, recognizing palliative care as

a right for all adults and children with life-limiting illnesses, and declaring pain and symptom control as a human right (Mpanga Sebuyira et al. 2003). The Declaration also stated the importance of ensuring palliative care at all levels of the healthcare system (Mpanga Sebuyira et al. 2003).

In April 2012, the African Union adopted the "Common Position on Controlled Substances and Access to Pain Management and Dugs" stating the need for focusing on greater access and availability of opioids and the "Declaration of Non-communicable Diseases" which included palliative care (Rawlinson and Luyirika 2014). In September 2013, the Ministers of Health of 21 African countries adopted a consensus statement entitled, "Consensus Statement for Palliative Care Integration into Health Systems in Africa: Palliative Care for Africa," which agreed on focusing on greater access and accountability in providing palliative care services (Rawlinson and Luyirika 2014). The statement also outlined six objectives critical for countries in integrating palliative care into health systems, including the importance of developing policy frameworks to integrate palliative care into hospital and community home-based care services; to integrate palliative care services into national health budgets; to ensure availability of and access to essential medicines in pain and symptom control; to integrate palliative care into nursing, medical, and other relevant health training curricula (including social workers, pharmacists, psychologists, and clergy); to share best case practices across the continent; and to develop partnerships across the continent (APCA 2013).

In 2014, at the seventy-seventh World Health Assembly, WHA67.19 was passed, which called for strengthening of palliative care as a component of comprehensive care throughout the life course; the document urged member states to develop and strengthen policies in palliative care; to ensure adequate funding and human resources for palliative care initiatives; to provide basic support through multi-sectorial partnerships; to include palliative care in education and training; to continually assess palliative care needs; to review legislation and policies for controlled medicines; to update lists of national essential medicines; to foster partnerships; and to implement and monitor actions (Sixty-seventh World Health Assembly, May 24, 2014).

More recently, in August 2016, at the Fifth International African Palliative Care Association Conference's second African Ministers of Health session on Palliative Care, representatives from 26 African countries agreed upon the Kampala Declaration, reasserting the importance of strengthening palliative care in Africa and reaffirming the commitment of Ministries of Health in implementing WHA67.19 and committing to invest in technologies to improve quality and palliative care services and to provide leadership to ensure implementation of WHA67.19 (APCA 2016a).

At the individual country level, to date, there are seven African countries with stand-alone national palliative care policies (Malawi, Mozambique, Rwanda, Swaziland, Tanzania, Botswana, and Zimbabwe), and one in the process of being adopted Uganda (Luyirika et al. 2016). Three African countries (Uganda, South Africa, and Tanzania) have integrated palliative care into their national health policies and strategies, and Uganda and South Africa have recognized palliative care as an examinable subject (Rawlinson et al. 2014). Uganda is unique in that it is the first country in Africa that has changed its laws to allow nurses and clinical officers with proper training to prescribe oral morphine (Jagwe and Merriman 2007). A more recent study shows that 22% (12/48) countries have stand-alone palliative care policies (Rhee et al. 2017). In general, Francophone countries lag behind Anglophone countries in terms of palliative care development and service implementation (Human Rights Watch 2015).

5.3 Education in Palliative Care

Palliative care education is provided by five overarching types of organizations: national palliative care associations, such as the Hospice and Palliative Care Association of South Africa; nongovernmental palliative care organizations, such as Hospice Africa Uganda, Mildmay Uganda, and

Island Hospice; universities, such as the University of Cape Town and Makerere University; the African Palliative Care Association; and other global organizations, such as the International Association for Hospice and Palliative Care (Rawlinson et al. 2014).

Higher level education in palliative care is now available in several countries in Africa, including South Africa, Uganda, and Tanzania (TRUMH 2015). The Institute of Hospice and Palliative Care in Africa in partnership with Makerere University, also provides training across Africa through certificate-, diploma-, and Bachelor's-level courses (with plans to release a Master's in Palliative Care soon) to healthcare professionals, done through distance learning combined with a few months of in-person learning (Hospice Africa Uganda 2016b). The University of Cape Town in South Africa offers postgraduate palliative care through a distance education program (Ens et al. 2011). Zambia, Uganda, South Africa, Kenya, Ghana, and Egypt reported some form of physician accreditation (Rhee et al. 2017).

Mildmay Uganda provides the only multidisciplinary pediatric palliative care diploma on the African continent (Rawlinson et al. 2014).

5.4 Medicine Availability

Despite the great need of opioids on the continent, according to data from the International Narcotics Control Board (INCB), Africa consistently reports the lowest morphine and total morphine equivalence consumption globally from 1980 to 2009, with a small decrease in consumption from 2004 to 2006 (Gilson et al. 2013). The countries with the highest morphine consumption in 2014 were, in order, South Africa, Seychelles, Swaziland, Rwanda, and Mozambique, though all were still below the global mean (Pain and Policy Studies Group 2014b).

As reported by the Global Opioid Policy Initiative, codeine and morphine are the primary medicines on formulary, but none of the 25 countries covered in the study had all seven essential opioids available (the seven essential opioids, as per the IAHPC, are codeine, immediate release oral morphine, controlled release oral morphine, injectable morphine, oral immediate release oxycodone, transdermal fentanyl, and oral methadone) (Cleary et al. 2013b). Six of the countries (Cote d'Ivoire, Liberia, Libya, Rwanda, Sierra Leone, and Tunisia) reported no oral immediate release morphine, and Sierra Leone and Tanzania had the most limited formularies with only two medications on the formulary (Cleary et al. 2013b).

Medicines were free in about half of the countries studied, and in those countries where medicines were not free, costs were usually borne fully by the patient (Cleary et al. 2013b).

Prescribing privileges were least restrictive for oncologists, where almost all studied countries except for Egypt, Liberia, and Morocco, always allowed for oncologists to prescribe opioids. Four countries (Kenya, Sierra Leone, Tanzania, and Uganda) allowed nurse prescriber privileges with special permit or authorization, and Madagascar, Malawi, and Sudan allowed nurse prescribing in cases of emergencies (Cleary et al. 2013b). Most countries had considerable restrictions to opioid accessibility (Cleary et al. 2013b).

5.5 Vitality and Advocacy

Palliative care growth in Africa has largely been due to the dedicated work of activists and civil society organizations on the ground and nongovernmental organizations and institutions. Currently, national palliative care organizations, such as the Palliative Care Association of Uganda, the Hospice and Palliative Care Association of South Africa, and the Kenyan Hospice Palliative Care Association provide policy-level support, education, advocacy, and mentorship in their respective countries (Harding et al. 2013). The African Palliative Care Association (APCA) provides country-level support to governments, national palliative care associations, and individuals in countries that are trying to start palliative care in their respective countries. Figure 6 shows a map of the countries included under the umbrella of the APCA. There are national palliative care associations in countries like Botswana, Malawi, Mozambique, Zambia, and Zimbabwe (APCA 2016b).

Palliative Care Model #1: Hospice Africa Uganda, Kampala, Uganda (Hospice Africa Uganda 2016a)

Hospice Africa Uganda (HAU) was started in 1993. It is a nongovernmental organization funded mostly by grants and donations, providing palliative care in Uganda. Since its conception, it has become an internationally renowned model for palliative care provision in Africa. HAU currently operates hospices in three locations in Uganda, and the core of its work is its outpatient services and home visits. In addition, it provides outreaches to communities, sees consultations at Mulago National Hospital, and conducts monthly visits to partner hospitals. It also provides innovative models such as mobile clinics.

HAU has also been core to advocacy in Uganda. Through its Morphine Production Unit, it produces morphine for the rest of the country. It has played a key role in advocating for a national palliative care policy as well as for nurses to be able to prescribe basic medications for palliative care in Uganda.

HAU has also grown outside of Uganda, providing education to healthcare providers across Africa through its Institute of Hospice and Palliative Care in Africa and its International Programs Department. It offers short courses, diplomas, and a Bachelor's in palliative medicine, and it is planning to start offering a Master's. Upon finishing the course, trainees are aided by HAU in building palliative care capacity in their hospital or country.

HAU provides medications free of charge to patients, and charges, for those who are able to pay, 10,000 Ugandan shillings per visit (equal to about $3 USD). The team is made up of a core team of nurses overseen by a Nurse Supervisor and a Clinical Director, who is a doctor. The team also

Palliative Care Model #1: Hospice Africa Uganda, Kampala, Uganda (Hospice Africa Uganda 2016a) (continued)

consists of social workers and lay counselors. They also have a team of Community Health Volunteers, who identify and provide linkage to care to eligible patients for community outreaches (Image 5).

Palliative Care Model #2: Radiation and Isotope Center Khartoum (RICK), Khartoum, Sudan (Gafer and Elhaj 2014)

Information for this section was provided by Dr. Nahla Gafer and Dr. Shaima Sideeg, Radiation Isotope Center Khartoum.

The palliative care team at the Radiation and Isotope Center Khartoum (RICK), the main oncology center in Sudan, was started by Dr. Nahla Gafer after receiving training at Hospice Africa Uganda. It started in 2010 as an outpatient clinic, as the first site of PC in Sudan, and in 2011, with funding from the African Palliative Care Association, opened a palliative care ward. The palliative care unit has nine beds and the outpatient service is open 5 days a week, providing care to patients from oncology units at RICK and from other hospitals. A home care service was also started in 2011 where staff volunteered to conduct home-care once a week on Saturdays. Patients' families provide transportation for personnel, showing a strong partnership between the care team and the community in which they work.

Since its inception, the palliative care unit has introduced liquid oral morphine to RICK and has improved availability to opiate and non-opiate palliative care medications; opiates are now available all week, including on holidays, though some regulatory barriers are still in place. Palliative care is available in

(*continued*)

Image 5 Hospice Africa Uganda Team. (Photo provided by Eddie Mwebesa)

Palliative Care Model #2: Radiation and Isotope Center Khartoum (RICK), Khartoum, Sudan (Gafer and Elhaj 2014) (continued)

two additional institutions in Sudan, through educational initiatives at RICK, and the three institutions coordinate in providing trainings for healthcare workers in Sudan.

The palliative care service has 24/7 coverage, and it works with the emergency room where there is a section dedicated for oncological emergencies, including for palliative care patients. The team also provides a specialized service for patients who need additional help with dressing and special needs. The team is working closely with the Ministry of Health to continue expanding its services and palliative care availability throughout the country.

RICK sponsors the palliative care team, and additional funds come from the local community. Palliative care services are provided free to all patients, even to those not from Sudan (Image 6).

6 Asia-Pacific

A total of 15 countries (Fig. 7) were included in this section. We thank Dr. Ednin Hamzah (Hospis Malaysia) and Dr. Young Seon Hong (Asia-Pacific Hospice Palliative Care Network) for reviewing and providing guidance on this section.

6.1 Implementation of Services

Development of palliative care across Asia is very heterogeneous (Lynch et al. 2013). Hong Kong

Image 6 Radiation and Isotope Center Khartoum, Sudan Team. (Photo provided by Shaimaa Sideeg)

and Singapore have achieved advanced levels of palliative care integrations, but many countries in the region have limited to no palliative care services (Lynch et al. 2013). In Western Asia, most countries range from one to four services throughout the region (Lynch et al. 2013). Australia and New Zealand rank second and third, respectively according to the Quality of Death Index (The Economist Intelligence Unit 2015) and have among the best hospice/palliative care service to population ratios of 1:67,000 and 1:89,000, respectively (Lynch et al. 2013).

According to the world mapping of palliative care, Japan, Singapore, South Korea, and Malaysia perform the best in terms of ratio of hospice/palliative care services to population, ranging from 1:183,000 in Japan to 1:250,000 in Malaysia; Pakistan performed the worst in the region with a ratio of 1:90,404 (Lynch et al. 2013).

According to the 2015 Quality of Death Index by The Economist Intelligence Unit, six countries from the Asia Pacific region were included in the top 20 Quality of Death Index scores, including Australia, New Zealand, Taiwan, Singapore, Japan, and South Korea (The Economist Intelligence Unit 2015).

A more recent article published by the Asia Pacific Hospice Palliative Care Network showed higher development of palliative care in East Asia compared to South and Southeast Asia, with South Korea, Taiwan, Japan, and Hong Kong having 13, 29, 35, and 59 beds per one million inhabitants, respectively (Yamaguchi et al. 2014). Australia had 107 specialist palliative care services, and New Zealand had 35 inpatient hospices and 41 beds per million inhabitants (Yamaguchi et al. 2014).

Hospices in Asia have a long history of being a grassroots movement, supported mainly by volunteers, nongovernmental organizations, and charities (religious and secular). Although there are many case studies of successful initiatives, in the long run, without integration into the health system, such programs may not be sustainable in the long run (Loucka 2012). As mentioned above, different models of hospice and palliative care delivery have been developed, each catered to the realities of the context of each region. For example, in East Asia (Mainland China did not participate in this particular survey), Hong Kong has the highest number of in-patient hospices (76) while Japan and Taiwan, though very developed in palliative care, have 0 (Yamaguchi et al. 2014). However, Japan has the highest number of hospital palliative care teams at 541, and Taiwan has the highest number of certified palliative care physicians at 562 (Yamaguchi et al. 2014). In Southeast Asia (without responses from Indonesia and Myanmar), Singapore has the highest level of service provision with 28 specialist palliative care service beds/one million inhabitants but has 0 oncology or general

Fig. 7 Member sectors of the Asia-Pacific Palliative Care Network

hospital-based palliative care units, while Malaysia, having 7 beds/one million inhabitants has the highest number of palliative care units, palliative care outpatient clinics, and home palliative care services at 19, 23, and 23, respectively (Yamaguchi et al. 2014).

6.2 Policies

The Asia Pacific region is very vast with very different cultures and levels of development. However, there have been significant advances in individual countries in recent years, and there are certain countries with much improvement in palliative care policies in the region. For example, Singapore has recently developed a national palliative care strategy, and Japan, which performed poorly in the 2010 Quality of Death Index, has jumped up to the top 20 in Quality of Death Index scores partially due to the institution of a new cancer control program and the incorporation of palliative care centers into the national budget (The Economist Intelligence Unit 2015). Taiwan,

ranked at number 6 in the Quality of Death Index, includes palliative care in its National Health Insurance, which allows for reimbursement of services (The Economist Intelligence Unit 2015). Bangladesh has incorporated palliative care into its National Cancer Strategy & Plan of Action (LCPC, October 8, 2016).

However, other countries still lag in policy development; the Philippines does not have any government-led strategy for the development and promotion of national palliative care, and in India and China, which together make up a significant portion of the world's population, has very little in terms of national palliative care policies (The Economist Intelligence Unit 2015). India has recently withdrawn its National Program for Palliative Care, which allocates a portion of the national budget for palliative care (although recent legislative changes have made it easier for doctors to prescribe morphine in India) (The Economist Intelligence Unit 2015). China has no national strategy or guidelines with limited use and availability of opioids, although the Ministry of Health officially endorsed the establishment of palliative care departments in hospitals in 2008 (The Economist Intelligence Unit 2015).

6.3 Education in Palliative Care

Flinders University (Australia), working with the Asia Pacific Hospice Palliative Care Network (APHN), has developed a Graduate Certificate in Palliative Care course, offered to students from the Asia Pacific region, with a particular emphasis on resource-challenged areas, though the program is currently not available (Hegarty et al. 2014). The course is being offered in Singapore through a distance-learning curriculum, in partnership with the National Cancer Center Singapore (Hegarty et al. 2014). There are also important advances at the country-level. Sri Lanka's Post-Graduate Medical Institute has approved a postgraduate diploma in Palliative Medicine for doctors, to be rolled out in 2017 (LCPC, October 8, 2016), and Bangladesh appointed its first Palliative Medicine professor in 2015 (LCPC, October 8, 2016).

The APHN has also, in concert with the Lien Foundation, started the Lien Collaboration for Palliative Care, where, through a "Training-the-Trainer" program, they are focusing on palliative care development in resource poor countries through a collaborative of 40 international healthcare experts in palliative care, training 140 healthcare professionals in the Asia Pacific Region (LCPC, October 8, 2016). The Lien Collaboration has also recently released a documentary on the recent development of palliative care in Bangladesh, Myanmar, and Sri Lanka (LCPC, October 8, 2016).

Palliative care is recognized as a specialty or subspecialty in Australia (Bolognesi et al. 2014), Taiwan, Singapore, Japan, Hong Kong, Mongolia, Malaysia, India, and the Philippines (data was not available for the other five sectors: Korea, Thailand, Indonesia, Vietnam, Myanmar) (Asia Pacific Hospice Palliative Care Network 2016). Taiwan had the shortest number of years required (1 year) while Australia (Bolognesi et al. 2014), Malaysia, Singapore, and India require 3 years for specialization/subspecialization (Yamaguchi et al. 2014). Hong Kong requires 4 years, but either concurrently with either advanced clinical oncology or through a dual certification process with internal medicine (Yamaguchi et al. 2014). However, the lack of specialist training in many countries in Asia continues to be a major barrier to the growth of the palliative care field (Hamzah 2016).

6.4 Medicine Availability

Asia, similar to Africa, with many countries that are still considered "developing," represents a small proportion of total morphine equivalents consumption globally (Gilson et al. 2013). Opioid consumption has remained stable, with most of the growth coming from Japan and South Korea (Gilson et al. 2013). New Zealand and Australia have much higher morphine consumption than any other country in the Asia-Pacific and are the only two countries in the region with morphine consumption higher than the global mean (Pain and Policy Studies Group 2014e).

Codeine and morphine were the most commonly available formulations in the region, and China, the Philippines, and Malaysia had all seven essential medicine formulations available, while Hong Kong (China), South Korea, Thailand, and Vietnam had six of seven available (Cleary et al. 2013c). Of the 20 countries studied by the Global Opioid Policy Initiative, 11 provided medications at no cost of <25% of the cost to patients. Except for Japan, South Korea, Indonesia, Nepal, and Bhutan, all other countries had four or more restrictive regulations to opioid accessibility (Cleary et al. 2013c). In fact, opioid restrictions continues to be a big barrier to the growth of palliative care in many countries in Asia (Hamzah 2016).

Nurses are allowed to prescribe with special permits or authorization in the Philippines, Bhutan, and Pakistan (Cleary et al. 2013c). All countries allowed oncologists to provide opioids, although eight countries required special permits or authorizations; China did not allow family physicians to prescribe opioids, and Bangladesh allows family physicians to prescribe only in cases of emergencies (Cleary et al. 2013c). In Japan, Taiwan, the Philippines, and Vietnam, physicians require a special license to prescribe opioids (Yamaguchi et al. 2014).

6.5 Vitality and Advocacy

The first regional conference to support palliative care development in Asia was held in 1989 and a second in 1996, both in Singapore (Goh 2002). The third, in Hong Kong, was held in conjunction with the 1997 fourth Asia Pacific Cancer Congress, where a decision was made to form a separate legal identity (Goh 2002). The Asia Pacific Hospice Palliative Care Network (APHN), based in Singapore, was formed in 2001 to develop and support the development of palliative care in Asia; it consisted initially of 14 sectors including the following: Australia, Hong Kong, India, Indonesia, Japan, Korea, Malaysia, Myanmar, New Zealand, Philippines, Singapore, Taiwan, Thailand, and Vietnam (Goh 2002). Mongolia was added as a sector in 2015 (Hamzah 2016). Figure 7 shows a map of the member sectors of the APHN.

Due to the heterogeneity of cultures and tradition as well as development economically and in relation to palliative care, the APHN has recently shifted its strategy to focusing on capacity building in certain countries with lower levels of palliative care development (Hamzah 2016). Currently, it is working closely with advocates focused in four countries: Bangladesh, Myanmar, Sri Lanka, and India (Hamzah 2016).

Palliative Care Model #1: Neighborhood Network Palliative Care Service, Kerala, India (Kumar 2007)

The Neighborhood Network in Palliative Care (NNPC) is a community-based project, aimed at empowering local communities to look after their own chronically ill and dying. In the program, community volunteers play an active role in planning, evaluating, monitoring, and modifying the program.

Community volunteers give 2 h a week to care for the sick in their area. They are trained through 16 h of interactive theory sessions and four clinically supervised days. The volunteers then form groups of 10–15 members, supported by trained doctors and nurses, to identify those who are ill in their community and organize and plan interventions. The group may work with existing palliative care facilities or may build their own. Volunteers make regular home visits to follow up on patients that are seen by the palliative care team, identifying and addressing nonmedical issues, linking the patient to the healthcare provider.

The program provides an additional layer of support through trained volunteers who visit patients in between outpatient or inpatient visits, resulting in better psychosocial and spiritual support and better

(*continued*)

Palliative Care Model #1: Neighborhood Network Palliative Care Service, Kerala, India (Kumar 2007) (continued)

identification of psychosocial needs, including financial problems.

The NNPC is comprised of more than 4,000 volunteers, 36 physicians, and 60 nurses. In less than 5 years, the NNPC model resulted in the establishment of 68 community-based palliative care initiatives in northern and mid-Kerala, which covers about 12 million persons. The project is supported by raising money locally through donations of less than 15 cents.

Development of palliative care in Asia has been most difficult in rural areas. Programs such as NNPC provide information on innovative models that can be utilized in settings with constrained resources (financial and human resources), to assist professionals in delivering high quality palliative care to patients (Image 7).

Palliative Care Model #2: Hospis Malaysia, Kuala Lumpur, Malaysia (Hamzah 2016)

Hospis Malaysia is one of the first hospices in Malaysia providing community palliative care. It was started in 1991, run from a donated room in a hospital, and the nurse would go out into the community to see patients. Since then, Hospis Malaysia has grown into a team of 4 doctors, 18 nurses, 1 occupational therapist, 1 pharmacist, 1 Patient Care and Volunteer Coordinator and many nonclinical support staff (Public Relations, Finance, General Manager, Research Assistants, rotating support staff), and provides home-care services, day care services, hospital consults and bereavement support. Hospis Malaysia also provides education and training in the undergraduate medical curriculum of six

Palliative Care Model #2: Hospis Malaysia, Kuala Lumpur, Malaysia (Hamzah 2016) (continued)

universities in Malaysia as well as postgraduate training to family medicine physicians (4-week practical training rotations), and specialist palliative care training for internists (6 month rotations; palliative care is a subspecialty of Internal Medicine in Malaysia). The hospice in collaboration with APHN also runs its own workshops on different topics (palliative care nursing, communication skills; ethics; hope and suffering; pain and symptom management; pediatric palliative care and grief and bereavement) that are held yearly and is open to anyone who would like to participate from the Asia-Pacific region; about 300 persons participate in the short courses each year.

Hospis Malaysia is unique among hospices in its area in that it uses an internally developed web-based electronic health record system, to keep track of patient records and allowing the Medical Director to work with nurses in following patients even when not physically in the country. The system is also used as an audit tool to monitor various indicators of care. Due to the fact that funding from the government has been inconsistent, the hospice is unique in the way that it has approached long-term financial planning. It has four core departments: Clinical; Education, Training, and Research; Communications & Fundraising; and Finance & Administration. It has approached running the hospital like a business model with middle- and long-term strategies and has built a strong donor engagement plan, providing financial stability and growth. It sends out frequent newsletters to donors on progress and has focused on educating the donor base on what palliative care is and the importance of palliative care in the community.

Hospis Malaysia also has an internal auditing system, run by two Research

Palliative Care Model #2: Hospis Malaysia, Kuala Lumpur, Malaysia (Hamzah 2016) (continued)

Assistants that provide ways of keeping track of outcomes, such as pain control, to allow for continuous improvement in processes and quality improvement.

Palliative Care Model #2: Hospis Malaysia, Kuala Lumpur, Malaysia (Hamzah 2016) (continued)

A strong base of management and clinical leadership has led to strong growth in clinical and education growth, which in turn has led to a greater role in national advocacy (Image 8).

7 Middle East

Due to the fact that the Middle East does not have an umbrella palliative care organization, we use the WHO's Eastern Mediterranean Regional Office (EMRO) in summarizing developments in this section, and therefore, some of the countries overlap with other regions. Figure 8 shows a map of the countries (22 countries) included in the WHO's EMRO. We thank Dr. Hibah Osman (Balsam Center) for reviewing and providing guidance on this section.

7.1 Implementation of Services

The availability and distribution of palliative care services across the Middle East is uneven. Higher levels of development are seen in Cyprus, Israel, Lebanon, and Jordan, which have inpatient palliative care beds, interdisciplinary palliative care, and pain teams (Silbermann et al. 2015b). The world map's updated study on palliative care services showed the following countries with higher levels of service provision in the region: Bahrain with a ratio of 1:791,000, Kuwait with 1:1,492,000, Jordan with 1:1,579,000, and Lebanon with 1:2,112,000 (Lynch et al. 2013). In absolute numbers, Saudi Arabia has the highest number of active PC services in the region, followed by Egypt and Jordan (Osman et al. 2017), but these services are not covered by government or reimbursed by private insurance (Osman 2016).

7.2 Policies

Information on national palliative care plans in the Middle East is scarce (Silbermann et al. 2012). Kuwait has palliative care-related regulations, Morocco and Kuwait are awaiting to pass a law regarding palliative care provision; Jordan has incorporated palliative care into its National Cancer Control Plan (Shamieh 2016), and Egypt has National Guidelines on management of acute and chronic pain as well as management of other physical symptoms (Silbermann et al. 2012).

Some preliminary results from a study on palliative care development in the region suggest that although Morocco and Qatar are the only countries with national palliative care programs; several other countries (Kuwait, Jordan, Egypt, and Lebanon) have programs under development (Osman 2016). Tunisia is unique in that it has a stand-alone national palliative care plan (Osman et al. 2017).

7.3 Education in Palliative Care

There is a need for more educational programs and curricula in the Middle East region. Many providers continue to seek education from countries with more advanced programs in Europe and North America (Shamieh et al. 2010).

According to one study of providers in the Middle East showed that one of the top barriers to providing palliative care included not having opportunities for training for health care professionals in palliative care (Silbermann et al. 2015b). Even countries that fare better in terms of opioid consumption in the region do not do so well in terms of palliative care training. For example, palliative care is being integrated into nursing curricula in Lebanon but not yet into medical school curricula, and there are no postgraduate training opportunities in the country. The Lebanese Ministry of Public Health launched, in 2011, a National Committee for Pain and Palliative Care to further progress in this area (Osman 2015a).

The country that stands out in terms of palliative care education is Saudi Arabia. It established the first fellowship training program in palliative medicine in Arabic countries at King Faisal Specialist Hospital and Research Center in 2000, and its graduates have been crucial in helping to set up palliative care programs in other Arabic-speaking countries such as the United Arab Emirates, Qatar, and Egypt (Al-Shahri 2009). Only Saudi Arabia and Lebanon have official certified licensing programs for palliative care physicians, and Egypt, Jordan, Qatar, Iran, and Oman have developed other licensing programs (Master's or Diploma) (Osman et al. 2017).

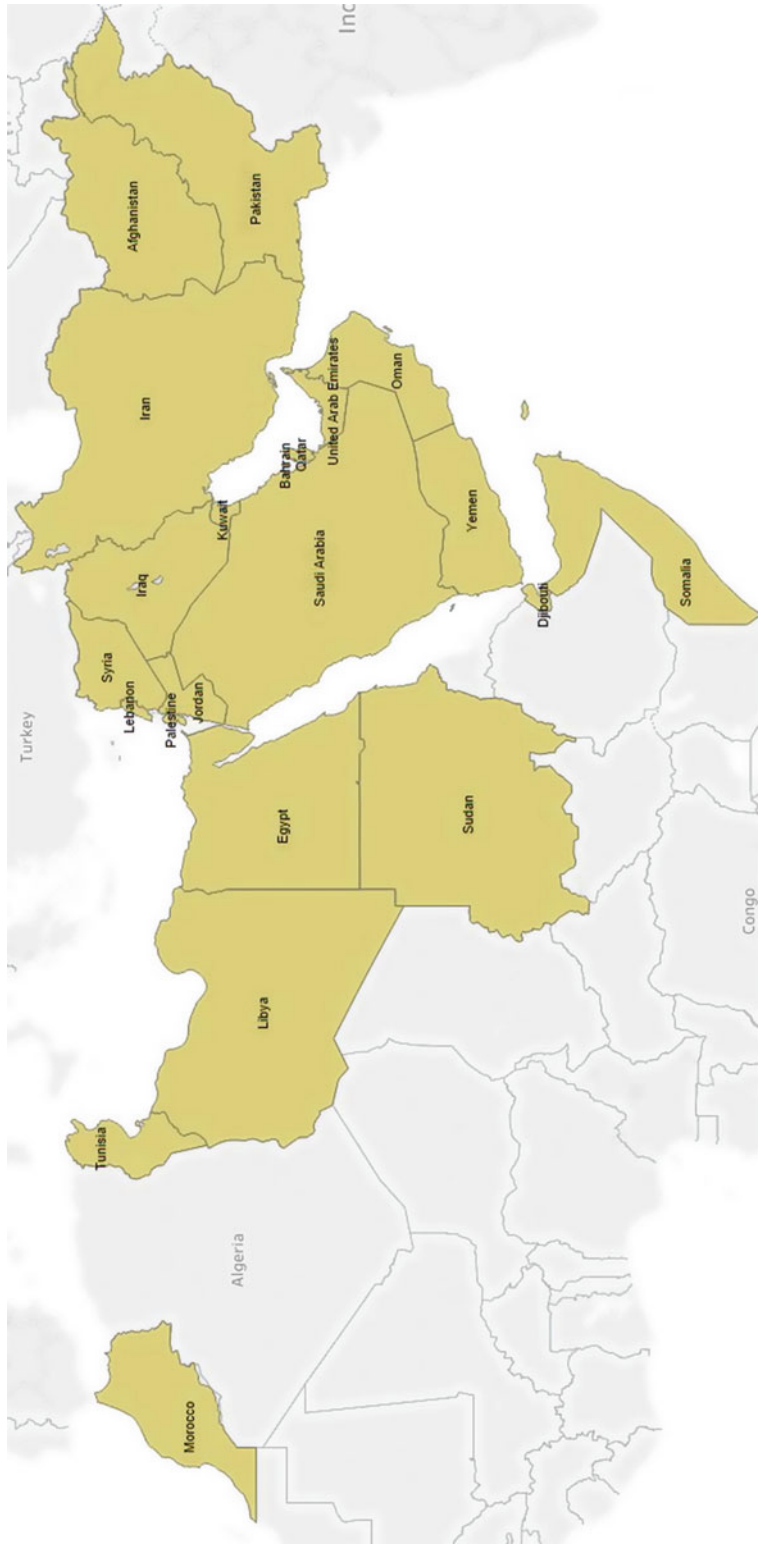

Fig. 8 Countries included in the World Health Organization's Eastern Mediterranean Regional Office

7.4 Medicine Availability

Opioid consumption and availability is, overall, very poor in the Middle Eastern countries. According to the Global Opioid Policy Initiative study in the Middle East, Lebanon and Bahrain had the greatest opioid consumption in 2011, though there was no data available for some countries more developed in palliative care, such as Jordan (Cleary et al. 2013d). The study showed, furthermore, that most countries had considerable regulatory restrictions to opioids (Cleary et al. 2013d).

According to data by the Pain and Policy Studies Group, the mean consumption of morphine in 2014 in the EMRO was 0.384 mg/capita compared to the global mean of 6.24 mg/capita. The group showed that Saudi Arabia had the highest morphine consumption in 2014, followed by Tunisia and Jordan (Pain and Policy Studies Group 2014d).

Another study pooled data from the International Narcotic Controls Board Report for 12 Middle Eastern Countries (Lebanon, Jordan, Syria, Qatar, United Arab Emirates, Saudi Arabia, Oman, Bahrain, Kuwait, Iraq, Egypt, and Yemen) and found that those 12 countries had lower opioid consumption than all regions globally except for Africa and Central America (Wilby and Wilbur 2017).

Furthermore, in addition to the fact that opioid consumption in the Middle East is much lower than Western countries, opioid consumption is also distributed unequally across the region. For example, in 2009, compared to the US, with opioid consumption of 29,487 sold-defined daily doses (S-DDD) per million inhabitants per day, Saudi Arabia had levels around 200 S-DDD, while Pakistan and Iraq had below 10 S-DDD per million inhabitants (Silbermann et al. 2012).

7.5 Vitality and Advocacy

The Middle Eastern Cancer Consortium (MECC), which includes Egypt, Jordan, Palestine, Israel, Cyprus, Turkey, and the USA, provides training and support in palliative care for those working in the oncology field (Silbermann et al. 2015a). It works closely with Ministries of Health in the region to help promote palliative care programs and activities (Silbermann et al. 2015a). Morocco, Tunisia, Lebanon, Jordan, Saudi Arabia, Kuwait, and Iran reported having national palliative care associations, though not all are currently active (Osman 2016; Osman et al. 2017).

Palliative Care Model #1: The Lebanese Center for Palliative Care – Balsam, Lebanon (Osman 2015a)

Information for this case model was provided by Dr. Hibah Osman, Balsam Center.

The Balsam Center in Lebanon is a non-governmental organization providing home-based care in Beirut. It has been in operation since 2009. The team is composed of one social worker, one outreach coordinator, three physicians (one part-time), five nurses, and clinical pharmacist and a clinical psychologist. Since its opening, it has cared for over 500 patients and families with 159 new patients enrolled in 2015. The Center trains palliative care teams in hospitals across the country and launched a large capacity building project in collaboration with the Ministry of Public Health, the World Health Organization, and Ain WaZein Hospital. It also serves as a training site for medical, nursing and social work students and has developed several courses including a mandatory module for 4 weeks to second-year medical students at the American University of Beirut.

Currently, the team expanding its research capacity and is undertaking a study to evaluate the impact of home-based palliative care on the cost of healthcare and quality of life for patients with advanced illness in partnership with GlobeMed, the American University of Beirut, and the Lebanese American University. The study aims to obtain data that would encourage integration of palliative care into

(*continued*)

Palliative Care Model #1: The Lebanese Center for Palliative Care – Balsam, Lebanon (Osman 2015a) (continued)

health. The team is also leading a project sponsored by the World Health Organization and in collaboration with the University of Navarra in mapping palliative care development in the Eastern Mediterranean Region.

The Balsam Team is involved in advocacy within the community, organizing awareness activities and engaging students at universities. The Team released a Short Film in October 2015, highlighting experiences of patients and families with the aim of helping others better understand palliative care.

The Team has recently launched a distance support program. Through telemedicine, the team is able to keep support patients and families that are located in geographical areas that are difficult to access (Image 9).

Palliative Care Model #2: King Hussein Cancer Center, Jordan (Shamieh 2017; Shamieh and Hui 2015; Shamieh et al. 2017)

Information for this case model was provided by Dr. Omar Shamieh, King Hussein Cancer Center.

The King Hussein Cancer Center (KHCC) is the largest tertiary cancer center in Jordan and treats more than 3,500 new cancer patients each year, more than 50% of patients with cancer in the country, as of 2016. In 2017, a new expansion is planned to open which will double the size of inpatient capacity (total of 370 beds) and will increase the outpatient capacity five times in space and also will double the outpatient capacity to two- to threefolds. This will enable KHCC to receive the majority of cancer cases in Jordan.

Palliative Care Model #2: King Hussein Cancer Center, Jordan (Shamieh 2017; Shamieh and Hui 2015; Shamieh et al. 2017) (continued)

The palliative care service at KHCC is the largest comprehensive palliative care program in the country and covers all medical and surgical oncology specialty services, including the emergency department. It comprised of an outpatient clinics, inpatient consultation service, inpatient service, a specialized palliative care unit, and a home-based palliative care program. The team is made up of American Board Certified palliative care physicians, registered nurses with training in palliative care and wound management, two clinical pharmacists, a social worker with experience in palliative care counseling, and a spiritual advisor. The service has available, as needed, a clinical psychologist, clinical dietitian, and physical and respiratory therapists.

The outpatient clinics operate 5 days a week and seeing about 10–15 patients per day. The inpatient consult team, in 2016, saw over 400 inpatient consultations. The KHCC palliative care unit has eight single-bed rooms with 24/7 visiting hours. The outpatient clinics operates 8 half-days a week from Sunday to Thursday and sees about 10–15 patients per clinic day. Home care expanded to four teams covering within a 100-mile radius of Amman, Jordan; each team consisting of two nurses and a driver and operating 5 days a week with weekend visits conducted when necessary. In 2016, the team provided for 2,300 visits.

The KHCC palliative care serves as a high-quality model of palliative care in the region for its education and international collaborative research and is a designated center of excellence for patient care. It is a WHO-designated regional center for

Palliative Care Model #2: King Hussein Cancer Center, Jordan (Shamieh 2017; Shamieh and Hui 2015; Shamieh et al. 2017) (continued)

palliative care education and training and many trainings are offered throughout the year. It provides postgraduate palliative clinical training for nurses from the University of Jordan and provides 1-month mandatory placements for the internal medicine residents. The team is very active in

Palliative Care Model #2: King Hussein Cancer Center, Jordan (Shamieh 2017; Shamieh and Hui 2015; Shamieh et al. 2017) (continued)

collaboration with the Jordanian Ministry of health in building capacity and services for palliative care across Jordan.

The KHCC is unique for its flexibility in reimbursement, allowing patients to receive palliative radiotherapy and procedures

(*continued*)

Palliative Care Model #2: King Hussein Cancer Center, Jordan (Shamieh 2017; Shamieh and Hui 2015; Shamieh et al. 2017) (continued)

according to needs and goals of care. The team is able to provide a range of palliative interventional procedures. The team provides respite care for patients with severe distress or caregiver burnout, and the service runs a 24-h phone help line and patients have access to KHCC's emergency department for emergency services (Image 10).

8 Conclusion and Summary

Though there has been much growth in palliative care development globally, development has been unequal. In many regions, such as Africa, Asia, and the Middle East, regulatory barriers to opioids still present a major challenge to palliative care development. In all regions, service provision is very unequally distributed, with some countries ranking among the top countries in the world in terms of palliative care integration and service implementation while other countries in the same regions have progressed very little; this is particularly pronounced in Africa, Asia, and Latin America. The major barrier in the Middle East seems to be a lack of education and training opportunities for those interested in palliative care as well as access to opioids, and it still lacks a regional palliative care network to assist in advocating for greater services and training in the region. Educational opportunities continue to be a barrier in many countries in Asia and Africa, although program development has increased greatly in Africa in recent years. Regional palliative care networks such as EAPC, ALCP, APHN, and APCA are essential in Europe, Latin America, Asia-Pacific, and Africa in aiding growth and development in palliative care at the country level.

Still, palliative care has come a long way over the past decade. It is now starting to be integrated into public health systems. International organizations, such as the WHO, European Union, and governments are gaining interest in palliative care and are integrating palliative care into policies and strategies. More patients have access to opioids than in the past, and there is now a field in medicine dedicated to the training and practice of palliative care. Globally, especially in regions that have identified barriers to palliative care, there has been vast growth in the past decade, and new and innovative models of palliative care delivery, influenced by local cultures, have expanded access to many. Key advocates in countries working with and for regional and national palliative care associations are vital in the continued growth in palliative care. Though there remains much work to be done, there has also been much progress in palliative care development globally.

Finally, this chapter has focused on regional palliative care organization and networks. However, before ending this chapter, we would be remiss not to mention the important role of international palliative care organizations such as the International Association for Hospice and Palliative Care, the Worldwide Hospice Palliative Care Alliance, and the International Children's Palliative Care Network in coordinating and advocating for improved hospice and palliative care access across all dimensions of the WHO Public Health Strategy at the global level.

Abstract

Palliative care is an essential element of any health care system and a component of comprehensive and integrated care. Access to good palliative care is a basic human right. Palliative care has evolved since its modern foundation: the *British Hospice model* proposed building comprehensive models of care (responding to all dimensions of needs of patients). Palliative care has since spread into all the different settings of the health care systems.

Key evolution of palliative care provision includes:

- The design and implementation of public health models as national or regional palliative care programs, and the policy proposed by the WHO in the World Health Assembly Resolution WHA67.19 in 2014: "*Strengthening of palliative care as a component of comprehensive care throughout the life course.*"
- The shift from the institutional and late care of terminal cancer patients toward the timely community- and population-based perspective and links to chronic care models.
- Initiatives of *compassionate communities* which aim at involving society to change attitudes toward end of life and propose integrated care at the community level.

1 Aims of This Chapter

To describe the development of palliative care from the initial experience of the British Hospices in the 1960s toward the public health approach from the 1990s onwards.

2 Definitions and Concepts in a Historical Perspective

2.1 Short History of Early Modern Palliative Care

Modern palliative care was initiated at St Christopher's hospice in 1967 (The term "palliative care" was first used by Dr. Balfour Mount at the Royal Victoria Hospital in Montreal Canada in 1974. The English word "hospice" translated in French speaking Canada as poor house, and In Spanish it means "house for abandoned children") by Cicely Saunders, who created a conceptual frame to identify the multidimensional needs of patients and their families and the concept of treating "total pain," defined as the suffering that encompasses all of a person's physical, psychological, social, spiritual, and practical struggles. A new model of care was proposed to respond to those multidimensional needs with symptom control, emotional support, and communication as the main elements; the patient and family as the unit of care; and promoting quality of life as the main purpose of care. To provide this approach, the practice of a competent interdisciplinary team was developed with contributions from all disciplines. This concept was initially provided in British inpatient hospices, with strong commitment and community and social support, with great success focused mainly on the care of patients with terminal cancer and very limited prognosis in hospice units across the UK.

2.2 Diversification and Spread into Other Systems

Gradually by the 1970s, this model of care developed different types of organizations, such as

home care services (St Christopher's), outpatient clinics and day care (St Luke's), and support teams (Thelma Bates). Palliative care was also extended into other settings such as acute bed hospitals (Royal Victoria Montreal), cancer institutes (Royal Marsden), support teams (St Thomas'), and comprehensive networks, and to look after other types of patients (AIDS (Krakauer et al. 2007), motor neuron disease, organ failure, etc.). From the mid-1970s to the late 1980s, palliative care services were disseminated into many other countries (Europe (Luczak 1993; Kaasa et al. 2007; Mosoiu et al. 2007), and some low- and middle-income countries (Stjernswärd 2002; Davaasuren et al. 2007)), adapting gradually to their health care systems and cultures.

2.3 The Public Health Programs

In the 1990s, the concept of palliative care as a public health topic was developed at the WHO, and several regions and countries (Catalonia and Extremadura in Spain (Gómez-Batiste et al. 1992; Herrera et al. 2007); Alberta, Canada (Fainsinger et al. 2007); Kerala, India (Kumar 2007); and others) developed palliative care programs with systematic planning and aims of coverage and equity.

During the 1990s, theory, education, and research were extended in many countries, academic positions were established, pre-graduate and postgraduate medical and nursing training developed, training for other members of teams created, and the specialty of palliative medicine established. It is now a recognized specialization in at least 30 countries. Experience, evidence, organizational indicators and standards, and many clinical procedures were developed during this period and added to textbooks and specialized journals (Connor and Sepulveda 2014).

2.4 Palliative Care in the Twenty-First Century

More recently and related to the increased prevalence and mortality of people with all chronic conditions, the concept of a palliative care approach has been developed, alongside the need for timely identification of people with all types of advanced chronic conditions in all settings of care, using community and population perspectives (Gómez-Batiste et al. 2012). In May 2014, the World Health Assembly approved the resolution on palliative care, "Strengthening of palliative care as a component of comprehensive care throughout the life course," to promote the concepts of palliative care for all people in need, from the time of diagnosis, in all settings of care (World Health Assembly 2014). Tools to identify patients at these so-called first transitions have been developed, and the concept of a palliative care approach in all settings is currently being extended, with public health policies implemented to develop these approaches.

Palliative care has been adapted to growing needs, extending from the focus on the care of patients with terminal cancer in institutions and interventions based in prognosis toward a wider perspective that includes the concept of "life-limiting" illness and early intervention; the care of persons with all types of serious chronic diseases and conditions, not just cancer (Murray et al. 2005); and planning based on prevalence, rather than mortality (Table 1).

This change in perspective has radically altered the scope of palliative care and its provision, toward a public health, global, population, and community perspective, introducing the concepts of the palliative care approach in all settings (Stjernsward et al. 2007; Stjernsward and Gomez-Batiste 2008), in combination with the initial concept based on specialist services, in the context of universal health care coverage and access (World Health Organization 2015a, b).

2.5 Summary of Key Current Concepts in Palliative Care

As a result of all these transitions, palliative care can be operationalized by several definitions and concepts (Table 2).

Table 1 Conceptual transitions in palliative care in the twenty-first century. (From Gómez-Batiste et al. 2017c)

	From	Change to
Concepts	Terminal disease	Advanced progressive chronic disease
	Prognosis of weeks or months	Limited life prognosis
	Cancer	All chronic progressive illnesses and conditions
	Progressive course	Progressive course with frequent crises of needs and demands
	Mortality	Prevalence
Model of care and organization	Dichotomy curative or palliative	Synchronized, shared, combined care
	Specific or palliative treatment	Specific and palliative treatment as needed
	Prognosis as criteria for intervention of specialist services	Complexity/ severity as criteria
	Late identification in specialist services	Early identification in community and all settings
	Rigid one-directional intervention	Flexible intervention
	Passive role of patients	Advance care planning
	Fragmented care	Integrated care
Perspective for planning	Palliative care services	Palliative care approach everywhere
	Specialist services	Actions in all settings of health care
	Institutional approach	Community approach
	Services' approach	Population approach
	Individual service	Systems approach

2.5.1 Updated Definition of Palliative Care According to the WHO Ad Hoc Technical Advisory Group on Palliative and Long-Term Care (TAG) (Gómez-Batiste et al. 2017a)

Definition of Palliative Care. Palliative care is the comprehensive and integrated care of persons with advanced chronic conditions and limited life prognosis and their families.

Definition of Palliative Care. Palliative care is the prevention and relief of suffering of any kind – physical, psychological, social, or spiritual – experienced by adults and children living with serious, chronic, complex, and life-limiting health problems and the promotion of dignity, best quality of life, and adjustment to progressive illnesses, using best available evidence. It is a person-centered accompanying of patients and their families throughout the illness course, including at the end of life that optimizes quality of life, promotes human development and well-being, and maximizes dignity.

Palliative care is a basic human right and an essential component of comprehensive and integrated care for persons with serious chronic, complex, and life-limiting health problems that should be practiced by health and social care providers of many disciplines, as well as palliative care specialists, and should be provided in any health care setting, including patients' homes.

Key principles of palliative care provision include the concepts of **comprehensive care** (responding to all multidimensional needs of patients and families), **integrated care** (into all services and settings, with coordination of care), **quality** (responding with effectiveness and efficiency), and **universal access** (equity, coverage, integration into all levels of the health system). The **values** of compassion and commitment are needed to care for persons who are in a frail

Table 2 Levels of the palliative care model. (Adapted from Gómez-Batiste et al. 2017a)

Targets and time
Palliative care is needed by persons suffering from all types of serious complex/chronic or progressive conditions in all settings
It is applicable early and timely in the course of serious chronic, complex, or life-limiting health conditions/illness in conjunction with disease-modifying or potentially curative therapies, for people living with long-term sequela of diseases or treatments, and to neonates and children with serious congenital or acquired health problems
Model of care
Palliative care starts with a multidimensional assessment of physical, emotional, social, and spiritual needs, values, and preferences of patients and their families followed by a systematic approach to care
It focuses on the essential needs of patients and their families such as spirituality, dignity, autonomy, hope, growth and well-being, and key relationships
It uses ethical principles and advance care planning to identify patients' priorities and goals in the case of children, the developmental stage, for care at the end of life, and shared decision-making along the process
It never hastens nor postpones death intentionally
It provides family care and personalized bereavement support for adults and children as needed
It should be integrated into standard responses to humanitarian disasters
Model of organization
Palliative care should be integrated into every setting of the health care system and should be accessible by anyone in need
It should be a standard part of training for medical and nursing students, primary care providers, and health care workers
It should be practiced by medical doctors, nurses, social workers, spiritual supporters, community health workers, therapists, volunteers, and other allied health professionals and caregivers, with adequate training
It should use a three-level structure: palliative care approach in all settings, general basic palliative care, and specialist palliative care with adequate skills at each level
It is best practiced by a competent interdisciplinary team
It uses care management principles to prevent crises and assure integration and continuity of care along the different settings
It encourages active involvement in care giving by family members, communities, and community members
It has proven its effectiveness in addressing patients and families' needs, and efficiency in the provision of care
Much avoidable pain and suffering continues to exist at the end of life. In both resource-rich and resource-poor countries, fewer than 14% of people currently access any end-of-life palliative care. The only way that palliative or end-of-life care can reach the vast majority of people who need it in any country is by integrating its availability in all settings for care: hospitals, care homes, and the community

and vulnerable situation (Gómez-Batiste et al. 2017a).

By operating as an *approach*, palliative care can be provided:

1. To all patients with progressive life-threatening illnesses
2. At all times. Be introduced at diagnosis of a life-threatening illness, not just in the last weeks or days
3. In all dimensions. Help integrate physical, social, psychological, and spiritual, not just the physical
4. In all settings. Extending its reach to people in hospitals, care homes, and most strategically in the community
5. In all regions of the world not just in economically developed countries
6. To all family members. Support family caregivers, at all stages (before, at the time of death, and after)
7. To all ages: applied to children with life-threatening illnesses as much as adults
8. To all society: Promote a public discourse about living in the face of dying and maximizing individual and community assets to promote individual and community growth

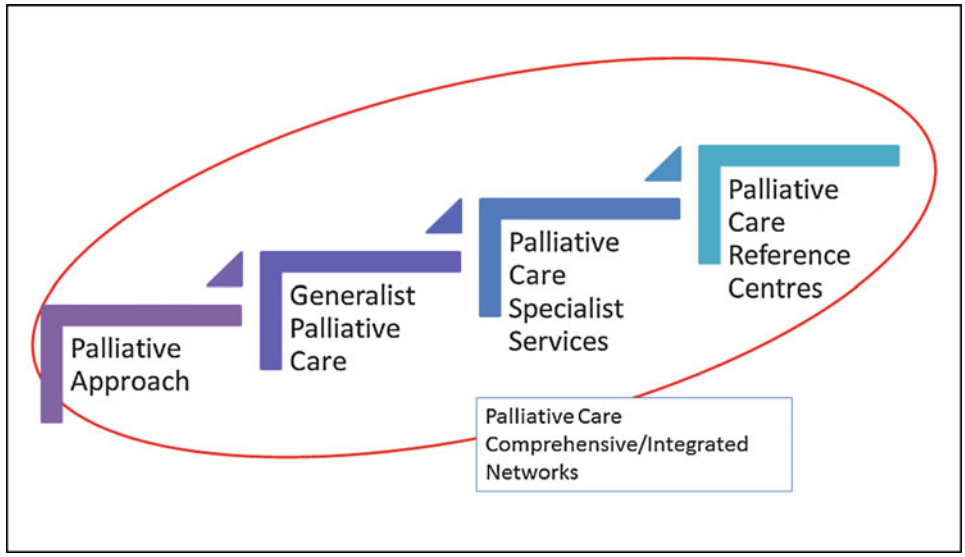

Fig. 1 Levels of palliative care complexity. (Adapted from Luyirika et al. 2017)

2.6 Models of Palliative Care Organization and Provision

2.6.1 Models of Organization

Persons with palliative care needs are cared for and attended to in all settings of the health care system (European Association for Palliative Care 2009). Palliative care can be provided in all of these settings with different levels of complexity and organization, according to the needs of patients and their families. In the context of universal coverage, all health care services need to address palliative care (Gomez-Batiste et al. 2008a).

2.6.2 Levels of Organization

Several levels of palliative care organization can be identified (Fig. 1). In the evolution of palliative care organization, there are also transitional models which can be the first actions prior to developing a specialist service.

2.6.3 Palliative Care Approach in All Settings of Care

Most health services attend to persons with advanced chronic conditions in different proportions and at different times in their disease process evolution. To assure quality of care and universal coverage for palliative care patients, the palliative care approach must be implemented in all services in the health system, especially primary care (for early identification and with a population perspective) and other services with highest proportions of palliative care needs.

The conventional medical services attending higher proportions of patients with palliative care needs are primary care, oncology, geriatrics, HIV/AIDS, and nursing or care homes. But all services have patients in need of different proportions of palliative care involvement.

There are measures that can be taken in any service to guarantee good quality of palliative care:

1. Establish and document a policy for palliative approach.
2. Identify patients in need using validated tools; these would identify needs, stratify the population at risk, and determine the prevalence.
3. Establish protocols, registers, and tools to assess patients' needs and respond to most common situations.
4. Train professionals and integrate palliative care training and review in the conventional training process (sessions, etc.).
5. Increase accessibility to continuing and emergency care, home care (if primary care services), and access for families in hospitals.
6. Identify the carers of patients and give them support and care, including bereavement support.

7. Increase team approach to jointly assess, plan, and implement care.
8. Establish links and criteria for intervention and access to palliative care specialized services in the area.
9. Evaluate results of the palliative approaches.

2.6.4 Primary Versus Specialist Palliative Care

With upwards of 61 million people needing palliative care annually and a very limited number of specialists, it is essential to the future of palliative care that primary care providers have the skills and knowledge to provide palliative care in their practices. An estimated two-thirds of those needing palliative care could be cared for without having to see a palliative care specialist (Connor and Sepulveda 2014). Additionally, specific times could be devoted to attend to those patients with higher needs. Some examples could be specific outpatient clinics in an oncology service for advanced patients, or specific times for bereavement or family support, specific home care visits, or programs of telephone support. In hospitals, patients with palliative care needs can be placed in designated areas (with individual bedrooms, etc.). Or in outpatient clinics, specific times and days can be devoted to these patients. This can also be the first stage before implementing a palliative care specialized service. To help differentiate primary and specialist palliative care, Quill and Abernathy (2013) distinguished the essential skill sets of each:

Primary Palliative Care

- Basic management of pain and symptoms
- Basic management of depression and anxiety
- Basic discussions about:
  - Prognosis
  - Goals of treatment
  - Suffering
  - Code status

Specialty Palliative Care

- Management of refractory pain or other symptoms
- Management of more complex depression, anxiety, grief, and existential distress
- Assistance with conflict resolution regarding goals of methods of treatment
  - Within families
  - Between staff and families
  - Among treatment teams
- Assistance in addressing cases of near futility

2.6.5 Specialized Palliative Care Service

A specialized palliative care service is a health care resource devoted specifically to attending to the complex needs of patients with progressive chronic life-limiting conditions and their families and to give support to other services. It is composed of a competent interdisciplinary team with advanced training and clearly identified by patients and other services.

There are different models and types of specialist services worldwide: Support teams (at home, hospitals, or comprehensive systems in territories), units, outpatient clinics, day hospitals, hospices, and comprehensive networks.

The key factors in the foundation of specialized services are leadership, training, institutional support, and the definition of the mission, values, aims, and internal and external consensus on the model of care and organization (Gómez-Batiste et al. 2008b). The most relevant aspect of the structure is a highly competent interdisciplinary team and the process/activities of PCS are well described (Table 3). The most relevant outcomes are the improvement of the quality of life of persons attended and their relatives. The most relevant criteria for success are the combination of good leadership, a competent team, institutional support, strategic planning, systematic quality assessment, and performance improvement. In most countries that recognize palliative care as a specialty, it is as a subspecialization.

Palliative care services can have diverse models of organization – according to needs of patients and the settings – including inpatient care (in specialist units or support to other services), outpatient clinics, home care, day care, phone/online support, continuing care, or emergency palliative care.

Palliative care services have demonstrated effectiveness, efficiency, and generate improvement of the quality of life of patients and their families (Gomez-Batiste et al. 2008c; World Health Organization 2016).

Table 3 Common activities (process) of palliative care specialist services. (Adapted from Gómez-Batiste and Connor 2017)

Care of patients: Interdisciplinary whole person assessment; care plan development; skilled medical, nursing, psychosocial, and spiritual intervention; follow-up and continuity of care
Care of families and bereavement follow-up
Ethical decision-making and advance care planning
Continuing care and case management
Liaison of resources
Support of other teams
Team work: meetings, roles, support, relations, climate
Registration and documentation
Evaluation of results
Internal training
External training to other services
Research and publications
Quality assessment and performance improvement
Volunteers
Advocacy
Links to society

In many countries, a "service" is an administrative concept, and can include different activities or resources (outpatients, inpatients units, support teams, etc.). In others, every activity will be named "service." A "palliative care team" is the specialized professional group providing these services or activities.

2.6.6 Elements of Specialized Palliative Care Services

- **Outpatient Clinics and Day Care**: Can be based in any setting of the health care system, and are crucial for early palliative care intervention and shared flexible models of cooperation (Gómez-Batiste and Connor 2017).
- **Mobile (or Support) Teams**: Interdisciplinary teams acting in support of other services. Can be based in Hospitals, Community/Home, or serve a district (acting in all or various settings).
  - The basic mobile team will include a medical doctor and at least one nurse, complemented by others, including psychosocial and spiritual professionals, therapy providers, and community health workers. Volunteers enhance the mobile team.
- **Inpatient Units** (called hospices in some locales with beds): Can be based in any setting of the health care system (hospitals, intermediate care centers, long-term nursing homes)
  - Adapted to the organization of health care inpatient services
  - Must respect privacy, and allow presence and access of families
  - Units may specialize in caring for different types of patients (cancer, organ failure, geriatric, children, AIDS, dementia, etc. or be mixed)
  - Can be based in acute, mid-term, or long-term settings or as individual stand-alone facilities
  - Size and resources vary according to country and setting, regulations, and standards
  - Processes and model of care are common to all services
  - Outputs and costs (mean age, length of stay, mortality) will be different according to types of patients.
- **Hospices**: Organizations exclusively devoted to care of advanced/end-of-life care patients, and can include all types of activities including home and inpatient care. Generally owned by NGOs but can be part of any system. The British Hospices were the first organizations implementing modern palliative care in the 1960s following the leadership/model of St Christopher's Hospice.
- **Comprehensive/Integrated Networks:** Organizations of **specialized** palliative care, serving a population and acting in all settings of this scenario (hospitals, intermediate settings, nursing homes, community) in an **integrated** way. In small districts, a **specialized** support team can be the only **specialized** resource needed to care in all settings. In districts with different providers, a common care pathway could be the formula for integrated care. In metropolitan districts, a complex integrated model can include various levels of complexity.

3 Population/Territorial Palliative Care: Integrated Models

The population and territorial perspectives are the key elements of a public health approach. The aim is to build an integrated model, bringing together all services involved.

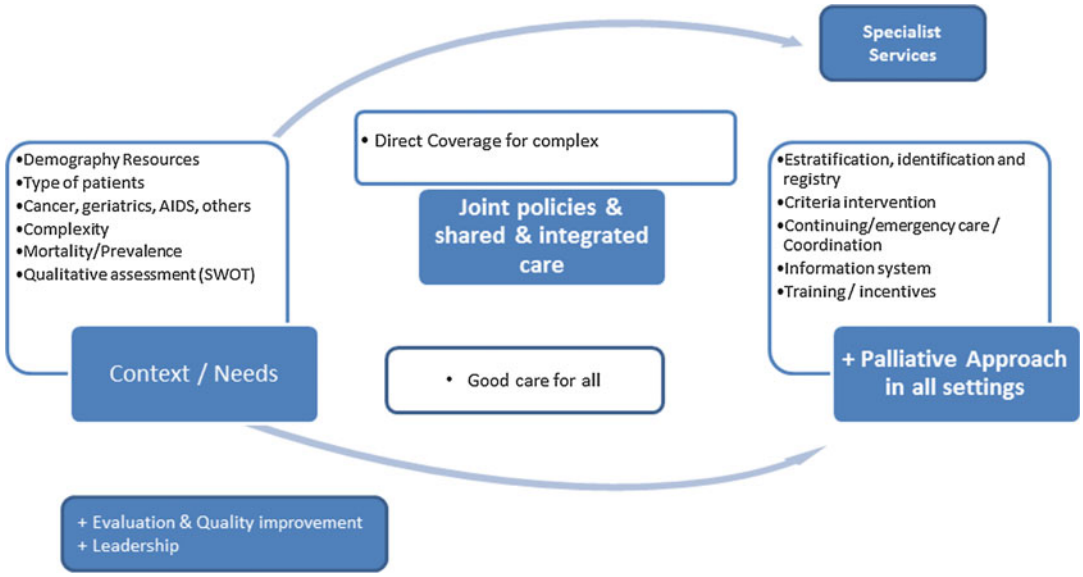

Fig. 2 Population and territorial approach for integrated palliative care. (Adapted from Luyirika et al. 2017)

A policy for a territory must start with an assessment of needs and context, mixing quantitative and qualitative methods. The aging proportion is a key factor. Once done, the next step might be to stratify the population, identifying the different groups that could be in need (McNamara et al. 2006; Murtagh et al. 2014). There are several tools to identify the people in need (Maas et al. 2013; Gómez-Batiste et al. 2017b). The most frequent figures in our context (21% of population over 65 years old) are that 4% of the population have complex chronic conditions, and may need intermittent and gradual palliative care interventions, the 1.5% are people with advanced/progressive chronic conditions and a limited life prognosis (Gómez-Batiste et al. 2014), and 0.4% have added social vulnerability (isolation, poverty, limitation of access, etc.). The next step is to define the roles of services, the pathways for patients (specially focused in transitions), and combined with an information system, incentives, training for professionals, and quality improvement. The most relevant factors for success are leadership and a funding model which incentives integrated over fragmented care (Fig. 2).

Policies for these different populations at risk must include the aims of care, the clinical issues, the ethical issues, and organizational issues (Fig. 3).

4 The Public Health National Policies and Practices

1. Establish a formal national or regional policy with participation of patients and all stakeholders (professionals, managers, policymakers, funders)
2. Determine (or estimate) the population- and setting-specific mortality and prevalence and needs assessment
3. Elaborate, agree, and validate an adapted tool for the identification of those in need of PC
4. Establish protocols to identify these patients in existing services
5. Establish clinical protocols and guidelines to assure good comprehensive, person-centered care for the identified patients
6. Identify the specific training needs, train professionals, and insert palliative care training in all settings
7. Promote organizational changes in primary care, specialized palliative care service, conventional services, and integrated care across all settings in districts
8. Identify and address the specific ethical challenges

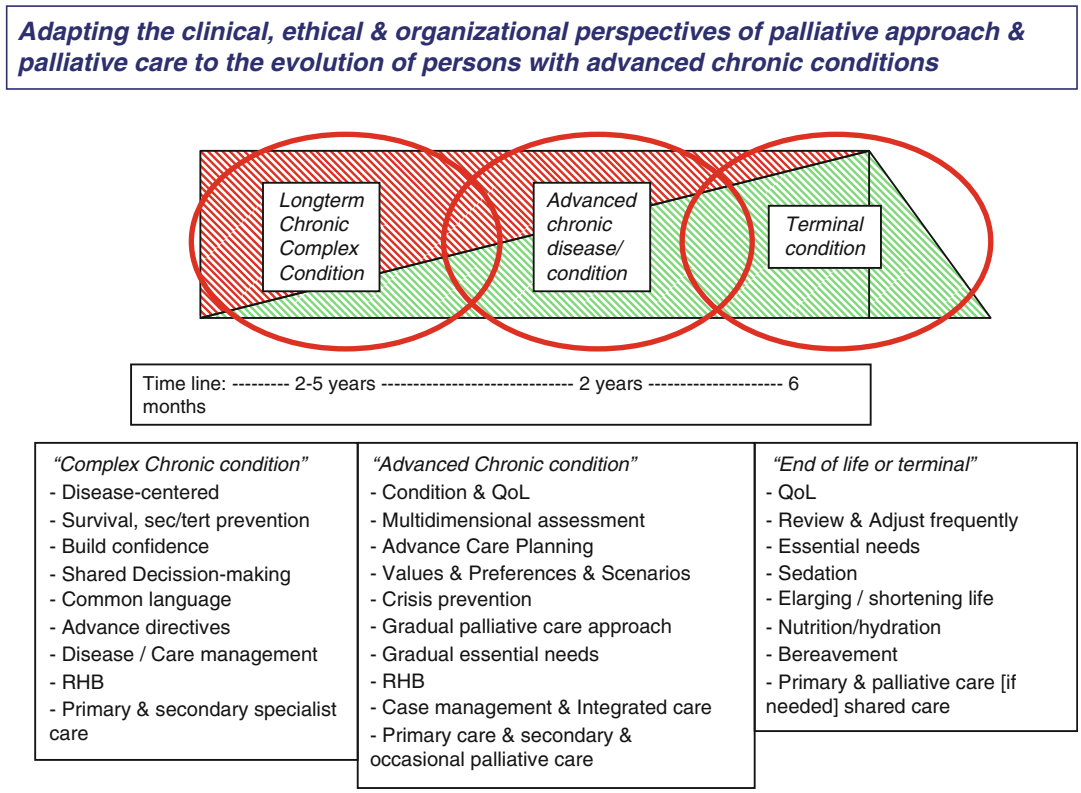

Fig. 3 Clinical, ethical, and organizational aims in different phases of evolution of chronic conditions. (Adapted from Gómez-Batiste et al. 2017a)

9. Insert palliative approach in all policies for chronic conditions (cancer, geriatrics, dementia, HIV, other, etc.)
10. Establish and monitorize indicators and standards of care and implementation plans and generate research evidence

Most of palliative care plans must be adapted to the extension of palliative care to all patients, at all phases, in all services. We can propose a recommendation to build up **National or Regional Programs**.

5 The Social Involvement: Compassionate Communities

In recent years, a new approach has been developed, as a necessary complement of the public health perspective. The programs of compassionate communities propose a new perspective of social involvement, empowering society and its organizations to participate in the change of culture and vision about end of life and in the design and evaluation of services (Kellehear 2013). It is a very interesting approach, which opens the scope of palliative care toward end of life and improves the so far paternalistic relationship of palliative care networks and services with society, frequently focused only in volunteers and funding (Abel et al. 2013; Abel and Kellehear 2016). The most relevant aims of these programs are to change the cultural and social approaches to end of life and dying, and also to provide integrated systems of care, especially for people combining a limited life prognosis and social vulnerability.

6 Conclusions and Summary

Palliative care has evolved since its modern foundation in the 1960s from the *British Hospice model*, from where the comprehensive model of

care (responding to all dimensions of needs of patients) and microorganization (as the team approach) were built. From this context, palliative care has been extended into the settings of the health care systems, with different organizational *models of teams and services*. A more developed model is *the comprehensive and integrated network in territories*. The other key evolutions moved from the institutional and end-stage care of terminal cancer patients to the timely, community- and population-based perspective and links to the chronic care models. The other key element has been the design and implementation of public health models as national or regional palliative care programs, and the policy proposed by WHO in the World Health Assembly Resolution WHA67.19: "*Strengthening of palliative care as a component of comprehensive care throughout the life course*." More recently, there are new initiatives of *compassionate communities* with the aim of further involving society in the cultural changes toward end of life and propose integrated care at the community level (Kellehear 2015).

Palliative care is a key element of any health care system, and access to good palliative care is a basic human right (Human Rights Watch 2009).

Abstract

The WHO public health strategy for palliative care requires enabling policy as one of its three key pillars (alongside drug availability and education) (Department of Health 2003). A major recent driver of palliative care as a core component of health systems around the world has been the World Health Assembly Resolution on Palliative Care (Department of Health 2008a). Expansion of access to appropriate, high-quality of palliative care for adults and children irrespective of country will require the emerging field of global health palliative care research (Department of Health 2008b) to inform the WHO public health strategy. In recent years, we have also greatly increased the evidence base which underpins and supports appropriate policy (Economist Intelligence Unit 2015). In this chapter, we draw on recent policy developments from different parts of the world: from the birthplace of the modern palliative care movement, the UK; from South Africa, which has promoted a strong model of advocacy, provider networks, and academia; from Southern and Eastern Africa, which have advanced policy and provision rapidly in recent years; and lastly from the field of pediatric palliative care, which has specific policy considerations.

1 Palliative Care Policy in the UK

1.1 Postwar Britain

The UK National Health Service was developed in 1948 with the aim of bringing good health care to all from "cradle to grave" (Aneurin Bevan). In this economically challenging postwar period, much of the focus initially, within the NHS, was on delivering care to those living with acute and chronic conditions. Prior to this time, families and religious communities were central to the delivery of care to the dying. It was not until the 1950s, with the work of Dame Cicely Saunders, that the modern hospice movement began.

1.2 The Hospice Movement in England

In 1967 Dame Cicely Saunders founded St Christopher's Hospice in South London. Saunders' compassionate and holistic approach to care recognized the needs of the individual and revolutionized care delivery for the dying – "*y*ou matter because you are you, and you matter to the end of your life" (Dame Cicely Saunders). Subsequently, more charitable hospices across the UK were created to care for dying people. Therefore, unlike other specialties

within medicine, palliative care developed largely outside of NHS settings.

In the 1990s, two organizations were formed "The National Council for Palliative Care" (formerly "The National Council for Hospice and Specialist Palliative Care Services," a single body to speak on behalf of palliative care service providers) and "Hospice UK" (formerly "Help the Hospices" the national voice of hospice care) with the aims to improve end of life care for all and to extend the breadth and reach of hospice care, respectively. However, government reports in subsequent years identified variations in quality of end of life care, particularly in areas of social deprivation and for those dying from nonmalignant conditions. In response to these reports, there was a policy drive to improve care for people approaching the end of life in England, Northern Ireland, Scotland, and Wales.

1.3 Policies, Programs, and Strategies

In 2003 a white paper was published by the Department of Health (Building on the Best Department of Health 2003) which set out to improve choice within the NHS. This included a commitment to spend £12m over 3 years to improve end of life care (The End of Life Care Programme 2004–2007), through the implementation of tools and methods beyond specialist palliative care, including the "Liverpool Care Pathway for the Dying Patient," which had been developed in hospice settings and was translated for hospitals; the "Gold Standards Framework" for general practitioners to identify and support those with palliative care needs; and initiatives to support care homes in the delivery of end of life care.

In 2008, a review of the NHS led by Lord Darzi (High Quality Care for All Department of Health 2008a) recognized a need to improve quality of care, as evidenced through patient outcomes and experiences, safety, and effectiveness. Within the review, end of life care was identified as one of the eight priority areas. That same year, the "End of Life Care Strategy," (Department of Health 2008b) the first major end of life care policy, was launched. This strategy recognized the distancing of death from British society, with the majority of individuals dying in hospital and many people failing to consider in advance their preferences and priorities for end of life and therefore not dying in the place they would have chosen nor receiving the quality care they needed. The strategy communicated a need for a whole system approach to improving end of life care with improvements in identification of those approaching the end of life, care planning and discussions about preferences and priorities, coordination of care, high-quality care wherever it is delivered, careful management of the last days, and support for carers throughout the illness and into bereavement.

Another initiative from the "End of Life Care Strategy" was "Dying Matters," launched in 2009, which focuses on changing attitudes at a population level by actively encouraging people to consider their preferences and priorities for end of life, before the end of life. Within the "Dying Matters" initiative, there is also a campaign aimed at general practitioners called "Find your 1%," which encourages GPs to identify those patients who may be in the last year of life (estimates suggest that is 1% of the population), and proactively start discussions about preferences and priorities.

1.4 Highs and Lows

In both 2010 and 2015, the UK was voted as number 1 in the "Quality of Death Index" (Economist Intelligence Unit 2015), which has often been attributed to the strong links between palliative care in the NHS and Hospice settings, alongside meaningful community engagement. However, this ranking was shaken in 2013 when reported failings in the implementation

and use of the "Liverpool Care Pathway for the Dying Patient (LCP)" resulted in an independent review by Baroness Neuberger (More Care, Less Pathway Department of Health 2013) and its subsequent withdrawal. This intervention which had been developed from best practice in the hospice setting, the model for the development of palliative care as a specialty, was withdrawn due to failings in implementation and use but also fundamentally due to the lack of evidence to underpin its use. For many, in the immediate aftermath of the withdrawal of the LCP, there were a resultant vacuum and fears around how to meet the needs of those approaching the end of life. The review however also recognized the need to return to the fundamental tenet of palliative care – "You matter because you are you" (Dame Cicely Saunders) – focusing on the individual and their needs through the development of individualized care plans.

In response to the review, an alliance of 21 national organizations was formed to give direction to, and focus upon, improving the care of people who are dying and their families. In 2014 they published "One Chance to Get it Right" (Leadership Alliance for the Care of Dying People 2014) which included five priorities for improving care for people who are dying: identifying that a person is dying, communicating sensitively with the patient and those close to them, making a holistic assessment of their needs (physical, psychological, spiritual, and social), respecting their wishes, and establishing an individualized care plan, including place of care and death.

1.5 Ambitions and Commitments

The "Ambitions for Palliative and End of Life Care"(National Palliative and End of Life Care Partnership 2015) published by the National Palliative and End of Life Care Partnership in 2015 took forward the focus on individualized care and whole system and community approach. They identified six key ambitions to achieve quality end of life care: each person is seen as an individual, each person gets fair access to care, maximizing comfort and well-being, care is coordinated, all staff are prepared to care, and each community is prepared to help. Aligned with this was the new national commitment on end of life care (Our Commitment to you for end of life care Department of Health 2016), published by the Department of Health in 2016, which focused not only on care that individuals deserve to receive, irrespective of care setting, but also on the steps to achieve that through improving care quality and increasing accountability and transparency, leadership and identification and dissemination of innovation, and working closely with voluntary and community services. This renewed focus on learning within and across organizations and care settings will be further strengthened by the forthcoming merger of the National Council for Palliative Care and Hospice UK, to provide a clear single vision for high-quality end of life care in England for the future.

2 Palliative Care Policy in South Africa

Palliative care has not been articulated in South African government policy to date. However, in 2014, South Africa was part of the WHO executive committee that sponsored the WHA resolution 67.19 on palliative care which was adopted unanimously and to acclaim by all member states. The SA Minister of Health, Dr. Aaron Motsoaledi, acknowledged the responsibility of the Department of Health to ensure the implementation of the WHA resolution in South Africa. To this end, he appointed a National Steering Committee for Palliative Care and provided clear terms of reference to guide the work of the committee. He charged the committee to create "a revolution in health care through palliative care."(National Steering Committee on Palliative Care 2017) The first action of the steering committee has been to

develop a National Policy Framework and Strategy for Palliative Care.

2.1 Background

Palliative care in South Africa has largely been provided by nongovernmental organizations since the first hospices were established in the 1980s. These hospices are charity organizations and raise funds for the provision of palliative care from the general public, corporates, and trusts and, as they are outside of the formal health-care sector, have received little funding from the government. However, with the recognition of palliative care as part of Universal Health Coverage (World Health Organisation) and evidence of the benefit of palliative care for patients and families, increasing attention has been paid to the importance of integrating palliative care into the South African health system. The South African government has undertaken an ambitious project to establish a National Health Insurance (NHI) (Department of Health Republic of South Africa 2015) to ensure that everyone in South Africa has access to quality health care with financial risk protection so that the cost of care does not put people at risk of financial hardship. Palliative care is written into the NHI as an essential component of primary health care.

There have been a number of champions for palliative care that have influenced the efforts to develop a National Policy Framework and Strategy for Palliative Care. The Hospice Palliative Care Association (HPCA) of South Africa was established in 1987 by 15 hospices in an effort to share best practice in palliative care, to support the work done by hospices, to develop standardized training courses in palliative care, and to advocate for the provision of palliative care. The care provided to hospice patients has been the most effective advocacy for palliative care, but as this care is provided respecting people privacy and ensuring confidentiality, it is often only family members and friends experiencing this care that understand the importance of palliative care. To date, HPCA and member hospices have been the leading providers of palliative care education. In 1989, HPCA developed the Short Course in Palliative Nursing, a year's course to train nurses in palliative care at the request of the South African Nursing Council. This course is presented at ten hospices in different provinces in South Africa. The HPCA Palliative Care Institute has 24 different courses in palliative care including an e-learning course as an Introduction to Palliative Care to assist health-care professionals to develop basic knowledge and skills in the discipline.

The other key palliative care service is the Gauteng Centre of Excellence for Palliative Care at Chris Hani Baragwanath Academic Hospital in Soweto, Wits Centre for Palliative Care, within the University Of Witwatersrand School Of Clinical Medicine and provides undergraduate and postgraduate training. Palliative care was initially provided to relief suffering among cancer patients within the Department of Internal Medicine as early as 1999. The service was later complemented by the N'doro Project (Hongoro and Dinat 2011), funded by Irish Aid and DFID, which responded to the high mortality rate due to HIV before the South African government agreed to the rollout of antiretroviral treatment. In 2007, Gauteng Department of Health established the Gauteng Centre of Excellence for Palliative Care with 18 fully funded posts and subsidy for staff transport to conduct home visit. The leadership provided by Wits Palliative Care in the formal health sector has been a strong influence in the drive to integrate palliative care into the health system. The Centre has developed a strong education and research focus to guide this integration.

In 2001, the HPCA sponsored the development of postgraduate training in palliative medicine at the University of Cape Town through donor funding from the Diana Princes of Wales Memorial Fund (Ens et al. 2011). This was the first and for many years the only postgraduate training in palliative medicine on the continent of Africa, and UCT has been influential in the development of

palliative care champions and leaders in many African countries. UCT was also undergoing a review of the undergraduate medical curriculum in 2001, and this provided an opportunity to integrate palliative medicine into the family medicine training curriculum at UCT.

HPCA established a pediatric palliative care portfolio and through donor funding developed a curriculum to teach children's palliative care and to support member hospices in establishing children's palliative care programs. One of the early children's hospices is Sunflower Hospice established in Bloemfontein in 1998. The founder of the hospice, Joan Marston, still working as a volunteer, went on to lead the HPCA pediatric palliative care portfolio and was instrumental in establishing the International Children's Palliative Care Network (ICPCN) and was the first CEO of ICPCN. The Bigshoes Foundation (BSF) started the first hospital-based pediatric palliative care program at the Chris Hani Baragwanath hospital in Soweto in 2006 and expanded to Durban in 2008 and to Cape Town in 2009. The BSF developed a multidisciplinary pediatric palliative care consultation model that worked closely with the primary care teams providing care and support to hospitalized children that also ensured continuation of care through liaison with community-based services.

Substantial international funding for palliative care development was received by HPCA in 2004 which allowed us to scale up development and the mentorship programme to establish additional hospice services in South Africa. The HPCA palliative care standards were further developed with guidance from the Council for Health Standards Accreditation of Southern Africa (Cohsasa). Emerging home-based care organizations were assessed in a stepwise fashion to become members of HPCA following a development plan with experienced palliative care staff providing training and mentorship to assist in meeting the goals of the development plan. Hospices were awarded stars according to their level of development, and HPCA engaged Cohsasa to conduct a survey of hospice compliance with standards and awarded the hospice five stars upon accreditation through Cohsasa.

In 2009, HPCA signed a memorandum of understanding with the Department of Correctional Services to provide training and mentorship to staff in correctional services and to inmates. This followed screening a television documentary "on the conditions of offenders in South African prisons. Harrowing footage showed a terminally ill offender suffering excruciating pain as he lay dying." A pilot project linked Highway Hospice in Durban with Durban Westville prison to ensure palliative care would be provided in correctional services facilities as well as a referral process for inmates who were released having served their sentence or having received compassionate parole (Sithole and Dempers 2010). The partnership with HPCA and DCS has led to a training course in spiritual care developed as a partnership between prison chaplains and hospice spiritual counselors.

Key events in the development of the National Palliative Care Policy include the following:

A meeting of African and international leaders in palliative care funded by DPWMF in Cape Town in 2002 resulting in the Cape Town declaration and the establishment of a steering committee to develop a pan-African organization which was to become the African Palliative Care Association (Mpanga Sebuyira et al. 2003).

In 2009, HPCA established the Alliance for Access to Palliative Care, a group of individuals from different organizations including the National Department of Health and the National Department of Correctional Services, the Gauteng Centre of Excellence for Palliative Care, and other academic institutions. The involvement of government assisted in bringing the need to integrate palliative care into government strategy to the fore and in developing champions for palliative care within government. The academic institutions have identified the need for palliative care to be integrated into undergraduate training for health professional and social workers.

At the recent palliative care conference held in Kampala and co-hosted by the African Palliative Care Association and the Worldwide Palliative Care Alliance African, health ministers attended a preconference meeting which resulted in the Kampala Declaration on Palliative Care (African

Palliative Care Association 2016). "African Ministers of Health and representatives of country delegations at the 2nd Session of the African Ministers of Health on Palliative Care" stated their commitment to (1) "invest in essential technologies that contribute to quality palliative care services"; and (2) to "provide leadership at the highest level to ensure the implementation of the WHA 67.19 Resolution on "strengthening palliative care as a component of comprehensive care throughout the life course in Africa."

2.2 The National Steering Committee for Palliative Care

Seven task teams were established to guide the work of the committee. These are task teams on policy, education and training, drug availability, vulnerable persons, families and careworkers, funding, and ethics. The Policy Task Team and Steering Committee initially focused on developing a draft Policy Framework and Strategy for Palliative Care and, together with the Funding Task Team's work on costing the Policy, presented the policy document to the Technical Committee of the National Health Council (TechNHC) in February 2017. The TechNHC recommended the policy for approval at the next meeting of the National Health Council. The next actions for the Policy Task team are to decide on models of care and clinical pathways and to review and update clinical guidelines for palliative care.

The Education and Training Task Team conducted research into palliative care curricula and internationally identified core competencies for different health-care practitioners. A survey of palliative care training for undergraduate medical students was carried out across the eight medical schools with seven of these responding to the survey which provides the foundation for development of recommendations for standardized training in the undergraduate curriculum. The initial survey has been adapted for schools of social work, nursing, and rehabilitation sciences. In addition, the HPCA e-learning course Introduction to Palliative Care has been identified as a method of training practitioners already qualified so that they can enroll on the course in order to develop the basic knowledge and skills in palliative care equivalent to the level of graduate students.

The Task Team for Vulnerable Persons has developed a statement regarding access to palliative care for people with disabilities, children, older persons, refugees and asylum seekers, inmates of correctional services facilities, and residents of institutions ranging from TB hospitals to children's homes and care homes for the elderly.

The Drug Availability Task Team has drafted a position paper on the availability of essential palliative care medicines and has submitted this to the Department of Health. The task team has also reviewed the essential medicines lists (EMLs) and made recommendations to the National EML committee. Building on years of lobbying for nurse prescribing of medicines including opioid medication, the task team has made representation to the Director-General (DG) of Health to license nurses with appropriate training to prescribe opioids. Some of the barriers to nurse prescribing have been the Pharmacy Council not permitting pharmacists to dispense a nurse's prescription and delays in the South African Nursing Council's review of the SA Nursing Act which intends to revise the scope of practice of nurses. The DG has advised that hospice- and palliative care-trained nurses can be licensed under the current regulation 56a of the Nursing Act and hospices have written to the DG for this authority.

The Task Team for Supporting Families and Careworkers has drafted a statement on the need for caring for carers and spiritual care for families and all categories of health-care workers. The task team will update the guidelines for caring for carers and develop spiritual care guidelines for the health-care setting. The Ethics Task Team has drafted a paper on ethical issues in care of patients with advanced illness and a position statement on euthanasia and assisted suicide. The paper states that euthanasia is not a clinical practice and that the doctor's duty is to heal where possible, to relieve suffering, and to protect the best interests of their patients and not to hasten death.

The draft Policy Framework and Strategy for Palliative Care identifies the related South African policies and legislation that will enable South Africa to integrate palliative care in to the public health-care system and advocates that palliative care be available from conception to death across a continuum of care. While the policy acknowledges the importance of specialist-level palliative care services in tertiary institutions, it recognizes that the majority of services will need to be provided at district level within community settings. For this reason, it recognizes the need to include palliative care as an integrated, patient-centered, and health system-based service within the current program to reengineer primary health care in South Africa (Barron and Pillay).

The policy framework is based on three overarching goals that include health systems strengthening, ensuring adequate numbers of health-care providers trained in palliative care and effective governance and leadership to support the implementation of the policy. A monitoring and evaluation framework with indicators for each goal is provided as well as a suggested implementation plan for South Africa's provinces.

While the steering committee assisting with the development of the palliative care policy for South Africa realizes that this integration will not be achieved overnight, it truly believes that a progressive realization of peoples' right to palliative care has the potential to revolutionize health care in the country.

3 Palliative Care Policies in East and Southern Africa

3.1 Introduction

One of the highest commitments of any government is to set out what it tends to do in form of a policy. Palliative care is a relatively new discipline and is not fully integrated in many of the health systems in Africa. Getting governments to develop policies that embrace the introduction, funding, and implementation of palliative care as a health service delivery component and as a discipline taught to health workers is a key issue.

3.2 Palliative Care in Disease-Specific Policies

As the HIV epidemic became a major disease in sub-Saharan Africa and before antiretroviral medications became available, the health systems were inundated with several patients who needed palliative care. This caused many health service providers especially in the nongovernment sector to respond with palliative care programs for patients who had developed AIDS. Eventually governments and funders of HIV programs picked best practices and also started taking it up. Subsequent development of national HIV strategic plans and implementation plans included palliative care (Harding and Higginson 2014). As a result, a number of countries have palliative care that included a number of disease-specific policies such as HIV and cancer.

In Kenya palliative care was included in the Kenya National AIDS Strategic Plan 2005/2006–2009/2010 under the objective on improving the quality of life; the government included a budget of 830 million Kenya Shillings to cover the service for AIDS patients (United Nations Educational Scientific and Cultural Organisation). In addition when Kenya developed its National Cancer Control Plan of 2011–2016, palliative was a major component of the planned national cancer response. Other included in the national HIV and cancer-related guidelines and policies (Republic of Kenya Ministry of Public Health and Sanitation and Ministry of Medical Services 2011). These policies recognize the role of palliative care as part of the HIV and cancer care plans throughout the disease trajectory. In the Uganda National HIV Strategic Plan 2007/2008–2011/2012, palliative care was stated as a major component of care and treatment under objective 7 on increasing access to prevention and treatment of opportunistic infections, including tuberculosis (Uganda AIDS Commission). In addition palliative care is also

recognized and is mentioned in the Uganda Cancer Institute Act of 2016 which gives the Uganda Cancer Institute autonomy. The Uganda National Cervical Cancer Control plan also has palliative care as a specific and important part of the national response (Ministry of Health Uganda 2010).

In the United Republic of Tanzania National Cancer Control Strategy of 2013–2022, palliative care is a key component of the objective 3 focusing on care and treatment (The United Republic of Tanzania Ministry of Health and Social Welfare). The government commits to offer the best care they can afford to all patients with cancer and who are in need of it.

In Zimbabwe, palliative care is part of the Zimbabwe National HIV and AIDS Strategic Plan of 2015–2018 and is included in their national response and continuum of care for people with HIV/AIDS under community care and support (Government of Zimbabwe). The Zimbabwe National Cancer Control Strategy 2013–2017 includes palliative care as part of the planned continuum of services including cancer prevention, early detection (early diagnosis and screening), diagnosis and treatment, palliative care and rehabilitation, and cancer surveillance and research (Zimbabwe Ministry of Health and Child Welfare). In the Malawi National HIV and AIDS Strategic Plan (2011–2016) under strategy 2.5, palliative care is a major strategic action which is aimed at to improving access to psychosocial support and quality palliative care for terminally ill patients (National AIDS Commission Malawi 2011).

In The Kingdom of Swaziland, the Second National Multisectoral HIV and AIDS Strategic Plan 2006–2008 under the thematic area on care, support, and treatment, palliative care was a key component (The Government of the Kingdom of Swaziland 2006). All these disease-specific plans and policies have resulted into a significant investment in palliative care in those countries that have resulted into development of national palliative care associations and or palliative care desks at ministries of health being instituted.

In addition using the disease-specific resources, training of palliative care providers has happened in all these countries, and they have also set a stage for the development of stand-alone national palliative care policies in seven of these countries.

3.3 Palliative Care in National Health Sector Plans

Within the Ugandan National Health Sector Plan 2015/2016–2019/2020, the seven priorities include strengthening the national health system including governance; disease prevention, mitigation, and control; health education, promotion, and control; curative services; rehabilitation, and palliative care services (The Republic of Uganda Ministry of Health 2015). This puts palliative care among the key priorities for the health sector in Uganda.

3.4 National Stand-Alone Palliative Care Policies

From 2011, the African Palliative Care Association working with its partners and ministries of health in Africa has supported eight countries to develop stand-alone palliative care policies. These countries are Malawi, Tanzania, Rwanda, Swaziland, Zimbabwe, Botswana, Mozambique, and Uganda. Seven of these countries had already approved and ratified the policies by beginning of 2017 while Uganda is yet to finalize (Luyirika et al. 2016). These policies cover most aspects of palliative care in those specific countries.

3.5 Other Legal Frameworks

In some of the countries, some other key legal frameworks have been established to support palliative care implementation. In 2004 Uganda introduced a statute that allowed appropriately trained nurses and clinical officers to prescribe oral liquid morphine as a way of improving access to opioids among palliative care patients. This statute has resulted in more patients accessing oral morphine in areas where they would not

have had access because previously it was only doctors who were allowed to prescribe and yet they are few (Government of Uganda 2004).

3.6 The Impact of the Palliative Care-Related Policies on Health Systems and Palliative Care Implementation in African Countries

As a result of the different policy frameworks developed in several African countries, the health systems are being impacted positively.

Human resources are being developed, and several palliative care courses are running on the continent including Bachelor of Science in Palliative Care Degree and Diploma in Palliative Care for Africa (Distance Learning), Hospice Africa Uganda; Clinical Palliative Care Course for nurses and clinical officers at Hospice Africa Uganda; Diploma in Palliative Care at Nairobi Hospice in collaboration with Oxford Brookes University (UK); MPhil in Palliative Medicine, University of Cape Town (African palliative Care Association 2017); as well as a pediatric palliative care diploma at Mildmay Uganda. This has resulted into the development of the initial team of specialist palliative care providers in Africa who are running programs.

Palliative care service delivery and coverage is also improving given the improving policy framework and there a number of providing institutions. Global Atlas of Palliative Care at the End of Life of 2014 also highlights the improvement with one of the countries in the region approaching full palliative care integration into the health system (Connor and Sepulveda Bermedo 2014).

Medicines and essential technologies are another aspect of palliative care delivery that is improving on the continent though from a very low base. Increasing access to opioids in Africa has been documented by the UICC with countries such as Malawi, Uganda, and Ethiopia using different models to do this (UICC).

Financing palliative care is a major challenge on the continent, but with increasing coverage in various policies in countries, some degree of government commitment is emerging and is augmented by donor support especially through nongovernmental palliative care providers. In a thesis by Amandua Jacinta, most of the palliative care providers in Uganda drew their funding largely from donors, self-generated funds with some government support (Amandua 2013).

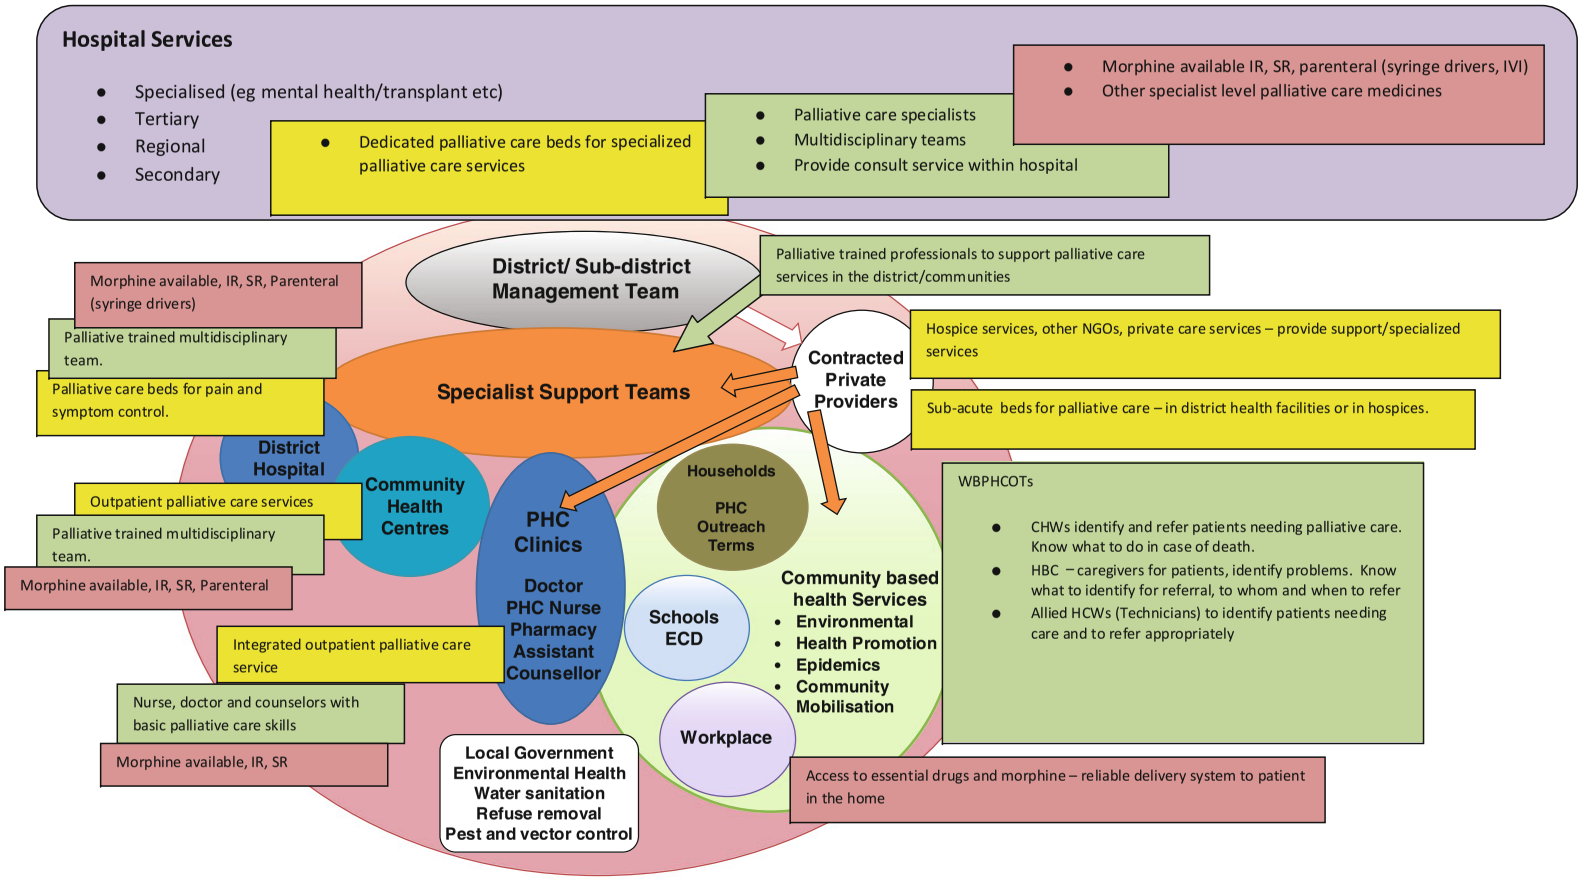
Health information including data collection and use is a key aspect of the palliative care service development. In Africa this is still a major issue that policies have not yet fully impacted.

Leadership and governance have been shown by some of the African governments that have developed policies that include palliative care.

4 Pediatric Palliative Care Policy

4.1 Context

The need for children's palliative care globally has until recently gone largely unrecognized, with the development of palliative care services for adults developing at a greater rate than that for children. Recently it was estimated that there are over 21 million children worldwide who would benefit from palliative care provision with more than 8 million children requiring specialist palliative care services (Connor et al. 2017). However, development has not kept pace with the need, with some countries, such as South Africa, where palliative care is relatively well developed, providing palliative care for less than 5% of those children requiring care (Connor et al. 2014). A systematic review of the provision of children's palliative care around the world completed in 2011, noted that 65.6% of countries globally had no known children's palliative care activity, with only 5.7% having provision that was reaching mainstream providers (Knapp et al. 2011). While developments have occurred in the past 10 years, some of which can be seen in the WHPCA global atlas for the provision of palliative care at the end of life (Connor and Sepulveda Bermedo 2014), there is still a long way to go for provision to meet



(DHS Strategy 2015 with modification to include integrated palliative care services at hospital and district levels)

the needs of children with life-limiting and life-threatening conditions (Downing et al. 2016, 2014a).

Approximately one quarter of the global population is under the age of 15, i.e., 26%, with that figure rising to around 40% in low-income countries (2014 World Population Data Sheet 2014). Challenges to the provision of children's palliative care will vary from country to country and include the following:

- The large number of children in some countries requiring palliative care due to the prevalence of conditions such as HIV, e.g., in Zimbabwe 113.3 children per 10,000 need palliative care (Connor et al. 2017), and conversely the relatively small numbers requiring palliative care in other countries, e.g., in Australia 21.0 children per 10,000 need palliative care
- Late presentation and underdiagnosis in constrained health-care systems, many of which have limited access to curative treatment
- A lack of access and availability of essential medicines for use in palliative care such as analgesics, with a lack of pediatric formulations
- A lack of education and therefore knowledge and skills for the provision of children's palliative care, thus leading to a lack of confidence among health workers and the need for a change in attitude toward the provision of children's palliative care
- A lack of specialist children's palliative care health professionals to provide not only clinical care but education and training and leadership
- Financial burden and inability to pay for care and treatment by the families, leading into a spiral of poverty
- A lack of awareness and understanding of children's palliative care
- The lack of government health policy, strategies, work plans, and funding for the provision of children's palliative care in the majority of countries worldwide (Downing et al. 2012, 2016; Downing and Ling 2012; Marston and Chambers 2012; Mwangi-Powell et al. 2015).

Many of these challenges could be addressed through an appropriate and comprehensive national palliative care policy for the provision of children's palliative care yet, at the same time, these challenges can make it hard to encourage governments to have a policy on children's palliative care.

4.2 Inclusion of CPC in National Policies

Differences exist with regard to whether there is a need for specific policies on children's palliative care within a country or whether a national palliative care policy should and will encompass children as well, ensuring that they are given full recognition and will not get forgotten or sidelined. It is important to remember that there are differences between children's and adult palliative care and that service provision and policy should reflect that difference, for example, ethical issues and how consent for treatment is provided, the broader range of people who may be involved in their care, and different use and preparations of medications (Marston and Chambers 2012; Amery 2009). Thus, if an overarching palliative care policy is to be in place, it is important that it recognizes these differences and that children are integrated throughout the policy and that an integrated approach, as outlined in the World Health Assembly Resolution(World Health Assembly 2014), is promoted.

Alongside the disparities in the provision of children's palliative care globally (Knapp et al. 2011; Downing et al. 2016; Harding et al. 2010), the provision of policy for children's palliative care varies and is at different stages of development and integration. Examples of policy from a range of countries including Uganda, Swaziland, New Zealand, Serbia, Ireland, and the UK will be discussed to illustrate some of these disparities.

Uganda has often been recognized as the country leading the development of palliative care in sub-Saharan Africa, with the provision of palliative care seen as reaching integration (Connor and Sepulveda Bermedo 2014; Clark

and Wright 2007) and capacity building not only for within Uganda but across the region (Merriman 2013; Rawlinson et al. 2014). However, despite this and the leadership from the Palliative Care Association of Uganda (PCAU), Uganda is only now in the process of approving a policy for palliative care (the detail of which has been described elsewhere in this chapter). Within Uganda they have taken the integrated approach with the assumption that children are included/implied throughout and that when talking about provision of care, education, access to medications, etc., the policy is talking about both adults and children. Indeed, in the background to the policy, children's palliative care is defined, and the governments set out their commitment to providing palliative care for all children and adults, and in discussing the principles underpinning the policy, the section on equity states that "The palliative care services shall be provided country wide while ensuring equity with respect to gender, age, and disease conditions with specific considerations for vulnerable groups of the population (Health TRoUMo 2014)," thus laying the foundation not only for children in terms of age but also for the wide ranging conditions for which children require palliative care. Similarly, the National Palliative Care Policy in Swaziland (2011) lays out the policy of universal access to palliative care as a guiding principle and includes an objective of "ensuring the delivery of palliative care services for persons with life-limiting illnesses at all levels, including children, as part of the comprehensive package"(Ministry of Health Kingdom of Swaziland 2011).

The situation within New Zealand – a high income country (World Bank 2017) – is very different, and demonstrates the complexity of the development of policy and frameworks for children's palliative care in a country. In September 2012, The "Guidance for integrated paediatric palliative care services in New Zealand"(Bycroft et al. 2012) was published which recognizes that there had been a variety of key documents within the country that have framed the development of children's palliative care. These include the following:

The Child Health Strategy (New Zealand Ministry of Health 1998a)

Through the Eyes of a Child: A National Review of Paediatric Specialty Services (New Zealand Ministry of Health 1998b)

The New Zealand Palliative Care Strategy (Health NZMo 2001)

Palliative Care: Report of the Palliative Care Expert Working Group to the Cancer Control Steering Group (New Zealand Ministry of Health 2003a)

New Zealand Cancer Control Strategy (New Zealand Ministry of Health 2003b)

The New Zealand Cancer Control Strategy Action Plan 2005–2010 (Cancer Control Taskforce 2005)

Specialist Palliative Care Tier Two Service Specification (New Zealand Ministry of Health 2014)

Gap Analysis of Specialist Palliative Care in New Zealand (New Zealand Ministry of Health 2009)

Positioning Palliative Care in New Zealand: A review of government health policy in relation to the provision of palliative care services in New Zealand (Palliative Care Council of New Zealand 2010)

While it was important that each of these was seen in the wider policy environment within the country, it is interesting to note that it was key documents addressing both adults' and children's palliative care, as well as general pediatric care, that were involved in shaping the children's palliative care services. This is in contrast with the development of the policy on children's palliative care in the Republic of Ireland, where a palliative care needs assessment undertaken in 2005 (Department of Health and Children and Irish Hospice Foundation 2005) estimated that there were approximately 1400 children living with a life-limiting condition, many of whom could not access care and for whom there was a lack of coordination of care. This was followed by the development of a policy – Palliative Care for Children with Life-Limiting Conditions in Ireland – A National Policy (2009) (Department of Health and Children (DOHC)

2009), which sets out the vision and framework for the development of services for children needing palliative care in Ireland. Following this there was a further needs assessment that looked at the need for respite service for children with life-limiting conditions and their families in Ireland (Irish Hospice Foundation (IHF) and Laura Lynn Ireland's childrens hospice 2013), with the most recent work of the National Development Committee for Children's Palliative Care (NDC) established in 2010, being to look at how things have progressed since the implementation of the policy, i.e., from policy to practice 2010–2016. Thus, a clear progression can be seen in the development of the national policy, its evaluation, and recommendations for ongoing service provision.

The UK is an example of a country where adults' and children's palliative care has developed alongside each other and in many ways separately. Together for Short Lives, the national body for children's palliative care, is working hard to influence policy in the UK on Children's palliative care, with ongoing work culminating in the development of an All-Party Parliamentary Group for Children who need palliative care (2017), which seeks to educate, inform, and motivate parliamentarians to take action to continue to develop children's palliative care services for all in need around the country.

For countries with limited palliative care delivery for both adults and children, there are opportunities for an integrated approach to the development of adult and children's palliative care services, where the two can develop alongside and be integrated with each other. An example of this can be seen in Serbia, where an EU-funded project "The development of palliative care in the Republic of Serbia"(European Union 2010) was implemented between March 2011 and November 2014. An important aspect of this project was the development of a national model of palliative care service delivery, for both adults and children, following the adoption of a national palliative care strategy by the Serbian Ministry of Health in 2009 (Government of Serbia 2009). While initially there was a lack of awareness of the need for children's palliative care, this was dispelled through a national needs assessment for children's palliative care. Alongside the provision of education and the development of palliative care services, a comprehensive model of care and service delivery appropriate for Serbia was set up that addressed both adult and children's palliative care service provision. This final document, adopted by the Ministry of Health in October 2013, addresses issues such as the assessment of requirements in terms of resources, operational procedures, referral protocols, standards, quality indicators, and best practice guidelines for adults (but not yet for children) (Downing et al. 2014b). The model explores issues related to both children's and adult palliative care provision and is based on the vision for palliative care in Servia such that all who need it will have access to high-quality, person-centered, holistic, and reliable palliative care regardless of age, diagnosis, stage of illness, or care setting (Milicevic et al. 2015). It looks at an integrated model of service development and addresses the integration of palliative care as outlined in the WHA resolution (World Health Assembly 2014).

5 Conclusion

Thus, there are different pathways that have led to the development of policy on children's palliative care in different countries, whether that be within policies specific for children, integrated with those for adults, within disease-specific policies, etc. However, children's palliative care remains a fairly new concept and is still not understood or well known in many countries; thus there is a need for ongoing advocacy to governments both nationally and through the support of organizations such as the International Children's Palliative Care Network (ICPCN) (Downing et al. 2014a) in order to support the development of appropriate policy. Regardless of the route to development or whether it is child specific or includes adults, the main emphasis is that there is some form of policy, strategy, or framework that will help to shape the development and implementation of children's palliative care within different countries and globally.

Palliative Care, Toward a More Responsive Definition

7

Eric L. Krakauer

Contents

Abstract

The World Health Organization (WHO) definition of palliative care requires clarification. While it has been interpreted as limiting its purview to people facing life-threatening illness, this definition makes little sense in low- and middle-income countries where the means to prevent and relieve any suffering are limited, including in people without a life-threatening illness. The most basic principle of palliative care, prevention and relief of suffering, requires that palliative care conform to the needs of the people it serves.

1 Introduction

The World Health Organization (WHO) definition of palliative care (Box 1) inadvertently has generated confusion (WHO 2002; Fallon and Smyth 2008; Pastrana and Jünger 2008; Van Mechelen et al. 2012; Hui et al. 2013). What is palliative care? Is it exclusively for people with a "life-threatening illness?" Or is it for any patient or family facing the types of **problems** "associated with life-threatening illness?" Many people who do not have clearly a life-threatening illness have problems like pain, dyspnea, anxiety, depression, impoverishment, or spiritual crisis that are "associated with life-threatening illness." The WHO definition also states that palliative care "improves the quality of life of patients and their families . . . through **prevention and relief of suffering**." It states further that "palliative care provides relief from pain and other distressing symptoms." These passages should resolve the confusion. Wherever pain and other distressing symptoms of people **without** a life-threatening illness are not

adequately addressed, palliative care has a role. Hospices – organizations devoted entirely to inpatient or outpatient palliative care for patients near the end of life – provide a crucial service in many settings. But it is neither medically sensible nor morally defensible to assert that clinicians trained to prevent and relieve suffering should do so only for one population in need (those with life-threatening illnesses) and not for others (Fallon and Smyth 2008; MacMahon 2011). This chapter will provide a definition of palliative care based on the most basic principle of the current definition: prevention and relief of suffering.

Box 1

WHO Definition of Palliative Care

Palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual. Palliative care:

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help the family cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counselling, if indicated
- Will enhance quality of life and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications

WHO Definition of Palliative Care for Children

Palliative care for children represents a special, albeit closely related field to adult, palliative care. WHO's definition of palliative care appropriate for children and their families is as follows; the principles apply to other pediatric chronic disorders:

- Palliative care for children is the active total care of the child's body, mind, and spirit and also involves giving support to the family.
- It begins when illness is diagnosed and continues regardless of whether or not a child receives treatment directed at the disease.
- Health providers must evaluate and alleviate a child's physical, psychological, and social distress.
- Effective palliative care requires a broad multidisciplinary approach that includes the family and makes use of available community resources; it can be successfully implemented even if resources are limited.
- It can be provided in tertiary care facilities, in community health centers and even in children's homes.

2 A Responsive Definition: Letting the Need Define the Field

A palliative care more responsive to the full variety of peoples' suffering, and thus more people-centred, could be defined as follows: Palliative

care is the prevention and relief of suffering of adult and pediatric patients – whether physical, psychological, social, or spiritual – and of the psychological, social, and spiritual suffering of family members. It:

- Entails early identification and impeccable assessment and treatment of any type of inadequately relieved suffering
- Enhances quality of life, promotes dignity and comfort, and may also positively influence the course of illness
- Provides accompaniment for the patient and family throughout the course of illness
- Should be integrated with and complement prevention, early diagnosis, and treatment of serious or life-limiting health problems
- Is applicable early in the course of serious illness in conjunction with disease-modifying and life-sustaining treatment
- Provides an alternative to disease-modifying and life-sustaining treatment of questionable value near the end of life
- Is applicable to those living with long-term physical, psychological, social, or spiritual sequelae of serious or life-limiting illnesses or of their treatment
- Accompanies bereaved family members after the patient's death
- Seeks to mitigate the pathogenic effects of poverty on patients and families and to protect them from suffering financial hardship due to illness or disability
- Does not intentionally hasten death but also provides whatever treatment is necessary to achieve an adequate level of comfort for the patient in the context of the patient's values. In keeping with the ethical principle of double effect (Krakauer et al. 2000), there may be rare cases of severe, refractory symptoms in a patient with a terminal illness or mortal injury when the intention of assuring comfort may result in unintentional but foreseeable hastening of death
- Should be applied by healthcare workers of various kinds, including primary care providers, generalists, and specialists in many disciplines and with various levels of palliative care training and skill, from basic to intermediate to specialist
- Encourages active involvement by communities and community members
- Should be accessible at all levels of healthcare systems and in patients' homes
- Improves continuity of care, strengthens health systems, and promotes universal health coverage (Gwyther and Krakauer 2011; Krakauer 2008; Krakauer et al. 2018)

In 2014, the World Health Assembly resolved that "it is the ethical duty of health care professionals to alleviate pain and suffering, whether physical, psychosocial or spiritual, irrespective of whether the disease or condition can be cured . . ."(WHO 2014). The same resolution states that "palliative care is an ethical responsibility of health systems . . ." and that integration of palliative care into public healthcare systems is essential for achievement of Sustainable Development Goal 3.8: universal health coverage. Thus, palliative care is not optional but a medical and ethical necessity that should be accessible by anyone in need at all levels of healthcare systems.

The specific types and severity of suffering vary by geopolitical situation, socioeconomic conditions, and culture. People in low- and middle-income countries (LMICs) often endure less healthy social conditions than people in high-income countries (HICs). They also typically have less access to disease prevention, diagnosis, and treatment, to social supports, and to specialists and specialized services of many kinds. For example, many people have limited or no access to cancer chemotherapy, radiation therapy, or surgery or to effective chemotherapy for multidrug-resistant tuberculosis. Palliative care should never be considered a substitute for disease prevention and treatment, and palliative care workers have a responsibility to advocate for them wherever they are not yet accessible (Gwyther and Krakauer 2011; Shulman et al. 2014). But palliative care also should be universally accessible (WHO 2014).

Many countries also lack rehabilitation medicine specialists and services and long-term care facilities to care for people with non-life-threatening but

Table 1 Comparison of palliative care needs of specific patient populations in different economic settings

Patient population	HICs palliative care need	LMICs palliative care need
Advanced chronic noncommunicable diseases	High	High
HIV/AIDS	Moderate	Very high
Drug-resistant tuberculosis	Very low	High in some regions
Critical illness	High	High
Older people with frailty or multi-morbidity	High	Very high
Neonates with severe prematurity, birth trauma, or congenital anomaly	High	Very high
Severe nonprogressive disabilities such as paraplegia and quadriplegia	Low	High
Severe social distress such as extreme poverty or stigmatization	Low	High
Acute symptoms related to illness, injuries, or surgery	Not applicable	High
Health emergencies and crises	Very low	High in some areas

HICs high-income countries, *LMICs* low- and middle-income countries

serious disabilities such as paraplegia or quadriplegia or those due to brain injuries or congenital anomalies. In addition, mental health services and social welfare programs may be of limited capacity, difficult to access, or unavailable. Palliative care can help to fill these needs (Table 1). Further, the types of suffering typically associated with life-threatening illness – pain, other physical symptoms, and psychological symptoms – also occur acutely or in association with non-life-threatening conditions. But in low-resource settings, prevention and relief of acute or non-life-threatening suffering is inadequate or unavailable. For example, in countries where pain medicine does not yet exist as a specialty, prevention and relief of pain from trauma or burns or surgery typically is inadequate, and clinicians trained in palliative care should help to fill this therapeutic void. Thus, in these settings, clinicians trained in palliative care should intervene either by training colleagues in symptom control, by providing direct symptom relief, or both. Planning and implementing palliative care services must be based on assessment of the types and extent of inadequately prevented or relieved physical, psychological, social, or spiritual suffering. This attention to local needs is necessary for palliative care services to be people-centered: tailored to local need and to the needs of individual patients and families (WHO 2016a, b; Knaul et al. 2017).

3 Conclusion and Summary

The definition of palliative care entails responsiveness to local need. The most basic principle of palliative care, prevention and relief of suffering, requires that palliative care conform to the needs of the people it serves. Patient and families facing life-threatening illnesses suffer everywhere, and palliative care always must address this suffering. However, pain and other types of suffering are common in many other patient populations. Where pain specialists are available and adequately address trauma pain and postoperative pain, involvement of clinicians trained in palliative care is not needed. Where rehabilitation specialists are available and adequately address the needs of disabled people, involvement of clinicians trained in palliative care is not needed. Where pain specialist or rehabilitation specialists or psychiatrists or social supports are not available and patients without life-threatening illnesses suffer unnecessarily as a result, palliative care must respond.

Abstract

The unprecedented global development of palliative care over the past 50 years, originating in a counterculture and evolving through to an integral element of the health-care system, has enabled many more of the world's population to have access to quality palliative care. More of the world's population, particularly those living in high-income countries, such as Europe, North America, Australia, and parts of Asia, now die at an older age of, or with, noncommunicable diseases. The need for palliative care is also significant and largely unmet in low- and middle-income countries such as sub-Saharan Africa where communicable diseases such as

HIV/AIDS, tuberculosis, and malaria continue to lead to expected deaths for many people.

These new patterns of dying have implications for the configuration of international, national, and local palliative care policies, health-care service delivery models, palliative care delivery, engagement with primary and specialist clinical streams, workforce education, and the focus of future research.

This chapter will describe the current and future challenges to palliative care development in low-, middle-, and high-income countries and the opportunities offered by adopting a public health approach, novel technologies, and remote monitoring and better engaging communities to increase palliative care access globally.

1 Introduction

Globally, differing political, economic, and social drivers have shaped each country's response to their population's palliative care needs (Human Rights Watch 2011; The Economist Intelligence Unit 2015). The original genetic coding of many palliative care services can be traced back to the traditional hospice model introduced by various religious orders over a century ago to provide care for the dying and destitute (Clark 2007). These religious order models of hospice care dominated until the 1960s when modern palliative care emerged largely as a counterculture to the unrealistic optimism of mainstream clinical care in the years immediately after the Second World War. Led by a number of visionary clinicians in England, Italy, and North America, this movement was successful in mobilizing funds to support the development of new models of care for the dying (Clark 2007). These new funding streams fuelled the establishment of specialist inpatient palliative care services initially in the UK and Canada, with similar models being subsequently adapted and implemented in other high-income countries and extended to include community-based services (Clark 2007). Establishing these specialist palliative care services has enabled palliative medicine to be recognized as a speciality in its own right in many jurisdictions.

Despite the rapid evolution of this clinical speciality, there continue to be significant barriers to many people accessing evidence-based palliative care. Disparities in access are now one of the greatest challenges faced by the 40 million patients and their families globally who currently require palliative care each year (Connor and Bermedo 2014). The large majority of these patients (80%) live in low- and middle-income countries and are older people ($\geq$60 years of age), while a smaller proportion are children (6%) (World Health Assembly 2014). Unfortunately, less than 8% of the world's population in need of this type of care have access to it (Connor and Bermedo 2014). However, limited access to palliative care is not just confined to people living in low- and middle-income countries; it is also experienced by many people in some of the world's most prosperous economies who often struggle to access the palliative care they need (The Economist Intelligence Unit 2015).

There are many factors that contribute to these disparities in accessing palliative care including inadequate integration, especially at the primary care level, ambiguity about which patients to refer to specialist palliative care services and when referral should be initiated, a very limited workforce globally, lack of access to universal health-care coverage (especially where fee-for-service models predominate in health-care delivery), and poor or absent access to essential medicines as listed by the World Health Organization (WHO) for palliative care, including opioids (World Health Assembly 2014; World Health Organization 2015). These factors impact adversely on patients' ability to receive timely and appropriate evidence-based palliative care and currently pose some of the biggest challenges facing people late in life internationally. Whereas once people predominately died suddenly, the majority of the world's population, especially those living in high-income countries, now have an "expected" death, at an advanced age having lived for some time with one or more noncommunicable diseases, increasing levels of disability, fragility, and symptom burden (World Health Organization et al. 2011), many of whom are older women aged over 85 years, living alone without the regular support of a carer (Local Government Association, NHS Confederation et al. 2012). This changing epidemiology of dying has significant implications for the future configuration, funding, and

integration of palliative care into the existing acute, community, and aged health-care systems. Without adequate health-care reform, the challenges associated with accessing palliative care are expected to increase in line with global population growth and ageing and the rapidly rising burden of noncommunicable diseases. Addressing this growing demand for palliative care in an environment of fiscal restraints and changing epidemiology of dying will only be possible through the widespread adoption of a sustainable public health approach (World Health Assembly 2014).

At the macro level, the focus for addressing the global disparities impacting on access to palliative care ought to be focused on the policy environment in which the values, principles, and strategies for palliative care services are developed and the decisions about resource allocation are determined (World Health Organization 2002). Since the start of the new millennium, a public health strategy has been at the core of all global palliative care policies, primarily because this approach offers the greatest potential to address these access disparities (Stjernsward et al. 1996, 2007). Strengthening global palliative care is a World Health Organization (WHO)(World Health Organization 2007) priority, and the action required to achieve this vision was endorsed at the 67th World Health Assembly in 2014 (World Health Assembly 2014). Positive public policy integrated across all levels of government and the health-care system and engagement and ownership by the community through collective and social action are the cornerstones for strengthening palliative care globally (Stjernswärd et al. 2007). However, realizing this vision requires each and every country to adopt the WHO advice and guidelines on how best to:

(i) Integrate palliative care into the existing health-care system, as one of the four pillars of a noncommunicable diseases program and with inclusion in all relevant health-care policies.
(ii) Implement appropriate policies to ensure essential medicine availability.
(iii) Invest in education of policymakers, health workforce (including volunteers), and community to embed palliative care services at all levels throughout the society (Fig. 1) (Stjernswärd et al. 2007).

This chapter will examine the ten top current and future challenges that palliative care faces globally and outline potential strategies to address each challenge.

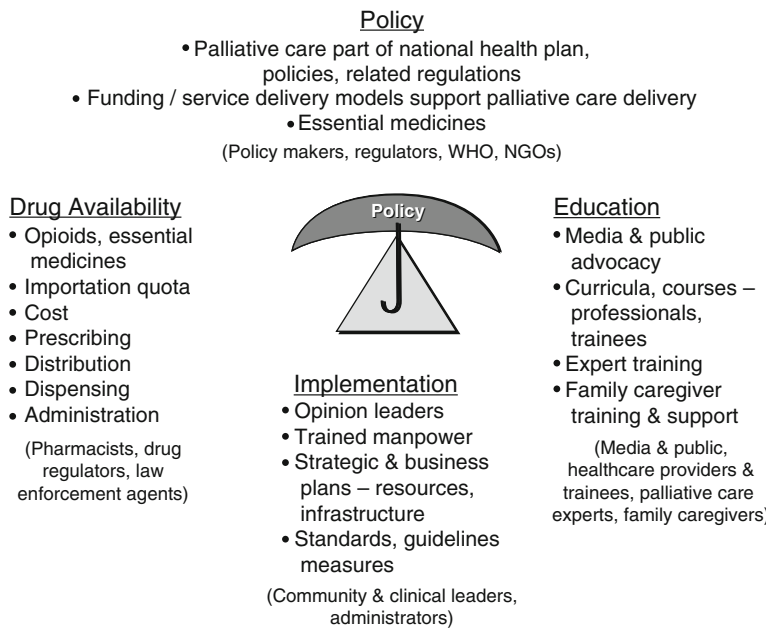

Fig. 1 WHO public health model applied to palliative care (Worldwide Hospice and Palliative Care Alliance and World Health Organisation 2014, p. 30)

2 The Ten Top Current and Future Challenges

Global policies provide governments with a framework for strengthening access to palliative care. However, operationalizing these global frameworks is left to each jurisdiction. As a result, one of the greatest and most immediate global policy challenges is the integration and financing of palliative care as part of usual clinical care irrespective of diagnosis, prognosis, or setting of care. The WHO also acknowledges the need to extend palliative care to other noncommunicable diseases in order to reduce unnecessary suffering (World Health Organization 2007). It positions palliative care as a humanitarian need and as an approach that should be integrated into the existing health-care system where active treatment(s), such as chemotherapy and radiotherapy, are offered in parallel to palliative care in order to improve patients' outcomes (World Health Organization 2007). While this approach is particularly important for low- and middle-income countries, it equally applies to high-income countries. The WHO has an aspirational goal that 80% of all people who die from cancer and 60–80% of people dying from HIV/AIDS should be seen by a palliative care service, but this is rarely achieved, regardless of the country's economic status (Palliative Care Australia 2017). Even in a high-income country like Australia, with universal health coverage and where palliative care services are well developed, many people who would benefit from this type of care do not have access to it. A recent report has found that of the 76,856 Australian inpatients who died in the hospital during 2014–2015, less than half had received palliative care during their final hospitalization; only 4% of aged care residents had a formal appraisal to indicate whether they required palliative care; and only 1 in 1000 patient encounters with GPs was palliative care-related (Palliative Care Australia 2017). Such data confirm that even within high-income countries with universal health coverage, there are significant opportunities to improve disparities in access to palliative care. Without significant positive public policy reforms, reorientation of health-care services, and additional incentives to address the unmet palliative care needs of underserved populations, the situation will rapidly worsen. We contend that there are ten major challenges that need to be addressed to ensure that more of the world's population has access to care based on the best available evidence.

2.1 Access to Essential Medications, Including Opioids

Ensuring timely access to opioids, preventing inappropriate use or diversion (Masman et al. 2015), and making essential medications affordable (United Nations 2016) are potentially the most pressing global palliative care challenges. Timely access to essential palliative care medications, especially opioids, continues to be a major challenge in many countries. While pain is omnipresent in palliative care and almost universally experienced by people with palliative care needs, this distressing symptom can largely be effectively managed with opioids. Yet 80% of the world's population, mostly people living in low-, middle-, and a small number of high-income countries, lack timely or, in many cases, any access to the essential palliative care medications they need, including opioids (World Health Assembly 2014), and at a price they can afford (United Nations 2016).

Currently, less than 10% of the globally manufactured morphine is used for palliative care needs, and its global use is unevenly distributed (United Nations Narcotics Control Board 2017). "Very inadequate" consumption is noted to occur in more than 100 countries, and "inadequate" access is evident across a further 21 countries (International Narcotics Control Board 2011). This reality contributes to some 6.5 million people with palliative care needs not having access to effective analgesia with patients forced to live with moderate to severe pain as a result of their advanced cancer and/or HIV-related disease (s) (World Health Organization 2012). Many of these opioid access issues stem from jurisdictional

efforts to prevent the illicit diversion and abuse of narcotics and psychotropic drugs. Balancing each country's needs to minimize opioid abuse while ensuring those who need opioids have affordable access presents a myriad of humanitarian, ethical, legal, and practical challenges. The United Nations (UN) guidance statements are designed to assist countries where access to opioids is severely restricted or not available in order to move to a more balanced approach by calculating the amount of controlled medications they need to meet their population's essential requirements and to obtain relevant licenses (International Narcotics Control Board 2011; World Health Assembly 2014). Despite this international policy guidance, the limited access to opioids is one of the most urgent global challenges that demands immediate attention.

The WHO Model List of Essential Medicines for adults and pediatric populations prioritizes the core medications required to manage common palliative care symptoms that ought to be available for all globally (United Nations 2016). The challenge is ensuring that all countries have a medicines policy that guarantees the availability of essential medicines, including opioids for the management of pain and chronic breathlessness (World Health Assembly 2014).

Access to medications across high-, middle-, and low-income countries is likely to be an ongoing affordability challenge that will impact on palliative care delivery globally. It is highly likely that as new advanced disease and/or symptom management medications are developed, they will be unaffordable for the majority of the world's population with palliative care needs. Affordability, therefore, poses a significant threat to the provision of evidence-based palliative care. The UN has identified that unaffordable medicines pose a significant threat to global health, largely as a result of a misalignment and tension between diverse drivers such as balancing human rights, public health objectives, intellectual property, and free-trade agreements (United Nations 2016). Addressing these anomalies requires transparency, accountability, and better governance arrangements as well as greater investment by governments in the creation of new research and development incentives (United Nations 2016). However, the real power in the UN's recommendation for affordable medications may lie in inspiring the public debate about options for reforming the research and development system to better serve the global public interest (Moon 2017).

2.2 Access to Universal Health Coverage

Access to universal health-care coverage fundamentally affects patients' and families' ability to access the care they need, including palliative care. The WHO policy imperative promoting universal health coverage is one of the most powerful drivers for increasing access to global health care, including palliative care (World Health Organization 2010; O'Connell et al. 2014; Worldwide Hospice and Palliative Care Alliance 2014). Universal health-care coverage is essential to improve palliative care outcomes globally. This level of coverage ensures that all people (children as well as adults) can use the promotive, preventive, curative, rehabilitative, and palliative health services they need, access health care that is of sufficient quality to be effective, and be protected from unnecessary financial hardship as a result of health-care costs (World Health Organization 2017).

At the macro level, there is an expectation that palliative care is integrated into all aspects of a country's national health-care financing and health system's structures (i.e., primary and community care, aged and acute care) (World Health Assembly 2014). However, this requires all countries to fund the delivery of palliative care and ensure that everyone who requires it has access. Universal health coverage is firmly grounded in addressing inequity and should distribute resources to meet population needs and targets (World Health Organization 2010; O'Connell et al. 2014; Quick et al. 2014) by providing financial risk protection, access to quality essential health-care services, and safe, effective, quality, and affordable medicines (Worldwide Hospice

and Palliative Care Alliance 2015). In the context of palliative care, in addition to improving quality of life, it may also reduce household poverty by minimizing unnecessary expenditure on medical care while enabling those affected (including carers) to continue to work (Worldwide Hospice and Palliative Care Alliance 2014). Further, by optimizing a person's function for as long as possible, it can also reduce reliance on family caregivers, many of whom would have to forego paid work for longer, and potentially reduce the quantum of paid community workers. However, for these advantages to be realized, palliative care needs to be an integral element of universal health coverage, that is, coverage that includes the costs of essential medicines; all inpatient and community palliative care; all necessary medical, nursing, and allied health care as part of the national health plan; and ongoing monitoring of the net effects of palliative care (Worldwide Hospice and Palliative Care Alliance 2014).

The power of driving change through universal health care is best illustrated in an example from Norway, a high-income country where all health care is fully funded by the government. The development of a Diagnosis-Related Group for palliative care paved the way for Norwegian hospitals to establish integrated palliative care teams within the acute care and community sectors, enabling palliative care to be rapidly developed across Norway and in the process reducing access disparities (Currow and Kaasa 2015). Similarly in the USA, the introduction of the Medicare Hospice Benefit in 1983 paved the way for establishing hospices for Medicare, Medicaid, and private insurance beneficiaries with a life expectancy of less than 6 months, who were prepared to forego curative treatment(s) (Meier 2011). Medicare-certified hospices now provide palliative care to more than 1.5 million Americans annually, helping to reduce health-care costs and improve patient outcomes (Meier 2011; National Hospice and Palliative Care Organisation 2015). However, in 2014, more than a third (35.5%) of hospice patients only received care for less than a week (National Hospice and Palliative Care Organisation 2015). These short admission periods reflect poor referral pathways, that most hospices provide limited resources, and that the past practices of linking hospice access to foregoing treatments with curative intent directly limited access to this key resource.

2.3 Integration of Palliative Care into Usual Care

Globally, each country has been largely left to determine how best to address their growing needs for palliative care. There is already wide variability in how palliative care is currently integrated into the existing health-care system. The diversity in global commitment to palliative care is evident in the 2015 study funded by the Lien Foundation in Singapore and led by the Economist Intelligence Unit Report (The Economist Intelligence Unit 2015). This report ranked palliative care development across 80 countries in the following five categories: the palliative and health-care environment, human resources, the affordability of care, the quality of care, and the level of human engagement. This ranking process revealed that 10 of the top 15 countries providing the highest quality of palliative care, including many high-income countries with very sophisticated health-care systems, do not have a national palliative care policy (The Economist Intelligence Unit 2015). Ensuring that all countries have a robust high-level national palliative care policy, backed by funding and agreed standards, is critical to increasing access to palliative care and addressing the unmet needs of underserved populations. Measuring and publicly reporting the impact of these policy initiatives is equally important to help optimize the number of countries which implement palliative care policies (World Health Assembly 2014). While the WHO guidance statements may provide the imprimatur for change, the strategies adopted to increase palliative care access need to be congruent with the country's cultural, social, ethical, and economic milieu. Positive public policy works best when policymakers understand the current context for palliative care, determine what the program aims to achieve in 3 years, and detail the strategies to achieve these outcomes (World Health Organization 2007).

Canada is a good example of a high-income country where palliative care has been well integrated into the existing health-care system (Currow and Kaasa 2015). This integration is largely because of having a strong policy framework, a national palliative care strategy, funding to support palliative care service development, and a commitment to evaluation. Canada has also established a surveillance working group who is seeking to better understand who is accessing palliative care services and how the quality of these services can be systematically measured (Currow and Kaasa 2015). Kerala, India, is an example of a state in a low-income, highly populous country that has developed palliative care services over three decades through strong local policy that emphasizes the importance of primary care and cross-sectoral support and cooperation (Worldwide Hospice and Palliative Care Alliance and World Health Organisation 2014; Currow and Kaasa 2015). Affording palliative care priority status within a public health and disease control program has enabled Kerala to effectively integrate palliative care into the existing health-care system, with a major focus on primary care delivery (Worldwide Hospice and Palliative Care Alliance and World Health Organisation 2014; Currow and Kaasa 2015). The provision of palliative care to those in need would not have been possible without the addition of a trained palliative care volunteer workforce working in partnership with clinicians to provide much-needed care and support in the community (Worldwide Hospice and Palliative Care Alliance and World Health Organisation 2014).

While Canada and Kerala exemplify how high-level WHO policy imperatives and guidance can be adopted to establish and strengthen palliative care services, there are many countries and jurisdictions which continue to struggle to do so (The Economist Intelligence Unit 2015). For example, currently no Caribbean country has successfully integrated palliative care into their health-care system (Spence and Greaves 2017), and in the USA, few hospitals currently meet national palliative care staffing requirements. Current US non-hospice palliative care programs reach very few inpatients (median of 3.4%), and half of all smaller services are nurse-only palliative care programs (Spetz et al. 2016). Of the 1.3 M US Medicare beneficiaries who received hospice care for 1 day or more in 2015, the median length of stay was 23 days, with 30% enrolled for less than 7 days (National Hospice and Palliative Care Organization 2016). Only a quarter of the programs surveyed meet the US Joint Commission interdisciplinary staffing requirements. As a result, few US patients in need of specialist palliative care actually currently receive it, which contributes to some patients being undertreated, while others are overtreated (Meier 2016). In part, this may be attributed to the lead American hospital accreditation authority, "The Joint Commission," not requiring hospitals to provide palliative care or to ensure that the care provided meets national palliative care quality guidelines. As a result, individual hospitals each determine whether or not they will seek palliative care certification (Meier 2016). Likewise, in Australia, the national accrediting body does not require palliative care to be available for a hospital to be fully accredited.

The challenges of integrating palliative care into the usual health-care system are not associated only with resourcing but rather reflect the value each country places on the provision of compassionate, affordable, and evidenced-based palliative care. Unfortunately, across the globe, the barriers that limit the integration of palliative care into existing health-care systems, even when curative care is unavailable, are much greater than the rewards for doing so. At a global macro level, there are few penalties for countries not funding palliative care delivery. As a consequence, too few health-care systems are designed to meet their country's current palliative care needs, leaving many patients with noncommunicable diseases to fall between the gaps or receive inappropriate and ineffective care, which contributes to increased health-care costs and needless suffering. This failure to implement the care required causes unnecessary suffering, especially when medically futile treatments are administered often at great cost to patients and families or symptoms are poorly managed (Davidson and Phillips 2010).

The lack of drivers to integrate palliative care into the existing health-care system, plus geopolitical issues, conflict, and economic instability, all poses significant threats to the future development and sustainability of palliative care globally. These threats also impact adversely on current funding for services, salaries, medicines, and transport. As the world becomes more uncertain, all of these factors have the potential to increase the demand for palliative care, as a humanitarian response (Powell et al. 2017), and to impact on a country's capacity to provide evidence-based palliative care. These factors, combined with changing epidemiological trends (ageing and the increasing prevalence of noncommunicable diseases), demand consideration of new models of palliative care (Connolly 2000; Franks et al. 2000; Wasson 2000). New models of palliative care are also needed to address consumers' growing health-care expectations and access disparities and to better meet the unmet needs of people who are financially disadvantaged around the world (World Health Assembly 2014). There are real opportunities to better integrate community-based nongovernment organizations in the delivery of palliative care, especially in the delivery of generalist palliative care, as educators and as advocates for better palliative care systems.

Any new palliative care models need to support the delivery and integration of generalist and specialist palliative care across health-care systems (Connor and Bermedo 2014; Gómez-Batiste and Connor 2017). For these models to be effective, all health professionals, regardless of speciality, discipline, or care setting, at a minimum need the capabilities to provide a palliative approach to care (Connor and Bermedo 2014). Increasing the capabilities of these generalist providers is essential as palliative care is not their substantive role. Adopting a public health model also ensures that specialist palliative care is care reserved for patients and families with the most complex needs and provided by health professionals whose substantive role is palliative care (Palliative Care Australia 2005). It also enables specialist palliative care providers to partner with and/or support their generalist colleagues to deliver best evidence-based palliative care.

Any new funding models will also need to reconcile the need for palliative care across care settings, in order to strengthen the coordination and integration required to reduce unnecessary fragmentation and to better reflect individual care inputs for patients' needs (Groeneveld et al. 2017). Current service-level funding is rarely linked to local population needs, which inadvertently perpetuates existing inequitable patterns in service provision and access (Groeneveld et al. 2017). New models of palliative care are urgently needed to foster and strengthen community partnerships to increase underserved populations' access to palliative care. Supporting the establishment and maintenance of effective partnerships between consumers (patients, families, and carers), health professionals (medicine, nursing, and allied health), organizations (health-care services and institutions), and communities (nongovernment organizations, volunteers, and friends and colleagues) will also be critical. The success of future palliative care models will be dependent upon them: being aligned with national policy (and often developing a national policy in the first place) and funding, having good systematic processes to identify and address unmet palliative care needs (Weissman and Meier 2011), and adopting dynamic and iterative practice improvement and policy review processes so that the models remain responsive to the needs of the population they serve.

Until recently, palliative care has largely been omitted from global efforts to manage mass causality events, communicable disease outbreaks, and the needs of displaced people living in refugee camps (Powell et al. 2017). Recent humanitarian crises, such as the *Ebola virus* outbreak in West Africa, highlighted the need for a palliative approach to be integrated into active treatment, especially given the virus's high mortality rate. Similarly, the 2010 Haiti earthquake left thousands of people with crush injuries, with many dying of acute renal failure in the weeks that followed without access to palliative care. As a society, we need to think about the minimal palliative care that needs to be provided as part of a humanitarian response and how we ensure essential medications, treatments, and care are provided

to those who need them (Powell et al. 2017). New nimble models of palliative care are needed that can respond quickly to better support families and communities and to effectively contribute to these humanitarian efforts.

2.4 Building Health Workforce Capabilities

Building the palliative care capabilities of each community, health workforce, and policymakers will continue to be a challenge into the foreseeable future. Primarily, this is because the vast majority of people who die expected deaths will be cared for by health professionals for whom managing dying is not their primary area of expertise and was often not part of their training (Al-Qurainy et al. 2009) and supported by family and friends who may not have been adequately prepared or appropriately supported for the roles they find themselves undertaking. This makes education of policymakers, health workforce, and the public an urgent and ongoing priority.

Strengthening and expanding human resources, including education and training of the existing and emerging health-care workforce, is required to ensure greater diffusion of a palliative approach to care. Enhancing palliative care delivery not only requires building the palliative care capacity of health professionals but also acknowledges the importance of having trained palliative care volunteers and an educated community (World Health Assembly 2014). The provision of a palliative approach requires that all health disciplines are able to provide primary palliative care (Quill and Abernethy 2013) and have an understanding of interdisciplinary practice (Hegarty et al. 2010). Having palliative care capabilities is essential, as the majority of people with palliative care needs will be cared for by their usual health-care providers, most probably their general practitioner and community or aged care nurses (primary providers) (Palliative Care Australia 2005; Quill and Abernethy 2013). At the same time, people with complex palliative care needs will be cared for by their specialist palliative care team (specialist providers). At a minimum, health professionals need to be able to respond to their patients' and families' palliative care needs, reflect on the interaction, understand what is not being said, identify and address any conflict, and effectively answer any questions patients or their families may have (Fisher 2002).

Despite the recognized importance of palliative care capabilities, there is wide variability in the level and quality of palliative care content taught to undergraduate health professionals (Field and Wee 2002; Oneschuk et al. 2004; Van Aalst-Cohen et al. 2008). Efforts to make palliative care content mandatory in European medical courses and to embed palliative care content into other health professional courses in the UK and Australia have been initiated. In addition to access to short palliative care courses, accreditation and inclusion of palliative care content in medical and nursing curricula is also required.

There are numerous examples of innovative approaches to building workforce capabilities including the US-based End-of-Life Nursing Education Consortium (ELNEC) Program (End-of-Life Nursing Education Consortium 2016) and the Australian Government (2005)-funded "Palliative Care Curriculum for Undergraduates" (PCC4U) Program. Since commencing in 2001, the reach of the ELNEC palliative care train the trainer program has been extensive, with some 21,400 nurses and other health-care professionals, representing all 50 US states and a further 90 countries participating in the program. It is estimated that over 25,000 nurses and other health-care providers have received ELNEC training internationally (End-of-Life Nursing Education Consortium 2016).

Similarly, PCC4U Program is designed to improve the palliative care capabilities of the emerging Australian health-care workforce using a suite of learning resources focused on the principles of palliative care, communicating with people with a life-limiting illness, palliative assessment and intervention, and optimizing function in palliative care (Australian Government Department of Health and Ageing 2005). In addition to these online resources, the program provides practical support to enable Australian universities to seamlessly integrate this learning content into their

medical, nursing, and allied health curricula (Phillips et al. 2010). The PCC4U curricula are used in 78.5% of the 205 Australian universities' courses preparing health professionals for entry into clinical practice (Australian Department of Health 2017). For the existing Australian health workforce, the Program of Experience in the Palliative Approach (PEPA) has funded a range of health workers (doctors, nurses, allied health professionals, and Aboriginal health workers) to gain short-term palliative care experience in a range of care settings and build a mentoring network between the specialist and nonspecialist workforce (Department of Health and Ageing 2012). Despite these exemplars, there continues to be wide variability in the degree to which palliative care has been integrated into medical, nursing, and allied health courses globally.

There will be an ongoing need to provide palliative care learning content to the future health workforce and for greater utilization of mobile technology and to increase the availability of learning content to health professionals, especially for those working in low- and middle-income countries and/or in remote communities in high-income countries. In addition to being adequately prepared to optimize symptom management, communicate effectively, and provide integrated palliative care, the global health workforce also needs to be able to respond effectively to future palliative care challenges such as promoting shared decision-making, managing medical dilemmas, and responding to a rapidly changing environment as physician-assisted suicide and euthanasia legislation changes around the world.

2.5 Promoting Shared Decision-Making and Preventing Medically Futile Care

As more people live longer with one or more noncommunicable diseases, the ethical and moral debates associated with withdrawing and withholding treatment are likely to become more complex. This is especially the case for some older people who may have reduced decision-making capacity as a result of cognitive impairment, and their nominated proxy may feel burdened by their inherited decision-making responsibilities (Miller et al. 2016). Having the capabilities to confidently assess older people's decision-making capacity and to tailor a supportive decision-making approach will become a core requirement for all health professionals. A supportive decision-making approach will be increasingly required to enable more people with a disability, including cognitive impairment, to have an opportunity to make their wishes and values known, develop and pursue their own goals, make choices about their life, and exercise some control over the things that are important to them (Legare et al. 2010). Improving the quality of shared decision-making and communication will be an ongoing challenge as it requires health professionals to be provided with intensive clinician training, use structured interpersonal communication interventions, and employ evidence-based decision aids (Hanson and Winzelberg 2013). Thinking creatively about how this learning content is delivered requires new models of learning that are underpinned by evidence and embrace novel approaches to building knowledge and skills while changing beliefs and practice.

Preventing clinically futile care from being offered to palliative care patients will also become more complex in the future, especially in an environment of scientific advances, new technologies, and health-care rationing. In the context of advancing noncommunicable and communicable diseases, having internationally agreed palliative care referral criteria is crucial to preventing clinically futile care from being initiated or pursued. Regularly reviewing life-prolonging interventions, such as renal dialysis and external ventricular assist devices (VADs) implemented to manage symptoms and prolong life, is critical to ensuring that these interventions do not, at some point, become unnecessarily burdensome for the patient. For example, the introduction of ventricular assist devices was initially used as a "bridge" to the definitive therapy of heart transplantation. It is now used in some clinical settings for high-technology palliation as a "destination" therapy. The use of targeted therapies late into the course of cancer has not been well studied, yet the practice is widespread with few data on the

attributable toxicities and burdens that this engenders. Failure to regularly review and clarify the role of these interventions in the context of the goals of care contributes to people receiving clinically futile, unnecessary, and potentially distressing and costly care (Hillman 2009). Such care is often not congruent with palliative care patients' wishes and values as the disease progresses (Belanger et al. 2011). Engaging in advance care planning conversations may not only help to improve communication between the patient-family-health professional triad, but these conversations are also likely to assist in preserving and promoting patient autonomy (Radbruch et al. 2016). Future technological and pharmaceutical advances guarantee that health professionals globally will be contemplating these dilemmas on a more frequent basis.

2.6 Responding to Calls for Physician-Assisted Suicide and Euthanasia

Since the first enactment by a democratic government in 1996 that made physician-assisted suicide and euthanasia legal acts, there have been growing societal debates across many jurisdictions about the need for such legislation (Radbruch et al. 2016). While palliative care does not include either of these approaches (Radbruch et al. 2016), there is an increasing expectation that palliative care leaders will contribute to the community debate. The challenge of responding to the calls for these legislative changes is unlikely to go away especially given population ageing and fears of loss of autonomy (Radbruch et al. 2016). As a society, we need to understand that individual requests for euthanasia and physician-assisted suicide are complex, and these requests are shaped by various personal, psychological, spiritual, social, cultural, economic, and demographic factors (Radbruch et al. 2016). Further, when studied prospectively, these requests are often not sustained over time. We need to ensure that any calls for euthanasia and physician-assisted suicide, especially in high-income countries, do not inadvertently sabotage global efforts to convince governments that pain relief and good end-of-life care are basic human rights (Asia Pacific Hospice and Palliative Care Network 2017). Licensing doctors to provide or administer lethal drugs to palliative patients poses serious risks for low- and middle-income countries as they work to establish better systems to address their populations' unmet palliative care needs (Asia Pacific Hospice and Palliative Care Network 2017). If physician-assisted suicide and euthanasia are legalized, it will change many doctor-patient relationships in end-of-life care. Within such a change, the impact on clinicians needs to be considered carefully.

2.7 Reducing Access Disparities Through Greater Use of Technology

As the majority of palliative care will continue to be provided in the community, consideration of technology-enabled care (TEC) will become increasingly important. Patients and carers are increasingly researching information, sharing care experiences, and identifying treatment options in an online environment. TEC represents the convergence of health technology, digital health, media, and mobile telecommunications. This type of technology is increasingly seen as an integral part of the solution to many of the challenges facing the health, social care, and wellness sectors (Taylor 2015). TEC offers the potential to enable more effective integration of care, including palliative care across the care continuum (Taylor 2015). As digital technology is advancing exponentially and its costs are rapidly falling, there are real opportunities to deliver safer, more efficient, and cost-effective care (Taylor 2015). For example, in one study, TEC solutions reduced community nurses' paperwork by 60% and increased their face-to-face time with patients by 29%, which enabled community nurses to see two additional patients per day (Taylor 2015). The right TEC solutions can also empower patients and carers by giving them more control of their health, making them less dependent on health professionals for information (Taylor 2015). The development of health-care biosensing wearables, such as digital blood pressure monitors

and glucose sensors, provides patients and their health professionals with real-time health-care data (Taylor 2015). Many of these features are now being incorporated into smart phone technology (Taylor 2015). However, this disruptive technology requires health-care professionals to work differently and to exploit such capabilities fully to improve care outcomes.

Telehealth enables clinicians to assess or monitor patients remotely from another health-care setting using videoconferencing or other technologies. A recent Australian pilot study demonstrated the feasibility of using a telehealth-based model of palliative care, which included patients entering self-reported data into the telehealth system (Tieman et al. 2016). Any changes in the patient's performance or symptom distress can trigger a service alert and prompt the service provider to contact the patient using videoconference, phone, or a face-to-face visit (Tieman et al. 2016). However further research is needed to identify the optimal time to introduce telehealth for community-based palliative care patients and whether a reduction on data entry ought to be considered as a proxy measure alerting clinicians that the patient may be deteriorating, prompting contact (Tieman et al. 2016). Despite these challenges, telehealth offers real opportunities to reduce disparities in access by thinking creatively about how to use existing services and resources to better support patients and families with palliative care needs living in the community.

2.8 Building Community Palliative Care Capacity

Involving consumers in the planning, co-creation, and delivery of health-care policy has long been advocated by the WHO (1978). This advocacy is primarily because community engagement enables communities and services to collaborate to understand local needs, to build capacity, and to address local palliative care issues (Sallnow and Paul 2015). At a minimum, it involves informing and consulting through to more active engagement such as co-production, collaboration, and empowerment which occurs when there is a desire for individual or collective change, signalling a transition to community development (Sallnow and Paul 2015; Noonan et al. 2016). As the demand for palliative care increases, there are opportunities to better engage communities and informal caregiving networks in the provision of palliative care. Consumer advocacy is required to ensure that the funding, availability, and accessibility of palliative care services are guaranteed, regardless of whether care is provided in primary, acute, or aged care settings. However, there are many barriers to effectively engaging consumers, ranging from managing stigma, language, and cultural differences. Acknowledging these barriers is essential to ensure successful consumer engagement and requires the employment of targeted strategies that address the lack of infrastructure support of organizations, lack of organizational skills or confidence, consumer skills deficits, limited opportunities for input from disadvantaged groups, weak links between providers of health information and recipients, and dissemination of information without consumer input (National Health and Medical Research Council 2006). Despite these challenges, authentically engaging consumers in palliative care reforms and initiatives offers the potential of determining the best use of scarce resources and creating services that best serve the population's unmet palliative care needs.

Engaging community members in palliative care delivery also helps foster death literacy, which is considered to be the net result of people's experiences of, and learnings about, death and dying making it an essential for a public health approach to palliative care (Noonan et al. 2016). Death literacy marks a shift away from relying solely on resource-intensive service delivery models toward more integrated models of care, where communities are engaged and reorientated to becoming more responsive to death, dying, loss, and bereavement (Noonan et al. 2016). Death literacy enables community members to more effectively manage the death of a close family member or friend at home in a way that is not entirely dependent upon the traditional palliative care model (Noonan et al. 2016). Community members with death literacy are able to build their

knowledge and skills and activate community resources in a timely and appropriate way to meet the dying person's and their family's needs.

There will be few general practitioners and community-based palliative care clinicians, especially nurses, who have not contributed to death literacy, as they walk with a patient and family, and provide practical suggestions to enable them to manage to spend as many days as possible at home. In many communities, a lack of resources but strong social cohesion facilitates greater involvement of community members in informal carer networks. This network of informal carers often provide additional physical, emotional, or spiritual care and often take on important practical tasks such as picking up children from school, taking them to before or after school activities, cooking meals, helping with laundry, shopping, and driving. A home death may be a community event where each person within the patient's carer network has an important role to play and is valued for their unique contribution (Noonan et al. 2016).

Death literacy provides a framework for effectively engaging communities in the planning and delivery of a palliative approach to care, through the acquisition of knowledge and skill from experiential learning, which often leads to social action (Noonan et al. 2016). However, the effective engagement of informal care networks will require many palliative care services to reevaluate their organizational values, recognize and value the primacy of caring networks, and address any inherent paternalism in health-care provision (Rosenberg et al. 2017).

Access to palliative care is also shaped by a range of cultural and social barriers, which makes addressing death and dying misconceptions a global concern (World Health Assembly 2014). Understanding cultural differences and responding appropriately will become increasingly relevant given global mobility. This is especially the case as end-of-life communication, preferences, and palliative care knowledge among first nation people and cultural and linguistically diverse populations are likely to differ from the majority of views reported from largely white English-speaking populations (Eneanya et al. 2016).

China is the most populous country in the world with a population of 1.3 billion and has one of the most rapidly expanding global economies. Despite its rapidly ageing population and cancer being the leading cause of death, there are few established palliative care services in mainland China (Li et al. 2011). Many of the 4.3 million mainland Chinese diagnosed with cancer in 2015 presented with very advanced disease and had significant palliative care needs, yet only 0.7% (146/22,000) of hospitals offer palliative care (Li et al. 2011; Wei and Ping 2017; Yin et al. 2017). Mainland China's slow adoption of palliative care has been shaped by a combination of factors including the country's focus on strengthening acute care services and the communities deeply held cultural beliefs about death and dying, filial duty, and social biases (Li et al. 2011; Wei and Ping 2017; Yin et al. 2017). Collectively, these factors have contributed to China being ranked 71 out of 80 countries in a recent global quality of palliative care study (The Economist Intelligence Unit 2015). A lack of national policy, guidelines, and financial support and limited professional opportunities to build health workforce capabilities have been identified as major barriers to developing palliative care in China (Hu and Feng), which the country is endeavoring to address (Hu and Feng). However, an even larger hurdle is addressing the public's misunderstanding about palliative care, dying, and death (Wei and Ping 2017). The intangible cultural factors surrounding the need to talk about and build service models designed to address unmet palliative care needs are one of the greatest palliative care challenges currently facing China (Health Intelasia 2013). Initiating death and dying conversations is difficult, and China's challenge is not that different to those experienced in other parts of world where individual autonomy is highly valued and death is feared. However, there are real opportunities to address these significant challenges by raising public awareness about the role of palliative care in minimizing suffering and maximizing function and well-being (Wei and Ping 2017) and through targeted policy, funding, and education initiatives (Hu and Feng).

2.9 Implementation of Best Evidence-Based Palliative Care

Good policy is underpinned by the best available evidence, program management experience, and political judgment (Head 2007). Yet, all too often, policy is implemented without being informed by evidence or consideration of how it will be operationalized or for political expediency. A recent example of palliative care policy that was implemented in an evidence void is the rapid rollout of the Liverpool Care Pathway firstly in the UK and its subsequent adoption in other parts of the world, prior to it having been adequately evaluated (Chan et al. 2014). Conversely, the lack of availability of opioids for palliative care patients in many parts of the world is an example of another evidence-based policy gap (Human Rights Watch 2011; Saini and Bhatnagar 2016). Despite there being abundant evidence of opioids being highly effective for cancer-related pain (Wiffen et al. 2016) and other symptoms (Ekstrom et al. 2017), it is not yet universally available for those in need (Human Rights Watch 2011; Saini and Bhatnagar 2016). However, there is too little evidence about how best to address community concerns about the illicit use of opioids and the wider ramifications for society or how a rapid opioid access program for palliative care could be feasibly established within the constraints of the existing social and health legislative and policy frameworks (Human Rights Watch 2011). Failure to consider and address these additional elements will continue to challenge the ability of countries to make opioids more widely available for those in most need of strong analgesics – palliative populations. The resulting suffering is unacceptable in a compassionate world.

Another policy failure is allowing palliative care patients to be ordered off-label medications for which there are no known optimal doses or no evidence supporting their use (To et al. 2013; Masman et al. 2015). This is especially the case when little is known about the adverse effects of these medications in this population, how they interact with other medications for chronic illnesses that the patient may be taking, or their functional impact on patients (To et al. 2013). As palliative care patients are at high risk of adverse effects from drugs, more prospective trials and pharmacokinetic and pharmacodynamics studies are needed to understand the place of various off-label medications that are often cited in consensus-based symptom management guidelines and frequently prescribed. Of the recent adequately powered, well-designed randomized controlled trials that have been completed on medications commonly prescribed for the management of common palliative care symptoms, several have been found to be ineffective and were actually noted to cause clinically significant harms (Hardy et al. 2012; Agar et al. 2015). Implementing this evidence into practice is essential to ensure that patients are not harmed unnecessarily.

In Australia over the past decade, the Palliative Care Clinical Studies Collaborative (PaCCSC) exemplifies the importance of both building and implementing the palliative care evidence. Over the past decade, this collaborative has completed nine phase III clinical trials. A need to encourage the reporting of adverse drug events prompted the development of the PaCCSC Rapid Pharmacovigilance studies, with more than 90 centers in 18 countries now participating (Currow et al. 2011). Collectively, the outcomes of the PaCCSC palliative care trials are improving the well-being of people with life-limiting illnesses, changing clinical practice as well as advancing health professionals' practices, influencing global policy, and helping to reduce unnecessary harm and waste within the global health-care system. Despite this incredible progress in such a short period of time, there is still much to be done in terms of building the evidence and preventing the inappropriate prescribing and administration of medications at the end of life. While this collaborative research model now exists in the USA and Japan, there are opportunities for this model to be replicated elsewhere to help accelerate the development of new palliative care evidence and to implement existing evidence into practice.

Just as there is an urgent need for all palliative care policy to be underpinned by robust evidence, sound program management, and informed political judgment (WHO and World Bank 2013), a greater investment in developing the evidence

base that will positively influence and inform appropriate policies globally is also required. Access to evidence-based treatments is dependent upon the generation of evidence backed by policy, creating an environment where the implementation of the best available evidence is expected (Rowett et al. 2009). As the palliative care evidence base increases (Tieman et al. 2008), there is mounting pressure for policymakers to integrate this evidence into policy that will inform clinical behavior. For example, policy at the national and local levels is required to halt the widespread practice of off-label prescribing of medications for palliative care symptoms where robust evidence now exists. The development of the evidence base for the use of off-label medications is required so that more patients have access to these medications if deemed effective or are not exposed to unnecessary harms if found to be ineffective for the symptoms they are prescribed for (Rowett et al. 2009). Funding these studies will most likely need to come from government or philanthropic sources as they are unlikely to appeal to the pharmaceutical industry, especially if the medication of interest is off-patent.

2.10 Measuring What Matters Most to Patients and Their Families

For the past 25 years, people with palliative care needs and their families have consistently reported what matters most to them in terms of end-of-life care: effective communication and shared decision-making, expert care, respectful and compassionate care, and trust and confidence in clinicians (Virdun et al. 2015). The final domains differed between patients and families, with financial affairs being important to families, while an adequate environment for care and minimizing burden are ranked equal fifth as being important to patients (Virdun et al. 2015). "Not being a burden" requires that palliative care services focus much more on maintaining a person's physical function and physical independence for bathing, toileting, dressing, and preparing food for as long as possible as a specific goal of care.

A recent review of available evidence highlights the varied approaches used globally for quality measurement of end-of-life care and noted that the care domains rated most important by patients and families are rarely covered (Zwerink et al. 2014). It also identified that only 5 out of the top 10 countries ranked in the "quality of care" category of the 2015 Quality of Death Index study (The Economist Intelligence Unit 2015) have national indicator sets, with only two indicator sets suitable for use by all service providers. No countries currently mandate indicator use, and there is limited evidence of consumer engagement in the development of indicators (Virdin, Luckett et al. under consideration – 5 August 2018). Two thirds of the 128 identified indicators were outcome measures (62%) with the remainder being process measures. Most indicators focus on symptom management (38%), social care (32%), or care delivery (27%) (Virdin, Luckett et al. under consideration – 5 August 2018).

A better understanding of who is missing out on palliative care and who most would benefit from accessing this type of specialist care is crucial to improving care outcomes (Currow et al. 2008a). However, until recently, few health-care services globally have endeavored to measure the degree to which their services are meeting their palliative care patients' and families' needs. Integration of quality palliative care indicators and measures across the health-care system that are relevant for use in low-, middle-, and high-income countries is required to demonstrate the value of this type of care. Without robust measures and agreed use, it will be difficult to demonstrate the impact palliative care has on patients and families, which has been a major driver for several outcome-related initiatives, like the development of the Palliative Outcome Scale (POS) (Collins et al. 2015) in the UK and the establishment of the Palliative Care Outcomes Collaborative (PCOC) in Australia (Currow et al. 2008b).

The POS has more than 8000 registered users in 126 countries and is an example of an instrument that is able to compare palliative care needs and quality of care across diverse contexts and patient groups (Collins et al. 2015). The Palliative Care Outcomes Collaborative (PCOC) is the first

national voluntary benchmarking system, funded since 2006 by the Australian government (Currow et al. 2008b). The rollout of the PCOC program over the past decade has enabled 80% of Australians seen by specialist palliative care services to have point-of-care service delivery data collected from their initial referral until their death (Currow et al. 2012). The use of PCOC's suite of standardized clinical assessment tools enables palliative care patients' outcomes to be measured and benchmarked, allowing services to reflect on their practice and to strengthen care practices in areas of need.

Perhaps one of the final great challenges facing palliative care globally is to be able to demonstrate that this type of care makes good economic sense. Research across high-income countries has consistently demonstrated that people who receive palliative care compared with those receiving usual care have less hospitalizations, shorter lengths of hospital stay, reduced use of intensive care units, and fewer emergency department visits (Smith et al. 2014; Palliative Care Australia 2017). Cost savings from palliative care interventions occur across a number of settings including delivery at home, in hospital, and in residential aged care, for cancer and non-cancer life-limiting illnesses and early versus late delivery of care (Palliative Care Australia 2017). However, it is imperative to expand the scope of economic evaluations to more fully understand and recognize the role palliative care plays in enhancing value in health care and improving the quality of life for people accessing this type of care (McNamara et al. 2013). However, a notable gap is our understanding how cost shifting from the health-care setting to the community impacts on family finances, especially given the financial toxicity of living with an advanced progressive illness (Zafar and Abernethy 2013).

In considering the net effects of palliative care on the health of the population, consideration needs to be given to the health and well-being of caregivers while providing care for a family member or friend and after having completed the caregiving role. The long-term health outcomes for caregivers need to be demonstrated to be better as a result of the involvement of palliative care. Without this broader benefit, palliative care will not realize its full potential (Abernethy et al. 2008; Burns et al. 2017).

3 Conclusion

Addressing the top 10 challenges facing palliative care is critical to improving global palliative care outcomes. A combination of scientific, technological, and pharmacological advances, population ageing, and growing community expectations will continue to challenge access to palliative care globally. The challenges that need to be immediately addressed if more of the world's population are to have access to evidence-based care are to:

- Ensure everyone has access to essential medications, including opioids for the management of pain and breathlessness.
- Implement universal health-care coverage in all countries without this coverage.
- Build the palliative care capacity of the existing health workforce.

Enhanced and expanded access to palliative care requires greater attention to ensuring all future models of palliative care are underpinned by a public health approach to care and embedded into a country's existing health-care delivery and accreditation systems. This includes a very specific focus on upskilling the primary care workforce. Rapid and sustained efforts in education, financing, and health systems management are required to prepare the health workforce to meet the palliative care needs of a growing and ageing population living with serious and complex chronic illnesses. Palliative care leaders need to work collaboratively to identify the areas of greatest need and evaluate the impact of policies intended to support palliative care. Adopting a public health approach, embracing novel technologies, and better engaging communities offer real opportunities to increase palliative care access globally.

Abstract

The person who presents to the clinician in the palliative care setting is not only afflicted by physical symptoms. They bring with them a complex, rich but often disabling tapestry of psychological symptoms as well as social disruption and existential or spiritual symptoms, such as loss of identity, meaning, and purpose. Exploring these various aspects that are framed within the biopsychosocial-spiritual model seeks to address all potential interests, worries, and questions of the person and provide a full "scientific" picture of each individual. This is a fundamental aspect of palliative care, to enable and support the whole person to be supported in living with a terminal illness.

1 The Biopsychosocial Model

In the late 1970s, George Engel (1977, 1981), a New York psychiatrist, proposed an alternative, hypothesized model of healthcare that acknowledged and inquired about more than the biological symptoms of the patient: the landmark biopsychosocial paradigm hinted at what we now identify as holism, which includes the psychological and social perspectives alongside the biological (Smith 2002; Sulmasy 2002; Weiss 1980).

In a response to what Engel saw as the paternalistic, somewhat cold, technical, biomedical approach of doctors toward patients, he proposed a more empathetic view accentuating human warmth, understanding, generosity, and caring, all based on the subjective experience of the patient. This biopsychosocial model encouraged an individually tailored approach toward individual patient care, linking science and a humanistic approach (Smith 2002).

2 The Biopsychosocial-Spiritual Model

In the 1990s, spirituality was cautiously added to the model, therefore becoming the biopsychosocial-spiritual model (Borrell-Carrió et al. 2004; McSherry and Jamieson 2011; Sulmasy 2002). This holistic model acknowledges that a person is made up of biological, psychological, social, and spiritual aspects: each facet relationally interacting and affecting the other (McSherry and Jamieson 2011; Sulmasy 2002). The biopsychosocial-spiritual model of health helped to articulate that well-being was associated with health across all of those dimensions. Conversely, suffering occurred when any of these domains are affected.

The term spirituality has its historical roots within a religious context (Muldoon and King 1995). For many people, this link with religion is maintained, and many use terms such as spirituality and religion almost interchangeably (Sloan et al. 1999). In more recent times, this view of spirituality as the domain of one or even any religion has been increasingly challenged. Many people now take the view that religion and spirituality are related but separate concepts (Sulmasy 2002; Edwards et al. 2010; Selman et al. 2011; Chochinov and Cann 2005). In this view, a person's spirituality can be expressed in many contexts outside a formal or even informal religion and acknowledges that spirituality means different things to different people (Egan et al. 2011).

A review of publications dealing with spirituality and end-of-life care has identified several dominant themes including transcendence both in relation to self and a higher being, a sense of communion or connection, faith or beliefs, and hope (Vachon et al. 2009). Transcendence is

defined variously, but the central issue is of "going beyond" our physical selves (Zinnbauer et al. 1999). Although it may be expressed within the context of a relationship with God or the sacred, it may also be about nature, art, music, family, or community (Puchalski and Romer 2000). In this broader view of spirituality, it is most commonly conceptualized in terms of those aspects of life that lie at the core of a person's identity and direction and may be understood at an individual or a population level. These aspects include the beliefs, values, activities, and relationships that provide meaning and purpose for life (Egan et al. 2011).

These issues of meaning and purpose have long been regarded as central to the concept of spirituality. Early proponents of the importance of existential or spiritual issues in suffering and resilience such as Viktor Frankl suggested that meaning and purpose lie at the heart of spirituality (Frankl 2006; Muldoon and King 1995).

What emerges from this literature is that while it is very difficult to reach consensus, spirituality can be broadly defined as an experience that incorporates a relationship with the transcendent or sacred that provides a strong sense of identity or direction which not only has a strong influence on a person's beliefs, attitudes, emotions, and behavior but is integral to a sense of meaning and purpose in life.

3 Symptoms and the Biopsychosocial-Spiritual Model

Therefore, the person who presents to the clinician is not only afflicted by physical symptoms such as intractable pain or breathlessness but brings with them a complex, rich, but often disabling tapestry of psychological symptoms such as anxiety, depression, hopelessness, guilt or fear, social disruption, and existential or spiritual symptoms such as loss of identity, meaning, and purpose (Beng 2004; Ellis and Lloyd-Williams 2012; Sulmasy 2002).

This biopsychosocial-spiritual model, with all aspects interacting equally, accommodates all potential interests, worries, and questions of the patient, providing a full "scientific" picture of each individual (Kelly 2012; Smith 2002). This is a fundamental aspect of palliative care, to enable and support the whole person to be supported in living with a terminal illness. Accompanying this is the need to ensure effective communication with all concerned.

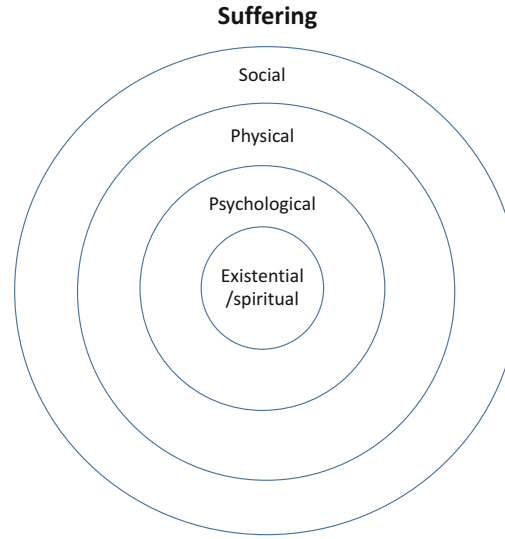

Fig. 1 The totality of suffering

Any existential crisis of being, meaning, and purpose brings spiritual pain and disconnectedness to the forefront within palliative care trauma (Burke and Neimeyer 2012; Puchalski 2002). The hearing of a terminal prognosis can confront an individual with the reality of nonexistence. It is therefore not surprising that some consider this the essence of spiritual pain.

4 Symptoms: Looking Before and After

Symptoms of course do not occur in isolation. By nature, symptoms are indicative of disease. Much of medical training is devoted to recognizing symptom clusters that indicate the presence of a specific disease that can then be treated. By definition, a primary focus of palliative care is palliation – symptom management. In fact, there can often be frustration at other professionals who, for a variety of reasons, encourage ongoing treatment when cure is no longer likely and

palliation and support are more appropriate. The transition from cure to palliation is not an easy one for the health practitioner or the person affected.

Although this transition is an important one, it is also important to not let go completely of that model which relies on symptoms to identify a treatable cause. Although the symptoms may be generally due to a cancer or another disease which is no longer treatable, they may be due to a specific pathology that is. For example, with someone with cancer and back pain, identifying the fact that the pain is due to vertebral metastases may have very specific implications for how it is managed. Therefore, although in some circumstances a decision may still be made against providing treatment, the first step in symptom management is to identify the underlying cause of the symptom.

Having done that, if it is decided that the focus of treatment is symptom management, then the next step is appropriate and skilled management of the presenting symptom. As described in the following chapters, there are evidence-based approaches and guidelines that can be applied to assist the person with these particular symptoms.

However, it is to be hoped that assessment and treatment do not stop with that specific symptom no matter how successful. Symptoms not only have a cause; they also have an impact. The impact affects the whole person: (a) physically through specific symptoms and general debilitation; (b) psychologically through depression, anxiety, fear, anger, hopelessness, etc.; (c) existentially or spiritually through the impact on identity, meaning, and life purpose, and (d) socially through the impact on relationships.

In the case of pain, this means not just identifying and assessing the cause and intensity of the pain and prescribing an analgesic but exploring the psychological, social, and spiritual/existential issues associated with the pain. All of these together make up potential suffering or, as Cicely Saunders termed it, "total pain."

Robert Twycross (1995) wrote descriptively about aspects of what had earlier been identified as the components of total pain. In illustrating the four principal dimensions of this symptom, he wrote about anger at delays in diagnosis and treatment, at therapeutic failure, at disfigurement, and at feelings of helplessness (psychological). He described worries about family, finances, job prestige, and income and feelings of abandonment and isolation (social). He described physical symptoms relating to illness, adverse effects of treatments, and the fatigue that follows the debility associated with disease progression (physical). Finally, he suggests that people ask: Why is this happening to me? Why now? What's the point of it all?" - in other words, spiritual distress.

Eric Cassell (1991) writes about suffering in similar terms – that is, in having many dimensions – although all may be viewed as making a whole person and any impending destruction or disintegration of the person may lead to suffering.

He writes of our inability to reduce a person to their parts in order to better understand them but to acknowledge that we all have certain features which define us. We have personality and character. We have a past, life experiences, a family, and a cultural background. Each person has roles, and none of those roles really exist without others; we have relationships that allow expression of happiness, anger, gratitude, and many other emotions. It is within relationships that we express our sexuality. We have relationships with ourselves and with others; we are political; we do things; we have behaviors; we have a secret life and a perceived future; and every person has a body, and everybody has a transcendent dimension. When one or another of these parts begins to peel away from the whole – disintegration – then perhaps that is when we begin to suffer. So, it is really impossible to reduce suffering without at least identifying and acknowledging these many facets of what it is to be human.

When looking at the management of symptoms, we need to at least try to envisage who this person is – in all their dimensions. Is there anything to suggest loneliness? How will this affect each symptom? The realization that one's future is

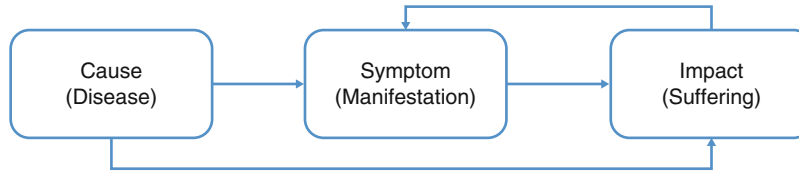

Fig. 2 Holistic view of a problem

short and is dissolving rapidly brings with it fears, anxieties, concerns, and even despair. There is often an acute awareness of the finitude of life and, with that, a sense of powerlessness and even at times a loss of meaning.

Palliative care is therefore more about moving toward the impact of the disease and its symptoms than treating its cause. It therefore calls for an approach that is holistic and that does more than merely treating symptoms but sees the impact of both the disease and its resultant symptoms on the person in their entirety. At the end of life, people present with a constellation of physical, psychological, social, existential, and spiritual issues that call for consideration on their own merits.

5 The Symptom of Pain

5.1 Pain as a Symptom

Pain is one of the most common presenting symptoms in palliative care, and the following section of this textbook contains a chapter which very thoroughly covers the management of pain as a symptom. It is not our intention to provide another overview of managing pain but rather to use pain as an example of the holistic approach that we have described so far.

5.2 Pain Is More Than a Symptom

In essence, pain has traditionally been regarded as a symptom. What this means is that pain is indicative of a disease process that needs to be fixed. While pain needs to be relieved, the main focus is identifying the cause so that the pain may be removed.

This traditional view of pain as a symptom works well in the management of acute pain. If we are working in the emergency department and someone presents with colicky abdominal pain or severe pain in a limb following a fall, it is appropriate that efforts are put toward determining the cause of the pain so appropriate treatment can be instituted. In this situation, pain as a symptom merely acts as a warning sign that something is wrong and needs to be fixed.

However, this traditional view of pain as a symptom has been questioned (Siddall and Cousins 2004). In the field of pain medicine, there has been a move to see pain not just as a symptom but as a disease in itself. This view is based on two underlying facts. One is the growing understanding and recognition of the multitude of physiological changes that accompany the sensation of pain. These changes extend from receptor changes in the periphery through to neuroplastic changes in the brain. This knowledge argues against the concept that the sensation of pain is simply due to activation of a peripheral receptor which is transmitted and then finally perceived as pain. These changes not only modify and modulate the transmission of sensory information which has a profound impact on pain, but they may also result in long-term changes that are responsible for the continued perception of pain even when there appears to be no noxious inputs.

5.3 Biopsychosocial Model

The second fact that underlines the limitations of viewing pain as a symptom is the growing incorporation of the biopsychosocial model of pain. Like palliative care, pain medicine has been a strong adopter of the biopsychosocial model, and it has become the dominant framework for

the understanding, assessment, and treatment of persistent pain (Keefe and France 1999; Loeser and Melzack 1999; Turk 1999).

Viewing pain as a symptom runs the risk of a singular focus on the physical and biomedical at the expense of the psychological and social. This approach is almost acceptable in the emergency department. However, it is hopelessly inadequate for almost any situation where pain lasts for more than 3 months or for where pain is accompanied by other issues which profoundly affect a person's psychosocial milieu, of which end of life is a prime example.

This incorporation of the biopsychosocial model means recognizing the bidirectional nature of these multidimensional interactions. Pain, as we have said, is not just a symptom that is merely registered by the brain. It has an impact. This includes the physical with increase in heart rate, blood pressure, and muscle tone. It includes the psychological with fear, anxiety, frustration, and depression. It includes the social with withdrawal or seeking help on one side and solicitousness, fear, and possibly helplessness on the other. Therefore, treating pain as a symptom means not just identifying its presence and intensity and relieving it but identifying and managing the secondary issues that almost invariably accompany pain in a myriad forms. This is a challenge, but treatment that does not recognize and address the impact on all these areas is likely to be incomplete.

5.4 The Addition of the Existential/Spiritual

The biopsychosocial model has been a major advance in many fields including the management of pain. However, as mentioned above, there has been a move to incorporating the existential and spiritual as an addition to this model. In the palliative care field, Cicely Saunders was an early advocate for the inclusion of the spiritual and the concept of "total pain."

So much has been written about Cicely Saunders and the concept of total pain that it is worth reviewing how that concept came about. Saunders was a meticulous keeper of records and recordings that give us insight into the ideas that she developed over time. As early as 1959, she wrote "Much of our total pain experience is composed of our mental reaction. . .." Saunders developed her ideas and published continually in order that the general readership could be alert to her findings. By 1964a she had more clearly articulated what later became the notion of "total pain" by describing an encounter with a patient. ". . .She said, 'Well doctor, the pain began in my back, but now it seems that all of me is wrong.'. . .And then she paused before she said, 'But it's so wonderful to begin to feel safe again.' Without any further questioning she had talked of her mental as well as physical distress, of her social problems and of her spiritual need for security." That phrase "all of me is wrong" is used later to introduce the concept of "total pain" that has become one of the hallmarks of palliative care practice (1964b) (All of this information comes from David Clark's manuscript "Total pain," disciplinary power and the body in the work of Cicely Saunders, 1958–1967. *Social Science & Medicine* 49 (1999) 727–736.).

5.5 The Biopsychospiritual Model and Pain

Although the field of palliative care has been a leader in advocating and using a biopsychospiritual model, it is increasingly recognized that it is a helpful approach in managing pain (Wachholtz and Keefe 2006; Büssing et al. 2009; Rippentrop 2005; Wachholtz et al. 2007). One of the possible reasons for its strong adoption in the palliative care field is the awareness of the importance of existential issues such as meaning and purpose which can loom larger in those facing death. Not surprisingly, studies that have examined these issues have found that spiritual well-being is profoundly impacted in people with cancer or HIV/AIDS (Boston et al. 2011).

While there are a large number of studies going back some time in the palliative care field that look at spiritual and existential factors, there are relatively few in the field of pain medicine. However, there are now several studies that indicate that spiritual or existential well-being in people

with chronic pain is impacted to the same extent as those who have cancer and are facing the end of life (Siddall et al. 2017).

These findings indicate that not only does pain have an impact physically, emotionally, and socially but it also has a profound impact on existential issues such as meaning and purpose. This highlights more strongly the importance of identifying and assessing these issues as part of the assessment of pain.

5.6 Addressing the Existential and Spiritual

It has been demonstrated that those with higher levels of spiritual well-being are more optimistic and have higher levels of self-esteem and higher levels of function (Cotton et al. 2006). This research in the palliative care field now overwhelmingly supports the importance of addressing spiritual issues in people facing a terminal illness (Cotton et al. 2006). This has led to the exploration, trial, and use of treatments that specifically seek to address spiritual issues (Breitbart and Heller 2003; Breitbart et al. 2010; la Cour and Hvidt 2010).

Recent evidence suggests that the use of spirituality and religiosity can be regarded as an active and positive coping process with beneficial effects (Büssing et al. 2009). For example, those who deal with persistent pain using positive spiritual coping practices such as looking to God for strength and support adjust better to pain and have significantly better mental health (Bush et al. 1994; Rippentrop 2005).

Religious and spiritual coping strategies are associated with feelings of spiritual support and connection as well reduced depression and anxiety and a greater sense of peace and calm. This may be due to a number of factors including the ability to ascribe meaning to the suffering, increased self-efficacy, spiritual and social support, distraction, relaxation, and positive reappraisal (Wachholtz et al. 2007; Dezutter et al. 2011).

The overall evidence suggests that spiritual well-being has a stronger link with higher pain tolerance and higher levels of psychological well-being including satisfaction with life (Moreira-Almeida and Koenig 2008; Dezutter et al. 2010).

5.7 Suffering

In talking about these issues, it can also be seen that the further we get from the symptom, the more general the impact. This total impact is what we often refer to as suffering. While pain and suffering are often linked, most physical symptoms will be associated with suffering. This combination of symptoms leads to suffering, and in the end, the relief of suffering – in all its dimensions – is the primary goal of the health professional caring for those at the end of life.

Although the relief of suffering has always been a goal of physicians, Eric Cassell brought suffering to the fore in medicine with his landmark paper (1982) and subsequent book (1991). He writes eloquently about the disintegration of the self and injuries to the integrity of the person that can be manifest as sadness, anger, grief, and withdrawal. However, he points out that these are merely outward expressions of injury, pain, and disintegration and if the injury is sufficient, then the person suffers. By attending to the meaning of such suffering and perhaps assisting patients to transcend it, Cassell suggests that such suffering (associated with the destruction of those aspects of personhood) may be ameliorated. To quote Cassell, "Transcendence is probably the most powerful way in which one is restored to wholeness after an injury to personhood" (p. 644) (Cassell 1991).

This recognition that all symptoms result in a shared impact on our psychological, social, and existential or spiritual selves argues for a layered approach that seeks first to identify physical symptoms as a totality and then explores the psychological, existential, spiritual, and social impact. It also means identifying management strategies that address each of these secondary issues independent of the presenting symptom. For example, while there is evidence to support the use of psychological approaches in managing pain, most of these are not specific to pain and may have limited impact on the intensity of pain.

Therefore, it could be argued that we should do our best to treat the physical aspects of each symptom first and then address the other symptoms that may accompany it.

6 Management of Some Other Symptoms

6.1 Breathlessness

Another symptom that lends itself to a holistic management approach is breathlessness. Historically, the assessment of breathlessness has tended to focus on the physical attributes of that symptom and has necessarily focused on the physical or sensory features, without including psychological reactions and subjective observations.

It is often suggested that the most effective treatment for breathlessness is prevention, so attention to the detail of the nonphysical dimensions of this complex symptom is essential. Breathlessness can be seen as a global symptom, but deconstructing the symptom is often helpful in its management. Adaptive breathing patterns are built up often over months or even years, and those patterns become familiar to each individual.

For each individual, however, there can be a disjunction between the rate and depth of breathing so that the health professional can remain confused by mere observation of breathlessness. Psychosocial therapies involved in the management of breathlessness not only rely on an understanding of an intensity measurement which shows the quantity of breathlessness, but attention must be paid to the *quality* of breathlessness in order to help to recognize the most appropriate therapeutic intervention. Skevington et al. (1997) underlined the potential value of the linguistic qualities of breathlessness, designing a scale of breathlessness that was proposed to help to direct the therapy to the most appropriate quality. Those authors reinforced the understanding that breathlessness was not purely a sensation but included significant affective and evaluative features. They also showed that breathlessness included a distinctive, consistent, but relatively small component of low energy which had often been subsumed within physical sensations in other studies (Table 1). One outcome was that asking the question "How would you describe your breathlessness today?" can prove useful in helping to identify the most helpful therapeutic intervention. For example, if a person describes their breathlessness by using descriptors such as frightening or panicky, then it is proposed that adopting a more psychological approach could be beneficial.

Table 1 Structure for a scale of breathlessness

1. Physical sensations
2. Affective/evaluative
3. Low energy
4. Hyperventilation
5. Speechless

Similar observations had previously been made by Kinsman et al. (1974, 1977) when exploring breathlessness in people with asthma. Their original studies focused on two *mood* symptom categories and two *somatic* categories, and this work was elaborated in later studies identifying categories of breathlessness and congestion alongside three secondary mood categories, worry, loneliness, and anger.

6.2 Exploring the Impact of Breathlessness

The process for identifying an appropriate approach to psychosocial management of breathlessness could include a number of elements (Corner et al. 2016):

1. An exploration of the *meaning* of breathlessness for the patient and family and the feelings associated with that meaning. This includes asking how those people respond to breathlessness psychologically:
   What fears do they have?
   – One of the most commonly held fears is that the patient will choke to death or suffocate.
   What has been lost by the development of breathlessness?
   – Loss of control, independence, or physical function is often seemingly relentless.

What degree of control do those people feel they have?

– They may feel that health professionals have control with the use of medications, or they may feel that their breathing controls them rather than the other way round.

Do they feel responsible in any way for their breathlessness?

– Exploration of their lifestyle before illness and any "blame" attached to that for the development of their breathlessness.

How do they respond to feelings of panic, anger, loneliness, or worry?

– Most people have learned coping strategies for similar emotions throughout their lives that may not be relevant or effective in this situation.

What are their hopes for future management of breathlessness?

– Is their hope realistic or are they hoping for an impossible cure?

What goals do they have for their future?

– Again, goals for the future must be set in realistic terms.

How can they see themselves developing greater control of their breathlessness?

– This can be a most effective way of rebuilding hope.

6.3 Case Histories

Pat was a 28-year-old woman with a neuroendocrine tumor that progressed rapidly. Throughout her involvement with the hospice team, her predominant symptom had been severe bone pain in multiple sites. About 3 weeks prior to her death, she developed intermittent but severe breathlessness with coughing and retching. No physical cause was identified and her distress became intense. She described her breathlessness as "choking," "suffocating," and "as if I can't get my breath." Exploration of her fears revealed that she was indeed fearful of suffocation, and ultimately she was able to confide in one of the team that she had previously been in an abusive relationship where her partner had tried to strangle her. Discussion of this with reassurance that there was no reason for her to choke or suffocate led to a dramatic reduction in her perception of breathlessness. Despite the later development of a bronchopneumonia, she never expressed feelings of breathlessness in such distressing terms again and remained in control of her breathing until she became unconscious prior to death.

James was a 72-year-old clergyman with chronic obstructive pulmonary disease who was steroid dependent and required continuous oxygen therapy when he was first seen by a hospice team member. He was concerned that he was achieving nothing and had nothing to look forward to. On further inquiry it transpired that he had lost his faith and had serious doubts about his previously strongly held religious convictions. A variety of techniques for relaxation including imagery were discussed, and work with the spiritual care team helped him to make some sense of his doubts and fears. Over a period of 2 weeks, he learned the effectiveness of imagery for him and became more relaxed and confident – looking forward to participating in his family life. He was able to discontinue his use of oxygen. He talked of his feelings of guilt for some past events and achieved a sense of resolution and forgiveness for himself.

1. A process of education for both patient and family about the meanings, significance, and process of breathlessness

   This includes an explanation of how and why breathlessness has developed including possible psychosocial and behavioral risk factors (e.g., smoking). The anatomy and physiology of breathlessness can be outlined, if appropriate. An understanding of the normal mechanisms for the control of breathing can be a simple and effective way of empowering people with breathlessness. The efficiency and effectiveness of differing breathing techniques should be explained using examples of positioning, muscle groups involved in breathing, and rate and depth of respirations associated with the unlearning of any maladaptive techniques that may have already been utilized.

2. An acknowledgment that breathlessness may be a symptom that may never "come right" and therefore exploring more helpful ways of carrying out everyday tasks and activities

   This aspect of management should include a discussion about the difficulty of maintaining hope while the prospect of cure is no longer possible or likely. An acknowledgment that the professional carers have a commitment to the patient and family and the confirmation that the carers will not lose interest in them as the illness progresses.

   Other modes of therapy can be hugely influential in improving symptoms. Over 20 years ago, music therapy was identified as a useful adjunct in many aspects of palliative care. The discipline continues to develop as evidenced by international activity and development of techniques.

   Given that breathlessness has many dimensions, music therapy can be a useful adjunct in the management of this symptom. In this context, music therapy is the controlled use of music, its elements, and their influences on the human being to aid in the physiological, psychological, and emotional integration of the individual during an illness. It can act as a catalyst in mobilizing deeply held beliefs and feelings and can assist in communication. From a psychosocial point of view, it can help in identifying and reinforcing self-concept and self-worth, it can help to improve the patient's mood, it can help with recall of past significant events, and it can help in exploring fantasy and imagery. From a social point of view, it can act as a means of socially acceptable self-expression, recreating a bond and a sense of community with family members, as a link to the patient's life before illness, and as entertainment and diversion.

6.4 Art Therapy

Restoring creativity to the dying patient has been long held as an important goal of palliative care teams. As with music therapy, art can be used to help to promote a healthy and safe environment. It can be used as a diversion from pain and breathlessness. It can assist in rehabilitation and can help to build esteem. Where art therapists are not available, this role has been sometimes filled by occupational therapists and physiotherapists. An art therapist has the specific goal of helping patients express themselves with communication being the prime goal. The artist is concerned with the patient, and the artwork is the expression of that patient, nothing more. Patients can be encouraged to become actively involved in creating a picture or painting, or they can choose to watch others. Being part of a creative process can provide an escape from everyday life and can help individuals explore their creativity and have fun, which can often be a useful diversion from troublesome or distressing symptoms.

For the purposes of definition, art can include all forms of creative and interpretative expression. Other aspects of the arts, which have been used successfully in the management of symptoms near the end of life, include biography work, journaling, reminiscence therapy, and poetry. It has been suggested that we can express in written words things that we find hard to say, and so poetry and prose can have a significant part to play in the discovery of the journey toward the end of life. The arts can also provide a most effective means by which a legacy can be left for the family. During the preparation of such items, a focus on relieving symptoms such as breathlessness can be maintained.

Using some of these approaches, as part of a rehabilitative dimension to the management of pain or breathlessness, has been reported anecdotally by many as being useful in complementing a more medical approach.

6.5 Case History

Mary was a 54-year-old woman with widely metastatic breast cancer who became severely breathless toward the end of her life as a result of lymphangitis carcinomatosis. Discussion with her about discharge from the hospice in-patient unit led to a recognition that she was fearful of going home because of the severe limitations she

perceived her breathlessness would have on her activity and quality of life. She chose to express this in artwork in which she drew "her life." This work indicated to the therapist the areas of her life that she perceived as difficult, and she was able to eliminate some of these through discussion and planning. She later redrew her life with "boundaries" in place that she felt comfortable with, and her discharge was completed successfully. She was confident that she would remain in control of her breathing – this was the case until the end of her life, at home, some weeks later.

6.6 Nausea and Other GI Problems

Many other symptoms can be used to illustrate this multidimensional nature. People approaching the end of life frequently experience symptoms such as nausea, anorexia, progressive weight loss, and, in some, malnutrition. Because of the social nature of food provision and acceptance, these symptoms and signs can impact heavily on the relationship between patient and carer. Taste and smell abnormalities are reported in a majority of people with advancing cancer (Brisbois et al. 2006). People with cancer face a number of barriers to food intake that include phantom smells, persistent bad tastes, hypersensitivity to odors, and food aversions to the point of nausea. Sometimes, little if anything is done to address these issues, and yet they can have a significant adverse effect on quality of life. Merely providing medication either to reduce nausea or to attempt to stimulate appetite is often a futile gesture aimed to encourage patients and families that "something is being done." Family members may go to fairly extreme lengths to monitor food intake when someone is nearing the end of life – monitoring intake is accompanied by tempting with favorite foods and adjusting portion sizes. One study even identified force-feeding taking place (Meares 1997). Anecdotal evidence suggests that healthcare providers are frequently challenged by family members to "do something" to ensure adequate food intake. This challenge often has the spillover effect of making the patient feel uncomfortable or even guilty.

What we know however is that chemosensory changes take place when someone is dying and these may be produced by numerous micronutrient deficiencies, medications, infections, poor oral hygiene, dry mouth, etc. There is no easy answer to these problems, but acknowledging them is the first step to finding solutions. Much social and psychological disquiet and even distress can arise with seemingly simple "physical" symptoms such as nausea and anorexia, so addressing them and talking with patients and families is a first step to helping them understand. Decreased sensitivity for sweet and sour is common, but also an altered sensation for bitter has been reported (Mahmoud et al. 2011) Sensory enhancement of food may help (adding spices, flavors, herbs), but working with the family and patient to find a solution together may be the best option available (Brisbois et al. 2006). Findings from a Canadian study (McClement et al. 2003) suggest that family members' behavior regarding nutritional care is influenced by "the personal beliefs they hold regarding the patient's illness experiences." Some will "fight back" in the belief that is promoted by much mainstream media that cancer and/or death is something that needs to be "fought," "defeated," or "beaten." Such an approach (which may not be taken by all involved) can have a devastating effect on the morale of either the patient or the family. Differing beliefs between patients, family members, and healthcare providers need to be identified and worked through in order that conflicting expectations of treatment regimens do not arise which in turn may cause social and psychological distress. Such a step is important in order to develop an effective holistic plan of care.

6.7 Fatigue

Perhaps one other symptom that best illustrates multidimensional aetiology and effect is fatigue. Fatigue is ubiquitous in end-of-life care with a majority of patients experiencing it, but in some studies, it has been found that patients rarely discuss it because of a perception of doctors to offer effective interventions or patients' lack of

awareness of effective treatments (Passik et al. 2002). However, we know that fatigue is one of the most frequent symptoms that has a significant effect on quality of life, not only in people with cancer (where the fatigue may well be related to treatment) but also in nonmalignant diseases such as heart failure and neuromuscular diseases and HIV/AIDS. Physical fatigue prevents participation in many of the activities of daily living, whereas cognitive fatigue makes many activities more challenging; many fatigued people feel grumpy, irritable, listless, or depressed (Radbruch et al. 2008). The qualitative difference of cancer-related fatigue to fatigue in everyday life has been stressed; "Fatigue in cancer patients is a subjective feeling of unusual tiredness, affecting the body (physical), the emotions (affective) and the mental function persisting for several weeks and relieved only partially or not at all by rest or sleep" (Glaus et al. 1999). Correspondingly, various modalities for treatment have been suggested. Physical treatments include anti-cytokine or anti-inflammatory pharmacological approaches, but other modalities include cognitive-behavioral and psychosocial interventions including mindfulness-based approaches, yoga, acupuncture, and exercise. All of these latter modes will necessarily impact on psychosocial or spiritual dimensions of this symptom. These forms of management have not been tested in any rigorous way but may be useful in addressing the multifaceted reality of fatigue in these patients (Radbruch et al. 2008). Given that this is such a common symptom, it is necessary that research efforts are strengthened to identify the most effective forms of management for this most distressing and persistent symptom not just for people with cancer near the end of life but also for those with debilitating nonmalignant diseases. Energy must be used not just to find pharmacological interventions that are effective but also non-pharmacological modalities that will address the nonphysical dimensions of fatigue. In fact, a recent review indicates that exercise and psychosocial interventions are significantly better than pharmacological interventions in reducing cancer-related fatigue and should be regarded as first-line treatment (Mustian et al. 2017).

6.8 The Role of the Practitioner

This chapter has so far focused on the concepts underlying a multidimensional approach to the management of symptoms and how this applies to the person facing many of the common issues seen at the end of life. The chapter would not be complete without also discussing the role of the other key person in any health interaction: the health practitioner.

The health practitioner is of course the central bridge between the concepts and the patient. It is what the health practitioner brings in terms of knowledge, beliefs, values, and even capacity that determines the effectiveness of the therapeutic encounter. The practitioner who brings a singular focus on the physical symptoms of the patient's presentation may have success in treating those symptoms. However, there is a very good chance that they will leave the patient only partially treated and only partially satisfied. Even worse, it can result in depersonalization that results in the classical description of the case with breathlessness in Bed 14.

There is abundant evidence that the modern patient is left curiously underwhelmed by modern medicine. Despite the many advances in disease treatment and symptom management, there are a growing number of people who are skeptical and rejecting of what modern medicine has to offer. This applies at both ends of the life spectrum. Our media abounds with stories and debates of everything from rejection of childhood immunization to rejection of chemotherapy in favor of "traditional" or folk medicines, sometimes with tragic consequences.

It is not possible to fully discuss all the reasons for this social shift, and it is not really relevant to the topic at hand. However, many have landed at least part of this skepticism and rejection at the foot of modern medicine's ever-increasing focus on the symptom at the expense of the person. Many people come away from a health encounter feeling fully investigated but hardly heard. Much of modern healthcare appears to focus perhaps inappropriately solely on the diagnosis and management of disease rather than on the management of a *person*

who happens to be experiencing the impacts of a disease.

It is encouraging to know that in a field of disciplines that have focused more and more on the symptom and less and less on the person, palliative care often stands out as a discipline that has had its beginnings in a rich tradition of holism and continues in that tradition. It is imperative for the best possible care to continue in that same tradition. Not only is it good for the people we care for; it is good for our own selves. Palliative care more than many disciplines offers a relationship with the person that is often rich and rewarding. The particular issues faced by those who are dying offer the opportunity to interact with a person not only on the level of the physical but also the psychological, social, and even existential and spiritual. As Christina Puchalski (2002) has eloquently stated:

> It is also through that dimension that I think the compassionate, caring part of the doctor/patient relationship is enacted. . . . . What has happened over the last 30 years is that science has really led medicine, and a lot of the nontechnical aspects of medicine have been neglected. The spiritual assessment brings us back to those compassionate, caregiving roots of the patient-doctor relationship. . . . . When you get involved in a discussion with a patient about his or her spirituality, you enter the domain of what gives that person meaning and purpose.

6.9 Which Practitioner?

Discussing the role of the practitioner necessarily raises another question: which practitioner? A dominant focus on the palliation of physical symptoms can mean that the primary role of palliative care falls to medical and nursing staff with some involvement of other practitioners such as physiotherapists, occupational therapists, psychologists, social workers, and pastoral care workers depending on the needs of the person.

However, a broader focus on not just physical symptoms but also psychological and existential/spiritual (i.e., the whole person) can mean a slightly different approach. Firstly, it may mean a stronger reliance on and involvement of the multidisciplinary team. Palliative care is a leader in multidisciplinary management and has traditionally recognized the important contributions that different disciplines make to the care of the dying person. Despite this, the involvement of other health professionals can be relatively minor or only occur when other symptoms become distressing or intrusive and need to be addressed.

Although physical symptoms are often seen as primary, facing the end of life has a major impact on a person's psychological state and, for most, raises deeper existential questions. For a large proportion, there is abundant evidence that the impact is severe enough to be clinically important and require intervention. A model that recognizes the importance of all dimensions – physical, psychological, social, and existential/spiritual – means firstly a keen awareness including formal assessment that addresses all of these domains as well as early referral to an appropriate practitioner to follow through with assessment and address the problem. Given the frequency with which facing the end of life has an impact on each of these domains, it is likely that other health practitioners are currently vastly underutilized. Providing excellent palliative care requires administrators to recognize the importance of these other health professionals in caring. It also requires those who have the primary role in management to value the contribution of these other health professionals and make use of them.

A broader view that sees the contribution of physical, psychological, social, and existential/spiritual to overall suffering brings us back to our original question: which practitioner? The previous paragraph may suggest greater involvement of specialists in each of those domains, for example, bringing in a clinical psychologist or psychiatrist to address psychological issues, a social worker to address social issues, and a clinical psychologist, psychiatrist, or pastoral care worker to address existential or spiritual issues. This approach is in line with the trend in modern medicine to specialization and recognized expertise in different domains and in some quarters has been recommended as an approach to address all of these factors in a holistic fashion.

Although there is no doubt that people with expertise and training in a specific domain bring a

specific set of skills that are valuable, there may be several dangers to a move to a specialization of care. First, it can result in a very reductionist approach that breaks down the person into various interrelated but separate domains that are the province of different specialists. This means that you need the doctor or nurse to help with your body, the psychiatrist or clinical psychologist to help with your mind, and the pastoral care worker to help with your spirit. This can mean that the doctor or nurse does not see the psychological or existential as their domain and either neglects to explore them or, if they are raised, quickly moves to organize a referral to another practitioner.

This division of labor has the potential to lose an opportunity to build on the trust and connection that may have developed with this practitioner and which are crucial factors in exploring these other domains. It may also deny the practitioner the opportunity to develop a deeper relationship with the person who is dying as they explore and wrestle together not just with physical symptoms but with deeper psychological, existential, and spiritual issues.

Although it is important not to diminish the contribution of someone with specific skills, it is also important not to diminish the contribution that any member of the team can make across all of these domains. In fact, for some patients, the most significant encounter of the day may be with the cleaner or kitchen hand who through their empathy and care exhibits a compassion that touches their psychological and even spiritual needs.

Therefore, we would suggest that if we are to see physical symptoms as one small dimension of the suffering experienced by the person who is dying, it necessitates a strong reliance on the whole multidisciplinary team. In many situations, this will be because of the specific training and expertise of some disciplines who may be called in to help with different aspects of the person's suffering. However, often it will not be the training and skills but the qualities that any member of the team brings that mean an opportunity for almost any encounter to have a profound impact for the patient which can also be deeply meaningful and satisfying for the health practitioner.

6.10 The Care of the Health Practitioner

The quote by Christina Puchalski raises an issue that is perhaps an important one to close this introductory chapter. If we are to approach the person as not just someone with physical symptoms but a person who brings a whole host of other issues in the psychological, social, existential, and spiritual domains, the therapeutic encounter and relationship may be immensely satisfying and effective for both parties. However, it also brings a cost.

As Puchalski states, the roots of caregiving are grounded not just in expertise in elucidating and managing relevant symptoms but in compassion. Compassion at its heart means "to suffer with." For those who aspire to practice a holistic model of care, this means not only sharing someone's distress at physical pain, breathlessness, or fatigue but their sadness and fear, their loss of relationships with loved ones, and even their existential distress at the prospect of death.

To turn to neuroscience, brain imaging clearly demonstrates that those who are empathetic share others' pain in a very real and active sense. Visualizing another person in apparent pain results in activation of brain regions that are part of the pain network (Singer et al. 2004). Thus, if we are to work with people who are suffering and if we are to care, then we will not just figuratively but physiologically share their pain with them.

Knowing this helps us understand the relatively high rates of burnout in those caring for people who are dying. There is an option of extracting ourselves emotionally, and in fact, those with less empathy have reduced brain activation and presumably less distress. However, is this the best option for ourselves or for the people we care for? The other option is to develop ways of dealing with our own suffering that enables us to continue to deliver care with both dispassionate professionalism and compassionate support.

The way to do this is varied and each individual has their own ways of self-care. However, it is important that all health professionals recognize the impact of compassionate palliative care and ensure that they have ways to ensure their own health. This will ensure that they are able to not

only continue to practice but practice in a way that provides the best possible for the people under their care. This will mean not just surviving but practicing with the energy and resources that enable them to provide the multidimensional care they would wish.

Abstract

Pain is one of the most common symptoms encountered in palliative medicine. Good pain management involves ensuring pain is screened for, adequately assessed if present and appropriately managed. This includes targeted and systemic, nonpharmacological, and pharmacological approaches. This chapter seeks to give an evidence-based overview of approaches to screening for assessing and managing a patient's pain.

1 Introduction

Pain is one of the most common symptoms experienced by people, especially those with serious illness. The prevalence of significant pain increases as patients near the time to death, from nearly a third of the general public reporting moderate to severe pain 2 years before their death, to nearly half of people in their last month of life (van den Beuken-van Everdingen et al. 2016). Pain remains common in far advanced, noncancer, life limiting illness with prevalences recorded at 63–80% of patients with Acquired Immune Deficiency Syndrome, 41–77% of patients with heart disease, 33–77% patients with Chronic Obstructive Pulmonary Disease (COPD), and 47–50% of patients with renal disease (Solano et al. 2006).

Despite pain being such a common symptom, it is often inadequately controlled (Solano et al. 2006; Deandrea et al. 2008). Field testing of the WHO Three Step Analgesic Ladder approach suggested pain control is possible in 70–90% of patients (Ventafridda et al. 1990). However, for patients admitted into acute hospice care, significant rates of moderate or severe pain were found in most patients during their first 48 hours of admission (cancer 91.5%, dementia 75%, COPD 82.4%). Adequate pain control was reached after 24 hours in 64.3% of patients with dementia, 41% of patients with cancer, and only 28.1% of patients with COPD.

This chapter will discuss screening for and assessing pain, and approaches to manage pain including nonpharmacological techniques, a review of the WHO pain ladder (Fig. 1) simple analgesics, weak and strong opioids, adjuvant analgesics, and other strategies that may be of benefit.

2 Definitions

Pain has been defined in multiple different ways from the pathologically based "unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association

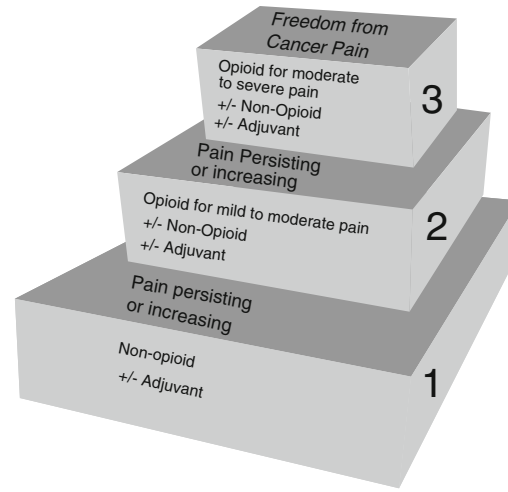

Fig. 1 WHO analgesia ladder (World Health Organisation 1987)

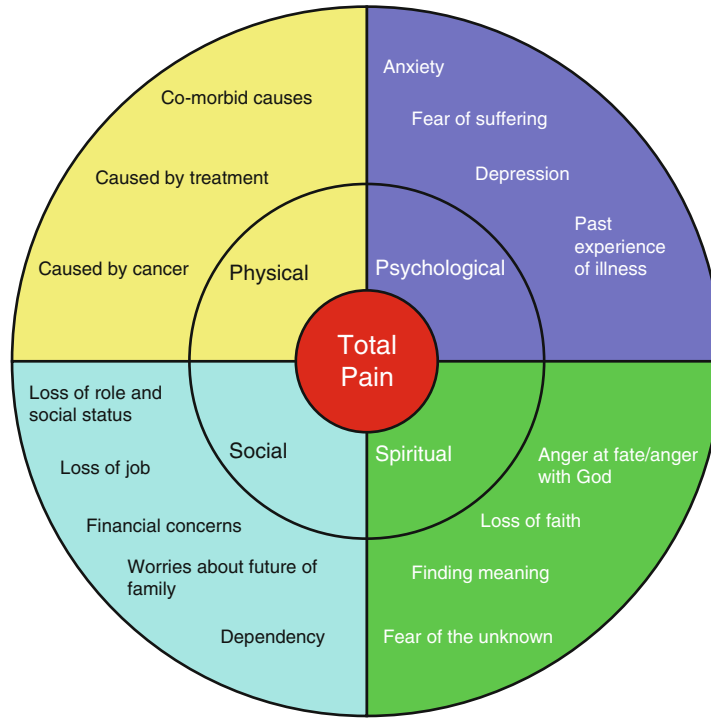

Fig. 2 Total pain (International Association for the Study of Pain 2009). This image is taken from the Total Pain Factsheet and has been reproduced with the permission of the International Association for the Study of Pain® (IASP). The image may not be reproduced for any other purpose without permission

for the Study of Pain 2017) to the more global approach by Margo McCaffery, who described pain as "whatever the patient says it is, existing whenever and wherever the patient says it does." The concept of "total pain" was very effectively defined by Dame Cicely Saunders, who wrote of hearing patients describe not just physical pain, but also associated psychological and social distress. She noted that some patients' pain did not respond to analgesia alone, but rather a holistic approach. Total pain encompasses the "division of a whole experience into physical, emotional, social and spiritual components." What we can take from this is that simply assessing patients for physical pain is likely to be inadequate (Fig. 2).

Physical pain can be due to the life limiting illness, comorbidities arising from the illness (e.g., pulmonary embolism), treatments for the illness (e.g., mucositis, post radiotherapy, chemotherapy induced peripheral neuropathy), or pre-existing disease (e.g., osteoarthritis). It is increasingly accepted that good symptom control, including pain, is linked with improved quality of life, lower levels of distress for both patients and caregivers, improved function, and indeed improved survival in patients with cancer (Davis et al. 2015). It is therefore of utmost importance that pain is assessed for, investigated, and managed appropriately.

3 Pathophysiology

The pathophysiology of pain has long been investigated. In 1664 René Descartes suggested that pain travelled along nerve fibers to the brain (Schug et al. 2015). The "Gate Theory" was first described in Melzack and Wall (1965) suggesting the involvement of both large and small diameter fibers modulating the pain response allowing pain modulation both by touch and central control mechanisms. The authors conclude in a statement still valid today "A 'modality' class such as 'pain', which is a linguistic label for a rich variety of experiences and responses, represents just such an abstraction from the information that is sequentially re-examined over long periods by the entire somesthetic system." Social and spiritual modulating factors have been included into this list in more recent time, leading to the biopsychosocial-spiritual model of pain.

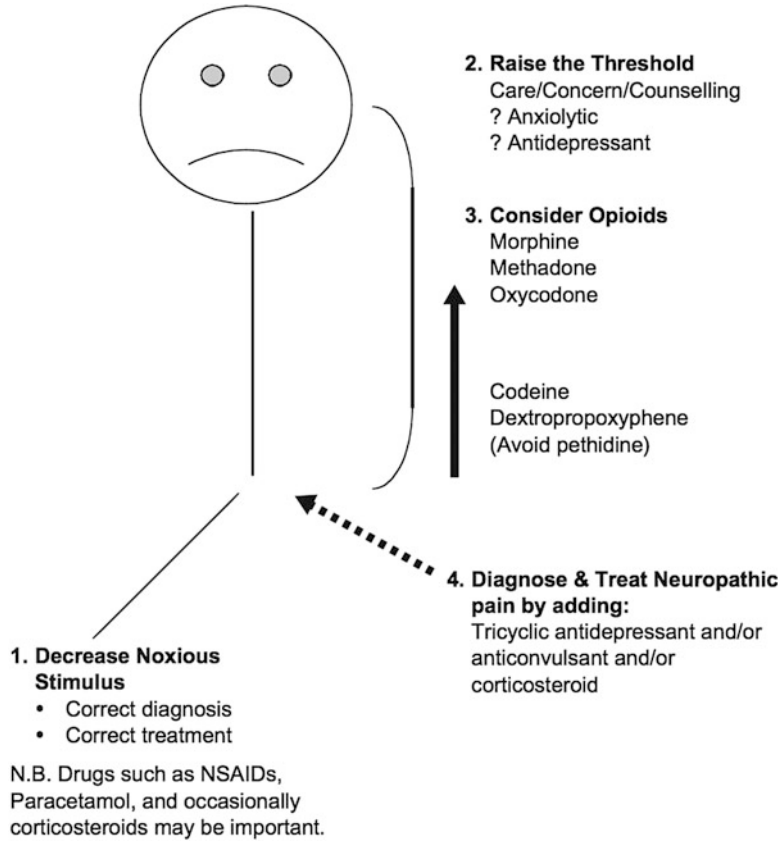

Fig. 3 The Sydney Stick Man (Lickiss 2001)

Norelle Lickiss suggested the concept of the "Sydney Stick Man" in the 1990s. It remains valid today when considering the pathophysiology of pain, as well as an approach to its management (Fig. 3).

As shown in Fig. 4, the pain pathway involves several processes: transduction, transmission, perception, and modulation. This requires interacting central and peripheral receptors as well as a group of factors unique to the individual experiencing the pain including environmental and psychological modifiers.

3.1 Transduction and Peripheral Transmission

The afferent pain receptors respond to physical (heat, cold, pressure) and chemical stimuli (the "chemical soup" e.g., COX-2, TNF-α, interleukins, prostaglandins, substance P, glutamate, proteinases, and chemokines). These receptors are widespread through the skin, muscle, joints, viscera, etc., and form part of both A-delta fiber (myelinated) and C fiber (unmyelinated) neurons.

Afferent fibers travel along the nerve (both myelinated A-delta fibers and unmyelinated C fibers), using mainly a fast sodium current, which may be blocked by local anesthetics, passing the cell bodies in either the dorsal root ganglion (for fibers coming from below the neck), or the trigeminal ganglion (for receptors based on the neck, face and oral cavity). The efferent fibers then synapse in lamina I and II of the dorsal horn or the spinal cord.

The peripheral nerve impulse can be modulated locally, NSAIDs can reduce the presence of chemical stimuli, and the presence of

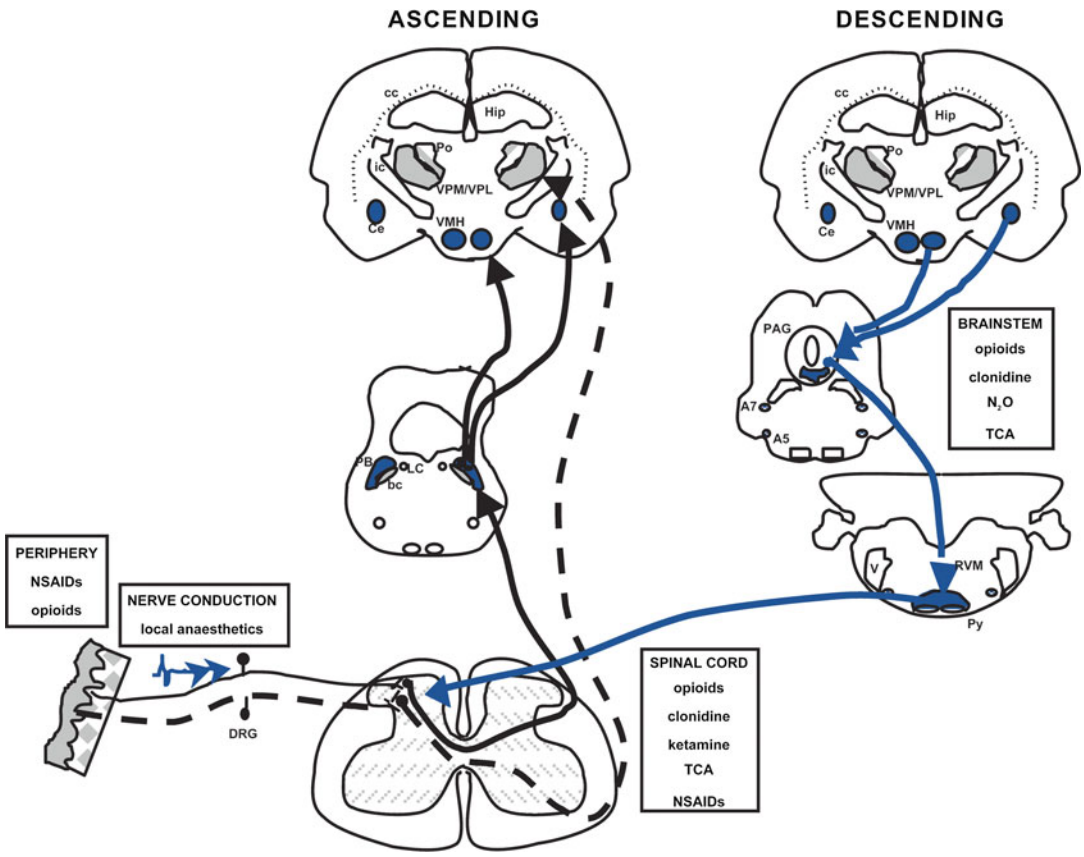

Fig. 4 The main ascending and descending spinal pain pathways (Hunt and Mantyh 2001; Schug et al. 2015). The site of action of some analgesics is included. Reproduced with permission of Acute Pain Management: Scientific Evidence

inflammation stimulates the transport of opioid receptors to the periphery, allowing topical opioids to be of benefit.

3.2 Central Transmission and Perception of Pain in the Higher Centers

At the dorsal horn synapse multiple chemical messengers are involved (e.g., glutamate, NMDA, aspartate, substance P, CGRP). With each stimulus, there is an increase in the action potential from the dorsal horn cell (the concept of "wind-up"), which over the long term may be involved in hippocampal learning and memory and spinal cord sensitization. Wind up, in association with the similar phenomena of long-term potentiation and secondary hyperalgesia, may contribute to central sensitization. From the dorsal horn, second order neurones ascend through the spinothalamic tract.

The spinothalamic tract is subdivided into the neo-spinothalamic (fast, pin-prick sensation to the thalamus, and then to the sensory cortex), the paleo-spinothalamic (slow, dull pain, with

collaterals to multiple areas; also involved with stimulation of descending, inhibitory fibers), and the archi-spinothalamic tract (innervating the hypothalamus and limbic systems). It is postulated the archi-spinothalamic tract could have effects on the autonomic nervous system, emotional and behavioral responses to pain.

3.3 Modulation and the Descending Pathways

Multiple descending pathways act as modulators at the dorsal horn, with input from the amygdala and hypothalamus via the periaqueductal grey matter. The main neurotransmitters involved at inhibitory pathways are glycine, GABA, and enkephalins. The dorsolateral funiculus has specific serotonergic and noradrenergic inhibitory descending pathways.

Considering these principles of pain pathophysiology allows an approach to assessment and management to be generated.

Radiotherapy or chemotherapy are options that can directly target a lesion causing pain. Splinting may stabilize and therefore reduce pain from a lesion. Physical treatment options including heat, massage, and TENS may be of benefit. Medications can reduce the chemical soup (NSAIDs) or target receptors themselves, either locally or centrally.

Higher-level modulation options have been the focus of much research of late and have an increasing evidence base.

4 Screening for and Assessment of Pain

The WHO definition states that palliative care should include "the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" (World Health Organisation 2016). It is therefore essential that pain is screened for at every meeting and thoroughly assessed if present. International guidelines suggest a comprehensive assessment of pain should be conducted if there is pain present, allowing an individualized pain management plan to be implemented if needed (Scottish Intercollegiate Guidelines Network 2008; National Clinical Effectiveness Committee 2016; National Comprehensive Cancer Network 2016; Australian Adult Cancer Pain Management Guideline Working Party 2016).

4.1 Screening

International guidelines suggest patients able to communicate their level of pain should be asked to rate any pain on a Numeric Rating Scale (0–10) at every clinical encounter. For patients who have communication difficulties, pictorial scales such as the Faces Pain Rating Scale for children can be used (Bieri et al. 1990). Ideally the patient should be the main assessor of the pain as health professionals have been shown to underestimate the level of pain a patient is experiencing. If the patient is unable to adequately assess their pain family members or health professionals may act as a substitute.

Example of numeric pain rating scale is "What is your current level of pain, between 0 and 10, with 0 being no pain and 10 being the worst pain you could imagine?" (Fig. 5).

For patients unable to use a scaling system (e.g., patients with dementia), an Abbey Pain Scale or PAINAD scale can be used (Abbey et al. 2004) (Fig. 7).

4.2 Pain Assessment

A comprehensive pain assessment should be undertaken in any patient scoring 2 or more on a Likert or Faces scale, three or more on an Abbey pain scale, or a patient reporting a new pain or an unexpected change in pain intensity. This should

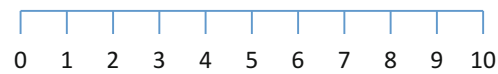

Fig. 5 Numeric Rating Scale

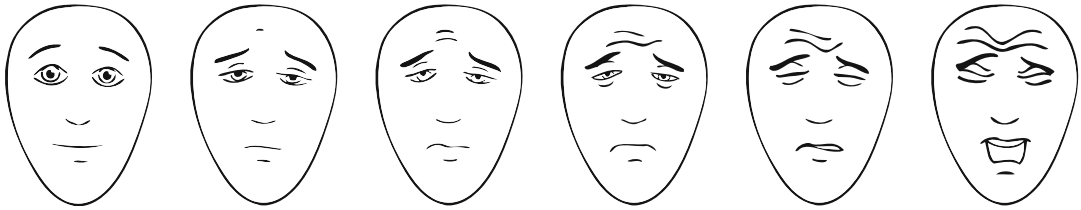

Fig. 6 The Faces Pain Scale- Revised has been reproduced with the permission of the International Association for the Study of Pain® (IASP). The figure may not be reproduced for any other purpose without permission

be tailored to the individual. It should be included as part of a full history, examination, investigation, and use of standardized assessment tools (Scottish Intercollegiate Guidelines Network 2008; Scottish Partnership for Palliative Care 2013; National Clinical Effectiveness Committee 2016; National Comprehensive Cancer Network 2016; Australian Adult Cancer Pain Management Guideline Working Party 2016):

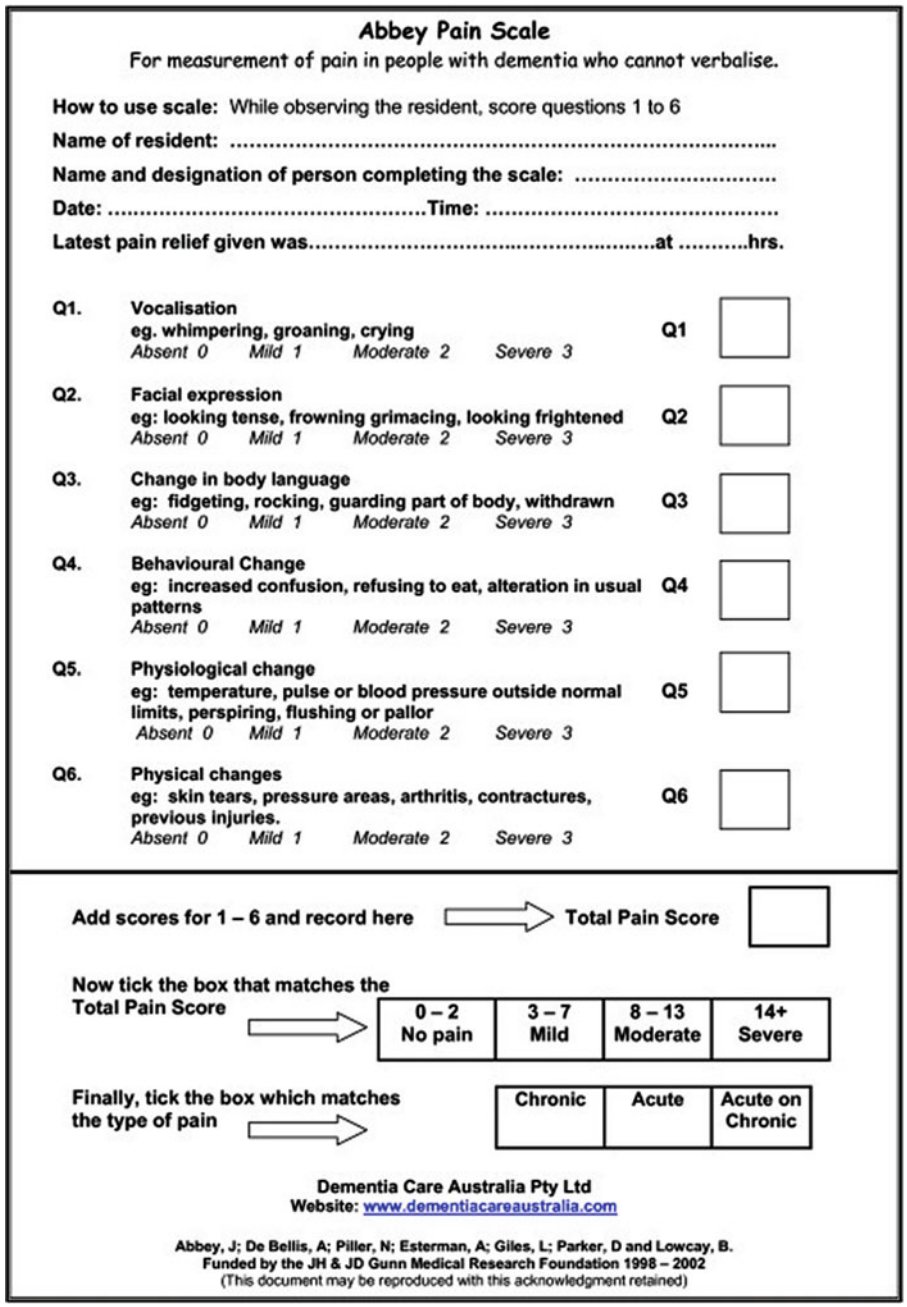
- Medical History
  - A medical history including disease status and treatment
  - Pain severity using a validated scale (e.g., Brief Pain Inventory (Cleeland 2009))
  - Pain experience (e.g., SOCRATES, PQRST see below)
  - Functional effects including interference with ADLs (including activity, walking, work, mood, sleep, relationships with people, and enjoyment of life)
  - Associated symptoms
- Medication History
  - Previous and current treatment for pain including compliance and any side effects
  - Use of any complementary and alternative medicines (approximately 40–50% of patients) (Horneber et al. 2012)
- Psychosocial history
  - Patient's fears and concerns about the pain including perceived meaning of the pain
  - Specific questioning to detect depression (e.g., the two question technique: "are you depressed? Have you experienced loss of interest in things or activities you would normally enjoy? (Mitchell 2008)),
  - Social, cultural and spiritual assessment (e.g., FICA, HOPE assessment (Puchalski et al. 2009))
  - Potential modulators such as substance abuse, alcohol and delirium
  - Any risk factors for medication misuse and abuse
- Physical examination
- Appropriate investigations
- Patient and carer preferences
- Factors suggesting a medical emergency

Pain assessment mnemonics:

SOCRATES
Site
Onset: when did the pain start, sudden or gradual?
Character: nociceptive or neuropathic features
Radiation
Associated symptoms
Time course-constant or fluctuating
Exacerbating or relieving features
Severity, e.g., using numerical-rating scale/Faces (Fig. 6)

PQRST
Provoking/precipitating factors
Quality of pain-nociceptive or neuropathic features
Region or radiation
Severity or associated Symptoms
Temporal factors

The aim of assessment is to identify the etiology and mechanism of the pain, diagnose any



Abbey Pain Scale

For measurement of pain in people with dementia who cannot verbalise.

How to use scale: While observing the resident, score questions 1 to 6

Name of resident: .....

Name and designation of person completing the scale: .....

Date: .....**Time:** .....

Latest pain relief given was.....at .....hrs.

Q1. **Vocalisation**
eg. whimpering, groaning, crying **Q1**
Absent 0 Mild 1 Moderate 2 Severe 3

Q2. **Facial expression**
eg: looking tense, frowning grimacing, looking frightened **Q2**
Absent 0 Mild 1 Moderate 2 Severe 3

Q3. **Change in body language**
eg: fidgeting, rocking, guarding part of body, withdrawn **Q3**
Absent 0 Mild 1 Moderate 2 Severe 3

Q4. **Behavioural Change**
eg: increased confusion, refusing to eat, alteration in usual patterns **Q4**
Absent 0 Mild 1 Moderate 2 Severe 3

Q5. **Physiological change**
eg: temperature, pulse or blood pressure outside normal limits, perspiring, flushing or pallor **Q5**
Absent 0 Mild 1 Moderate 2 Severe 3

Q6. **Physical changes**
eg: skin tears, pressure areas, arthritis, contractures, previous injuries. **Q6**
Absent 0 Mild 1 Moderate 2 Severe 3

Add scores for 1 – 6 and record here → **Total Pain Score**

Now tick the box that matches the Total Pain Score →

0 – 2 No pain	3 – 7 Mild	8 – 13 Moderate	14+ Severe

Finally, tick the box which matches the type of pain →

specific medical emergencies, and understand patient-specific goals of care. It should also provide an opportunity to consider specific symptom clusters. Research on symptom clusters in advanced cancer has found that dyspnea, drowsiness, and fatigue often cluster with pain (Dong et al. 2014).

5 Pain Management: General Approach

The WHO suggested five areas to target in approaching a patient with pain in 1990 and this remains applicable today (World Health Organisation 1996). These include:

- Modification of the disease process
  - Radiotherapy, hormone therapy, chemotherapy, surgery
- Psychological approaches
  - Understanding, education, companionship, cognitive behavioral therapy (CBT)
- Interruption of the pain pathways
  - Local anesthetics, neurolytic agents
- Medications
  - Analgesics, antidepressants, anticonvulsants, anxiolytics, neuroleptics
- Modification of activities of daily living or immobilization
  - Rest, cervical collar, splints or slings, orthopedic surgery

Cancer-related pain may respond well to treatment of the cancer itself including hormonal treatments, radiotherapy, and chemotherapy. For noncancer-related illnesses, other appropriate treatment options (e.g., antibiotics for pneumonia, internal fixation of a hip fracture) may help with analgesia.

6 Nonpharmacological Pain Management

All patients with pain should receive education on pain and its management as this has been shown to reduce cancer pain intensity (Scottish Intercollegiate Guidelines Network 2008; Rueda et al. 2011; Marie 2013; National Comprehensive Cancer Network 2016; Australian Adult Cancer Pain Management Guideline Working Party 2016). This process should involve the treating team being aware of the patient, family, and caregiver's existing knowledge of pain and treatment options and their level of understanding of the education provided. Patients should understand that describing their pain to health care workers is essential to allow the best plan of management to be made. It is important to convey that there is no medical benefit to suffering from pain and pain can usually be controlled, as can any side effects of treatment. Strategies to enable patients to be more involved in their own pain management appear to be most effective when employed as jointly created pain management plans, goal setting, and pain diaries.

Psychosocial and spiritual interventions have been shown to have a positive impact on pain (Sheinfeld Gorin et al. 2012) through their ability to provide active coping processes. CBT has been shown to be of benefit in patients with cancer pain (Tatrow and Montgomery 2006); however, a Cochrane review of psychological therapies for management of chronic neuropathic pain found insufficient evidence to support psychological interventions in this group (Eccleston et al. 2015).

When assessing the evidence for other nonpharmacological management of pain, there is low level evidence supporting orthoses for pain post stroke (Tyson and Kent 2011; Hebert et al. 2016) and Motor Neurone Disease (European Federation of Neurological Societies Task Force 2012). Transcutaneous Electrical Nerve Stimulation (TENS) is based on delivering low voltage electrical currents to the skin. Reviews have looked at the effectiveness of TENS in acute pain (tentative evidence for TENS) (Johnson et al. 2015b), phantom limb and stump pain (inadequate evidence to support TENS) (Johnson et al. 2015a), and cancer pain (inconclusive due to inadequate evidence) (Hurlow et al. 2012; Bao et al. 2014). It is unlikely that these interventions will cause harm so trialing on a case by case approach may be appropriate. There is currently insufficient evidence to support acupuncture for cancer pain in adults (Paley et al. 2015).

Music therapy may be of benefit for reducing pain in palliative care patients and palliative care patients suffering from cancer. Studies are generally weak (Archie et al. 2013; McConnell et al. 2016). There is weak evidence for massage therapy, either with or without aromatherapy oils for a pain population (Boyd et al. 2016). There is no

current evidence to support the use of massage for symptom relief in patients with cancer (Shin et al. 2016). There is low level evidence to support Reike, reflexology, homeopathy (Traumeel), and creative arts therapy (Bao et al. 2014).

7 Pharmacological Management of Pain

7.1 Paracetamol

Paracetamol (acetaminophen) is widely used as a treatment for pain. The mechanism of action of paracetamol remains uncertain (Schug et al. 2015; RACGP 2016) although it is thought that it inhibits central (but not peripheral) prostaglandin synthesis, modulates inhibitory descending serotinergic pathways, and possibly plays a role in activation of the endocannabinoid system (Schug et al. 2015). Paracetamol inhibits low level inflammation but does not suppress high level inflammation such as inflammatory arthropathies (Schug et al. 2015).

Recent studies have shown paracetamol is not as effective as nonsteroidal anti-inflammatory drugs (NSAIDs) in knee and hip pain osteoarthritis (da Costa et al. 2016).

Caution should be used in total paracetamol daily dosing given the risk of liver injury. Physicians should be aware of the possibility of excess paracetamol dosing due to combination medications. The total dose should not exceed 4 g of paracetamol per day (National Comprehensive Cancer Network 2016).

Paracetamol in Palliative Care

There is no high quality evidence to support or refute the use of paracetamol alone or in combination with opioids for cancer pain (Wiffen et al. 2017b). It is also noted that paracetamol dosing carries a significant tablet burden.

Paracetamol should be considered in the palliative care patient on a case by case basis (National Clinical Effectiveness Committee 2016); there is insufficient evidence to support the addition of paracetamol in palliative care patients taking high doses of strong opioids (National Clinical Effectiveness Committee 2016).

Research is ongoing comparing paracetamol in combination with opioids with opioids alone.

7.2 Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs are split into nonselective (nsNSAID, acting on both the COX-1 and COX-2 pathways) and selective (COX-2 inhibitors) (Schug et al. 2015). NsNSAIDS and COX-2 inhibitors have anti-inflammatory, analgesic, and antipyretic actions. Data have shown both groups of drugs to be more effective than paracetamol in treatment of osteoarthritis pain, with nsNSAIDs likely giving more effective analgesia than COX-2 inhibitors (da Costa et al. 2016). Both are effective in acute postoperative pain (Schug et al. 2015).

Significant side effects can be encountered with both nsNSAIDs and COX-2 inhibitors. Both nsNSAIDS and COX-2 inhibitors can provoke or worsen renal failure. They should be used in caution with patients at risk of developing renal failure or who are taking other potentially nephrotoxic drugs and patients' renal function should be monitored.

NsNSAIDS carry a higher risk of gastrointestinal complications than COX-2 inhibitors although both can cause ulceration which can extend throughout the gastrointestinal (GI) tract (Jarupongprapa et al. 2013). The risk is increased in patient age >65 years, those with previous peptic ulcer disease, significant alcohol use, major organ dysfunction, and with concomitant use of medications increasing the risk of ulceration (e.g., steroids) or bleeding (including low dose aspirin) (National Comprehensive Cancer Network 2016). Low dose ibuprofen (<1200 mg/day) has the lowest risk of gastrointestinal complications of nsNSAIDs. Ketoprofen and piroxicam have the highest risk of GI complications (RACGP 2016). Double dose H2 antagonists or single dose proton pump inhibitors (PPI) are effective prophylactic agents. It is possible that the combination of COX-2 inhibitors and a PPI are the safest for gastrointestinal protection.

NsNSAIDs inhibit platelet function through their action on COX-1; COX-2 inhibitors do not

inhibit platelet function. Both nsNSAIDs and COX-2 inhibitors are associated with an increased risk of cardiovascular effects and may increase blood pressure. It is likely that diclofenac has the highest risk of cardiovascular effects and naproxen the lowest of nsNSAIDs (RACGP 2016).

All NSAIDs are contraindicated in severe liver dysfunction.

NSAIDS in Palliative Care

There is no high-quality evidence to support or refute the use of NSAIDs alone or in combination with opioids for cancer pain. There is very low-quality evidence that some patients with moderate or severe cancer pain can obtain substantial levels of benefit within 1 or 2 weeks (Derry et al. 2017).

Given the lack of evidence for benefit and potential for side effects, NSAID use should be decided on a patient by patient basis, using the lowest effective dose and giving consideration to prophylactic GI protection (RACGP 2016). Patients not responding to one NSAID may gain effective analgesia from a different NSAID (RACGP 2016).

7.3 Step 2 WHO Ladder: Codeine, Tramadol

A traditional approach to pain management in palliative care has been following the WHO step-wise approach to pain (World Health Organisation 1996). Step two has traditionally involved the use of "weak" opioids including codeine, dihydrocodeine, hydrocodone, and tramadol. More recently, research has challenged this approach, suggesting that step 1 direct to step 3, bypassing weak opioids, may be a better approach (Caraceni et al. 2012). This is proposed to be of benefit by introducing potent analgesics early, preventing long periods of poor pain control, and giving good quality of life while using more potent Step 3 analgesics with similar side effect profiles to step 2 analgesics (Tassinari et al. 2011). A systematic review in 2011 concluded that the evidence available at that time to support either a two- or three-step approach was inconclusive (Tassinari et al. 2011). A multicenter RCT from 2015 compared low dose morphine with tramadol, tramadol plus paracetamol, and codeine plus paracetamol in patients with cancer with moderate pain. The results showed better analgesia from the low dose morphine with similar side effects to the weak opioids (Bandieri et al. 2015). Further research is currently being carried out in this area.

7.3.1 Codeine

Codeine itself is a very weak mu receptor agonist. Its main efficacy is based on its metabolism to morphine via the CYP2D6 cytochrome P450 isoenzyme (Crews et al. 2014). The amount of conversion is variable, usually around 10% (30 mg of oral codeine being the equivalent of 3 mg of oral morphine). In Caucasian populations, 8–10% of patients are poor metabolizers (receiving very limited analgesic action from oral codeine), while 3–5% are ultrarapid metabolizers, converting significantly more codeine to morphine, with consequently higher risk of opioid-related side effects. The proportion of ultrarapid metabolizers is significantly higher in Middle Eastern and North African populations (10–30%) and lower (0.5%) in Asians. Asians and African Americans are less likely to be poor metabolizers than Caucasians (Crews et al. 2014; Schug et al. 2015; RACGP 2016). Current research is evaluating CYP2D6 genotype targeted analgesia advice.

As codeine is metabolised to morphine, which has renally excreted metabolites, codeine should be avoided in patients with renal failure. Dose reduction may be required in hepatic failure (Schug et al. 2015; RACGP 2016). Its side effects are mainly related to its opioid action (constipation does not occur in poor metabolizers of codeine).

Codeine in Palliative Care Patients

While previous research in palliative care has used oral and intramuscular routes of administration, in Australia (and many other countries) codeine is currently only available in oral preparations (RACGP 2016). Current limited data suggest codeine is more effective than placebo for cancer pain in adults but with significant side effects (Straube et al. 2014).

There is no current evidence to support the use of paracetamol, with or without codeine or

dihydrocodeine, in adults with neuropathic pain (Wiffen et al. 2016a).

7.3.2 Tramadol

Tramadol is a dual action analgesic agent. It is structurally related to morphine and codeine and consists of two enantiomers. The (+)-Tramadol enantiomer and its more potent metabolite, (+)-*O*-desmethyl-tramadol, are mu opioid receptor agonists. (+)-Tramadol also inhibits serotonin reuptake. The (−)- Tramadol enantiomer inhibits norepinephrine reuptake (Schug et al. 2015; Grond and Sablotzki 2004). As with codeine, tramadol is metabolized via the CYP2D6 enzyme pathway, with significant interpatient variability and subsequently analgesic effect (Crews et al. 2014).

Ninety percentage of tramadol excretion is in urine; hence, dose reductions are necessary in renal failure (creatinine clearance <30 ml/min). Dose reduction may also be necessary in severe hepatic impairment (Schug et al. 2015; RACGP 2016).

Tramadol in Palliative Care Patients

There is limited, very low quality evidence from randomized controlled trials that tramadol reduces cancer-related pain in some adults. There is no evidence to support the use of tramadol in children. There is very low quality evidence that tramadol is not as effective as morphine. The role of tramadol for cancer pain as part of step 2 of the WHO analgesic ladder therefore is unclear (Wiffen et al. 2017a).

A systematic review investigating the role of tramadol to treat chronic neuropathic pain in adults (of any cause) showed low or very low quality evidence only (Duehmke et al. 2017).

Adverse Effects

The most common side effects are nausea, vomiting, fatigue, dizziness, weakness, and loss of appetite. Tramadol causes less constipation than codeine.

Much has been written on the risk of serotinergic syndrome with tramadol. This classically presents with the triad of altered mental status, autonomic hyperactivity, and neuromuscular abnormalities. It is important when prescribing tramadol that note is made of any concurrent serotinergic drugs, and side effects monitored for. Medications that may act on serotinergic pathways include SSRIs, SNRIs, other antidepressants including MAOIs, Trazodone, Mirtazepine, buproprion, St. Johns Wort, 5HT3 antagonists, opioids including fentanyl and methadone, triptans, antiepileptics including valproate and carbamazepine, dopamine agonists, and illicit drugs including cocaine, MDMA, LSD, and alcohol (RACGP 2016).

7.4 Strong Opioids

Opioids act by binding to receptors in three families: mu, kappa, and delta. The mu receptor has multiple subtypes partly explaining the differences in effects of opioids in patients. Most opioids are mu agonists. There are pure agonists (e.g., morphine, fentanyl, hydromorphone, oxycodone), partial agonists (e.g., buprenorphine), and drugs with mixed actions (e.g., tramadol and tapentadol) (Pasternak 2014; Portenoy and Ahmed 2014).

Morphine is suggested as the first line strong opioid for moderate to severe cancer pain by the WHO (1996). There is no current evidence suggesting one strong opioid has improved efficacy or toxicity in the cancer patient population (Caraceni et al. 2011).

When initiating opioid analgesia in the opioid naïve patient, several guidelines exist (Scottish Intercollegiate Guidelines Network 2008; Klepstad et al. 2011; Caraceni et al. 2012; Portenoy and Ahmed 2014; National Clinical Effectiveness Committee 2016; National Comprehensive Cancer Network 2016; Australian Adult Cancer Pain Management Guideline Working Party 2016). These suggest using the oral route if possible, starting at doses of 5 mg oral morphine equivalent regularly fourth hourly, with hourly review and titration of doses. However, in patients previously taking weak opioids starting a low dose fentanyl patch or oral long acting low dose opioid also may be reasonable (Klepstad et al. 2011; Wiffen et al. 2016b). All patients being treated with opioids should have psychosocial support provided, education about pain management,

prevention and management of dry mouth, nausea and constipation, and consideration of non-pharmacological interventions and adjuvant analgesics (National Clinical Effectiveness Committee 2016; National Comprehensive Cancer Network 2016). Opioids can be switched due to inadequate effect, side effects, or patient request for a change of route of drug delivery. There is varying conversion between different states in Australia (Syrmis et al. 2014) and in different countries. Conversion charts or smart phone apps are available to guide dosing (ANZCA and FPM 2017).

Example for initiating opioids:

Opioid naïve patient

(a) 5 mg oral morphine Q4H and review dosing each hour for sedation/ongoing pain.
(b) 10–15 mg extended release morphine twice daily with daily review for sedation/pain.

In the elderly or very frail patients initial dosing of 2.5mg oral morphine Q4H and review dosing each hour for sedation/ ongoing pain

In patients previously taking weak opioids

(a) calculate oral morphine equivalent dosing in 24 hours based on previous requirements.
(b) dose reduce by 33% when converting to oral morphine dosing.

Divide total oral morphine equivalent in 24 hours by 2 for extended release morphine dosing or divide total oral morphine equivalent in 24 hours by 6 for 4 hourly immediate release formulation dosing.

Side Effects

While all opioids may cause adverse events (e.g., nausea, constipation, dry mouth, drowsiness), there is a lack of systemized reporting in trials and therefore direct comparisons between the rate of adverse events in different opioids are difficult to ascertain (Oosten et al. 2015).

Opioid-induced constipation (OIC) remains a significant challenge. Although long-acting opioid preparations containing oral naloxone and new medications including peripherally restricted mu receptor antagonists such as tapentadol theoretically may be of benefit to patients, more evidence is needed of their clinical efficacy (Camilleri 2011). Current guidelines for opioid-induced constipation suggest preventative measures including ensuring adequate fluid/fiber intake, encouraging exercise and regular prophylactic aperients (National Comprehensive Cancer Network 2016).

Up to 40% of patients may experience opioid-induced nausea (OIN). Antiemetics should be prescribed to all patients commencing opioids to be taken in case of nausea. The management of OIN includes preventing constipation, excluding other causes of nausea, and use of regular antiemetics. Patients may become tolerant to OIN, however if not, trialing a change of route of delivery or opioid switch may be of benefit (Laugsand et al. 2011; National Comprehensive Cancer Network 2016).

Management of opioid-induced itch includes excluding other causes of itch, considering true opioid allergy and trialing opioid switching. If this is unsuccessful subcutaneous low dose naloxone infusion (Kjellberg and Tramèr 2001; Reich and Szepietowski 2010; Miller and Hagemann 2011), ondansetron and antihistamines may be of benefit (National Comprehensive Cancer Network 2016).

Breakthrough Analgesia

Once a patient's analgesic regimen is stabilized, most patients requiring strong opioids will require regular long acting opioids with as needed "breakthrough" or "intense episodic" pain relief (Løhre et al. 2016). It is important to enquire if patients perceive incident or idiopathic breakthrough pain (see Table 1 for definition), and also if the pain is end of dose pain rather than true breakthrough pain (Vellucci et al. 2016). Breakthrough assessment tools such as the Alberta Breakthrough Pain Assessment Tool (ABPAT) (Sperlinga et al. 2015) or the Breakthrough Pain Assessment Tool (BAT) (Webber et al. 2014) are available to help guide patient management.

Breakthrough analgesia is recommended in guidelines at 1/6–1/10 of the 24 hours oral morphine equivalent dose in an immediate release formulation. There are a number of transmucosal

Table 1 Definitions of terms relating to pain (International Association for the Study of Pain 2017; Schug et al. 2015). § This Taxonomy/statement has been reproduced with permission of the International Association for the Study of Pain® (IASP). The Taxonomy/statement may NOT be reproduced for any other purpose without permission.

Term	Definition
Acute pain	Pain of recent onset and probable limited duration. It usually has an identifiable temporal and causal relationship to injury or disease
Chronic pain	Commonly persists beyond the time of healing of an injury, often thought to be 12 weeks. Frequently there may not be any clearly identifiable cause
Nociceptive pain§	Pain that arises from actual or threatened damage to non-neural tissue and is due to the activation of nociceptors (a high-threshold sensory receptor of the peripheral somatosensory nervous system that is capable of transducing and encoding noxious stimuli)
Somatic pain	A type of nociceptive pain. Often sharp, well localized, throbbing or pressure like. From superficial or bony structures
Visceral pain	A type of nociceptive pain. Often diffuse, achy, or crampy. Due to compression, infiltration or distension of abdominal or thoracic viscera
Neuropathic pain§	Pain caused by a lesion or disease of the somatosensory nervous system
Hyperalgesia§	Increased pain from a stimulus that normally provokes pain
Dysesthesia§	An unpleasant abnormal sensation, whether spontaneous or evoked
Allodynia§	Pain due to a stimulus that does not normally provoke pain
Sensitization§	Increased responsiveness of nociceptive neurons to their normal input, and/or recruitment of a response to normally subthreshold inputs
Breakthrough pain	Pain of moderate or severe intensity arising on a background of controlled chronic pain. Breakthrough pain may be described as spontaneous (unexpected) or incident (expected or predictable)
Adjuvant analgesics	Drugs with other primary indications that can be effective analgesics in specific circumstances

fentanyl citrate preparations available for intranasal, buccal, or oral administration. However, a recent Cochrane review which suggested transmucosal fentanyl may provide superior analgesia for breakthrough pain has been withdrawn because of concerns that the findings were misleading (Zeppetella and Davies 2015).

7.4.1 Buprenorphine

Buprenorphine is a semi-synthetic, partial mu receptor agonist and kappa receptor antagonist with high receptor affinity. Buprenorphine dissociates slowly from the mu receptor. In transdermal (low) doses, buprenorphine effects are similar to a full mu receptor agonist, without antagonism of other administered mu agonist medications.

Buprenorphine has a lower risk of respiratory depression compared to other strong opioids. Two-thirds of the drug is excreted unchanged, and one-third is metabolized in the liver. Buprenorphine dosing is unaffected by renal impairment.

Buprenorphine is available in transdermal (TD) and sublingual preparations. The TD patch is applied weekly and takes approximately 3 days to reach steady state. Approximately one in eight patients may develop itch with the patch (Ale et al. 2009, Kress 2009). Applying topical steroid aerosol prior to the patch may help with TD system-induced itch (Hans and Robert 2009; Wen et al. 2013).

Sublingual buprenorphine has a bioavailability of 30–50%. It has a mean half-life of 28 hours and hence delayed respiratory depression with frequent use has been reported.

Buprenorphine in Palliative Care

Buprenorphine may be more effective in neuropathic pain than other strong opioids although a recent Cochrane review showed insufficient research to support this (Wiffen et al. 2015a). A Cochrane review assessing the effectiveness of buprenorphine for cancer pain suggested that it should probably be used as second line to pure agonist opioids in cancer pain; however, it may be useful in some patients, with the sublingual formulation having more rapid onset of action than transdermal (Schmidt-Hansen et al. 2015).

7.4.2 Fentanyl

Fentanyl is a highly potent synthetic opioid, metabolized mainly in the liver to minimally active metabolites. There is minimal renal excretion. Fentanyl is highly lipophilic. Transdermal and transmucosal delivery systems are available. Conversion charts are available to guide dosing in conversion from other opioids. It is likely that transdermal fentanyl causes less constipation than oral morphine (28% vs. 46%) in a Cochrane review, although data is limited (Hadley et al. 2013).

Transmucosal fentanyl should only be used in patients stabilized on a morphine equivalent dose of at least 60 mg per day (RACGP 2016).

Multiple transmucosal delivery systems are available for fentanyl. These are not interchangeable. Most studies have shown no specific dose conversion between background opioid dose and the effective dose of transmucosal opioid (Zeppetella 2011). If switching delivery system, the patient should use the lowest dose and titrate as appropriate (RACGP 2016).

Oral Transmucosal Fentanyl Citrate (OTFC) is a lozenge on a stick. This has a bioavailability of approximately 50% and a time of onset of analgesia of less than 5 minutes. Dosing should start at 200microg and be titrated up as needed to 1600microg. Doses should not be repeated within 4 hours. If the long acting opioid dose increases, OTFC should be re-titrated starting at the lowest dose (RACGP 2016).

Fentanyl buccal tablets (FBT) have a higher bioavailability (65%) and a time to onset of analgesia of 10 minutes.

Sublingual fentanyl citrate orally disintegrating tablets (ODT) dissolve under the tongue. They have a bioavailability of 70% and a time to onset of analgesia of 15 minutes.

Practice Points

Fentanyl patches should only be started in opioid tolerant patients with stable pain (Actavis 2012; RACGP 2016). Switching between brands is not advised due to possible changes in absorption.

If changing from a long acting oral opioid, apply the patch at the same time as giving the last dose of 12 hours acting opioid or 12 hours after the last dose of 24 hours acting oral opioid (RACGP 2016).

Fentanyl patches take 24–72 hours to reach maximum effect (RACGP 2016).

Used fentanyl patches must be disposed of safely as 30–50% of the fentanyl content remains after 72 hours of use (RACGP 2016).

For patch reactions, topical beclometasone inhaler may be used prepatch application (off label use).

Matrix patches may be cut diagonally to allow low dose titration (off label use) (Scottish Partnership for Palliative Care 2013).

Advise patients not to apply heat (e.g., hot water bottle) over the patch as this will increase local absorption of the fentanyl leading to possible opioid toxicity (RACGP 2016).

TD fentanyl absorption may be lower in cachectic patients compared to normal weight patients with cancer pain (Heiskanen et al. 2009).

7.4.3 Morphine, Hydromorphone, and Oxycodone

Morphine remains the gold standard opioid endorsed by the WHO although the evidence base is small (Wiffen et al. 2016b). Morphine is metabolized via glucuronidation in the liver to morphine-6-glucuronide and morphine-3-glucuronide. M6G is a highly active metabolite giving analgesia as well as respiratory depression. M3G does not give analgesia but may give neurotoxicity symptoms. M3G and M6G are both renally excreted; therefore, morphine is not recommended in patients with renal failure (Schug et al. 2015). If no alternatives exist, then the dose and the frequency of morphine administration should be reduced.

Hydromorphone

Hydromorphone is approximately five times more potent than morphine. The main metabolite is hydromorphone-3-glucuronide (H3G) which, like M3G, has no analgesic activity but may cause neurotoxic side effects. H3G requires renal function for clearance; hence, hydromorphone should be used with caution in renal failure. Low level evidence suggests the chance of opioid

toxicity in patients with renal failure is less than with morphine (King et al. 2011; National Clinical Effectiveness Committee 2016).

Oxycodone

Oxycodone has a higher oral bioavailability than morphine. Oxycodone's main metabolites are noroxycodone (via CYP3A) and oxymorphone (via CYP2D6). Oxycodone and oxymorphone are responsible for the majority of the analgesic effect. CYP2D6 polymorphism may explain the variation in analgesic effect between patients. CYP3A inhibitors (e.g., ketoconazole) may increase oxycodone effect and toxicity (Schug et al. 2015).

Morphine, Oxycodone and Hydromorphone in Palliative Care

Studies suggest that morphine, oxycodone, and hydromorphone have similar efficacy and toxicity in the cancer patient population (Caraceni et al. 2011, 2012; Wiffen et al. 2016b). In patients not responding to one opioid, it is reasonable to trial opioid switching (Dale et al. 2011; Mercadante and Caraceni 2011; Wiffen et al. 2016b; Schmidt-Hansen et al. 2017). Studies are currently underway comparing multiple opioids for efficacy in cancer pain.

Uncertainty continues for the possible role of opioids to treat neuropathic pain. There is currently a lack of high quality research data. Adverse effects from opioids being used to treat neuropathic pain are common (McNicol et al. 2013). A Cochrane review has found insufficient evidence to support or refute the use of hydromorphone (Stannard et al. 2016) or methadone for use in adults with chronic neuropathic pain (McNicol et al. 2017).

7.4.4 Tapentadol

Tapentadol is a combination mu agonist (20 times lower affinity than morphine) and noradrenaline-reuptake inhibitor. Due to its combination action, clinically tapentadol appears to be approximately three times less potent than morphine (Mercadante et al. 2013). Tapentadol has no significant effect on serotonin reuptake.

Tapentadol is metabolized by glucuronidation. Liver dysfunction may require a dose reduction. It has no active metabolites and at recommended doses (maximum 500 mg/24 hours) has no adverse effects on heart rate or blood pressure. It is recommended not to use tapentadol in severe renal failure (eGFR <30). Use of tapentadol is contraindicated within 14 days of treatment with an irreversible, nonselective monoamine oxidase inhibitor (MAOI) (Schug et al. 2015; RACGP 2016).

Tapentadol in Palliative Care

As a relatively recently introduced medication, there is limited research data available. A meta-analysis of oral tapentadol for cancer pain found limited evidence only. Analgesia and adverse effects were similar for tapentadol, morphine, and oxycodone (Wiffen et al. 2015b).

7.4.5 Methadone

Methadone is a synthetic opioid. It is available as a racemic mixture of R and L enantiomers; however, it is the R-enantiomer principally responsible for its mu receptor effect. Methadone also has weak NMDA antagonist and noradrenaline and serotonin reuptake inhibitor effects.

Methadone has good oral bioavailability (70–80%) and high potency and is metabolized via the cytochrome p450 pathway. Medications that induce or inhibit the cytochrome p450 pathway may lead to a relative decrease or increase in methadone levels. Methadone has a long, unpredictable half-life making titration complex and leading to the risk of accumulation. High doses of methadone have been associated with prolonged QTc in patients.

Dose adjustments may be required in severe renal failure. No dose adjustments are needed in stable liver disease. Use of methadone in severe hepatic failure is not advised unless for use in terminal care (Schug et al. 2015; RACGP 2016).

Methadone in Palliative Care

A recent meta-analysis investigating the role of methadone for cancer pain suggested based on low-quality evidence, methadone had similar efficacy to morphine (Nicholson et al. 2017). There is inadequate evidence available to form

conclusions on the use of methadone for chronic neuropathic pain (McNicol et al. 2017). The EAPC suggest that methadone can be used as a first line strong opioid for moderate-severe cancer pain (Caraceni et al. 2012).

Practice Points

Higher doses of methadone may increase the QT interval. Avoid co-administration of other medications, which may prolong the QT interval.

Consider ECG monitoring of QT interval if using high doses of methadone.

Methadone is metabolized by many Cytochrome P450 iso-enzymes – beware of interactions that may increase or decrease methadone plasma levels (Twycross 2016; RACGP 2016).

Subcutaneous methadone can cause local irritation. Intermittent boluses may cause less irritation than continuous subcutaneous infusion (Shaiova et al. 2008). If continuous infusion is required, the addition of low dose dexamethasone to the syringe driver may be if benefit; however, this may cause solution instability (Leppert 2009).

When switching from other strong opioids to methadone (as opposed to adding methadone as a co-analgesic), several conversion options are described (McLean and Twomey 2015):

Three-Day Switch (3DS)

Day 1: 30% of opioid given in equianalgesic TDS dose of methadone, 70% usual opioid.

Day 2: 60% usual dose of opioid given in equianalgesic TDS dose of methadone, 40% usual opioid.

Day 3: 100% of dose given as equianalgesic TDS dose of methadone.

Rapid Conversion (RC)

Original opioid is discontinued. Daily methadone dose is calculated according to evidence-based conversion ratios given in 3 equal divided doses. This dose is then titrated to give good analgesia.

Ad Libitum (AL)

Original opioid is discontinued. Equivalent daily total methadone dose is calculated. One-tenth (this may be too high, episodes of toxicity have been noted, some studies have had good effects as low as 1/40th) of calculated dose (max 30 mg) is given as needed (not more than three hourly. On day 6 the total requirement of the previous 2 days is calculated and split into 12 hourly dosing.

Outpatient Titration

Original opioid continued. Methadone is commenced at low dose (e.g., 5 mg Q4H) and then increased by 5 mg/dose every 3 days until good analgesia is achieved. The original opioid is weaned and methadone increased over a variable period.

Current evidence suggests the AL titration may be the safest (McLean and Twomey 2015). Methadone switch should only be done by a clinician experienced in its complex pharmacology and its uses. Preexisting opioid-induced hyperalgesia may lead to significantly higher calculated dosing of methadone than necessary causing subsequent toxicity.

Conversion tables are available. One of the commonly used conversion tables is from the Royal Perth Hospital (Ayonrinde and Bridge 2000).

7.4.6 Opioids in Renal Failure

There is low quality existing evidence for opioid treatment in cancer patients with renal failure (Twycross et al. 2016; Sande et al. 2017). Guidelines were published by EPCRC in 2011 (King et al. 2011).

These suggest for mild to moderate renal impairment (eGFR 30–89)

1. Assess for any reversible factors
2. Be aware estimations of GFR may be less accurate in cachexia, low protein states, edema, and acute renal failure.
3. Monitor for changes in renal function and consider pre-emptively changing opioids in rapidly deteriorating renal function
4. All opioids that are appropriate for cancer pain can be used with consideration of reduced dose or frequency.

Metabolite activity and risk stratification shows (King et al. 2011)

Group 1 (no clinically significant active metabolites)
Fentanyl, alfentanyl, methadone
Group 2 (active or probably active metabolites)
Tramadol, hydromorphone (possible reduced risk of toxicity)
Oxycodone, morphine, diamorphine, codeine
Group 3 (insufficient evidence)
Buprenorphine

Severe and end stage renal failure (eGFR <30) (King et al. 2011)
1st line: fentanyl
2nd line: alfentanyl
Use with care: tramadol, hydromorphone

It is suggested that automatic conversion to a possibly safer opioid, with which the prescriber has limited experience, may not be of benefit in the last hours to days of life if a current dose and time appropriate opioid providing symptom relief without significant side effects (Twycross 2016).

Opioid use in dialysis patients (King et al. 2011)
Fentanyl: not dialyzable, safe, use with caution
Methadone: not dialyzable, safe, use with caution
Tramadol: dialyzable, use with caution, max 200 mg/24 hours
Hydromorphone: metabolite dialyzable, safe, use with caution
Buprenorphine: not dialyzable, safe, use with caution
Avoid if possible: morphine, codeine.

Opioid Switch

Opioid switching or rotation to a different opioid may be of benefit either when pain control is inadequate, the patient prefers a different route of delivery, changing clinical status (e.g., unable to swallow tablets) or when side effects are intolerable (Dale et al. 2011; Mercadante and Caraceni 2011; Syrmis et al. 2014; National Clinical Effectiveness Committee 2016). It is postulated that improved analgesia is from incomplete cross-tolerance between strong opioids in individual patients. The current evidence base to support this is low (Dale et al. 2011).

Tables and electronic applications are available to guide dosing in opioid rotation although there remains variation between geographic sites and services (ANZCA; Mercadante and Caraceni 2011; Syrmis et al. 2014; Twycross 2016). See Fig. 8 for an example of an Opioid Conversion Chart. Conversion ratios are less predictable at higher doses (Schug et al. 2015). A dose reduction of 25% is often suggested on opioid switching given the possible incomplete-cross tolerance although this may not be necessary when severe pain is the reason for opioid rotation and rather should be assessed on a case by case basis (Mercadante and Caraceni 2011; Caraceni et al. 2012; National Comprehensive Cancer Network 2016). When switching opioids, frequent clinical review and reassessment of pain and adverse effects is recommended.

When converting from oral morphine or hydromorphone to subcutaneous, ratios of 2:1 to 3:1 (oral: subcut) are commonly used (i.e., 10 mg po morphine is equivalent to 3.3–5 mg subcutaneously (Scottish Intercollegiate Guidelines Network 2008; Caraceni et al. 2012). Because of oxycodone's high oral bioavailability a conversion ratio of 1.5:1 (oral to subcutaneous) may be appropriate (Twycross 2016).

Methadone has an oral bioavailability of approximately 80%. Guidelines when converting from oral to subcutaneous suggest a conversion of 2:1 or 1:1 at low dose (oral to subcut) and note that 2:1 may be underdosing requiring appropriate breakthrough analgesia doses to be available (Shaiova et al. 2008; Leppert 2009; Twycross 2016).

7.5 Adjuvant Analgesics: Antidepressants and Antiepileptics

Neuropathic pain descriptors are present in up to 40% of cancer pain patients (Caraceni and Portenoy 1999). Neuropathic cancer pain is associated with greater analgesic requirements and a larger impact on activities of daily living than nociceptive cancer pain (Rayment et al. 2013).

PALLIATIVE CARE OPIOID CONVERSION CARD
Conversion factors are a guide only; Patients should be titrated individually. Patients on opioids require regular laxatives (eg Coloxyl with Senna)

CONVERTING FROM MORPHINE TO OTHER OPIOIDS AND *VICE VERSA*

Drug	Oral	Subcut	Equi-analgesic conversion to oral Morphine
Morphine	10mg	5mg	
Hydromorphone	2mg	1mg	Multiply by 5
Codeine	100mg	Avoid	Divide by 10
Note : 1 tablet Panadeine Forte = 30mg Codeine.+ 500mg Paracetamol 1 tablet Panadeine = 8 mg Codeine.+ 500mg Paracetamol Doses of codeine over 60mg every 4-6 hours are not recommended			
Oxycodone	7mg	3.5mg	Multiply by 1.5
Tramadol	100mg	Avoid	Divide by 10
Methadone	Variable		Discuss with consultant

CONVERTING FROM MORPHINE TO TRANSDERMAL FENTANYL

Oral Morphine mg/4 hrs	Oral Morphine mg/24 hrs	Fentanyl Patch mcg/hr
5	20-59	12
10-20	60-134	25
35	135-224	50
50	225-314	75
65	315-404	100

PALLIATIVE CARE OPIOID CONVERSION CARD

CONVERTING FROM TRANSDERMAL BUPRENORPHINE AND TRANSDERMAL FENTANYL TO MORPHINE

	Patch size	Hourly rate	Conservative conversion to oral Morphine
BUPRENORPHINE (Norspan) (change weekly)	5mg	**5mcg/hr**	12mg/day
	10mg	**10 mcg/hr**	24mg/day
	20mg	**20 mcg/hr**	48mg/day
FENTANYL (Durogesic) (change every 72 hrs)	2.1mg	**12mcg/hr**	30mg/day
	4.2mg	**25 mcg/hr**	60mg/day
	8.4mg	**50mcg/hr**	120mg/day
	12.6mg	**75mcg/hr**	180mg/day
	16.8mg	**100mcg/hr**	240mg/day

Due to the possibility of poor transdermal absorption in palliative care patients,conversion from transdermal Buprenorphine (Norspan) or Fentanyl (Durogesic)
to Morphine should be **very conservative**

HammondCare Palliative & Supportive Care Service Opioid Conversion Card – revised September 2010

Fig. 8 Example of an Opioid Conversion Chart. (Reproduced courtesy of HammondCare Palliative and Supportive Care Service. These values are a guide only and doses should be reviewed for individual patients)

Adjuvant analgesics (e.g., antidepressants, antiepileptics, lignocaine) can be helpful in the management of neuropathic pain. There is limited evidence to support use of medications for neuropathic pain and often choice is guided by the side effects of the medication chosen (e.g., more or less sleep), the comorbidities of the patient, and potential drug interactions (Fallon 2013).

7.5.1 Adjuvant Analgesics in Neuropathic Pain in the General Population

As limited data is available regarding treatment options for neuropathic pain in palliative care patients, it is reasonable to assess the data for neuropathic pain in the general population in case there is some crossover (National Clinical Effectiveness Committee 2016).

Recent Cochrane reviews looking at antidepressants to treat neuropathic pain in the general population found evidence to support the use of duloxetine (Lunn et al. 2014), inadequate research but longstanding note of clinical effectiveness of amitriptyline (Moore et al. 2015a), and little or no evidence to support the use of milnacipran (Derry et al. 2015a), venlafaxine, nortriptyline, imipramine, and desipramine (Hearn et al. 2014a, b; Derry et al. 2015b; Gallagher et al. 2015).

Antiepileptic medication treatment for neuropathic pain has also been the subject of reviews by the Cochrane library. Pregabalin and gabapentin have been shown to be the most effective antiepileptics for neuropathic pain management (Moore et al. 2009; Wiffen et al. 2013b) with lesser evidence for levetiracetam (Wiffen et al. 2014b), lacosamide (Hearn et al. 2012), carbamazepine (Wiffen et al. 2014a), sodium valproate (Gill et al. 2011), and oxcarbazepine (Zhou et al. 2013). No evidence was found to support the effectiveness of topiramate (Wiffen et al. 2013a), zonisamide (Moore et al. 2015b), and there was inadequate research to support the role of clonazepam (Corrigan et al. 2012).

Opioids have equivocal evidence in the use of neuropathic pain. Intermediate term studies have been of poor quality, and the effects of opioids in long-term neuropathic pain management have not been studied (McNicol et al. 2013; Stannard et al. 2016).

A meta-analysis of pharmacotherapy for neuropathic pain in a general (nonpalliative) population was published by the Neuropathic Pain Special Interest Group (NeuPSIG) of the International Association for the Study of Pain (IASP) in 2015 (Finnerup et al. 2015). They note that patients with neuropathic pain often do not receive appropriate treatment.

Their research suggested first-line options (strong recommendations) for use of gabapentin, pregabalin, duloxetine, venlafaxine, and tricyclic antidepressants. There were weak recommendations (second line) for capsaicin 8% patches and lidocaine patches for peripheral neuropathic pain. Tramadol was also given a weak recommendation for use (second line). Strong opioids (with note of the risks of this) and botulinum toxin A (subcutaneously to the painful area, specialist use only) both received third-line, weak recommendations.

Similar findings have been published by NICE suggesting first-line treatments for all neuropathic pain (excluding trigeminal neuralgia) in the general population should be with amitriptyline, gabapentin, pregabalin, or duloxetine (NICE 2013).

7.5.2 Antiepileptics in Palliative Care Pain Management

The gabapentinoids gabapentin and pregabalin are structurally similar compounds thought to be presynaptic calcium channel blockers. Pregabalin has a higher oral bioavailability, hence requiring lower dosing. Pregabalin has a more rapid absorption and is more rapidly titratable (Pruskowski and Arnold 2015). Both undergo renal excretion and require dose reduction in renal failure. There are no known drug interactions with gabapentin or pregabalin. The main side effects are fatigue, sedation, tremor, and dizziness. Increases in peripheral edema can occur (RACGP 2016).

Recent reviews looking at gabapentinoids for cancer pain and opioids in conjunction with either antiepileptics or antidepressants for cancer pain comment on the limited evidence base, the challenge of purely assessing response to specific pain types (e.g., neuropathic pain), and the risk of

adverse effects. They suggest there may be benefits for some patients, and this should be balanced against the risks on a patient-by-patient approach (Kane et al. 2017; Jordan et al. 2018).

Sodium valproate has been studied in a phase 2 trial only (Hardy et al. 2001).

7.5.3 Antidepressants in Palliative Care Pain Management

There are very few studies assessing the benefits of amitriptyline (Kane et al. 2017). Given its widely accepted use in nonpalliative patients with neuropathic pain, it is reasonable to trial starting at low dose while observing for any intolerable side effects, particularly dry mouth, dizziness, urinary retention, and sedation (RACGP 2016).

It may be reasonable to trial duloxetine or venlafaxine given the evidence for their benefit in the nonpalliative patient population. There is inadequate evidence to support the use of SSRIs for neuropathic pain (National Clinical Effectiveness Committee 2016).

7.6 Other Analgesia Options

7.6.1 Ketamine

Ketamine is predominantly an antagonist of NMDA receptors, with some effects on muscarinic receptors, descending monoaminergic pathways, calcium channel and central opioid receptors (Prommer 2012; RACGP 2016). Ketamine is used as a general anesthetic, however at lower doses has a use as an adjunct in postoperative pain management, acute burns pain management, management of patients with opioid-induced hyperalgaesia, and specific neuropathic pain syndromes (Prommer 2012; Schug et al. 2015).

Side effects of ketamine include emergence reactions, which may include unpleasant dreams and hallucinations, local skin reactions, somnolence, and dizziness. In a randomized control trial in a palliative care patient population, low doses of ketamine (0.5–1 mg/kg/day) were not associated with significant side effects (Salas et al. 2012). High dose slow intravenous bolus injections of ketamine in palliative care patients were associated with patients developing hallucinations (Mercadante et al. 2000). The hallucinations were treated successfully with diazepam.

Evidence in Palliative Care

A recent meta-analysis looking at the role of ketamine as an adjuvant to opioids for cancer pain found a very limited evidence base and was unable to assess the benefits and harms of ketamine as an adjunct to opioids for the relief of cancer pain. There was no clinical benefit associated with a rapid dose escalation of ketamine (ketamine burst), and this may be associated with serious adverse events (Bell et al. 2017).

Ketamine should only be used on a patient by patient basis by experienced clinicians given the possible side effects.

Further trials looking specifically at groups with neuropathic pain and using a weight-based dosing approach may be of benefit.

7.6.2 Lidocaine

Lidocaine is a local anesthetic agent. It reversibly interrupts impulse conduction in peripheral nerves and inhibits depolarization of cell membranes by blocking sodium channels (RACGP 2016). It can be used topically, by local infiltration, regional nerve block, neuraxial routes, intravenously or subcutaneously (Schug et al. 2015; Twycross 2016; RACGP 2016). Side effects have been noted at higher dosing and include perioral numbness, metallic taste, nausea, tinnitus, sedation, and cardiac arrhythmias. ECG monitoring has been shown to not be necessary in the cancer pain population when appropriate doses are used-reported protocols include an infusion of 5 mg/kg over 1 hours, titrated up to a maximum of 10 mg/kg over 1 hours (Peixoto and Hawley 2014) or an initial bolus of 1–2 mg/kg over 15–20 minutes followed by a continuous infusion of 1 mg/kg/h (Thomas et al. 2004). Lidocaine should not be used in patients receiving class one antiarrhythmics (e.g., flecainide) (Scottish Partnership for Palliative Care 2013).

Topical lidocaine patches (5%) are licensed for treatment of post herpetic neuralgia (Meier et al. 2003); however, they can be expensive. The patches have a dual action, the mechanical action of the hydrogel patch, and the pharmacological

action of the local anesthetic. One to three patches can be applied (and can be cut to size) to dry, nonirritated skin. The patches are applied in a "12 hours on, 12 hours off" regime, ideally with showering happening in the patch free time. Skin reactions to the patch are common. There is some systemic absorption ($3 \pm 2\%$), but steady states were reached after 4 days with no evidence of accumulation (BioCSL 2015). Heat should not be directly applied to the patch as this may increase absorption.

A systematic review of pharmacotherapy for neuropathic pain in adults in all patient populations from 2015 found weak evidence to support the use of topical lidocaine patches (suggested second line treatment) (Finnerup et al. 2015).

Mexilitine and lidocaine administered systemically appear to be superior to placebo for neuropathic pain (Challapalli et al. 2005).

Systemic Lidocaine in Palliative Care

There is preliminary evidence for the benefit of systemic lidocaine in palliative care patients, and its use should be limited to specialist palliative care settings (Sharma et al. 2009; National Clinical Effectiveness Committee 2016; Seah et al. 2016).

Topical Lidocaine Patches in Palliative Care

High quality evidence is lacking. There appears to be benefit in neuropathic pain with associated allodynia. Patient satisfaction was high (65%) and adverse events rate low (Fleming 2009; Garzon-Rodriguez et al. 2013).

7.6.3 Steroids

Corticosteroids are potent inhibitors of inflammation and can exhibit predominately glucocorticoid effect (e.g., dexamethasone), mineralocorticoid effect (e.g., fludrocortisone) or both (e.g., hydrocortisone). Dexamethasone is often used in palliative care given its high potency anti-inflammatory effect. Dexamethasone is approximately 6–12 times more potent than prednisolone.

Side effects vary from early to late. Early side effects include hyperglycemia, hypocalaemia, psychiatric effects, and gastric irritation. Long-term side effects include proximal myopathy, fluid retention, bone density loss, and fat redistribution (Twycross 2016; RACGP 2016).

Steroids in Palliative Care

There is little high quality evidence to support the use of steroids for pain in palliative care patients (Paulsen et al. 2013, 2014; Haywood et al. 2015).

Dexamethasone may have a role in prophylaxis of radiation-induced pain flare after palliative radiotherapy for bone metastasis (Chow et al. 2015).

Guidelines suggest a limited trial of steroids may be undertaken, particularly for nerve compression or inflammation, if no benefit the treatment should be rapidly tapered (National Comprehensive Cancer Network 2016).

7.6.4 Bisphosphonates/Denosumab

Bisphosphonates are osteoclast inhibitors licensed for the treatment of osteoporosis, hypercalcaemia of malignancy, Paget's disease of bone, and prevention of skeletal-related events (SRE) in patients with malignancy involving bone (Twycross et al. 2016; RACGP 2016). Bisphosphonates are available in oral and intravenous forms. Side effects include hypocalcaemia, flu-like symptoms (particularly iv formulations), esophagitis (especially alendronate), reflux, and gastritis. The risk of osteonecrosis of the jaw (ONJ) is higher with increased potency, iv route, total dose of bisphosphonate, and a history of dental surgery. Zoledronic acid seems to have a higher risk of ONJ than pamidronate (RACGP 2016).

Calcium nadir is usually 4–7 days post-treatment. Adequate hydration must be ensured as bisphosphonates can affect renal function. No dose adjustment is necessary for mild-moderate renal failure (Twycross 2016).

Denosumab prevents activation of the receptor activated nuclear-kappa β ligand (RANKL), reducing formation and activation of osteoclasts. It is licensed for treatment of osteoporosis, hypercalcaemia of malignancy, and prevention of SRE due to bone metastases from solid tumors and has some indications in giant cell tumors of bone. Side effects include hypocalcaemia (calcium nadir is usually 8–11 days post-treatment, although may be later), musculoskeletal pain, and ONJ. Calcium and vitamin D supplements are recommended unless hypercalcaemia is present (RACGP 2016). Denosumab does not

require dose adjustment in renal failure (Twycross 2016).

Bisphosphonates and Denosumab for Pain in Palliative Care Patients

A Cochrane review has examined the role of bisphosphonates in multiple myeloma (2012) showing a reduction in pathological vertebral facture, SRE, and pain with a number needed to treat of 5–13 to reduce pain in one patient (Mhaskar et al. 2012). A Cochrane review looking at bisphosphonates and denosumab in patients with breast cancer bone metastases found bisphosphonates may reduce bone pain and improve quality of life (Wong et al. 2012).

A recent systematic review investigating the evidence for the analgesic role of bisphosphonates and denosumab in the treatment of pain due to bony metastases as a part of the European Association for Palliative Care guidelines project has shown weak evidence only for the role of bisphosphonates or denosumab for analgesia. Their main role may be in delaying the onset of bone pain (Porta-Sales et al. 2017). This review has replaced the Cochrane review of bisphosphonates for bone metastases pain from 2002 (Wong and Wiffen 2002).

A meta-analysis looking specifically at bisphosphonates or denosumab in patients with breast cancer showed high level evidence for reduction in skeletal related events and moderate level evidence for reduced bone pain (O'Carrigan et al. 2017).

8 Interventional Procedures

Procedures may be broadly categorized into local (e.g., nerve block), regional (e.g., sympathetic, plexus, roots, paravertebral blocks), or central (e.g., intrathecal, epidural blocks). Interventions may be temporary (e.g., local anesthetic/steroid injection), longer term (e.g., radiofrequency ablation, pump delivery device), or permanent (e.g., neurolysis, spinal cord stimulator). Evidence reports that 8–11% of palliative care patients could benefit from an interventional procedure (de Courcy 2011). Interdisciplinary collaboration with specialist pain services is supported by evidence-based guidelines (Scottish Intercollegiate Guidelines Network 2008; National Clinical Effectiveness Committee 2016; National Comprehensive Cancer Network 2016).

8.1 Coeliac Plexus Block

This is the commonest neurolytic sympathetic block and is used for relief of pain of pancreatic and other upper abdominal malignancies (de Courcy 2011). The block is performed either under radiological guidance or via endoscopic ultrasound guided approach. There is evidence to support improved analgesia, possible reduction in opioid use, and consequent reduction in side effects of medications (Arcidiacono et al. 2011; Mercadante et al. 2015).

8.2 Intrathecal Pumps

Intrathecal pumps deliver medication directly into the CSF. Intrathecal catheters have a lower risk of complications such as blockage and catheter tip fibrosis than epidural catheters (de Courcy 2011). Analgesics options for infusion include opioids, local anaesthetics, clonidine and baclofen. These can either be delivered via a subcutaneously tunneled line leading to an external pump or an implanted pump delivery system, which is refilled periodically (Lynn et al. 2011; Upadhyay and Mallick 2012). Implanted pumps are more expensive but have a lower infection risk and are likely to be more useful for people with longer life expectancies (Chambers 2008).

Complications include surgical, mechanical, or pharmacological complications (including the potential risk of decreased respiratory function with intrathecal opioids) and the risk of infection (Upadhyay and Mallick 2012).

8.3 Spinal Cord Stimulators

Wire stimulators are placed via the epidural space on the dorsal surface of the spinal cord. The

stimulation is thought to work via the gate theory principles, inhibiting peripheral noxious stimuli. They do not themselves use any medications and can be used in conjunction with multimodal analgesia. A meta-analysis from 2015 found case report evidence only. There were generally reduced analgesia requirements in patients, with the main adverse effects being implantation site infection, CSF leakage, dislodgement of electrodes, and system failure. It concluded current evidence was insufficient to establish the role of Spinal Cord Stimulators in refractory cancer-related pain (Peng et al. 2015).

8.4 Cordotomy

Percutaneous cordotomy can be of benefit to unilateral pain in a specific area, e.g., a limb or the chest wall. A relatively frequent indication is unilateral chest wall pain from mesothelioma. It is carried out under CT guidance targeting the C1/2 level spinothalamic tract contralateral to the side which is symptomatic for the patient (Shepherd et al. 2017). The patient must be able to lie flat for a period of approximately 30 minutes and answer questions appropriately when stimulation testing is carried out to allow adequate localization. It is a highly specialized procedure and not widely available (de Courcy 2011). Systematic reviews note poor quality evidence level but that cordotomy appears to be safe and effective (France et al. 2014).

Side effects are usually transient and include headache, weakness and mirror pain (France et al. 2014).

9 Conclusion

To best manage a patient's pain, the pain must be recognized, a full pain assessment undertaken and an appropriate management plan formed involving the patient and those around them. Evidence is continually evolving for many approaches to pain management. It is reassuring to note that most patients will manage good pain control, often using a multimodel strategy employing targeted treatments, nonpharmacological, and pharmacological options.

Abstract

Breathlessness is pervasive in late stage disease both because of the disease itself, comorbidities, and cachexia. Given its high prevalence, it is sad that the options for symptomatic treatment (having optimized the management of underlying cause(s)) is so small. Careful assessment of potentially reversible causes contributing to breathlessness is paramount. Nonpharmacological interventions have a relatively strong evidence base as does regular, low dose, extended release oral morphine. There is a need for ongoing research into this pervasive and frightening symptom given the impact it has on patients, their caregivers, and health professionals.

1 Definitions

1.1 Chronic Breathlessness

Chronic breathlessness is a distinct clinical entity. In 2017, an international consensus document was published that identified chronic breathlessness as a distinct clinical syndrome defined as:

> Breathlessness that: persists despite optimal treatment of the underlying pathophysiology; and results in disability. (Johnson et al. 2017)

It is of note that a stated duration was not needed for "chronic." This means that the clinician determines that breathlessness is likely to persist from this point onward. The definition also does not seek to differentiate between underlying etiologies of breathlessness, especially given the fact that for many people a combination of a dominant cause and comorbidities contributes to the subjective sensation. The definition also does not seek to define the level of disability that a person needs to experience in order for it to be labeled *chronic breathlessness syndrome*.

Like other symptoms, breathlessness is a subjective sensation, and the person's own account of the experience forms the basis of the clinical evaluation. Studies have sought unsuccessfully to relate physiological changes to the degree of chronic breathlessness, but any relationships correlate poorly (Nishimura et al. 2002). Likewise, descriptors of the breathlessness most often do not help to distinguish underlying causes clinically. The one exception is in chronic obstructive pulmonary disease (COPD) where the description of breathlessness is more commonly associated with emotional descriptors like "frightening," "helpless," and "awful" (Williams et al. 2008).

In practical terms, this means that people with chronic breathlessness are likely to be experiencing problems with basic activities of daily living

(toileting, bathing, dressing, preparing meals) or in moving around their environment.

1.2 Acute Breathlessness

Recent work has defined episodes of acute breathlessness in the palliative care population that have been defined both in terms of duration and underlying etiology (Simon et al. 2016, 2013). The key characteristics that have clinical and management implications include:

- Significant burden as it is high frequency, high intensity and for a proportion of people has no identifiable precipitating cause; and (Simon et al. 2013)
- The duration of these episodes is often measured in minutes (median in people with chronic obstructive pulmonary disease (COPD) 7 min; lung cancer 5 min). (Weingartner et al. 2015)

The first of these factors is important because the unpredictability of these episodes is, in itself, a cause of anxiety and distress. For people with obvious precipitating causes, at least the precipitant can be avoided or, failing that, identified and managed proactively.

The latter is important because the available pharmacological symptom control measures are not going to be bioactive in the necessary timeframe even if they are immediately at hand to take. As such, other approaches are needed to lessen the impact of these distressing episodes.

1.3 Acute-on-Chronic Breathlessness

For many people, episodes of acute breathlessness are superimposed on chronic breathlessness in the palliative care setting. For practical purposes, this may need clinicians to consider management of the chronic breathlessness that occurs at rest or on minimal exertion *and* separately have a management plan for acute exacerbations, especially if there is no identified precipitant for the breathlessness in that setting.

2 Community Prevalence of Chronic Breathlessness/ Duration of Chronic Breathlessness/Patient Attributable Causes of Chronic Breathlessness/Preexisting Breathlessness as People Come to Palliative Care

Across the community, rates of chronic breathlessness have rarely been measured (in contrast to rates of breathlessness in specific care settings or with specific clinical conditions). Across the last 60 years, a handful of studies have been undertaken using a variety of measures. Ultimately, the rates vary slightly, but there are data that suggest more women than men experience breathlessness across the community and that the burden of breathlessness increases with age. Attributable causes include respiratory, cardiovascular, and neuromuscular disorders. By far the most prevalent causes relate to respiratory disease most frequently due to tobacco smoking. The duration of breathlessness in this population that impinges on day-to-day activity varies widely depending on the underlying cause(s), but for people with attributed respiratory causes, the duration of chronic breathlessness tends to be much longer than for other attributable causes. For many people significant symptom burden and limits to activities of daily living may last for decades in those with respiratory causes.

In the setting of palliative care, not all symptoms are attributable to the life-limiting illness. Indeed, many people have long-standing symptoms that predate their life-limiting illness. This is the case with breathlessness also. Given the community rates of chronic breathlessness, many people will experience this as an intercurrent symptom which may worsen during the course of their life-limiting illness due to the life-limiting illness, the comorbid condition, or a combination of both.

3 The Meaning of Breathlessness

As with many sensations, there is a stimulus, the transmission of the stimulus, and the response of the host. Models in pain and breathlessness have

an additional step between transmission and response. This involves the meaning of the symptom to the patient and involves cortical processing of the stimulus. It is one of the major reasons that there is a real gulf between studies of healthy volunteers where breathlessness is induced in a laboratory session (and therefore where there is control over the duration and intensity of the stimulus) and people who experience breathlessness as part of their existence with no likelihood of the underlying causes being further improved.

The lived experience of breathlessness must be considered when seeking to understand the magnitude of its impact on patients and their families. The meaning of breathlessness is important as clinicians seek to reduce the impact on people's lives. Different underlying etiologies give rise to potentially clinically important differences that may have relevance to how patients discuss their breathlessness and how clinicians respond. For example, in people with COPD, breathlessness is a constant reminder of mortality and help for it is only sought in crises (Gysels and Higginson 2010, 2011). Discussion about prognosis, even in the face of it shortening, is often limited or absent (Gysels and Higginson 2010). Worse still, for people with lung cancer, it is often perceived that the disease is self-inflicted, limiting patients' ability to elicit all of the help that they need from clinicians.

4 Mechanisms Leading to Breathlessness

Breathlessness is a complex sensation of breathing discomfort modulated by the interaction of physiological, psychosocial, and external factors (Nishino 2011). This is probably one reason why the experience of breathlessness varies so widely from person to person and might in fact correspond to different sensations depending on the relative weight of each contributor (Elliot et al. 1991).

Brain regions like the insular cortex, cingulate cortex, and amygdala (Herigstad et al. 2011) have been repeatedly implied in the perception of breathlessness in neuroimaging studies. For example, the perceptions of air hunger inflicted by ventilation restriction and the sensation of discomfort caused by resistive breathing are processed in the insular cortex (Banzett et al. 2000). In these cases, the intensity of breathlessness grows in direct proportion to the stimulus intensity which suggests a simple underlying physiologic mechanism. Conversely, the right posterior cingulate cortex seems to be involved in the modulation of the sensation of breathlessness which is unrelated with the stimulus intensity and may involve emotional processing (Peiffer et al. 2001). An additional study implied the anterior insula and amygdala process the unpleasantness of breathlessness (von Leupoldt et al. 2008). Notably, these were experimental studies with healthy volunteers in which breathlessness was artificially induced.

Neuroimaging studies in people with breathlessness, particularly chronic breathlessness, are rare. However, preliminary data shows that central processing of chronic breathlessness is different than experimentally induced breathlessness (Johnson et al. 2015) involving different brain regions and mechanisms. For example, chronic breathlessness in people with COPD is associated with activation of the prefrontal cortex that regulates fear-related memory and emotional learning. Similar to acute breathlessness, chronic breathlessness is also associated with activation of the anterior cingulate cortex. However, this activation directly correlates with emotional processes like depression, fatigue, and hypervigilance which may play a key role in modulating this symptom (Herigstad et al. 2015).

5 Measuring and Describing Breathlessness/MCID

5.1 Taking a History

Clinically, eliciting an accurate history of breathlessness is something that we do not do well. People who are obviously struggling to breathe will often deny that they are breathless. One crucial

reason for this is that people adjust their activities to minimize their risk of becoming more breathless.

When taking a clinical history, most of us ask "How are you doing?" rather than "What are you doing?" Arguably, the most important question is to ask *is* "What have you had to give up in order to avoid breathlessness?" People adjust their activities of daily living to minimize their experience of breathlessness, often leading to a shrinking footprint as the underlying cause(s) worsen. In turn, for many people with chronic breathlessness, this leads to increasing levels of social isolation that is distressing and a cause of suffering in itself.

5.2 Measuring Breathlessness

There are a large number of tools that help to measure breathlessness. Many of these are only suited to the research setting. In clinical practice, a simple 0–10 numerical rating scale (NRS) (Wilcock et al. 1999) asking about average and worst breathlessness intensity in the previous 24 h is going to most closely reflect the lived experience of that person. In acute breathlessness (such as an acute worsening of asthma), the minimum clinically important change in an NRS for a person to start to feel less breathless is 2 points on the NRS (Ries 2005). More recent work suggests that in chronic breathlessness, a reduction of one point will be discerned by patients as an improvement worth experiencing (Johnson et al. 2015). This is reflected strongly in qualitative work with people who are experiencing breathlessness and their caregivers (Rocker et al. 2013). In this study, respondents made it clear that even small reductions in the intensity of the symptom made a big difference to how they felt.

Although there are multidimensional tools that measure breathlessness and a number of established tools that take into account a range of domains that reflect the complexity of the symptom and people's response to it, their use is largely limited to the research setting. Tools such as the St George's Respiratory Questionnaire (SGRQ) (Jones et al. 1991), Baseline Dyspnea Index (BDI)/Transition Dyspnea Index (TDI) (Mahler et al. 1984), Multidimensional Dyspnea Profile (MDP) (Banzett et al. 2015), or the Chronic Respiratory Questionnaire (CRQ) (Guyatt et al. 1987) are important in helping to fully evaluate breathlessness; they are relatively long and take a great deal of time. Their utility in a busy clinical setting is therefore somewhat limited (Glaab et al. 2010).

6 Clinical Framework for Palliating Breathlessness

Good palliation of breathlessness reflects principles common to all symptom control (Wiseman et al. 2013). It is best outlined as a "breathlessness ladder" by the Canadian Thoracic Society (Marciniuk et al. 2011). As with any symptom, ensure that reversible causes are adequately addressed. Addressing these causes should only occur if they are going to be symptomatically relevant to the patient's symptom. The next step is to consider non-pharmacological approaches that can help to reduce the person's breathlessness or its impact on their lives and, finally, consider safe, evidence-based pharmacological therapies to improve the symptom.

7 Evaluating Reversible Causes of Chronic Breathlessness

Many clinicians assume that some other clinician has evaluated systematically each patient's potentially treatable causes of breathlessness. The one consecutive case series that has been published would suggest otherwise (Dudgeon and Lertzman 1998). In this consecutive cohort of 100 patients with cancer, there was a median of five causes likely to contribute to the person's breathlessness. These include people with hypoxemia (40%), anemia that was likely to be symptomatically significant (20%), and people with evidence of bronchospasm (52%). Optimizing the management of each of these contributing factors is pivotal to good symptom control, even very late in life.

8 Non-pharmacological Interventions for Breathlessness

There is a strong evidence base underpinning non-pharmacological interventions for chronic breathlessness. This includes a comprehensive systematic review of the available randomized studies (Bausewein et al. 2008). Key, evidence-based interventions with high levels of evidence include:

- Chest wall vibration which involves high-frequency chest wall oscillation administered by an inflatable vest worn by the patient for 10–15 min twice daily for 12 weeks.
- Neuroelectrical muscle stimulation of quadriceps, hamstrings, and calf muscles (thought to work by helping to reverse the breathlessness-deconditioning-worsening breathlessness cycle). Interestingly, although the benefit is there for the time it is being used (20 min/day, three times per week for six continuous weeks), by week 12 (6 weeks off therapy) any benefit had disappeared. This is an area where continued clinical trials are occurring.

Those with moderate levels of evidence include:

- Walking aids such as frames (likely by their impact on the mechanics of the chest wall and hence helping to make breathing more efficient).
- Breathing training, which requires to be cognitively intact and motivated to work with therapists. Elements of this include relaxation, activity pacing, and planning for activities.

9 Oxygen for Breathlessness

Oxygen is widely used in the setting of palliative care and people with breathlessness, often without adequate assessment of oxygenation (Currow et al. 2009). Oxygen is easily started in ambulances, in the emergency department, or on the wards. Having started oxygen, it is often difficult to cease oxygen even when there is little objective evidence of symptomatic improvement. Like any therapy, there are benefits and harms which need to weighed up when considering the use of oxygen.

For more than three decades, there has been evidence of survival advantage for people with severe hypoxemia ($PaO_2 \leq 55$ mmHg) or moderate hypoxemia (PaO_2 56–59 with cor pulmonale or polycythemia) (Tarpy and Celli 1995; McDonald et al. 2005). These data fail to speak to the symptomatic benefit of oxygen. Three recent studies help to inform this. One is a large, double-blind, randomized controlled trial (RCT) of oxygen compared to medical air, and the other two were meta-analyses of oxygen studies dating back 30 years (Abernethy et al. 2010; Uronis et al. 2008, 2015).

The RCT enrolled 239 participants, none of whom qualified for long-term oxygen therapy (LTOT) (Abernethy et al. 2010). Participants were asked to use oxygen or air for greater than 2 L per min for more than 15 h per day for 7 days. No primary measure was significantly different across the study although those with worse hypoxemia tended to benefit more, and morning scores were better in the oxygen study, with the likelihood that people tended to use oxygen overnight as one way to achieve their required use although this was not measured in the study.

The first meta-analysis was of oxygen in people with cancer as their life-limiting illness who did not qualify for LTOT. There was no symptomatic benefit from oxygen over medical air (Uronis et al. 2008). By contrast, the other study focused on RCTs in people with COPD who did not qualify for LTOT but where breathlessness was measured as a secondary outcome (Uronis et al. 2015). Every 1 of the 18 studies favored oxygen over medical air, and the point estimate with very tight confidence intervals was strongly in favor of oxygen. Fundamentally, this is a change in the way oxygen is currently prescribed and funded. Uptake of this finding into practice has been variable.

Clinically, given the evidence base from rigorous clinical trials, people with chronic breathlessness should be considered for a time-limited trial

of LTOT. Clearly defined end points are needed for such n-of-one trials.

9.1 Patients', Prescribers', and Caregivers' View of Oxygen in the Palliative Setting

Caregivers tend to support the use of oxygen for people with chronic breathlessness in the palliative setting. Oxygen is considered to have a vital role in relieving breathlessness, decreasing breathlessness-associated anxiety, and essentially in sustaining life (Collier et al. 2017). Caregivers also think that oxygen has a major role in improving patient's quality of life (Goldbart et al. 2013). Disadvantages reported include mobility conditioning, the equipment required, and associated costs (Collier et al. 2017).

10 Pharmacological Interventions for Reducing the Sensation of Chronic Breathlessness

10.1 Opioids

10.1.1 Basic Science Including Mechanisms of Action for Opioids for Chronic Breathlessness

Meta-Analyses

All adequately conducted meta-analyses for the use of opioids for the reduction of chronic breathlessness indicate clinical benefit without the harms that many clinicians associate in their minds for people with respiratory disease and opioids – respiratory depression. The largest studies have used extended-release preparations of morphine orally as the basis for the pharmacological intervention.

Jennings et al. (2002), Ekström et al. (2015; for COPD only, with an emphasis on steady state), and a more recent Ekström et al. review (2018) all show that symptomatic benefit consistently favors morphine. These are now sizable meta-analyses with results reflected across a range of study designs and outcome measures.

Initiation and Titration of Morphine for Chronic Breathlessness

The largest randomized studies to date have initiated therapy in opioid-naïve patients with once-daily extended-release morphine 20 mg (Currow et al. 2017). Titration has not been widely studied. One large longitudinal dose ranging study suggested that when responding symptomatically to successful titration (with a maximum dose of 30 mg per 24 h), there was a marked benefit in the first 24 h, but the maximal benefit was not seen for up to 5 days (Currow et al. 2013b). This suggests that upward titration should occur cautiously. There is no evidence to support the use of supplemental or "as-needed" immediate-release morphine solution in people with chronic breathlessness nor in the setting of acute-on-chronic breathlessness. In people already on opioids for other indications, the only guidance from randomized controlled trials is that an upward titration of 25% of the baseline dose is likely to be of benefit (Allard et al. 1999; Currow et al. 2011).

Predictors of Response

Pooled data from prospective studies of morphine for chronic breathlessness identify two major predictors of response for the symptomatic reduction of chronic breathlessness: younger age and more severe breathlessness (Johnson et al. 2013). Further work needs to be done to understand fully the factors that underlie response and, importantly, lack of response. The latter may include factors relating to variations in opioid metabolism or receptors (Currow et al. 2015).

11 Other Pharmacological Approaches

11.1 Buspirone

The largest study done to date was a randomized, double-blind, placebo-controlled trial of buspirone 20 mg/day orally for 4 weeks, an

anxiolytic in 432 participants (Peoples et al. 2016). Despite being adequately powered and with a cogent underlying theoretical base that reducing anxiety would help people to cope with breathlessness, this was a strongly negative study. The intervention was well tolerated but delivered no symptomatic benefit for breathlessness nor anxiety. Physiologically, there was no difference in oxygen expenditure.

11.2 Anti-depressants

There are tantalizing pilot data that suggest there may be benefit from the use of antidepressants in reducing chronic breathlessness. The mechanism of action has yet to be defined, but it appears to be independent of underlying anxiety or depression. A large placebo-controlled, randomized trial has been completed and the results are awaited with interest (Watts et al. 2016).

11.3 Benzodiazepines

Benzodiazepines are widely used in people with breathlessness. In a meta-analysis, the evidence base for their use has not demonstrated benefit over placebo (Simon et al. 2016), and although one may be able to make a case for benefit in someone who is acutely distressed by new breathlessness, the case for their use in the chronic setting (and the tolerance that rapidly develops to them) mitigates against their use for chronic breathlessness.

12 Clinician Education

The existing workforce of both family physicians/general practitioners and specialists are likely to have been trained before currently available evidence for the existence of a distinct syndrome nor that it is safe and effective to use low-dose, regular extended-release morphine to reduce the intensity of chronic breathlessness. This means that clinician education should target both existing practitioners and tomorrow's practitioners also.

In qualitative work, prescribers identify very similar themes. Family physicians and specialists both identify the concerns about insufficient knowledge as this was not part of their training and fear of legal censure for prescribing opioids for an indication other than pain (Young et al. 2012; Rocker et al. 2012; Collier et al. 2015). These identified barriers require specific interventions that target clinicians' concerns (Currow et al. 2013a; Hutchinson et al. 2017). Simply publishing guidelines or presenting data at conferences or in peer-reviewed journals, for example, is not sufficient.

13 Implications for Caregivers

Providing care for someone with chronic breathlessness is a challenge for caregivers. The role most often falls to family and friends. It is daunting to watch someone that you love struggle to breathe. It goes to the very heart of being alive and having that life threatened. One challenge is that the care that needs to be offered can be for very long periods of time (often measured in years) with stable but debilitating disease (Johnson et al. 2012). As noted, many people experience worsening of their chronic breathlessness, sometimes without an obvious precipitant (Simon et al. 2013). Not only is this challenging for patients, but it is difficult for caregivers. Structuring an agreed approach for the things that will help the patient in this setting is one of the most important conversations to have with patients and their caregivers. Like many such plans, the agreed approach will need to be revisited as social and clinical issues change. A clear level at which to escalate care to the emergency department is part of this work (Luckett et al. 2017).

14 Health Service Implications of Breathlessness

Breathlessness is a frequent cause of contact with health services – in primary care 0.9% of all adult consultations relate to breathlessness

(Currow et al. 2013b). Acute-on-chronic breathlessness is a major reason for the use of prehospital services such as ambulance and in attendances at the emergency department (Hutchinson et al. 2017). In one large consecutive case series in a high-income country, acute-on-chronic breathlessness accounted for 20.2% of all major emergency presentations to the emergency department and 5.2% of all presentations (Hutchinson et al. 2017). In primary care, breathlessness increases the likelihood of the consultation being a home visit or a visit to a residential aged care/skilled nursing facility threefold and increases the likelihood of an urgent transfer to hospital by 2.5-fold (Currow et al. 2013a). A large proportion of the presentations to the emergency department appear to be related to acute-on-chronic exacerbations of breathlessness and have often settled from the crisis point that precipitated the decision to seek professional help by the time that they are assessed clinically (Hutchinson et al. 2017).

14.1 Self-Management Strategies

Such patterns of presentation raise the important question of whether there are opportunities to improve systematically self-management skills for patients and their families to reduce reliance on emergency services. Tentative steps are being taken in formative studies to improve the way people are educated and supported when they have a chronic condition and breathlessness that may lead to acute exacerbations (Disler et al. 2014; Luckett et al. 2016, 2017).

Ensuring that people are able to identify the precipitants of their breathlessness and have specific management plans for the likely triggers is an important first step. Having good caregiver understanding of the condition and ways that its impact can be minimized is also likely to be helpful. Caregivers consistently identify that they do not fully understand the lived experience of chronic breathlessness and are not sure how best to help but clearly want to be able to do something during acute exacerbations (Gysels and Higginson 2011).

15 Driving and Breathlessness: Opioids

Being able to drive is crucial for most adults enhancing their participation in different daily activities and providing a sense of personal freedom and independence (King et al. 2011). Conversely, driving cessation is associated with social isolation, worse health-related outcomes, higher mortality, and decreases in quality of life (Marottoli et al. 2000; Mezuk and Rebok 2008; Chihuri et al. 2016). Importantly, 23% of people receiving palliative care are still driving and an additional 16% still considering it in the future (Widman and Bergstrom 2014). Many of these patients are prescribed opioids for symptom control and are advised not to drive while taking them (Weir et al. 2017). However, a systematic review on the quality and generalizability of the studies evaluating therapeutic opioids and driving reported a large heterogeneity in study designs which may contribute to conflicting results and limited generalizability (Mailis-Gagnon et al. 2012). The most recent systematic review on opioids and driving reported no significant impact of oral or transdermal opioid agonist formulations on patient's driving-related skills (Ferreira et al. 2018). However, only three empirical studies were included in this review in which the need for further research is this area is highlighted.

At this stage, some guidelines recommend that clinicians advise patients not to drive while initiating and up-titrating therapeutic opioids (Drug & Alcohol 2008; Austroads 2014). This precautious approach is mainly based on research with healthy volunteers using single-dose, immediate-release opioid formulations. Also, psychometric tests are frequently the outcome measures although their translation for on-the-road driving outcomes is questionable. Interestingly, it is not known if initiating therapy with extended-release formulations would have detrimental effects on driving-related skills.

There is also some data showing the impact of uncontrolled symptoms on people's driving-related skills. In one study, nonmalignant pain was shown to be more detrimental than opioid intake for driving-related outcomes assessed

by a driving simulator (Nilsen et al. 2011). In another study, participants with chronic malignant pain performed worse in psychometric tests than controls taking opioids (Sjøgren et al. 2000). Although no similar studies are available for other symptoms, there is evidence suggesting that chronic breathlessness significantly also affects outcomes on the road (Karakontaki et al. 2013).

Given the scarcity of robust evidence in this field, clinicians face some challenges when providing advice in regard to opioids and driving. At this point, it is important to recognize that (i) advising a patient not to drive may have severe psychosocial implications, (ii) there is limited evidence associating oral and transdermal opioids with negative driving-related outcomes, and (iii) symptoms may play an important role in the ability to drive safely. As such, it is recommended that advice should be tailored individually based on the anamnesis (including symptom severity), physical exam, and, for some doubtful cases, a driving assessment. It is important to note that all patients should be advised not to drive if they experience side effects like sedation, dizziness, or confusion.

Fatigue

12

Martin Mücke and Dmitrij Kravchenko

Contents

Abstract

Fatigue is a subjective multidimensional illness that plays an immense role, sometimes having an even greater impact than symptoms such as pain, nausea, and vomiting, in a patient's quality of life. Once treatable causes

for fatigue are excluded, a multimodal therapy plan should be developed with considerations toward the wishes and preferences of the patient. Research suggests that feelings of physical well-being and emotional stability are the most important aspects with respect to the quality of life, regardless of cultural and individual differences. Similarly, the social integration of the patient and their ability to self-reliantly live out their day-to-day life is also of great importance.

1 Introduction

Fatigue is part of a regulatory system that serves to keep the balance between activities and rest. Unfortunately, patients who are suffering from life-limiting disorders tend to experience fatigue with an overwhelming intensity, leading to a state of imbalance where sleep and rest do not lead to recuperation. This combination of physical, emotional, and cognitive weariness or exhaustion is termed fatigue. The exact causes and mechanisms are not yet well understood, with no definitive diagnostic criteria or lab markers available, making fatigue difficult to recognize and properly diagnose. A thorough description of the symptoms ailing the patient is of utmost importance in the clinical setting. What is known to date is that in most cases, fatigue is not attributable to one single cause; it has a multifactorial genesis and is more than just the sum of its causes. It is an ailment with multiple layers which severely limits the patient's quality of life during their disease trajectory. The vast majority of palliative care patients are subjectively affected by this complex symptom. Fatigue in patients with life-limiting diseases reduces, alone or in combination with other symptoms such as pain, dyspnea, or nausea, the overall quality of life considerably and plays a significant role as one of the most important prognostic factors. Fatigue can manifest itself at any time in the course of a life-limiting disease and can even be observed many years after cancer therapy. Data regarding the prevalence of fatigue varies tremendously depending on the clinical definition of fatigue, diagnostic tools, the form of therapy, and the point in time during which examinations are carried out. The clinical appearance of fatigue has many faces and includes physical, cognitive, and affective aspects. Problems such as the multidimensional clinical appearance of fatigue and the lack of a unifying model explaining its etiology and pathogenesis make it most difficult to formulate a universal definition of this syndrome.

The identification and treatment of fatigue is an interdisciplinary task which involves all parts of the health care team. In the last few years, there has been enormous growth in literature regarding clinical experience with fatigue, as well as fundamental research into the mechanisms of this syndrome. This chapter is geared toward all professional health care groups which provide care to palliative care patients. By discussing topics such as the clinical manifestation of fatigue, etiology, leading theories and promising research, diagnostics, management, non-pharmaceutical therapies, pharmaceutical therapies, and rehabilitation, this chapter aims to provide an overview but also highlights how much is left to research and how little we understand this prevalent syndrome. We hope that this chapter will aid our colleagues in the health care field to better recognize, understand, and effectively treat this very complex ailment.

2 Overview

Fatigue is defined by the EAPC (European Association of Palliative Care) as a subjective feeling of tiredness, weakness, or lack of energy (Radbruch et al. 2008). It can be thought of as a cluster of symptoms affecting the physical and cognitive capabilities of a person. These two aspects can then be further generalized as weakness representing the physical part and fatigue/weariness representing the cognitive aspect. Approximately up to 80% of advanced stage cancer patients suffer from fatigue, making it next to pain and cachexia one of the most common symptoms of late-stage cancer. Fatigue can affect people of all ages, although there is currently insufficient research regarding children

and adolescents. Unlike healthy individuals, who recover their energy during rest and sleep, cancer patients suffering from fatigue do not, leading to a feeling of a heavy continuous strain and disability, as well as a lower perceived quality of life. Glaus, a leading expert on fatigue, stresses the importance of the qualitative differences between general fatigue that healthy people may experience and cancer-related fatigue (CFR), the latter which affects the long-term physical, affective, and cognitive aspects of the patient's well-being. However, other authors have stressed that differences between general fatigue seen in healthy people and fatigue in palliative care patients may be due to the more overwhelming intensity of fatigue in palliative care patients rather than the qualitative difference between cancer patients.

The pathophysiology is not yet fully understood; this makes it difficult to suggest a broad general therapeutic approach. Fatigue is a multidimensional condition which requires a multimodal therapy. This includes physical, psychiatric, social, and spiritual interventions, which together can lead to an improved disease management and to a better quality of life.

3 Definition and Prevalence

Multiple definitions have been suggested for the tumor-associated fatigue, also referred to as "cancer-related fatigue." David Cella, who was the first to define fatigue in 1995, defined it as "a subjective state of overwhelming, sustained exhaustion and decreased capacity for physical and mental work that is not relieved by rest" (Cella et al. 1998). Over time, criticism emerged regarding the seemingly arbitrarily chosen duration and intensity of the symptoms. A consensus was reached when the Fatigue Coalition USA suggested to use the ICD-10 criteria, shown in Table 1 (Cella et al. 2001).

The National Comprehensive Cancer Network (NCCN) defined fatigue as follows: "Cancer-related fatigue is a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning" (Berger et al. 2015).

Table 1 Proposed ICD criteria for CFR

	Six (or more) of the following symptoms have been present every day or nearly every day during the same 2-week period in the past month, and at least one of the symptoms is significant fatigue (A1)
A1	Significant fatigue, diminished energy, or increased need to rest, disproportionate to any recent change in activity level
A2	Complaints of generalized weakness or limb heaviness
A3	Diminished concentration or attention
A4	Decreased motivation or interest to engage in usual activities
A5	Insomnia or hypersomnia
A6	Experience of sleep as unrefreshing or nonrestorative
A7	Perceived need to struggle to overcome inactivity
A8	Marked emotional reactivity (e.g., sadness, frustration, or irritability) to feeling fatigued
A9	Difficulty completing daily tasks attributed to feeling fatigued
A10	Perceived problems with short-term memory
A11	Post-exertional malaise lasting several hours
B	The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning
C	There is evidence from the history, physical examination, or laboratory findings that the symptoms are a consequence of cancer or cancer therapy
D	The symptoms are not primarily a consequence of comorbid psychiatric disorders such as major depression, somatization disorder, somatoform disorder, or delirium

The EAPC definition considers the physical and cognitive dimensions of fatigue as the least common denominator in their discussion, regarding the affective attributes as part of a natural consequence of the reduced quality of life. On the other hand, other definitions have highlighted additional dimensions of fatigue. Glaus, for example, described fatigue as a multidimensional symptom complex, which consisted of 59% physical, 29% affective, and 12% cognitive sensations (Glaus 1998). The physical symptoms are made

up of decreased performance, weakness and lack of strength, extreme physical exhaustion, as well as an unusually increased need for sleep and rest. The affective and emotional level is comprised of a sense of helplessness, irritability, limited participation in usual activities, sadness, fear, and lethargy. The cognitive symptoms consist of difficulty concentrating, thought disorders, as well as sleep problems (falling asleep, staying asleep).

Research has shown that fatigue is the most common and most debilitating of the problems faced by tumor patients after the conclusion of cancer therapy (Lawrence et al. 2004; Stark et al. 2012). Symptoms such as lack of energy and drowsiness have been observed in 74% and 60% of tumor patients, respectively. Around 30–50% of these patients reported undiminished fatigue even years after successful cancer treatment. The chances of suffering from fatigue rise to nearly 99% after chemo- or radiotherapy, making fatigue one of the most debilitating side effects of these therapies. Not only cancer patients are plagued by this syndrome, patients suffering from other chronic life-threatening illnesses such as congestive heart failure, respiratory failure from COPD or lung fibrosis, or HIV/AIDS have a high chance of being afflicted by a significant fatigue symptom burden. For multiple sclerosis, fatigue is reported as the most common symptom with 83% of the patients being affected. In contrast to disease-related fatigue, the long-lasting chronic fatigue syndrome (CFS) can be observed in 0.3% of the population. Seventy percent of the CFS cases develop after an infection, so that an immune disorder or viral component is being hypothesized. The proposed diagnostic criteria are made up of three main criteria: a substantial reduction or impairment in the ability to engage in pre-illness levels of occupational, educational, social, or personal activities that persist for more than 6 months and are accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest; post-exertional malaise; and unrefreshing sleep (Committee on the Diagnostic Criteria for Myalgic Encephalomyelitis/Chronic Fatigue Syndrome, Board on the Health of Select Populations, and Institute of Medicine 2015). A psychological component is found in 40% of CFS patients.

Fatigue in palliative care patients must be differentiated from cachexia, or the anorexia-cachexia syndrome (ACS).

Fearon et al. defined cachexia as:

> . . . a multifactorial syndrome characterised by an ongoing loss of skeletal muscle mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment. The pathophysiology is characterised by a negative protein and energy balance driven by a variable combination of reduced food intake and abnormal metabolism. (Fearon et al. 2011)

Further diagnostic criteria for cachexia include weight loss of over 2% over 2 months, more than 5% over 6 months, or a body mass index (BMI) less than 20 kg/m^2. Muscle mass and stomach fat are not the only tissues affected by cachexia: atrophies and loss of functionality are seen in other systems, and until ultimately, heart failure leads to death.

3.1 Potential Causes of Fatigue

Patients presenting with fatigue should be checked for treatable causes of the symptoms. For example, depression or side effects from medications can mimic fatigue and should be excluded before the diagnosis of fatigue is made. Depression can be difficult to distinguish from fatigue due to overlapping symptoms such as weakness and lack of energy. Symptoms such as recurrent feelings of worthlessness or recurrent thoughts about death can be an indication for depression rather than fatigue. A list of potential causes of fatigue can be found in Fig. 1.

3.2 Etiology and Pathophysiology

To date, there exists no unifying theory which explains the etiology and pathogenesis of fatigue. Although, multiple different pathophysiological pathways have been described, it is widely

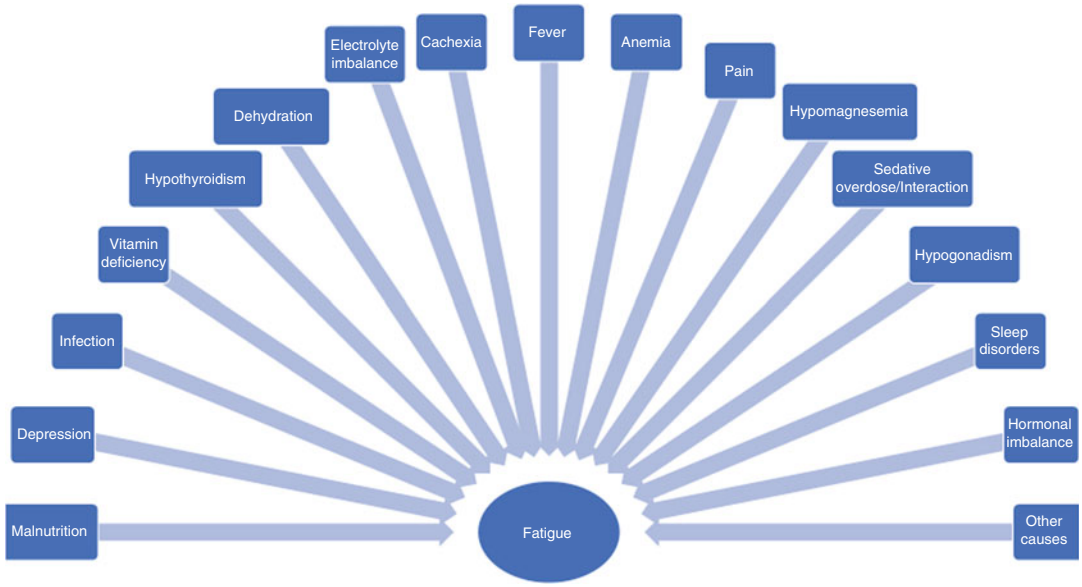

Fig. 1 Possible disorders leading to fatigue

believed that the origin of fatigue can be categorized as either peripheral or central. Peripheral fatigue has been associated with changes in muscle metabolism, while central fatigue has been related to a disorder in the hypothalamic-pituitary-adrenal (HPA) axis as well as the circadian rhythm, resulting in cognitive disabilities (Stone and Minton 2008; Wang 2008). It is possible that the various causes of fatigue require specific therapies and management. The etiology of cancer-related fatigue (CRF) has not been yet fully explained. Cancer-associated symptoms, including CRF, are influenced by polymorphisms. For example, polymorphisms of genes regulating inflammatory cytokines were shown to be risk factors for cancer-related fatigue (Bower and Lamkin 2013; Collado-Hidalgo et al. 2008). Because of this, a multifactorial pathophysiology is presumed. The development of CRF can either be due to direct influences of the cancer or can result as a side effect of antineoplastic radio- or chemotherapy. Radio- or chemotherapy may also cause other side effects such as paraneoplasias, anemia, metabolic disorders, or cachexia, all of which may aggravate CRF.

Cancer-related fatigue may also be classified into primary and secondary. Primary CRF is thought to be directly related to the tumor itself, while secondary CRF is the result of physical distress related to pain, sleeping disorders, infections, malnourishment, hypothyroidism, and anemia, but also emotional stress and depression. Many factors are likely to contribute to CRF in late-stage cancer, so that a clear distinction between primary and secondary is not always possible (Radbruch et al. 2008). The use of pharmaceuticals can also contribute to the development of fatigue. For example, the use of opioids can lead to an opioid-induced fatigue due to their sedative attributes.

Due to our poor understanding of the pathophysiology of fatigue in palliative care patients, there is a pronounced need for more research. A few talking points which are currently being discussed as contributing or causal factors are:

- An increased production of pro-inflammatory cytokines, such as TNF-α, IL-1β, and IL-6 either by the tumor, as a reaction of the immune system, or by the paraneoplastic entity.
- A high serotonin level due to a dysregulation favors a reduction in the somatomotor drive.
- Activation of afferent vagal nerves by released neuroactive substances leads to suppression of

somatic muscle activity and induction of weakness and weariness.
- Disruptions in the hypothalamic-pituitary-adrenal (HPA) axis pathway through cytokines, IFN-α, or IL-2 lead to ACTH (adrenocorticotropin) suppression and consequently a reduction in cortisol secretion.
- ATP (adenosine triphosphate) dysregulation in muscle cells due to a defect in ATP regeneration, muscle mass loss caused by cortisone intake, or certain chemotherapeutic substances.
- Disruption of the circadian rhythm and melatonin secretion. These hypotheses are partly based on studies that focused on illnesses characterized by the occurrence of fatigue, such as work-induced tiredness, CFS, and rheumatoid arthritis.

4 The Patient's Perception

Most patients view CRF as part of an inevitable progression of their disease, which results in them rarely addressing it in conversation with their physicians. This may be reinforced by the patient's assumption that there is nothing that can be done to alleviate CRF or that CRF treatment could have unwanted side effects. If the maintenance of physical performance is an important part of the patient's self-perception, it may be difficult for them to admit a weakened resilience. In oncology, medical staff tend to put the emphasis of care on the main illness, leading to fatigue being perceived as a symptom of secondary importance which may distract from the primary goal of treating the cancer. A structured assessment with the help of questionnaires like the Edmonton Symptom Assessment System (ESAS) or the "minimal documentation system" (MIDOS) is helpful for the screening of relevant symptoms in clinical practice. The MIDOS2 is a German adaptation of the ESAS and functions as a tool for repeated symptom self-assessments by the patients. It tests ten items (with two additional items being labeled as "other" which the patient can specify) on a four-step visual rating scale ranging from "not present," "light," "middle," and "strong." The ten items include pain, nausea, vomiting, dyspnea, constipation, weakness, lack of appetite, tiredness, depressive mood, and fear. In addition, the current state of well-being is also assessed (very bad, bad, moderate, good, and very good). Screening instruments such as the ESAS or MIDOS are easy to use and require little time to fill out, resulting in a lower burden for the patient but allowing a good overview of the patient's situation for the medical staff (Stiel et al. 2010).

4.1 Fatigue and Depression

It is not uncommon to see depression being associated with CFS. Differentiation between depression and fatigue is difficult, as there is considerable overlap in the diagnostic criteria. This becomes apparent when comparing the ICD criteria for depression with those for fatigue. For example, weariness is a pronounced symptom of depression, while sadness, fear, and lethargy have been described as part of an affective dimension of fatigue. Depression may aggravate the perceived burden of fatigue and the subjective suffering of the patient. Vice versa, it has been shown that fatigue is able to induce and intensify depression. However, differentiating between which parts of the symptom burden are attributable to fatigue and which to depression, and if predominantly one or both are contributing, may be important for the therapeutic regimen. In some cases, depression may be easier to treat than fatigue, and the successful treatment of depression may partly or even completely alleviate the fatigue symptomatic. When considering differential diagnoses, keep in mind that feelings of guilt, self-deprecation, and a sense of imminent death are more typical of depression rather than fatigue. The differentiation between depression and fatigue is not always possible, even a skilled psychiatric specialist utilizing a structured clinical interview will sometimes not be able to distinguish the two. The patient history can be a helpful tool for separating the two syndromes if it includes questions regarding previous depressive episodes, if the symptoms of fatigue preceded the depressive symptoms, and whether the fatigue

symptomatic is a new experience which occurred parallel to the underlying disease.

5 Fatigue and the Social Sphere

Fatigue is not just distressing for the affected patient, but is also a challenge for the whole surrounding social system, including the partner, family, and friends. The chronic form of fatigue, especially after long periods of therapy, often makes it difficult for patients to return to a daily routine. Friends and family have to realize that joint activities are no longer a trivial thing due to the lack of energy of the patient. Interpersonal roles, relationships, and social relations can change as a consequence of the illness. Friends might be reluctant to spend time together, as they feel overwhelmed by the condition of their friend and might not know how to react. This often leads to a feeling of disappointment and isolation by the patient and may in turn produce negative developments and setbacks in the course of the illness. Afflicted patients should be informed that their limitations due to exhaustion, their needs, and their expectations should be openly communicated within their social sphere. Only the greatest possible candor can minimize misunderstandings and help improve relationships. Professional help in the form of psychotherapists should also be offered early on to not only the patient but also to family and friends.

6 Fatigue When Returning to Work

For most patients, the ability to work is an integral part of their quality of life and strengthens their sense of self-reliance and purpose. Patients may be limited in their ability to work due to a lack of concentration, memory problems, and the reduced ability to think clearly, depending on the level of exhaustion. This can often lead to a delayed reintegration into their work life. Thus, patient information and education on topics such as acceptance of their illness, neuropsychological deficits, and the complex somatic limitations that go hand in hand with fatigue is of utmost importance. Rehabilitation assessments can offer a possibility to gauge the patient's personal performance deficits, making it possible to arrange a personalized rehabilitation plan for the reintegration of the patient back into the workforce. An important aid for the return to work are stepwise reintegration programs where employee, employer, and physician agree on a step-by-step workload increase over a period of time until either a 100% workload or the highest possible workload that does not affect the patient's recovery is reached. Unfortunately, this is not always feasible so that individual solutions must be found. An excessively demanding workload must be avoided as it can create recurring frustration and commonly ends in resignation which further amplifies the fatigue symptomatic. A similar strategy of openness and candidness as with family and friends is recommended in the work environment and with the employer. Problems should be addressed early on and openly to find solutions that include, for example, reduction of work hours per week or transfer to a different workstation within the company if possible. Patients should take their time with tasks and be aware of their physical needs, taking special consideration as to possible signals of over-working. A detailed consultation with the health care provider team (physician, social worker, psychologist/psychiatrist) should take place to allow the planning of a personalized reintegration plan and offer a chance for the patient to ask questions, as well as considerations to be made for disease-related retirement.

7 Diagnostics

The goals of fatigue diagnostics in seriously ill patients are:

- To better understand the symptoms and problems ailing the patient
- To capture the "as is" status of the patient at that moment
- To aid in the structuring of their day-to-day life
- To be able to effectively prioritize energy reserves to complete vital tasks

– To document the successes, but also failures, of therapeutic options

Screening should include explicit questions regarding unusual tiredness or exhaustion as part of the patient's history, as there are no reliable lab parameters or physical tests for fatigue. Answers to these screening questions will always be subjective, but self-assessment is the cornerstone of the fatigue diagnosis. Rating fatigue intensity on categorical, numerical, or visual analog scales, akin to the ones used to assess pain, can be useful to gauge the progression of the syndrome and the impact of therapeutic interventions. A differentiated and detailed fatigue and performance assessment also includes social anamnesis, physical activities and limits, and sleeping habits (Fig. 2).

In addition to the patient history, physical examination, and routine lab parameters, specific fatigue questionnaires are an effective way to round up the assessment. Some of the most commonly used quality-of-life questionnaires include the Short Form-36 Health Survey (SF-36) and the Quality of Life Questionnaire-C30 (QLQ) from the European Organisation for Research and Treatment of Cancer (EORTC), the latter being the official standard to assess quality of life in oncology which includes items regarding fatigue. The "Brief Fatigue Inventory" (BFI) and the fatigue extension of the FACT-F (Functional Assessment of Cancer Therapy: Fatigue) are used in scientific research.

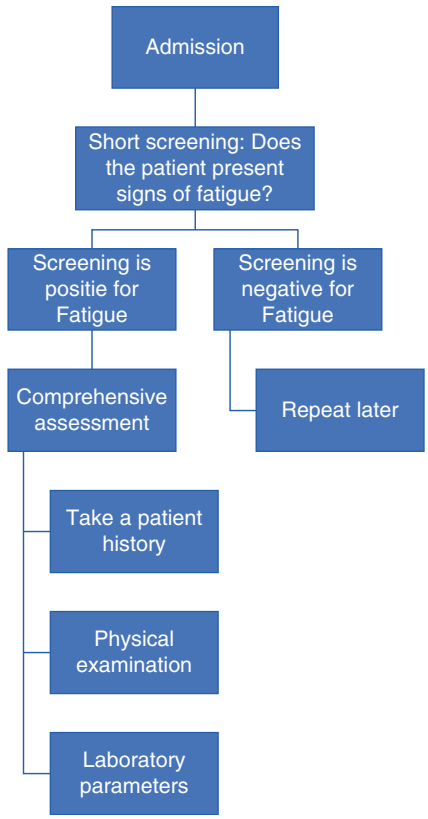

Fig. 2 Fatigue and weakness assessment on admission

8 Short Form-36 Health Survey (SF-36)

The SF-36-Item Health Survey looks at eight concepts: physical functioning, role limitations due to physical health, role limitations due to personal or emotional problems, energy/fatigue, emotional well-being, social functioning, pain, and overall health perceptions. A single item is included to gauge the perceived change in health. The answers to the questions have a weight tied to them with one getting a score of 0 and 5 a score of 100 or vice versa so that an answer with the score of 1 yields a weight of 100. Similar items get grouped together in the aforementioned categories and are averaged to form a scale. This is a good system for research but is not a quick way to assess the patient's condition in the clinical setting (Ware 2000).

8.1 European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire-C30 (EORTC QLQ-C30)

The QLQ-C30 is a 30-item self-assessment questionnaire about the quality of life. Items include questions like "During the past week: Were you short of breath? Have you had pain? Did you need to rest?" with 28 of these questions scored from 1 (not at all) to 4 (very much). The last two items are scored from 1 to 7. Similar to the SF-36, some items have to be reversed to get all scales in the

same direction and then computed in groups and single items: physical functioning, role functioning, social functioning, emotional functioning, cognitive functioning, fatigue, nausea and vomiting, dyspnea, sleeping disturbances, appetite loss, constipation, and diarrhea. This scoring system, again like with the SF-36, makes it difficult for physicians to draw conclusions at a glance (Jocham et al. 2009; "Questionnaires | EORTC" 2017; Aaronson et al. 1993).

8.2 Functional Assessment of Cancer Therapy: Fatigue (FACT-F)

The FACT-F is a 41-item questionnaire used to assess fatigue and anemia-related problems in patients suffering from cancer. It consists of the four groups of items from the general FACT: physical well-being (7 items), social/family well-being (7 items), emotional well-being (6 items), functional well-being (7 items), and the additional module on fatigue (13 items). Items, for example, "I feel weak all over. . .," are scored on a 5-point Likert rating scale ranging from 0 (not at all) to 4 (very much). As with the questionnaires above, some items must be reversed for the scoring. As an example, the fatigue subscale is scored by summing the scores of the relevant items, multiplying by 13, and dividing by the number of items answered for the subscale score, with a higher score indicating a better quality of life. The questionnaire only requires a sixth-grade level of reading comprehension to complete and usually takes no longer than 10 min to finish (Yellen et al. 1997).

8.3 Brief Fatigue Inventory (BFI)

An explicit look will be taken at the BFI Score. The BFI was specifically developed for the evaluation of fatigue in patients with oncological illnesses and can be completed (by a patient with no cognitive disorders) in about 5 min. The questionnaire entails ten items and allows to capture six different dimensions that are affected by fatigue with the question "during the past 24 h, fatigue has interfered with your: general activity, mood, walking mobility, normal work (includes both work outside the home and daily chores), relations with other people, and enjoyment of life." Each category is scored from 0 (does not interfere) to 10 (completely interferes), plus the three other questions relating to fatigue levels now, at worst time, and usually are also scored from 0 to 10 which leads to a maximum score of 90. Values between 30 and 40 indicate a moderate fatigue, while scores over 70 are typical for a severe fatigue. The advantage of the one-page BFI is that it is shorter than other questionnaires, lowering the burden for patients to complete it (Mendoza et al. 1999).

A quick screening can be performed on admission to judge a patient's level of fatigue if they are presenting symptoms. For the screening, a short survey composed of two questions inquiring about the patient's weakness (physical dimension) and tiredness (cognitive dimension) can be very effective and useful. If the screening is positive, a comprehensive assessment should be performed. Symptom severity should be evaluated, for example, with the BFI, to define the starting point before initiating treatment. The next step would be to identify treatable causes for fatigue and weakness. Figure 2 shows a suggested procedure for a fatigue screening, while Fig. 3 presents important aspects which require special attention during the taking of a history. Some laboratory parameters which could help to shed light onto treatable causes for fatigue are listed in Fig. 4.

The assessment should be repeated during causal and symptomatic treatment, with assessment intervals individually adjusted for the patient. The fatigue intensity will most likely change over the course of the disease trajectory, and periods of increased burden on the patient should be identified and the symptom management intensified accordingly. Reassessment also helps medical staff to evaluate the effectiveness of the treatment and make decisions regarding whether to initiate additional or alternative interventions if the current regimen shows inadequate effectiveness. As an objective assessment of fatigue is not possible, the patient is the only person who can assess their well-being. Subjective self-

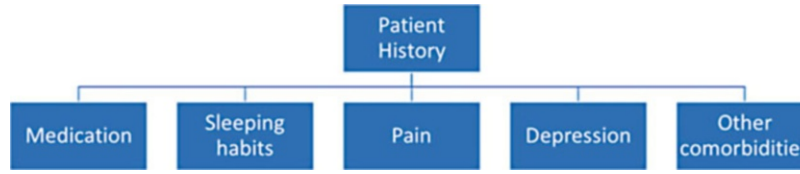

Fig. 3 Items which require special attention during a patient's history

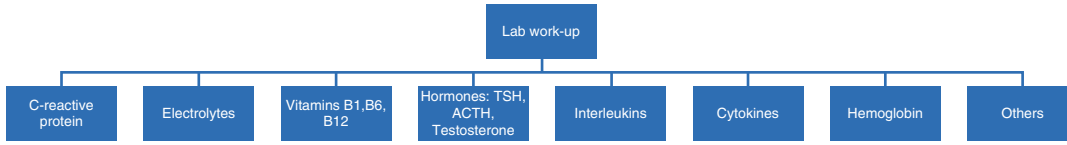

Fig. 4 Laboratory parameters suggested for routine assessment of fatigue

assessments of fatigue are an important part of the patient-reported outcome measures (PROMs) process, which is the gold standard of outcome measurement in palliative care (Bausewein et al. 2016). Unfortunately, in advanced stages of the disease, the patient's cognitive abilities may be severely impaired, preventing the use of self-assessment questionnaires. In this setting, assessment may be done by family caregivers or medical staff.

9 Therapy and Management

Fatigue management is based on comprehensive internal medicine and oncological care, which includes the treatment of comorbidities, infections, hormonal and endocrine irregularities, and a review of the medication regimen. The underlying philosophy of palliative care should be considered in all aspects of assessment and treatment of fatigue. The patient's individual needs and preferences should also be considered, and shared decision making should prevail in all situations. Discussions with the patient should take place along every step of the way, with them participating in all health care decisions. The physician should be able to clearly communicate the pros and cons of all available treatment options to the patient using language that the patient can understand so that informed consent and shared decision making can take place for all pharmaceutical as well as non-pharmaceutical interventions. The management of fatigue requires a high level of cooperation and communication between the health care provider, the patient's family and friends, and the patient themselves. Therapeutic goals, for either pharmacological or non-pharmacological interventions, can only be achieved when all persons around the patient actively work together.

Fatigue in end-stage terminally ill patients should be viewed as a natural part of the dying phase and not be considered a symptom that requires treatment. In this setting, fatigue may ease the transition to death, shielding the patient from distress, anxiety, and burdening symptoms. Symptomatic treatment of fatigue in dying patients could worsen the patient's well-being by forcing them to experience the last excruciating hours of their lives in full detail. Medical staff should recognize the appropriate time to stop treatment for fatigue to allow patients to die without distress (Mücke et al. 2016).

10 General Supportive Measures When Treating Fatigue

A fatigue diary is a useful tool in the management of fatigue. This diary should include a timeline for each day, the activity that was being performed and at what time it was performed, a comments section, and separate columns for intensity of weakness and tiredness. These last two columns should use simple scales such as a four-step categorical scale (no = 0, slight = 1, moderate = 2, severe = 3, intensity of weakness/tiredness). The diary serves as a visualization of the symptom

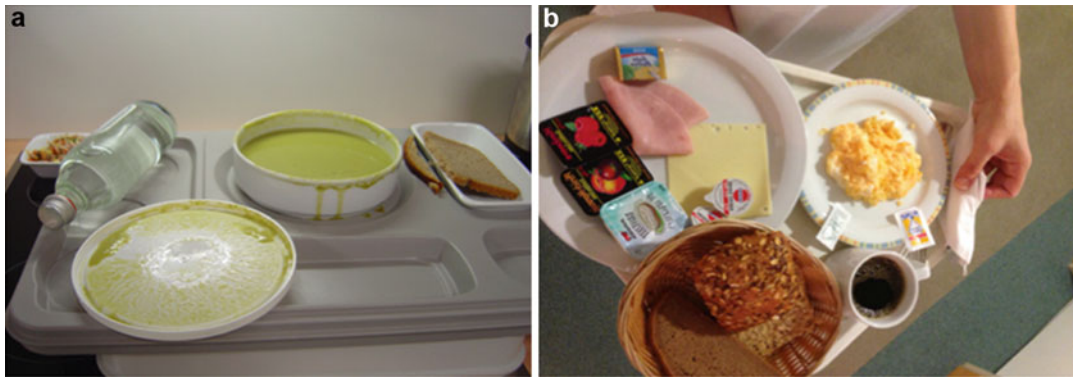

Fig. 5 (**a**) Shows unappealing, sloppily prepared food that would most likely dampen the appetite of a healthy individual. (**b**) Presents an esthetically pleasing meal which does not take much more effort to prepare than A but is more likely to be appetizing

burden and allows patients to better plan their energy reserves when they become familiar where the main limitations are. For the health care team, it allows the monitoring of the effectiveness of interventions.

A sufficient intake of water and vitamin supplements has been discussed as having a positive effect on fatigue, although there are currently no scientific studies to support this (Mochamat et al. n.d.). Drinking more fluids has been hypothesized to increase the elimination of fatigue inducing metabolites which form during chemo- and radiotherapy or other processes. Most palliative care patients suffer from a vitamin deficiency, so that a substitution with multivitamins and minerals can be justified in most cases. Nutrition plays another key role in the energy imbalance of fatigue. Diverse and varied meals should be prepared and administered in small portions. Sometimes the support of nutritional specialists and ecotrophologists (specialists in nutrition, household management, and home economics) may be needed. Clinical experience has shown that the way food is presented plays an important role on appetite in severely ill patients with appetite disorders. This is demonstrated in Fig. 5, which meal would you rather eat? Patients with severe fatigue prefer meals that do not require much effort to chew and are easy to swallow. Studies have shown that appetite and cachexia may influence each other and that treatment of appetite loss with megestrol acetate can decrease fatigue intensity. Beverages such as coffee, tea, or soft drinks can have a stimulating and pleasing effect on the patient. Alcohol, especially in the form of a predinner apéritif, has the potential to kick-start the appetite so that a glass of wine or beer is potentially recommended for those patients who report this as favorable from their history. Air quality, temperature, smells, sounds, light, and colors can also have profound effects on the well-being and should be utilized in the management of fatigue.

11 Recommendations for Pharmacological Therapies

Treatable causes of fatigue should be excluded before symptomatic pharmacological treatment of fatigue is initiated (Fig. 1). Anemia should be treated with iron supplements, vitamin B12 substitution, or folic acid depending on the cause. Even blood transfusions or erythropoietin substitution (EPO) can be considered albeit with rigid indications. Electrolyte imbalances should be corrected, and infections should be adequately treated. Endocrine disorders such as adrenocortical insufficiency or a hypothyroidism should be substituted with the respective treatment. Side effects of medications such as analgesics (especially opioids), sedatives, anticonvulsants, antiemetics, or antihypertensive drugs should be kept in mind as causes or enhancers of fatigue,

and switching to similar medications with fewer or less severe side effects should be considered.

Symptomatic pharmacological treatment of fatigue is restricted to very few options. Two Cochrane reviews have summed up the evidence on this topic (Mücke et al. 2016; Minton et al. 2010), but were not able to present clear recommendations. There are a sufficient number of studies included in these reviews, but patient numbers were small or patients from heterogenous groups were included. The comparability of the included studies was difficult due to a wide range of assessment instruments used.

Methylphenidate was evaluated in five studies including cancer patients (Bruera et al. 2006; Butler et al. 2007). One study showed no significant effect with a daily dose of 18–54 mg/day, while the other four displayed a slight improvement under a continuous intake of dosages between 5 and 30 mg/day. The mechanism of action of methylphenidate includes the inhibition of noradrenaline and dopamine reuptake in the synaptic cleft, thus resulting in increased sympathetic nervous system activity. But noradrenaline and dopamine seem not to be the only systems affected by methylphenidate; research suggests it plays another role as a serotonin receptor agonist.

Modafinil seemed to be able to effectively treat severe fatigue with dosages of 100 and 200 mg/day according to two studies (Lange et al. 2009; Spathis et al. 2014), but had no effect on mild to moderate fatigue. Similarly, modafinil was not effective in treating CFS patients with lung cancer. The therapeutic effect of modafinil is attributed to its ability to affect the sleep-wake rhythm, but due to its numerous side effects, which include severe psychiatric symptoms and cutaneous reactions, its indication is limited to the treatment of profound drowsiness in adults.

Taking a look at corticosteroids for the treatment of fatigue, dexamethasone and methylprednisolone were only included in two studies although these two drugs are recommended in official guidelines and extensively used in clinical practice. It is assumed that glucocorticoids play a positive role in managing tumor-associated fatigue due to their ability to influence the central nervous system and their anti-inflammatory attributes (Shih and Jackson 2007). A recent study demonstrated that 4 mg/day of dexamethasone was significantly superior to placebo (Yennurajalingam et al. 2013). However, there was no significant difference in the improvement of individual symptoms, psychological distress, anxiety, and depression in the dexamethasone group compared with placebo. Further studies examining the effects of dexamethasone on fatigue are needed.

Mistletoe extract PS76A2 improved fatigue symptoms in a study including breast cancer patients (Marvibaigi et al. 2014), while thyreoliberin (thyrotropin-releasing hormone, TRH) was also successfully tested but has yet to receive licensing. TRH exhibited an important influence on the central regulation of energy homeostasis, inflammatory processes of the organism, and fatigue. This is most likely due to its extra-hypothalamic and central nervous system activity (Kamath et al. 2009). Ginseng showed positive results in a few studies. Its possible pharmacological effects in the treatment of CFS are theorized to lie in its affinity to glucocorticoid receptors, its membrane stabilizing effect, and its anti-inflammatory feature (Radad et al. 2011; Rasheed et al. 2008). Erythropoietin was, until 2004, globally one of the most successful drugs for cancer-related fatigue. Unfortunately, in 2009 a meta-analysis consisting of 53 clinical trials with almost 14,000 patients concluded that the mortality rate of cancer patients after receiving EPO treatment increased by a factor of 1.17. This may be related to EPO receptors that were found on various tumor cell surfaces, leading to the hypothesis that EPO could stimulate malignant neoplasm growth. Not only did EPO increase the likelihood of tumor progression, but it also contributed to a higher risk of venous thromboembolisms in patients with solid mass tumors. This restricted the use of EPO to symptomatic adult patients with therapy-induced anemia, but only for hemoglobin levels below 12 g/dl.

Acetylsalicylic acid (aspirin, ASA) showed impressive results in the treatment of fatigue in patients with multiple sclerosis (Wingerchuk et al. 2005; Shaygannejad et al. 2012), but, according to the latest publications, has not yet been tested for CRF. Paroxetine was investigated in one study with cancer patients (Morrow et al. 2003) and

another with patients suffering from chronic obstructive pulmonary disease (COPD), but neither study was able to confirm a significant improvement. In consequence, selective serotonin reuptake inhibitor (SSRI) antidepressants only seem to present a therapeutic option when a depressive disorder is diagnosed. The systematic review also found no significant improvements for drugs like testosterone, amantadine, carnitine, megestrol, or medroxyprogesterone.

Thalidomide has become a talking point as a treatment for cachexia in tumor patients but has so far failed to show tangible results (Davis et al. 2012; Reid et al. 2012; Yennurajalingam et al. 2012).

Based on limited evidence, we cannot recommend a specific pharmaceutical for the treatment of fatigue in palliative care patients. Fatigue research in palliative care seems to focus on modafinil and methylphenidate, which may be beneficial, although further research regarding their efficacy is needed. Dexamethasone, methylprednisolone, acetylsalicylic acid, armodafinil, amantadine, and L-carnitine should also be further examined.

12 Non-pharmacological Management

The preservation and protection of available energy reserves as well as the patient's self-reliance in day-to-day activities plays an especially important role for tumor patients with fatigue. The proper management includes a conscious intake of calories and a protein-rich diet, as well as maintenance of a proper sleep routine which avoids caffeinated drinks before bedtime, too much daytime sleep, or arousing activities in the late afternoon or evening. The patient will need time to get used to this new activity and energy management. Priorities must be set to differentiate between useful/important and less important activities. Energy and stamina should be rationed accordingly and necessary breaks between activities planned for. Moderate physical exercise is useful, even for cancer patients suffering from exhaustion and reduced physical ability, in order to retain existing physical abilities and to counteract progressive muscle loss, reduced efficiency of the cardiovascular system, and general condition. Multiple studies have shown the benefits of light endurance training during anticancer therapy (Hilfiker et al. 2017; Safari et al. 2017) regardless of the type of exercise. Physiotherapy can contribute significantly to the patient's well-being with mobilization, breathing exercises, and teaching techniques for self-training. On the other hand, the use of medical aids such as a wheelchair or walker has to be learned and accepted. Psychosocial measures such as stress management and relaxation therapy (autogenic training, progressive muscle relaxation, or yoga) contribute to the management of CRF. Cognitive behavioral therapies are also of great value. Psychosocial support from caregivers is, likewise, beneficial to relieve the patient from fears and concerns. However, a recent review from 2017 was unable to recommend any specific non-pharmacological intervention, although physical exercise and psychoeducational therapies seem to be promising options and should be researched further.

13 Conclusion

Fatigue is a subjective feeling of extraordinary weakness, tiredness, and energy loss which affects the body (physical aspect), feelings (affective aspect), and mental function (cognitive aspect) and can occur at any age. Fatigue is not, or only incompletely, alleviated by sleep and rest. CRF is a subjective, multidimensional illness, with significant impact on the quality of life of patients. Once treatable causes for CRF are excluded, a multimodal treatment regimen should be developed. Symptomatic management of fatigue requires a high level of cooperation and communication between all health care professionals attending to the patient, the patient's social sphere, and the patient themselves. Treatment strategies must be multimodal and multi-professional. Past systematic reviews have provided no clear recommendations for pharmacological or non-pharmacological interventions for the relief of cancer-related fatigue. Treatment of underlying causes, such as infections, may be an effective measure to reduce fatigue

symptoms. Current ongoing studies are exploring therapeutic options such as energy homeostasis, glucocorticoid receptor stimulation, as well as influencing neurotransmitter receptors and anti-inflammatory processes. Physical training can be effective and should be used in combination with pharmaceutical interventions.

Edema and Lymphedema

13

Elizabeth S. Dylke and Sharon L. Kilbreath

Contents

Abstract

Edema or swelling is a common occurrence during the palliative care phase for many conditions. Various causes and forms of edema are possible, with most palliative care patients suffering from a mixed form with lymphatic and venous contributions. Edema is most frequently present in the limbs but may be found in any region of the body, including the head and neck, trunk, and genitals. Edema can cause significant distress, reducing mobility and independence. Screening and assessment for edema therefore should be comprehensive and systematic to ensure the underlying causes of the swelling are discovered. Furthermore, the treatment goals of the patient should be accounted for in determining the treatments offered. Various treatments, with particular focus on compression and exercises, may be used but often require modification from traditional usage in the palliative care setting. In this setting, treatment focus is often on symptom management rather than volume reduction.

1 Introduction

Edema and lymphedema are common in the palliative care setting, with many possible contributing factors. The aims of this chapter are to:

1. Explore the pathophysiology, incidence, and presentation of edema in a palliative care setting.
2. Describe screening and assessment requirements for determining the presence, severity, and distress caused by edema.
3. Explain the conservative treatment options commonly used for edema in a palliative care setting.

2 Pathophysiology of Edema in Palliative Care Setting

Swelling is a frequently reported symptom during the palliative care phase of many conditions. While the lymphatic form of swelling, lymphedema, is commonly associated with cancer treatments, particularly breast cancer (Fig. 1), edemas and lymphedema can occur during the palliative care phase of many diseases including chronic renal and heart failure, end-stage liver disease, and neurological conditions such as Parkinson's and chronic obstructive pulmonary disease, among others (Real et al. 2016). Patients with swelling may suffer from edema, lymphedema, or a mixed presentation (Real et al. 2016).

In non-palliative care patients, non-lymphatic edema occurs as a result of change in the permeability of the capillary walls. As a consequence, a gradient change occurs between the hydrostatic pressures of the blood vessels and tissues. This results in extraneous fluid in the tissues (Real et al. 2016). In contrast, lymphedema results due to disruption to lymphatic pathways caused by surgery or other treatments or traumas affecting the lymphatic pathways, the congenital absence or limited presentation of lymphatic pathways, or an overload of lymphatic fluid beyond the capacity of the lymphatic system (Real et al. 2016; Padera et al. 2016; Lawenda et al. 2009). Additional causes or contributing factors to the development of edema and/or lymphedema in a palliative care setting have been summarized by Real et al. (2016) and may include:

- Lymph node blockage and/or lymphadenopathy
- Abdominal involvement/blockage caused by tumors or ascites
- Medical causes such as hypoalbuminaemia (Bar-Sela et al. 2010), anemia, venous hypertension, cor pulmonale, and general deterioration
- Symptomatic or asymptomatic deep vein thrombosis (DVT)
- Dependency and/or immobility
- Organ failure
- Overhydration (Nwosu et al. 2016)
- Previous or ongoing treatments such as taxane-based chemotherapies or long-term steroid use

In palliative care, both forms of edema are seen, often with the two forms combining (mixed edema), resulting in possible significant swelling. A recent retrospective study found that 46% of edemas were of the mixed variety, 29% were lymphedema, and 10% were non-lymphatic-related edema (Real et al. 2016). While clearly there are many forms of swelling, the more general term edema will be used from here on in this chapter to avoid confusion.

The incidence of edema varies among studies and disease states. For example, various studies found that swelling occurs in 39% (Lau et al. 2010) to 73% (O'Connor and Kumar 2012) of chronic renal failure patients. This lack of agreement may be due, in part, to differences in diagnostic criteria for determining the presence of the edema (Dylke et al. 2016). A conservative estimate would suggest that at least one-third of patients with cancer or noncancer end-stage conditions suffer from some form of edema (Lau et al. 2010).

Edema may present in any region of the body during palliative care, although peripheral edema is the most common presentation

Fig. 1 Breast cancer patient with significant lymphedema of the forearm

(Steindal et al. 2013). It is most commonly found in the lower limbs irrespective of the underlying disease state (Real et al. 2016), particularly in older patients (Steindal et al. 2013), possibly due to immobility and deconditioning. The location of edema may also depend on the underlying condition that has led to the swelling. For example, secondary to breast cancer treatment, the edema may present in the affected side's upper limb, while secondary to oral cancers, the swelling may present in the head and neck region.

Edema presentation can change or progress (Lawenda et al. 2009). This progression may either be an increase in volume or change in tissue composition or a combination of both (Lawenda et al. 2009). When edema first develops, the increase in volume of the swollen region is fluid-based, due to increase in either intracellular fluid, extracellular fluid, or a combination (International Lymphedema Framework and Canadian Lymphedema Framework 2010). For some, despite treatment, the volume of the limb may continue to increase, while for others the limb volume may stabilize (Dylke et al. 2013) and reduce in response to treatment (Ezzo et al. 2015). Beyond the increases in volume, particularly with edema with a lymphatic contribution, the edema may lead to changes in the tissue composition of the limb (Dylke et al. 2013). This change in tissue composition is not well understood but likely has multiple underlying causes including the high protein levels and inflammatory factors found in extracellular fluid (Padera et al. 2016). In the early stages, the high protein fluid in the limb leads to a presentation of pitting, where localized pressure leaves an indent in the tissues (Lawenda et al. 2009; International Lymphedema Framework and Canadian Lymphedema Framework 2010). With progression, pitting may cease and localized increases in fatty and fibrotic tissue occur (Dylke et al. 2013). These changes in limb composition are not simply a result of time with edema and have been found in patients with both large and small limb volume increases (Dylke et al. 2013). As with increases in limb volume, it is currently unclear which patients are most at risk for changes in tissue composition.

Another possible consequence of edema progression is skin changes. For some this will result in fibrotic, woody, or thickened skin (Padera et al. 2016; Lawenda et al. 2009), while others may experience fragile skin (International Lymphedema Framework and Canadian Lymphedema Framework 2010). Which presentation occurs may be due to the underlying condition causing the edema, with heart and liver failure-related edema as well as dependency edema all being more likely to lead to fragile skin (International Lymphedema Framework and Canadian Lymphedema Framework 2010). Both thickened and fragile skin cause susceptibility to lesions or ulcers as well as skin infections (cellulitis) (Moffatt et al. 2003). Lymphorrhea, a leakage of lymphatic fluid through the edematous skin, may also occur with progressing edema. Lymphorrhea also causes susceptibility to cellulitis and has been shown to be a poor prognostic indicator in a palliative care setting (Real et al. 2016).

3 Screening

Screening for edema should be done systematically, through the use of targeted questioning or a questionnaire. Reliance on patients to volunteer that edema is present likely leads to vast underdiagnosis of its presence as well as its impact. Homsi et al. (2006) found that without systematic questioning, only 4% of palliative care patients volunteered that they were experiencing swelling. However, the incidence rose to 30% of patients when they were systematically questioned about the presence of edema, a finding also identified by others (White et al. 2009).

In addition to identifying more cases of edema through systematic questioning or the use of a questionnaire, on average, eight more symptoms were identified than when a patient was left to self-report what they were experiencing (White et al. 2009). Importantly, the symptoms discovered on systematic questioning were often as severe in presentation and as distressing to the patient as those that were self-reported without prompting (Homsi et al. 2006). Notably, for edema, the relationship between physical

changes of edema and level of distress was asynchronous, with small increases in limb volume associated with high levels of distress in some patients but not all (Homsi et al. 2006). Severity and distress caused by the edema, therefore, should be assessed separately in determining the priorities for treatment.

Due to the commonality of edema, a standardized approach to screening and onward referral for assessment of edema is required. Without such processes in place, many of those with edema are likely not detected and therefore not offered treatment (Thomson and Walker 2011). There is currently no agreed upon questionnaire nor screening method for detection of edema in either the non-palliative or palliative care setting. Commonly used, validated multi-symptom cancer assessment instruments such as the MD Anderson Symptom Inventory (Portenoy et al. 1994) and the Edmonton Symptom Assessment System (Bruera et al. 1991) do not include a question related to edema. Of the small number of questionnaires validated in the palliative care setting that focus on symptom presence (Stromgren et al. 2002), only the Memorial Symptom Assessment Scale Short Form (Chang et al. 2000) specifically asks about swelling or edema. This scale includes a single item, in which patients are asked whether or not edema is present in either the arms or legs. If the patient indicates that swelling is present, further questioning of the patient occurs in regard to the severity and distress. However, a limitation of this scale is that it does not ask about swelling elsewhere, e.g., the head and neck or trunk. As the currently available validated questionnaires are not comprehensive in assessing all of the symptoms reported by patients and symptoms are not comprehensively recorded in patient records (Homsi et al. 2006), screening for edema and likely other symptoms cannot rely on a single questionnaire; screening should be supplemented by questioning of the patient.

In the non-palliative care setting, the limb is also physically measured to detect the presence of swelling. Tools used to assess whether swelling is present in the "at-risk" limb include a tape measure to quantify limb circumference and/or used to derive limb volume, water displacement and Perometry to assess limb volume, and bioimpedance spectroscopy to assess extracellular fluid volume (of which lymph is a major contributor). The measurement methods for using these tools will be discussed further below.

Ideally, edema is detected and treated when it is mild. However, one of the challenges for all edemas has been the determination of criteria for its detection in a clinical environment. The lack of clear diagnostic criteria has resulted in the formation of a range of arbitrary thresholds (Dylke et al. 2016). This issue has been addressed for detection of mild upper limb lymphedema arising from treatment for early breast cancer. Comparison of a range of commonly used and normatively based thresholds against a reference standard led to the identification of evidence-based diagnostic thresholds for detection of upper limb lymphedema (Dylke et al. 2016). However, similar evidence-based diagnostic thresholds for other regions, such as the lower limbs, have not been developed for either a non-palliative or a palliative care setting.

4 Comprehensive Assessment

If swelling is likely present, it is important to determine the underlying cause(s) as this will inform treatment. While imaging methods such as lymphoscintigraphy, magnetic resonance lymphography, or indocyanine green lymphography can provide additional information about the underlying morphology of the lymphatic system (Munn and Padera 2014), they are rarely undertaken in a palliative care setting unless they will alter management strategies (Real et al. 2016). The focus, instead, is on a thorough clinical assessment of the areas with or at risk for swelling. As there are many factors that may contribute to both the edema and the treatment decisions associated with assessment findings, only those with advanced training in edema should undertake both the assessment and treatment of edema.

The clinical assessment for edema is multifaceted. As part of any standard assessment, the history related to the edema, treatments received,

and any benefit they received from the treatment in controlling the swelling and symptoms is obtained. A review of the medications prescribed may be useful, as a number of common medications, such as nonsteroidal anti-inflammatories (NSAIDs), may contribute to the development or severity of the edema (International Lymphedema Framework and Canadian Lymphedema Framework 2010). Importantly, the patient is asked whether they are experiencing any symptoms in relation to the edema and, if present, the level of distress associated with the symptoms and swelling. Typical symptoms of edema may include sensations of heaviness, achiness, discomfort, or fullness (Lawenda et al. 2009). In addition, patients are asked about the extent to which the edema impacts on their physical abilities.

Visual inspection and palpation of the region with edema will identify issues that could impact on treatment (Lawenda et al. 2009). The region should be inspected for the presence of wounds, skin breakdowns, signs of venous insufficiency, skin infection, and lymphorrhea, all of which may contraindicate certain treatments for the edema and/or require modification of other treatments. Signs indicative of venous insufficiency include the presence of varicose veins, difficultly locating ankle pulse, and pain or discomfort in the legs that is relieved when legs are elevated. Hands-on assessment will provide an indication as to the state of the tissues. The presence of pitting edema, tested by the application of pressure for a specified amount of time (often 10–30 s) and then observing for the presence of a dent in the tissues once pressure is removed, provides an indication of edema progression. In contrast, palpation of fibrosis or skin and tissue hardening indicates a later progression of edema, which may respond better to different treatments than does pitting edema.

Measurement of the limb size can be done to indicate the severity of the edema and provide a benchmark against which response to treatment can be determined. However, for some patients, this may be too burdensome for the patient to undertake (International Lymphedema Framework and Canadian Lymphedema Framework 2010). Multiple assessment tools may be used, which one (or ones) selected depends on the availability of the tools and the location of the swelling. For upper and lower limb edema, the most commonly used tool is a simple tape measure with which circumferential measurements are taken at regular intervals along a limb. When completed in a standardized manner, they have excellent reliability (Czerniec et al. 2010). If one limb is swollen, its circumference measurements are often compared to the unaffected limb to give an indication of extent and severity of edema. For bilateral swelling where this is not possible, circumference measurements may be most useful to monitor the changes in the size as a response to treatment. Protocols have also been developed for the measurement with a tape measure of head and neck (Deng et al. 2016) and breast edema (Kovacs et al. 2007). Circumference measurements may also be converted to a volume; however, this is mostly done in a research setting and unlikely to provide additional assessment or treatment guidance in a clinical environment. Other ways of measuring limb volume may include water displacement or Perometry, both of which are less commonly used in clinical settings.

If the edema likely has a lymphatic component, bioimpedance spectroscopy (BIS) may provide an alternative for assessment of limb swelling, measuring the volume of extracellular fluid specifically. Surface electrodes are attached to extremities, and a harmless low-level current is passed though the region to determine the resistance. Each limb is assessed separately and an interlimb ratio determined. BIS has several advantages to other measures of limb volume, including less intrusive and being specific to extracellular fluid. Other measures used to assess limb volume, such as tape measurements, include fat, bone, muscle, and all fluids and therefore may miss small increases in extracellular fluid. Indeed, BIS is particularly well-suited to detection of mild edema (Ward et al. 2008) but is also suited to monitoring change in edema over time (Czerniec et al. 2016). When standardized protocols are used, BIS has excellent reliability (Czerniec et al. 2010). Currently standardized protocols are available for the measurement of unilateral and

bilateral upper and lower limb lymphedema (Ward et al. 2011a, b).

Further objective assessments may be required to ensure appropriate treatments are offered dependent on the region affected and additional symptoms being reported. These may include a measurement of range of motion or strength of both the area with swelling and the whole body, an assessment of speaking or swallowing, gait assessment, or a pain and/or neuropathic pain assessment. After completing the subjective and objective assessments, if questions remain about the contributing factors to the swelling, additional investigations may need to be undertaken to ensure the cause of the edema is determined and appropriate treatment is given (Box 1).

Although the physical assessments used for edema are well-described and reliable to perform, there are gaps. For example, it is unclear what are the expected responses to treatments for most forms of edema. The measurements ascertained, therefore, need to be used in conjunction with the results from the additional investigation, as well as the patient's self-report of the issues and clinical reasoning to guide the intensity, level, and types of treatments offered.

Box 1 Additional assessments may need to be undertaken if the cause of the swelling is unclear and/or to guide treatment decisions

Assessment	Reason	Possible alternations to treatment decisions
Electrocardiogram (ECG)	Cardiac failure	Medical management including medications may be indicated Lower compression pressure may be indicated
Ankle-brachial pressure index (ABPI)	Venous insufficiency	An ABPI of less than 0.8, particularly in the presence of ulceration or wounds, suggests that high pressure bandaging is contraindicated
Blood tests	Albumin levels	Albumin is a protein that assists in preventing fluid leakage into the tissues Low levels of albumin (hypoalbuminemia) may be indicative of kidney or liver disease or the body not absorbing enough nutrients Further investigations and/or medical management of underlying condition required
Ultrasound	Deep vein thrombosis (DVT)	Medical management may be indicated Use of compression may need modification

5 Treatment of Lymphedema

To date, management of most edemas is conservative or surgical and not with pharmaceutical approaches. Surgical approaches are rarely warranted in a palliative care setting. However, with better understanding of the underlying contributions to edema, pharmaceutical approaches may become available. For other edemas encountered in the palliative care setting, medical management (including pharmaceutical) in combination with conservative treatment such as the use of compression may be warranted.

Ideally, edemas are detected when the condition is mild. At this phase, the impact on function is minimal; the aim of treatment, therefore, is to manage symptoms through reduction in swelling volume. Exercises and compression may be all that is required in the mild stage (International Lymphedema Framework 2006). Frequently, however, more comprehensive treatments are required.

Traditionally, conservative treatment for edema is divided into two phases: (i) intensive phase in which the aim of treatment is to reduce the volume of the limb and improve its shape and (ii) maintenance phase in which the aim is to

maintain the reduction (International Lymphedema Framework 2006). However, in the palliative care, it is recognized that these distinct phases are blurred (International Lymphedema Framework and Canadian Lymphedema Framework 2010), with treatment focused on reducing the burden to the patient in terms of both the impact of the disease and the treatment.

5.1 Complex Decongestive Therapy

The most common treatment advocated for edema is complex physiotherapy treatment (a.k.a. complex decongestive therapy) (International Lymphedema Framework 2006). Complex decongestive therapy is multifocal and comprises the following components: (i) manual lymphatic drainage, (ii) compression therapy, (iii) skin care, (iv) education, and (iv) exercise. This approach is time-consuming and, in its fullness, may not be tolerated by patients in the palliative care setting (Cheville et al. 2014).

(i) Manual Lymphatic Drainage

Manual lymphatic drainage (MLD) is a specialized form of light massage designed to encourage the drainage of lymphatic fluid from the limb (International Lymphedema Framework 2006). It is performed by MLD therapists trained in the anatomy and physiology of the lymphatic system to facilitate lymph drainage of the vessels (Ezzo et al. 2015). It is proposed that MLD can "assist nature" by stimulating the natural peristaltic contractions of the lymphangions, reducing hydrostatic resistance to lymph flow, and rerouting lymph away from areas of stasis and into viable lymphatic vessels (Ezzo et al. 2015). The evidence supporting its use, however, is weak, particularly for upper limb lymphedema secondary to breast cancer (Ezzo et al. 2015). However, synthesis of the data in a Cochrane review provided preliminary data in a secondary analysis that MLD may be particularly effective early in the development of edema, where the lymphatic system is still functioning relatively well (McNeely et al. 2004). Consequently, massage would be capable of both stimulating lymphatic flow and rerouting lymphatic flow via collaterals. When edema has progressed, MLD may not have a major impact on reduction in limb volume. The addition of MLD to compression in studies which included moderate to severe upper limb lymphedema only reduced limb volume by 7% (Ezzo et al. 2015).

While MLD may not contribute to significant volume reduction, it does have additional benefits, particularly in the palliative setting. In a study investigating the effect of MLD on palliative patients, it was noted that MLD was tolerated by most patients, and it was associated with significant reduction in both pain and dyspnea above that received from administration of opioids in combination with analgesics and co-analgesics (Clemens et al. 2010). MLD is typically given in a quiet, calm environment; this form of massage is very gentle and soothing which may contribute to the improved dyspnea and reduced pain. In contrast to simple massage, manual lymphatic drainage is also associated with improved emotional function in terms of reducing worry, irritability, tension and feelings of depression, dyspnea, and reduced sleep disturbance (Williams et al. 2002). Thus, while MLD may not be effective in addressing the increase in limb volume, it does offer benefit to the patient in other domains.

Although MLD can be beneficial, there are instances when it is contraindicated. Particularly when swelling is present in the lower leg, it is important to first rule out the presence of deep vein thrombosis. If present, MLD to that region may be contraindicated.

(ii) Compression

Compression is considered a keystone for treatment of edema. The mechanisms underpinning the impact of compression on the lymphatic and vascular system are currently unclear, particularly as tissue composition within the edematous limb changes over time. Studies, particularly in relation to compression on venous blood flow, suggest that the increase in local pressure obtained from compression limits capillary fluid filtration while improving lymphatic drainage. The

increased tension on the anchoring filaments of the initial lymphatics contributes to the opening of these initial lymphatics. As the valves in these lymphatics are unidirectional, fluid is pulled in and toward the lymph collectors which will be pulled open. Although the mechanism underlying how it works is unclear, it does contribute to decrease in limb volume (Ezzo et al. 2015; Badger et al. 2004). Compression may be delivered through a range of products. Types of devices used to apply compression include short-stretch bandages, off-the-shelf or customized compression garments, Velcro wraps which are easy to don and doff, or the use of compression pumps.

Short-stretch bandaging is typically advocated as part of Phase 1 of complex decongestive therapy to reduce volume and improve the shape of the limb (International Lymphedema Framework 2012). For upper limb lymphedema, compression levels are suggested in the range of 20–30 mmHg, whereas with lower limb lymphedema, compression levels of 60 mmHg are recommended (Partsch et al. 2011). These bandages, in contrast to others such as traditional tensor or "ace" bandages, stretch less than 50% when extended longitudinally. The pressure mediated by the bandages can be controlled by the width and number of layers used in combination with the tension of the fabric (Partsch et al. 2008). Another advantage in the use of bandaging is that it can be used in combination with padding and "chip bags" to ensure pressure is not applied to bony areas and to help soften hard fibrotic regions. The traditionally used multilayer compression system for reduction of limb volume has some limitations: this form of bandaging is associated with inconsistency in application techniques resulting in inconsistent pressures, variable results, and bulkiness, which can impede patients from wearing normal footwear and clothing, leading to a low level of adherence and the potential risk of falling (Lamprou et al. 2011). Another problem can be slippage and bunching, leading to uneven distribution of compression, which can result in discomfort at night and the potential for skin breakdown.

New approaches to bandaging are being explored. For example, the two-component compression 3M Coban system is less bulky, with preliminary data suggesting that the findings are equally effective in both treatment of chronic venous insufficiency (Moffatt et al. 2008) and moderate to severe lower limb lymphedema (Lamprou et al. 2011). Importantly, although not formally assessed, participants treated with the two-component compression system reported enhanced mobility and comfort during walking than with previously worn compression systems (Lamprou et al. 2011). The two-component Coban system comprises latex-free roll bandages in which the inner layer is polyurethane foam and the outer layer is a cohesive bandage. The foam replaces the padding used in traditional multilayer bandaging, protecting bony prominences and providing the necessary grip to prevent slippage. The cohesive outer surface enables the layers to bond to each other, providing a stiff stable layer with no internal movement (Lamprou et al. 2011; Moffatt et al. 2012). Rosidal Soft (Activa Healthcare Ltd) foam rolls have also been used to replace bulky wadding typically used with patients with lymphedema. Following application of the foam, cohesive short-stretch bandages were applied in figure of eight techniques, leading to significant reduction in the volume of the affected leg after a course of 12 days of bandaging (Whitaker et al. 2015).

The evidence clearly supports bandaging to reduce limb volume in lymphedema (Badger et al. 2004). However, the patient in palliative care may not tolerate this form of intervention, nor has its effectiveness been explored for other causes of edema. Alternative methods of compression may need to be explored.

Compression garments are readily available. Depending on the severity and location of the swelling, garments may be off-the-shelf or custom-made. However, patients may not tolerate the sustained pressure or be able to complete the application and removal of the compression garment. Other factors may also interfere with the use of compression garments, such as fragile skin, which can be stressed with the use of compression garments, lymphorrhea, and open wounds. An alternative to compression garments are compression "wraps," in which low-elastic material

section wrap across the limb and are secured with Velcro (Williams 2016). The advantage with a wrap is that they are easy to put on and adjust the pressure. However, it was noted that there is difficulty in using wraps if the person is overweight or inflexible or if there were severe shape distortion of the limb (Mosti et al. 2015).

(iii) Exercise

Typically, as part of standard treatment for edema, patients are encouraged to exercise (International Lymphedema Framework 2006). Depending on the individual's ability in relation to disease status, exercises such as resistance training, stretching, and aerobic exercise may be beneficial. Exercises are typically performed while using a form of compression, e.g., compression garment. In non-palliative care patients, resistance training has been shown to be protective against exacerbations of lymphedema, and associated with reduced symptoms, and increased strength (Schmitz et al. 2009). However, at the palliative stage, vigorous exercises may not be feasible. Rather, the focus may be on functional activities, such as rising from a chair and walking or repetitive contractions and relaxation of muscle groups in the lymphedematous region (Cheville et al. 2014).

5.2 Alternative Treatments for Patients in Palliative Care

Subcutaneous drainage of lower limb edema has been piloted in patients in palliative care due to advanced cancer (Bar-Sela et al. 2010; Jacobsen and Blinderman 2011). Patients with severe lymphedema of the lower body and leg, in whom diuretics and other conservative approaches were not providing any benefit, were offered this novel treatment. As part of the informed consent, patients were explicitly informed of the lack of supporting evidence for this treatment as well as the potential side effects of treatment (Bar-Sela et al. 2010). This approach evolved, from inserting subcutaneous catheters into the medial and lateral sides of the ankle and then connecting the catheter via tubing to an enclosed drainage baggage to creating subcutaneous tracts with needles in both ankles and following removal of the needles, wrapping the region with absorbent pads (Bar-Sela et al. 2010). The most recent modification was to remove both the needles and padding and let the region drain into a bucket. Five of eight patients who underwent this procedure identified improvement in mobilization that impacted their quality of life (Bar-Sela et al. 2010).

There are currently no medications available for the prevention or treatment of most forms of edema (International Lymphedema Framework 2006). In a non-palliative care setting, diuretics have been shown to be ineffective in the management of lymphedema (Kligman et al. 2004). However, in other forms of edema, particularly if the peripheral edema is a result of congestive heart failure, diuretic therapy can help reduce the severity of the swelling (Brake and Jones 2017). The dosage of diuretics given may need up or down titration depending on various factors and needs to be done in the context of the wider symptoms and medical presentation (Brake and Jones 2017). Alternatively, as some medications, such as methadone for pain, may cause or worsen edema, a review of the medications being taken by the patient may lead to improvements in symptoms (International Lymphedema Framework and Canadian Lymphedema Framework 2010; Dawson et al. 2014).

Hydration levels may also impact on edema severity, with patients with higher hydration levels, suffering from worse edema (Nwosu et al. 2016). However, following guideline-based artificial hydration therapy protocols has been shown to lead to a significant improvement in edema (Nakajima et al. 2014).

6 Conclusion and Summary

Edema in a palliative care setting is a common, complicated, multifaceted, and often distressing side effect of the end stage of many diseases. It can have numerous contributing factors, thereby requiring thorough screening and assessment to

ensure the underlying causes are known and appropriate treatments are offered. Treatment of edema in a palliative care setting has been shown to improve quality of life and mobility and reduce other symptoms such as pain and dyspnea. While there are a range of treatments available, in a palliative care setting, the focus is often on managing the symptoms and distress caused by the edema rather than reducing the volume of the limb. This often results in necessary modifications to the approach and intensity of the treatment. A growing understanding of the lymphatic system and its role in fluid management may lead to new treatments in the future.

14 Gastrointestinal Symptoms: Constipation, Diarrhea, and Intestinal Obstruction

Katherine Clark

Contents

Abstract

Disturbed bowel function, including constipation, diarrhea, and bowel obstructions, commonly affects palliative care patients. This chapter aims to summarize these problems, focusing on the current understanding of the prevalence, etiology, and palliative management. The first issue that will be discussed is the most prevalent distal gut problem of constipation. Despite the fact that the majority of

palliative care patients require laxatives, the etiology of constipation in palliative care is not well described. The next topic is diarrhea, which, although less, common is still equally distressing. A systematic approach to assessment and management is recommended. Lastly, the evidence that describes the palliative management of inoperable bowel obstructions will be explored.

1 Constipation

1.1 Definition

Although a common symptom in palliative care, there remains sparsity of information to best define, diagnose, and effectively manage this problem.

Gastroenterology guidelines highlight that the Rome III criteria are a useful and standardized tool on which to base an objective diagnosis of constipation (Vazquez and Bouras 2015). In order to fulfill these criteria, people must have experienced at least two clusters of symptoms for 12 weeks of the last 6 months including straining at defecation on at least one quarter of occasions, stools that are lumpy/hard on at least one quarter of occasions, sensation of incomplete evacuation on at least one quarter of occasions, and three or fewer bowel movements a week.

However, the Rome criteria are not considered useful in palliative care (Erichsen et al. 2015). This is despite the fact that many people are likely to have experienced problems for many years before their diagnosis of a life-limiting illness (Currow et al. 2015). Recently, observational data highlight that many of the same problems of infrequent bowel actions, straining, and dissatisfaction are equally bothersome to constipated palliative care patients as other groups (Clark et al. 2016a). There is a real need for agreed diagnostic criteria to objectively diagnose and assess the severity of constipation in palliative care using a tool that is sensitive to change over time (Clark and Currow 2013).

In the meantime, it is inadequate to base a diagnosis of constipation solely on the frequency of bowel actions per week as the normal frequency of bowel actions varies so widely between individuals. Perhaps a much more meaningful measure is what is perception of each person as to what is a normal bowel habit for them, how their experiences have changed over time, and what problems are they experiencing that they attribute to disturbed bowel function.

1.2 Prevalence

The prevalence of constipation is variously quoted as likely to affect between 10% and 100% of palliative care patients (Erichsen et al. 2015; Clemens et al. 2013). While there is little doubt that this problem commonly affects patients being cared for with palliative care intent, there are reasons that quoted prevalence ranges are so broad. This includes the lack of agreed definition of constipation as highlighted above, and, as a result, reported figures are based on different observations including clinician's observations, prescription of opioids, patient's reports, and the types and numbers of laxatives prescribed. While some of these appraoches are objective, assessments of altered bowel function, the personal experinces of constiaption are highly subjective. Given this, it seems most appropriate to focus on patient's self-reports at a population level to understand the extent of the problem. To this end, there are a number of reasonably large population-based studies conducted in Europe, Australia, and the United States (Laugsand et al. 2009; Kamal et al. 2015; Clark et al. 2012). Combined, the results of these studies support that constipation symptoms affect at least 30% of palliative care patients with the incidence of the problem affected by diagnosis (cancer vs. non-cancer) and possibly performance status.

1.3 Impact of the Problem on Palliative Care Patients

There are a number of aspects of the impact of the problem that need to be considered. This includes the physical, psychological, and cost aspects of this problem.

The term "constipation" is used interchangeably in palliative care as both a diagnostic label and to indicate a bothersome physical symptom. However, it may be more correct to consider constipation as a cluster of symptoms that occur as the result of disordered function of the normal structures of defecation. Frequently occurring symptoms that affect people who identify themselves as constipated include straining, dissatisfaction, difficult or painful passage of stool, bloating, abdominal pain and discomfort, and nausea. Similar to chronically constipated patients, recent observations support palliative care patients also have a similar intensity most akin to those chronically constipated gastroenterology patients who are dissatisfied with their treatment (Clark and Currow 2014). This becomes even more problematic when the detrimental impacts of constipation symptoms on people's quality of life are considered (Clark et al. 2016a).

Even aside from the impacts of constipation symptoms on people's physical and psychological well-being, there are other impacts that affect the care of palliative care patients experiencing constipation symptom. These include the fact that constipated patients are more likely to receive more visits from community palliative care teams and more likely to be hospitalized (Addington-Hall et al. 1998; Addington-Hall and Altmann 2000). When hospitalized, these patients tend to occupy more of the ward staff's time (Wee et al. 2010).

1.4 Etiology

Constipation may be a primary disorder of the enteric nervous system of the colon or a functional disorder of defecation also known as dyssynergic defecation (Sbahi and Cash 2015; Wald 2016) with these disorders classified in the table below. It is estimated that up to 14% of the total population are likely to be affected by these primary causes of constipation to varying degrees (Table 1).

In some groups such as older patients or palliative care patients, the problems of disturbed bowel function are much higher. This is because not only are these groups equally likely to be affected by primary disorders of constipation but in addition are exposed to other factors that might contribute to disordered bowel habits such as increasing weakness, increased dependency, and polypharmacy. As a result, the incidence and prevalence of the problem in these specific cohorts is much higher compared to the general population (Vazquez and Bouras 2015; Clark et al. 2012). Despite this, the objective data that describes the physical impact on gut structures is weak in all area but especially so in palliative care as highlighted in Table 2.

Table 1 A summary of functional bowel problems (Sbahi and Cash 2015)

Slow transit constipation: This occurs as the result of impaired colonic propulsive motor activity, inadequate gastrocolic reflex, and delayed emptying of the proximal colon. Typically, people experience infrequent defecation sometimes less than one bowel action per week. The cause of this problem is still poorly defined
Functional defecation disorders: These disorders occur as a result of impaired rectal propulsive forces, paradoxical anal contraction, and/or inadequate relaxation of the anal sphincter. Typically, people experience prolonged and excessive straining (even with soft stool), the need for digital manipulation including exerting vaginal or perineal pressure to pass a bowel movement, and a failure to respond to standard laxatives

1.5 Assessment

1.5.1 History and Physical Examination

The history and clinical presentation of disordered bowel habits is highly variable. This is not surprising given this is so personal and subjective. Although it is common in palliative care to pay attention to the frequency with which people are able to pass a bowel action, palliative care data highlights that it is not uncommon for this cohort to be symptomatic with other problems including excessive straining, discomfort, or a sense of incomplete evacuation. The assessment must include a comprehensive history of people's subjective experiences which includes an appreciation of the duration that people have

Table 2 Factors commonly suggested as contributory to constipation

Factors suggested as contributory to secondary constipation in palliative care	Studies conducted in a palliative care cohort		Studies conducted in other patient groups	
	Constipation diagnosis	Contributes to constipation based on most objective research available	Constipation diagnosis	Contributes to constipation based on most objective research available
Opioids (Wald 2015)	Objective diagnosis of slow transit	Yes	Objective diagnosis of slow transit	Yes
Anticholinergic load (Leroi et al. 2000; Clark et al. 2014):				
Extrinsic	Use of laxatives	Yes	Objective diagnosis of slow transit	Yes
Intrinsic (i.e., secondary to age, inflammatory states)	Use of laxatives	Yes	–	Not examined
Blockade of gut histamine receptors (Fosnes et al. 2011)	–	Not examined	Patient report	So far, impact based on theory and patient reports
Blockade of gut serotonin receptors (Bjornsson et al. 2002)	–	Not examined	Objective diagnosis of slow transit	Yes
Physical activity (Kamal et al. 2015; Bjornsson et al. 2002; Muller-Lissner et al. 2005; Kim et al. 2014)	Use of laxatives	Yes	Objective diagnosis of slow transit	Mixed results
Age (Clark et al. 2016a; Bai et al. 2016)	Patient report	No	Objective diagnosis of slow transit	No
Gender (Clark et al. 2016a; Fischer and Fadda 2016)	Patient report	No	Objective diagnosis of slow transit	No
Duration of constipation symptoms (Clark et al. 2016a; Brandt et al. 2005)	Patient report	Yes	Patient report	Yes
Hypercalcemia (Lamy et al. 2001; Ragno et al. 2012)	Frequency with which bowels open	Yes	Rome criteria	No
Metabolic causes:				
Diabetes (Faria et al. 2013)	–	Not examined	Objective diagnosis of slow transit	Yes
Chronic renal failure (Wu et al. 2004)	–	Not examined	Objective diagnosis of slow transit	Yes
Hypothyroid (Rahman et al. 1991)	–	Not examined	Objective diagnosis of slow transit	Yes

experienced problems. This should include not only rectal problems and difficulty passing bowel actions but, in addition, abdominal problems such as bloating, pain, and nausea. Other history should include an appreciation of oral intake, performance status, comorbid illness aside from the problem that has underpinned referral to palliative care, and medication history.

Table 3 Components of a rectal examination that correlate with objective investigations of constipation (Talley 2008)

Inspection Inspect the appearance of the perineum looking specifically for external hemorrhoids, rectal prolapse, and evidence of fecal soiling or scarring	The presence of a scar at the anus correlates with lower incremental anorectal squeeze (Dobben et al. 2007)
Ask the patient to strain and observe the perineum in particular for a gaping anus	The presence of a gaping anus indicates lower resting pressures on anorectal manometry (Dobben et al. 2007)
Assess the anal sphincter tone at rest (internal anal sphincter) and on squeezing (external anal sphincter)	There appears to be a good correlation between absent, decreased, and normal resting and squeeze pressures with anorectal manometry (Dobben et al. 2007)
Ask the patient to strain and push the finger of the examiner away. This should result in the perineum descending 1–3.5 cm. A failure to descend is representative of pelvic dyssynergia	Perineal descent assessed by examination correlates with descent assessed by dynamic MRI (Bharucha et al. 2005)

A comprehensive and systematic physical examination is also necessary which includes assessment of hydration, abdominal examination, and neurological and rectal examination. The abdominal examination includes an assessment of bloating, tenderness, masses, and bowel sounds.

The rectal examination is perhaps the section of the examination that will provide the most objective evidence to help guide management of the problem as many of the steps involved in such an examination are well correlated with objective assessments of constipation (Table 3). A well-conducted rectal examination should involve up to eight steps including consent, observation, palpation, and dynamic maneuvers such as straining down to observe the degree to which the anus gaps or the pelvic floor descends (Talley 2008). Despite the fact that aspects of this physical examination are well correlated with objective investigations, it is increasingly neglected (Clark et al. 2010).

Other investigations are aimed at understanding whether there are factors that might be easily reversible. However, it is important to remain cognizant that in palliative care situations, investigations must be considered in the context of the disease trajectory and patient's ability to tolerate them. Beyond a full blood count, renal and liver function tests, thyroid function tests, and electrolytes such as calcium and magnesium, few other tests are warranted. Although palliative care guidelines not uncommonly recommend plain radiographs to assess the severity of the problem, there is little data to support this practice (Clark et al. 2016b). Furthermore, recent data highlights the lack of interrater agreement suggesting that this tool in its current context is insufficiently accurate and should not be used to base treatment decisions (unpublished data).

1.5.2 Constipation Assessment Scales

There are numerous constipation assessment tools in common use with palliative care guidelines suggesting that the use of such tools is appropriate. While many such tools are available, the optimal tool for use in palliative care is not yet clear. It is generally recommended that should such a tool be required to assist patients with recall or descriptions that the tool selected should be easy to use and quick to complete (Izumi 2014). Some of the constipation assessment tools previously recommended in palliative care guidelines or adopted in palliative care studies (references) are summarized in Table 4 with respect to their content and the population the tool was validated in.

1.6 Management

1.6.1 Pharmacological

While there are many recommendations made regarding the choice of laxatives in palliative care, the fact remains that the evidence is still limited, and this is particularly true when objectively considering whether one medication is more effective than another (Clemens et al.

Table 4 Constipation assessment tools (Izumi 2014; Coffin and Causse 2011)

Tool	Description	Validation population	Comments
The Bristol Stool Form Scale (BSFS) (Saad et al. 2010)	This commonly used tool is used to assess stool characteristics based on the observation that stool form accurately reflects colon transit times	Healthy and constipated volunteers	The tool has been validated in healthy populations where colon transit was artificially altered and chronically constipated patients not taking laxatives. The accuracy of the tool for chronically constipated requiring regular laxatives is not known
Constipation Assessment Scale (CAS) (McMillan and Williams 1989)	This eight-item scale was designed to assess the presence and severity of constipation in less than 2 min. The criteria for constipation include straining, a sensation of incomplete defecation, bloating, gas, oozing, rectal pressure, rectal pain, and small stool volume	Cancer patients treated with morphine or vinca alkaloids	While some of the elements of the Rome criteria are incorporated into this tool, whether or not stools are hard is missing
Victoria Bowel Performance Scale (Hawley et al. 2011)	This quick to complete scale was designed to assess three parameters including stool shape, bowel patterns, and ability to control defecation	Palliative care	While this tool has been tested in a palliative care population, it does incorporate the appearance of stool as a marker of successful treatment. This remains a problem given stool form has only been validated in patients with normal bowel function when taking laxatives and constipated patient not taking laxatives
The Bowel Function Index (Rentz et al. 2009)	This three-item scale is simple to use and is based on the patient's experience over the last 7 days. People are asked to numerically score ease of defecation, feeling of incomplete defecation, and their impression of the severity of the problem	Cancer and non-cancer patients treated with opioids	To date, this has been best validated in opioid-induced constipation
Patient Assessment of Constipation Symptoms (Slappendel et al. 2006)	Twelve-item scale that is based on the Rome criteria divided into three domains. These include abdominal symptoms, rectal symptoms, and the experiences of passing a bowel action based on the patient's experiences over the last 14 days	Chronically constipated patients and patients with lower back pain taking opioids	While this tool has been shown to be reliable and responsive to change, the studies that report its use have been mostly performed in the context of opioids being the main constituting factor to constipation

2013; Pitlick and Fritz 2013). This current lack of robust evidence to inform evidence-based prescribing guidelines reinforces the need for clinicians to understand as best as possible (1) the possible causes of constipation; (2) the currently available medications, their actions, and adverse profiles; and (3) the patient's experiences. This information may then be used to implement a trial of therapy. For standard laxatives, the correct choice of laxative is most likely to be an agent that is well tolerated by the individual and acceptable to them in terms of restoration of more usual bowel function. This may require a period of trial and error. The different classes of laxatives that are available are summarized in Table 5.

Table 5 Laxatives by class

Laxative class	Mode of action	Expected time to effect	Adverse effects	Evidence for use in palliative care
Osmotic: saline and sugar laxatives (Wald 2016; Pitlick and Fritz 2013)	Saline laxatives promote an influx of fluid into the gut lumen Sugar-based laxatives such as lactulose pass unchanged into the colon. In the colon, the sugar is broken down into fatty acids and lactic acid which in turn changes the intraluminal pH and increases intraluminal pressures. These changes increase peristalsis and promote water retention in the lumen	1–2 days	Bloating, abdominal pain, cramping, electrolyte disturbances	Moderate when co-prescribed with senna
Polyethylene glycols (Pitlick and Fritz 2013)	Polyethylene glycol possesses a water binding capacity. The orally administered fluids soften the stools in the large bowel without causing an influx of fluid into the bowel lumen	1–3 days	Abdominal pain, bloating, nausea	Poor but in routine use
Stimulant (Wald 2016; Hawley and Byeon 2008)	Stimulants include medications such as senna and bisacodyl which induce propagated colonic activity leading to increased colon transit times. Bisacodyl may also be given as a suppository with the main action being in the rectum	8–12 h	Watery diarrhea, cramping abdominal pain, nausea, dehydration, and electrolyte disorders	Moderate
Softeners (Pitlick and Fritz 2013)	This includes both emollients and lubricants. Emollients include docusate and lubricants include mineral agents. The aim of these agents is to make the actual passage of the stool easier	These agents do not induce laxation but cause softening in 2–3 days	Fecal soiling	Low but in routine use
Prokinetics: prucalopride (Quigley and Neshatian 2016)	The neurotransmitter serotonin has well-documented effects on gut motility. Based on this, a number of agents that are the highly selective 5-HT4 agonists have been developed including prucalopride	Hours	Headache, nausea, abdominal pain, diarrhea	Low
Intestinal secretagogues (Quigley and Neshatian 2016)	Alternative ways to increase gut transit include activation of the epithelial ion channels to promote secretion. Lubiprostone is a secretagogue that activates gut-based chloride channels resulting in water secretion to the gut lumen	Within 24 h	Diarrhea, nausea	Low

1.6.2 Management of Opioid-Induced Constipation

While there are numerous causes of constipation symptoms in palliative care patients, this is also a group who are highly likely to be receiving opioid analgesia. It is estimated that up to 40% of patients receiving opioids (Prichard et al. 2016) will develop constipation with this symptom unlike other adverse effects of opioids unlikely to moderate over time (Bell et al. 2009). While the initial treatments should be as usual, there are a number of agents including naloxone and methylnaltrexone which are the two most commonly used agents in palliative care. Either of these could be considered if the patient has not responded to simple treatments; opioids are considered the agents predominantly contributing to the problem and the person as no factors would contradict the use of these agents.

Methylnaltrexone is a peripheral opioid antagonist that has been studied in a palliative care population (Prichard et al. 2016; Nelson and Camilleri 2015). It is recommended for patients with presumed opioid-induced constipation who have not responded to standard treatments. It is administered as a once-daily subcutaneous injection and is expected to induce laxation within hours of administration. The main adverse effects include abdominal pain, diarrhea, nausea, and sweating. It should not be administered until a bowel obstruction has been excluded.

Naloxone combined with oxycodone was developed with the intent of naloxone displacing oxycodone from the opioid receptors in the gut. While it has been identified as effective when compared with oxycodone alone, it is notable that this combination reduces but does not eliminate opioid-induced constipation, and standard laxatives are often still required (Anon 2011). The maximum strength available is oxycodone 40 milligram (mg) with naloxone 20 mg with suggestions that at doses higher than this the medication is less effective (Mercadante et al. 2011) presumably because first-pass metabolism of the naloxone is decreased. The main adverse effects are nausea, vomiting, headache, and diarrhea. The medication should be used with great caution in those patients with liver dysfunction.

1.6.3 Nonpharmacological

Although the evidence in both chronic constipation and palliative care is weak, nonpharmacological approaches to improve constipation symptoms are routinely recommended as summarized here:

- Ensuring that people have privacy, avoid difficult situations such as the use of bedpans (Folden 2002) and try to maintain a regular routine. This latter point is often made in conjunction with the recommendation that people aim to pass a bowel action in the morning as this is when the colon is most active (Rao et al. 2001).
- Keep a bowel diary with this recommendation based on the fact that people's recall of their bowel actions is not always accurate (Hsieh 2005).
- Maintain adequate fluid intake (Spinzi et al. 2009).
- Remain as mobile as possible (Spinzi et al. 2009).

As noted above, while such recommendations are included in palliative care guidelines, they must be considered in the context that this population is heterogeneous, and while they might be applicable earlier in disease trajectories, as people become frailer, capacity to tolerate interventions becomes more difficult.

2 Diarrhea

2.1 Definition

Diarrhea is defined as the passage of loose or watery stools occurring at least three times per day (reference). It may occur as an acute short-lived problem (<14 days), a persistent problem (>14 days but <30 days), or chronic (>30 days) (Gale and Wilson 2016).

2.2 Prevalence

While diseases associated with diarrhea account for significant numbers of deaths worldwide, the problem of diarrhea in wealthy countries is far less significant. As a result of this, while still considered a distressing problem for individuals treated with palliative intent, estimates suggest that less than 10% of palliative care patients are likely to be bothered by this (Fallon and O'Neill 1997).

2.3 Impact: Physical, Psychological, and Cost

The fact that this problem, when more than a shorted-lived episode, is not commonly examined in the palliative care literature does not mean that it is a problem that should be ignored. This is because, regardless of the cause, severe and persistent diarrhea may have significant physical and psychological detrimental effects (Cherny 2008).

Physically people with persistent diarrhea may be very symptomatic. This is because of both the constancy and frequency of bowel actions and their complications. The physical symptoms may depend upon the site of the problem and the subcategory of the problem. The complications of diarrhea of small bowel include large volume and watery stools often associated with urgency and cramping. These patients are at risk of excessive fluid losses leading to dehydration which in turn may cause postural symptoms and other complications. In contrast, diarrhea that originates from problems in the large bowel is likely to cause frequent but painful, small bowel movements. Other problems likely to be experienced by patients include increasing fatigue due to both the constant activity of passing bowel actions and the resultant loss not only of fluid but electrolytes.

Aside from physical impacts, diarrhea may have detrimental psychological impacts again as the result of a number of issues. Many people express embarrassment at this problem not only due to the constant bowel movements but, in addition, embarrassment due to noise, malodorousness, and soiling as the result of urgency.

2.4 Etiology

Diarrhea may be classified as watery, fatty, or inflammatory with the definition of these disorders and examples that may affect palliative care patients summarized in Table 6.

2.5 Assessment

2.5.1 History and Examination

The most critical first step is to understand what the patient is experiencing exactly when he/she complains of diarrhea. This includes the frequency with which they are passing bowel actions, the appearance of the stool (including consistency and color), associated symptoms such as pain or bloating, and the duration of the problem. Other features that are important to glean include a description of the person's normal bowel habits and how has this changed. For example, if the patient is experiencing intermittent constipation and diarrhea, it is important to consider whether in fact this is a presentation of fecal impaction. Lastly, the history must include current medications and changes to medications; recent use of antibiotics; food history; recent surgery, radiotherapy, or other tumor treatments; and family history (Table 7).

Physical examination is also important. This includes abdominal and rectal examination. In particular it is important to consider whether the patient has evidence of bloating and pain or signs of peritoneal irritation including rigidity or rebound.

2.5.2 Investigations

The extent of investigations depends not only on the capacity of a person to tolerate investigations but equally on the duration which the person has been experiencing problems and the features of physical examination.

Table 6 Subtypes of diarrhea with some clinical examples that may affect palliative care patients (Gale and Wilson 2016; DuPont 2016)

Watery	Fatty	Inflammatory
Secretory Alcohol withdrawal Bacterial enterotoxins (e.g., cholera) Bile acid malabsorption Hyperthyroidism Medications (e.g., antineoplastics colchicine, NSAIDs, antibiotics) Neuroendocrine tumors Non-osmotic laxatives (e.g., senna, docusate) Postsurgical (e.g., cholecystectomy, gastrectomy, bowel resection)	*Malabsorption* Amyloidosis Carbohydrate malabsorption (e.g., lactose intolerance) Lymphatic engorgement (e.g., congestive heart failure, some lymphomas) Mesenteric ischemia Noninvasive small bowel parasite (e.g., *Giardia*) Postresection diarrhea Short bowel syndrome Small bowel bacterial overgrowth	Inflammatory bowel disease Diverticulitis Ulcerative colitis *Clostridium difficile* Invasive bacterial infections (e.g., tuberculosis) Invasive parasitic infections (e.g., *Entamoeba*) Viral infections (e.g., cytomegalovirus, herpes simplex virus) Tumors (e.g., colon carcinoma, lymphoma) Radiation colitis
Osmotic Celiac disease Osmotic laxatives (e.g., magnesium, phosphate, sulfate)	*Maldigestion* Hepatobiliary disorders Pancreatic exocrine insufficiency	

Table 7 Clinical features of subcategories of diarrhea

Watery	Fatty	Inflammatory
Secretory: Watery stools that do not change with fasting Nocturnal bowel actions	Greasy or bulky stools that are difficult to flush Oil in the toilet bowl that requires a brush to remove	Frequent, small-volume, bloody stools May be accompanied by tenesmus, fever, or severe abdominal pain
Osmotic: Watery stools that decrease with fasting		

Acute-onset diarrhea probably does not warrant testing unless the person is exhibiting signs of dehydration or features of peritoneal irritation. In the former, depending upon the person's capacity to tolerate investigations, it may be appropriate to check the person's renal function. The latter may require abdominal radiography to exclude either an ileus or bowel obstruction.

When the problem is more chronic or the etiology is not clear from the history, further investigations may be necessary. However, even in this context, it is important to consider whether it is the best interests of a patient to investigate further and whether the burden of investigations and treatments outweighs the benefits. If investigations are considered necessary, recommendations suggest that it is preferable to try and categorize by type of diarrhea based on history and, by doing so, narrow the diagnostic possibilities. This has the benefit of both reducing unnecessary testing and enhancing the diagnostic yield (Sweetser 2012; Juckett and Trivedi 2011) (Table 8).

2.6 Management

It has been suggested that the most common cause of loose bowel actions experienced by palliative care and other patients remains to be medications in particular, laxatives (Fosnes et al. 2011; Fallon and O'Neill 1997; Chassany et al. 2000). The initial step after assessing the patient's hydration and comfort is to cease medications that are likely contributing factors.

Table 8 Diagnostic approach (Sweetser 2012; Juckett and Trivedi 2011; Barr and Smith 2014)

1. Determine whether or not the person really has diarrhea
2. Eliminate drug causes
3. Define whether this is an acute or chronic problem
4. Stool cultures are indicated for patients with bloody stool, severe dehydration, signs of inflammatory disease, or persistent symptoms lasting more than 3–7 days, immunocompromised patients, or those with suspected hospital-acquired infections
5. Routine testing for ova and parasites in acute diarrhea is not necessary in developed countries unless the person has been recently overseas or at high risk (e.g., HIV +ve)

The most important next step to manage acute onset of diarrhea is oral rehydration therapy with fluids that contain glucose and electrolytes for those who can tolerate. Less effective but sometimes more easily tolerated are parenteral fluids. Usually, acute onset of diarrhea does not require medications. However, when more rapid symptom control is required, anti-diarrheal medications are indicated with the combinations of loperamide together with simethicone more likely to provide more rapid relief and more complete relief of symptoms (Barr and Smith 2014). The main caveat to this recommendation is if the stool is bloody. In this situation, loperamide should be avoided as it may lead to a more prolonged course of illness (Barr and Smith 2014).

More persistent problems require both the provision of symptom control and prescription of medications likely to correct the underlying problem. With regard to symptom control, this may include either oral codeine or parenteral morphine. Treating the underlying causes may include:

- Antibiotics according to the identification of the underlying infection
- Pancreatic enzymes for pancreatic insufficiency
- Aspirin and cholestyramine for radiation-induced colitis
- Octreotide for profuse secretory diarrhea (Kim-Sing et al. 1994)

3 Intestinal Obstruction

3.1 Definition

Bowel obstruction is defined as any mechanical or functional obstruction of the intestine that limits or prevents the physiological transit of gut contents and the normal processes of digestion. However, this definition is very broad and likely to apply to many different situations: benign or malignant, curable or incurable (Tuca et al. 2012). In any situation, patients presenting with a bowel obstruction are critically unwell with this problem even more challenging when a patient has an underlying malignancy. Internationally agreed criteria to definitively diagnose a malignant bowel obstruction (MBO) include (1) clinical evidence of bowel obstruction, (2) obstruction occurring distal to the ligament of Treitz, (3) the presence of primary intra-abdominal or extra-abdominal cancer with peritoneal involvement, and (4) the absence of reasonable possibilities for a cure (Anthony et al. 2007). It is this cohort of people who almost universally have a very poor prognosis that this next section will specifically focus on.

3.2 Prevalence

Overall, it is estimated to be between 3% and 15% of all cancer patients who are likely to be affected by a MBO with women at greater risk than men (Tuca et al. 2012). The incidence is much higher in specific malignancies including ovarian cancer where 20–50% of patients with stage III–IV disease are likely to be affected. Further, up to 30% of patients with advanced colorectal cancers will experience this problem (Ripamonti et al. 2008; Ferguson et al. 2015). Other cancers have also been identified as more likely to result in MBO including cancers that arise from the abdomen and cancers that arise elsewhere as summarized in Table 9.

Table 9 Tumors most likely to result in MBO

Intra-abdominal cancers most likely to result in MBO: Colon, ovary, stomach, pancreas, bladder, endometrium
Extra-abdominal cancers most likely to result in MBO: Breast, melanoma

3.3 Impact: Physical, Psychological, and Cost

The most common physical symptoms that accompany a MBO include nausea, vomiting, colicky abdominal pain, constant pain secondary to gut distension, and changes in bowel habits. It is estimated that nearly 100% of people will have nausea with the other symptoms likely to occur in up to 80% of people (Arvieux et al. 2006). Clinically, the presenting symptoms may occur intermittently or progressively depending upon whether the obstruction is complete, partial, or resolving.

While the majority of people will experience nausea and vomiting, it is generally accepted that the pattern of vomiting may help define whether the obstruction is more proximal or distal. More proximal obstructions tend to present with constant and frequent vomiting with this occurring as a later presentation in more distal obstructions. Eventually the vast majority of patients experience vomiting which is often dark and malodorous. This is often described perhaps erroneously as feculent vomiting. However, this is not as sometimes believed a presentation of retrograde transit but rather the result of bacterial liquefaction of intraluminal contents proximal to the obstruction.

Many people will experience both colicky pain and constant pain with the colicky pain likely to be due to both exaggerated peristaltic movements and gut spasms. A more constant pain is likely to be multifactorial and occurring as the result of gut distension, tumor deposits, and irritation of the peritoneum.

Along with the unpleasant physical symptoms, MBO are likely to expose people to significant emotional and psychological stressors (Dolan 2011). These problems are likely to be complex and, like other symptoms, may impact quality of life. Previous qualitative work has identified the fact that people are unable to eat is not only physical debilitating but, for some people, a significant emotional and social issue. The loss of capacity to eat for some has been identified as confronting to people's sense of social relevance and perhaps a sign of transition from a life worth living to impending death. Other patients described the experience as bewildering with a sense that there was no direction in their treatment and they were left wondering and waiting as to what might occur in the future (Gwilliam and Bailey 2007).

Table 10 Factors that underlie MBO (Frago et al. 2015; Lynch et al. 2012)

Tumor-related factors:
Extrinsic compression of the gut
Intraluminal occlusion
Intraluminal tumor causing intussusception
Mesenteric or omental caking
Malignant infiltration of the myenteric plexus
Paraneoplastic neuropathies
Non-tumor-related factors:
Chronic constipation
Medications
Mesenteric thrombosis
Biochemical (chronic renal failure, hypercalcemia)
Adhesions
Dehydration

3.4 Etiology

The majority of malignant bowel obstructions occur in the more advanced stages of illness (Tuca et al. 2012). Obstructions may present as partial or complete affecting one or multiple levels simultaneously. The reasons that obstructions occur are complex and varied as summarized in Table 10 (Frago et al. 2015; Lynch et al. 2012).

A mechanical obstruction results in a sequence of self-perpetuating events of distension and secretion. Gastric, pancreatic, and biliary secretions accumulate which in turn stimulate further intestinal secretions proximal to the obstruction. At the same time, the gut's capacity to absorb salt and water is decreased, and instead, there is increased secretion of fluid into the lumen as the result of both increased distention of the gut and

Table 11 Radiological investigations

Test	Changes in BO	Sensitivity and specificity
Plain erect and supine radiographs	Distended gut with the presence of air-fluid levels	The diagnostic sensitivity and specificity of plain radiographs in diagnosing obstruction is 82% and 83%, respectively (Thompson et al. 2007)
Abdominal CT	Compared with plain radiographs, CT provides more detailed information including the extent of disease and the level of obstruction	The diagnostic sensitivity of CT in determining the obstruction level is 93%, with a specificity of 100% (Peck et al. 1999)
MRI	Compared with CT, MRI increases the ability to diagnose peritoneal disease	The sensitivity of MRI in diagnosing the level of the obstruction is 93–95%, with a specificity of 63–100% (Beall et al. 2002)

as an inflammatory response around the site of obstruction (Roeland and von Gunten 2007). This inflammatory response includes secretion of serotonin which in turn leads to the release of substance P, nitric oxide, acetylcholine, somatostatin, and vasoactive intestinal peptide. This combination exacerbates local gut wall edema increasing secretion of secretions, exacerbating dissention, and increasing intraluminal pressures (Ferguson et al. 2015).

3.5 Assessment

3.5.1 History and Physical Examination

Patients with advanced cancers who present with the combination of nausea, vomiting, and abdominal pain (colicky and constant) along with disturbed bowel function should prompt consideration of whether this could indicate this patient has developed a bowel obstruction. Such changes should prompt a physical examination. In particular, patients need to be examined for abdominal distention, tenderness including signs of peritoneal irritation, and changes to auscultated bowel sounds. With regard to the latter signs, changes consistent with MBO include either absent bowel sounds or isolated metallic sounds with the latter presumed to result from the accumulations of air and fluid in the distended gut proximal to the obstruction.

3.5.2 Investigations

The extent of investigations depends upon the person's estimated prognosis. For some patients this is purely a clinical diagnosis based on history and physical examination. For others, more invasive investigations are required to inform discussions with interventional radiologists, gastroenterologists, or surgeons. This includes investigations to both (1) confirm the diagnosis and (2) assess the physiological status of the patient (Table 11).

3.6 Management

There are a range of strategies to manage MBO. While all are conservative in that this is universally a condition with a poor prognosis, this may at times include surgery while at other times a more conservative approach is necessary. Above all, it is important that treatments are based on the following:

1. An understanding of the underlying pathophysiology of the obstruction
2. Detailed clinical assessment including the extent of disease and whether there are life-prolonging treatments available to this person, overall prognosis, health and performance status, the presence of ascites, and whether this is the first or a recurrent presentation of a bowel obstruction
3. The patient's and family's expectations of care

3.6.1 Interventional

There are three main options if interventional treatment is being considered: namely, stenting, venting, and surgery (Table 12). While there is an

Table 12 Therapeutic interventions for MBO

Intervention	Patients for whom this is applicable	Complications
Self-expanding metallic stents (Kim and Kim 2016; Kaplan et al. 2014; Hong and Kim 2014)	Single site of obstruction that is accessible by upper GI or colonic scope Limited expectancy, unable to tolerate surgery but otherwise well-controlled pain	Stent occlusion Perforation Stent migration Bleeding Pain Infection
Percutaneous gastrostomy (DeEulis and Yennurajalingam 2015)	Intractable vomiting due to inoperable MBO	Stent occlusion Perforation Infection Bleeding
Surgery (Folkert and Roses 2016; Paul Olson et al. 2014)	Patient not actively dying and if the obstruction was reversed, would have life-prolonging therapies available. While not absolute, the following have been suggested as poor prognostic indicators and should be taken into account if surgery is considered: complete small bowel obstruction (SBO), non-gynecological cancer, ascites, decreased albumin, elevated total white cell count age >65 years, poor nutritional status, poor performance status, liver metastases, previous abdominal radiotherapy, pulmonary metastases	It is estimated that there is a 40% mortality associated with surgery in this group Other complications of surgery include enterocutaneous fistula, wound infection, wound dehiscence, early obstruction, high output ostomy, myocardial infarction and cardiac failure, deep vein thrombosis and pulmonary embolus, pneumonia, and other infections
Oral gastrografin (Mercadante et al. 2004)	Recent data suggests that administration of gastrografin, a hyperosmolar water-soluble contrast agent, results in an increased pressure gradient at the level of obstruction in the bowel resulting in resolution of the bowel obstruction	

increasingly robust body of literature that describes such interventions, much of the evidence that supports them is observational and, in some instances, very limited in number (Bischoff et al. 2015). As such, this is a very poor situation that at present leaves people with limited surgical options (Kucukmetin et al. 2010).

3.6.2 Pharmacological

Regardless of whether a patient is referred for an intervention, knowledge and implementation of strategies to improve symptom control are required. The most commonly recommended types of medications and the reasons for their use are listed in Table 13. As ever, it is important to critically appraise clinical guidelines as the levels of evidence that support most of recommendations are limited.

3.6.3 Nonpharmacological

One of the main concerns experienced by both patients and families is the fear that the person will not be able to eat, feel hungry, and even worse starve to death (Whitworth et al. 2004). This concern must be discussed as the implications of this fear are significant for all involved. It is imperative that families are reassured that MBO is typically a problem associated with very advanced disease with such patients very typically experiencing anorexia and early satiety. Oral intake may in fact make the person feel worse. More important is the need to ensure that all are reassured that this is a presentation of very advanced disease from which the person is now dying (Soriano and Davis 2011).

It is important to work with patients and families to ensure that their concerns are appropriately

Table 13 Symptom control in MBO

Problem	Typically recommended	Reason for prescription	Comment
Bowel obstruction	IV or SC dexamethasone (Bischoff et al. 2015; O'Connor and Creedon 2011; Lee et al. 2012)	Anti-inflammatory Antiemetic	A previous review suggested a trend toward successful resolution of BMO. However, this was not statistically significant and further work is required to objectively document net harms and benefits
Pain	Parenteral (IV, SC, transdermal) opioid (Tuca et al. 2012; O'Connor and Creedon 2011)	Constant severe pain presumed due to gut distension, peritoneal inflammation, or infiltration of the myenteric plexus	According to the WHO ladder, severe pain requires opioid analgesia
	SC or IV hyoscine butylbromide or hyoscine hydrobromide (Tuca et al. 2012; O'Connor and Creedon 2011; Currow et al. 2005; Prommer 2013)	Cramping abdominal pain	Clinical guidelines recommend antispasmodic agents should be added if cramping pain persists despite opioids. Clinical guidelines recommend caution given that such agents may transition an incomplete obstruction to a complete obstruction
	Somatostatin analogues such as octreotide or lanreotide (Ferguson et al. 2015; O'Connor and Creedon 2011; Kubota et al. 2013)	Reduced secretions and intestinal blood flow presumed to reduce abdominal distension	Somatostatin analogues have been recommended in MBO based on the fact that they reduce secretions. However, as an analgesic intervention, their use is questionable given a recent trial demonstrated statistically higher use of hyoscine in MBO compared with placebo
Nausea	IV or SC metoclopramide (O'Connor and Creedon 2011; Dolan 2011)	Facilitate gastric emptying and concurrent central activity	There is no data to support the benefit of one antiemetic over the other
	SC haloperidol (Dolan 2011)	Predominately central effect on nausea	Metoclopramide has both peripheral and central action. Ongoing cramping is commonly listed as an adverse effect in MBO
	SC, IV, or sublingual serotonin antagonists (Tuca et al. 2012)	Reduce serotonin release from enterochromaffin cells of the stomach and with central effects on the chemo trigger zone	Haloperidol has a predominantly central effect with little impact on the gut
	Sublingual Olanzapine (Dolan 2011; Kaneishi et al. 2012)		Lastly serotonin antagonists may be useful in bowel obstruction when other agents are proving less effective with this statement based on observational data

(*continued*)

Table 13 (continued)

Problem	Typically recommended	Reason for prescription	Comment
Vomiting	SC or IV hyoscine butylbromide or glycopyrrolate (Tuca et al. 2012; Prommer 2013)	Anti-secretory to reduce the incidence of vomiting	Although there are three different approaches to reducing the amount of vomiting people experience, the data to date that recommends one agent as superior over the over is limited. Further, it is not clear if agents are best used on combination or as single agents
	Somatostatin analogues such as octreotide or lanreotide (Tuca et al. 2012; Ripamonti 2000)	More specific anti-secretory	
	H2 receptor antagonists or proton pump inhibitor (Tuca et al. 2012; Clark et al. 2009)	Specifically target gastric secretions	

addressed. This includes preempting advice as how to best manage a dry mouth. Many people will require reassurance that this does not routinely require total parenteral nutrient or artificial hydration. Rather, reassurance must be provided that rather than improve outcomes, in some situations, such interventions may even worsen symptoms (Ripamonti et al. 2008; Dy 2006). It is important however that this advice is not treated as a blanket rule and each case considered on an individual basis (Soriano and Davis 2011).

Gastrointestinal Symptoms: Nausea and Vomiting

15

Bertrand Behm, Carlos Fernandez, and Mellar P. Davis

Contents

Abstract

This chapter examines nausea and vomiting affecting patients who suffer from serious illness. A deeper understanding of these physiologic processes allows for better assessment and management. There are several different pharmacological and nonpharmacological options to improve palliation, including complementary and alternative medicines. Ultimately, there should be an individualized approach that considers the trajectory of illness and comorbidities, and most importantly it should be patient centered.

1 Demographics

Nausea is a symptom proven difficult to define and not as clearly as the objective sign of vomiting. Its first use in medicine can be traced back to the Greek terms ναυτια and ναυσα, both referring to the physical effects of seasickness. It was then translated into the Latin, and came to mean "a sense of queasiness" or "qualm" (Andrews and Sanger 2014). The concept of nausea, as it was understood in ancient times, related more to a constellation of symptoms that included asthenia, inability to carry out focused activities, and tendency to avoid work of mental or physical kind. Today nausea has a narrower definition that refers primarily to the subjective feeling of a need to vomit.

Vomiting is the forceful expulsion of gastrointestinal contents by mouth through retropulsion that is accomplished by involuntary contractions of thoracoabdominal and gut muscles. Typically vomiting is preceded by nausea, but this is not always the case. Teleologically, vomiting constitutes a reflex that allows the body to eliminate toxins.

Both sign and symptom have a significant negative impact on patients suffering from serious illness (Bruera et al. 2000; Bliss et al. 1992). There are a limited number of studies that have looked at the prevalence of nausea and vomiting in palliative care. Solano et al. carried out a systematic review looking at 11 symptoms, including nausea and vomiting, in adult patients. The prevalence of nausea in advanced cancer ranged from 6% to 68%, in AIDS it ranged from 43% to 49%, in advanced heart disease 17% to 48%, and in renal failure 30% to 43% (Solano et al. 2006). Thirty six percent of referrals to outpatient palliative care were nauseated, and 22% had vomiting (Kirkova et al. 2012). In the same study, nausea and vomiting were more prevalent among women, and the prevalence increased with age. Others have suggested that there is a relationship between worsening performance status and both nausea and vomiting (Glare et al. 2011; Kirkova et al. 2012).

Despite advances in our understanding of the pathophysiology of nausea and vomiting, both remain a major challenge in caring for palliative care patients. Nausea becomes a common symptom with declining performance status and near the end of life (Glare et al. 2011; Chang et al. 2004). Both nausea and vomiting are undertreated, and those suffering from more severe symptoms are less likely to receive antiemetic drugs (Greaves et al. 2009). Nausea and vomiting rarely occur in isolation. Nausea clusters with anorexia, fatigue, lack of energy, shortness of breath in patients with advanced malignancies (Cheung et al. 2009). Clarifying the potential demographic influences on symptom prevalence will hopefully lead to better tailor our treatment approach.

2 Nausea and Vomiting Pathophysiology

Nausea is a multidimensional symptom which includes interoceptive, emotional, and cognitive domains (Napadow et al. 2013). Teleologically, nausea is a control mechanism that signals one not to eat when the food is poisonous, when the stomach is malfunctioning, or when a threat is perceived for which a full stomach would have a survival disadvantage (Stern 2002). Similarly, Vomiting is not a reflex that can be predicted based on the intensity of neurophysiologic stimulation. The threshold for emesis is variable and response is modified by experience and can be conditioned based on experience (Horn 2008).

There have been advances in our understanding of the pathophysiology of nausea and vomiting; however, the final common pathway for emesis has yet to be defined. Although nausea and vomiting are usually seen together, it is believed that nausea and vomiting have at least partially separate physiologic processes; some patients experience them independently. Treatment of emesis is not necessarily effective in controlling nausea (Chiu et al. 2016). Furthermore, there is more information about the physiologic basis for vomiting than nausea which is subjective and more difficult to study in animal models (Horn 2008).

The causes of nausea and vomiting are numerous and in patients with serious illnesses is often multifactorial (Collis and Mather 2015). Nausea and vomiting can be seen in diseases arising from almost any organ. Treatments may be perceived as "toxic," including medications commonly used in

palliative medicine such as opioids, chemotherapy agents, and radiation therapy.

The development of nausea and vomiting is the end result of a complex interplay between the GI tract (interstitial cells of Cajal, ICC), autonomic nervous system, brainstem, vestibular system, higher CNS centers, and endocrine system (Singh et al. 2016).

2.1 Gastrointestinal Tract

There is a growing interest in gastric electrophysiology, especially in the setting of gastroparesis, nausea and vomiting. The ICC are gastric slow wave pacemakers governing smooth muscle resting membrane potential gradients. Abnormalities of the ICC are a common histological finding in both idiopathic and diabetic gastroparesis, and the severity of ICC loss has been correlated with the severity of gastric retention, and electrogastrography (EGG) abnormalities. Motion sickness causes gastric dysrhythmias resulting in nausea/vomiting in humans. The shift from the normal gastric 3 contractions per minute slow wave rhythm to a faster 4–9 contractions per minute rhythm precedes the development of nausea and the intensity of this tachygastric response/motility pattern correlates with the severity of nausea. The resolution of nausea and vomiting in gastroparesis has been associated with improvements in EGG abnormalities (O'Grady et al. 2014).

2.2 Autonomic Nervous System

Activation of mechano-, osmo-, and chemoreceptors in the gut stimulate vagal afferent fibers which carry information about the state of the GI tract to the dorsal vagal complex (DVC: nucleus of tractus solitarius (NTS), dorsal motor vagus (DMV), and area postrema(AP) in the caudal brain stem). The role of vagal afferents has been most extensively studied in the context of chemotherapy-induced nausea and vomiting. Chemotherapy cause the release of serotonin, (5 HT), and tachykinins (substance P) from intestinal enterochromaffin cells which activates 5 HT3 and tachykinin receptors on vagal afferents. The action does not seem restricted to the peripheral sites since there are also 5-HT3 and tachykinin receptors in the CNS (Babic and Browning 2014; Hasler 2013; Tageja and Groninger 2016). Neurokinin 1 receptors antagonist, like the 5-HT3 receptor antagonists, are effective in treating CINV as well as postoperative nausea. The combination of NK1 receptor and 5-HT3 receptors antagonists is synergistic in reducing nausea and vomiting (Rojas and Slusher 2012; Steinhoff et al. 2014).

2.3 Brainstem

Vagal afferents activate neurons in the NTS which then project to groups of loosely organized neurons throughout the medulla, called "central pattern generator" (CPG) rather than a "vomiting center." The CPG coordinates the vomiting reflex through diverse population of neurons in the ventral medulla and hypothalamus (Hornby 2001). Under normal conditions, the NTS exerts a tonic gamma aminobutyric acid (GABAergic) influence over the adjacent DMV. The DMV contains preganglionic parasympathetic neurons that transmit to the GI tract via the efferent vagus nerve. In this way, the sensory inputs from the vagal afferents and AP result in activation of abdominal muscles, diaphragm, and esophagus culminating in the emetic response (Rojas and Slusher 2012). This DMV output can be modulated by numerous neurotransmitters and neuromodulators, including opioid peptides, serotonin, endocannabinoids, tachykinins, and dopamine.

The area AP is a chemosensitive organ adjacent to the NTS that was first identified as the chemoreceptor trigger zone. It is extensively vascularized with highly fenestrated capillaries and, therefore, it is not isolated from peripheral circulation by the blood brain barrier. This allows AP neurons to receive both neuronal and humoral signals for emesis and relay this information to the NTS. The AP contains receptors for multiple neurotransmitters: dopamine, neurokinins, serotonin, opioids, as well as, neuropeptides and hormones

involved in the regulation of gastrointestinal, cardiovascular, and immune function (Babic and Browning 2014; Richards and Andrews 2007).

2.4 Vestibular System

The vestibular system is critical to generating nausea and vomiting with motion. Nausea and vomiting are frequent symptoms of vestibular pathology such as: vertigo, vestibular neuritis, labyrinthitis, and benign paroxysmal positional vertigo. Motion sickness is a mismatch of converging visual input, vestibular, and visceral signals. Vestibular neurons have receptors for several neurotransmitters, including acetylcholine, muscarinic, dopamine D2, serotonin 5-HT2, and histamine H1 and H2. In practice, only antagonists to muscarinic cholinergic receptors and antihistamines are effective in relieving motion sickness (Babic and Browning 2014).

2.5 Higher CNS Centers

Higher CNS centers are important in the integration of various sensory, affective, and emotional responses which govern nausea and vomiting, but how these are related to nausea is not well understood (Farmer et al. 2015). The sensation of nausea is assumed to involve the cerebral cortex; in contrast, the emetic reflex is elicited in decerebrate animals demonstrating that vomiting can occur independent of forebrain involvement. Recent studies using fMRI in patient with motion sickness revealed activation of cerebral areas prior to the sensation of nausea: amygdala, putamen, and dorsal pons/locus cerueleus. Furthermore, severe nausea was associated with sustained activation of the insula and middle cingulate cortex. Linked connectivity between these two areas is postulated to integrate the cognitive, affective, and interoceptive domains leading to the experience of nausea (Napadow et al. 2013). Another study revealed that nausea in the healthy was associated with an increase in sympathetic activity with a concomitant reduction in parasympathetic activity. Nausea caused the release of vasopressin and impaired release of ghrelin, an orexigenic gastric hormone that is associated with appetite. This might explain anorexia experienced with nausea sensation. The significance of vasopressin with the nausea stimulus is not known. Water retention occurs ahead of anticipated vomiting, followed by reduction of mesenteric blood flow, gastric dysrhythmias, then activation of central emetic pathways via the area postrema. Functional MRI demonstrates activation of the inferior frontal gyrus and decrease activity in other areas such as: cerebellar tonsil, declive, lingual gyrus, culmen, cuneus, and posterior cingulate cortex. The decreased activity in the posterior cingulate cortex explains in part the decreased parasympathetic activity with nausea. Taken together, these studies suggest that nausea is associated with changes in brain activity (region specific increases and decreases) in a diverse regions involved with sensory discrimination, cognitive evaluation, and affective motivation consistent with the nature of nausea (Farmer et al. 2015; Sclocco et al. 2015).

A better understanding of the neurobiology of nausea and vomiting provides targets for potential therapies and is a step toward developing drugs which retain efficacy, but lack nausea and vomiting as side effects (Horn 2008).

3 Assessment and Management of Nausea and Vomiting

It is helpful to clarify first if the patient is truly presenting with nausea, or if the complaint is better described as dyspepsia. The same applies to vomiting versus rumination. This step is critical, as it will direct the diagnostic approaches and treatment considerations. Dyspepsia as defined by the Rome IV criteria is the presence of at least one of three symptoms: early satiety, postprandial fullness, or epigastric abdominal pain, often described as a burning sensation (Stanghellini et al. 2016). Up to 75% of patients suffering from dyspepsia will have no underlying structural disease and thus will be classified as having functional dyspepsia. The rest fall under the structural

dyspepsia category, and further evaluation will depend on the presence of alarm features (weight loss, anorexia, vomiting, dysphagia, odynophagia, and a family history of gastrointestinal cancers), patient functional capacity, and goals of care (Mayer et al. 2013).

Rumination is characterized by the passive flow of ingested gastric contents into the oral cavity, followed by repeat mastication and swallowing or spitting out of the food bolus. It is not related to an anatomical alteration of the stomach, esophagus, or lower esophageal sphincter. The gastric distension by the food bolus triggers contraction of the stomach and simultaneous relaxation of the lower esophageal sphincter with subsequent rechewing of the food bolus. It is not associated with nausea (Stanghellini et al. 2016).

The traditional approach to evaluating and treating nausea and vomiting in serious illness is centered on understanding the etiology behind the symptom. Those with advanced malignancies, an etiology is identifiable in 75%, and in 25% there are multiple factors involved in the development of nausea and vomiting (Ang et al. 2010; Stephenson and Davies 2006).

In the typical elderly patient suffering nausea and vomiting, it is helpful to consider four broad categories: the primary disease, adverse effects related to disease directed therapy, frailty, and events brought on by unrelated comorbid conditions (Glare et al. 2011). Newly introduced cholinesterase inhibitors or opioid pain medications rather than the underlying disease may be the cause. Other potential etiologies include changes in bowel habits due to cancer, sytemic anti-neoplastic therapies, acute decompensation of chronic heart failure and uremia in those with advanced renal disease.

Assessment should ideally be carried out by a standardized tool such as the Edmonton Symptom Assessment System, the Memorial Symptom Assessment Scale, or the more recently introduced Integrated Palliative Care Outcome Scale. It is important to determine intensity, frequency, and associated symptoms, paying attention to descriptors and associated symptoms. These scales can be adapted to become a part of an electronic health record for patients, and permit quality improvement (Bruera et al. 1991).

3.1 Primary Disease Process

3.1.1 Gastroenterology (GI)

Acute onset of nausea (minutes to hours) should prompt one to exclude bowel obstruction, mesenteric ischemia, or myocardial infarction. Nausea associated with rapid onset of worsening colicky pain, in the setting of diminishing stool and flatus output with high pitched bowel sounds, will likely be related to bowel obstruction. An abdominal film will help differentiate bowel obstruction from other etiologies. If bowel obstruction emesis may lead to transient relief of nausea, and a strong feculent odor may be pervasive when dealing with a gastrocolic fistula. Distant and proximal etiologies of bowel obstruction will influence the volume and frequency of emesis. On physical examination, palpable periumbilical node can be suggestive of advanced intra-abdominal malignancy. Other important features in the clinical evaluation should include changes in stool consistency and frequency, as well as rectal examination, that may reveal a fecal impaction, or a palpable ridge found in some patients with advanced pancreatic, gastric, and lung cancer (Hussain et al. 2014).

If nausea has been present for weeks to months, the most common causes are: gastric stasis (cancer related such as carcinoma of the stomach, hepatomegaly with ascites) and dysmotility disorders (primary colorectal cancer, peritoneal carcinomatosis, ascites, adhesions, constipation, fecal impaction) (Glare et al. 2011; Stephenson and Davies 2006; Bentley and Boyd 2001).

3.2 Chemical and Metabolic Effects

Impaired gastric emptying should be suspected as the most likely cause when nausea and vomiting are intermittently present, with small volume of emesis and associated early satiety, abdominal distension, bloating and a feeling of fullness. Typical causes are anticholinergic medications, opioids, extrinsic compression of the gastric vault by ascites, and hepato- or splenomegaly (Ang et al. 2010). Diabetic gastroparesis occurs in frail

elderly patients with long-standing history of diabetes mellitus. Less often NSAIDs induce gastritis. In a series of 121 patients admitted to hospice, impaired gastric emptying was responsible for up to 44% of patient suffering from nausea and vomiting (Stephenson and Davies 2006).

Nausea and vomiting that are aggravated by sight and odors of food will typically be related to toxins, such as tumor necrosis or bacterial toxins. Digoxin and iron are medications that are linked with persistent nausea. Other common causes in advanced illness are liver metastases, hypercalcemia, and uremia with progressive renal dysfunction. This syndromic presentation can be identified in up to 40% of cases (Ang et al. 2010).

The presence of anxiety and/or personality changes and delirium will usually be caused by metabolic abnormalities such as hyponatremia, hypercalcemia, uremia, or adrenal insufficiency. Sepsis can also be linked to this clinical presentation.

Opioid-induced nausea and vomiting is present in up to 40% of cancer patients started on opioids (Campora et al. 1991). Mechanistic factors are constipation, gastroparesis, stimulation of the chemoreceptor trigger zone, and vertigo (Coluzzi et al. 2012). Opioid rotation has grade D evidence to suggest a switch from morphine to oxycodone, or hydromorphone benefits nausea. Subcutaneous use of methylnaltrexone has been reported to reduce nausea from methadone suggesting that the mechanism is peripheral (Yuan et al. 1999). Dopamine (D2) receptor antagonists such as haloperidol and prochlorperazine, as well as atypical antipsychotics such as olanzapine, have been utilized with varying degrees of success. Consideration of tapentadol as an alternative to oxycodone may also reduce the incidence of opioid-induced nausea and vomiting (Smith and Laufer 2014).

3.3 Neurologic Causes

Increased intracranial pressure as a cause behind nausea and vomiting (CNS metastatic disease, primary brain neoplasms, leptomeningeal disease) is associated with early morning headache and altered consciousness due to increased pressure on the reticular formation. Associated physical exam symptoms include 6th cranial nerve palsy, papilledema, and more ominously Cushing's triad of bradycardia, respiratory depression, and hypertension (Dunn 2002). This has been found in 2–8% of patients in palliative care (Ang et al. 2010; Glare et al. 2011).

Patients suffering from movement disorders and associated nausea and vomiting, typically with vertigo, are found in 2% or less of palliative care patients.

3.4 An Algorithmic Approach to Nausea and Vomiting Management

The decision to proceed with laboratory and imaging studies depends on the initial history and physical examination. In hospice evaluation may be perceived as excessively burdensome if the goals of care are to avoid aggressive interventions. Patients who suffer from acute dehydration will benefit from IV hydration. Measuring electrolytes will help identify potential culprits and lead to appropriate correction: sodium, potassium, calcium, creatinine, and blood urea nitrogen as well as albumin. Hypercalcemia is common with malignancies such as squamous cell carcinomas and multiple myeloma, hydration and bisphosphonates, or denosumab, a monoclonal antibody that binds to nuclear factor-kappa ligand (RANKL) will reduce calcium levels and nausea. Denosumab has become the preferred agent if renal impairment is present, or if hypercalcemia of malignancy has proven refractory to bisphosphonate therapy (Thosani and Hu 2015).

In patients with good performance status (defined as 2 or less on the Eastern Cooperative Oncology Group performance scale, >70% Palliative Performance Scale), an abdominal film will help differentiate bowel obstruction from severe constipation. If bowel obstruction is suspected based on KUB results, a computed tomography scan of the abdomen and pelvis may also be more specific for GI tract obstruction and is required if a surgery is being considered. In a similar fashion,

CT scan of the brain or magnetic resonance imaging helps clarify the role of stereotactic brain radiation and use of dexamethasone treatment for metastatic brain disease.

4 Pharmacology

4.1 Complementary and Alternative Medicine

The use of complementary and alternative medicine (CAM) is common in the general population. In 2012, the prevalence was 42% over the last year and 80% felt that CAM was helpful (Dossett et al. 2014).

Complementary and alternative medicine can be defined as a group of medical practices, such as herbs, acupuncture, chiropractic, and massage, among others, which are not in conformity with the standards of the medical community and may have fewer adverse effects than traditional treatments for nausea and vomiting in patients or may offer therapies that are more consistent with the patient's cultural or health care beliefs (Pan et al. 2000).

Most of the data about CAM in the treatment of nausea and vomiting are derived from studies that involve patients with CINV. In a small trial involving patients at the end of life, acupressure wrist band was not better than the placebo wrist band (Pan et al. 2000).

A systematic review in 2013 evaluated acupuncture in cancer pain found 11 trials that evaluated the effectiveness of acupuncture in the treatment of CINV. Eight trials were considered to have a high risk of bias, two were unclear. Only one positive trial in patients with breast cancer on high dose chemotherapy had a low risk of bias (Garcia et al. 2013).

Acupressure in the P-6 acupoint has been used in the treatment of postoperative nausea and vomiting. The intervention is considered effective; however, the quality of the data is considered low due to heterogeneity (Lee et al. 2015). Acupressure for the treatment of CINV has also been addressed. There have positive and negative trials. A recent trial comparing acupressure wristbands, sham acupressure, or antiemetics alone was a negative trial (Molassiotis et al. 2014).

Topical ABHR gel, a combination of lorazepam, diphenhydramine, haloperidol, and metoclopramide, has been reported in the use for refractory nausea and vomiting, especially for those unable to take medications by mouth in the hospice setting, despite the lack of absorption of these medications by that route. It is not currently recommended the use of topical ABHR gel as per the choosing wisely campaign from the American Board of Internal Medicine due to lack of benefits in well-designed studies (Currow and Abernethy 2013). Serum levels were unmeasurable (Gupta et al. 2014).

Therapeutic touch is reported to decrease the duration, frequency, and intensity of CINV compared to placebo. However, there was not description of the placebo intervention (Vanaki et al. 2016).

The impact of psychological factors on nausea and vomiting is widely acknowledged. Trials of relaxation training, coping preparations, imagery, music therapy, distraction techniques, or hypnosis demonstrate mixed results. Mind-body techniques are reported in the prevention CINV. Nevasic, which is an audio program, which uses specially constructed audio signals to generate an antiemetic reaction, did not reduced nausea and vomiting related to chemotherapy but did reduce the use of antiemetics (Moradian et al. 2015).

Ginger is commonly used to treat nausea, its potential mechanism of action as 5-HT3 antagonist. Ginger has anti-inflammatory properties and modulates gastrointestinal motility. Ginger reduces CINV and nausea associated to pregnancy. The studies are generally considered of low quality due to lack of standardized extracts, are poorly controlled studies with limited sample size (Marx et al. 2015).

In conclusion, CAM may be added to traditional care for the management of patients with nausea and vomiting associated to chemotherapy. CAM therapies can also give patients an added sense of control over the treatment of their symptoms. Little is known about the role of CAM in other causes other than CINV.

4.2 Conventional Pharmacological Approach

When considering best management practices for the pharmacologic treatment of nausea and vomiting in a palliative care setting, we can take a mechanistic or an etiologic approach. Given that even patients with advanced disease have potentially reversible causes for nausea and vomiting, following a therapeutic path based on the identification of a specific etiology and modifying or removing the offending cause of nausea is reasonable. This may not be feasible in very frail patients near end of life where an empiric antiemetic make more sense. There are no quality head-to-head studies comparing the two approaches. In the empirical approach, drug selection is based on single antiemetic agent efficacy based on clinical studies. Here, priority has been given to safety, efficacy, and pharmacokinetics shown in clinical studies. There is no convincing evidence that one approach is superior to the other (Bruera et al. 2004; Glare et al. 2004).

4.2.1 Prokinetic Agents

Given the prevalence of impaired gastric emptying in palliative care patients, and their low cost, these agents have traditionally been considered first-line agents in management of nausea and vomiting. As we consider the potential etiologic factors involved, they can enhance coordinated transit through the GI tract by promoting the release of excitatory neurotransmitters through activation of 5HT4 receptors in the enterochromaffin cells along the gut wall promoting peristalsis and intestinal tone, as well as by blocking central and peripheral 5 HT3 and D2 receptors and stimulating motilin receptors. Clinical considerations should include avoidance of these agents in the presence of complete bowel obstruction, GI bleeding, or during the immediate postoperative period (Glare et al. 2011).

4.2.2 Metoclopramide

Metoclopramide is a competitive dopamine 2 (D2) receptor antagonist; it is a benzamide derivative that primarily acts by blocking D2 receptors centrally and activating 5HT4 receptors resulting in release of acetylcholine mainly at the level of the lower esophageal sphincter, stomach, and proximal small bowel. Metoclopramide improves antroduodenal coordination and gastric emptying (Lee and Kuo 2010). At higher doses, it is a weak competitive 5HT3 blocker. According to the guidelines published by the Multinational Association of Supportive Care in Cancer/European Society of Medical Oncology (MASCC/ESMO) metoclopramide is the drug of choice for advanced cancer patients with nonchemotherapy related nausea and vomiting (Walsh et al. 2017). There have been two randomized control trials that showed moderate evidence in a with a small number of patients, and more recently a systemic review that determined moderate quality evidence for its clinical efficacy (Davis and Hallerberg 2010). Dosing is started as 5 mg every 8 h, and to maximize its absorption should be administered on an empty stomach, 30 min prior to meals. Drug half-life is 4–6 h, with an onset of action of 30–60 min when given orally, versus 1–3 min when administered intravenously. It can be given subcutaneously as a bolus or continuous infusion. Pharmacodynamically, it is more effective with continuous administration. In a retrospective assessment of cancer patients suffering from chronic nausea, patients tended to respond better and with less adverse effects to a continuous infusion up to 5 mg /hcompared to divided doses of immediate release metoclopramide. Tardive dyskinesia, akathisia, and other extrapyramidal reactions occur with higher doses (Grimes et al. 1982).

4.2.3 Domperidone

Domperidone is currently available in the United States only through the Federal Drug Administration's Expanded Access to Investigational drugs program. Please refer to ▶ Chap. 16, "Gastroparesis and Cancer-Related Gastroparesis" for more details.

4.2.4 Methotrimeprazine

Methotrimeprazine is a phenothiazine neuroleptic agent originally used in the management of schizophrenia that binds to multiple neurotransmitter receptor sites (Kennett et al. 2005). It has potent antagonist actions at a variety of drug target sites, including dopamine, histamine, adrenergic,

muscarinic, cholinergic and serotonin (5HT2 at the vomiting center) receptors. As a broad spectrum agent, it has potential application in patients with advanced disease due to likely multifactorial causes (Cox et al. 2015). Data on its effectiveness comes mainly from uncontrolled and observational studies (Eisenchlas et al. 2005; Dietz et al. 2013). It is effective in 60–80% of patients. Benze's review of chronic nausea and vomiting in palliative care patients found the level of evidence is low to moderate (level C), but deemed it an acceptable second- or third-line option (Benze et al. 2012). Methotrimeprazine via oral and subcutaneous route remains stable in a normal saline solution for up to 14 days. The preferred starting dose is 6.25–12 mg by oral route twice daily or 3.125–9.375 mg per 24 h via subcutaneous route. The oral dose can be increase up to 35–50 mg per 24 h (Amesbury et al. 2004; Eisenchlas et al. 2005). It may be considered in patients with underlying pain and nausea, as it has been described to possess analgesic benefits, particularly in neuropathic models of pain (Patt 1994). Monitoring for sedation, anticholinergic effects, as well as orthostatic hypotension are important considerations particularly in frail elderly patients. QT prolongation has been described, but is rarely encountered (Dahl and Refsum 1976).

4.2.5 Haloperidol

Haloperidol is considered a relatively potent butyrophenone neuroleptic that targets more specifically D2 receptors in the CTZ (Anchin et al. 1991; Helmeste and Seeman 1983; Sherman and Bolger 1988; Hardy et al. 2010). It has activity at sigma-1 receptors, and this activity has recently been linked to inhibition of pain hypersensitivity and facilitation of enhanced opioid antinociceptive effects (Romero et al. 2016; Entrena et al. 2009). Evidence of this benefit has recently been investigated in patients rotated from high-dose opioid regimens to methadone in combination with haloperidol (Salpeter et al. 2013). Concerns exist regarding the potential for QT prolongation with its administration via the intravenous route (Hatta et al. 2001). There have been no RCT published supporting the use of haloperidol as an antiemetic (Walsh et al. 2017). A moderate quality study that evaluated "ABH" topical gel concluded that the compound was comparable to placebo (Fletcher et al. 2014). An open-label trial showed clinical response in 20 of 33 evaluable patients, with 8 having a documented complete response. One trial suggested effectiveness of 65% (Lee and Kuo 2010). Dosing of haloperidol as an antiemetic is typically lower than its use as a neuroleptic. Starting dose is usually 0.5 mg every 6–8 h, and can be as high as 5 mg every 8 h via the oral route. Intravenously, usual doses are 0.5–2 mg every 8 h. Care should be taken when dosing in severe hepatic impairment, and in patients with advanced renal disease, it is recommended that starting doses be reduced by 50%. It should be avoided in patients suffering from Parkinson's disease, and those with narrow angle glaucoma and seizure disorders. Main adverse effects are extrapyramidal symptoms, and anticholinergic effects are possible. Drug-drug interactions occur via the CYP 3A4 system; care should be taken when using carbamazepine, phenytoin, and phenobarbital (Glare et al. 2011).

4.2.6 Olanzapine

This agent is classified as a thiobenzodiazepine atypical antipsychotic. Binding occurs at 5 HT-3, dopamine, histamine, and catecholaminergic receptors, and may be an alternative to those who do not respond to single antiemetics such as haloperidol and ondansetron. Evidence for its use comes primarily from trials evaluating chemotherapy-induced nausea and vomiting (Passik et al. 2004; Navari and Brenner 2010; Navari et al. 2007). It has been incorporated into both MASCC/ESMO and NCCN guidelines for CINV. A recent single-center study looked at 108 patients with advanced cancer at doses between 2.5 and 5 mg orally per day, with median treatment duration of 39 days (Kaneishi et al. 2016). Other uncontrolled series also showed evidence for difficult to control nausea and vomiting (MacKintosh 2016; Atkinson 2014; Passik et al. 2002). Dosing for CINV vary between 5 and 10 mg via oral route, ideally given at bedtime due to sedation. Desirable secondary effects in the palliative care setting are increased appetite and weight gain (Navari et al. 2008). Rare but

serious adverse events are insulin-resistant diabetes mellitus, a lowered seizure threshold and a prolonged QT interval. Common adverse events include somnolence, postural hypotension, constipation, dizziness, fatigue, dyspepsia, restlessness, and weight gain (Atkinson 2014; Chanthawong et al. 2014).

4.2.7 Prochlorperazine and Chlorpromazine

Both agents are widely used in both cancer- and noncancer-related palliative care settings. Like haloperidol, they block D2 receptors in the CTZ, as well as histaminergic, muscarinic, serotonergic, and alpha-adrenergic receptors. Doses for prochlorperazine range from 5 to 10 mg every 6 to 8 h by oral route, or 25 mg via rectal route 2–3 times daily. Chlorpromazine is typically given initially at 12.5 mg every 6 h usually to a maximum of 150 mg per 24 h. It can also be given intramuscularly at 25 mg 3–4 times daily. There are no quality studies looking at the effectiveness of prochlorperazine. Chlorpromazine has been evaluated in combination regimens with tropisetron and metoclopramide and found to be effective in only 20–30% of cases (Mystakidou et al. 1998). Chlorpromazine will typically have sedation as its most significant adverse effect, and thus tends to be more appropriate near end of life, particularly if delirium is part of the clinical picture. Other common adverse effects are anticholinergic effects, confusion, and extrapyramidal effects. Particularly with elderly males, glaucoma and benign prostatic hypertrophy can make them particularly susceptible to adverse events with these agents (Glare et al. 2011).

4.2.8 HT-3 Receptor Antagonists (5HT-2RA)

Serotonin antagonists target the 5HT-3 receptors found both in the periphery at vagus nerve terminals, and centrally in the NTS and CTZ (Aapro 2005). These agents have been used primarily in the setting of chemotherapy-induced nausea and vomiting (CINV). They are typically used in combination with corticosteroid and neurokinin-1 antagonist. A meta-analysis that looked at a total of 7808 patients concluded that all first-generation 5HT-3 RA are equally efficacious at preventing acute and delayed CINV following the use of highly emetogenic chemotherapy (Jordan et al. 2007) The evidence for its use in palliative care setting of nonchemotherapy-related chronic nausea is less robust. In one study, tropisetron was superior to metoclopramide and chlorpromazine in controlling chronic nausea in advanced cancer patients (Chanthawong et al. 2014). A different study demonstrated no difference when comparing ondansetron, metoclopramide, and placebo in the control of opioid-induced nausea among advanced cancer patients (Hardy et al. 2002). Doses recommended in the latest MASCC/ESMO guidelines are for ondansetron 8 mg or 0.15 mg/kg via IV route daily, or 16 mg daily orally. Granisetron is to be given in doses 1 mg IV (0.01 mg/kg) daily or 1–2 mg via oral route daily. Dolasetron 100 mg via oral route daily, tropisetron 5 mg IV via oral route daily, and palonosetron 0.25 mg IV or 0.5 mg via oral route (Roila et al. 2016). For palliative care patients being treated for pain with opioids, constipation as an adverse effect of5 HT-3 RA can be concerning. They also are known to prolong QT interval, and should be avoided when other QT-prolonging agents are used (Goodin and Cunningham 2002). In the palliative care setting, methadone can have a potentially additive pro-arrhythmic effect (Hafermann et al. 2011). They should thus be also avoided in patients with advanced cardiovascular disease. These are also very costly drugs which can be a limiting factor in a cost-conscious health system.

4.2.9 Antihistamines

There is a variety of antihistamine agents used in clinical practice for palliative care patients. Cyclizine, promethazine, and diphenhydramine are among some of the most common agents in this class. There is some evidence for their effectiveness in vestibular and chemical causes of nausea (Davis and Walsh 2000). Given their many potential drug-drug interactions via CYP2D6 pathway and significant anticholinergic adverse effects, these agents tend to be less frequently chosen for palliative care patients (American

Geriatrics Society Beers Criteria Update Expert Panel 2012). Evidence for their use is limited in the palliative care setting, and response rates reported in the range of 5–10% (Bentley and Boyd 2001).

4.2.10 Hyoscine

Hyoscine, also known as scopolamine, is an anticholinergic agent that binds preferentially to muscarinic receptors in the gastrointestinal tract, as well as blocking nicotinic receptors in a ganglion-blocking effect (Tytgat 2007). The drug is available in two formulations: butylbromide and hydrobromide. It is primarily reserved for management of refractory bowel obstruction symptoms near end of life, as it may reduce both GI secretions and smooth-muscle contractions that result in painful cramps. Evidence for its use comes primarily from experimentally-induced motion sickness-related nausea and vomiting in healthy volunteers (Pyykko et al. 1985). Statistically significant differences were found when the drug was compared to placebo in a series of 16 patients. The butylbromide formulation has low bioavailability, and is usually administered via subcutaneous infusion with doses ranging from 80 to 120 mg over 24 h. The hyoscine hydrobromide formulation is typically used in transdermal formulation in the US, ranging from 1.5 to 3 mg, but can also be used via oral (0.1 to 0.4 mcg every 4 h) and parenteral (0.6 to 2.4 mg administered over 24 h) routes (Glare et al. 2011). Particularly in patients with underlying delirium, dementia, it will be more likely to worsen confusion, and in the elderly, anticholinergic effects can be particularly troublesome: dry mouth occurred in up to 67%, and drowsiness in approximately 16% of subjects. Other adverse effects reported much less frequently are dry eyes, eye pain and eye pruritus, and blurred vision, and is contraindicated in narrow-angle glaucoma (Clissold and Heel 1985).

4.2.11 Octreotide

Octreotide (OCT) has a role primarily in the treatment of malignant bowel obstruction (MBO) in patients who have not responded to specific oncologic disease-targeted therapies, and deemed poor surgical candidates. Octreotide main mechanism of action is akin to somatostatin. It decreases splanchnic blood flow, inhibits release of serotonin, secretin, vasoactive intestinal peptide, among others, thus reducing intestinal and pancreatic fluid secretion as well as gastrointestinal motility (Glare et al. 2011). Most studies investigating the efficacy of OCT in a palliative care setting have significant limitations due to flawed design, power, and drop-out rates. One study evaluated OCT at doses ranging from 300 to 600 mcg/day in combination with haloperidol. Nausea, vomiting, along with thirst and need for IV hydration, were improved, with a reduction in total nasogastric output (Lee and Kuo 2010; Hisanaga et al. 2010). A prospective trial including 22 cases from 2006 to 2009 looked at assessing the clinical efficacy of OCT for vomiting in advanced gynecological malignancies not amenable to surgical interventions. Overall response rate was 82%, in 14 patients who had nasogastric tubes placed the response rate was 93% (Watari et al. 2012). Main adverse effects reported are diarrhea, abdominal pain, headache, fatigue, and malaise. Special consideration should be given to those patients with evidence of prolonged QTc interval, as well as those with significant bradycardia.

4.2.12 Cannabinoids

Currently available in the US in two formulations: dronabinol and nabilone. Both are approved by the US Food and Drug Administration for use in CINV refractory to first-line therapy. Both act via peripherally via CB1 receptors reducing intestinal motility in the gut, and may also act centrally on the dorsal vagal complex (Pertwee 1999; Parker et al. 2011). Dronabinol was compared to ondansetron and placebo in an RCT that showed a response rate 71%, ondansetron 64%, and placebo 15% for placebo. This study used lower doses than previous trials, resulting in less adverse effects and more compatible with current clinical practice (Meiri et al. 2007). A meta-analysis evaluated 13 RCT, 5 included dronabinol and 6 nabilone. Comparators used were prochlorperazine, alizapride, chlorpromazine, or domperidone. Dronabinol showed superiority over the comparator ($p = 0.03$, NNT 3.4,) while

nabilone showed no statistically significant difference ($p = 0.21$) (Machado Rocha et al. 2008). Doses with dronabinol are 2.5–5 mg by oral route three times daily, and with nabilone 1–2 mg twice daily, up to 6 mg daily. Most commonly reported adverse effects are somnolence, feeling of a "high" and sedation. Dizziness was reported significantly more frequently with cannabinoids when compared to metoclopramide and domperidone (Smith et al. 2015). Dysphoria was the most common cause for discontinuation of either medication among clinical trial patients, cited by 11% of patients withdrawing from treatment (Slatkin 2007).

4.2.13 Corticosteroids

Most of the evidence comes from the study of corticosteroids, particularly dexamethasone is in management of CINV. It has been suggested to work by various potential cellular mechanisms. Besides its known anti-inflammatory effect, it can have a direct central action by activation of glucocorticoid receptors at the level of the NTS in the medulla (Ho et al. 2004; Ho et al. 2004). There is also a possible interaction with 5 HT-3, tachynins NK1 and NK2, as well as alfa-adrenergic receptors (Andrews and Sanger 2014). Other clinical scenarios where dexamethasone has been included in treatment algorithms include malignant bowel obstruction and nausea due to raised intracranial pressure (Gralla et al. 1999). Doses have ranged from 4 to 8 mg per day, maximum doses of 16 mg over 24 h have been used in selected cases of malignant bowel obstruction (Glare et al. 2011). General recommendations are for limited trials to limit their potential adverse effects. Most concerning in the advance cancer population tends to be the risk for serious, life-threatening infections, as well as potential to induce hyperglycemia in diabetic patients, as well as delirium and sleep disruption in elderly patients, and those suffering from dementia. Efficacy rates vary significantly, and seem to be maximized at up to 75% when combined with metoclopramide (Bruera et al. 1996).

4.2.14 NK-1 (Tachykinin) Receptor Antagonists

This class of antiemetics are used primarily in the treatment of chemotherapy-induced nausea and vomiting (CINV). Specifically, these agents are recommended in the prevention of acute and delayed nausea in moderately to highly emetic risk chemotherapy regimens based on MASCC/ESMO and NCCN guidelines (Hardy et al. 2002). Agents currently available include aprepitant, fosaprepitant (parenteral formulation of aprepitant), netupitant, and rolapitant. Recommended doses for acute and delayed emesis are: aprepitant 125 mg on the day of chemotherapy followed by 80 mg daily for 2 days after chemotherapy, fosaprepitant 150 mg i.v. once on the day of chemotherapy; rolapitant 180 mg via oral route once on the day of chemotherapy and netupitant/0.5 mg palonosetron orally once on the day of chemotherapy. A recent systematic review looked at 17 trials, with a total of 8740 patients, assessing the role of NK-1 RA added to standard antiemetic treatment (5 HT-3 RA plus dexamethasone) for the prevention of CINV. NK-1 RA increased the likelihood of complete response (OR 0.51, 95% CI 0.46–0.57; 13 trials; $\mathbf{I}^2 = 12\%$) with a reduced need to use rescue antiemetic, as well as the reported frequency of nausea and vomiting. This benefit was found to be statistically significant for both highly emetogenic (OR 0.46, 95% CI 0.40–0.53) and moderately emetogenic OR 0.59, 95% CI 0.51–0.67) (dos Santos et al. 2012). The most common adverse effects experienced tend to be diarrhea and singultus; others include asthenia, alopecia, anorexia, and headache.

4.3 Nonpharmacological Management

Malignant bowel obstruction is described as the association of clinical and imaging evidence of bowel obstruction beyond the ligament of Treitz with incurable intra-abdominal cancer or extra-abdominal primary cancer with intraperitoneal

spread. The most common intra-abdominal cancers to cause malignant obstructions are ovarian and colorectal cancer. Meanwhile, breast cancer and melanoma are the most common extra-abdominal cancers to cause malignant bowel obstruction (Laval et al. 2014).

Nausea and vomiting usually result from malignant obstruction due to a combination of mechanical impedance, motility dysfunction, aggregation of secretions, diminished intestinal absorption, and inflammation (Teriaky et al. 2012). Medical management is therefore based on the use of steroids, antisecretory management, gastric antisecretory drugs, somatostatin analogues, and antiemetics (dos Santos et al. 2012), and nonpharmacological interventions generally include surgery (resection or palliative colostomy), stent placement, and decompression therapy (NGT, venting gastrostomies) (Dolan 2011).

The role of surgical versus nonsurgical management of patients with malignant bowel obstructions in patients with gynecologic and colorectal cancer is controversial. The management is basically empiric and there are marked variations in clinical practice. Retrospective cases showed wide variation in success rates, reobstruction and postoperative morbidity and mortality. There were no data about quality of life (Cousins et al. 2016).

The traditional surgical approach for treating malignant lower bowel obstruction (MBO) is associated with high rates of morbidity, mortality, and stoma formation. Less invasive alternatives such as colonic stents represent an option to overcome the high cost of hospital stays and poor quality of life associated with complications from surgery. Self-expanding metallic stents (SEMS) are expandable metallic tubes that are advanced to the site of obstruction along a guidewire in a collapsed state, under fluoroscopic and/or endoscopic guidance. Once deployed, the stents slowly expand radially to their maximum diameter under their own force, thereby achieving patency of the obstructed anatomy. They are generally well tolerated by patients with only conscious sedation, or no anesthesia. They are considered a less-invasive strategy than surgery, but complications still occur. Rates of stent migration, perforation, and reconstructions have been reported as 11%, 4.5%, and 12%, respectively, that limits its long-term efficacy (Watt). Stents treatment is associated with shorter length of stay, reduced ICU admissions, fever stoma formation, and shorter time to initiation of adjunct chemotherapy. The studies lack of information about quality of life and cost effectiveness. The shorter interval to chemotherapy and significant lower rates of 30-day mortality and short-term complications suggest that stents maybe reasonable alternative for treating patients with extensive metastatic disease or who are poor operative candidates due to severe comorbid conditions (Zhao et al. 2013).

Percutaneous endoscopic gastrostomy PEG tubes have been used commonly to supply alimentation since first described in 1980. A less common indication for PEG tubes is to be a long-term alternative to NGT in decompressing the gastrointestinal tract in benign and malignant diseases (Shaw et al. 2013). Patients with advanced malignancies who present with small bowel obstruction resistant to medical treatment and intractable vomiting have a very poor prognosis and end-stage palliation is usually sought, as the risk of surgery generally outweighs the benefit. Survival after venting gastrostomy placement is usually measured in weeks (Diver et al. 2013; Teriaky et al. 2012; Brooksbank et al. 2002). But a single center reported a mean survival of 135 ± 347.9 days (Issaka et al. 2014). Venting gastrostomy can facilitate the transition of these patients to home hospice. Improvements in nausea and vomiting are reported and it can also sometimes allow patients to eat small amounts of food for pleasure (DeEulis and Yennurajalingam 2015).

Some authors suggest that the time to place PEG is probably late in patients with malignant obstruction and that early PEG placement may lead to better outcomes (Laval et al. 2014).

Most venting gastrostomies are performed endoscopically. Reported complications include PEG occlusion and infection. Infections are particularly more likely in patients who have ascites.

The predictors of complications after PEG placement in the first 30 days were those with American Society of Anesthesiology (ASA) scores of 4, 4E, and 5E. Multivariate analysis revealed ASA scores >4, elevated WBC count, and advanced tumor stage to be independent predictors of mortality in the first 30 days and INR >1.5 and venting indication for PEG were independent predictors for overall mortality (Richards et al. 2013).

Ascites is commonly considered a relative contraindication for venting PEG placement in patients with malignant GI obstruction for the following reasons: the fluid can make puncturing the anterior wall of the stomach more difficult, the development of ascites between the stomach and the abdominal wall can increase the intraperitoneal catheter length and may predispose to tube dislodgement; and finally, ascites may prevent maturation of a tube track, thus facilitating pericatheter leakage of ascites and or gastric contents, which may result in skin breakdown and or peritonitis.

Fluoroscopic-guided placement of a PEG is feasible in most patients with malignant bowel obstruction and ascites, with a technical success rate of 72% and 77.4%. Ascites is managed with paracentesis and most frequently with intraperitoneal catheter (Shaw et al. 2013).

Gastroparesis can affect patients with serious illnesses, especially those with a history of diabetes and can also affect patients with cancer (Barkin et al. 1986). It can present with nausea and vomiting in addition to early satiety, postprandial fullness, and upper abdominal pain. It is better explained as a syndrome of objectively delayed gastric emptying in the absence of a mechanical obstruction. Opioid therapy can cause delayed gastric emptying and this should be considered before assuming a diagnosis of gastroparesis. The treatment usually consists of fluid, electrolyte, and nutritional support, optimization of glucose levels, and postpyloric feedings if there is evidence of unintentional weight loss of more than 10% during a period of 3–6 months, and or repeated hospitalizations for refractory symptoms. The use of prokinetics (metoclopramide) is indicated at the lowest effective dose.

Gastric electric stimulation can be considered for compassionate treatment of diabetic or idiopathic gastroparesis who present with refractory nausea and vomiting despite conventional therapy – prokinetics, fluid, electrolyte, and nutritional support, per open label studies. Complications from the device such as local infection or lead migration, as well as complications related to surgery, may occur in up to 10% of patients implanted (Camilleri et al. 2013; O'Grady et al. 2009).

Surgical options for the treatment of gastroparesis are: gastrojejunostomy, pyloromyotomy, and completion or subtotal gastrectomy. Major gastric surgery can relieve distressing vomiting from severe gastroparesis and improve quality of life in patients with a high risk for renal failure and poor life expectancy (Ejskjaer et al. 1999; Watkins et al. 2003).

In conclusion, nausea and vomiting from bowel obstruction are associated with a short-term survival. Pharmacological therapies are not always effective. Palliative venting gastrostomies and colonic stents are alternatives for symptomatic relief for patients with high surgical risk. However, these interventions are not without risk. Further research is needed to evaluate the benefit of early palliative interventions in the disease trajectory.

5 Summary General Guidelines

Initial assessment of the patient suffering from nausea and vomiting should identify those patients who are imminently dying. Here rapid optimization of symptom control should be the priority, and an empiric approach may be the most reasonable. Initial choice in advanced cancer based on the existing evidence would be metoclopramide, unless signs of bowel obstruction are present. Alternative agents can be haloperidol, levomepromazine, or olanzapine. Refractory symptoms at the end of life may lead to the consideration of palliative sedation.

In those patients who have a more extended prognosis, a more concerted effort to find reversible causes may be more appropriate. In patients

with advanced COPD and heart failure, a closer look at medications such as methylxanthines and digoxin may be warranted (Barr et al. 2003). Patients with uncontrolled diabetes mellitus may present with hyperglycemia. Correction with insulin and appropriate IV fluid administration should be considered. Hyponatremia may also be a contributing factor in patients with end-stage liver, kidney, or heart disease. Collaboration with an endocrinologist may be appropriate. Patients with liver failure may also present with symptomatic ascites leading to increased abdominal pressure. Therapeutic paracentesis and placement of an indwelling intraperitoneal tunneled catheter should be considered. If bowel obstruction or opioid bowel syndrome is suspected, a flat plate of the abdomen should be obtained. Confirmation of bowel obstruction should lead to insertion of a nasogastric tube, the initiation of around the clock octreotide plus haloperidol as first-line agent, based on MASCC recommendations. If this combination proves ineffective, anticholinergic antisecretory agents, such as scopolamine butylbromide, and/or dexamethasone can be added. In those expected to survive weeks to months, placement of a percutaneous endoscopic gastrostomy (PEG) tube should be considered. If a fecal impaction is present, a cotton seed enema may be administered.

Patients presenting with suspicion for raised intracranial pressure, CNS metastatic disease, should be managed up-front with dexamethasone. Those suspected of opioid-induced nausea and vomiting should be considered for opioid rotation. Antiemetics may be helpful, though no clear guideline exist to recommend one agent over another. Prophylactic treatment has not been shown to be effective.

Poor response to a single antiemetic should prompt treatment with a combination regimen. Here, medications that have complementary mechanisms of action may be more effective (e.g., choosing a prokinetic or haloperidol in combination with a 5 HT-3 RA). Failure of first- and second-line treatment options (metoclopramide, haloperidol respectively) should prompt consideration of broad spectrum of agents such as levomepromazine or olanzapine.

Nonpharmacologic options should always be considered in combination with any antiemetic regimen. Drug-drug interactions need to be considered before selecting a specific drug. Minimization of polypharmacy and frequent clinical reassessment are cornerstones of good palliative management of nausea and vomiting.

Abstract

Gastroparesis is an underrecognized cause of nausea, vomiting, early satiety, postprandial fullness, and weight loss in advanced cancer. Causes for gastroparesis include reduced pyloric compliance and mobility, impaired duodenal contractions, widespread neuropathy, and selective loss of interstitial cells of Cajal. Patients with cancer may develop gastroparesis because of chemotherapy-induced neuropathy, immunosuppression followed by opportunistic viral infections involving the gastrointestinal tract, procedures such as celiac blocks, paraneoplastic neuropathy or myopathy, and as a sequalae of graft-versus-host disease after allogeneic bone marrow transplant. The symptoms of gastroparesis do not correlate with the degree of impairment observed in gastric emptying studies. Treatment includes prokinetics such as metoclopramide, erythromycin, azithromycin, and domperidone. Symptoms may respond to mirtazapine, granisetron, and acupuncture. Gastric electrical stimulation and pyloromyotomy procedures have been reported to reduce symptoms, but there are no randomized trials to validate either procedure. In those failing to respond to medical management, a percutaneous endoscopy-placed gastric tube for decompression with a jejunal extension feeding tube (PEG-J) can be used to reduce symptoms and provide nutrition.

1 Introduction

Gastroparesis is defined as a delay in gastric emptying without mechanical obstruction (Camilleri 2016). Symptoms of gastroparesis are nonspecific and include nausea, vomiting, postprandial fullness, early satiety, and dyspepsia with a subset experiencing upper abdominal pain (Pasricha and Gastroparesis Clinical Research Consortium 2016). The three most common published causes of gastroparesis in the literature are idiopathic, a diabetic, and postsurgical. Gastroparesis associated with malignancies has been reported only in patient reports or small series (Pasricha and Parkman 2015; Leung and Silverman 2009). How frequently gastric paresis occurs in patients with cancer is not known. The pathophysiology of gastroparesis in non-cancer patients appears to be heterogeneous and consists of impaired fundus accommodation, visceral hypersensitivity, autonomic dysfunction, lack of compliance of the pylorus, and duodenal dysmotility (Nguyen and Snape 2015). The standard test for gastroparesis, gastric emptying by scintigraphy after a test meal, correlates poorly with symptoms of gastroparesis and quality of life (Pasricha and Parkman 2015; Borges et al. 2013). The principles to managing gastroparesis include: excluding gastric outlet obstruction, evaluating for iatrogenic causes (such as medications and surgery), and a trial of prokinetic medications (Camilleri 2016). The differential diagnosis includes functional dyspepsia,

which has similar symptoms, but can be associated with accelerated gastric emptying. Functional dyspepsia is also associated with impaired gastric accommodation and gastroduodenal hypersensitivity to distension. The rumination syndrome may superficially resemble gastroparesis and consists of repetitive regurgitation of gastric contents usually within minutes after a meal which is mistaken for vomiting. Effortless regurgitation in the rumination syndrome is preceded by a sensation of the need to belch which lasts 1–2 h. Treatment of the rumination syndrome is behavioral modification and not prokinetic medications. Finally, bulimia associated with anorexia nervosa may resemble gastroparesis associated with weight loss. Anorexia nervosa occurs in young women as does gastroparesis. In advanced bulimia, gastric emptying can be delayed (Camilleri 2016; Mascolo et al. 2016).

2 Diagnosis

Nausea and vomiting of all symptoms correlate the best with the degree of objective gastroparesis, but these symptoms are nonspecific for gastroparesis as are early satiety and postprandial fullness. Symptom tools like the Gastroparesis Cardinal Symptom Index (GCSI) have frequently been used in clinical trials and can be helpful in symptom assessment (Stanghellini and Tack 2014). A second patient questionnaire, the Patient Assessment of Gastrointestinal Symptoms (PAGS), has also been used in studies (Malik et al. 2015; Rentz et al. 2004). Objectively the retention of 10% of a test meal at 4 h measured by scintigraphy is the cardinal objective measure of gastroparesis. The 4 h gastric emptying test uses a ^{99m}Tc sulfur colloid-labeled egg sandwich as the test meal (Shin and Camilleri 2013; Camilleri et al. 2013; Abell et al. 2008). A wireless motility capsule (WMC) that measures pH, pressure, and temperature can also be used to assess gastric emptying as measured by the acidic gastric residence time of the capsule. There is a high correlation between the WMC capsule test and scintigraphy gastric emptying study. A third test, the ^{13}C-octanoate breath test, has also been approved for the same purpose by the FDA (Saad 2016; Nguyen et al. 2013).

3 Pathophysiology

3.1 Pyloric Compliance and Motility

Endoscopic functional luminal imaging probe investigations of pyloric function found reduced pyloric compliance and narrowed luminal diameter in a subset of patients with gastroparesis, early satiety, and postprandial fullness (Malik et al. 2015; McMahon et al. 2005). In another study, reduced fasting pyloric compliance was associated with objective gastroparesis, gastroparesis-related symptoms, and reduced quality of life (Gourcerol et al. 2015). In a third study, increased pyloric pressures measured by endoscopic functional luminal imaging probes were associated with impaired gastric emptying. This occurred in 42% of those with delayed gastric emptying and was associated with nausea and vomiting (Snape et al. 2016). The findings of reduced pylori compliance and increased pressures have led to the use of such modalities as intrapyloric injections of botulinum toxin, pyloric stenting, pyloroplasty, and other procedures directed toward the pylorus as a way of improving gastroparesis (Friedenberg et al. 2008; Arts et al. 2006; Clarke and Snape 2015; Khashab et al. 2013, 2015, 2017).

3.2 Impaired Duodenal Contractility

Impaired duodenal contractility rather than impaired antral contractility has been associated with gastroparesis measured by the GCSI (Barshop et al. 2015).

3.3 Widespread Neuropathy

Diabetic gastroparesis is associated with widespread autonomic and sensory neuropathy as measured by reduced heart rate variability, visceral hypersensitivity, and increased incidence of

sensory neuropathy. Unfortunately, though glycemic control is recommended by guidelines, tight glycemic control does not improve gastroparesis. Diabetics with retinopathy have a greater prevalence of gastroparesis (Softeland et al. 2014; Bharucha 2015a, b; Bharucha et al. 2015a, b). Symptoms normally associated with gastroparesis (nausea, vomiting, early satiety, and postprandial fullness) can occur in diabetics with normal gastric emptying. Unfortunately, the four symptoms which cluster in gastroparesis do not differentiate diabetics with and without gastroparesis (Bharucha 2015a, b; Bharucha et al. 2015a, b).

3.4 Loss of Interstitial Cells of Cajal

Interstitial cells of Cajal (ICC) are the pacemaker cells of the gastrointestinal tract and are lost in gastroparesis. A subset of macrophages (M2) act as "protectors" of ICC. Loss of gastric M2 cells is associated with loss of ICC and gastroparesis (Bernard et al. 2014; Choi et al. 2010).

3.5 Malignancy-Related Gastroparesis

Now, we do not know the prevalence of gastroparesis in patients with cancer; it is likely that the cause is heterogeneous. Reports of gastroparesis in patients with cancer are largely based on individual patient case reports or case series. Malignancy-associated gastroparesis can present clinically at initial diagnosis and is often associated with nausea, vomiting, and nutritional failure (Vaidya et al. 2014; Kelly et al. 2014). The differential diagnosis includes the possibility of pre-existing gastroparesis particularly in a diabetic who has developed pancreatic cancer. Individuals may have pre-existing idiopathic gastroparesis made worse or clinically apparent with the onset of cancer or with the development of chemotherapy neuropathy, surgical complication from an upper abdominal procedure, or the use of opioids. Post-viral infections cause gastroparesis in the immunosuppressed or from graft-versus-host disease. Paraneoplastic polyneuropathies are associated with gastroparesis (Pardi et al. 2002). Cancers can directly invade the myenteric plexus or mesentery, interrupting connections between extrinsic and intrinsic enteric neurons, causing a "functional bowel obstruction." A celiac block and abdominal radiation are known causes of gastroparesis (Iftikhar and Loftus 1998; Layer et al. 1986). Calcium channel blockers for co-morbid hypertension or arrhythmias cause gastroparesis independent of the cancer and can be mistaken as malignancy-related gastroparesis. Tricyclic antidepressants used as adjuvant analgesics delay gastric emptying. Amyloid infiltrates visceral smooth muscle or enteric neurons resulting in symptoms of gastroparesis and weight loss (Lee et al. 2016). Pancreatic cancer which invades the duodenum may present as idiopathic gastroparesis (Cengia et al. 2016). Loss of mesenteric artery blood flow by tumor compression or invasion causes ischemic gastroparesis (Liberski et al. 1990; Meneghini et al. 2008). Gastroparesis is reported after bone marrow transplant and may be the cause of prolonged nausea and vomiting after transplant (Johansson et al. 2003; Eagle et al. 2001). Individuals with intra-abdominal cancers which invade or cause ischemia to the celiac plexus may cause gastroparesis. Individuals with extra-abdominal cancers (most frequently breast, Hodgkin's lymphoma, and small cell cancers) are more likely to have paraneoplastic gastroparesis than individuals with intra-abdominal cancers (Pardi et al. 2002; Hejazi et al. 2009; Nguyen-tat et al. 2008; Donthireddy et al. 2007; Moskovitz and Robb 2002; Lucchinetti et al. 1998; Lautenbach and Lichtenstein 1995).

Management of gastroparesis associated with cancer is largely based on small case series and based on little to no evidence from randomized trials. There are no published guidelines established for managing gastroparesis associated with cancer but there are recommendations based on expert opinion. In regard to management, hydration and electrolyte replacement should be done initially (Leung and Silverman 2009;

Donthireddy et al. 2007). Gastric emptying scintigraphy is rarely done in individuals with cancer nausea, vomiting, early satiety, or postprandial fullness. Most recommend excluding gastric outlet obstruction. Dietary changes as recommended for non-malignant gastroparesis have not been tested in individuals with malignancy-associated gastroparesis (Shone et al. 1995). Metoclopramide has the greatest evidence base for treating nausea and vomiting in advanced cancer and is noted to improve tumor-associated gastroparesis (Davis and Hallerberg 2010; Shivshanker et al. 1983). A trial of metoclopramide should be over 2 days. Alternative prokinetics such as low-dose erythromycin and domperidone, though not reported in the management of malignancy-related gastroparesis, can be tried. If prokinetics fail to improve nausea and vomiting, an alternative antiemetic, either haloperidol or a phenothiazine, should be empirically tried. If this fails, then an NG tube is placed, and if the patient's symptoms respond, then a percutaneous endoscopic gastrostomy (PEG) with a jejunal feeding tube (PEG-J) is placed (Watson et al. 1997). Alternatively, if the patient has a short expected survival and is not expected to benefit from palliative feeding due to a short expected survival, a PEG external drainage with or without hydration may be offered.

4 Management of Non-malignant Gastroparesis

4.1 Diet

Low-fat liquid diets are better tolerated than high-fat liquid, low-fat solid, and high-fat solid diets (Homko et al. 2015). Small-sized particles are better tolerated than roughage (Olausson et al. 2014). There are foods which are poorly tolerated: orange juice, fried chicken, cabbage, oranges, pizza, sausage, peppers, onions, tomato juice, lettuce, coffee, salsa, broccoli, bacon, and roast beef. Better tolerated foods include ginger, gluten-free diet, tea, white potatoes, sweet potatoes, pretzels, white fish, clear soups, salmon, popsicles, white rice, and applesauce (Wytiaz et al. 2015).

4.2 Prokinetics

Prokinetic drugs enhance and coordinate gastrointestinal motility improving transit. It is assumed that the symptoms associated with dysmotility and that with improved smooth muscle contraction and coordination, symptoms will improve. However, as mentioned above, there is a poor correlation between dysmotility and the symptoms of gastroparesis, so it is an assumption that remains unproven (Janssen et al. 2013). Prokinetics increase acetylcholine release from primary motor neurons in the myenteric plexus which increases muscular contraction. Other transmitters which improve motility and are targeted by different classes of prokinetics include substance P and its receptor, motilin and its receptor, and ghrelin and its receptor. Serotonin improves motility through 5HT4 (5-hydroxytryptamine-4) receptors (Acosta and Camilleri 2015). The pathophysiology of gastroparesis includes not only gastric dysmotility but other abnormalities such as impaired pyloric sphincter, reduced capacitance, duodenal dysmotility, as well as other gastrointestinal hormones which adversely influence motility (cholecystokinin and peptide YY) (Kumar et al. 2008; Khoo et al. 2010). It is likely that prokinetics will only benefit a subset of patients with gastroparesis because gastric dysmotility accounts for only a subtype of gastroparesis (Stanghellini and Tack 2014; Malik et al. 2015; Gourcerol et al. 2015; Barshop et al. 2015; Stanghellini et al. 1997).

4.3 Metoclopramide

Metoclopramide is the only prokinetic drug approved by the US Federal Drug Administration (FDA) for treatment of gastroparesis which can also be given for greater than 12 weeks. Metoclopramide blocks dopamine D2 receptors and is an agonist for 5HT4 receptors (Albibi and McCallum 1983). At high doses (>120 mg) metoclopramide blocks 5HT3 receptors (Marty et al. 1990; Sanger and Alpers 2008). D2

receptors in the area postrema may be one of the mechanisms for nausea associated with hypomotility. It is likely that activation of peripheral 5HT4 receptors is the primary mechanism behind metoclopramide's prokinetic benefits (Broad et al. 2014; Sanger 2014a). Multiple studies with the primary objective of gastric emptying have demonstrated metoclopramide benefits in improving gastric emptying. Open label studies demonstrated symptom responses (Shivshanker et al. 1983; Lata and Pigarelli 2003; Seibert et al. 1989; Trapnell et al. 1986; Ricci et al. 1985; Snape et al. 1982; Muls and Lamberigts 1981; Malagelada et al. 1980; Hartong et al. 1977; Longstreth et al. 1977). A recent randomized trial which compared oral and intranasal metoclopramide with placebo found that symptoms improved in all three trial arms as measured by the GCSI (Parkman et al. 2015). This study illustrates that symptoms related to gastroparesis are subject to placebo responses. However, in this trial, women responded better to metoclopramide than placebo, indicating that benefits may be gender related. Metoclopramide can be given orally, intranasally, per rectum, subcutaneously, or intravenously. Initial oral doses are 5 mg three times daily with titration up to 40 mg per day (Camilleri et al. 2013). Doses are usually given prior to meals and at bedtime. Metoclopramide elixir may be better tolerated than the tablets. Side effects include involuntary movements, akathisia, dystonia, and tardive dyskinesia. Side effects are more frequent in women, children, and at higher doses and are less prevalent in those individuals getting continuous infusion of metoclopramide rather than oral bolus doses (Cavero-Redondo et al. 2015; Bateman et al. 1985). Metoclopramide is metabolized through CYP2D6 and has potential drug interactions as it reversibly inhibits CYP2D6. Metoclopramide has been associated with a prolonged QTc interval (Livezey et al. 2014; Sarganas et al. 2014). Doses will need to be reduced in renal and hepatic failure (Siddique et al. 2009; Lehmann et al. 1985; Albani et al. 1991).

5 Motilin Agonists

5.1 Erythromycin

Motilin agonists directly activate smooth muscle and interact to a lesser extent with enteric neurons. At low doses (50–100 mg), erythromycin enhances cholinergic activity and facilitates smooth muscle contraction. At high doses (200 mg), erythromycin causes non-propagating smooth muscle contractions and atropine-resistant non-cholinergic dependent segmental contractions (Broad and Sanger 2013; Broad et al. 2012). Low-dose erythromycin does not cause tachyphylaxis or down-regulate motilin receptors and is less likely to cause nausea or vomiting than high doses (Broad et al. 2012; Sanger 2012, 2014b; Sanger et al. 2013a; Cuomo et al. 2006). An open label study found that symptoms improved in 83% of those who received erythromycin 50–100 mg four times a day (Dhir and Richter 2004). Clinical responses appeared to be sustained over weeks. In a systematic review of oral erythromycin, five studies were reviewed whose primary outcome was gastric emptying with a demonstrated improvement in 43% (23/60 patients) and a symptom response in 48% (11/23 patients). Studies were methodologically flawed, participants were few, and there were significant risks of bias in these studies (Maganti et al. 2003). Recommended doses range from 3 mg/kg IV every 8 h to 50–100 mg orally before meals and at bedtime (Camilleri et al. 2013; Janssens et al. 1990; Tonelli et al. 2009). Erythromycin is an inhibitor of CYP3A4 and thus has significant risks for drug interactions. Erythromycin also prolongs the QTc interval which can lead to arrhythmias (Pal and Mitra 2006; Freeman and Platt 1997).

5.2 Azithromycin

Azithromycin has been compared with erythromycin during small bowel manometry in 30 patients with gastroparesis. Doses of erythromycin were

250 mg IV and azithromycin 250–500 mg. Azithromycin at these doses had similar improvement in motility. The promotility effects of azithromycin lasted longer than erythromycin. Two observational studies found that azithromycin had clinical benefits equivalent to erythromycin with fewer drug interactions and less effect on QTc intervals. However, there are no randomized trials comparing the two macrolides (Potter and Snider 2013; Larson et al. 2010; Moshiree et al. 2010).

5.3 GSK962040 (Camicinal)

Camicinal is a motilin agonist which is not a macrolide. It does not appear to produce tachyphylaxis. Camicinal improves gastric emptying in type 1 diabetics and accelerates gastric emptying in normal volunteers. In a phase II trial, camicinal improved diabetic gastroparesis (Chapman et al. 2016; Hellstrom et al. 2016; Hobson et al. 2015; Barshop and Kuo 2015). In a randomized trial involving ventilated patients who were intolerant of gastrointestinal feeding, 50–75 mg of camicinal improved gastric emptying measured by the ^{13}C-octanoate breath test (117 vs. 76 min), increased glucose absorption, and reduced gastric residual volumes (Chapman et al. 2016).

6 Dopamine Blockers

6.1 Domperidone

Domperidone is a D2 receptor antagonist which does not cross into the CNS and thus has limited extrapyramidal side effects. It is not licensed in the United States but can be made available through a compassionate clearance under the FDA. Domperidone chemical structure is based on butyrophenones. It has a low oral bioavailability (15%) but a high affinity for gastrointestinal D2 receptors (Van Nueten et al. 1978). Domperidone improves antroduodenal coordination via interactions with specific dopamine receptors located on nervous structures in the gut wall (Schuurkes and Van Nueten 1984). Dopamine-induced gastric relaxation is prevented by dopamine antagonists. D2 antagonists exert gastric stimulatory effects and improve gastroduodenal coordination (Schuurkes and Van Nueten 1984; Van Nueten and Schuurkes 1984; Schuurkes et al. 1985). In a study involving 125 patients, domperidone 10 mg was given 3–4 times daily in a group of patients, most of whom had idiopathic gastroparesis. Assessment was done 2–3 months after initiating therapy. Forty-five of the patients have had moderate improvement in their symptoms as measured by the GPGAS. Nausea and vomiting as well as postprandial fullness improved. Side effects included headache, tachycardia, palpitations, and diarrhea (Schey et al. 2016). Domperidone has potential drug interactions through CYP3A4 and can prolong the QTc which can lead to arrhythmias (Youssef et al. 2015; Templeton et al. 2016; Ioannou et al. 2016).

7 Serotonin Receptor Agonists

7.1 Prucalopride

Prucalopride is a highly selective 5HT4 agonist which does not have the cardiovascular risks of cisapride (Briejer et al. 2001). Prucalopride is licensed outside of the United States for chronic idiopathic constipation. Preliminary evidence suggests prucalopride could improve symptoms of gastroparesis and gastric emptying. Prucalopride at low drug levels ($3 \times 10(-7)$ M) enhances the electrically evoked release of acetylcholine in gastric circular muscle (Leclere and Lefebvre 2002). In normal healthy individuals, prucalopride accelerates gastric emptying and reduces gastric residual volumes measured at 120 min (Kessing et al. 2014). Prucalopride improves nausea, vomiting, and early satiety relative to placebo in patients with idiopathic gastroparesis. A large phase III study is presently open to accrual. The ability of prucalopride to block cardiac repolarization is 20-fold less than

that of cisapride and hence clinically safe (Potet et al. 2001). However, prucalopride has poorly defined pharmacokinetics. Prucalopride may reduce the efficacy of oral contraceptives. Miscarriages have been reported in clinical trials. Prucalopride should not be taken during pregnancy (Prucalopride 2011).

7.2 Ghrelin Analogs

Motilin and ghrelin receptors are members of the same subfamily of G-protein-coupled receptors. In fact, there is a 52% amino acid identity between the two receptors. However, the receptors do not bind the same ligands. Ligands are in different areas of the gastrointestinal tract. Ghrelin is located within gastric oxyntic cells, whereas motilin is located within antral and duodenal villous epithelial cells (Sanger 2013). Ghrelin stimulates gastric motility and appetite mostly via vagus-dependent pathways. Ghrelin does not appear to improve gastric emptying or symptoms and neither does the ghrelin analog TZP-102 (Sanger et al. 2013b; McCallum et al. 2013). Relamorelin is a potent ghrelin receptor agonist which is a pentapeptide amide. It has a half-life of 4.5 h and clinically is injected twice daily. In a randomized phase II controlled trial, twice daily relamorelin 10 mcg accelerated gastric emptying and reduced vomiting frequency and severity relative to placebo in adults with diabetic gastroparesis. There was also improvement in nausea, bloating, and early satiety as a composite outcome compared with placebo (Lembo et al. 2016). Side effects were like those of placebo. There were no QTc interval changes noted. Requirements of injections twice daily are a drawback, perhaps less so for diabetics on insulin.

8 Symptom Management

8.1 Granisetron

Transdermal granisetron has been used in a prospective observational study involving 51 patients with gastroparesis. The study was 2 weeks in duration and used the GCSI to measure the primary outcome. Most the participants had idiopathic gastroparesis. Thirty-one (76%) had improvement in nausea and vomiting. Early satiety, postprandial fullness, loss of appetite, and upper abdominal pain also improved. Side effects included erythema at the patch site, pruritus, and constipation (Midani and Parkman 2016). There are no randomized trials which compare granisetron to other antiemetics.

9 Antidepressants

9.1 Tricyclic Antidepressants

Nortriptyline has been compared to placebo in a randomized trial (Parkman et al. 2013). The outcomes were not better than placebo. A randomized comparison between placebo, amitriptyline, and escitalopram over 10 weeks found that amitriptyline improved ulcer-like pain symptoms associated with gastroparesis. However, there was no improvement in dysmotility-like symptoms (Talley et al. 2015).

9.2 Mirtazapine

Mirtazapine is an indirect 5HT1a receptor agonist; an inverse agonist at 5HT2c; and an antagonist to histamine (H1), 5HT2, 5HT3, and alpha-2 adrenergic receptors. Mirtazapine improves gastric emptying in diabetics but does not accelerate gastric emptying in normal individuals (Kim et al. 2006; Yin et al. 2014; Gooden and Takahashi 2013; Choung et al. 2008; Tack et al. 2016). Mirtazapine has been effective in improving symptoms associated with functional dyspepsia and weight loss. However, there are no randomized trials of mirtazapine in patients with gastroparesis. Mirtazapine has minimal inhibitory effects on CYP1A2, CYP3A4, and CYP2D6 in vitro. Little is known about its interactions with other drugs (Owen and Nemeroff 1998). Mirtazapine has a significantly lower risk of cardiovascular adverse events and drug reactions than other antidepressants (Spindelegger et al. 2014).

10 Complementary Approaches

10.1 Acupuncture

In annulus, acupuncture improves gastric emptying through stimulation of the vagus nerve (Ouyang et al. 2002). Acupuncture increased the regularity of slow waves in the stomach and improved gastric arrhythmias. Acupuncture points include pericardium 6 (Pc6), stomach 36 (ST36), and stomach 44(ST44) (Lin et al. 1997). Electroacupuncture (EAP) and transcutaneous electroacupuncture (TEAP) have frequently been used in various studies. In a short randomized controlled trial of 2 weeks, EAP improved symptoms in a group of patients with diabetic gastroparesis (Wang 2004). In the second randomized trial involving patients in critical care who had delayed gastric emptying, acupuncture was superior to prokinetic in improving gastric emptying (Pfab et al. 2011). TEAP has been compare to sham TEAP in a group of patients with functional dyspepsia. TEAP improved gastric accommodation and the power of gastric slow waves relative to sham (Xu et al. 2015). A large study of 712 patients compared a prokinetic agent (itopride), placebo, and acupuncture in patients with functional dyspepsia. Acupuncture improved symptoms and quality of life than either placebo or the prokinetic drug (Ma et al. 2012). The advantage of TEAP is that patients can be taught self-administration and apply TEAP at home. TEAP is a low risk procedure but does require skill.

10.2 *Zingiber officinale* (Ginger)

Ginger reduces nausea associated with pregnancy, in the postoperative setting, and nausea associated with motion sickness. It has also been used to reduced chemotherapy-related nausea with mixed results (Ding et al. 2013; Giacosa et al. 2015; Lete and Allue 2016; Montazeri et al. 2013; Palatty et al. 2013; Ryan et al. 2012; Thomson et al. 2014). Ginger blocks serotonin receptors as the proposed mechanism of its antiemetic action. Ginger in a dose of 1200 mg as a single dose has been demonstrated to accelerate gastric emptying in patients with functional dyspepsia (Hu et al. 2011; Wu et al. 2008; Lazzini et al. 2016). However, there are no randomized trials of ginger in the management of gastroparesis (Leung and Silverman 2009).

11 Non-pharmacological Therapies

11.1 Gastric Electrical Stimulation

Transcutaneous and endoscopy placed leads with gastric electrical stimulation (GES) has been used as a means of improving gastroparesis. In non-randomized studies, gastric stimulation has reduced nausea and vomiting and total symptom burden (Shah et al. 2017). In a systematic review, there were five studies reviewed with randomly allocated patients to periods with or without GES. Total symptom severity scores did not differ when the electrodes were on or off (0.17 [95% confidence interval: −0.06 to 0.4]; $P = 0.15$). In 16 open label studies of GES, there was a significant decrease in symptoms (2.68 [2.04–3.32]; $Q = 39.0$; $P < 0.001$) (Levinthal and Bielefeldt 2017). Improvement seen in studies when the current was off suggests that a significant number of responses seen in the open label studies could have been placebo responses. Randomized trials are needed before adopting this approach.

11.2 Procedures Directed at the Pylorus

Pyloromyotomy, pyloroplasty, pyloric stenting, botulinum toxin injections into the pylorus, and per-oral endoscopic antropyloromyotomy have been reported to improve gastroparesis in case series (Snape et al. 2016; Clarke and Snape 2015; Khashab et al. 2015; Gonzalez et al. 2017; Lebaras and Swanstrom 2016; Mancini et al. 2015; Soares and Swanstrom 2015). These procedures have not been subject to randomized trials and should be considered experimental until

further evidence as to benefits or lack thereof emerges (Camilleri et al. 2013).

12 Percutaneous Endoscopically Placed Gastric Drainage Tube with a Jejunal Feeding Tube Extension (PEG-J)

A PEG-J should be considered in patients who failed to improve with medical management. Nausea and vomiting can improve and patient nutritional failure can be reversed with a PEG-J. It has been suggested that a trial of NG suctioning should be done before placing a PEG-J to see if symptoms do improve. Minor complications from the procedure occur in 57% and serious complications in 13%. Serious complications include gastric perforation, bleeding, infections, wound leakage, hematoma, gastric ulceration, and cellulitis (Table 1).

Table 1 Recommendations for gastroparesis

1	Suspect gastroparesis in anyone with intractable nausea, vomiting, postprandial fullness, early satiety, abdominal pain, and GERD-like symptoms who does not have a gastric outlet obstruction
2	Exclude iatrogenic diseases and medications (opioids, anticholinergics, cyclosporine, cannabinoids, GIP-1 analogs)
3	Exclude thyroid disease; control hyperglycemia in a diabetic (blood glucose <275 mg/dl)
4	If significant weight and/or reduced performance score, consider an underlying malignancy and an abdominal CT scan
5	Review previous abdominal surgeries
6	Do a standard 4 h gastric stimulation test
7	Correct fluid deficits and electrolyte abnormalities
8	Diet should be low fat and small particle. Certain foods may be better tolerated than others
9	Metoclopramide is the drug of choice; start with 5–10 mg before meals and at bedtime. If in the hospital or unable to take orally, start metoclopramide at 40 mg/d IV in divided doses or as a continuous infusion
10	Alternative drug therapy includes domperidone at 5–10 mg before meals and at bedtime or erythromycin 50–100 mg orally before meals and at bedtime
11	Symptom medications include granisetron, mirtazapine, amitriptyline (depending on the symptom cluster) and ginger
12	Butyrophenones (haloperidol), phenothiazines, and atypical antipsychotics (olanzapine) could be used for nausea but should not be combined with metoclopramide. Olanzapine may be tolerated by individuals who have extrapyramidal adverse effects from metoclopramide or haloperidol
13	Gastric electrical stimulation and acupuncture could be considered in those not responding to medical management
14	If symptoms are intractable, consider a PEG-J tube

13 Summary

Gastroparesis is a common disorder in the population. The frequency of gastroparesis in cancer is not known. Malignancy-associated gastroparesis likely has a several etiologies which will likely influence responses to therapy. Management of malignancy-associated gastroparesis is guided by therapies developed in populations with non-cancer gastroparesis and the meager evidence derived from published literature. Future studies are needed to clarify the incidence and management of malignancy-associated gastroparesis.

Abstract

Symptoms related to anorexia (loss of appetite), cachexia (muscle loss and wasting) and dysphagia (reduced ability to eat) are devastating for a person with a palliative illness and their families. They are common, especially as illness advances, and occur in both malignant and non-malignant illness. Not only do the conditions serve as a visual reminder of the chronic disease, they also affect the psychology governing the social aspects of eating. For many years, anorexia, cachexia and dysphagia as distinct conditions were overlooked by healthcare professionals and researchers as the focus was on the primary chronic illness instead (Fearon et al., Understanding the mechanisms and treatment options in cancer cachexia. Nat Rev Clin Oncol 10(2):90–99, 2013). Clinical research, particularly in the field of cancer cachexia, has gained new insight in the pathogenesis and management of the conditions including anorexia and dysphagia. This chapter will define the conditions and outline the epidemiology, etiology and pathophysiology and assessment and management of these symptoms.

1 Introduction

Cachexia is a complex metabolic syndrome characterized by the profound reduction of lean body mass (LBM) and adipose tissue and involuntary loss of more than 10% of premorbid weight and is associated with anorexia (loss of appetite), asthenia (physical weakness) and changes in body image (Del Fabbro et al. 2006). Cachexia comprises a complex interplay of inflammatory and metabolic imbalances, compromised immune system responses (with increased susceptibility to infections), and associated changes in glucose, lipid and protein metabolism (Macciò et al. 2012). Cachexia may occur in up to 80% of patients with advanced cancer and is a marker for poor prognosis (decreased adherence to treatment, lengthy hospital stays and increased mortality) and the main cause of death in 20% of patients (Inui 2002). Cancer cachexia is more common in patients with solid tumors, in children and in elderly patients. Cachexia is also common in acquired immune deficiency syndrome (AIDS), chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF) and other chronic illnesses, such as dementia, tuberculosis, malaria, chronic kidney disease, liver disease and rheumatoid arthritis (Del Fabbro et al. 2006). "Weight gain" may come in the form of ascites or edema and may mask the progression of cachexia, and so can obesity, which may have underlying muscle wastage (Fearon et al. 2013). The management of major contributors to this syndrome, such as chronic nausea, constipation, early satiety, taste alteration, anemia, dyspnea, deconditioning and depression, may result in significant improvement. Megestrol or corticosteroids are current pharmacological treatments which predominantly stimulate appetite. Nutritional supplementation and appetite stimulation alone cannot overcome muscle mass wasting, and this makes cachexia difficult to treat and reverse (Del Fabbro et al. 2006). Cachexia is a significant burden to both the patient and families. Along with helplessness and fear, frustration sets in with some family members resorting to force-feeding their loved ones, hoping that the food would give them the energy to fight the cancer (Fearon et al. 2013). Dysphagia issues, which are common in head and neck cancer patients, include choking, dehydration, malnutrition, aspiration and a resulting loss of eating (Raber-Durlacher et al. 2012). Any treatment will require careful assessment and alternatives to oral administration. This chapter will use the latest literature to provide a comprehensive summary of

anorexia, cachexia and feeding difficulties that are experienced by cancer and noncancer populations.

2 Anorexia-Cachexia Syndrome

2.1 Definitions

Anorexia is clinically defined as the reduction or loss of appetite (Muscaritoli et al. 2010). There may be associated symptoms such as nausea and vomiting, early satiety and changes in taste and smell (Muscaritoli et al. 2010). Anorexia can be part of the anorexia-cachexia syndrome, but there are multifactorial causes for appetite and appetite-related problems.

Sarcopenia is characterized by loss of muscle mass and strength (Muscaritoli et al. 2010).

Cachexia is characterized by severe loss of body weight, fat and muscle and increased protein catabolism. The causes of cachexia are multifactorial and include the underlying disease, disease-related metabolic abnormalities and reduced availability of nutrients (Muscaritoli et al. 2010). A staging classification for cancer cachexia has been developed (pre-cachexia, cachexia, refractory cachexia) (Box 1) (Fearon et al. 2011).

Box 1

Pre-cachexia

- Anorexia
- Impaired glucose tolerance
- Weight loss ≤5%

Cachexia

- Weight loss >5% OR Body Mass Index (BMI) <20 and weight loss >2% OR sarcopenia and weight loss >2%
- Often reduced food intake and systemic inflammation

Refractory cachexia

- Low performance status (WHO score 3 or 4)

Box 1 (continued)

- Life expectancy <3 months
- Rapidly progressive cancer unresponsive to anticancer therapy

Source: Fearon et al. (2011)

2.2 Epidemiology

The occurrence of cachexia is not only limited to cancer but also found in other terminal conditions such as chronic heart and kidney disease, chronic obstructive pulmonary disease (COPD), neurological diseases, systemic inflammatory conditions and HIV/AIDS. It is estimated that around 0.5–1% of the global population suffers from cachexia (Haehling et al. 2016).

Table 1 summarizes the prevalence of cachexia in several chronic diseases based on US, Japanese

Table 1 Prevalence of cachexia in several chronic diseases based on US, European and Japanese populations[a] (Japan figures in brackets)[b]

Disease	Prevalence in population	Prevalence in the disease	1-year mortality rate (%)
Cancer	0.5	28–57 (advanced) (45.6) 50–80 (several types)	20–80
Chronic heart disease	2.0	13.6 (33) 16–42[c]	20–40
Chronic renal disease	0.1	30–60	20
COPD	3.5	27–35 (31–41)	15–25
Rheumatoid arthritis	0.8	18–67[c]	5
HIV/AIDs		10–35[c]	

COPD chronic obstructive pulmonary disease, *HIV/AIDS* human immunodeficiency virus/acquired immunodeficiency syndrome

[a]Haehling et al. (2016)

[b]Konishi et al. (2016)

[c]Farkas et al. (2013)

and European populations. Unfortunately, data outside these industrialized countries is scarce. Depending on the cachexia criteria used, the reported prevalence may vary (Haehling et al. 2016) as seen in the Japanese figures (in brackets below).

Due to changes in physiology of oral intake endured by head and neck cancer patients, a study showed a 42% prevalence of cachexia in newly diagnosed patients (Jager-Wittenaar et al. 2017). In advanced head and neck squamous cell carcinoma, cancer cachexia was identified in 6.1% and 18.7% of the enrolled patients at pretreatment and 12 months post treatment, respectively, with a higher probability of cancer-specific death, noncancerous death and overall death ($p < 0.05$) (Kwon et al. 2017). In Irish oncology outpatients, cachexia was highest in hepatobiliary (65.2%) and upper gastrointestinal tumors (64.3%) and was associated with poorer performance status, adverse global quality of life (QoL) ($P = 0.003$), poor appetite ($P < 0.001$) and nausea and vomiting ($P < 0.001$) (Cushen et al. 2015). In a systematic review of palliative care-related problems, anorexia was found to be prevalent (50% or more) in both cancer and noncancer patients (Moens et al. 2014). In patients who survived to the final phase of dementia, it was found that 53.2% were more likely to die from cachexia or dehydration (Koopmans et al. 2007). Although there have been improvements in antiretroviral therapies of HIV, wasting and anorexia continues to be a problem (Keithley and Swanson 2013).

Recent findings in COPD patients have discovered gene variations in the phenotypes of two muscle-wasting genes associated with cachexia (McDonald et al. 2014).

The burden of cachexia influences many facets of society including morbidity and mortality, impaired quality of life, and healthcare costs. In the USA, cachexia included an older cohort (average age 67.85 years), longer hospital duration (around double), loss of function in the "major" category (52.6%), and increased economic costs (around 66%), compared to non-cachexia patients (Arthur et al. 2014).

2.3 Clinical Assessment

Clinical assessment should evaluate appetite and related symptoms (changes in taste (hypogeusia) and smell (hyposmia), early satiety, nausea), food intake (including protein and calories), muscle mass and strength, factors promoting catabolism, and performance status (Fearon et al. 2011). Thus, anorexia may be diagnosed earlier than cachexia if the patient reports cessation of eating due to early satiety, nausea, and bloating caused by gastrointestinal delays (Davis et al. 2004). The effects of cachexia and its meaning from the patient's perspective should also be captured, and so the impact on their caregivers (Fearon et al. 2011). This might include the inability to undertake activities of daily living, understanding it as a flag of poor prognosis, feeling under pressure to eat, guilt, and altered mood. Families may constantly urge the patient to eat and express frustration when the person does not want to eat anything (Fearon et al. 2011).

The consideration of reversible causes, such as mucositis, unrelieved symptoms such as pain and breathlessness, constipation, and difficulty in sourcing meals, should be considered (Fearon et al. 2011). Referral to a dietician for a detailed dietary assessment may be appropriate.

Weight, weight loss history, current height and weight (to calculate BMI) and previous stable weight (to calculate percentage weight loss) are required (Fearon et al. 2011).

Systematic inflammation may be present and contribute to increased catabolism and may be evaluated by serum C-reactive protein (Fearon et al. 2011). Indirect indicators of a hypercatabolic state are the rate of progression of the cancer itself and/or non-responsiveness to anticancer therapies (Fearon et al. 2011).

The assessment of muscle strength and mass is advocated, and a range of methods are available, and consensus about which can be routinely used in clinical practice has not been reached (Fearon et al. 2011). Upper limb hand grip strength is useful to assess muscle strength, and muscle mass by cross-sectional imaging (CT, magnetic resonance imaging (MRI)), dual energy X-ray imaging (DEXA), and anthropometry (mid-arm

Table 2 Causes of anorexia

Peripheral *Tumor-producing*	Peripheral *Chemotherapy-producing*	Cytokine release	Central
Substances that alter food intake, e.g., increased lactate, tryptophan, or parathormone-related peptide Alterations in nutrients resulting in anorexia, e.g., low zinc levels result in hypogeusia Decreased ghrelin	Altered taste perception and causing nausea, vomiting, mucositis, abdominal cramping, bleeding, and ileus Dysgeusia	Increased: IL-1 IL-6 TNFα	Depression Pain Alterations in central neurotransmitters (e.g., serotonin and corticotropin-releasing factor (CRF)

muscle area) and bioimpedance (Fearon et al. 2011).

2.4 Pathophysiology

2.4.1 Anorexia

Anorexia results from the failure of appetite signals and much of this is governed by the hypothalamus. In animals, these are proposed to be caused by the reduced expression and release of ghrelin by interleukin (IL)-1 and reduction in neuropeptide Y expression and signaling (Davis et al. 2004). A recent study has shown that plasma ghrelin levels were associated with anorexia, but not cachexia, in patients with non-small cell lung cancer (NSCLC) (Blauwhoff-Buskermolen et al. 2017). The causes of anorexia can be classified as peripheral (due to the tumor (including cytokine release) and chemotherapy) and central causes. In humans, these causes are summarized in Table 2. Other proposed pathways include via neuronal nitric oxide synthase (nNOS), increased serotonin by IL-1, increased ciliary neurotropic factor, increased activity of anorexigenic neuropeptides (corticotropin-releasing factor (CRF) and melanocortin) and dynamin (Ezeoke and Morley 2015).

2.5 Cachexia

The pathophysiology of cancer cachexia is multifactorial consisting of heightened inflammatory responses, oxidative stress, negative protein and energy balance, hormonal imbalances, altered lipid and carbohydrate metabolism and gastrointestinal function, contributing to muscle wasting and fatigue (Kaasa et al. 2015). A summary of each contributing factor is given below and is shown in Fig. 1.

Inflammation*:* The inability of the immune system to definitively counteract tumor growth results in chronic cytokine activity (by both the host and tumor) with deleterious effects on cell metabolism, body composition, nutritional status and immune system efficiency. A complex interplay of proinflammatory cytokines including interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α, which are produced both by the activated immune system and by tumor cells, is implicated in the pathogenesis of cancer-related anorexia and cachexia syndrome and associated metabolic changes (Macciò et al. 2012).

TNF-α increases gluconeogenesis (generation of glucose from noncarbohydrate sources), lipolysis (breakdown of lipids and involves hydrolysis of triglycerides into glycerol and free fatty acids) and proteolysis (breakdown of proteins into smaller polypeptides or amino acids); decreases the synthesis of glycogen, lipids and proteins; induces the formation of IL-1; and stimulates the expression of uncoupling proteins (UCP) 2 and UCP 3 in cachectic skeletal muscle. The levels of IL-6 were observed to be higher in patients with cachexia (Aoyagi et al. 2015). C-reactive protein (CRP, prognostic combined with decreased plasma albumin) positively correlated with weight loss, the occurrence of cachexia, and recurrence in advanced cancer (Suzuki et al. 2013). STAT3 activation (implicated in muscle wasting) and fibrinogen are increased (Fearon et al. 2013). Elevated acute-phase protein response (APPR), which is correlated to elevated REE and reduced

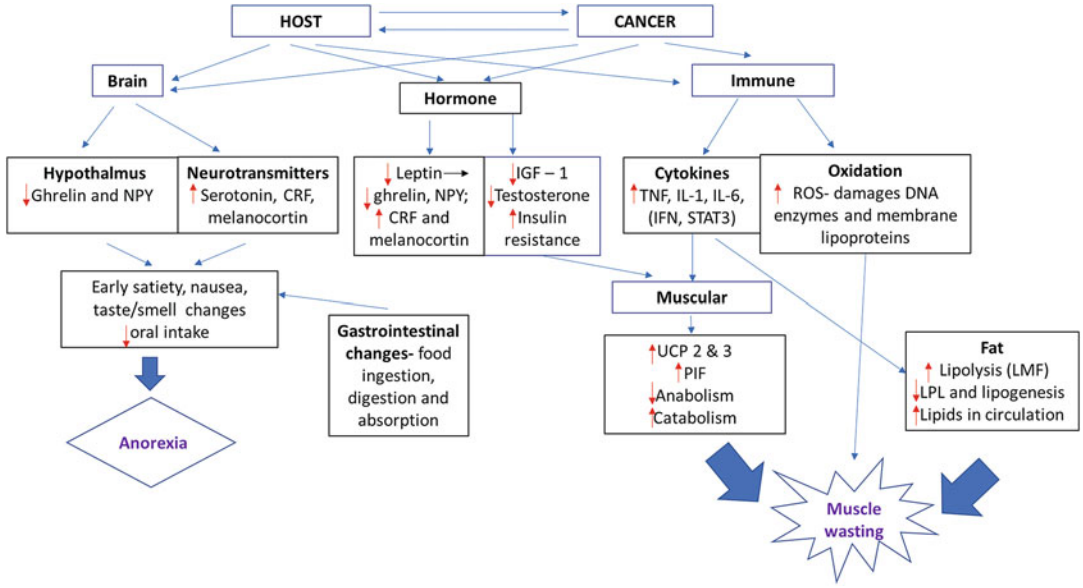

Fig. 1 Cancer-related cachexia mechanisms. *CRF* corticotropin-releasing factor, *IFN* interferon, *IGF* insulin growth factor, *IL* interleukin, *LMF* lipid-mobilizing factor, *LPL* lipoprotein lipase, *NPY* neuropeptide Y, *PIF* proteolysis-inducing factor, *ROS* reactive oxygen species, *TNF* tumor necrosis factor, *UCP* uncoupling proteins (Macciò et al. 2012; Aoyagi et al. 2015; Suzuki et al. 2013; Fearon et al. 2013; Inui 2002; Del Fabbro et al. 2006)

energy intake, has been seen in 50% of patients with solid epithelial cancers (Suzuki et al. 2013). Tumor-derived factors such as proteolysis-inducing factors and the recently discovered myostatin (which is upregulated) also play a central role in the pathogenesis of muscle wasting, through the activation of the ubiquitin-proteasome proteolytic pathway (Macciò et al. 2012).

Oxidative stress is characterized by increased levels of ROS due to the increased activity of the immune system. This damages DNA, enzymes and membrane lipoproteins, and its inadequate detoxification leads to muscle wasting (Macciò et al. 2012).

Altered protein metabolism may be influenced by tumor progression, comorbid conditions, old age, physical deconditioning, nutritional deficiency, drugs (especially those that target both tumor pathways and muscle protein anabolism), and medical interventions (Fearon et al. 2013). In patients with cachexia, the rate of muscle protein catabolism increases in cachexia, while anabolism of new proteins decreases (especially in times of reduced protein intake), resulting in net protein breakdown and subsequent muscle mass loss. Uncoupling proteins (particularly UCP 2 and UCP 3), which are associated with energy metabolism in skeletal muscle, are upregulated in the cachectic state. The proteins may increase resting energy expenditure (REE) which is also increased, and this is dependent on the tumor (Aoyagi et al. 2015).

The loss of skeletal muscle mass in cachectic cancer patients has been shown to correlate with the presence of a proteolysis-inducing factor (PIF) in the serum that is capable of inducing protein degradation, as well as inhibiting protein synthesis, in isolated skeletal muscle.

Gluconeogenesis, with a depletion of protein and lipid stores, results in weight loss (Macciò et al. 2012).

Hormonal: Starvation or a loss of body fat can lead to a decrease in leptin, a protein hormone marker of nutritional status, whereby food intake exceeds energy expenditure. In cancer cachexia, excessive decrease in leptin by cytokines results in the suppressed production of ghrelin, neuropeptide Y (NPY) and other appetite-stimulating

neuropeptides, and increased activity of anorexigenic neuropeptides such as corticotropin-releasing factor (CRF) and melanocortin. Low concentrations of testosterone and other anabolic hormones are major contributors to cachexia-related wasting of skeletal muscle. Insulin-like growth factor 1 is also down-regulated, which increases protein breakdown and induces muscle wasting via angiotensin II (Suzuki et al. 2013).

Carbohydrate metabolism undergoes changes to sustain the increasing macronutrient demands of the tumor (Inui 2002). Hypoinsulinemia and/or peripheral resistance to insulin results in the inability of the host cells to use newly formed glucose (Macciò et al. 2012).

Altered lipid metabolism includes enhanced lipid mobilization (via lipid mobilization factor: LMF), decreased lipogenesis and decreased activity of lipoprotein lipase (LPL), the enzyme responsible for triglyceride clearance from plasma. Cytokines prevent LPL from removing lipids from circulation for storage (Inui 2002).

Gastrointestinal dysfunction encompassing the mouth and the digestive tract, resulting from the disease or its treatment, may interfere with food ingestion, digestion and absorption (Inui 2002).

Although increased concentrations of cytokines in the plasma, peripheral tissues and central nervous system have been found in cachexia associated with other chronic diseases, there are also other characteristic features that differentiate the diseases (Seelaender and Batista 2014). Table 3 outlines the features, triggers and distinct characteristics of cachexia in other chronic diseases. Due to these differences, there are no common treatment options for anorexia and loss of lean body mass in these diverse and distinct disease states. In syndromes involving either cardiac or renal disease, cachexia may contribute to further damage of the other organ (Cicoira et al. 2011).

2.6 Prevention

Early assessment and routine monitoring of cachexia is vital to prevent or mitigate symptoms. Screening by quality-of-life questionnaires such as Malnutrition Universal Screening Tool (MUST) scores and CT assessment of body composition will identify at-risk patients and allow for prompt interventions in these patients (Cushen et al. 2015).

Malignancy-related cachexia has detrimental effects to physical function, which, in turn, reduces the tolerance of anticancer therapy and subsequently increases mortality. Thus, nutritional support to preserve energy and protein intake before or while concurrently treating the disease is an important factor in the prevention of cachexia and thus the survival of the patient. This was seen in a study of newly diagnosed, treatment naïve cancer patients with cachexia, whereby a patient-tailored nutrition therapy plan maintained body weight and improved survival rate (De Waele et al. 2015).

Through its anti-inflammatory effect, exercise has been shown to be effective at counteracting the muscle catabolism by increasing protein synthesis and reducing protein degradation, thus successfully improving muscle strength, physical function (cardiovascular fitness and decreasing fatigue) and quality of life in patients with non-cancer-related cachexia such as rheumatoid arthritis (Gould et al. 2013). Thus, it is suggested that exercise is included early in the treatment plan for cancer-related cachexia.

One physiological factor that occurs before a clinical diagnosis of cachexia is made is muscle wasting. In a Phase III study using enobosarm, a nonsteroidal selective androgen receptor modulator (SARM), subjects prior to receiving chemotherapy were eligible to apply, allowing the clinical trial to examine both prevention and treatment of the condition (Crawford et al. 2016). Given that the best outcome would be the prevention of muscle wasting, and hence cancer cachexia, future research should focus on both prevention and treatment of this condition.

2.7 Intervention

2.7.1 Nonpharmacological Therapies

To address malnutrition in the cancer patient, it is recommended that the nutritional regime should provide 30–35 kcal/kg/day, 1–1.2 g protein/kg/

Table 3 Characteristics of cachexia in other chronic diseases

	Chronic heart failure (HF) (Loncar et al. 2016)	COPD (Remels et al. 2013)	Chronic renal/kidney disease (CKD) (Laviano et al. 2010)	Chronic liver disease (Plauth and Schütz 2002)	Rheumatoid arthritis (RA) (Roubenoff 2009)
Features	Progressive tissue wasting; bone and fat compartments also affected	Pathological changes in intracellular mechanisms of muscle mass maintenance (i.e., protein and myonuclear turnover)	Leptin as an inflammatory cytokine and influencing appetite, energy homeostasis	Increased hypermetabolism and specific REE; portal hypertension	Loss of body fat-free mass often accompanied by increased fat mass and stable body weight Demonstration of increased metabolic syndrome in patients underlines complex interplay between fat mass, lean mass and insulin resistance
Triggers	Immune (increased circulating levels of proinflammatory cytokines combined with increased or reduced anti-inflammatory mediators), metabolic (reduced circulating testosterone and dehydroepiandrosterone sulfate), and neurohormonal consequences, which induce catabolic and anabolic imbalance. The overall net catabolic dominance provokes systemic tissue wasting Both epinephrine and norepinephrine can cause a catabolic metabolic shift, leading to a graded increase in REE	Oxidative stress, myostatin and inflammation	No renal update of leptin and ghrelin Thus, increased circulating levels	Pro- and anti-inflammatory cytokine-driven hypermetabolism	"Sarcoactive" molecules ((TNF)-α and IL-1β, IL-6, IFN-γ, transforming growth factor-β1 and MyoD), energy expenditure, protein metabolism, physical activity levels and hormones
Effects	Anabolic deficiency induces loss of skeletal muscle mass and function. GH/IGF-1 axis may impact the anabolic/catabolic balance in the wasting syndrome. Adiponectin, an adipokine with multiple metabolic actions, increases both locally and globally with HF severity and is highest in cachectic patients. The overactivation of the ubiquitin proteasome pathway (UPP) in the skeletal muscle has been attributed to increased oxidative stress	Peripheral muscle characterized by a fiber-type shift toward a more type II, glycolytic phenotype and an impaired oxidative capacity (collectively referred to as an impaired oxidative phenotype)	Leptin signaling, through the hypothalamic melanocortin receptors, may play an important role in the pathogenesis of inflammation-associated cachexia in CKD Increased ghrelin reduces appetite/food intake	Elevation of the activity of the adrenergic (e.g., epinephrine and norepinephrine) sympathetic system	Decreased body cell mass (BCM) and increased REE in patients

day, and 30–50% of fat covering the nonprotein calories (Nicolini et al. 2013). Although there is a component of malnutrition in cachexia patients, cachexia cannot be treated by nutrition alone (Konishi et al. 2016). In a systematic review evaluating dietary counseling given to cancer patients, the results showed no improvement in weight or energy balance in the different stages of cachexia (Balstad et al. 2014). This was reiterated in a meta-analysis of nutritional supplementation in COPD patients (Ferreira et al. 2000).

It is suggested that exercise (which can be classified as low-intensity balance training to high-intensity treadmill walking) may attenuate the effects of cancer cachexia via the modulation of muscle metabolism, insulin sensitivity and levels of inflammation. However, a Cochrane systematic review concluded that there was insufficient evidence to determine the safety and effectiveness in patients with cancer cachexia (Grande et al. 2015). Nevertheless, aerobic exercise training has been shown to counteract skeletal muscle wasting in patients with cardiac cachexia (Alves et al. 2015). However, it is envisaged that patients would need to exceed their dietary intake to counter the effects of anabolic resistance, and this could be difficult to achieve in already frail patients. For COPD patients, pulmonary rehabilitation is now a standard of care (Fearon et al. 2013).

2.8 Pharmacological Agents

For anorexia, corticosteroid use has strong evidence in patients with malignancies; however, a recent review could not recommend a corticosteroid or a dosing regimen. Methylprednisolone (125 mg iv) for 8 weeks showed promising results. On the contrary, corticosteroids have not demonstrated efficacy in end-stage nonmalignant disease (Miller et al. 2014). Corticosteroid resistance is reported in cachexia associated with COPD (Barnes and Celli 2009).

Megestrol acetate (MA) is approved in the USA for use in AIDS patients for weight gain and appetite stimulation (Ezeoke and Morley 2015). However, MA is associated with adverse effects, in particular, venous thromboembolism (Ruiz Garcia et al. 2013). Current evidence does not support the use of progesterone (viz., MA and medroxyprogesterone (Provera)) therapies for non-cancer cachexia in terms of weight gain. Its impact on symptoms such as appetite and HRQOL, however, is generally positive (Taylor and Pendleton 2016).

Synthetic delta-9-tetrahydrocannabinol (delta-9-THC) cannabinoid, dronabinol, sold as MARINOL®, has been approved by the FDA for AIDS-related anorexia and appetite loss (Food and Drug Administration 2004). However, trials for cancer anorexia have been inconclusive (Whiting et al. 2015).

Due to the multifactorial nature of cachexia, a variety of pharmacological agents have been trialed to alleviate inflammation, stimulate appetite and increase anabolic tone and decrease catabolic events (Anderson et al. 2017).

Table 4 outlines the pharmacological agents in their class category and their proposed mechanism of action on anorexia/cachexia. The latest literature on the pharmacological interventions and the findings has been summarized in Table 4. Note that much of the data published is from anorexia/cachexia in cancer patients.

Fish oil encompasses polyunsaturated fatty acids (PUFAs), omega-3-fatty acids, or *n*-3 fatty acids, namely, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Ries et al. 2012), and most products deal with EPA and DHA in combination. *n*-6 Fatty acids are also present, and the ratio between the *n*-3 and *n*-6 fatty acids needs to be kept as high as possible due to the pro-inflammatory nature of the *n*-6 fatty acids (Colomer et al. 2007). The authors acknowledged that certain cancers responded better to PUFAs, namely, the gastrointestinal and pancreatic cancers. The relatively short length of the studies may not reveal significant catabolic changes which take many months to restore, and higher doses may need to be considered (Mazzotta and Jeney 2009). In newly diagnosed patients with NSCLC, 2.2 g of fish oil per day stabilized weight and muscle mass compared to standard care (Murphy et al. 2011). The study highlights the importance of initiating supplementation from the onset

Table 4 Proposed pharmacological agents and their mechanism of action in anorexia/cachexia

Anti-inflammatory	Mechanism of action
Corticosteroids	Inhibition of synthesis and/or release of proinflammatory cytokines such as TNF and IL-1, which decrease food intake directly or through other anorexigenic mediators, such as leptin, CRF and serotonin 4 Enhance NPY levels in the hypothalamus, which may increase appetite and food intake. NPY-induced feeding is known to be dependent on circulating glucocorticoid levels (Inui 2002)
Progestins	Action on cytokines, and its inhibiting effect on TNF from acting on fatty cells and their products (López et al. 2004)
NSAIDS	Nonselective blockers of the cyclooxygenase pathway and inhibiting production of prostaglandins that cause inflammation and pain (COX-2 pathway). Block formation of thromboxane A2 (TXA2) in platelets preventing aggregation (Solheim et al. 2013)
Thalidomide	Shown to downregulate the production of TNF and other proinflammatory cytokines (Gordon et al. 2005)
Fish oil known as PUFAs/EPA/DHA/n-3-FA	Prostaglandin E2 synthesis and suppression of proinflammatory factors, such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) (Mazzotta and Jeney 2009)
Anabolic	
Ghrelin	Stimulates the synthesis of growth hormone and increases appetite through the production of neuropeptide Y (Mansson et al. 2016)
Anamorelin (ghrelin analogue)	Potent and selective GHSR-1α agonist (Temel et al. 2016)
Testosterone (and synthetic derivatives oxandrolone, nandrolone)	Increase muscle mass through upregulation of protein synthesis (through binding to the androgen receptor) and interaction with insulin regulatory system (Gullett et al. 2010)
SARMS, e.g., enobosarm	Induces conformational changes in the androgen receptor upon binding. This selectively alters the interaction of the receptor with proteins in different tissues and changes the receptor's ability to regulate gene expression (Dobs et al. 2013)
Antipsychotic	
Mirtazapine	Blockage of postsynaptic 5-HT1$_b$ and 5-HT$_2$ receptors with inhibition of release of neuropeptide Y, a brain peptide involved in appetite stimulation; blocks 5-HT$_3$ receptor (anti-nausea); blocks H$_1$ receptor; and alters serum levels cytokines (Riechelmann et al. 2010)
Olanzapine	5-HT$_3$ (anti-nausea) and 5-HT$_{2c}$ (may underlie appetite stimulation) receptor blockage (Braiteh et al. 2008)
Multimodal	
Cannabis/cannabinoids	Appetite stimulation via its action on the cannabinoid Type I receptors (CB1) in the hypothalamus, increasing the palatability of food via a complex biochemical cascade incorporating ghrelin, chime and digestive signaling hormones. Anti-inflammatory and antiemetic (Ezeoke and Morley 2015)
Espindolol	Reduced catabolism, through nonselective β receptor blockade; reduced fatigue and thermogenesis, through central 5-HT1$_a$ receptor antagonism; increased anabolism, through partial β2 receptor agonism (Stewart Coats et al. 2016)
Carvedilol	α1-/β1-/β2-receptor antagonist (Clark et al. 2017)

of first-line chemotherapy and continuing during treatment.

Along with the adverse effects below, ghrelin, a peptide of 28 amino acids, produced primarily in cells at the base of the stomach, had long-lasting effects such as altered liver function, headaches and bronchitis. In COPD patients, acute myocardial infarction and small intestine perforation were observed at 20 μg/kg of the synthetic ghrelin (Mansson et al. 2016).

In an earlier study, lower doses of olanzapine (up to 7.5 mg) stabilized or increased weight in 6 out of 14 patients with cancer, with improved appetite, Mini-Nutritional Assessment (MNA) and Karnofsky performance scores (Braiteh et al. 2008).

Testosterone and its derivatives such as oxandrolone have shown positive effects on body weight and LBM in HIV/AIDS and COPD cachectic patients (Gullett et al. 2010).

Although there are single studies that show positive results with vitamin, mineral and protein supplements, and rare adverse events, there was insufficient evidence to recommend their use in cancer cachexia (Cuhls et al. 2016) (Table 5).

2.8.1 Unproven Treatments

In cachectic patients with advanced cancer, oral melatonin (a hormone produced by the pineal gland that regulates sleep and wakefulness) 20 mg at night did not improve appetite, weight, or quality of life compared with placebo (Del Fabbro et al. 2013).

In a double-blind, randomized, placebo-controlled clinical trial, pentoxifylline (a TNF inhibitor) 400 mg, three times a day, did not have any effect in weight gain and arm circumference in cachectic patients. Although QoL was improved after 1-month treatment, 2-month treatment was not significantly different to placebo (Mehrzad et al. 2016).

Hydrazine sulfate, a TNF inhibitor, has shown limited evidence for its use in cachexia and anorexia (PDQ® Integrative 2017).

Cyproheptadine, a histamine antagonist with antiserotonergic properties, was shown to mildly enhance appetite but failed to negate weight loss in patients with advanced cancer (Kardinal et al. 1990).

Prokinetic drugs such as metoclopramide are used for gastroparesis and may relieve chronic nausea and early satiety which influence caloric intake. In particular, controlled-release metoclopramide (20–80 mg over 12 h) showed a 50% reduction in the severity of vomiting, with some improvement in appetite and bloating (Wilson et al. 2002).

2.8.2 Combinational Treatments/ Interventions

In cancer cachexia patients, a fish-oil-enriched supplement (2 g of EPA and 600 kcal daily) resulted in increased lean tissue mass and functional ability compared to relative weight stability produced by fish oil or EPA alone and no effect from nutritional supplementation alone (Barber 2001).

In a Phase II open-label study in pancreatic and lung cancer patients, a multimodal intervention consisting of exercise, anti-inflammatories and energy-dense nutritional supplements combined with dietary advice showed improved weight compared to standard cancer care (Kaasa et al. 2015). It has been noted that dietetics and exercise compliance is an issue in patients who are unfit and at an advanced stage of their cancer (Forget et al. 2014). Taken together, the results indicate that a multimodal treatment approach personalized to the patient should include early assessment of the symptoms and combines non-pharmacological (e.g., nutritional support, exercise) and pharmacological interventions (e.g., orexigenic, anabolic, anti-catabolic and anti-inflammatory) required to address the underlying pathophysiology (Zhang and Garcia 2015; Dev et al. 2017).

In a Phase III randomized study, the most effective treatment in terms of all three primary efficacy endpoints LBM, REE and fatigue, and the secondary endpoints appetite, IL-6, Glasgow Prognostic Score (GPS) and Eastern Cooperative Oncology Group performance status (ECOG PS) score was the combination regimen that included medroxyprogesterone (500 mg/day) or megestrol acetate (320 mg/day); oral supplementation with eicosapentaenoic acid; L-carnitine (4 g/day); and thalidomide (200 mg/day) agents (Mantovani et al. 2010).

3 Feeding Difficulties

Dysphagia (swallowing difficulty) can be caused by many conditions which alter the normal function of the mouth, pharynx, larynx and esophagus. It can be associated with painful swallowing, known as odynophagia. Dysphagia is classified from an anatomical point of view as either oropharyngeal and esophageal, or by pathophysiology (structural or physiological) (Clavé and Shaker 2015). Oropharyngeal dysphagia occurs when there is difficulty or inability to form or

Table 5 Summary of literature of pharmacological agents examined for anorexia and cachexia in chronic disease

Drug	Disease	Dose	Adverse effects	Outcome
Methylprednisolone dexamethasone Betamethasone (Miller et al. 2014) *R*	Anorexia	Orally, iv (with dexamethasone equivalent doses ranging from 3 to 25 mg per day)	Hyperglycemia and gastrointestinal bleeding Higher doses may contribute to increased side effects	All studies showed improvement in appetite with the corticosteroid used, however not always statistically significant
Megestrol acetate (MA) (Ruiz Garcia et al. 2013) *R*	Cancer cachexia, anorexia Approved for AIDS	Varying doses: 100–1600 mg	Impotence in men, edema of the lower limbs, deep vein thrombosis, gastrointestinal Intolerance, death	Improves appetite and is associated with slight weight gain in cancer, AIDS, and in patients with other underlying pathology. Higher doses more related to weight improvement than lower doses
Indomethacin (I), celecoxib (C) (Solheim et al. 2013) *R*	Cancer cachexia	I: 400 mg 3 × daily; C: 200 mg × 2	None, although known side effects include gastrointestinal ulcers/ hemorrhage and cardiac events at higher NSAID dosage	Improved weight, physical performance, self-reported quality of life and inflammatory parameters. Evidence is too frail to recommend NSAID for cachexia outside clinical trials
Thalidomide (Gordon et al. 2005)	Pancreatic cancer cachexia	200 mg	Peripheral neuropathy, rash, daytime somnolence, constipation	Improvement in physical functioning correlated positively with weight gain
PUFAs (Mazzotta and Jeney 2009) *R*	Anorexia-cachexia Cancer	EPA: 170 mg–4.9 g DHA: 115 mg–3.2 g	None	No dose-response effect of EPA and DHA on weight, lean muscle mass, symptoms, QoL, or survival
Fish oil (Ries et al. 2012) *R*	Cancer cachexia	12 g per day tolerated	Abdominal discomfort, fish belching, fish aftertaste, nausea and diarrhea	Likely that the anti-inflammatory effects of n-3 FA are not effective in refractory cachexia
Ghrelin (Mansson et al. 2016) *R*	Cancer, heart failure, COPD cachexia	Variable: 2, 8, 13 μg/kg/ day iv	Stomach rumble (borborygmus), body heat, somnolence, thirst, nausea constipation; hematoma at the site of administration, increased frequency of evacuations, fatigue, atrial fibrillation	Positive effect on growth hormone plasma levels, weight gain, increases in lean mass, and reductions in loss of adipose tissue

Anamorelin (ghrelin analogue) (Temel et al. 2016)	NSCLC Cachexia/anorexia	100 mg	Hyperglycemia (up to 1%) as grade 3–4	Increased LBM, but not handgrip strength; improvements in symptoms such as appetite and food intake
Oxandrolone (Orr and Singh 2004) *R*	HIV-AIDS, COPD	Up to 200 mg/day	Hepatic dysfunction. Take note of virilizing effects and cholesterol changes	Improvements in body composition, muscle strength and function, status of underlying disease or recovery from acute catabolic injury and nutritional status
Enobosarm (Dobs et al. 2013) *R*	NSCLC, colorectal, non-Hodgkin's lymphoma, chronic lymphocytic leukemia, or breast cancer cachexia	1 and 3 mg	Generally same between groups	Improved LBM, physical function, and QoL
Mirtazapine (Riechelmann et al. 2010)	Cancer cachexia/anorexia	15–30 mg po/day	Moderate confusion, dizziness and blurred vision, mild dry mouth and drowsiness	24% improved appetite and gained 1 kg or more; 6% health-related QoL
Olanzapine (Naing et al. 2015) *R*	Cancer cachexia/anorexia	2.5–20 mg po/day	Somnolence, pancreatitis, extrapyramidal symptoms, nausea/vomiting (all grade 2)	Changes in metabolic cytokines and body weight did not correlate. Trend toward attenuation of weight loss (not statistically significant)
Cannabis/cannabinoids (Lutge et al. 2013) *R*	HIV Anorexia	2.5–20 mg/day	Concentration difficulties, fatigue, sleepiness, or sedation, mood-altering effects, reduced salivation, and thirst	Stabilization or increase in weight
Espindolol (Stewart Coats et al. 2016)	NSCLC or colorectal cancer cachexia	10 mg × 2 daily	Treatment emergent (>10% of patients): anemia, cough, dyspnea	Significantly reversed weight loss, improved fat-free mass, and maintained fat mass
Carvedilol (Clark et al. 2017)	Cardiac Cachexia	3.125–25 mg × 2 daily	None reported	Prevented weight loss; promoted weight gain

COPD chronic obstructive pulmonary disease, *DHA* docosahexaenoic acid, *EPA* eicosapentaenoic acid, *FA* fatty acids, *NSAID* nonsteroidal anti-inflammatory drugs, *iv* intravenous, *LBM* lean body mass, *NSCLC* non- small cell lung cancer, *po* by mouth, *PUFAs* polyunsaturated fatty acids, *QoL* quality of life, *R* review

move a food bolus safely from the mouth to the esophagus, whereas esophageal dysphagia is where the food bolus fails to pass through the esophagus.

Oropharyngeal dysphagia can be associated with regurgitation, coughing, oropharyngeal aspiration (entry of food and liquids or secretions into trachea or lungs) and choking (Clavé and Shaker 2015). Esophageal dysphagia can be associated with regurgitation and odynophagia, but respiratory symptoms are less common unless advanced or untreated (Clavé and Shaker 2015).

3.1 Epidemiology

Dysphagia is common in people with head and neck diseases and neurological or neurodegenerative diseases and older people (Clavé and Shaker 2015). Oropharyngeal dysphagia is reported in up to 40% of older people, due to neural and muscular changes characteristic of aging, which is then compounded by multi-morbidity, medications and frailty (Clavé and Shaker 2015). High prevalence rates in dementia of 80–100% and Parkinson's disease of 60–80% also are reported, in particular, in advanced disease (Clavé and Shaker 2015).

The prevalence of dysphagia in head and neck cancers pretreatment has been reported to be 28% in patients with stage T2 or more oral cancer, 51% in pharyngeal cancer and 28% in laryngeal cancer (Clavé and Shaker 2015; Raber-Durlacher et al. 2012). Prevalence varies depending on tumor stage and site, which impact differently on motility or structures involved in swallowing (Raber-Durlacher et al. 2012). Acute dysphagia is common in patients receiving concurrent chemoradiation or radiotherapy to the chest region, with rates of 20–40% seen (Raber-Durlacher et al. 2012).

3.2 Etiology

Swallowing is a complex biomechanical and physiological process by which food and drink passes and is cleared through the oral cavity, pharynx and esophagus to the stomach at an appropriate rate (Clavé and Shaker 2015; Raber-Durlacher et al. 2012). The oral phases of swallowing are voluntary, followed by a highly coordinated involuntary reflex controlled by the medulla and cerebral cortex, involving 6 cranial nerves and over 25 muscles (Fig. 2). The process of swallowing is altered to cater for different volumes and viscosity of the food bolus (Raber-Durlacher et al. 2012).

Causes (Clavé and Shaker 2015; Raber-Durlacher et al. 2012; Cook 2009) include:

- Structural – malignancy (esophageal, gastric, thyroid, mediastinal, larynx, pharynx, oral cavity)
- Neurological – cerebrovascular disease, brain tumors, Parkinson's disease, dementia
- Poor dentition
- Medications which reduce saliva (opioids, tricyclic antidepressants, atropine, hyoscine)
- Radiotherapy to the head and neck, mediastinum, or lung
- Surgical procedures to the head and neck
- Acute and chronic graft-versus-host disease
- Mucositis

3.3 Approach to Assessment

An assessment of swallowing includes clinical evaluation, swallow trials and, in some cases, instrumental evaluation (Raber-Durlacher et al. 2012). On history, key symptoms include difficulty swallowing liquids or solids, food getting stuck, coughing, choking, regurgitation, avoidance of particular food consistencies and poor oral intake. The possible causes of dysphagia should be considered in the past medical history.

Examination requires inspection of the oral cavity for dental status, dryness, mucositis and other abnormalities; strength, motion, symmetry of the tongue, lips, cheeks and soft palate; and evidence of aspiration pneumonia on chest examination. The level of consciousness and neurological examination are also crucial. There may be also dysarthria (motor speech disorder) and dysphonia (inability to produce a voice) present (Raber-Durlacher et al. 2012).

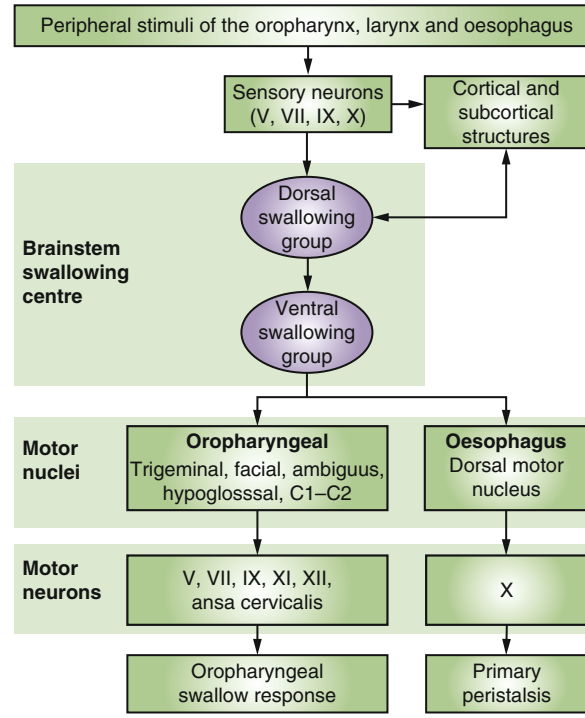

Fig. 2 Oropharyngeal swallow response and primary peristalsis (Clavé and Shaker 2015 - reproduced with permission)

An observed swallowing test may also be conducted if deemed safe, and one may try various food and fluid consistencies. Videofluoroscopy, to allow radiographic assessment of the dynamics of swallowing, may be required for objective assessment (barium or gastrografin) (Raber-Durlacher et al. 2012). Endoscopy may offer visualization of the pharynx, larynx, or esophagus (Raber-Durlacher et al. 2012). A chest radiograph may be required if aspiration pneumonia is suspected.

3.4 Approach to Management

The management of dysphagia aims to ensure adequate nutrition and hydration, maximize swallowing function, minimize risk of aspiration, and maintain the enjoyment associated with eating and drinking a range of foods and fluid. A multidisciplinary approach is needed, and input may be required from speech and language pathologists, ear nose and throat specialists, radiologists, neurologists, gastroenterologists, dieticians and geriatricians (Clavé and Shaker 2015).

Recommendations may include increasing chewing of food and number of swallows for each food bolus. A modified diet may be required, which includes soft or pureed foods and thickened fluids. This risk of aspiration and poor nutrition needs to be balanced carefully with the goals of care and impact of modified diet on quality of life, and shared decision making with the patient and their caregiver is critical. Some patients may choose to accept a risk of aspiration, for the quality of life associated with being able to eat normal food. Strategies can be used to increase the safety of swallowing, such as advice related to position, eating when fully alert, and moving food bolus to the stronger side of the mouth in case of tongue unilateral paralysis. Oral hygiene is important, and so is ensuring appropriate fit of dentures to allow adequate chewing. It is also important to consider transdermal and subcutaneous routes for essential medications, if difficulty in swallowing medications is occurring (Mercadante 2017).

In most cases, oral-assisted comfort feeding, where patients are offered food by mouth, is appropriate (Lembeck et al. 2016). Enteral feeding should be considered in the context of the

progression of the underlying disease and evidence-based nutritional support to improve nutritional or functional status in that clinical situation, goals of care of the patient, and reversibility of the swallowing problem. Enteral feeding does not reduce the risk of aspiration pneumonia. Nasogastric tubes can cause bleeding, trauma, nasal discomfort, esophageal perforation, and aspiration and can be displaced. In longer-term situations, a percutaneous gastrostomy tube may be appropriate, which, in most cases, can be inserted endoscopically. Complications include bleeding, skin infections, peritonitis and tube leakage. When discussion and recommendation is to avoid enteral feeding, it is important that careful communication about the quality of life associated with comfort feeding and the adverse effects that are being avoided is relayed. Attention is required to understand the cultural, social and individual meaning that appetite loss and dysphagia play.

Local interventions may be appropriate for esophageal strictures and malignant obstruction, including dilatation, endoscopic ablation, stent placement and radiotherapy (Glen 2016). In esophageal cancer, radiotherapy can be given in a single dose or a short-fractioned course over 1–2 weeks, and there is increasing evidence that brachytherapy may give better palliation than stenting (Glen 2016). Laser ablation can be helpful if there is concurrent bleeding (Glen 2016). Self-expanding metal stents can provide good palliation within a single procedure that can be tolerated in very unwell patients, but are less suited for high esophageal tumors (Glen 2016). Fully or partially covered stents are the ideal in palliation as they have patency advantages due to the metal preventing ingrowth (Glen 2016). The complications of stent placement can include esophageal bleeding, stent migration, stent obstruction, pain and gastroesophageal reflux (especially in low or junctional cancers). After stent placement, approximately two-thirds of patients can return to a normal diet. Re-intervention may be needed for migrated partially or fully covered stent or tumor regrowth (Glen 2016).

Proton pump inhibitors and prokinetic medications (such as metoclopramide) for concurrent gastroesophageal reflux can also be helpful.

4 Conclusion and Summary

Anorexia, cachexia and dysphagia are all multifactorial conditions correlated to poor outcomes and quality of life which require careful assessment. Along with defective appetite signaling characteristic in anorexia, both anorexia and cachexia encompass a complex pathophysiology that includes inflammation, anabolism and changes in hormonal status. In addition, appetite (encompassing taste and smell), feeding and swallowing difficulties (resulting in decreased oral nutritional intake), gastrointestinal support (e.g., nausea, decreased motility of food, early satiety), physical exercise, pain, current treatment (chemotherapy, radiotherapy, surgery) and psychosocial and psychological assessment will need to be considered in patients with cachexia. A multimodal treatment plan which includes early and routine screening, nutritional support, targeted pharmacological treatment counteracting the mechanisms of the disease (if possible, concurrently with cancer treatment) and appetite stimulation needs to be personalized for the patient. Furthermore, caregivers need to be included in the conversation to provide better understanding and support to the patient. More data is required for anorexia, cachexia and dysphagia in non-cancer chronic diseases.

Swallowing Difficulties

18

Prudence Ellis and Jacqui Allen

Contents

Abstract

In the many considerations that arise during end-of-life care, swallowing problems are common and may have a disproportionately large impact on the patient and family. Inability to eat safely or tolerate diet results in nutritional challenges, difficulty maintaining physiological reserve and resilience, and isolation from social activities. The latter may in fact be the most troubling aspect for those wishing to optimize remaining precious time, given that most social interactions are based on meals and deglutition. A clinician providing care and support in a palliative care setting must recognize the risk of swallowing impairment and should actively query the presence and degree of problems encountered.

Many interventions and strategies are available to mitigate swallowing difficulties and are best managed in a team setting with input and

feedback from all team members in conjunction with the patient. This chapter will cover key aspects of deglutition, how it may be altered in unwell patients, and available interventions that may be appropriate for those receiving palliative care.

1 Introduction

Humans are social animals and nearly all our social situations revolve around conversation and food. This presents a real problem when you have swallowing difficulties when it can be embarrassing, unsafe, or anxiety-provoking to consider a meal with friends and family. When patients face limited time, these situations become even more acute, and quality of life (particularly with eating and drinking) is of paramount consideration.

Problems with swallowing can develop for many reasons in patients nearing the end of life. These include the direct effect of the illness, effects of treatment or management, cognitive issues, medication effects, deconditioning and fatigue, change in taste, loss of saliva, mood disorders, and inanition. The clinician should be particularly cognizant of deglutitive changes and inquire about these directly as they often impact quality of life and, in many cases, there are options to ameliorate symptoms. Managing swallowing problems is a multidisciplinary challenge. Teamwork can be the critical factor in preventing life-threatening complications and long-term morbidities and in offering support and timely intervention. Regular and clear communication between team members and the patient can relieve anxiety, provide education, and optimize function.

In this chapter, we will review the importance and impact of deglutition and swallowing dysfunction in the environment of palliative care. This will provide a practical platform for clinicians who care for those receiving palliative care which includes anticipating possible problems, recognizing symptoms and signs of swallowing disorders, and identifying management strategies and options.

2 Swallowing

Swallowing is a complex process requiring a series of muscles to work in synchronicity to perform a relatively short movement. Some movements are voluntary, and others reflexive, but they are codependent (Logemann 1998).

2.1 The Normal Swallow

It should first be noted that the "normal" swallow shows great variability among healthy individuals. Deglutition involves 30 muscle pairs, 5 cranial nerves and accessory nerves, coordinating with cortical, subcortical, and medullary respiratory centers and the swallow central pattern generator (Shaw and Martino 2013). The complexity of deglutition and its need to coordinate precisely with respiration results in a series of protective airway reflexes and responses. Disordered deglutition is an airway risk and may result in significant morbidity and mortality. Understanding neurologic control points enables better management of patients with swallowing problems. A summary of cranial nerve function involved with swallowing is provided below. Deglutition has been arbitrarily divided into phases. However, in reality, it is a continuous process, and many aspects occur simultaneously within a predetermined sequence. Recent research indicates the interdependent aspects of deglutition should be treated as a continuum, rather than in separate phases. Nonetheless, historically swallowing has been divided into four phases (oral preparatory, oral, pharyngeal, and esophageal).

Assessment of all aspects is required to understand swallowing ability and dietary/nutrition risk.

The swallow begins with a person being alert and able to sense food. It is common practice to include both the oral preparatory phase and oral phase under a single heading in an assessment, namely, the oral phase. This is considered the voluntary stage/s of the swallow where bolus may be voluntarily ejected from the oral cavity.

Food is placed in the mouth and the lips are closed to prevent anterior spillage. The food or

fluid in the mouth is then masticated (chewed) and mixed with saliva to create a cohesive bolus. The bolus is held between the tongue and the anterior hard palate. Mastication is in a lateral rotary movement, and the tongue manipulates the bolus to the back of the mouth. The bolus is held in place by contraction of the soft palate against the base of the tongue and contraction of the buccal muscles. Dentition influences deglutition by contribution to bolus breakdown, allowing salivary enzymes to begin digestion, tastants to be sensed, airway closure to begin, and lubrication to be provided to form a cohesive bolus.

The tongue begins to move the bolus toward the back of the mouth, against the hard palate. Negative pressure is created by muscle contraction, and the bolus moves toward the faucial pillars.

Innervation is predominantly via the trigeminal nerve (CNV), the facial nerve (CNVII), and the hypoglossal nerve (CNXII). The vagus nerve (CNX) innervates the palatoglossus muscle. CNVII innervates the muscles of the face, while CNV innervates those muscles used to chew, elevate, and lateralize the mandible. The intrinsic and extrinsic muscles of the tongue are innervated by CNXII (other than the palatoglossus). Finally, the soft palate is innervated by CNV and CNX (Drake et al. 2010; Moore 2010). Sensation is provided by the lingual nerve (a branch of CNV) and the glossopharyngeal nerve (CNIX) with special taste senses provided by the chorda tympani (branch of CNVII, hitchhiking with the lingual nerve) and CNIX. Sensation of the valleculae is via CNX, superior laryngeal nerve. This nerve is critical in guarding the larynx and mediating laryngeal closure and airway protection when bolus or secretions are identified.

The swallowing reflex is initiated as the bolus passes the faucial arches triggering the pharyngeal phase of the swallow, which is stereotyped, involuntary, and centrally coordinated. Total pharyngeal transit time in adults is usually less than 1.5 s and must encompass airway closure, laryngeal elevation, pharyngeal peristalsis, and pharyngoesophageal segment (PES) opening. This requires coordination with the respiratory system.

The soft palate retracts to close the velopharyngeal port. The bolus passes over the base of the tongue, which retracts toward the posterior pharyngeal wall. The pharyngeal muscles create peristaltic waves traveling at approximately 15 m/s, which carry the bolus through the pharynx. Simultaneously, the epiglottis deflects the bolus laterally to protect the laryngeal vestibule and retroverts which smoothes the valleculae. The aryepiglottic folds, false and true vocal folds all contract to achieve airway closure and prevent penetration and aspiration. The hyoid moves anterosuperiorly (approximately the distance of one vertebra) which acts as a drawstring to assist in distension of the upper esophageal sphincter (UES). Cessation of tonic UES contraction occurs within 0.3 s after suprahyoid muscular contraction starts to ensure an open sphincter when the bolus arrives. Bolus size influences duration of hyolaryngeal elevation and airway closure duration, with larger volumes resulting in greater opening duration and displacement.

The vagus nerve transmits pharyngeal sensory information via pharyngeal and superior laryngeal branches and is the key mediator of the airway closure reflex (adductor reflex). Afferent information converges at the nucleus tractus solitarius (NTS) of the medulla and then travels through interneurons to the nucleus ambiguous (NA) which produces efferent (motor) output. Motor signals return to the pharynx via vagal branches (pharyngeal plexus and recurrent laryngeal nerve), with additional input from the dorsal motor nucleus (DMN) of the vagus (inhibitory). The DMN input likely prevents mis-sequencing. Vagal outflow also initiates airway protective mechanisms, and accessory nerve and C1 and C2 nerves produce hyoid elevation (Drake et al. 2010; Moore 2010).

Relaxation of the upper esophageal sphincter occurs and lasts less than 1 s. In reality this is a cessation of tonic contraction, rather than an active relaxation (Allen 2016; Miles et al. 2016). The UES then contracts to protect the pharynx from regurgitated material and to limit air swallowing. The bolus is carried via esophageal peristalsis (circular and longitudinal muscle contractions) to the lower esophageal sphincter (LES)

(Shaw and Martino 2013). Once the LES has relaxed, the bolus moves into the stomach. The process of transportation through the esophagus takes from 8 to 20 s for liquid but may be as long as 60 s for pills or solids (Logemann 1998; Miles et al. 2015, 2016).

CNX mediates UES function allowing bolus into the esophagus during deglutition (Drake et al. 2010; Moore 2010). Esophageal peristalsis is under vagal and myenteric control through the NA and DMN of the vagus combined with sympathetic and parasympathetic neural networks. Differential latencies and a pool of inhibitory vagal neurons enable a sequential waveform to occur from proximal to distal within the esophagus.

2.2 The Disordered Swallow

The "normal" swallow demonstrates variability which, at times, can be difficult to differentiate from disordered deglutition. Physical trauma, tumors, neuromuscular conditions, surgery, medicines, and aging all contribute to changes in a swallow.

2.2.1 Common Features of Swallowing Dysfunction

Change to the musculature or innervation of the swallow may result in disordered deglutition. Ultimately, the purpose of a swallow is to pass food and fluids from the mouth to the stomach via the pharynx and esophagus. Given the interdependence of the swallow phases, it follows that disruption to any stage may result in dysphagia (swallowing problems) (Table 1).

Altered oral sensation may yield anterior spillage of a bolus, incomplete mastication, oral incompetence, and delayed initiation of a swallow (if a swallow is initiated at all). Problems with lateralization of the jaw, or rotary mastication, or damaged dentition may give rise to an incompletely masticated or two-phase/piecemeal bolus, which poses a risk of aspiration. A cohesive bolus is required for safe transportation throughout a swallow, as a piecemeal bolus heightens the risk of pooling, residue, and material breaking away into the laryngeal vestibule. A two-phase bolus may compromise airway closure mechanisms due to differential bolus velocities and therefore confusion over appropriate airway closure duration.

Table 1 Common contributors to swallow impairment

Contributor	Effect	Complaint
Mass or tumor	Deflect bolus incorrectly Obstruct deglutitive pathway Neural compromise – sensory and motor Pain – reduced effort and mobility of pharynx Loss of airway protection	Solid and liquid dysphagia Pill dysphagia Lump in the throat Cough Loss of appetite Choking
Dryness (xerostomia, xerophagia)	Mucosal irritation (abrasion) Thick mucus Reflux Impaired bolus cohesion and transit	Pain Cough and hawking Acid or bile taste, burning pharynx/chest pain Food sticking or spitting out food
Medications	Dryness Drowsiness Loss of appetite Constipation	Solid food dysphagia Loss of appetite Weight loss Early satiety
Cognitive issues	Reduced urge to eat Depression – loss of appetite Fear of choking	Weight loss Low mood No interest in food
Deconditioning	Loss of muscle tone and strength Loss of compensatory reserve	Solid and liquid dysphagia Weight loss Fatigue Reduced volume of food intake

Saliva is critical in mastication, helping to achieve a cohesive bolus, providing lubrication, initiating digestion, enabling tastant dissolution, mechanically flushing the oral cavity, and protecting dentition and mucosal lining. One need only see a patient following radiotherapy with xerostomia and its significant impact on oral bolus control and dental health to appreciate the benefit of saliva.

If oral incompetence is present, bolus transit may be affected, either with anterior loss (i.e., from the lips) causing skin irritation and embarrassment or inappropriate posterior spillage into the pharynx with potential for airway soiling. Velopharyngeal incompetence will also affect oral transit, as the bolus may escape North into the nasopharynx. Loss of the stable velopharyngeal diaphragm impairs pressure generation and ability to provide impetus to the bolus in the oropharynx. Residue may be observed in the valleculae or tongue-base regions or pyriform apices and intra-deglutitive or post-deglutitive aspiration of residue may occur.

From the time that bolus contacts the tongue dorsum, airway closure begins. Once the bolus reaches the posterior third of the tongue, the involuntary swallow is triggered. A coordinated sequence of events occurs. This begins with three-level airway closure, hyolaryngeal elevation and consequent epiglottic retroversion, and pharyngeal constrictor peristalsis. Cessation of upper esophageal sphincter contraction enables distraction of the UES and generation of negative pressure in the pharyngoesophageal segment which combine to effect bolus transit. This all occurs in approximately 1.5 s, and even slight mismatching of event timing may have significant ramifications. Consequences include misdirection of bolus +/− airway violation, incomplete bolus transit with residue which may then be aspirated, and anatomic changes such as development of a diverticulum. Poor sensation due to neurological disease, surgical distortion, and post-radiotherapy damage or injury will prevent the SLN from identifying incoming bolus in a timely fashion. Airway closure may then be late or absent and aspiration may occur. Loss of strength in pharyngeal musculature reduces impetus of the bolus and means it must rely on gravity and tongue pumping to coincide with UES opening and allow bolus flow. Anterosuperior hyoid elevation and cessation of tonic UES contraction result in a distracting effect, opening the UES. If hyolaryngeal elevation is present, this may be enough to permit bolus transit, but if there is poor elevation or mistiming of bolus arrival at the UES, then penetration and aspiration will ensue. At times only part of the bolus may traverse the UES leaving bolus remnants in the pyriform fossae. Given that the larynx descends post-deglutition and protective airway constriction relaxes, this can expose the airway to misdirected bolus. Surgical tethering of tissue and radiation fibrosis often limit hyolaryngeal elevation. Stroke or progressive neurologic disease frequently impairs pharyngeal strength and results in reduced UES opening duration and diameter.

If material enters the laryngeal vestibule, then penetration has occurred. When material passes the vocal folds into the airway, aspiration has occurred. Either incident may be associated with a response to eject the material, and in many cases bolus penetration is simply cleared during the swallow by the closure of the airway "squeezing" bolus out of the larynx. If there is no response, then aspiration is deemed "silent." This presents the greatest risk as bolus may remain lodged in the lower airways and produce pneumonitis, lung abscess, pneumonia, or death.

UES constriction persists after bolus passage to ensure no retrograde movement of the bolus into the pharynx (esophagopharyngeal reflux, EPR). Poor peristaltic wave in the esophagus may impair bolus transport and risk reflux of the material into the pharynx. This may prompt compensatory UES hyperfunction as a protective mechanism to prevent pharyngeal transgression. In some patients this is felt and described as a lump on the throat or globus sensation. If mechanical obstruction is present in the esophagus (e.g., unfolded or stiff aorta; peptic, malignant, or caustic stricture; Schatzki's rings; or external compression), bolus may also be impeded at that site.

Assessment of esophageal function may be performed by various individuals and varies between centers. For example, in Australia, it is

formally the domain of the gastroenterologist. However, in New Zealand, otolaryngologists, gastroenterologists, radiologists, and speech pathologists may assess and comment on the esophageal phase of swallowing.

Aspiration and Penetration

Aspiration and penetration describe entry of bolus material into the larynx. Penetration occurs when bolus crosses the plane of entry of the laryngeal vestibule (a line following the aryepiglottic folds to the epiglottic tip), and aspiration when the bolus passes beneath the vocal folds. A response may occur in either situation, e.g., a cough to clear; however, if a response is lacking, then silent aspiration has occurred. This is a major risk factor for pulmonary problems as bolus remains within the lower airways. Rosenbek and colleagues described the penetration-aspiration scale (Rosenbek et al. 1996) which categorizes the degree of airway violation and whether a response is seen (Table 2). This is one of many forms of categorizing severity of penetration and aspiration.

A major goal of dysphagia management is to prevent adverse consequences of aspiration, namely, fever, decreased oxygen saturation, chest infections, aspiration pneumonia, decreased quality of life, increased length of stay, and death. It is also important to note the additional financial burden that dysphagia imparts on the healthcare system. Although no data is available for palliative care, international data estimates that the cost of dysphagia per person, within 1 year of ischemic stroke, is $4510 more than those without dysphagia (Bonilha et al. 2014). Additionally, Sutherland, Hamm, and Hatcher (2010) estimated the mean cost of treatment for a person with aspiration pneumonia to be $17,000. Although these figures do not dictate the management of a person with dysphagia, it is an important administrative fact in advocacy for early dysphagia management.

Table 2 Penetration-aspiration scale[a]

Score	Description of events
1	Material does not enter the airway
2	Material enters the airway, remains above the vocal folds, and is ejected from the airway
3	Material enters the airway, remains above the vocal folds, and is not ejected from the airway
4	Material enters the airway, contacts the vocal folds, and is ejected from the airway
5	Material enters the airway, contacts the vocal folds, and is not ejected from the airway
6	Material enters the airway, passes below the vocal folds, and is ejected into the larynx or out of the airway
7	Material enters the airway, passes below the vocal folds, and is not ejected from the trachea despite effort
8.	Material enters the airway, passes below the vocal folds, and no effort is made to eject

[a]Rosenbek et al. (1996)

2.3 Swallow Dysfunction in Selected Conditions

Although aging alters swallow physiology, many older adults maintain functional swallows well into their tenth decades. Certain high-risk illnesses are associated with increased swallowing problems, and management is determined by the underlying causes, patient factors, and resources. Some of these conditions are discussed in the following sections.

2.3.1 Head and Neck Cancer

Representing around 5% of all cancers in Australasia, head and neck cancer is most commonly squamous cell carcinoma (HNSCC) arising from the epithelial lining of the upper aerodigestive tract. There is also a contribution from skin-related carcinoma which may involve deeper structures and thyroid carcinoma which is intimately related to the recurrent laryngeal nerve putting the voice and swallow safety at risk. Risk factors for head and neck cancer include male gender, age >60 years, smoking, alcohol intake (and a combination of the two), and human papilloma virus (HPV) infection. Subsites within the head and neck vary as to which causative factor is most commonly responsible; e.g., oropharyngeal carcinoma is associated with HPV infection in >80% of cases now (Gillison et al. 2015). There is variation in treatments of sites, responses to treatment, and subsequent

functional deficits that follow treatment. This is seen most starkly in the differential treatment response of HPV-positive carcinoma of the head and neck vs non-HPV positive carcinoma. In the last decade, HPV has been identified as a major contributor to disease in younger, nonsmoking, nondrinking individuals. The upside to this early onset disease is that it is typically far more responsive to treatment and demonstrates a greater cure rate. This has now led to trials in which therapy is being de-escalated to evaluate whether oncologic control can be achieved with a lower treatment burden. The aim is to reduce treatment-related morbidity such as dysphagia, voice change, osteoradionecrosis, and secondary malignancy (Mirghani et al. 2015; Masterson et al. 2014).

Malignancy at any subsite of the head and neck affects deglutition. Oral cavity lesions create pain on tongue motion; affect sensation, taste, and oral competence; and disturb mastication. Oropharyngeal malignancy may be obstructive and painful and reduce superior laryngeal nerve sensation leading to increased risk of aspiration. Hypopharyngeal tumors often result in obstruction of the pyriform apex or PES and may reduce vocal fold mobility compromising airway protection. Laryngeal cancer impairs airway protection reflexes and cough efficiency. Dysphonia is often an early sign in glottic-level tumors (Figs. 1 and 2) but may not be seen in supraglottic malignancy until advanced disease is present.

Most importantly in head and neck cancer patients, the treatment is also highly likely to impair both deglutition and phonation. Whether the treatment is surgical resection, radiation/chemoradiation, or a combination of surgery and postoperative radiotherapy, vital structures will be in the "line of fire" at all times. Achieving cure of the cancer does not guarantee a functional swallow or voice. In many patients, swallowing parameters deteriorate in the 5 years following completion of treatment for HNSCC regardless of cancer eradication. Radiation-induced xerostomia and osteoradionecrosis are unique complications seen only following HNSCC treatment, not from the tumor itself. Xerostomia exposes dentition to increased risk of caries, periodontal disease, and tooth loss, further impairing oral bolus control and mastication. Radiation may also induce trismus such that mouth opening is grossly reduced and fitting food or a toothbrush into the oral cavity can be difficult. Resection of tongue or pharyngeal tissue may create sumps, insensate regions, and poor mobility even if reconstruction occurs.

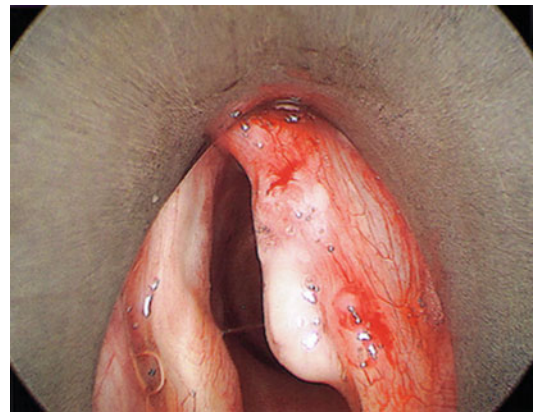

Fig. 1 Endoscopic clinical photograph of right vocal fold squamous cell carcinoma

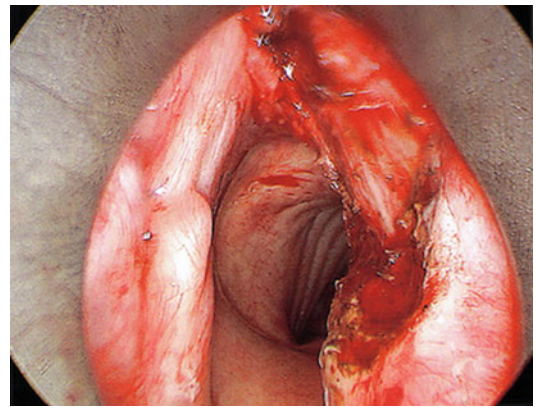

Fig. 2 Endoscopic clinical photograph of right vocal fold post-resection of squamous cell carcinoma

2.3.2 Neuromuscular Diseases

Conditions that affect cortical control, brainstem coordination, peripheral neural pathways, or the neuromuscular junctions of the muscles of the swallow yield changes in deglutition. This increases the risk of penetration and aspiration.

Motor Neurone Disease

As deterioration of the upper and lower motor neurons occur, the response of the muscles to stimuli decreases. This can affect all muscles relating to the swallow. It may present as difficulty initiating a swallow, reduced hyoid elevation, poor epiglottic deflection, and incomplete relaxation of the UES. This might also affect the peristaltic wave, and therefore a person may show difficulty with solid consistencies earlier than liquid consistencies. As noted by Langmore, Grillone, Elackattu, and Walsh (2009), "virtually all patients experience swallowing problems at some point in the disease if they live long enough." Prevalence of dysphagia is estimated at 81% at the time of death (Hardiman 2000).

Cerebrovascular Accident

Both cortical cerebrovascular accidents (CVAs) and brainstem strokes will affect swallowing. Dysphagia is present in 27–30% of persons with traumatic brain injury, and from 8.1 to 80% of those with acquired brain injury, with an average of 50% for those with stroke (Langdon et al. 2007; Takizawa et al. 2016; Ramsey et al. 2003). Presentation of dysphagia in these cohorts varies, with symptoms in stroke relating to the area of lesion. Presentation in those with TBI or executive function impairment includes nonmechanical symptoms of dysphagia, for example, overfilling the mouth and drinking/eating too quickly or slowly. A large proportion will improve spontaneously but this may be over months. Brainstem lesions tend to fair worse as it is more likely that cranial nerves IX–XII will be affected creating a combined swallowing insult. Both impaired motor (poor hyolaryngeal elevation, weak pharyngeal constriction, incomplete airway closure, uncoordinated pharyngoesophageal segment function) and sensory (inability to feel bolus and trigger airway protection and patterned swallow phases) function is found. Screening of all individuals presenting with CVA is vital. Many screening tools have been proposed including bedside assessments and questionnaires. Unfortunately, these tools will miss a significant proportion of impaired swallowers – those with silent aspiration. Instrumental assessment is the most reliable way to assess swallow safety but requires additional resources and time and is not always appropriate in the palliative care setting. Disordered deglutition post stroke is associated with worse outcomes, longer hospital stay, increased likelihood of readmission, and pneumonia within the first 3 months (Ramsey et al. 2003). Early rehabilitation can greatly enhance swallow recovery and protect against complications.

Parkinson's Disease

Parkinson's disease may affect both the motor and non-motor aspects of the swallow. It is noted that dysphagia occurs in a high proportion of people with Parkinson's disease. This figure ranges from 33% (based on subjective bedside assessments) to 80% (based on objective assessments) (Kalf et al. 2012). Dysphagia in Parkinson's disease is more prevalent in males; however, it is also linked with the duration of the disease and the presence of dementia (Cereda et al. 2014). As with other cohorts, dysphagia may be evident with reduced efficiency of mastication, poor base-of-tongue contraction, poor hyoid elevation, and pharyngeal residue, all of which pose a risk of penetration and aspiration.

It should be particularly noted that only a small proportion of people with dysphagia and Parkinson's disease are able to identify symptoms of swallowing problems. This figure is estimated to be between 20 and 40% upon questioning and only 10% reporting dysphagia spontaneously (Bird et al. 1994; Suttrup and Warnecke 2016). This is significant, as pneumonia is the most common cause of death in the population of people with Parkinson's disease (Morgante et al. 2000).

Multiple Sclerosis

Oropharyngeal dysphagia occurs in over 30% of multiple sclerosis cases (Prosiegel et al. 2004). As with all other forms of oropharyngeal dysphagia, this entails risk of aspiration and penetration and subsequent pneumonia. Persons with MS are also noted to have insufficiency of velopharyngeal elevation, which leads to the presence of hyper +/− hyponasality (Vitorino 2009). This could also increase the risk of nasal regurgitation, given the

role of the soft palate in preventing bolus entry into the nasopharynx.

Dementia

It is estimated that around 45% of persons with dementia also present with dysphagia (Horner et al. 1994). Others report prevalence as high as 80% (Wasson et al. 2001) and 84% (Horner et al. 1994).

Dysphagia may present differently depending upon the particular dementia experienced (Easterling and Robbins 2008). For example, persons with Alzheimer's disease may forget to eat, be unable to chew, forget to swallow, and show poor pharyngeal clearance (Horner et al. 1994), while persons with frontotemporal dementia may experience an increase in appetite and change in food preferences, have larger bite sizes, and eat nonedible items (Easterling and Robbins 2008). Furthermore, persons with vascular dementia show difficulty chewing and coordinating a swallow (Gallagher 2011).

2.3.3 Gastric Conditions

Gastroesophageal reflux disease is highly prevalent, with estimates of 14% of adults reporting weekly reflux symptoms (Eusebi et al. 2017). Therefore, a large proportion of those receiving end-of-life care will experience reflux as a pre-existing comorbidity. Factors related to the terminal disease and its treatment may further impact this and increase reflux related irritation. These include medications, radiotherapy, body position, saliva production, and surgery. In patients who receive narcotic analgesia, there is a diminution of the spontaneous swallow rate, and oral dryness can be a medication side effect – a combination which can produce swallow issues. Loss of saliva increases reflux irritation due to loss of buffer, lubrication, and mechanical flushing protection. In rare cases impingement on the esophagus or gastric inlet by malignant disease may impair bolus throughput, and certainly esophageal and gastric cancer can produce marked feeding difficulties both through direct obstruction and loss of appetite.

Stomach emptying typically occurs within 90 min. Medication can slow this process and result in induced gastroparesis. Symptoms reported are early satiety and loss of appetite resulting in smaller meal volumes.

2.3.4 The Aging Swallow

As we age, our swallow naturally changes. These changes may not result in direct swallow impairment but may reduce physiological reserve when the swallow is challenged. This has been termed "presbyphagia" to indicate the relationship to the aging process.

Logemann et al. (2013) noted significant changes in the swallow, including a change in the method of propelling the bolus from the front to the back of the mouth increasing duration of the oral stage. There is also a delay in the triggering of the swallow reflex (and subsequent pharyngeal phase), with a delay in the hyoid and larynx returning to the pre-swallow position (older persons have a slower refractory period). An increased number of penetration events are also noted, but in the absence of aspiration. In a recent normative study, quantitative oropharyngeal and esophageal swallowing parameters remained fairly constant in those up to 80 years after which there was an appreciable increase in oropharyngeal and esophageal transit times and reduction in pharyngeal constriction (strength) (Miles et al. 2016).

2.4 Summary

Swallowing problems are present in many individuals nearing their end-of-life with wide-ranging and overlapping causes but are poorly reported and subsequently may not receive enough attention. Swallowing comprises a series of interconnected phases, whereby disruption can occur at any stage. The greatest risk of swallow impairment is penetration and aspiration with development of chest infection and its associated mortality.

Dysphagia can occur in any person, whether it is part of the natural aging process, brain injury, or a neuromuscular disorder. Given the complex nature of deglutition, we recommend that people who are deemed at risk of dysphagia by a health

professional (due to diagnosis or reported symptoms) should undergo swallow screening and assessment. This would then determine the need for diagnostic assessment. This will be further expanded in the next section.

3 Assessment

In order to prevent the consequences of swallowing problems, it is crucial to be able to identify those at risk or with impairments who need expert management. Complete swallow assessment is time-consuming, so initial screening tools have been proposed to allow a more targeted approach.

3.1 Screening

Screening for swallowing problems is recognized as the first part of a holistic swallow assessment. Screening can usually be completed by any health professional and is mandatory within 24 h in some locations for all people who have had a stroke (Cichero et al. 2012).

Screening is not intended as a substitute for a comprehensive assessment. It is intended to identify symptoms of dysphagia and signs of swallow impairment and therefore identify those who may require comprehensive assessment by a speech pathologist (Martino et al. 2009).

Various screening tools are available within the literature. Broadly speaking, these cover areas which can be examined by any health professional (Cichero et al. 2009; Martino et al. 2009; Stewart 2003). Speech Pathology Australia, the Australian SP representative body, suggest the inclusion of:

- Diagnosis: Determining if the person's diagnosis heightens their risk of dysphagia (e.g., stroke, neurodegenerative condition, head and neck cancer).
- Interview: This involves discussing the person's history of swallowing, presenting symptoms (e.g., frequency of overt signs of aspiration, chest infections, feelings of food being stuck).
- Symptoms: Symptoms of slurred speech, facial weakness, drooling, coughing on saliva, weak/absent cough (note: gag reflex is not a predictor of swallowing impairment and is excluded from screening) (Martino et al. 2009).
- Sip test: Where appropriate, patients are given a sip of thin water, and observations are made for coughing, throat clearing, change in voice quality, drooling, and change in respiration. Some debate exists about the validity of water-sip tests, but screening with water-sip tests where appropriate is still recommended in the Speech Pathology Australia Dysphagia Guideline (Cichero et al. 2012; Osawa et al. 2013).

Various local health districts have designed their own adapted version of these screening tools; however, the content remains largely similar. Screening tools are also part of the usual admission process for residential aged care facilities (both high- and low-level care) and often form part of acute-care policy for initial admission screening.

Those who "fail" the screening (i.e., demonstrate signs suggestive of aspiration or other risk factors for swallowing problems) are referred to speech pathology for comprehensive assessment of swallowing, leading to accurate diagnosis and targeted management.

3.2 Comprehensive Assessment

Comprehensive assessment of dysphagia most commonly begins with a functional assessment. This involves an extensive case history, cranial nerve examination, oromotor examination, and food/fluid trial (where appropriate) at the bedside. Further assessment with instrumental measures such as fibreoptic endoscopic evaluation of swallowing (FEES) or videofluoroscopic swallowing studies (VFSS) may be performed although this is not always possible in every setting.

3.2.1 Functional

A speech pathologist begins examination with an extensive case history. Examination of the medical file, previous SP intervention, comorbidities

and medications, current diet/fluids, palliative care phase/PCOC stage, concerns about eating, and recent chest history are reviewed. Preliminary hypotheses are then formed about a person's likely presentation.

Bedside Assessment

The first part of the assessment is determining if a more in-depth assessment is warranted.

Patient Presentation

First and foremost, a patient must be sufficiently alert for assessment. It would be inappropriate to attempt an assessment on a person who is delirious, unable to maintain eye contact, and unable to stay awake to sufficiently swallow a bolus (e.g., 2 min). The lack of alertness will make assessment unreliable and increase risk of aspiration. The decision must be made for each individual by the supervising clinician. Similarly, it may be inappropriate to perform a full assessment on someone with severe pain, and assessment may need to be deferred until pain is controlled.

A patient is observed for their ability to manage their own secretions, the presence of tubes (e.g., nasogastric, nasojejunal, tracheostomy), and their ability to cooperate with an assessment (Cichero et al. 2012).

Cranial Nerve Examination/Oromotor Examination

To begin the physical examination, the speech pathologist observes the oral cavity. Assessment includes the health of the oral mucosa (e.g., pink), moisture, health of the soft tissue (e.g., presence of oral thrush), and dentition (presence of dentures/own dentition, cleanliness of teeth). The odor of the mouth may be observed, and quality of the secretions (e.g., stringy, clear), as well as the pre-existing anatomy of the oral cavity.

A cranial nerve examination will assess those nerves innervating muscles throughout the swallow. The speech pathologist will request the patient to perform a series of movements and will observe symmetry, deviation, range/rate of movements, strength of movements, and sensation. If the patient is unable to follow instructions, the speech pathologist may complete the movements in front of the patient so that they may copy their movements.

- CNV – observe the jaw for range of lateral and opening/closing movements, strength of jaw, strength of masseters, and mandibular sensation, tongue sensation, and taste.
- CNVII – observe the face for closure at rest, droop, sensation to upper face, lip rounding, lip speed during "oo-ee" said in quick, repetitive succession, strength of facial movements, and lip retraction.
- CNIX and CNX – observe the soft palate for symmetry of elevation, and observe nasal emission, voice quality, pitch variation, volume control, and respiration.
- CNXII – examine tongue movement, range and strength of movement, fasciculations, weakness, or atrophy.
- Observe a volitional cough for strength and productivity. Cough reflex testing may also be performed at bedside in some settings (see below).
- Observe and palpate the hyoid for dry swallow strength and perceived range of movement.
- The gag reflex is no longer consistently recommended as part of the assessment as it is innervated by a different nerve than the larynx and pharynx and does not have predictive value (Cichero and Murdoch 2006).

It should be noted that not all parts of the assessment will always be possible. In palliative care, a patient may be highly distressed and only able to tolerate small amounts of oral intake or remain alert for very short periods. In this case, a cranial nerve examination may not be possible in a formal, structured way, and priority may be given to ensuring the person's comfort.

Food/Fluid Trial

If deemed appropriate, the speech pathologist may commence a food and/or fluid trial to determine the most appropriate recommendations.

Positioning

Ideally, a person would be positioned upright for assessment. Recent evidence suggests that sitting at 90 degrees upright may not be best for those

with poor sitting balance or trunk control, as this places undue pressure on their respiration, and that 45 degrees is adequate for this population (Park et al. 2013).

Self-Feeding

It is most useful to assess a person as close to their natural abilities as possible, particularly if the person is at home or will return home. It is important to determine if the person feeds themselves and if they use any prescribed or specific cutlery or other utensils.

To begin, the speech pathologist instructs the subject to take a single bite or mouthful of drink or food. The attending speech pathologist will determine if the food and fluids should be those which the person is already receiving or the safest oral diet (e.g., puree and extremely thick, in most cases).

As the person consumes the food or fluids, observations are made for the oral preparatory/oral phase and the pharyngeal phase. The esophageal phase is not assessed at bedside.

Oral Phase

Observation of the presence of any anterior spillage, oral pooling, bolus control, mastication, oral transit time, and anterior-posterior movement of the bolus is made.

Pharyngeal Phase

Pharyngeal phase: observation of the timing of the swallow, effort required for the swallow, laryngeal movement, voice quality post swallow, coughing, throat clearing, nasal regurgitation, and swallows per bolus are documented. Aspiration may be suspected based on cough response, cervical auscultation, or change in oxygen saturations. Laryngeal movement is not objectively assessed at bedside, but is assessed via palpating the hyoid during the swallow. Assessment of timing of a swallow is not possible at bedside, as the true location of the bolus for swallowing is unknown.

At bedside, the speech pathologist may also try compensatory strategies with the food and fluids, which may allow different recommendations to be made.

In many cases, a bedside examination is all that is available to a speech pathologist for assessment. Though objective measures are considered the "gold standard," these are not necessarily appropriate for someone receiving palliative care or for someone in a subacute facility. It may cause them unnecessary inconvenience, may tire them, and may yield no changes to their management.

3.2.2 Instrumental

Additional ancillary assessments may be considered on a case-by-case basis.

Cervical Auscultation

As part of a comprehensive assessment, a speech pathologist may utilize cervical auscultation to provide aural information about the swallow. It is not suitable as a stand-alone assessment, but can be useful for supporting hypotheses as an adjunct to additional assessments. Cichero and Murdoch (2006) provide an exemplary summary of this method.

Cervical auscultation utilizes a standard stethoscope. Some speech pathologists prefer pediatric stethoscopes, as they better fit under the neck with a firm seal and account for additional skin surface area.

The speech pathologist places the stethoscope with a firm seal, just below the cricoid cartilage and in a central location (Hirano et al. 2001). The patient performs a swallow of saliva, and the speech pathologist observes the normal sounds of the swallow. Usually, two clicks signify (1) the closure of the laryngeal valve and the projection of the base of the tongue to the posterior pharyngeal wall and (2) the opening of the upper esophageal sphincter and the pharyngeal stripping wave (Cichero and Murdoch 2006). Pharyngeal residue may be audible, as well as multiple swallows per bolus. The sounds of swallowing become longer as we age, and this may be perceived by the ear (Cichero and Murdoch 2006). During the observation of quiet respiration, the speech pathologist can often hear the clarity of the breath sounds and if there is any fluid, food, or saliva sitting in the airway.

Pulse Oximetry

The measure of oxygen saturation is another useful adjunct to assessment. Again, this is not suitable for use as a stand-alone assessment but provides useful information about suspected aspiration.

To utilize pulse oximetry, a pulse oximeter is placed on the person's index finger while a food and fluid trial takes place. The baseline oxygen saturation is observed, as well as the usual fluctuations in saturation for that person. The value is observed for change during assessment, and a drop of 2% is significant for indicating the presence of aspiration (Lim et al. 2001). However, most devices have a 2% error rate, so information must be used in conjunction with other clinical indicators to determine the outcome of assessment. As oxygen saturation does not drop immediately at the time of aspiration, monitoring of saturation is necessary for several minutes after the trial.

Cough Reflex Testing

Current research is analyzing the effectiveness of screening patients in acute care utilizing cough reflex testing to assist with identification of silent aspiration at bedside. This is completed with a standard nebulizer mask with free-flow output of 8 L and restricted flow of 6.6 L/min and 0.4–0.8 mol/L of citric acid (Miles et al. 2013). This assists with identification of silent aspiration at bedside. This is useful as an adjunct to assessment to assist with identification of those at risk of silent aspiration. However, the application of this measure may not be appropriate in all settings, particularly in palliative care.

Manometry and Electromyography

Manometry can be used to examine the pharyngeal contraction during a swallow and is conducted by a gastroenterologist. A small tube is passed through the nasal passage into the esophagus. Electromyography is performed with electrodes placed on the skin over muscles of interest or directly into the muscles themselves (Cichero and Murdoch 2006).

With these measures, pharyngeal and esophageal contractions are measured for effectiveness. Again, this may be a useful adjunct for some assessments, but application in palliative care and subacute settings is limited due to the absence of radiological machines and the patient status (i.e., invasive investigations may not be appropriate).

Fibreoptic Endoscopic Evaluation of Swallowing (FEES)

Fibreoptic endoscopic evaluation of swallowing (FEES) is an instrumental evaluation technique that can be performed at bedside but requires specialized equipment and a trained clinician familiar with endoscopy. Also known as functional endoscopic evaluation of swallow, this involves the insertion of a flexible endoscope (fiberoptic or videoscope) passed per naris Assessment is made of anatomy, function, secretions, and sensation alongside evaluation of penetration, aspiration, and regurgitation when the subject is given food or fluid or swallows saliva. The study can be tailored to the individual's needs and abilities, and the clinician must have clear goals for the study and appreciate the anatomy and function of the laryngopharynx when performing this evaluation.

FEES can provide invaluable information about laterality of deficits, secretion management, compensatory strategies, and swallow safety. It is quick to perform and usually well tolerated. There is no exposure to ionizing radiation and FEES may be performed in both adults and children. Impediments to utilizing FEES include the cost of equipment and need for training, patient discomfort and nasal access issues, difficulty in performing in those with poor cognition, "whiteout" effect wherein the view is obscured mid-deglutition as the pharynx constricts around the endoscope, and ability to clean and disinfect endoscopic equipment. FEES may also be used as a training tool through biofeedback wherein the patient can watch the video screen and practice maneuvers that alter swallows. Examination can be recorded to video files allowing review at leisure and by clinicians not present during the performance of the study.

With the advent of efficient battery-powered endoscopes, FEES is more accessible than

previously and may represent the instrumental evaluation that is easiest to achieve in a palliative setting, given the difficulty in moving ill patients to radiology suites for videofluoroscopic evaluations.

Videofluoroscopic Swallow Study (VFSS – Also Known as Modified Barium Swallow, MBS)

VFSS (previously termed modified barium swallow – MBS) is a dynamic, real-time videofluoroscopic swallow evaluation. Ionizing radiation is administered to obtain images through a fluoroscope, and therefore this must be performed in a radiological facility by a speech pathologist or medical radiation technologist +/− a radiologist (Figs. 3 and 4).

The VFSS utilizes barium sulfate (either powder or liquid) as a contrast agent which is then mixed with food and fluids.

The patient is positioned upright for assessment, and contrast is consumed. On VFSS, the following areas are visible (in addition to those seen at bedside):

- Base of the tongue to the posterior pharyngeal wall contraction
- Bolus cohesion
- Soft palate retraction and elevation
- Contraction of the pharyngeal constrictors
- Deflection of the epiglottis (Fig. 3)
- Elevation and anterior movement of the hyoid
- Opening of the upper esophageal sphincter
- Passage of the bolus through the pharynx to the esophagus and stomach
- Airway violation (aspiration) (Fig. 4)
- Residue or bolus oscillation

On VFSS, some anatomic abnormalities may be observable. These include osteophytes, diverticula, and cricopharyngeal bar. VFSS provides an excellent overview of the swallowing function from the oral cavity to stomach. It delivers a raft of information which can inform management and allows testing of any potential rehabilitation and compensatory strategies, as well as the safest food and fluid consistencies. By using quantitative measures, further data may be extracted from VFSS (Leonard and Kendall 2014; Leonard et al. 2000; Miles et al. 2015, 2016) and compared to well-documented normative data for age and

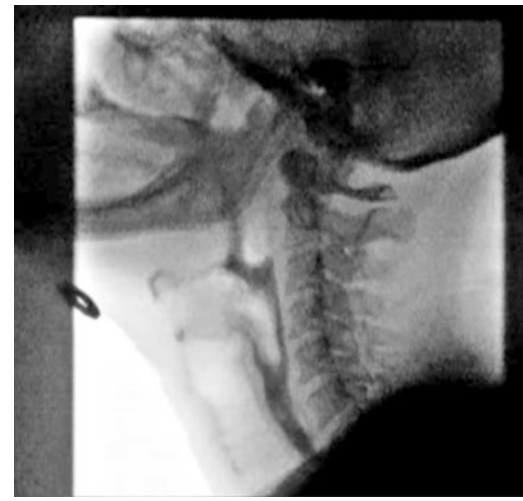

Fig. 3 Lateral fluoroscopic view mid-swallow demonstrating retroflexed epiglottis outlined by barium bolus with hyoid elevation and closed airway anteriorly and bolus flowing through the open pharyngoesophageal segment posteriorly

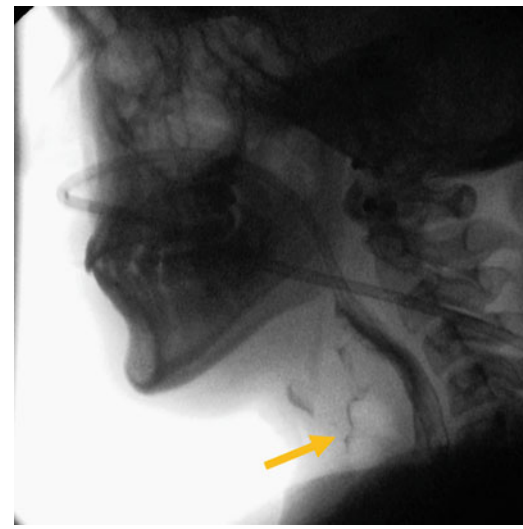

Fig. 4 Lateral fluoroscopic view mid-swallow demonstrating aspiration of bolus into the airway anteriorly (*short arrow*) with majority of the bolus passing posteriorly through the pharyngoesophageal segment. Note a nasogastric tube is in situ

gender. As exposure to ionizing radiation occurs, it behoves the clinician to maximize the value of the study. VFSS should not be considered a binary test of aspiration alone.

4 Intervention

The combination of functional and instrumental assessments allows the multidisciplinary team to make recommendations for diet and management. The SP provides recommendations regarding the safest oral diet (if any), environmental support, behavioral strategies, and rehabilitation and may support discussions regarding choice making for quality of life. Otolaryngologists, physicians, oncologists, and supervising medical personnel can provide additional advice regarding surgical options and pharmacological treatments.

4.1 Non-pharmacological

Non-pharmacological interventions are most commonly guided by a speech pathologist. These vary from compensatory techniques (behavioral strategies, food/fluid modification, environmental modification, and symptom management) to rehabilitative exercises and to a quality-of-life approach which places the emphasis on choice-making.

4.1.1 Compensatory

Behavioral Strategies

Behavioral strategies are those designed to optimize the safest oral diet by teaching a person to perform an action before, during, or after a swallow. It should be noted that these may be conservatively used in palliative care, and only under the direction of a speech pathologist and medical team. This might involve the following:

- Head tilt/rotation – tilting the head or turning it to the side of weakness, directing the bolus to the stronger side (Logemann 1998; Logemann et al. 1989).
- Chin tuck – tucking the chin in toward the chest to widen the pharyngeal space (Logemann 1998).
- Body posture – this may involve side lying to the stronger side, allowing a person to swallow and clear residue with the aid of gravity (Sura et al. 2012).
- Supraglottic swallow – a swallow is performed followed by an immediate cough; the cough is *not* preceded by breathing in (intended to clear material in the airway) (Martin et al. 1993).
- Super-supraglottic swallow – a supraglottic swallow is performed with the addition of an effortful swallow (Martin et al. 1993).
- Multiple swallows – several swallows to ensure clearance of a bolus and any remaining pharyngeal residue.
- Effortful swallow – swallowing as hard as you can to increase hyolaryngeal excursion, oral and pharyngeal pressures, and subsequent movements (Kahrilas et al. 1991).

This is not an exhaustive list of all behavioral strategies, but those most commonly utilized and those that may apply to the palliative care setting. More rigorous approaches (such as neuromuscular electrical stimulation – NMES) are not appropriate for the palliative care setting (Xia et al. 2011).

Food/Fluid Modification

Food and fluid modification is designed to ensure a person is able to adequately manipulate, form, and swallow a bolus with minimal residue and minimal entry into the airway. Thicker viscosities may slow the bolus transportation; softer foods make it easier to chew or moister to allow for better cohesion.

The names and definitions of food textures vary across the globe; however, they generally involve:

- Full/normal – unmodified food.
- Soft/texture A – food with lumps up to 1.5 cm in size. Food should be well cooked, moist, and fork mashable (some networks break this further into two levels of soft diets).

- Minced/texture B – has small lumps (up to 0.5 mm), which are moist and soft. Lumps should be tongue mashable.
- Puree/texture C – smooth, lump-free food that holds its shape on a spoon.

Fluid consistencies also vary, but they are generally:

- Thin/normal – unmodified fluids
- Mildly thick/level 150/nectar/level 1 – runs through the prongs of a fork in a continuous stream
- Moderately thick/level 400/honey/level 2 – runs through the prongs of a fork slowly in large drips
- Extremely thick/level 900/pudding/level 3 – sits on a fork and does not run through

Given the numerous labels of each classification, as well as the variety across the world, Cichero et al. (2013) sought to develop standardized classification for terminology. The "International Dysphagia Diet Standardisation Initiative" (IDDSI) recommends a total of ten textures, on a continuum labeled from 0 to 7. Most noticeably, there has been a suggested addition of "slightly thick" and "liquidized" diet. Slightly thick refers to fluids which naturally occur and are thicker than normal fluids, and liquidized foods refer to smooth, lump-free and liquid food (moderately thick). The latter is a very useful diet in palliative care (as well as in other settings), particularly for those that prefer drinking to eating (such as those with MND, dementia, or esophageal cancers).

There remains a great variety in the application of recommended diets. Standardization is not yet mandatory, and communication between speech pathologists is vital to prevent incorrect diet and fluid provision. This standardization project shows great promise for improving the continuity of modified diets and fluids across the world, reducing confusion, and improving quality of life for patients.

Free-Water Protocol

A speech pathologist may recommend modified diet and fluids, but may also make suggestions for a "free-water protocol" to assist with hydration and maintenance of quality of life.

The Frazier Free Water Protocol involves the provision of as much thin water as desired to a patient (Panther 2005). Criteria for recommended use of this protocol include nil excessive choking and subsequent physical stress, waiting for 30 min after a meal, use of any recommended swallowing strategies, diligent oral care, medications with thickened fluids/fruit puree, and family education. Karagiannis and Karagiannis (2014) provided additional criteria of good mobility and cognition, resulting in nil significant increase in rates of aspiration pneumonia and significantly improved quality of life of participants. Research remains inconclusive about the overall effectiveness in increasing hydration, and implementation should be at the discretion of the supervising clinicians.

Environmental Modification

In addition to the above strategies, environmental modification may be utilized to aid safe swallowing without requiring the person to change their behavior. Environmental modification may involve altering the method of feeding, distractions, and the local environment. For example:

- Use of a straw or spout cup – moderates the bolus flow and amount and assists with poor upper limb control.
- Use of adapted cups (e.g., cutout cup) – moderating the amount that can flow from the cup with the maximum tipping of the cup.
- Use of finger foods – useful for those who eat well with their hands but not with cutlery or other utensils.
- Reduction of local distractions – ensuring a person is focused on their meal by turning off the television and reducing the number of people in the room (Kyle 2012).
- Eating with the patient to provide a model of eating behavior (also often useful for those with dementia).
- Providing six smaller meals instead of three large meals to reduce the burden of eating large meals.
- Dentition may affect texture choices. Ill-fitting dental appliances can be an impediment and

cause xerostomia. Loss of dentition may make eating solid foods impossible, and input of a dentist may help in some cases.
- Lubrication is crucial to deglutition. Saliva helps form the bolus, initiates digestion, protects the mucosal lining and dentition, provides antibodies and antibacterial molecules, mechanically flushes oral and pharyngeal spaces, and dissolves tastants in food. Xerostomia is a common consequence of disease treatment, particularly radiotherapy and medications. It must be considered and compensated as far as possible with introduced hydration, minimizing drying medications, moisturizing food, and meticulous dental hygiene (see ▶ Chap. 20, "Mouth Care").

Feeding Strategies

Feeding strategies may be useful with presenting symptoms. These can be implemented by carers and professionals and for those persons who require full assistance with feeding. As always, a person should only be fed when they are alert and able to swallow.

- Alternate between food and fluids to assist with washing away oral and pharyngeal residue.
- Alternate between tastes, textures, and temperatures (Easterling and Robbins 2008).
- Alternate between bolus and an empty spoon – light pressure on the tongue with the spoon may assist with initiating a swallow.
- Gentle touch may increase nutritional intake and attention to the meal (Eaton et al. 1987).
- Discuss the food taste, smell, and color (Wasson et al. 2001).

Independence is always encouraged and, for the most part, yields better swallowing. However, feeding strategies assist with swallow stimulation for someone whose initiation is compromised.

Symptom Management

In some cases, it may be appropriate to recommend rehabilitative exercises to improve the function of a swallow. These are rarely used in palliative care and are most commonly recommended in a rehabilitation setting.

4.1.2 Rehabilitative

- Masako – this involves placing the tongue between the upper and lower teeth and holding it in position while swallowing. The Masako improves the base of the tongue to posterior pharyngeal wall contraction (Fujiu and Logemann 1996).
- Mendelsohn – this involves raising the larynx and consciously inhibiting the lowering of it for a sustained period. The Mendelsohn assists with opening the upper esophageal sphincter (McCullough et al. 2012; Mendelsohn and McConnel 1987).
- Shaker – this involves lying in supine, keeping the shoulders on the bed, and lifting the head to look at the toes, thereby improving the anterior movement of the larynx and the opening of the UES (Shaker et al. 1997).

4.1.3 Choice Making

Above all, the primary consideration of the speech pathologist for the person receiving palliative care is their ability to choose what they wish. A speech pathologist may make recommendations which are believed to be the safest based on available evidence, but the person may at any time elect their preferred diet and fluids.

At the forefront in all forms of healthcare is the necessity to treat each person as an individual. A person may wish to accept the risks and consequences of aspiration, or they may wish to take a more conservative approach. They may choose to have a combination of approaches or implement the Frazier Free Water Protocol.

It is the role of the speech pathologist and the multidisciplinary team to educate the patient and family, ensure they feel able to make a choice, and assist them in carrying out their wishes to ensure their quality of life is maximized.

4.2 Pharmacological

Medication is part of holistic care of the terminal patient. They may require analgesics and regular medication for comorbid conditions. In addition they may receive treatment-specific medication such as chemotherapy. All medications may

have side effects, some of which can impair deglutition. As mentioned, drying of the pharyngeal lining impairs swallow and can result in pain or opportunistic infection, particularly *Candida* spp. Careful consideration should be given to current medications and their risk benefit profile, as well as any new proposed or introduced medications.

Pharmacological therapies that may offer benefit for swallow disorders include lubricants (artificial saliva, lozenges (sugar-free), gum (sugar-free), and alginates), antacids (H2 blockers, proton pump inhibitors, binders/alginates), analgesics which allow swallow without pain, prokinetic agents (domperidone, metoclopramide, erythromycin) which enhance esophageal function and help secretion control, anti-inflammatories (non-steroidal and steroidal), and antifungals. Each medicine should be carefully evaluated and considered in conjunction with other current medicines to avoid drug interactions. There are no specific medications to "treat dysphagia," and use of medicines will be determined by symptoms and comorbid disease. Rarely should drying medications be used as these typically result in thickening of sputum and make it more difficult to clear. In specific cases amitriptyline given at 10 mg nocte may reduce overall saliva production without severe side effects, but all medications should be discussed with the supervising clinicians.

4.2.1 Surgical

Rarely is surgery appropriate in palliative care, although a terminal illness is not a complete contraindication to targeted surgery. Again, each individual case will require appropriate consideration. For example, airway protective procedures such as injection laryngoplasty or medialization may be very helpful in preventing choking and aspiration. This improves quality of life and communication during a patient's final days. For some, an injection laryngoplasty may be performed in the clinic under local anesthetic, obviating the need for general anesthesia and speeding recovery. There are several other procedures to protect the airway such as laryngeal framework surgery (arytenoid adduction), tracheostomy, laryngeal suspension, or laryngotracheal separation; however, these are increasingly invasive and often not appropriate in a palliative care setting.

Dilatation of aerodigestive sphincters, strictures, rings, or bars may be appropriate as these can often be accomplished under local anesthetic or sedation and may improve bolus transit and reduce residue that predisposes to airway violation. Feeding tube placement such as percutaneous endoscopic gastrostomy (PEG) may be undertaken during treatment and in place when patients transition to palliative care. These can be invaluable as a medication delivery system and to provide adequate hydration but have not been shown to significantly reduce mortality associated with aspiration. Nutritional supplementation can also be provided but must be undertaken after careful discussion with a dietitian and palliative care consultant. Cricopharyngeal myotomy or botulinum toxin injection of the cricopharyngeus muscle may improve swallow in patients with obstructive pharyngoesophageal segments. Onabotulinum toxin can also be utilized for laryngeal spasm or cervical dystonia and has been used to reduce saliva output from the submandibular glands in some cases.

5 Conclusion and Summary

When an individual is approaching the end of their life and is aware of a terminal diagnosis, the ability to communicate and to be part of social events with family and friends is of the utmost importance. Nearly all social situations include eating, and when this is impaired, there can be a significant decrement in the quality of life for the individual. Many patients will experience swallowing difficulties as a result of their disease process, the treatment of the disease whether it be surgical or medical, and of increasing frailty and deconditioning. Palliative care teams should be aware of the high prevalence of swallow impairment and should directly inquire about symptoms and observe for signs of disordered deglutition. Early and frequent assessment by speech pathologists can provide a marked improvement in swallow function and reduction in risk associated with

poor swallowing. Limiting pulmonary soiling is vital in maintaining health, and a competent swallow is at the heart of this.

Simple dietary and behavioral measures can be employed to facilitate swallowing. Careful medication management will minimize xerostomia and reduce pain. Targeted surgical procedures may minimize airway violation or treat strictures. Non-oral feeding can maintain nutrition but deprives the individual of the pleasure of food. Even taking a small amount of oral diet or liquid for pleasure should be considered, particularly in the terminally ill. At times, the risk of aspiration may be accepted where the overall quality of life gain from eating outweighs the swallow risk – a decision that only the patient can make. The most important approach is to involve all team members and the patient to individualize the treatment plan so that each patient receives the options most suited to their needs. Education of the individual and their family around safe eating practices, food preparation, and compensatory strategies can go a long way to mitigating swallow risks. It also empowers the patient and their support network allowing them to plan day-to-day life. At all times the patients' wishes and preferences must be at the core of recommendations and management strategies.

Mucositis

19

Contents

Abstract

Mucositis is an inflammatory reaction of the mucosa of the alimentary tract (AT) caused by chemotherapy, radiotherapy, and targeted therapy for cancer. It presents a significant burden not only to patient quality of life but also may result in diminished tumor control (through dose reductions) and increased treatment costs (due to extended hospital stays and supportive care). Mucositis symptoms may vary not only due to the treatment modality but also according to genetic predispositions of the patient toward developing toxicity (toxicogenomics). Management of mucositis is at present supportive only, with treatments that reduce incidence, severity, and duration of clinical symptoms, but do not prevent or cure mucositis altogether. A great deal of current research into the mechanisms involved in development and progression of mucositis is also being carried out; it is hoped that a clear understanding of mucositis pathophysiology, along with comprehensive toxicogenomics, will enable more preventative treatments to be developed.

1 Introduction

Mucositis is a common side effect of cancer treatment and affects the entirety of the alimentary tract (AT). It occurs in 50–100% of cancer patients (Gibson and Stringer 2009) receiving cytotoxic treatment including chemotherapy (CT), radiotherapy (RT), targeted anticancer therapy (TAT), and combinations thereof. It presents with various signs and symptoms, including ulceration, xerostomia, pain, nausea, vomiting, and diarrhea. These clinical symptoms significantly impact not only patient quality of life (QOL) but may lead to treatment reduction or cessation, which severely impacts the effectiveness of cancer treatment (Lalla et al. 2014). Furthermore, the fiscal burden of mucositis is substantial, costing approximately 25,000 US dollars per cycle of chemotherapy in increased hospital stays due to complications (such as infection, malnutrition, and dehydration) and supportive care resources (Carlotto et al. 2013). The importance of mucositis prevention and intervention is paramount and is contingent upon a firm understanding of the underlying pathophysiology.

Mucositis literally means "inflammation of the mucosa," with factors including (but not limited to) ulceration, pain, and diarrhea manifesting as clinical symptoms, rather than distinct conditions. However, mucositis is often used as a blanket term to describe both the cause and the symptoms (Keefe 2006). Mucositis is also often used to refer solely to oral mucositis (OM); however, it can occur in any region of the AT; care must therefore be used regarding terminology in this field (Keefe 2006).

Slight structural and functional differences delineate the distinct regions of the AT (Keefe 2004). It is these divergences that may underlie the development of distinct clinical symptoms specific to certain regions, for example, xerostomia occurring in the oral cavity and diarrhea occurring in the lower GI tract (Keefe 2004; Sonis 2011). It is also apparent that different cancer treatments can cause distinct conditions, a finding made evident with increasing use of targeted anticancer therapy (TAT, such as TKIs, mAbs, and mTOR inhibitors), whereby symptoms of mucositis are ostensibly observed, but with possibly different underlying mechanisms and responses to treatment than those caused by CT or RT (i.e., aphthous ulcers with mTOR inhibitor use (Peterson et al. 2016; Van Sebille et al. 2015)). This is most probably due to the difference in therapy targets (and consequent off-target effects)

(Keefe and Bateman 2012) but is no doubt compounded by regional characteristics of the AT (Keefe 2004; Van Sebille et al. 2015).

Recent studies in our laboratories (Van Sebille et al. 2015; Bowen 2014; Bowen et al. 2014) have suggested TAT, in particular ErbB tyrosine kinase inhibitors, induced diarrhea in very different ways. This comes from a preclinical model demonstrating no significant histopathology in the small and large intestines of rats following TAT treatment for up to 28 consecutive days, despite developing consistent diarrhea (Bowen 2014; Bowen et al. 2014). In contrast, our findings in traditional preclinical chemotherapy and radiotherapy models have demonstrated significant damage throughout the gastrointestinal tract associated with diarrhea and other clinical indicators of mucositis including diarrhea (Gibson et al. 2003; Bowen et al. 2006; Gibson et al. 2005; Logan et al. 2007a; Yeoh et al. 2007; Bateman et al. 2012).

Current understanding of the underlying pathophysiology of mucositis is based largely upon preclinical animal models, made useful by the fact that observation and sampling of patient tissue can be difficult, particularly with GI mucositis. The findings of these animal models lead to the development of Sonis' widely accepted five-phase model of mucositis (Sonis 2004) (Fig. 1). These phases are essentially a biological sequence of dynamic events that depends on effective communication between the epithelium and the mesenchyme; Fig. 1 shows each stage and the linked yet divergent nature of CT/RT-induced mucositis versus TAT-induced mucositis. Stage IV, which is the loss of epithelial integrity, is the symptomatic phase, and the phase against which the vast majority of treatments are used to assuage symptom severity and duration. However, the most effective interventions would be those targeting earlier stages, in order to prevent or reduce the development of mucositis.

While the AT has several distinct regions (oral, gastrointestinal, colorectal) that manifest distinct clinical symptoms in response to injury, the AT mucosa is also a continuum, whereby symptoms of injury are often underpinned by similar pathophysiologies (Al-Dasooqi et al. 2013) and do not occur in isolation. Applications of distance matrices are beginning to answer some crucial questions regarding toxicity clustering, such as whether severity of clustered toxicities are also linked, whether risk for one implies risk for another, and whether certain toxicities occur more frequently together than others. Bayesian analysis of retrospective patient data compares pairs of toxicities and whether the toxicities are related. The strength of association is known as Bayes factor (BF), and BF >1 shows some evidence of association, BF >3 supports a strong evidence of association, and BF >7 provides decisive evidence in favor of association. The limitation with Bayesian analysis for toxicity clustering is that it can only detect a link between one other toxicity; Markov network, based on Bayesian analysis, can detect more than one link and allows for development of closed loops or clusters of related toxicities. Recent studies (Aprile et al. 2008, 2009) have generated toxicity clusters and loops for common toxicities experienced by 300 adult colorectal patients receiving chemotherapy using Bayesian and Markov analysis, showing that many toxicities heretofore treated as discreet can be clustered together due to strong associations. These clusters may have a common pathobiology which may lead to a common treatment, reducing the incidence, severity, and duration of the entire cluster, which would greatly improve QOL and possibly increase cancer cure. Nevertheless, more work is needed to show if this holds for other cancers and other treatments.

Effective treatment needs to be similarly multidisciplinary yet holistic, as it is becoming increasingly evident that cancer treatment toxicities exist in clusters (Aprile et al. 2008; Walsh and Rybicki 2006). In the burgeoning field of toxicogenomics, patients are being profiled not only for suitability of a cancer treatment to maximize tumor control but also for the treatment that also will elicit the least toxic response.

1.1 Diagnosis and Assessment

The assessment of oral mucositis is relatively straightforward as the oral cavity can be easily

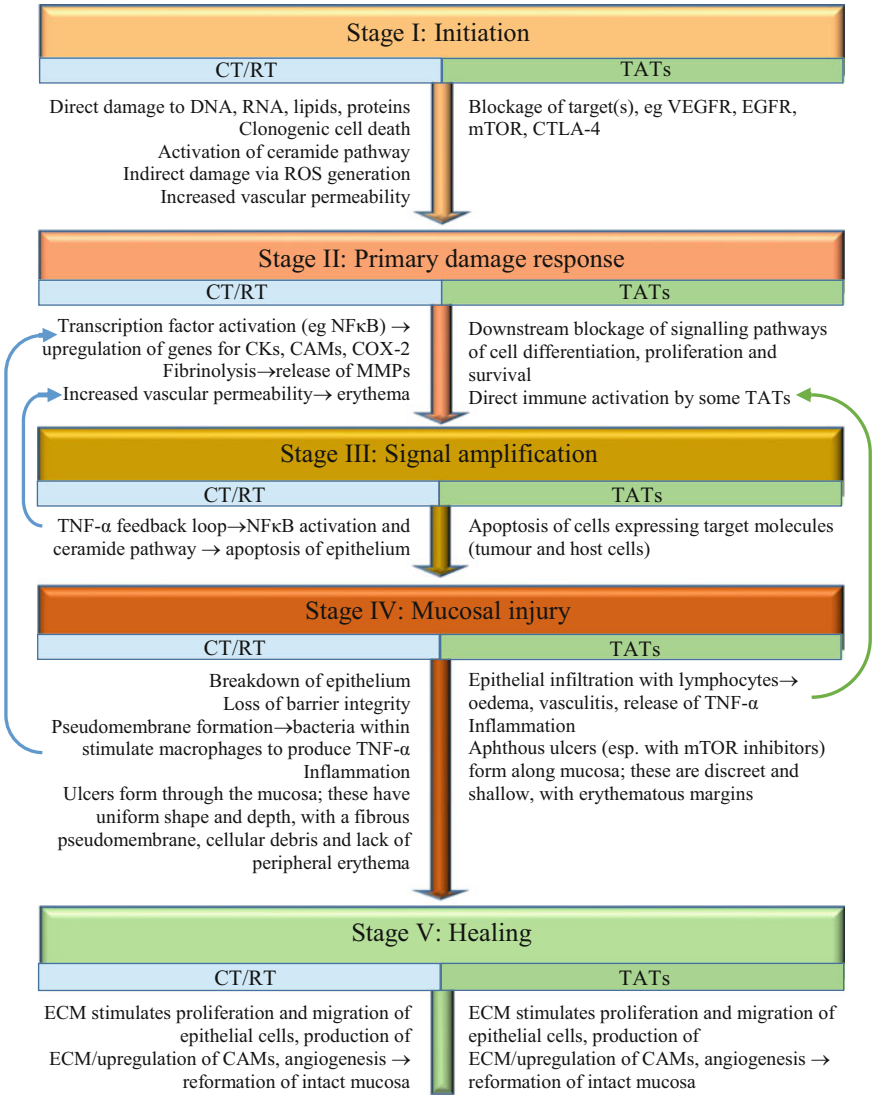

Fig. 1 The five-phase model of the pathophysiology of mucositis (Modified from Keefe and Bateman in press)

visualized and, for many patients undergoing cancer treatment, the development of oral mucositis is predictable. For example, patients undergoing conventional head and neck radiotherapy for oral squamous cell carcinoma will most often start to develop mucositis in the form of oral pain and erythema within the field of radiation early in their course of treatment. Subsequently, this will usually progress to obvious oral ulceration that continues throughout the remainder of their radiotherapy and begin to resolve on the completion of the treatment. Likewise, the majority of patients undergoing hematopoietic stem-cell transplantation (HSCT) will develop mucositis along with many other oral complications in the course of their treatment (Elad et al. 2015). Different chemotherapy regimens are associated with different risks of the development of mucositis depending on the drugs that are used; furthermore, a combination of chemotherapy with radiotherapy also increases the risk (Al-Mamgani et al. 2013). Improvements in the provision of radiotherapy (e.g., intensity-modulated radiotherapy) have

allowed a treatment to be more targeted; however mucosal toxicity still occurs (Hoffmann et al. 2015).

Oral mucositis can present as a spectrum of changes that are evident clinically, dependent on the timing of cancer treatment. Initially it can present as areas of mucosal erythema accompanied by pain (Fig. 1). This evidentially develops into more widespread, confluent areas of ulceration (Fig. 1) associated with significant pain. This is associated with increasing functional problems including the need for parenteral nutrition in some patients and, in the "worst case" scenario, the need to suspend treatment. This has implications for the effectiveness of the cancer treatment and is a major reason why mucositis needs to be effectively managed.

The clinical diagnosis of oral mucositis, while generally straightforward, can be made more complicated by other adverse effects that can affect the oral cavity, including salivary gland hypofunction, oral infections (e.g., candidiasis), dysgeusia, increased dental caries, and osteoradionecrosis. Furthermore, the increasing use of chemotherapy regimens with newer targeted agents have resulted in the occurrence of other toxicities that manifest in the mouth, including osteonecrosis and risk of hemorrhage. Accordingly, it is important that assessment by a dentist or health professional with experience in assessing the oral mucosa is undertaken, in order for patients to have optimal oral health prior to the commencement of their cancer treatment, and it is also important for a dentist to be available to monitor their oral health and function as they proceed through their treatment. This enables patients to have the optimum treatment and also the optimum quality of life during their treatment (Elad et al. 2015; McGuire et al. 2006).

Unlike the oral cavity, the remainder of the alimentary tract is not easily visualized clinically, and assessment is therefore difficult, relying on patient-reported symptoms. Endoscopic evaluation of patients is often complicated by other factors including increased risk of infection from myelosuppression and also thrombocytopenia. Recent reviews have highlighted the potential for tests that indirectly indicate gut damage that can be used to assess the degree of gastrointestinal mucosal injury occurring as a result of cancer treatment (Tooley et al. 2009; Gibson and Bowen 2011). Ideally, this would be done prior to the development of gastrointestinal symptoms of abdominal bloating, pain, and diarrhea so that these can be prevented or managed before they become so severe that treatment regimen modification or cessation is required. Alternatively, the use of biomarkers could indicate the extent of intestinal damage so that patients can be appropriately provided additional support (e.g., parenteral nutrition) on the basis of objective assessment criteria (Herbers et al. 2010).

The measurement of plasma citrulline levels has been promising as a marker for small intestinal damage (Herbers et al. 2010; Lutgens et al. 2003). Physiologically, citrulline levels in the plasma provide a surrogate marker for small intestinal epithelial cell mass (Lutgens and Lambin 2007). In the setting of radiation damage from total body irradiation as part of treatment for hematological malignancies (Lutgens et al. 2005) or abdominal fractionated radiotherapy (Lutgens et al. 2004), plasma citrulline levels correlated with clinical toxicity grading. Furthermore, plasma citrulline levels have been shown to be able to differentiate between different myeloablative chemotherapy regimens and the degree of intestinal damage between regimens (Herbers et al. 2010). Another factor that is important from a clinical perspective is that the use of citrulline as a marker of regimen-related intestinal damage has also been demonstrated in a pediatric population (van Vliet et al. 2009).

Noninvasive tests have also been examined with respect to the assessment of intestinal damage with respect to small intestinal function. Examples of these tests include the hydrogen breath test (H_2BT) and the ^{13}C-sucrose breath test (SBT) (Howarth et al. 2006). Both tests are simple breath tests that are noninvasive, assess small intestinal function, and pose essentially no risk to patients (Tooley et al. 2009). H_2BT does have some limitations in that it relies on the presence of hydrogen-producing bacteria residing in the colon and can be influenced by diet and antibiotic use (Tooley et al. 2009). The SBT is an

indicator of sucrase activity and integrity of brush border and enterocyte function, and in the context of gastrointestinal mucositis, small intestinal sucrase activity is reduced (Tooley et al. 2009). Both animal and clinical trials have demonstrated its potential effectiveness as a marker of intestinal damage in chemotherapy-associated small intestinal mucositis (Tooley et al. 2009; Pelton et al. 2004). While promising, SBT, like H_2BT, has limitations. The timing required to implement the test requires multiple tests every 15 min over a period of 2 h, which for some patients may not be practical. Furthermore, the lack of availability of specialized equipment required for the analysis of samples may also preclude its use in some centers (Gibson and Bowen 2011).

Despite these limitations, the need for a noninvasive marker to assess intestinal damage in patients undergoing cancer is important in order to effectively monitor and manage these patients during treatment, before clinical symptoms become a burden.

1.2 Comprehensive Assessment

Objective and comprehensive assessment of cancer treatment toxicities is paramount in their effective management. Gone are the days when clinician-reported outcomes using variable scoring systems solely dictated symptom management, often at the cost of patient quality of life. Nowadays, there are validated scoring systems used worldwide to assess and report cancer treatment-related toxicity, and it is increasingly common for patient-reported outcomes (PROs) to be considered when deciding on treatment modifications and supportive care measures. It has long been established that the severity of mucositis and its symptoms are often underreported (Bateman and Keefe 2011).

The most commonly used assessment tool to measure oral and GI mucositis is the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (NCI-CTCAE, current version 4.03; Table 1). However, it must be recognized that some Asia-Pacific regions continue to use the World Health Organization (WHO) scoring system (Table 1). For the most part, these grading tools align well; however, some disparities mean that some toxicities may be underreported or missed entirely, for example, if the WHO scale is used instead of the NCI-CTCAE for OM, where NTC-CTCAE grade 3 OM is described as severe, but grade 3 OM delineated by WHO criteria only describes mild symptoms and does not extend to downstream events (Table 1). Limitations are also evident when considering the WHO criteria in treating nausea and vomiting as a single toxicity, which may result in over- or under-reporting. These gaps may be widened further when patient-reported outcomes (PROs) are taken into account in toxicity reporting. This often renders the development of evidence-based clinical guidelines difficult; to perform best practice based on best evidence, we need to use a standardized, validated scoring system.

For toxicity reporting in targeted therapies, modified scoring systems are the most useful; for example, even though mTOR inhibitor use is associated with the development of mouth ulcers (as is the use of CT and RT), the etiology is somewhat different, with ulcers being described as aphthous; standard OM scoring systems will thus misrepresent the true manifestation of the toxicity. Thus, tools are increasingly being developed which adequately capture unique or unexpected toxicities; universal adoption and dynamic updating of these tools is crucial in order to best provide care for all patients.

1.3 Guidelines and Management

The importance and benefits of evidence-based medicine have seen progressive development of clinical practice guidelines that are based upon systematic review (Lalla et al. 2014; Rubenstein et al. 2004). It is imperative that these guidelines are continuously updated. For cancer treatment-induced mucositis, the Multinational Association of Supportive Care in Cancer/International Society of Oral Oncology (MASCC/ISOO) has developed such guidelines. However, compared to other treatment-related toxicities (such as fatigue

Table 1 NCI-CTCAE and WHO assessment criteria for mucositis (oral and GI)

Adverse event	Scale	Grade				
		1	2	3	4	5
Oral mucositis	NTC-CTCAE, version 4.03	Asymptomatic or mild symptoms. Intervention not indicated	Moderate pain. Not interfering with oral intake, modified diet indicated	Severe pain. Interfering with oral intake	Life-threatening consequences. Urgent intervention indicated	Death
Oral mucositis	WHO	Mild erythema or ulceration $<1cm^2$	Mild erythema and ulceration $<1cm^2$	Mild erythema and ulceration 1–3 cm^2, or severe erythema and ulceration $<1cm^2$	Severe erythema and ulceration 1–3 cm^2, or mild erythema and ulceration $>3cm^2$	Severe erythema and ulceration $>3cm^2$
Nausea	NTC-CTCAE, version 4.03	Loss of appetite without alteration in eating habits	Oral intake decreased without significant weight loss, dehydration, or malnutrition	Inadequate oral caloric or fluid intake, tube feeding, or hospitalization indicated		
Vomiting	NTC-CTCAE, version 4.03	1–2 episodes (separated by 5 min) in 24 h	3–5 episodes (separated by 5 min) in 24 h	≥6 episodes (separated by 5 min) in 24 h. Tube feeding, hospitalization	Life-threatening consequences: urgent intervention indicated	Death
Nausea and vomiting	WHO	Nausea	Transient vomiting	Vomiting requiring therapy	Intractable vomiting	–
Diarrhea	NTC-CTCAE, version 4.03	Increase of <4 stools per day over baseline Mild increase in stoma output compared to baseline	Increase of 4–6 stools per day over baseline. Moderate increase in stoma output compared to baseline	Increase of ≥7 stools per day over baseline Incontinence, hospitalization indicated, severe increase in stoma output compared to baseline	Life-threatening consequences. Bloody diarrhea, need for parenteral support. Urgent intervention indicated	Death
Diarrhea	WHO					

or febrile neutropenia), there are relatively few defined guidelines for mucositis interventions, as not only is there is a paucity of well-designed randomized controlled trials but also a lack of a universally validated and universally accepted assessment scale that would allow for a more comprehensive toxicity reporting. The best-established guidelines for mucositis treatment are targeted toward symptom management, such as controlling dehydration caused by diarrhea and vomiting and ameliorating pain caused by ulcers. The MASCC/ISOO guidelines for oral and GI mucositis are presented in Table 2.

There are no established pharmacological interventions available for mucositis, apart from palifermin for the treatment of oral mucositis (Lalla et al. 2014; Spielberger et al. 2004). There are several emerging pharmacotherapies in various stages of investigation and development; however, existing treatments for mucositis are supportive and focus on symptom management. The field of study associated with developing pharmacological interventions for mucositis is often hindered by the lack of comprehensive understanding of the underlying mechanisms; however, a shift in focus from preclinical and clinical study back to in vitro

Table 2 MASCC/ISOO clinical practice guidelines for oral and gastrointestinal mucositis (Lalla et al. 2014)

Oral mucositis	
Recommendations in favor of an intervention	1. That 30 min of oral cryotherapy be used to prevent oral mucositis in patients receiving bolus 5-fluorouracil chemotherapy (II)
	2. That recombinant human keratinocyte growth factor-1 (KGF-1/palifermin) be used to prevent oral mucositis (at a dose of 60 μg/kg per day for 3 days before conditioning treatment and for 3 days after transplant) in patients receiving high-dose chemotherapy and total body irradiation, followed by autologous stem cell transplantation, for a hematological malignancy (II)
	3. That low-level laser therapy (wavelength at 650 nm, power of 40 mW, and each square centimeter treated with the required time to a tissue energy dose of 2 J/cm^2)), be used to prevent oral mucositis in patients receiving HSCT conditioned with high-dose chemotherapy, with or without total body irradiation (II)
	4. That patient-controlled analgesia with morphine be used to treat pain due to oral mucositis in patients undergoing HSCT (II)
	5. That benzydamine mouthwash be used to prevent oral mucositis in patients with head and neck cancer receiving moderate dose radiation therapy (up to 50 Gy), without concomitant chemotherapy (I)
Suggestions in favor of an intervention	1. That oral care protocols be used to prevent oral mucositis in all age groups and across all cancer treatment modalities (III)
	2. That oral cryotherapy be used to prevent oral mucositis in patients receiving high-dose melphalan, with or without total body irradiation, as conditioning for HSCT (III)
	3. That low-level laser therapy (wavelength ~632.8 nm) be used to prevent oral mucositis in patients undergoing radiotherapy, without concomitant chemotherapy, for head and neck cancer (III)
	4. That transdermal fentanyl may be effective to treat pain due to oral mucositis in patients receiving conventional or high-dose chemotherapy, with or without total body irradiation (III)
	5. That 0.2% morphine mouthwash may be effective to treat pain due to oral mucositis in patients receiving chemoradiation therapy for head and neck cancer (III)
	6. That 0.5% doxepin mouthwash may be effective to treat pain due to oral mucositis (IV)
	7. That systemic zinc supplements administered orally may be of benefit to prevent oral mucositis in oral cancer patients receiving radiation therapy or chemoradiation (III)
Recommendations against an intervention	1. That PTA (polymyxin, tobramycin, amphotericin B) and BCoG (bacitracin, clotrimazole, gentamicin) antimicrobial lozenges and PTA paste not be used to prevent oral mucositis in patients receiving radiation therapy for head and neck cancer (II)
	2. That iseganan antimicrobial mouthwash not be used to prevent oral mucositis in patients receiving high-dose chemotherapy, with or without total body irradiation, for HSCT (II), or in patients receiving radiation therapy or concomitant chemoradiation for head and neck cancer (II)
Recommendations against an intervention	1. That sucralfate mouthwash not be used to prevent oral mucositis in patients receiving chemotherapy for cancer (I) or in patients receiving radiation therapy (I)[a] or concomitant chemoradiation (II)[b] for head and neck cancer
	2. That sucralfate mouthwash not be used to treat oral mucositis in patients receiving chemotherapy for cancer (I) or in patients receiving radiation therapy (II) for head and neck cancer
	3. That intravenous glutamine not be used to prevent oral mucositis in patients receiving high-dose chemotherapy, with or without total body irradiation, for HSCT (II)

(*continued*)

Table 2 (continued)

Suggestions against an intervention	1. That chlorhexidine mouthwash not be used to prevent oral mucositis in patients receiving radiation therapy for head and neck cancer (III)[c]
	2. That granulocyte-macrophage colony-stimulating factor mouthwash not be used to prevent oral mucositis in patients receiving high-dose chemotherapy, for autologous or allogeneic stem cell transplantation (II)
	3. That misoprostol mouthwash not be used to prevent oral mucositis in patients receiving radiation therapy for head and neck cancer (III)
	4. That systemic pentoxifylline, administered orally, not be used to prevent oral mucositis in patients undergoing bone marrow transplantation (III)
	5. That systemic pilocarpine, administered orally, not be used to prevent oral mucositis in patients receiving radiation therapy for head and neck cancer (III), or in patients receiving high-dose chemotherapy, with or without total body irradiation, for HSCT (II)
Gastrointestinal mucositis	
Recommendations in favor of an intervention	1. That intravenous amifostine be used, at a dose of $\geq$340 mg/m^2, to prevent radiation proctitis in patients receiving radiation therapy (II)
	2. That octreotide, at a dose of $\geq$100 μg subcutaneously twice daily, be used to treat diarrhea induced by standard- or high-dose chemotherapy associated with HSCT, if loperamide is ineffective (II)
Suggestions in favor of an intervention	1. That intravenous amifostine be used to prevent esophagitis induced by concomitant chemotherapy and radiation therapy in patients with non-small cell lung carcinoma (III)
	2. That sucralfate enemas be used to treat chronic radiation-induced proctitis in patients with rectal bleeding (III)
	3. That systemic sulfasalazine, at a dose of 500 mg administered orally twice a day, be used to prevent radiation-induced enteropathy in patients receiving radiation therapy to the pelvis (II)
	4. That probiotics containing *Lactobacillus* species be used to prevent diarrhea in patients receiving chemotherapy and/or radiation therapy for a pelvic malignancy (III)
	5. That hyperbaric oxygen be used to treat radiation-induced proctitis in patients receiving radiation therapy for a solid tumor (IV)[d]
Recommendations against an intervention (continued)	1. That systemic sucralfate, administered orally, not be used to treat gastrointestinal mucositis in patients receiving radiation therapy for a solid tumor (I)
	2. That 5-acetyl salicylic acid (ASA), and the related compounds mesalazine and olsalazine, administered orally, not be used to prevent acute radiation-induced diarrhea in patients receiving radiation therapy for a pelvic malignancy (I)
	3. That misoprostol suppositories not be used to prevent acute radiation-induced proctitis in patients receiving radiation therapy for prostate cancer (I)

[a]Level of evidence: level I. Evidence obtained from meta-analysis of multiple, well-designed, controlled studies; randomized trials with low false-positive and false-negative errors (high power)
[b]Level of evidence: level II. Evidence obtained from at least 1 well-designed experimental study; randomized trials with high false-positive and/or false-negative errors (low power)
[c]Level of evidence: level III. Evidence obtained from well-designed, quasi-experimental studies such as nonrandomized, controlled single-group, pretest-posttest comparison, cohort, time, or matched case-control series
[d]Level of evidence: IV. Evidence obtained from well-designed, nonexperimental studies, such as comparative and correlational descriptive and case studies

studies (incorporating newer toxicogenomic and metabolic profiling) is likely to contribute greatly to drug development.

1.4 Pharmacological/Interventional Therapies Specific to Mucositis

1.4.1 Palifermin

Palifermin is a human recombinant version of keratinocyte growth factor (KGF-1), a substance that occurs naturally in the body that is involved in growth and repair of the GI mucosa. Palifermin decreases the severity and duration of oral symptoms of mucositis and is indicated for use in patients with hematological malignancies who are undergoing high-dose chemotherapy and total body irradiation (TBI), followed by autologous stem cell or bone marrow transplant. Current MASCC/ISOO guidelines recommend administration of 60 μg/kg/day of intravenous palifermin 3 days prior to TBI conditioning and 3 days following transplant for the prevention of oral mucositis in this subset of patients (Table 2) (Raber-Durlacher et al. 2013). In patients receiving only high-dose chemotherapy (such as melphalan) as a conditioning regimen, it has been shown that palifermin has no significant impact on oral mucositis (Blijlevens et al. 2013; Goldberg et al. 2013), supporting the evidence that the underlying mechanisms of CT- and RT-induced mucositis are slightly different.

1.4.2 Other Pharmacological Agents in Preclinical Trials

GLP-2 Analogues

Glucagon-like peptides (GLPs) are regulatory peptides that are released by L cells of the ileum and colon in response to nutrient consumption. GLP-2, upon binding to GLP-2 receptors, stimulates crypt cell proliferation, aids nutrient absorption, reduces GIT mobility, and reduces epithelial permeability; however, naturally occurring GLP-2 has a very short half-life of approximately 7 minutes, making it impractical as a pharmaceutical agent. GLP-2 analogues created by changes to the N-terminus cleavage site have an increased resistance to enzymatic degradation, thus increasing the half-life to 2–3 hours. The GLP-2 analogue teduglutide has been shown to improve symptoms of a number of debilitating GI diseases (such as Crohn's disease, ulcerative colitis, and short bowel syndrome (SBS)), which have similar symptom profiles as cancer treatment-induced mucositis. Following this, a number of preclinical studies have investigated the effects of GLP-2 analogues on CT-, RT-, and TAT-induced mucositis (Boushey et al. 2001; Kissow et al. 2012, 2013; Rasmussen et al. 2010), and these studies have shown promising results, with increased body weight, decreased inflammatory response, reduced incidence of diarrhea, and improved histological parameters. Progression into phase II and phase III clinical trials has already begun in the case of teduglutide in SBS patients (Schwartz et al. 2016); further studies into mechanisms of GLP-2 analogue-induced improvement of cancer treatment-induced mucositis may precipitate similar progression into clinical trials in the near future.

R-spondin1

R-spondin1 is a protein that is involved in the modulation of the Wnt/b-catenin signaling pathway, which is involved in maintaining the homeostasis of the GI mucosa by promoting epithelial cell growth and regeneration. Several preclinical studies using mouse models have demonstrated R-Spondin1-induced increases in small intestinal length, weight, and diameter, coinciding with increased crypt hyperplasia and maintained tissue architecture and goblet and Paneth cell characteristics (Abraham and Cho 2005; Kim et al. 2005). Other preclinical studies have shown that R-Spondin1 was able to ameliorate RT-induced GI mucositis (Bhanja et al. 2009) and CT- and RT-induced oral mucositis, both oral and GI (Zhao et al. 2009). Further studies have suggested that R-Spondin1 is able to activate stem cells; in mouse models, R-Spondin1 administered to animals following a lethal dose of either 5-FU or whole body or abdominal radiation and was shown to significantly improve the rate of survival compared to controls, presumably through reduced loss of intestinal stem cells, increased

epithelial proliferation and improved intestinal architecture (Zhou et al. 2013). These findings are very encouraging and will hopefully translate into the clinical setting.

1.5 Current and Emerging Therapies

1.5.1 Basic Oral Care

The importance of basic oral care in the prevention and management of oral mucositis has been highlighted in several clinical guideline sets and is recommended for all patients receiving cancer therapy. Systematic review in 2012 resulted in the development of a MASCC/ISOO guideline recommending the use of basic oral care before and during all cancer treatment modalities in patients of all ages, to prevent the development of the symptoms of OM (Table 2) (McGuire et al. 2013). Institution and continuation of oral care protocols (such as brushing, flossing, rinsing, and moisturizing), dental care before initiation of and during cancer therapy, and the use of bland rinses such as normal saline or sodium bicarbonate are likely to play a role in achieving and maintaining a healthy oral environment that is less likely to be involved in the development of OM (Rubenstein et al. 2004).

1.5.2 Cryotherapy

Cryotherapy was first reported as a suitable intervention for oral mucositis in patients receiving 5-fluorouracil (5-FU) in 1991 (Mahood et al. 1991) and has been investigated in a number of clinical trials and meta-analyses since then (Peterson et al. 2013). The therapy is simple and cost effective and based around holding ice within the mouth for up to 30 minutes. The exact mechanisms of action have not been fully elucidated; however, the consensus is that vasoconstriction limits the delivery of cytotoxic drugs to the vulnerable tissue, therefore preventing the development of OM. The MASCC clinical guidelines regarding cryotherapy recommend use in patients receiving bolus doses of 5-FU, edatrexate, and high-dose melphalan as an HSCT conditioning agent (with or without TBI) to prevent and decrease symptoms of oral mucositis (Table 2) (Raber-Durlacher et al. 2013; Peterson et al. 2013). Time of application varies from 20 to 30 minutes; it has been shown that holding ice within the mouth for longer than 30 minutes causes discomfort and that no benefit is gleaned in extending the application period.

1.5.3 Low-Level Laser Therapy (LLLT)

The use of low-level laser therapy (LLLT) is based on the fact that low doses of radiation are beneficial to cells, rather than harmful. LLLT is a phototherapy, which is thought to work by promoting photophysical, photochemical, and photobiological changes in cells through absorption of visible light by endogenous photoreceptors, without inducing excess heat (above 37 °C) (Smith 1991). The most common sources for low-intensity lasers (LILs, representing coherent light) and light-emitting diodes (LEDs, representing incoherent light) are those that emit energy in the red or near-infrared end of the spectrum (in the wavelength range of 630–650 nm) and include the helium-neon laser (632.8 nm), the gallium-aluminum laser (630–685 nm), the helium-neon-arsenate laser (780–870 nm), the gallium-arsenate laser (904 nm), and LEDs (670–950 nm). Use of these wavelengths allows for deep penetration into tissues; additionally, hemoglobin does not absorb these wavelengths, meaning that oxygen delivery into tissues is not adversely affected. It is proposed that LLLT has a biostimulatory effect, causing increased cell proliferation (which aids in wound healing) and anti-inflammatory effects, both of which are required to decrease severity of mucositis.

In the most recent MASCC/ISOO systematic review, no difference between the use of coherent vs incoherent light was found (Migliorati et al. 2013). A recommendation was formed for the use of a LIL (wavelength 650 nm, power of 40 mW, with each square centimeter of tissue being treated for the time required to reach a tissue energy dose of 2 joules per square centimeter) for the prevention of oral mucositis in patients receiving HSCT with high-dose chemotherapy conditioning, with or without TBI (Table 2) (Lalla et al. 2014; Migliorati et al. 2013). A suggestion was

made for the use of a LIL of approximate wavelength of 632.8 nm, to prevent oral mucositis in patients undergoing radiotherapy without concomitant chemotherapy for head and neck cancer (Table 2) (Lalla et al. 2014; Migliorati et al. 2013).

1.5.4 Zinc Sulfate

Zinc is required for tissue repair processes in the body, specifically by exerting antioxidant action. Due to its essential role in epithelial proliferation, synthesis of extracellular matrix, and wound healing, zinc has become a focus as a possible intervention for mucositis. Some small RCTs have found that zinc sulfate (given either as a 0.2% mouthwash twice daily for 2 weeks or as 220 mg capsules (three per day)) results in decreased oral mucositis (decreased pain and xerostomia) as measured by the Spijkervet scale and WHO criteria (Arbabi-kalati et al. 2012; Mehdipour et al. 2011). Based on these studies, a guideline was developed, suggesting the provision of zinc supplements to prevent oral mucositis in oral cancer patients receiving radiation therapy or chemoradiation (Table 2) (Yarom et al. 2013). However, since these studies were performed in small cohorts, further investigations are required for validation.

1.5.5 Probiotics

Lactobacillus spp.-containing probiotics have been shown to be effective in preventing CT- and RT-induced diarrhea in a number of RCTs. MASCC guidelines suggest their use to reduce diarrhea in patients with pelvic malignancies, based on the best available evidence (Lalla et al. 2014; Gibson et al. 2013) (Table 2). While originally being developed to treat symptoms of GI mucositis, recent research has shown probiotics (in lozenge form) reduced the symptoms of peri-implant mucositis (Flichy-Fernandez et al. 2015); however, in another study, no improvement in mucositis was shown (Hallstrom et al. 2016). Despite these conflicting results, it may be valuable to translate the study to a cancer treatment-related oral mucositis setting.

A great deal of work has also been performed in various animal models of CT- and RT-induced GI mucositis, in order to investigate the possible mechanisms of action of probiotics. Studies by Stringer and colleagues have demonstrated that not only is the commensal bacteria within the GI tract essential for homeostasis, but can be adversely affected by cancer treatments and contribute to clinical symptoms of AT mucositis, such as diarrhea (Stringer et al. 2009a, b). A preclinical study using a tumor-bearing rat model of CT-induced mucositis showed that a probiotic mixture, VSL#3, significantly reduced clinical symptoms of mucositis, such as weight loss and diarrhea (Bowen et al. 2007). These clinical improvements correlated with improved histopathology compared to controls, including reduced apoptosis and increased proliferation of crypt epithelia. Similar observations have been reported in other preclinical studies (Prisciandaro et al. 2011); however, the mechanisms underpinning the anti-mucotoxic effects of probiotics remain poorly understood, highlighting the need for a more comprehensive in vitro investigation into the AT microbiome.

1.5.6 Honey

The use of topically applied honey is gaining evidence for effective use, with a number of recent meta-analyses and RCTs showing that honey effectively reduces the incidence, duration, and pain of CT- and RT-induced oral mucositis (Xu et al. 2016; Samdariya et al. 2015; Cho et al. 2015; Song et al. 2012). However, there are often some conflicting findings, and it is widely suggested that more robust clinical trials need to be performed to provide a higher level of evidence (Xu et al. 2016; Samdariya et al. 2015; Cho et al. 2015; Song et al. 2012). The mechanisms by which honey is able to reduce OM are not clear. However, there are a number of hypotheses to explain its effectiveness, including the fact that honey has a very high sugar content, which confers antimicrobial properties (by dehydrating microorganisms). Honey also contains glucose oxidase, which catalyzes glucose oxidation to hydrogen peroxide, a known antimicrobial agent (Xu et al. 2016). It has also been shown honey can promote wound healing through granulation formation and epithelial migration (Al-Waili et al. 2011). One of the key drawbacks is that prolonged

application of honey in the mouth is unpalatable and can give rise to a high dropout rate (e.g., >50% in an RCT investigating manuka honey) (Hawley et al. 2014). More study into this potential intervention for OM is needed for any clinical guideline to be made.

1.5.7 Complementary and Alternative Medicines (CAMs)

There are an increasing number of studies investigating the possible anti-mucositis effects of complementary and alternative medicines (CAMs) (Kuchay 2017), including (but not limited to) ginger (Rangwala et al. 2012), emu oil (Abimosleh et al. 2012; Mashtoub et al. 2016), grape-seed extract (Cheah et al. 2014), and curcumin (Yao et al. 2013); however, these studies are often preclinical models, based on small cohorts, anecdotal, and/or express conflicting data. The majority of these CAMs work by modulating the immune system, decreasing the pro-inflammatory response, and thus potentially assuaging mucositis; much of the work being done at present is in determining CAM mechanisms of action, so that these agents may be advanced into clinical trials as potential treatments of mucositis in the near future.

1.5.8 Other Non-pharmacological Therapies

Barometric Chambers

Studies have shown that the use of hyperbaric oxygen chambers may be effective in alleviating symptoms of lower GI mucositis. There exists a current MASCC/ISOO clinical guideline, suggesting the use of hyperbaric oxygen for treating proctitis in patients receiving radiation for solid tumors (Table 2) (Gibson et al. 2013). Hyperbaric oxygen is thought to work by increasing the oxygen gradient in damaged tissues to promote angiogenesis and healing (Allen et al. 2012).

Yoga, Exercise, and Acupuncture

It is suggested that symptoms of mucositis can be partly alleviated by non-pharmacological means, such as exercise (Stubbe and Valero 2013), yoga (Metri et al. 2013), and acupuncture (Pan et al. 2000). However, studies investigating these treatments are often based on small cohorts and poor study design and/or have conflicting results, making generation of clinical guidelines difficult (Lotfi-Jam et al. 2008).

2 Future Research Directions

Mucositis research has evolved greatly over the decade. It is evident that the future of treatment development for mucositis is contingent upon continuing to understand specific pathophysiologies involved, in particular, those associated with different cancer treatment modalities.

2.1 Mucositis, TLR4, and Pro-inflammatory Cytokines

Homeostasis of the gut is carefully balanced by interactions between the resident microflora, epithelial barrier function, and the mucosal immune system (Kelly et al. 2004). Recent research from our laboratory has shown that mucositis disrupts the delicate balance of these three factors (Al-Dasooqi et al. 2014; Wardill et al. 2014a, b, c). This leads to a substantial inflammatory response (Logan et al. 2008) and changes in both epithelial turnover (Gibson et al. 2002) and microflora characteristics (Stringer et al. 2009b). TLR signaling is vital for the maintenance of epithelial homeostasis (Rakoff-Nahoum et al. 2004), is an important modulator of gut bacteria (Lee et al. 2006), and is expressed on the immune cells of the gut. Recently, TLR4 has gained specific interest to mucositis (Wardill et al. 2014b, c, 2015a, b; Gibson et al. 2016). In particular, we have demonstrated TLR4 is overexpressed in the jejunum following chemotherapy during peak intestinal injury; however it is undetectable during the later time points associated with the healing phases (Gibson et al. 2016). These time points were also associated with changes in tight junctions (Wardill et al. 2014b) and changes in matrix metalloproteases (MMPs) (Al-Dasooqi et al. 2010), suggesting there may be a link between them.

Using TLR4 −/− mice, further research conducted by our laboratory demonstrated TLR4 is associated with the development of mucositis and chemotherapy-induced pain (Gibson et al. 2016; Wardill et al. 2016a). It is well established that the gut microbiome is involved in mucositis (Stringer et al. 2008; Stringer 2013), and our recent research has demonstrated that activation from increased exposure to bacterial influx is due to compromised gut barrier integrity (Wardill et al. 2014a, 2016b). Further research is essential in this area.

Activation from increased inflammatory mediators is known to have extensive roles in the pathogenesis of mucositis (Logan et al. 2007a, b, 2008). Specifically, over the time course of mucositis, there is increased production of pro-inflammatory cytokines, in particular TNF, IL-1β and IL-6, and NF-kB, a key transcriptional regulator of these pro-inflammatory cytokines in the gut mucosa (Logan et al. 2008). These are excellent markers of, and play an important role in, the pathogenesis of the chemotherapy-induced inflammatory response and treatment-induced gut toxicity. These markers offer an ideal new research direction for mucositis.

3 Conclusions and Summary

Mucositis research is a rapidly developing field. Over recent years, there has been a number of emerging areas of research that have been postulated to be involved in the pathogenesis of the condition. We have made huge leaps in our understanding of the disease, and new research directions have been undertaken. However, despite these emerging areas, very little has been able to be translated to clinical practice to assist clinicians in treating cancer patients with mucositis. It is hoped that with our continued understanding and new research directions, this will change in the future.

Abstract

Mouth care is very commonly neglected in people with life-limiting illness and in the elderly and frail. However, people with life-limiting illnesses, the treatments required to manage them and the medications used for symptom management, have significant effects on the mouth. The focus of this chapter will be on good oral assessment and care of the mouth in order to maximize quality of life, maintain self-esteem, feelings of well-being and comfort at the end-of-life. The compartmentalization involved in viewing the mouth separately from the rest of the body must cease because oral health affects general health by causing considerable pain and suffering and by changing what people eat, their speech, and their quality of life and well-being (Sheiham 2005).

1 Introduction

Palliative care is an interdisciplinary medical specialty that focuses on prevention and relief of suffering, and yet mouth care is often seen by health professionals as of minor importance despite the high incidence of oral discomfort and infection. People, therefore, do not perceive these symptoms as clinically important and will not always report them and subsequently suffer significant discomfort (Oneschuk et al. 2000). Mouth problems can make a person miserable and prevent them enjoying a healthy diet.

The intraoral structures: the tongue, palate, and teeth serve a number of important functions such as defense, mastication, incision, and signaling with facial expressions. Good oral health is vital for carrying out activities of daily living such as speaking, eating, swallowing, and socializing. It maintains self-esteem, dignity, and respect, providing quality of life. People at the end-of-life are susceptible to a range of oral complications including pain, salivary gland dysfunction, dysphagia, and oral mucosal infections (Wilberg et al. 2012).

The aim of this chapter is to raise awareness of the importance of mouth care for all health professionals involved in the care of people with life-limiting illness and in the older person and those with dementia as oral care is often a neglected area of care. It has distressing implications for quality of life for these people if poorly managed and must therefore become part of individualized care plans. Mouth care is an important indicator as to the quality of care a person is receiving.

2 Anatomy and Function of the Mouth

The oral cavity includes the lips, cheeks, palate (roof of the mouth), floor of the mouth, and the part of the tongue in the mouth, and ducts of the salivary glands. A mucous membrane lines and protects the inside of the mouth. All these organs work together to aid in the ingestion and digestion of food. The structures in the mouth also play an important role in speech, taste, and the first steps of digestion.

Saliva from the salivary glands enters the mouth through ducts. There are four pairs of salivary glands. The submandibular glands are under the jaw, the sublingual glands are under the tongue on the floor of the mouth, the parotid glands are between the ear and the jaw, and the buccal glands are in the mucous membrane in the cheeks and mouth, but they only produce a small amount of saliva. Saliva plays an important role in digestion and is made up of electrolytes, mucus, antibacterial compounds, enzymes, and the main component is water, which forms 98% of the saliva. The saliva moistens the mouth and helps a person chew and swallow food.

Saliva is important for maintaining a healthy mouth by cleansing and lubricating it. It is antimicrobial so reduces the risk of oral infection. It is important for taste and the enzymes it contains helps with the breakdown of food and digestion. Saliva helps maintain mucosal integrity. Saliva maintains oral hygiene.

Taste is another major function of the mouth as the tongue, a strong muscle which moves food around, also has around 10,000 sensory structures (taste buds) located at the sides and base of the tongue. This helps us distinguish four main

flavors: sweet, sour, salty, and bitter. It lets us distinguish flavors and warns us when food should not be eaten.

The gingiva (gums) is the pink soft tissue that surrounds the teeth and covers the jaw bone. Gums are a delicate tissue that can easily get irritated, inflamed, and start to bleed if infected by the bacteria.

3 Why Worry About Mouth Care?

1. People at the end-of-life are vulnerable to oral problems.
2. The impact of oral discomfort impacts on many aspects of the lives of people – the ability to communicate, socialize, and enjoy food and drinks.
3. People at the end-of-life are frequently exposed to compromising factors – the disease process, medications, and the inability to maintain oral fluids.
4. Research has ranked xerostomia in people with advanced disease as the third most distressing symptom (Sweeney and Bagg 2000).

3.1 Risk Factors for Mouth Problems

Preventive mouth care is essential for people receiving palliative care. In a study looking at nursing knowledge and attitudes concerning preventive mouth care, 1 in 20 nurses did not think that mouth care was his/her duty. This care was considered unpleasant and difficult (Bellior and Riou 2014). As disease advances, people become frailer and more debilitated and so the oral mucosa becomes more vulnerable. Medications for symptom management, for example, opioids and anticholenergics, and treatments such as irradiation or chemotherapy can lead to dryness of the mouth allowing the entry of infection through damaged mucosa. The person may be less able to maintain oral intake leading to dehydration and dryness of the mouth. Regular dental appointments may not be a priority, and damaged teeth and dental caries are an added risk for mouth problems.

3.2 Physical Effects of Poor Oral Care

- The person's comfort is compromised.
- Loss of enjoyment of food.
- Loss of appetite and inability to maintain nutrition.
- Swallowing difficulties.
- Poor protection from infection.
- Communication difficulties.

3.3 Psychological Effects of Poor Oral Care

- Frustration.
- Loss of taste means lack of enjoyment of food and fluids.
- Prolonged periods of eating pureed foods.
- Unbearable at times.
- Frustration gives way to annoyance and anger.
- Being misunderstood because of slurred speech.

3.4 Social Effects of Poor Oral Care

- Difficulties in communication leading to embarrassment.
- Social impact of not being able to enjoy and share meals with family and friends.
- Limits social outings and participants at special occasions.
- People avoid close physical contact.

4 Assessment of the Mouth

4.1 Individualized Care

As with all palliative care, planning must be holistic and individualized to be effective. Timely oral care assessment and an individualized regime are required to establish the frequency and type of care required in order to limit the occurrence of oral complications (McGuire 2003).

The key questions to assess oral care are: Is there infection present? Is the mouth dry? Is the mouth dirty? Is the mouth painful? Inspect the mouth carefully and gently using a torch or

light source and a spatula to depress the tongue. Listen carefully to what the person has to say about their mouth and the issues they are experiencing physically, psychologically, and socially.

The use of an oral assessment tool is recommended, and there are many available. When deciding on an oral assessment tool, ensure that it assesses the lips, tongue, mucosa, gingiva, saliva, and teeth or dentures. It should also assess the four phases of oral health: when the mouth is healthy, any early warning signs of problems developing, problems that are present, and any serious problems that need urgent and more intensive treatment. Ensure it is appropriate to the setting where it will be used. (Links to some examples are in the appendix at the end of the chapter). This will ensure better planning of an individualized care regimen.

4.2 Oral Assessment Guide

- Listen to the person's voice – Has it changed?
- Are they able to swallow or are they experiencing any difficulties?
- What is the texture of their lips? (dry, cracked, bleeding?)
- Look at the tongue – Is it coated, blistered, red, dry or sore?
- Do they have saliva? What is the consistency?
- Look at the mucous membrane – Is it coated? Are there any ulcers?
- What does the gingiva look like? (edematous, red, bleeding?)
- Check the teeth/dentures (plaque or debris, broken or cracked?)

4.3 Dry Mouth (Xerostomia)

This is a common symptom causing significant morbidity and distress as a result of a lack of saliva. There are multiple causes and each needs careful consideration (Figs. 1 and 2).

- Dehydration
- Psychological such as fear and anxiety

Fig. 1 Severe mucositis caused by radiation

Fig. 2 Candidiasis (oral thrush) in a dehydrated person

- Medications such as antidepressants, anticholinergics, morphine
- Radiation to head and neck
- Diabetes mellitus
- Liver cirrhosis
- Infections
- Sjogren syndrome
- Oral candida must be excluded or if present treated

To manage a dry mouth, it is necessary to keep it moist and to replicate or stimulate saliva production. The oral cavity, including the lips, requires moisture for its integrity.

Several options may need to be tried to gain relief.

- Treat any causes that are treatable such as candida
- Have frequent sips of water and/or artificial saliva spray/drops

- Sucking on sugar-free candy or chewing sugarless gum
- Drinking diet drinks which have a low pH
- Reducing caffeine and alcohol
- A cool mist humidifier at night may provide some relief
- Eat soft, moist foods that are cool or at room temperature
- Moisten dry foods with broth, sauces, butter, or milk
- Semifrozen fruit juice or pieces of fruit
- Moisten lips or apply lip balm
- Clean teeth after each meal with a soft tooth brush
- Dental referral as necessary
- Medications such as pilocarpine **(check drug information before using)**
- Avoid dry, coarse, or hard foods
- Avoid acidic or spicy foods that can burn the mouth
- Avoid glycerine and thymol mouthwash as this is hygroscopic

Oral pain needs to be treated with both systemic and topical treatments. Opioids may be necessary especially when there is severe mucositis or candida infections. Local anesthetics can be used topically.

4.4 Care Plan Summary

Meticulous documentation of the assessment and plan of care for managing any identified problems is important to ensure continuity of oral care. Mouth care should be offered at least four times a day: after each meal and at night. The oral assessment should be repeated daily and management changed as needed.

5 Oral Care for People with Dementia

The number of people with dementia is increasing as the population ages. Dementia is a life-limiting illness, and these people need a palliative approach to care from diagnosis. Special attention to oral hygiene is therefore important as they may be neglecting it themselves or no longer able to attend to their own oral care. "Poor dental health can affect the person's comfort, appearance, eating, nutrition, behaviour and general health. Every person with dementia needs an individualised preventive approach to dental care." (Boyle et al. 2014).

When a person is diagnosed with dementia, an oral hygiene plan should be established. Family and/or carers will need to be part of the planning and ongoing explanations of the importance of good oral hygiene are given to the person with dementia. The use of an assessment tool will be useful as the information provided by the person with dementia may be unreliable.

Dementia is under recognized and therefore oral problems can occur and become problematic. Challenging behaviors may occur in these people as they may have significant pain, infection, and broken teeth or ill-fitting dentures that have not been addressed.

As dementia progresses, communication may also be impaired, and it is vital that an individualized preventive oral hygiene plan is in place and must involve the family, carers, and person's dentist. Prevention of issues is preferable to the person needing dental procedures as they may cause unnecessary anxiety and pain.

Oral hygiene prevention must be part of care planning for all people with dementia and there needs to be resources, policies, and procedures in place to ensure that this is done.

6 Care of the Mouth as Death Is Imminent

The desire to eat or drink at the end-of-life usually decreases. This is a natural response of the body as the organs are slowing down, and it becomes difficult to manage the intake of food and/or fluids and the person can feel quite dry. This is a normal part of having advanced disease – it is not that "they are starving to death." They are dying from their advanced disease and trying to force them to eat or giving artificial fluids through artificial

means will not alter the dry feeling they have. Communicating this to the family is an important part of palliative care.

The best way to make the person feel better is to provide frequent fluids while they are able to drink and when that is no longer possible to keep moistening their mouth as will be discussed below. Good mouth care is as important as death approaches as at any other time when living with a life-limiting illness.

People at the end-of-life are vulnerable to oral problems, such as candida, no matter how well their mouth is cared for so it is important to assess the mouth regularly as discussed earlier in this chapter.

Xerostomia (the subjective sensation of dryness of the mouth) is the most common oral issue experienced as a person is dying. The options suggested previously can be used but first assess the person's ability to swallow.

6.1 Dry Mouth Alternatives That May Be Tolerated at the End-of-Life

- Semifrozen tonic water and gin
- Semifrozen fruit juice or pieces of frozen pineapple
- Frequent sips of cold water or water sprays
- Warm tea or coffee
- Warm miso soup or other familiar tastes
- Frozen popsicles made from fluids the person likes
- Lip balm on the lips

6.2 Mouthwashes

There is little conclusive evidence to support the use of many of the proprietary mouth washes, but some people have used them daily for much of their life and may wish to continue to do so, but often towards the end-of-life the taste can be too strong. Outlined are some mouthwashes that may be tried and may need to be used for short periods if there is oral candida or coating in the mouth.

In end-of-life care, it is more important that fluids used are acceptable and palatable to the person.

- Water – is usually acceptable, it is inexpensive, but it will not remove coating.
- Normal saline (salt and water – 1 tsp to 500mls) – is inexpensive, mildly antiseptic but may not be acceptable if a person has altered taste or feels sick.
- Sodium bicarbonate – can clean coated tongue, **BUT** it has an unpleasant taste and can be irritant. Sodium bicarbonate is sometimes on sponge swabs – these can be used for **short** periods for a coated tongue but not as the regular mouth swab.
- Cider and soda water 1:1 – pleasant tasting and the effervescence may help in loosening debris.
- Over the counter mouthwashes – often too astringent and painful in sore mouths.
- Glycerine and lemon mouthwashes or mouth swabs **should be avoided.**
  - **INCREASE** dryness as they are hygroscopic
  - Exhaust the salivary glands from the effects of lemon
  - Citric acid damages tooth enamel
  - Accelerates decalcification
  - Increases the likelihood of painful tooth sensitivity
  - No evidence of cleaning properties (Milligan et al. 2001)

6.3 Oral Care for the Person Who Is Dying and Can No Longer Drink

This is an important aspect of end-of-life care and is something that family, friends, and carers can be taught to do very easily, if they wish, and this can allow them special time with the person. As food has significant cultural connection to caring for a person, inviting the family to do the oral care can help reduce the feeling that their loved one is being "starved to death." People with advanced disease at some point, lose their appetite, stop eating, and drinking and mouth care is a very

special way to care and maintain comfort and dignity until death.

- Find out from the person and the family what fluids they like.
- Mouth care should be done two hourly or more frequently if required to keep the mouth moist.
- Use large plain swabs not swabs that are impregnated with sodium bicarbonate or other substances.
- Teeth can be gently cleaned with a soft toothbrush.
- Use any fluids familiar to the person to swab the mouth – cooled tea or coffee, fruit juice, carbonated drinks, alcohol, cooled clear soups, ice cream, or yogurt. This will allow family to provide special things for their loved one. The familiar fluids and touch of family or friends will lessen the shock for the person, of having something placed in their mouth, particularly if they are not fully awake.
- Avoid iced water – this can be a shock for a person especially if they have sensitive teeth.
- It is the act of moistening the mouth and **NOT** the fluid you use that is important in the last days of life.
- Take care if the mouth is painful or ulcerated and bonjela may be useful to relieve the pain – just put a little on a swab and very gently coat any sore areas. Bonjela is contraindicated if there are bleeding mouth ulcers.
- If a person has a history of high alcohol intake, swabbing their mouth with alcohol may keep them more settled.
- Clean dentures and soak in antiseptic solution overnight.
- Take care not to put a toothbrush or swab near the back of the mouth or it may cause gagging.
- Use gentle pressure with swabs or toothbrush.
- Lip balms are useful to keep lips moist.

7 Changing Practice

Stress the importance of mouth care to all health professionals and provide ongoing education to begin the process of change. Creating guidelines and implementing protocols and procedures for oral assessment and care planning will be imperative and will also provide a way to audit oral care practice.

Ensure resources and products are available. Providing information leaflets for health care professionals and for people and their families about the importance of oral care and how to assess the mouth will give understanding of the significance of oral symptoms by all concerned.

8 Conclusion

Oral problems especially dryness are a significant problem for people at the end-of-life and impact on people's feelings and affect their quality of life. Oral care must therefore be raised to a clinical priority in hospice, hospital, and community settings to improve standards of holistic palliative care (Rohr et al. 2011). Oral care documentation must be implemented in all settings and audit used to ensure oral care is seen as a priority in order that people are not subjected to unnecessary discomfort and die with dignity and comfort.

Skin Symptoms

21

Frank Brennan, Mathew Dutton, and Linda Magann

Contents

Abstract

The skin is the largest organ of the body. In life-limiting illnesses, there are a number of important skin manifestations that may cause considerable suffering to patients and, indirectly, to their family and carers. They include pruritus, pathological sweating, skin failure, and malignant cutaneous wounds. This chapter will review the pathophysiological mechanisms, epidemiology, assessment, and management

of these manifestations. Each section will be accompanied by a set of evidence-based management recommendations for clinicians.

1 Introduction

This chapter will review the symptomatology of the skin. The skin is our largest organ. It provides a protective border between the internal and external environment. Life-limiting illnesses can often manifest with skin problems. Those manifestations include troubling symptoms (pruritus, sweating), skin failure, and malignant cutaneous wounds. All are vexatious. All may add grievously to the suffering of the patient. Historically, management of these skin manifestations has largely been empirical, hampered by an inadequate understanding of their pathophysiological bases. Greater understanding is leading to a more strategic approach to management.

This chapter will examine, as they relate to life-limiting illnesses:

1. Pruritus
2. Sweats
3. Skin failure
4. Malignant cutaneous wounds

2 Pruritus

Itch or pruritus is defined as "an unpleasant sensation associated with the desire to scratch" (Haffenreffer 1660). The symptom of pruritus has a physical and psychosocial dimension and can cause great suffering to patients. Until recent years it was a poorly understood symptom. Pruritus can manifest in several life-limiting illnesses including:

1. Cholestatic pruritus in disorders of the liver and biliary tract
2. Uremic pruritus in chronic renal disease
3. Paraneoplastic pruritus

Prior to reviewing the current understanding of these discrete pruritus syndromes, it is useful to summarize the current knowledge of the pathophysiology of pruritus generally. Hopefully, that knowledge illuminates the etiology and management of each syndrome and guides future treatment strategies. Management of these pruritus syndromes disconnected from an understanding of underlying pathophysiology means that treatment remains empirical. For pruritus, "management divorced from mechanism reveals only part of a complex story. An alliance between mechanism and management will, ultimately yield greater dividends for basic scientists, clinicians and patients alike" (Brennan 2016).

The Pathophysiology of Pruritus: A Brief Summary

As with other somatosensory modalities, the initial signaling of pruritus occurs in the skin and is transmitted by sensory fibers to the dorsal horn of the spinal cord and via spinothalamic fibers centrally to the thalamus and brain. Modern research reveals:

1. The signal of itch is transmitted from the skin by C and A delta fibers. A small cohort (approximately 5%) of C fibers are itch-dedicated fibers.
2. Of those itch-dedicated C fibers, 10% are histamine dependent, and 90% are histamine independent. Those cohorts of neurons are mutually exclusive.
3. Histamine activates histamine-dependent itch fibers.
4. Multiple other pruritogens activate non-histaminergic itch fibers.
5. The activation of nerve endings transmitting the signal of itch results from a complex interaction or "cross talking" between skin cells in the epidermis and dermis.

For a more detailed overview of the pathophysiology of pruritus, readers are advised to consult a recent review (Brennan 2016). The above summary reveals that several widely held conceptions of pruritus are false. The first is that itch, of whatever etiology, is the result of peripheral histamine released by dermal mast cells triggering histamine itch receptors on nerve afferents. Certainly, that mechanism reflects histaminergic

itch, but 90% of itch is transmitted via a non-histaminergic pathway. The second myth, a corollary of the first, is the first-line therapy for all forms of pruritus is antihistamines. For itch that has a non-histaminergic etiology, antihistamines have little if any efficacy.

Itch Assessment

There are various instruments used to measure the severity of pruritus. In research, the most widely used has been the visual analogue scale (VAS). In recent years there has been an increasing focus on developing multidimensional itch instruments to better reflect the full experience of itch by a patient, including the effect of itch on sleep quality, quality of life, and anxiety and depression. One of these instruments is the 5-D itch scale. It comprises five questions that address the duration, degree (severity using a 5-point numerical rating scale), direction of severity (change of symptom in the past 2 weeks), disability, and distribution of pruritus on the skin. It has been validated in patients with chronic pruritus.

Main Pruritus Syndromes Encountered in Patients with Life-Limiting Illnesses

The following section examines in detail the epidemiology, etiology, and management of the main pruritus syndromes encountered in the practice of palliative care. It is a fundamental truth that clinicians will not be aware of a symptom experienced by a patient unless the patient complains of the symptom or the clinician enquires. Given the prevalence of pruritus, it is imperative that clinicians enquire regularly, respond competently, and, where they cannot relieve a symptom such as pruritus, refer wisely to clinicians with an expertise in symptom management such as palliative care.

2.1 Cholestatic Pruritus

Cholestatic pruritus is pruritus that results from cholestasis. Cholestasis, in turn, is defined as an impaired secretion of bile. Normally, bile is produced by hepatocytes, is secreted into the biliary system, and ultimately flows into the small intestine. Accordingly, any interruption to this enterohepatic system leads to an accumulation of substances that are normally excreted into bile. That accumulation causes pruritus, directly or indirectly. The interruption of this enterohepatic circulation has three main causes:

1. *Hepatocellular cholestasis* – failure of hepatocellular secretion of bile. Causes include chronic viral hepatitis or significant hepatic metastases.
2. *Cholangiocellular cholestasis*. This is pathology of the intrahepatic bile ducts. Examples here are primary biliary cirrhosis, primary sclerosing cholangitis, and hepatic metastases.
3. *Obstruction of the intrahepatic and extrahepatic bile duct system*. Examples here are cholangiocarcinoma and carcinoma of the head of the pancreas.

Cholestatic pruritus may be mild to excruciating in severity. It is circadian in presentation with the highest intensity typically occurring in the evening and early night (Kremer et al. 2008). As a result, it may be associated with sleep deprivation and daytime somnolence. The pruritus may be localized or generalized. While there are no primary skin lesions, scratching results in excoriations and if persistent, prurigo nodularis, a pathological response to repeated scratching manifested by skin thickening with nodules (Swain 1999).

Historically, elucidating the precise mechanism of cholestatic pruritus has been elusive. Many theories have been proposed including bile salts, bile acids, endogenous opioids, histamines, serotonins, or steroids. None of these theories have satisfactorily explained the cause of cholestatic pruritus, and for each, no correlation between serum and tissue concentrations and itch intensity has been demonstrated (Kremer et al. 2014). A significant breakthrough in our understanding of the pathogenesis of cholestatic pruritus came recently with the discovery of elevated levels of autotaxin in cholestatic patients with pruritus and, crucially, that the levels correlate with the intensity of pruritus

(Kremer et al. 2012). Autotaxin is an enzyme that converts lysophosphatidylcholine (LPC) to lysophosphatidic acid (LPA):

$$\text{LPC} \xrightarrow{\textit{Autotaxin}} \text{LPA}$$

LPA is a phospholipid. There are several facts that suggest LPA may be critical in the pathogenesis of cholestatic pruritus:

(a) LPA is an active compound and signaling lipid.
(b) LPA injected intradermally causes pruritus. That pruritus is dose dependent (Kremer et al. 2010).
(c) LPA signals LPA receptors that lie on afferent nerve endings in the skin.
(d) LPA activates TRPV1, a known itch channel on afferent nerve endings (Nieto-Posadas et al. 2012).
(e) LPA induces substance P (SP) released from afferent nerve endings.

Substance P is an important signaling neurotransmitter in pruritus and appears to be an important part of the mechanism of cholestatic pruritus. The concentration of serum SP is increased 12-fold in patients with liver diseases experiencing cholestatic pruritus compared to those liver patients without cholestatic pruritus (Trivedi and Bergasa 2010). Substance P stimulates dermal mast cells to release pruritogens. SP is an agonist of the NK-1 receptor, an itch receptor on primary afferent itch nerve fibers in the skin and at the dorsal horn. Substance P acts locally in the skin to increase the production of nerve growth factor (NGF) by keratinocytes. NGF, in turn, causes fresh sprouting of afferent nerve endings in the epidermis.

Another theory of the pathogenesis of cholestatic pruritus that is regularly cited is the so-called opioid hypothesis (Bergasa 2014). This hypothesis states that cholestatic pruritus is mediated by an increase in central opioidergic tone. The evidence for this is that endogenous opioids accumulate in the liver and bile of patients with liver disease (Bergasa et al. 2002), that there is an opioid withdrawal-like reaction triggered by opioid antagonism (Thornton and Losowsky 1988), and that opioid antagonists relieve cholestatic pruritus (Tandon et al. 2007).

Table 1 A clinical approach to the management of cholestatic pruritus

1. Establish the diagnosis. Exclude other causes of pruritus
2. If there is a reversible extrahepatic obstruction, consider a biliary drainage procedure such as a biliary stent or transcutaneous drainage. This involves a careful balancing of the potential benefits and burdens of the procedure and the patient's prognosis, performance status, and wishes
3. Consider one of the following medications:
(a) Cholestyramine 4 g 1 h before and 1 h after breakfast
(b) Rifampicin 300–600 mg/day either 30 min prior to or 1 h after a meal
(c) Ursodeoxycholic acid 15 mg/kg in two to three divided doses per day
4. Other medications with evidence – sertraline, SNRIs, naltrexone, lignocaine, UVB therapy

2.1.1 Management

Cholestatic pruritus is notoriously difficult to treat. Necessarily, that difficulty has been compounded by the mystery of its mechanism. The interventions with the highest level of evidence are listed below. Table 1 summarizes the recommended management.

Surgical Interventions

The objective of a surgical intervention is biliary drainage. That drainage may take various forms – the insertion of a biliary stent, transcutaneous drainage, nasobiliary drainage, or an extrabiliary diversion. As with any surgical intervention in patients with life-limiting illnesses, a careful evaluation is needed of the benefits and burdens of the intervention including the anesthetic risk, performance status, prognosis, and wishes of the patient.

Medical Interventions

The current treatment recommendations for cholestatic pruritus are based on a modest body of literature and clinical experience.

Cholestyramine

Cholestyramine is an anion-exchange resin. It is not absorbed, binds to anions in the small intestine, and is fecally excreted. The level of evidence for its use in cholestatic pruritus is modest. Its efficacy has been shown in small, uncontrolled case series (Datna and Sherlock 1966). Cholestyramine should be avoided in primary biliary cirrhosis (Weisshaar et al. 2012). The dose is 4 g 1 h before and 1 h after breakfast. The most common side effect is constipation.

Rifampicin

Rifampicin is a pregnane X receptor (PXR) agonist. The activation of this receptor inhibits the expression of autotaxin. There are several randomized controlled trials showing significant efficacy in the management of cholestatic pruritus (Ghent and Carruthers 1988). Approximately 10–15% of treated patients develop hepatotoxicity if the treatment extends for weeks to months (Heathcote 2007). The recommended dose is 150 mg bd-tds, either 30 min before or 2 h after a meal.

Ursodeoxycholic Acid

Ursodeoxycholic acid reduces cholestasis by stimulating the secretory capacity of hepatocytes and cholangiocytes. There is limited evidence in cholestatic pruritus. It is not recommended in patients with a significant biliary stenosis. The recommended dose is 10–15 mg/kg/day in two to three divided doses. It is generally well tolerated with few side effects.

Naltrexone

Naltrexone is a mu-opioid receptor antagonist. Several small placebo-controlled trials showed a moderate antipruritic effect (Bergasa et al. 1992; Terg et al. 2002; Wolfhagen et al. 1997). The recommended dose is 25 mg bd on Day 1 and then 50 mg daily.

Sertraline

Sertraline is a selective serotonin reuptake inhibitor (SSRI). In a small pilot, randomized placebo-controlled study, sertraline was reported to be associated with a significant reduction in cholestatic pruritus (Mayo et al. 2007). The recommended dose is 100 mg/day.

Cannabinoids

The endocannabinoid receptors CB1 and CB2 have an antipruritic effect (Gingold and Bergasa 2003). Dronabinol relieved intractable cholestatic pruritus in three patients with chronic liver disease (Neff et al. 2002).

Metronidazole

Refractory cholestatic pruritus in a group of patients with primary biliary cirrhosis was relieved by metronidazole (Berg and Gollan 1992). Metronidazole has not been studied in cholestatic pruritus secondary to malignancy.

Thalidomide

In a small double-blind, placebo-controlled pilot study to assess the efficacy of thalidomide in primary biliary cirrhosis, an improvement in pruritus was felt by five out of seven patients with pruritus in the treatment arm compared to three out of six patients in the placebo group (McCormick et al. 1994). The overall change in itching score did not reach statistical significance.

Ultraviolet Therapy

In an observational case series, Decock and colleagues reported a reduction in pruritus scores in a heterogeneous group of patients with cholestatic pruritus treated with UVB therapy for 8 weeks (Decock et al. 2012).

Lignocaine

Lignocaine has been reported to relieve cholestatic pruritus (Villamil et al. 2005).

Antihistamines

There is no correlation between histamine concentrations and pruritus. In an authoritative review, the authors concluded that histamine is “highly unlikely to play a causative role in cholestatic pruritus” (Beuers et al. 2014). Antihistamines are mostly ineffective in management.

Gabapentin

In a double-blind, randomized, placebo-controlled trial in the management of cholestatic pruritus, gabapentin did not provide significant benefit over placebo (Bergasa et al. 2006).

Ondansetron

In a systematic review of the role of ondansetron in the management of cholestatic and uremic pruritus, To et al. found that ondansetron had negligible effect in both forms of pruritus on the basis of a limited number of studies (To et al. 2012).

2.1.2 Future Therapies

Undoubtedly, the growing level of understanding of the mechanism of cholestatic pruritus will lead to an exploration of new therapeutic agents. Examples include autotaxin inhibitors and LPA receptor antagonists. Examples of a promising class of medications that is currently available are NK-1 receptor antagonists. Aprepitant is a NK-1 receptor antagonist. Substance P triggers the NK-1 receptor located in multiple skin cells and at the dorsal horn. Logically, given the role of substance P in cholestatic pruritus outlined above, and the efficacy shown by NK-1 receptor antagonists in other pruritic conditions in which SP plays a critical role (Stander and Luger 2015), this medication has a promising role. At time of writing, there are no studies on the efficacy of aprepitant in cholestatic pruritus.

2.2 Uremic Pruritus

Uremic pruritus (UP) is itch secondary to chronic kidney disease. It is also named chronic kidney disease-associated pruritus (CKD-aP). It is a common symptom of patients with end-stage kidney disease (ESKD) being managed with dialysis or conservatively. The most comprehensive epidemiologic data is from DOPPS (Pisoni et al. 2006), a large study of dialysis patients which found that 41.7% of patients reported moderate to extreme pruritus. Uremic pruritus is also common in patients with end-stage renal disease being managed conservatively, with a prevalence in studies ranging from 47% (Noble et al. 2010) to 74% (Murtagh et al. 2007).

Uremic pruritus is associated with a decreased quality of life (QOL). Mathur et al. showed a statistically significant relationship between the intensity of UP and health-related quality of life (HR-QOL), particularly with regard to mood, social relations, and sleep. Conversely, they noted that a decrease in intensity of UP of 20% was sufficient to produce a significant improvement in HR-QOL (Mathur et al. 2010). UP is associated with depression, is an independent predictor of mortality, and amplifies other symptoms, especially poor sleep, that impairs QOL and can lead to other poor patient outcomes.

The precise mechanism of UP remains opaque. Multiple theories abound including inadequacy of dialysis, xerosis (dry skin), hyperphosphatemia, hypercalcemia, or hyperparathyroidism. None of these theories are consistently convincing. Indeed, "despite this vast array of possible explanations, none consistently have been demonstrated to be the underlying cause of pruritus associated with CKD. Large epidemiological studies ultimately may facilitate our understanding of the elusive pathophysiological process of this distressing symptom" (Patel et al. 2007). Future basic research has several challenges – to determine the precise precipitant (s) of UP, the immunochemical cascade in the skin in UP that results in the signaling of itch along afferent itch fibers, and the precise neurotransmitters and itch receptors at the dorsal horn and more centrally.

2.2.1 Clinical Presentation

A prospective observational study of 103 HD patients followed over 12 weeks found that 84% of patients with UP experienced itching daily or nearly daily and had itching that affected large, discontinuous but bilateral and symmetric skin areas, which was worse at night and was likely to persist for months to years (Mathur et al. 2010).

It is important to note at the outset that not all patients with ESKD who have itch have uremic pruritus. A differential diagnoses for the cause of pruritus should always be considered in these patients. Diagnoses such as scabies, fungal rashes, psoriasis, allergic reactions to medications, and atopic dermatitis are among the many possible

etiologies. Therefore, the etiology of pruritus in a patient with ESKD is likely, but not invariably, to be uremic pruritus.

2.2.2 Management

As with other pruritic conditions, the management of uremic pruritus has struggled with an inadequate understanding of its mechanism. Over time, multiple therapies have been suggested. Management, if commenced, may be largely empirical. What does the evidence state? Table 2 contains a recommended therapeutic approach.

The management of uremic pruritus may be usefully categorized as:

1. Topical therapies
2. Systemic therapies
3. Ultraviolet therapies
4. Acupuncture

Table 2 Current clinical practice in the management of uremic pruritus

1. Take a careful history. Not every patient with end-stage kidney disease with pruritus has UP. There are a wide number of other dermatological or systemic diseases that may present with pruritus
2. Physical examination with a particular focus on checking for rashes consistent with other dermatological conditions
3. If a diagnosis of uremic pruritus is made:
(a) Check biochemistry, especially calcium, phosphate, and parathyroid hormone (PTH) levels
(b) Check the efficiency of the dialysis. If poor, consider a trial of an increased dialysis dose
(c) If xerosis (dry skin), apply moisturizers bd-tds, especially after bathing. Use gentle soap
(d) Gabapentin. This is a good choice if the patient with UP also reports uremic restless legs syndrome and/or painful diabetic peripheral neuropathy. There is evidence for the efficacy of gabapentin in both. Dosing for dialysis patients – 100 mg post dialysis. For patients with eGFR <15–100 mg, every second night. If eGFR >15–100 mg nocte. Titrate all doses by 100 mg increments according to response and side effects
(e) Other medications to consider: pregabalin, gamma-linolenic acid (GLA) (an active constituent of evening primrose oil), capsaicin cream, sericin cream, pramoxine cream, sertraline, montelukast, kappa-opioid agonists, thalidomide, and UVB phototherapy

Topical Therapies

Emollients

Xerosis is not a cause of UP. Nevertheless its presence exacerbates the symptom. Skin hydration with aqueous skin emollient (Morton et al. 1996) and baby oil (Lin et al. 2012; Karadag et al. 2014) reduces skin dryness and the severity of UP. It is recommended that treatment should therefore begin with moisturizers and cleansers with a low pH (Yosipovitch and Bernhard 2013).

Capsaicin Ointment

Several small placebo-controlled trials have shown a significant benefit in UP with capsaicin cream 0.025–0.03% ointment applied two to four times per day to affected areas (Breneman et al. 1992; Markhlough et al. 2010; Tarng et al. 1996). Unfortunately capsaicin is not well tolerated due to a transient burning feeling on the skin.

Sericin Cream

Aramwit et al. conducted a randomized, double-blind, placebo-controlled experimental study on the use of sericin cream in UP. The mean itching score decreased significantly from moderate to severe at the time of enrollment to mild pruritus after 6 weeks of treatment (Aramwit et al. 2012).

Pramoxine Lotion

Pramoxine hydrochloride 1% lotion was shown to be effective in a randomized controlled double-blind study on 28 hemodialysis patients when applied twice daily for 4 weeks (Young et al. 2009).

Tacrolimus Ointment

There are conflicting results in studies of the efficacy of tacrolimus for UP. Kuypers et al. conducted an uncontrolled prospective study on the effect of 6-week treatment with sequential concentrations of tacrolimus ointment (0.1% and 0.3%) on the severity of UP in 21 hemodialysis patients and again after 2-week washout. The study showed tacrolimus ointment significantly reduced the severity of UP and was well tolerated) (Kuypers et al. 2004). Subsequently, however, in a randomized, double-blind, vehicle-controlled

study of hemodialysis patients, Duque et al. did not demonstrate a significant improvement of tacrolimus 0.1% over a vehicle ointment in relieving UP (Duque et al. 2005).

It is important to note that the US FDA, in response to case reports and animal studies reporting rare associations with malignancies such as lymphoma and skin cancer, issued a black box warning for tacrolimus ointment and recommended that its use be limited to those who have failed other therapies and to treatment periods of less than 6 weeks.

Gamma-Linolenic Acid

In a crossover, placebo-controlled trial of 17 patients with severe refractory uremic pruritus, Chen et al. showed significant efficacy with gamma-linolenic acid, a constituent of evening primrose oil (Chen et al. 2006).

Systemic Therapies

Gabapentin

Gabapentin effect on UP has been studied in 11 studies (8 randomized and 3 observational). In the randomized trials, gabapentin was compared to placebo in five studies. A qualitative systematic review examined this data and recommended gabapentin use for patients not responding to emollients, but that the "results should be interpreted cautiously due to the lower quality of included studies." The authors recommended starting at a dose of 100 mg orally after hemodialysis three times weekly (Lau et al. 2016). In practice, the recommended commencement dose for patients having peritoneal dialysis is 100 mg post dialysis. For those patients on a conservative, non-dialysis pathway, we recommend commencing gabapentin 100 mg every second night if eGFR is <15 mls/min and 100 mg nocte if eGFR is >15 mls/min.

Pregabalin

There is one study that compares pregabalin with placebo in a randomized, double-blind methodology. This was contained in a three-way study conducted by Yue and colleagues (Yue et al. 2015). The trial was a 12-week prospective, randomized, double-blind study of UP in dialysis patients comparing pregabalin 75 mg twice weekly, ondansetron 8 mg daily, and placebo. Over the 12-week period, only pregabalin improved UP significantly. Several prospective cohort studies of pregabalin in UP have shown efficacy (Aperis et al. 2010; Shavit et al. 2013).

Gabapentin and Pregabalin in Sequence

Rayner et al. conducted a trial in a mixed cohort of hemodialysis patients, peritoneal dialysis patients, and patients with chronic kidney disease (CKD) Stage 4 or 5 who were not on dialysis (Rayner et al. 2012). All had UP (median itch severity on VAS was 8 (range 6–10)) with a median duration of pruritus of 6 months. Patients were commenced on gabapentin 100 mg after dialysis or daily. If intolerant to gabapentin, patients were offered pregabalin 25 mg after dialysis or daily. Gabapentin or pregabalin relieved itching in 85% of the 71 patients.

Gabapentin Versus Pregabalin

Solak et al. examined a cohort of hemodialysis patients with *both* UP and neuropathic pain (Solak et al. 2012). Strictly speaking, therefore, then it may be difficult to draw broader conclusions from this study. Looking specifically at the symptom of pruritus, both gabapentin and pregabalin improved the symptom significantly. Indeed, there was no difference between the two medications.

Gamma-Linolenic Acid (an Active Constituent of Evening Primrose Oil)

The efficacy of gamma-linolenic acid has been studied in the management of uremic pruritus in both topical and systemic forms. In the oral form, Yoshimoto-Furuie et al. found that oral gamma-linolenic acid-rich evening primrose oil improved overall skin symptom scores (pruritus, erythema, and dryness) significantly compared to those who received linolenic acid alone (Yoshimoto-Furuie et al. 1999). The pruritus scores obtained from the evening primrose oil group showed a trend toward a greater improvement ($0.05 < p < 0.1$). The mechanism of action is unknown although almost

certainly involves the supplementation of early parts of the n-6 essential fatty acid cascade in the epithelium, thereby increasing the balance of anti-inflammatory cytokines over pro-inflammatory and pruritogenic substances.

Sertraline

Shakiba et al. conducted a before-and-after trial of 19 HD patients with uremic pruritus. Each was given 50 mg daily for 4 months. The itch instrument was an itch questionnaire. The difference in the level of pruritus before and after sertraline was significant (Shakiba et al. 2012).

Thalidomide

There is a single randomized, double-blind placebo-controlled crossover trial of thalidomide showing significant efficacy in the management of UP (Silva et al. 1994). The dose of thalidomide was 100 mg daily.

Kappa-Opioid Agonists

Recent neuroscience literature reveals that activating kappa-opioid receptors has an antipruritic effect. Nalfurafine, a kappa-opioid agonist, has been tested in oral and intravenous form in UP (Kumagai et al. 2010, 2012). The oral form was studied in a randomized, double-blind, placebo-controlled trial and an open-label single-arm prospective trial. In both studies there was a significant response. In the intravenous form, Wikstrom et al. reported a statistically significant effect in two randomized, double-blind placebo-controlled trials of 144 patients on HD with UP who received 5 mcg nalfurafine intravenously three times per week after hemodialysis for 4 weeks. The authors did a meta-analysis of these two studies and showed a moderate, although significant, benefit in pruritus (Wikstrom et al. 2005).

Montelukast

Montelukast is a leukotriene receptor antagonist. Leukotriene B4 is a potent pruritogen. Nasrollahi et al. conducted a randomized, single-blind, placebo-controlled crossover study of the efficacy of montelukast in the treatment of refractory UP in 16 hemodialysis patients in 5 dialysis centers (Nasrollahi et al. 2007). The patients were divided into two groups to receive, firstly, montelukast and then placebo or vice versa. The dose of montelukast was 10 mg daily for 20 days with a washout period of 14 days. With montelukast, the severity of pruritus was reduced by 35% (95% CI, 9.5–6.2%), while it was reduced 7% (95% CI, 0.5–15.9%) with placebo ($p = 0.002$).

Antihistamines

Antihistamines have not been shown to be effective in UP (Weisshaar et al. 2004). They are not recommended in recent reviews of UP (Mettang 2014; Combs et al. 2015). Crucially, fMRI reveals that the central transmission of itch in UP is through a non-histaminergic pruritus pathway and not a histaminergic pathway (Papiou et al. 2014).

Naltrexone

The rationale behind the use of naloxone is the so-called opioid theory of pruritus. It has been noted that mu-receptor agonists can precipitate itch, especially the use of morphine in spinal anesthesia. Does naloxone have an antipruritic effect in UP? There are three randomized controlled trials examining the antipruritic effect of oral naltrexone in UP. Two were placebo-controlled, double-blind crossover trials. In the third study, the comparator was antihistamine. The studies have conflicting results. One of the placebo-controlled trials of 15 hemodialysis patients showed a statistically significant benefit (Peer et al. 1996). The second placebo-controlled study of 16 dialysis patients showed no statistically significant benefit (Pauli-Magnus et al. 2000). In the study comparing naltrexone to antihistamine, there was no significant difference in the VAS scores of pruritus after treatment with oral naltrexone (Legroux-Crespel et al. 2004).

Ondansetron

A randomized, placebo-controlled, double-blind trial of ondansetron in UP showed that ondansetron was no better than placebo (Murphy et al. 2003). In a systematic review, To et al. found that ondansetron has a negligible effect on UP on the basis of a limited number of trials (To et al. 2012).

Ultraviolet Therapy

The results of the studies on the efficacy of ultraviolet light for uremic pruritus are inconsistent. That inconsistency may, with time, be explicable on the basis of the specific bandwidth of the ultraviolet therapy employed. In the 1970s Gilchrest et al. published two small studies showing efficacy for broadband UVB (BB-UVB) therapy for UP (Gilchrest et al. 1977; Gilchrest et al. 1979). In 1991, Tan et al. published a meta-analysis of randomized controlled trials of UP and concluded that UVB therapy successfully fulfilled the criteria for clinical significance of a reduction in pruritus scores of at least 50% (Tan et al. 1991). More recently, a single-blind, randomized controlled trial of narrowband UVB (NB-UVB) therapy by Ko et al. did not show a significant benefit compared to a control group for refractory UP (Ko et al. 2011).

Acupuncture

Kim et al. published a meta-analysis of six studies (three RCTS and three uncontrolled observational studies) of needle acupuncture for UP (Kim et al. 2010). The authors concluded that, despite all trials reporting efficacy, most of the trials showed a high risk of bias, and therefore current evidence is insufficient to support its efficacy.

Future Therapies

Various agents have been mooted as possible future therapies. They include cannabinoids and NK-1 receptor antagonists.

A summary of current clinical practice based on this literature appears in Table 2.

2.3 Paraneoplastic Itch

Pruritus may be a paraneoplastic manifestation of malignancy. It is defined as "the sensation of itch as a systemic (not local) reaction to the presence of a tumor or a haematological malignancy neither induced by the local presence of cancer cells nor tumor therapy" (Weisshaar et al. 2015).

There is limited data on the epidemiology of paraneoplastic pruritus. One retrospective study of 700 patients with solid tumors and hematologic malignancy reported a 5.85% prevalence of pruritus (Kilic et al. 2007). The most common malignancy associated with generalized pruritus is Hodgkin's lymphoma with a prevalence of 25% of presentations (Rubenstein and Duvic 2006). Other malignancies associated with pruritus are cutaneous T-cell lymphomas (CTCL), multiple myeloma, breast cancer, carcinoid syndrome, and gastrointestinal and hepatocellular carcinomas.

Cutaneous T-cell lymphomas are characterized by a clonal accumulation of T lymphocytes in the skin. There are multiple subtypes. The most common variant is mycosis fungoides; the most aggressive variant is Sezary syndrome. Pruritus is common in both variants. It occurs more commonly in Sezary syndrome than mycosis fungoides. In both conditions, pruritus is significantly more severe in the later rather than earlier part of the disease trajectory.

2.3.1 Pathogenesis

The pathogenesis of pruritus in malignancy is unknown. Almost certainly, malignant cells release substances that, directly or indirectly, precipitate the triggering of itch. To date, evidence for the precise details of this process is circumstantial. For instance, Hodgkin's lymphoma is a B-cell lymphoproliferative syndrome characterized by the presence of Reed-Sternberg cells. Between 25% and 50% of patients suffer various B-cell symptoms including weight loss, fever, sweats, and pruritus. Sezary syndrome is characterized by an increased production of Th2 lymphocytes. This leads to an imbalanced production of Th2 cytokines (IL-4, IL-5, IL-10, IL-31) and IgE and an infiltration of eosinophils. The level of serum IL-31, a key pruritogen produced by Th2 lymphocytes, correlates with the level of pruritus in CTCL, and resolution of pruritus correlates with a decreased serum IL-31. There is a circumstantial evidence for the pruritogenic role of substance P in Hodgkin's lymphoma and CTCL as there is a positive role for aprepitant, a NK-1 receptor antagonist, in the management of intractable pruritus in these conditions.

2.3.2 Management

Paraneoplastic pruritus is often refractory to conventional medications such as antihistamines or corticosteroids. In Hodgkin's lymphoma, case studies have shown a significant improvement with thalidomide (Gonclaves 2010) and aprepitant (Villafranca et al. 2014). The pruritus of Hodgkin's lymphoma may be enhanced by concurrent *Staphylococcus aureus* colonization of the skin and may settle with antimicrobial treatment (Rubenstein and Duvic 2006). In non--Hodgkin's lymphoma, kappa-opioid receptor agonists have been shown to rapidly reduce pruritus (Dawn and Yosipovitch 2006). For the management of pruritus in CTCL, there is a modest body of evidence. Antihistamines have no or negligible response. High-dose topical steroids have shown efficacy in early-stage CTCL. Gabapentin and mirtazapine have been reported to show efficacy (Demierre and Taverna 2006). In Sezary syndrome, aprepitant is a promising intervention. Several case series have shown a significant improvement (Duval and Dubertret 2009). A similar benefit for aprepitant was shown in a small case series of patients with mycosis fungoides (Booken et al. 2011). Histone decarboxylase inhibitors, such as vorinostat and romidepsin, inhibit the replication of T lymphocytes and, as a result, their release of pruritogens including IL-31. This class of medications could be considered, therefore, in patients with CTCL suffering from pruritus to treat both the underlying malignancy and the pruritus (Rowe and Yosipovitch 2016).

3 Sweating

3.1 Introduction

Sweating is a normal physiological response to hyperthermia or physical exertion. If sweating is pathological, it may be highly distressing and debilitating. Like pruritus, this symptom is often overlooked, underdiagnosed, and poorly managed. The underlying mechanism of normal sweating is poorly understood by most clinicians, and its pathological manifestation beyond sepsis is mysterious and inexplicable. Inevitably, this inexplicability leads to faltering management and therapeutic nihilism. The objective of this section is to review the normal physiology of sweating, the etiology of pathological sweating with a particular focus on sweating as a symptom of life-limiting illnesses, and its management.

3.2 Physiology of Normal Sweating

In a resting condition, humans dissipate body heat at a rate approximately equal to heat production. The body is sensitive to changes in temperature and adapts to higher or lower temperatures. The human body has central and peripheral thermoreceptors. The central receptors are in the brain stem, spinal cord, and viscera. The peripheral thermoreceptors lie in the skin. Of the two sets of receptors, the central thermoreceptors have the most influence on the body's response to temperature change.

An elevated or reduced temperature activates these thermoreceptors. That information is communicated to the central thermoregulatory center, located in the anterior hypothalamus. In this center, warm-sensitive and cold-sensitive neurons respond to variations in body temperature. The center integrates this information. Efferent nerves pass from the hypothalamus to effect both an autonomic and peripheral thermoregulatory responses. If the body temperature is high, the autonomic thermoregulation takes the form of heat dissipation by two methods: vasodilation of the blood vessels in the skin and sweating. Sweating reduces the body temperature by evaporation. Classically, sweating "is the greatest avenue of heat loss in hyperthermia" (Smith and Johnson 2016).

Impulses originating from the central thermoregulatory center are transmitted via the spinal cord, exit the spinal cord at the ventral horn, and synapse with sympathetic ganglia. Postganglionic fibers combine with the peripheral nerves and travel to and entwine around the sweat glands. The sympathetic nerves consist principally of cholinergic terminals (M3 receptors) and, to a lesser extent, adrenergic terminals (alpha and

beta receptors). The sympathetic nerve fibers that release acetylcholine (ACh) stimulate M3 receptors on sweat glands. While ACh is the major neurotransmitter responsible for sweating, there is also an activation of alpha- and beta-adrenergic receptors. In addition to a central drive for sweating, a local enhancement occurs. ACh stimulates an axonal reflex which travels back up the nerve to other nerve terminals culminating in the further release of ACh.

In the practice of palliative care, sweating may be a pathological and disabling symptom of a life-limiting illness or its management. Such pathological sweating may be the source of significant suffering. For a list of causes of pathological sweating, see Table 3.

Paraneoplastic fevers and sweating are difficult to diagnose with certainty. These symptoms are identical to a presentation with sepsis as a complication of the malignancy itself or the cancer treatment. There are three indications that the symptoms may be paraneoplastic in origin. The first is that the results of blood cultures are consistently negative. The second is that antibiotics have no effect on the symptoms. The third is a diurnal rhythm to the pyrexia or sweats. It is usually at this juncture that the possibility of cancer-related pyrexia and sweats is considered.

Table 3 Causes of pathological sweating

Localized pathological sweating
1. *Disruption of sympathetic chain or white rami*
An example here is the Pancoast's tumor involving the apical lung causing localized loss of sweating (anhidrosis). Another example occurs in neurogenic tumors at the level of the hypothalamus or spinal cord.
2. *Irritation of sympathetic chain*
The sympathetic chain may be irritated by an encroaching tumor. Examples are lung cancer, lymphomas, or mesothelioma. This cause sweating on one side (unilateral hyperhidrosis).
Generalized pathological sweating
Systemic diseases
Endocrine conditions
Diabetes mellitus
Diabetes insipidus
Acromegaly
Pheochromocytoma
Thyrotoxicosis
Carcinoid syndrome
Infections – tuberculosis, HIV/AIDS
Endocarditis
Malignancy
Drugs (opioids), antidepressants (fluoxetine, naproxen)
Drug withdrawal
Malignancy

Malignancy can cause a local or generalized disruption to sweating. A Pancoast's tumor involving the apical lung may cause a localized loss of sweating (anhidrosis). Another example occurs in neurogenic tumors at the level of the hypothalamus or spinal cord. The opposite may occur (excessive sweating) if the sympathetic chain is irritated by an encroaching tumor. Examples are lung cancer, lymphomas, or mesothelioma. This causes sweating on one side (unilateral hyperhidrosis). Unilateral sweating in mesothelioma usually signifies advanced disease and has a poor prognosis (Waran 2016).

Classic causes of generalized excessive sweating (hyperhidrosis) are Hodgkin's and non-Hodgkin's lymphoma. Hodgkin's lymphoma is a B-cell lymphoproliferative syndrome, and in addition to lymphadenopathy, patients may present with a constellation of fever, pruritus, excessive sweating, and weight loss. The excessive production of IL-1 by activated macrophages may be involved. IL-1 increases the synthesis of PGE-2 in the hypothalamic central thermoregulatory center causing an elevation of the body's temperature. In addition, an excessive production of IL-6 by Hodgkin's lymphoma cells may also be implicated in fever and sweating. Apart from lymphomas, advanced solid tumors may also cause sweating via an immunologic mechanism related to TNF-alpha and interleukins on central thermoregulation.

3.3 Management

A critical threshold in the management of paraneoplastic sweating is making the diagnosis or at least considering the possibility of its presence. As stated above, it is often a diagnosis of

exclusion. This can cause significant delays in commencing management. A localized absence or excess of sweating should alert the clinician to think of a local mechanism. In terms of generalized sweating, an attempt should be made to identify the timing, duration, and severity of the sweats and whether they are associated with pyrexia. Non-pharmacological approaches include a tepid sponge, a cooling fan, or a cooling bath or shower. There is limited evidence for a pharmacological approach to sweating and/or pyrexia. Nevertheless, it is important to try a series of medications to determine which one or combination has efficacy and relieves the suffering of the patient. The first approach is to commence antipyretics such as paracetamol and, if considered safe, nonsteroidal anti-inflammatories. If there is no response, consider antimuscarinic medications such as oxybutynin, amitriptyline, Pro-Banthine, or glycopyrrolate (Twycross et al. 2014). Other medications that may be used include olanzapine (Zylicz and Krajnik 2003), cimetidine, propranolol, nabilone (a cannabinoid) (Maida 2008), and thalidomide (Calder and Bruera 2000). Table 4 summarizes this information with the recommended doses of each medication.

Table 4 The clinical approach to pathological sweating

1. Is the sweating localized or generalized?
2. For localized dysfunction (absence or excess of sweating), think of the mechanism. If the cause is cancer mass, is it amenable to radiotherapy?
3. For generalized sweats:
(i) Non-pharmacological approaches – tepid sponge, fan, cool bath/shower
(ii) Pharmacologic management. Stepwise approach:
(a) Commence with simple antipyretics – paracetamol, NSAIDS (if safe to use)
(b) If insufficient, consider antimuscarinics:
Oxybutynin 5 mg bd (2.5 mg bd if older patient)
Amitriptyline 10 mg nocte and titrate to efficacy
Pro-Banthine 15 mg bd – tds
Glycopyrrolate up to 2 mg tds po
(c) If insufficient, consider: olanzapine 5 mg bd, propranolol 10–20 mg bd-tds, cimetidine 400–800 mg bd, thalidomide 100 mg nocte, and nabilone

4 Skin Failure

The skin itself is the largest organ of the body, and as is the case with any other organ of the body, it too can fail. Multiple papers since 1989 have used the term "skin failure," though this is often poorly defined and is often defined within the parameters of multiple organ failure (MOF) (Brown 2003; Goode and Allman 1989; Hobbs et al. 1993; Irvine 2016; La Puma 1991; Witkowski and Parrish 2000; Worley 2007). In MOF, damaged tissue loses its ability to resist pressure and trauma, and as the body shunts its blood supply to the core organs in order to preserve life, the skin is deprived (Worley 2007). Skin failure has therefore been defined as when the skin and its underlying structures die due to hypoperfusion that occurs concurrently with severe dysfunction or failure of other organ systems (Langemo and Brown 2006).

Skin failure has further been subcategorized into acute, chronic, and end-of-life skin failure (Langemo and Brown 2006; Worley 2007). Acute skin failure is an event in which skin failure occurs concurrently with a critical illness and is related to hypoperfusion. Such events can include, but are not limited to, trauma, stroke, sepsis, cardiac events, or complications from surgery. Mortality rates range from 33% within 30 days of the detection of skin failure up to 73.3% at 12 months in the intensive care setting (Brown 2003). Chronic skin failure is represented by hypoperfusion which occurs during a chronic or multiple chronic disease states. For example, a patient may have multiple comorbidities, such as end-organ failure, diabetes, ischemic heart disease, stroke, or any innumerable combinations of comorbid conditions. This type of skin failure occurs progressively over time as opposed to the quicker presentation of acute skin failure. End-of-life skin failure occurs when the skin and its underlying structures die due to hypoperfusion concurrent with the end of life (Langemo and Brown 2006). Mortality rates range from 20.8% within 30 days of the detection of skin failure up to 73.3% at 12 months in the long-term care setting (Brown 2003).

The result of skin failure ultimately ends in skin compromise through localized hypoperfusion and hypoxia which may occur at the tissue cellular and molecular levels (Sibbald et al. 2009). In 2009 a consensus group gathered to discuss and describe these phenomena and coined the mnemonic Skin Changes at Life's End (SCALE) (Sibbald et al. 2009). The Kennedy Terminal Ulcer (KTU), often described as a subcategory of pressure injury, is associated with skin failure, particularly skin compromise at life's end. The KTU is described as an ulcer that occurs and deteriorates rapidly, despite preventative measures, often accompanying an impending death (Schank 2009). A KTU is usually shaped like a pear, butterfly, or horseshoe and is primarily located, but not limited to, the skin overlying the coccyx or sacrum. Hanson et al. (1991) reported that 62.5% of hospice patients with a pressure injury had their pressure injury develop in the 2 weeks prior to their death.

Unfortunately, the majority of the literature surrounding skin failure is observational in nature. There are currently no diagnostic criteria for skin failure to aid in a clinician's diagnosis. Therefore, currently a diagnosis is made by the clinician's knowledge of the phenomena and diagnosing its presence in an individual patient. This is not an ideal situation. Skin failure is a phenomena that needs and deserves further research, especially surrounding diagnostic criteria.

4.1 Pressure Injuries

Previously known as decubitus ulcers, pressure injuries include pressure sores, bed sores, and pressure necrosis or pressure ulcers. A pressure injury is damage to the skin with or without concurrent injury to the underlying tissue as a result of pressure or a combination of shear and/or friction with pressure (Australian Wound Management Association 2012).

As defined by the National Pressure Ulcer Advisory Panel (2016), pressure injury can be categorized into the following stages:

Stage 1 pressure injury: non-blanchable erythema of intact skin
Stage 2 pressure injury: partial-thickness skin loss with exposed dermis
Stage 3 pressure injury: full-thickness skin loss
Stage 4 pressure injury: full-thickness skin and tissue loss

Unstageable pressure injury: obscured full-thickness skin and tissue loss, i.e., unable to visualize the wound bed due to necrosis or slough.

Deep tissue pressure injury: persistent non-blanchable deep red, maroon, or purple discoloration.

Risk assessment for pressure injury should be attended on all patients and should include a clinical history, pressure injury risk scale, skin assessment, mobility and activity assessment, nutritional assessment, continence assessment, cognitive assessment, and an assessment of extrinsic risk factors (Australian Wound Management Association 2012). If a patient is found to be at risk, the appropriate prevention regime should be instituted including appropriate positioning, the use of an appropriate support surface, reducing shear and friction, and making the appropriate referrals to any allied health teams (such as dieticians for nutritional support).

5 Malignant Cutaneous Wounds

Malignant cutaneous wounds are caused by the infiltration of skin and its blood and lymph vessels by tumor (Alexander 2009). These wounds can occur anywhere on the body. Unless the patient is having anticancer therapy such as chemotherapy, radiotherapy, or targeted therapies, malignant cell division will continue to occur and therefore cause the malignant wound to progress/enlarge. These wounds most commonly occur in breast and head and neck cancers, although are often seen in patients with skin cancers and vulva and bladder cancers (Seaman 2006). See Figs. 1 and 2.

Malignant cutaneous wounds can be described as either ulcerative or proliferative in nature.

Fig. 1 Ulcerative malignant cutaneous wound

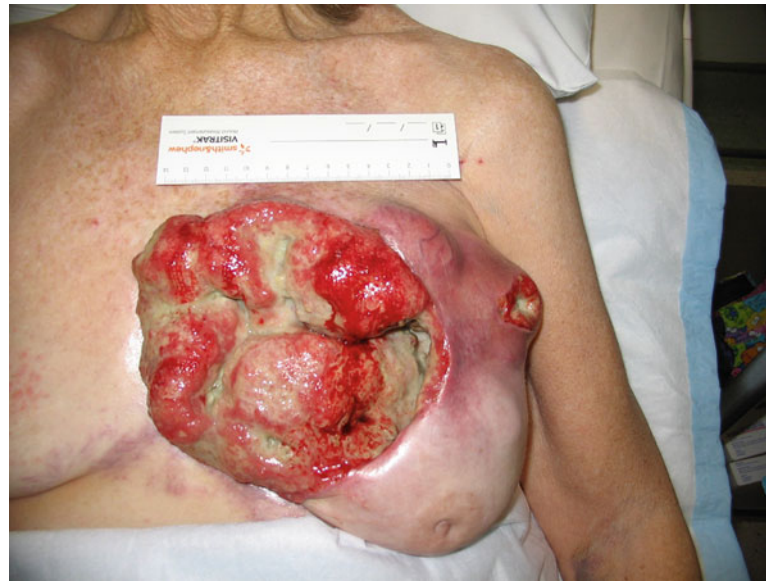

Fig. 2 Fungating malignant cutaneous wound

Fungating wounds rarely heal, so palliation through effective pain and symptom management as well as psychological support is essential. Although most fungating wounds occur in more advanced disease, it is possible for people to live many years with such a wound if the disease is localized. Incorporating the key principles of palliative care to managing these difficult wounds is, therefore, essential to reduce the impact of the wound on the patient's quality of life. A multidisciplinary approach to these wounds is also essential with input often required from wound care specialists, stomal therapy, social work, psychology, as well as palliative care teams (Maida et al. 2009).

The management of malignant cutaneous wounds is very often challenging for health-care professionals, and the symptoms can be vastly different between patients. Priorities for care involve good management of pain, exudate, odor, and bleeding and the provision of psychological support for patients and their loved ones.

Body image and self-esteem are also often adversely affected requiring ongoing emotional and psychological supports.

5.1 Patient Assessment

A comprehensive patient and wound assessment is essential to the development of a patient-centered plan of care and should include:

- A good understanding of the patient's disease process and plans for further anticancer treatments versus comfort measures.
- Review of the patient comorbidities such as peripheral vascular disease and diabetes.
- History of the wound – how long it has been there, and how has it changed?
- Assessment of the wound location and appearance.
- Pain and symptom assessment.
- Signs of infection/odor noted.
- Amount of exudate.
- What has the patient tried and what has worked for pain and symptoms or dressing requirements?
- What medications are prescribed for pain or symptoms associated with the wound?
- Assessment of the psychological impact of the wound on the patient and on their carers.
- Assessment of the risk of bleeding or airway obstruction needs to be taken into consideration as part of assessment depending on the location of the wound (Dowsett 2002; Wilson 2005).

5.2 Pain Management

Causes of pain in patients with malignant fungating wounds can be many, and it is important to take into account the emotional factors associated with these wounds. Pain may be caused by the infiltration or pressing of nerves and blood vessels, or there may be exposure of the dermis (Seaman 2006).

Providing optimal pain management is essential, and careful titration of systemic opioids may be necessary. Adding an antineuropathic agent into the pain regimen is also an important consideration following a thorough pain assessment. Using breakthrough opioid analgesia 20 min prior to dressings or the use of immediate acting sublingual fentanyl or fentanyl lozenges may prove very effective for the incident pain associated with movement or dressings.

Topical opioids such as morphine gel may also be useful for management of painful malignant wounds. The use of topical opioids remains controversial, and there are still few high-quality studies to support it. Nevertheless, it is worth consideration especially in patients who are experiencing side effects with systemic opioids.

Radiotherapy is often an effective treatment for the management of painful or bleeding tumors. The aim of radiotherapy is not to cure the cancer but rather to improve symptom burden and improve quality of life.

5.3 Bleeding

If a patient's wound is situated near major vessels, the risk of bleeding or hemorrhage may be significant. For most fungating tumors, bleeding is often characterized by slow capillary ooze. Medications which may be useful to slow or stop bleeding include oral tranexamic acid, sucralfate paste applied to the wound, topical adrenaline as a vasoconstrictor, as well as the use of non-adherent dressings.

For tumors which have the capacity to erode major vessels causing catastrophic bleeding, the prescribing of medications for such a crisis is important. An opioid for pain and benzodiazepine for anxiety are recommended. In the hospital setting, however, evidence is growing that the most reassuring thing a health professional can do for a patient with catastrophic bleeding is remain with and reassure the bleeding patient rather than leave the patient to retrieve medications to administer. Providing red or green drapes or towels to disguise the sight of blood can also reassure the patient (Grocott 1995; Seaman 2006; Naylor 2001).

5.4 Exudate

Malignant fungating wounds can produce exudate which can be quite challenging to control. Inflammation and edema are commonly present in malignant fungating wounds and can contribute to the exudate. Exudate is often increased if there is infection. Excessive exudate may cause leakage through dressings, staining of clothes, and further embarrassment for the patient.

Most fungating wounds produce moderate to high amounts of exudate, and when choosing an appropriate dressing, it is important to choose a dressing that will be absorptive but still able to maintain a moist environment. These may include alginate or hydrofiber dressings, foam dressings, soft silicone dressings, or knitted viscose with an absorptive pad. In cases of high exudate and where able to site, a stoma bag may be an appropriate way of managing the excessive exudate for the patient (Grocott 1995; Seaman 2006; Naylor 2001).

5.5 Odor

Management of odor is of particular importance for patients with malignant fungating wounds. An offensive smelling wound can lead to feelings of embarrassment, shame, and guilt and to social isolation and even depression. Uncontrolled malodor can lead to nausea and vomiting, decreased sense of taste, and decreased appetite.

Malodor is often due to a number of factors:

- Bacteria – aerobic and anaerobic
- Necrotic tissue
- Poor vascularization
- Exudate

Debridement of the necrotic tissue causing the malodor may be an appropriate treatment for a patient depending on the patient's condition and their wishes. Caution needs to be taken with debridement due to the increased risk of bleeding.

To combat the bacteria contributing to the malodor, antibiotic therapy is often useful, in particular metronidazole. This can be given systemically but also topically as gel. Metronidazole gel is often not as effective if the wound has excessive exudate. Caution should be used with the use of systemic metronidazole as it may cause nausea, neuropathy, and alcohol intolerance. Impaired blood supply to the tumor may also limit systemic metronidazole's effectiveness.

Topical antiseptic dressings may also be useful here such as silver-impregnated dressings which have a broad antimicrobial cover and exist in a variety in dressings that may aid in exudate management. Polyhexamethylene biguanide (PHMB) is another commonly used antiseptic that comes in a variety of applications including as a cleansing solutions which, as a result, can be used with a combination of other dressing types to aid in more versatile dressing choices.

Cleansing the wound is important as it reduces odor by removing debris and reducing bacteria counts, and it is also important as it makes the patient feel clean. Patients often feel self-conscious and distressed by the unpleasant odors so air fresheners, air filters, aromatherapy, and odor neutralizers can be helpful to disguise the smell. However, please take into consideration that the sense of smell is an extremely potent memory stimulator and that the patients' carers and loved ones may associate any aromatherapy scents with their loved ones' wound or death for the rest of their life (Grocott 1995; Naylor 2001; McMurray 2003; Seaman 2006).

5.6 Psychological Supports

Psychological care of patients with malignant cutaneous wounds is as vital as the care of their physical symptoms. Patients may experience many emotions including shame, guilt, embarrassment, anxiety, and anger. Some patients may withdraw from family and friends, and carers may be left with feelings of anxiety and helplessness (Lo et al. 2008). Fungating wounds may also lead to a degree of social isolation especially if there is malodor or exudate which is difficult to control. Impact on relationships and sexuality can also be significant (Probst et al. 2013).

A wound such as this is a constant reminder to both patient and those they love that they are living with a life-limiting illness. The many physical symptoms experienced by patients can significantly impact patient's physical, emotional, and spiritual well-being which is why a holistic approach to care is paramount (Probst et al. 2013).

Clear and honest communication to patient and family is important in building trust and rapport. Exploring therapeutic strategies and goals of care can reassure patients and families and decrease feelings of anxiety and fear (Seaman 2006).

6 Conclusion

The direct and indirect effects of malignancy and end-organ failure on the skin are protean. Each may cause significant suffering to the patient and carers. Our understanding of the pathophysiology, diagnostic criteria, assessment, and management of these manifestations is limited but growing. This chapter has sought to synthesize the current knowledge of those skin syndromes that have the most impact on the practice of palliative care – pruritus, paraneoplastic sweating, skin failure, and malignant cutaneous wounds. Rather than greeting these manifestations with therapeutic nihilism, we should be confident that basic interventions can provide significant comfort, relief, and support to our patients.

Abstract

Wounds are a significant issue in palliative care, and to deliver the best wound management, it is essential to understand the principles of wound management and how the body heals. The pathophysiology of wound cause is an essential part of wound assessment as treatment is based on a clear diagnosis of the underlying etiology. The management of a wound in palliative care will be impacted by specific issues such as pain, odor, exudate, and infection. Although it may not be possible to prevent all wounds, good skin care is important. The principles of wound assessment and wound management including the specific problems are explained.

1 Overview of the Principles of Wound Management

Wounds either acute, postsurgical, or chronic are a growing area of palliative care practice and it is important to review the current methods of management and developments in diagnosis, assessment, and treatment. The aim of this chapter is to explain how wounds heal, what impacts on healing and how to deal with the specific issues in palliative wound care.

Wound management is now defined as "The provision of the appropriate environment for healing by both direct and indirect methods together with the prevention of skin breakdown" (Sussman 1998) and thus on wound management is not merely the application of a dressing to an acute or chronic wound but must be part of an holistic approach to the patient to ensure the best practice is applied in treatment – we should "treat the whole patient and not just the hole in the patient."

1.1 The Basic Principles of Wound Management

1.1.1 Etiology of Wounds

Wounds are either acute or chronic in nature and the approach to each type can be different.

Acute wounds	Chronic wounds
Higher risk of infection	Lower risk of infection
Due to debris contaminating wound	Symptom of underlying condition
Inflammation occurs	Heal by secondary intention
May heal by primary intention	Not sterile
May require antiseptic use and antibiotics	May be sloughy and exudative

Wounds heal either by:

- Primary intention

  Involves the apposition of the wound edges and the reunion of tissue structures and should result in minimal scaring.
- Secondary intention

  Open, gaping wounds where there is loss of tissue, or infected, closed wounds heal by the formation of granulation tissue (vascular and fibroblast proliferation) which fills the defect and by contraction of the wound edges. Healing by secondary intention is slow and can result in a large distorted scar.

1.1.2 Physiology of Wound Healing

Healing should be considered as a continuum of the three phases of wound healing: inflammatory (destructive), proliferative (regenerative), and maturation (reparative). Each phase continues on in a steady process merging with the next phase and one wound may be in more than one phase at one time. During all of these phases, there are a number of cells that are essential to the process of the healing including platelets, neutrophils, macrophages, and fibroblasts.

1.1.3 Phases of Healing

Inflammatory Phase

The inflammatory phase is normally the shortest, and is manifest at the beginning of the wound itself where a wound is either surgically created, caused by trauma, or some other reason. There will be bleeding, and a clot will develop to induce hemostasis. The tissue around the wound may often be red, hot, sore and swollen. This does

not indicate infection, it is merely the inflammatory process itself; consequently, it is not always necessary to apply topical antiseptics or topical antibiotics. Wound exudate is often seen during the inflammatory phase. It is not a passive component of the healing process, but serves to nourish the tissues and to flush out necrotic tissue and foreign debris from the wound. The continued presence of foreign material, necrotic tissue, or even excessive antimicrobial use or other continued disruption of the wound can result in prolonged inflammation thereby preventing the onset of proliferation and maturation; this may lead to fibrosed tissue. At this stage, one of the most important cells are the platelets whose task is not only hemostasis, but also the production of a growth factor. Neutrophils, are also involved, in the phagocytosis of bacteria as well as aiding in the extracellular release of protease – an enzyme used by the body for the destruction of necrotic tissue (Sussman 2001, 2014).

Proliferative Phase

During the proliferative phase, the new vascular bed is formed by angiogenesis. Capillary buds are formed which link up with the existing capillary network and allow oxygenated blood to provide a lush bed of capillary vessels. During the proliferative phase, collagen is deposited by the fibroblasts and forms the essential framework for the connective tissue which will eventually fill the wound. Fibroblasts also synthesize proteoglycans or ground substance, and it is collagen and ground substance which form the scaffolding for wound repair. The collagen then realigns itself by cross-linking, resulting in an increase in the tensile strength in the wound. There are a number of elements essential for collagen production and deposition including vitamin C, oxygen, iron and zinc. A deficiency in these nutrients could lead to the development of a weakly bonded matrix, and ultimately to dehiscence of the wound.

During the proliferative phase, wound contraction occurs. This is an action of the myofibroblasts, contractile cells which pull the wound margins together. Contraction and granulation are the processes by which the wound becomes smaller. During the latter stage of the proliferative phase epithelialization occurs, involving the growth of the epidermal cells over the surface of the granulation tissue, a process which is completed most efficiently in a moist, clean environment.

Maturation Phase

The maturation phase is the final stage of healing. During this stage, the fibroblasts decrease in number, vacuolization decreases, and the tensile of strength of the wound increases. Maturation is the most misunderstood phase of healing. It is assumed that a wound is healing once the epithelium has closed the surface of the wound but the tensile of strength of the wound may in fact may take quite a considerable time, and in some patients it can take up to 12 months. A re-ephithelialized wound may not be fully healed but the wound may not be totally healed beneath the surface and the lack of tensile strength in a wound will increase the risk of breakdown that may be related to tension the tissue below the surface (Sussman 2001, 2014)

1.1.4 General Principles of Management

The major objective is to facilitate optimal healing (that is, with as little scar tissue as possible, with a good cosmetic appearance). Therefore, to treat an acute wound, you should first ensure it is clean and then, if necessary, the wound edges should be held together by sutures or tape, and finally an appropriate dressing applied. Medical intervention may be necessary if there is a possibility of tetanus spores or other foreign bodies being trapped in the wound.

For contaminated wounds, closure is not recommended since the risks of infection and breakdown are considerable treat as a delayed primary closure – cover with sterile dressing for approximately 4 days, then treat as a primary wound.

The management of the wound environment is now based on the concept of wound bed preparation (WBP) interventions, which address

debridement, bacterial balance, exudate management, and the local tissue in the wound environment. These important assessment elements have led to the development of the concept of the TIME principles (**T**issue, **I**nflammation/**I**nfection, **M**oisture, **E**dge/**E**pithelialization). This simple principle enables a wound to be assessed for most of the important aspects of the wound; this enables the health professional to consider the factors for healing or delayed healing and what must be considered in the choice of treatment (Leaper et al. 2014; Schultz et al. 2003).

1.1.5 Moist Wound Management

Knowledge and understanding of wounds, tissue, and healing have grown rapidly over the past 30 years, resulting in a major change in the method of wound management. There has been a growing awareness that traditional wound-care products do little to aid healing, and in many cases actually delay it.

Traditional theory has always been that wounds should be kept clean and dry so that a scab may form over the wound, the wounds should be exposed to the air and sunlight as much as possible, and where tissue loss is present, the wound should be packed to prevent surface closure before the cavity is filled, and then the wound should be covered with dry dressing.

The clear disadvantages of these principles are that the scab, which is made up of the dehydrated exudate and dying dermis, is a physical barrier to healing, which is then delayed because the epidermal cells cannot move through the scab formed and this may ultimately result in a poor cosmetic results even scarring. Exposure to the air reduces the surface temperature of the wound and further delays healing causing peripheral vasoconstriction affecting the flow of blood to the wound. This lower blood flow will also effect the supply of oxygen, nutrition, and other factors to the wound. Air exposure will also cause the wound to desiccate and forma scab.

Where a wound is packed with dry gauze, the quality of healing is impaired due to adhesion of the material to the surface of the wound causing it to dry out. Equally covering the wound with a dry dressing that adheres to the wound surface may traumatize the wound surface on removal. Wounds covered by an occlusive dressing do not form a scab, so epidermal cells are able to move rapidly over the surface of the dermis through the exudate which collects at the wound/dressing interface. The application of a totally occlusive or semipermeable dressing to wound can also prevent secondary damage as a result of dehydration.

Dr. George D. Winter was able to demonstrate scientifically the difference between wounds of a similar nature when healing was open to the air, and when healing was under occlusive dressing (Winter 1962). The experiment showed that the wounds healing under moist conditions healed 50% faster than the wounds healing under dry conditions, open to the air. Winters work has since formed the basis of the principles of modem moist wound management. Many subsequent studies have confirmed the theory that wound heal faster in a moist compared to a dry environment (Hinman and Maibach 1963; Winter 1962).

Moist wound healing also simplifies debridement by assisting in the autolytic debridement of wounds. It facilitates wound cleansing, since the wound exudate is part of the healing cascade. It also protects granulation and encourages epithelialization. It has now been shown to carry a number of growth factors essential to the healing of wounds (Sussman 2014).

2 Wound Assessment

Wound Assessment is the most important function to enable the clinician to identify both the patient and the wound-specific issues.

To help differentiate the basic etiology of a wound, such as a leg ulcer, information is needed:

- History
- Medical/surgical
- Health status, e.g., cardiorespiratory function
- Concurrent illness such as diabetes, autoimmune diseases
- Diet and smoking
- Medications

- Psychosocial issues
- Examination
- Wound (color, depth, and exudate)
- Surrounding skin
- General condition
- Investigation
- FBE – anemias, ESR
- Blood glucose, HbA1c
- Serum albumin and liver function
- Renal function
- ABI
- Bacteriology to identify infection
- Histology to diagnose a carcinoma/metastasis or for atypical wounds

Disruption of circulation and perfusion impairs delivery of cell nutrients and immune cells (leukocytes, macrophages), which delays wound healing. Note any concurrent illnesses that might have an effect on healing, i.e., diabetes mellitus or atherosclerosis, autoimmune diseases, e.g., SLE (Grey et al. 2006; Sussman 2001, 2014).

All these areas should be checked and particular attention paid to the following.

2.1 Medication

A number of medications may impair wound healing, in particular corticosteroids and other immunosuppressive drugs, some over the counter medication, such as NSAID. . . and complementary medication, including Ginko, may also impact healing. However, this may not be a major consideration in palliative care as the aim is often not wound healing. With patients living longer and having earlier palliative care, healing may be an aim/possibility (Graves and Sun 2013; Sussman 2007).

2.2 Nutritional Status

Nutrition plays a very important role in tissue repair and wound healing, and patients who are malnourished do not heal well and are at a greater initial risk of developing pressure injuries. It is essential to perform a nutritional assessment examining issues such as weight loss or gain, caloric intake, macronutrients, and hydration. The estimation of albumin level may be helpful – a serum albumin less than 3.5 gm/dl indicates the need for further assessment and action, and a level below 3.0 gm/dl is correlated with poor patient outcomes (Harris 2004; Wild et al. 2010).

2.3 Ageing Issues

Wounds in general and leg ulcers, pressure sores, and skin tears in particular are common problems in an ageing population. To fully understand the nature and causes of these chronic wounds, it is essential to consider the main physiological effects of ageing on tissue and the factors that influence healing. The ageing process will impact on most of the structures of skin. Ageing skin loses hair follicles, sebaceous glands that supply natural moisture to the skin, receptors, blood supply, and sweat glands. The result of these tissue changes is that the skin becomes thinner, brittle, avascular, and more prone to injury. Thus, the elderly have thinner and more fragile skin will often present with skin dryness, thinning, laxity, uneven skin pigmentation, and hair thinning, the skin is often tissue paper thin at risk of skin tears (Gosain and DiPietro 2004; Sussman and Golding 2011; Sussman 2016). Although healing may be slower and may be more complex in older patients, it is still important to aim for healing. Patients receiving palliative care are often elderly and have multiple morbidities and wound management should be for comfort, and, if possible, for healing. It is important to continue, to manage and not to just give up small gains can have a significant impact on the patient.

2.4 Patient/Family Awareness

As the patient and the family will be caring for the wound at home the support and psychosocial aspects of the patient, within their family, is important. Assessment of their abilities and willingness to be involved is important as coping with a deteriorating family member with a wound is often very stressful (Probst et al. 2013).

2.5 Wound Assessment

After patient assessment, the next step is to carefully assess the wound. Wound assessment includes the wound's etiology, its location and its size and depth. A thorough wound assessment also includes evaluation of the wound bed in terms of type of tissue present; observation of the quality and amount of exudate; and determination of the presence or absence of infection. It also involves assessment of the condition of the peri-wound area and evaluation of any past and current treatments (Grey et al. 2006; Sussman 2001, 2014).

2.6 Determination of the Presence or Absence of Infection

It is important to determine if a wound is infected before treatment is initiated. Most chronic wounds with tissue loss are contaminated, but this contamination only becomes significant when local defenses can no longer contain the bacterial growth (10^5 organisms per gram of tissue). Therefore, culturing is of little use unless true signs of infection are present for although many strains of bacteria will be found this may not be an indication of true infection, only contamination. The classic signs of infection include advancing erythema, fever, warmth, edema/swelling, pain, and purulence (pus). However, these are not always observed and more commonly the signs may be of delayed healing, change in color of wound bed including friable granulation tissue, increased or abnormal odor, increased serous drainage, and increased pain at wound site, these are the secondary signs of infection (International Wound Infection Institute 2016).

3 Different Wound Types

A large proportion of wounds seen in clinical practice are chronic in nature. The difficulty in the management of any chronic wound is that there is always an underlying physiological cause of the wound which must be treated, but many patients have multifactorial issue and comorbidities. For best results, the basic cause of the problem must be managed, and the negative factors altered.

It should be understood that some patients may never heal due to the basic pathophysiology of the disease process and our inability to alter some or all of the major factors influencing the nonhealing of the wound. However, even in the most extreme cases, good wound care can be a great help in minimizing the worst effects of such chronic wounds.

3.1 Leg Ulcers

Leg ulcers have a number of different causes, including venous insufficiency, arterial disease, diabetes mellitus, vascular complication of autoimmune disease (such as rheumatoid arthritis), malignant disease, trauma, and deliberate self-injury.

Part of the diagnosis of a leg ulcer to differentiate the cause is to obtain an Ankle/Brachial Index (ABI) – this compare ankle systolic pressure with brachial systolic pressure with a normally ratio should $= 1$ ABI < 0.8 implies arterial insufficiency. If ABI < 0.7 no compression should be applied. The result can be > 1.2; this is due to pain at site, incompressible (calcified) vessels.

3.2 Venous Ulcers

Venous ulcers result from the breakdown of the venous circulation of the leg and are an association of the inability of the leg to force the passage of blood through the various connecting veins via the bicuspid valves by muscular contraction. They are most often found in the lower one-third of leg, in the gaiter area, are usually irregular in shape, not painful, and edema is often present. The skin is often stained and also has changes, e.g., eczema, atrophy blanche (white stippled scars on the skin), and there is a history of varicose veins, obesity, past DVT, poor mobility resulting in venous stasis. Venous leg ulcers are usually

often painless, irregular shape, and there may be copious exudate.

As venous incompetence is often the main cause of the ulcer treatment is the application of compression therapy toe to knee 30–40 mmHg at ankle. It is, however, essential to exclude arterial involvement before commencing compression.. It is important to encourage exercise and address occupational factors such as long periods standing that lead to venous stasis.

Leg ulcers may also result in patients with lymphedema, caused by a reduction in the function of the lymph vessels to drain extracellular fluid. The resultant edema will place the patient at risk of ulcer development as a result of minor trauma and by the hyperkeratotic nature of the skin (Alexander House Group 1992; Sussman 2014).

The management of venous and lymphatic ulcers will depend on the depth, exudate level, and if infected.

Table 1 list the appropriate products depending on the wound. If the wound is infected, then Table 3 lists appropriate management.

3.3 Ischemia or Arterial Ulcers

The death of skin automatically follows occlusion of its arterial blood supplies unless this is gradual enough to allow a collateral blood supply to be established. Atheroma (thickening) is the most common cause of arterial ulcers of an ischemic nature. The loss of arterial circulation may be also due to extramural strangulation, with scar tissue or other factors causing strangulation of the arterioles, or fibrosis resulting from longstanding, chronic edema, or chronic infection may also obstruct arterial flow. Mural changes (to vessel wall), Atherosclerosis (deposits on the wall surface) caused by plaque formation reducing blood flow until thrombosis, embolism, or infection cause complete closure.

Intramural occlusion of small vessels by changes in blood viscosity, platelet adhesiveness, and fibrinogenesis (especially in small painful ulcers of the feet and ankles).

Arterial ulcers are very painful, especially at night. This pain is observed in both small and larger arterial ulcers. Their edges are sharply defined and the ulcer is "punched out." The base is often covered with slough. This may deepen to bare the tendons. There is usually a history of intermittent claudication (pain on exercise), dependent foot (dusky foot) white on elevation, a history of peripheral vascular disease, lower ABI, weak/absent pulses, sluggish/poor capillary refill. The ulcer site is usually below ankles to toes, the skin is often shiny and friable. Uncontrolled diabetes and smoking are significant factors causing arterial insufficiency. Healing is often slow and may depend on control of the underlying cause.

Treatment of arterial ulcer may involve a surgical opinion – angioplasty, stenting, bypass grafting, and ultimately amputation. Pain control is an important aspect of the management of arterial ulcers (Hopf et al. 2006; Sussman 2014). In addition, for the wound itself Tables 1 and 2 lists products for management.

It is important to note that between 10% and 15% of leg ulcers are of mixed etiology. These ulcers are often hard to heal due to associated edema, cellulitis, thrombophlebitis, diabetes, or underlying vascular disease, rheumatoid diseases especially in bedridden patients, general conditions of the skin in elderly patients which is often associated with malnourishment (Humphreys et al. 2007).

3.4 Other Causes of Ulcers

In addition to the more common forms of ulceration, there are a number of less familiar causes. Vasculitic ulcers may develop as a result of other medical conditions, such as rheumatoid arthritis and polyarthritis. Infections of the skin can produce ulcers especially if necrotizing bacteria are involved and skin conditions like pyoderma gangrenosum and epidermolysis bullosa (Sussman 2001, 2014). These autoimmune and inflammatory wounds are managed by immunosuppression and topically with hydrogels and secondary dressings.

Table 1 Management of the exudate (This will depend on the volume of exudate)

Exudate volume	Wound type	Dressing type
None (Dry)	All	Simple NA dressings Hydrogels IntraSite®, Purilon®, Flaminal®
Scant	All	Simple NA dressings Hydrogels IntraSite®, Purilon®, Flaminal®
Small	All	Hydrocolloids DuoDerm®, Comfeel®, Hydrocoll®
Moderate	Surface	Foam Allevyn®, Lyofoam Max®, Permafoam® Silicone Foam Mepilex®, Allevyn Life®, Foam-like Biatane®, Tielle®, Super absorbents ExuDry®, Mesorb®, Zetuvit®, Mextra®
Moderate	Cavity	Foam Allevyn®, Foam-like Biatane®, Fiber dressing (Alginate, CMC) Kaltostat®, Algisite M®, Aquacel®,

3.5 Mechanical Etiologies

Pressure injury is the most preventable of all of the chronic wounds – see ▶ Chap. 23, "Pressure Injury Prevention and Management in Palliative Care." Pressure injury may be as simple as the blister which occur from footwear to the extensive pressure sores experienced by bedridden patients suffering from stroke, spinal injury, multiple sclerosis, dementia, and receiving palliative care.

The capillary pressure in the arterial blood system is some 32 mm of mercury. It therefore requires a pressure of only about 30 mm of mercury to restrict the arterial blood flow. The consequence of this restricted blood supply is a reduction in oxygen supply and nutrition to the tissue, accompanied by the problem of waste products not being removed from the site of the wound. The result of this is hypoxia, tissue acidosis, increased capillary permeability, which allows intravascular fluid to escape causing edema and cell death.

The main causes of pressure wounds are (Leigh and Bennett 1994) the following:

3.5.1 Pressure

Direct pressure on tissue over a bony prominence in excess of 30 mm of mercury will cause ischemia in the surrounding tissue. This will occur not only from a patient being in bed but also on a trolley or sitting in a chair. The extent of tissue damage will depend on the intensity of the pressure and the length of time the pressure remains unrelieved. The tissue can tolerate pressure for short periods of time. However, even low pressure over a long period of time will have some detrimental effect.

3.5.2 Friction

Friction occurs when the top layers of skin are worn away by continued rubbing against an external surface. This can manifest itself in a simple blister or tissue edema, or an open pressure wound. This can be caused by ill-fitting footwear, or even bed linen.

3.5.3 Shearing Forces

Shear is when the skin remains in place, usually unable to move against the surface it is in contact with, while the underlying bone and tissue are forced to move. This force will contribute to the destruction of microvasculature in a manner similar to direct pressure. This type of pressure injury

Table 3 Management of infected, odorous, bleeding wounds, and fungating

Wound issue	Surface	Cavity
Infection	Silver dressings Acticoat®, Atrauman Ag® Aquacel Ag®, Silvercel® If exudating use a silver foam Mepilex Ag® or silver CMC foam Aquacel Ag Foam® Iodine complex dressings Iodosorb®, Inadine® Metronidazole gel Medicinal honey dressings	Silver ribbon dressings Acticoat Absorbent®, Aquacel Ag®, Silvercel® Acticoat Flex®
Odor	Metronidazole gel Activated charcoal dressings Carboflex® Actisorb Plus® Medicinal honey dressings	Metronidazole gel plus packing gauze plus Activated charcoal as a secondary dressing
Bleeding	Calcium alginate dressing Kaltostat®, Algisite M® Silver nitrate	Calcium alginate ribbon dressing Kaltostat®, Algisite M®
Fungating These wounds are the most difficult as they often combine all of the above issues	A combination of products may be needed. There is a product that combines calcium alginate, absorbent CMC, and activated charcoal CarboFlex®	

Sussman (2017)

is seen in patients left sitting up in bed or on a chair, while gravity causes the patient to slide down with the skin adhering to the bed linen or the surface of the chair.

The prevention and management of pressure injury requires that the patient has pressure relieving surfaces on which to lay. The management of the wound itself will depend again on size, depth, tissue type, exudate, and presence of infection. Tables 1, 2, 3 indicate the products for management.

4 Management of Wounds in Palliative Care

The most common wounds found in palliative care include pressure injury, arterial/Ischemic wounds, neoplastic wounds, and surgical wound breakdown (Brink et al. 2006; Langemo and Black 2010). The main issues in palliative care are the management of the following factors.

4.1 Pain

It is important to consider pain control as all wounds are painful and over time wounds may become more painful, the skin surrounding the wound can become sensitive and painful and for some patients, the lightest touch can be intensively painful.

Analgesic medications are used to provide symptomatic pain relief; they do not modify the underlying cause of pain. Combining pharmacological and nonpharmacological approaches may allow lower drug doses to be employed. Selection of medication should be based on the highest likelihood of gaining pain relief with the lowest likelihood of side effects.

The WHO analgesic ladder recommends simple analgesia for minor pain adding NSAID or codeine for more severe pain and opioids for major pain. The choice of analgesic will also depend on the pain type, nociceptive pain is managed with the standard analgesia as per the WHO pain ladder. Neuropathic pain, when there is associated nerve damage, is managed with specific medication including tricyclics and Gabapentin, Pregabalin and GTN patches, or ointment. Nonpharmacological methods include the use of relaxation methods, coping strategies, distraction, warm socks, legs down, and raising the bed head.

The goal of analgesic therapy needs to be established as complete pain relief is rarely achievable when dealing with pain of neuropathic

origin and the aim may only be to reduce it to tolerable levels. Pain management requires a balance between pain relief and the maintenance of function.

Where wound pain is an issue then it must be established is the pain constant, intermittent, or only as dressing changes. Where dressing pain is the issue, then consider the careful selection of dressings for pain reduction, such as soft silicone dressings. Where the pain is more general, then in addition to any oral or systemic medication, topical treatment can be added. Topical analgesia includes opioids as patches or gels, capsaicin, local anesthetics (such as lignocaine). Topical morphine has been successfully used in the palliative setting the usual strength is 1 mg of morphine to 1 gm of sterile hydrogel, e.g., IntraSite gel. There is evidence for the use of topical Lignocaine from 3% to 5% (Braschi et al. 2017; Desai et al. 2014; Graham et al. 2013; LeBon et al. 2009; Peppin et al. 2015; Steele 2017; Woo et al. 2008).

In addition to analgesia for pain management use a pain assessment form/scale and minimize procedural pain. If necessary, medication may be given prior to a wound care procedure and all involved should be aware of pain at dressing changes. It is also important to select appropriate dressings that are atraumatic on removal. It is helpful to develop guidelines to prevent tissue damage and to educate staff about pain/trauma with dressing.

4.2 Odor

According to Gethin "Malodour is cited as one of the most distressing symptoms of these wounds, is a complex phenomenon with multiple potential causes, and may signify infection or necrosis. Malodor can cause depression, social isolation, nausea, anorexia and, in some individuals, a gagging or vomiting reflex." (Probst et al. 2013, p. 48). The cause of malodor includes the presence of both anaerobic/aerobic bacteria but this does not always indicate infection The issue is that odor is a major problem often caused by bacteria often on the surface of the wound and not infecting tissue. Odor removal is very important as it impacts not only the patient but family and staff. The management of odor will depend on the cause. The most commonly used treatments are topical metronidazole gel that will kill anaerobic bacteria, topical antiseptics including silver and iodine dressings, and honey. The secondary method of odor removal is the use of absorption activated charcoal dressings as some come combined with silver and some with hemostats and absorbent fibers, see Tables 1, 2 (Akhmetova et al. 2016; Finlay et al. 1996; Haycocks and Chadwick 2014; Kuge et al. 1996).

4.3 Exudate

Exudate management is very critical, both to remove excess exudate and to prevent primary damage to the wound and secondary damage to the peri-skin. This is the skin around the wound that has an important function to aid in wound contraction it needs to be in good condition.. The type and level of exudate will impact on the choice of product to manage the exudate, see Table 1.

Exudate is generated as part of the inflammatory response (Cutting and White 2006). It is essential to the healing process and, together with inflammation, should not be considered as a necessary evil but as a vital component of the reparative process. Exudate may be regarded as a transport mechanism, as plasma, from which exudate is derived, delivers all the necessary ingredients, oxygen, and nutrients to the tissues and organs of the body. Similarly, exudate on its way to the surface delivers these components to the wound bed. Traditionally, wound fluid has been considered a reflection of the internal wound environment and it has been used to monitor and reflect on the chronic status of a wound or to measure the efficacy of wound treatment. However, on closer inspection of chronic wound fluid, certain components of the fluid, particularly matrix metalloproteinases (MMPs) and their subcomponents (MMP-9) have been found to exist at higher levels in wound fluid than in the corresponding wound, and there is mounting

evidence that much of the destructive effects observed in chronic wounds may be compounded by these components of the wound exudate which are corrosive in nature resulting in a continuum of extra cellular matrix (ECM) breakdown, the ECM is the combined fiber structure providing tensile strength to the tissue. Additionally, an association has been made between high bacterial levels and elevated MMP9 in chronic wounds.

It is also important to clearly identify both the volume and the type of exudate. The volume may be none, scant, small, moderate, or large and exudate appearance will vary including serous (clear, watery consistency), fibrinous (cloudy, contains fibrin protein strands), purulent (contains pyogenic organisms and other inflammatory cells), Hemo-purulent (contains neutrophils, dead/dying bacteria, and inflammatory cells damage to dermal capillaries leads to blood leakage), and Hemorrhagic (blood is the major component of this type of exudate) (Chadwick and McCardle 2015; Cutting and White 2006; Tickle 2015; Vowden et al. 2015).

Where the exudate is very large and there is a need to change the dressings multiple times a day to keep the cost in check then the use of continence pads can be used. It is, however, essential to apply a contact material over the wound such as modern tulle or silicone tulle dressing first so that the pad does not come into direct contact with the wound. See Tables 1, 2, 3 (Sussman 2014; Weller and Sussman 2006).

4.4 Hemostasis

Where bleeding is present in the wound, the simplest method is to apply firm pressure over the area. The use of hemostatic agents, such as a calcium alginate, will help speedup the process of clot formation. The use of topical adrenaline for vasoconstriction in severe/terminal bleeding has been found to be helpful. It is essential to establish if there is any blood vessel damage, and if there is, prompt medical intervention is mandatary. It is also helpful to ascertain whether the patient is taking any anticoagulation medication. See Table 3 (Terrill et al. 2003).

4.5 Cleansing (*Decontamination I Cleansing*)

If the wound is basically clean, then water or saline are most suitable. If there is any level of contamination, a surfactant solution such as QV Wash™ or some similar product is the most satisfactory, due to the ability of the product to remove material by a soap-like action without altering the acid pH of the skin.

The use of topical antiseptics have a place in acute wounds, it is entirely different from that used in chronic wounds. In a traumatic wound, the risk of infection from contamination at the time of wounding is very high. In general, chronic wounds do not require the use of topical antiseptics unless they are heavily colonized or infected then the use of the less toxic antiseptics, e.g., Polyhexamine methyl biguanide (PHMB) are indicated (Cutting 2010; International Wound Infection Institute 2016).

5 Wound Management Principles

The management of a wound must start with appropriate cleansing with minimal trauma palliative wounds often have fragile tissue. If there is slough present, if possible gentle debridement is helpful. The choice of product will depend on the wound itself in particular the level and type of exudate. It is essential to prevent wound contamination and infection. The role of wound products is to control the wound environment and to protect damaged and healing tissue and the peri-skin. In palliative care, it is pivotal to ensure patient comfort. Dressing selection is important for management of the wound environment and the dressings choices overwhelming will take a function-based approach for selection. In general, avoid adhesive dressings other than those with a soft silicone adhesive due to the fragile nature of the skin.

The secondary considerations are the specific wound properties. A deep cavity wound needs to be gently packed to fill the dead space and absorb exudate if dry then packing with a

hydrogel is appropriate. Wounds that are locally infected or heavily contaminated need a topical antiseptic. Wound related pain and other patient comfort issue must be addressed. Care must be taken at dressing changes to minimize wound trauma and pain.

6 General Rules for Dressings Use

When applying a dressing allow 2–3 cm of dressing greater than wounds, this will enhance the product wear time. Place one-third above and two-third below the wound, this will allow the greatest surface area for exudate absorption. The dressing should remain in place for as long as possible, only remove when strike through occurs. With older patient or those with fragile skin, remove the dressings with great care; if necessary remove under the shower. The choice of management product may change as the condition of the wound changes.

7 Neoplasia and Complex Wounds with Infection

Neoplasia both directly and indirectly play a major role in palliative care. Many patients with terminal cancer of various types are referred to palliative care services. Some specific neoplastic wounds such as fungating breast cancer are a challenge to manage. They are painful, exudating, malodorous, and tend to bleed and may hypergranulate. Squamous Cell Carcinoma (SCC) can develop in nonhealing wounds and these are called Marjolin Ulcers SWCC's and some will metastasize. There are many forms of treatment for skin cancer but surgery is the most successful treatment, radiotherapy and intralesional interferon are also used, however, surgery is the only suitable treatment for SCCs and melanoma. Management of these wounds is complex specific issues such as management odor and bacteria are addressed in Table 3 (Addison and Richard 2014; Merz et al. 2011).

8 Skin Care

Skin integrity reduces with age and disease, dermal thickness is reduced, there is a weakened dermal-epidermal junction. The level of vitamin D, collagen, and moisture is reduced. Migration of capillary epithelial cells, epidermal turnover is reduced, and fragility of capillaries is increased. There is also a compromised inflammatory response and concomitant illnesses and many medications impact on both skin integrity and on healing.

It is important to ensure that all patients receive good skin care and their skin integrity is assessed regularly; the greater the emphasis on skin protection and integrity, the significant reduction in the risk of skin breakdown. Good skin care can have a significant impact and reduce skin damage. Adequately hydrating dry skin with effective moisturizing agents, ointments, lotions are better than creams and should be used twice a day on dry skin areas and extremities (Peppin et al. 2015; Sussman 1998). The essential aspect of the use of skin moisturizers is to ensure that the moisturiser used is ones that will not cause a greater loss of moisture through the skin or damage skin cells. Aqueous creams are known to increase transepidermal water loss and dry the skin; some aqueous creams have also been shown to be cytotoxic (Carville et al. 2014; Greive 2015; Kempf et al. 2011; Mohammed et al. 2011; Tsang and Guy 2010).

9 Conclusion

The management of palliative wounds should be the first and foremost patient comfort and symptom reduction. The patient and the absolute requirement for quality of life is to ensure the symptoms which impact not only on the

patient's but on the patient family, and the treating staff are managed to ensure the lowest impact (Graves and Sun 2013).

Abstract

Pressure injury, pressure ulcer, decubitus ulcer, bed sore are synonymous terms that define a wound that is deemed by many to be preventable. However, palliative care patients who are close to death may have compromised skin perfusion and ischemic skin changes as physiological responses divert blood flow from the integument to other major organs. Tissue tolerance to pressure, shear, and friction is further compromised by malnutrition, cachexia, immobility, and inactivity and comorbidities, which are frequently associated with end of life. Palliative care patients are considered to be at high risk of pressure injuries because of these challenges and an informed and collaborative approach to prevention and management is of paramount importance. The chapter provides an overview of the etiology of pressure injuries and the evidence presented in the National Pressure Injury Advisory Panel, European Pressure Injury Advisory Panel, and Pan Pacific Pressure Injury Alliance (NPUAP, EPUAP, and PPPIA) *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline* (Prevention and treatment of pressure ulcers: clinical practice guideline. Cambridge Media, Perth, 2014) and the dedicated chapter on palliative care.

1 Introduction

Pressure injury, pressure ulcer, decubitus ulcer, bed sore are synonymous terms that define "a localized injury to the skin and/or underlying tissue, usually over a bony prominence, resulting from sustained pressure (including pressure associated with shear)" (NPUAP et al. 2014, p. 18). Pressure injury prevalence among palliative populations has been reported to range between 10.5% and 26.0%, although these findings appear to be limited to small palliative care units or home care cohorts (Artico et al. 2017; Brink et al. 2006; Galvin 2002; Hendrichova et al. 2010; Queiroz et al. 2014). Pressure injuries pose significant health issues for susceptible individuals regardless of age or care setting. They result in increased morbidity and mortality and increase demands on clinical resources and health expenditure (Carville 2017). Furthermore, they contribute to a significant decline in quality of life, increased pain and discomfort, carer and family stress, and potentially lead to an earlier than anticipated demise. The chapter aims to provide an overview of the etiology, risk factors, and prevention and management options for pressure injuries among palliative care patients.

2 Pressure Injury Etiology

The development of a pressure injury is subject to factors that affect the "mechanical boundary" conditions which describe: the magnitude of mechanical load, the type of loading (pressure, shear and friction) and the duration of the load applied to the tissues (Coleman et al. 2013; NPUAP et al. 2014; Oomens 1985; Takahashi et al. 2010). Secondly, the susceptibility and tolerance of the individual's tissues is influenced by the: mechanical and morphological properties of their tissues, physiology and repair properties, and transport and thermal properties of tissues (Coleman et al. 2013; NPUAP et al. 2014; Oomens 1985; Takahashi et al. 2010).

Pressure is defined as perpendicular force (or force applied at right angles) applied to an anatomical surface per unit area of application (Takahashi et al. 2010). Capillary-closing pressure or the pressure required to collapse capillaries and inhibit blood flow was cited by Landis (1930) as 32 mm Hg. However, capillary-closing pressure will vary between individuals, depending on vessel structure, adipose tissue deposition overlying bony prominences, tissue turgor, blood pressure, and general health status (Burman 1994). When compression exceeds the perfusion pressure and structural resistance of capillaries, oxygen and nutrient supply to the skin and underlying tissue is impaired.

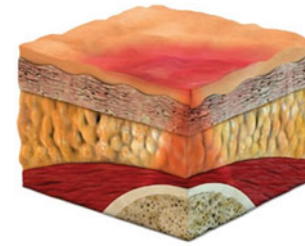
Shear stress is defined as parallel or tangential force and produces distortion of the tissues, causing two adjacent internal tissues to deform in the transverse plane (Reger et al. 2010; Takahashi et al. 2010). Shear results from sliding or dragging the skin across a support surface. Shearing injuries commonly occur in the cachexia or dehydrated palliative care patient when skin turgor and elasticity is impaired and the skin and underlying tissues are flaccid. Shear stress more readily distorts flaccid tissues, resulting in compression of capillaries or larger blood vessels in subdermal tissues. Shear is a common problem when an individual is positioned in a high or semi-Fowler's position on a resistant surface and they slide down the bed or chair.

Friction defines the parallel force or load applied to the skin surface (NPUAP et al. 2014). Friction is commonly referred to as rubbing or sliding of one surface against another or the force that resists the relative motion of two objects that are touching (Reger et al. 2010). The coefficient of friction is the measurement of the amount of friction existing between two surfaces and is dependent upon the contact surface material, the skin or support surface moisture, and the ambient humidity (Reger et al. 2010). The coefficient of friction is higher in the presence of macerated skin or contact with wet support surfaces or rough or wrinkled textiles or bedding (Carville 2017). Injuries that result from friction alone or friction and pressure combined are commonly seen on the heels or elbows and may present as intact or open blisters (NPUAP et al. 2014). Sustained mechanical loading results in the following sequelae: vessel occlusion, tissue hypoxia, pallor, ischemia, increased capillary permeability, alterations in skin pH due to accumulation of metabolic waste products in the interstitial space; edema, and necrosis (Pieper 2007; Takahashi et al. 2010). Pressure injuries are generally categorized or staged according to the NPUAP and EPUAP (2009) terminology (Australian Wound Management Association (AWMA) 2012; NPUAP 2014).

3 Staging Pressure Injuries

3.1 Stage I

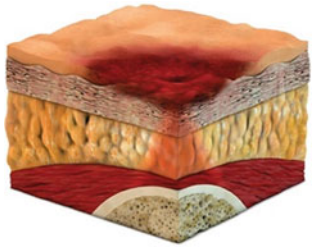
Intact skin with non-blanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, warmer, or cooler as compared to adjacent tissue. May be difficult to detect in individuals with dark skin tones. May indicate "at risk" persons (a heralding sign of risk) (NPUAP et al. 2014).



3.2 Stage II

Partial thickness loss of dermis presenting as a shallow, open wound with a red pink wound bed, without slough. May also present as an intact or open ruptured serum-filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising (bruising indicates suspected deep tissue injury).

Stage II should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation (NPUAP et al. 2014).

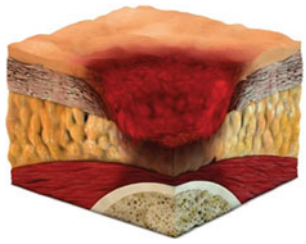


3.3 Stage III

Full thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling.

The depth of a stage III pressure injury varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and stage.

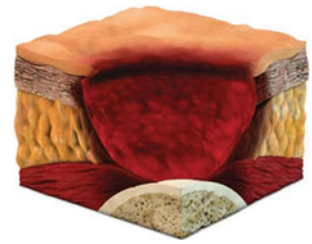
Stage III pressure injuries can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure injuries. Bone/tendon is not visible or directly palpable (NPUAP et al. 2014).



3.4 Stage IV

Full thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. The depth of a stage IV pressure injury varies by anatomical location.

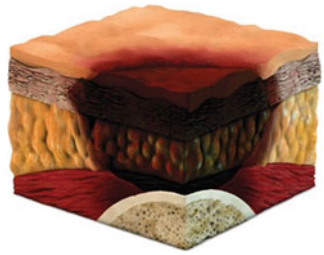
The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and these pressure injuries can be shallow. Stage IV injuries can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule) making osteomyelitis possible. Exposed bone or tendon is visible or directly palpable (NPUAP et al. 2014).



3.5 Unstageable Pressure Injury

Full thickness tissue loss in which the base of the pressure injury is covered by slough (yellow, tan, grey, green, or brown) and/or eschar (tan, brown, or black) in the pressure injury bed. Until enough slough/eschar is removed to expose the base of the pressure injury, the true depth, and therefore the stage, cannot be determined.

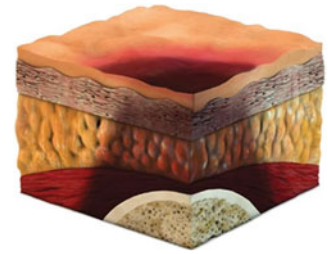
Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as the body's natural biological cover and should not be removed (NPUAP et al. 2014).



3.6 Suspected Deep Tissue Injury

Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared to adjacent tissue.

Deep tissue injury may be difficult to detect in individuals with dark skin tones.



Evolution may include a thin blister over a dark wound bed. The pressure injury may further evolve and become covered by thin eschar. Evolution may be rapid exposing additional layers of tissue even with optimal treatment (NPUAP et al. 2014); Images and graphics "Reproduced with permission of Wounds Australia. 4 When Is a Pressure Injury Not a Pressure Injury?

Palliative care patients can have coexisting wounds such as skin tears, leg ulcers, dehisced or draining wounds, and pressure injuries. A comprehensive health history and clinical assessment will assist in identifying the etiology of these wounds and direct appropriate care decisions. Nevertheless, the skin is the largest body organ and like other body organs, it is subject to pathophysiological and morphological changes when confronted with ageing, injury, critical illness, active dying, or the effects of vasopressor medications that induce vasoconstriction. In critically ill and end-of-life patients, acute "skin failure" is an emerging concept, albeit one that is based on anecdotal clinical observation rather than

quantifiable diagnostic markers. Skin failure has been described as a pressure-related injury reported to occur simultaneously with circulatory or organ failure, acute hypoperfusion, hemodynamic instability, and sepsis (Nowicki et al. 2017). However, some authors deem end-of-life skin failure to be a distinctly different pathological disorder as compared to pressure injuries (Curry et al. 2012; Delmore et al. 2015; Levine 2016).

Attempts to describe pathological skin alterations at end of life have resulted in palliative care practitioners reference to the term "Kennedy Terminal Ulcer" (KTU), which was first described in 1989 as a red, yellow, black, or purple pear, butterfly- or horseshoe-shaped lesion occurring primarily over the sacrococcygeal region within days to weeks of death (Kennedy 1989; Kennedy-Evans 2009). It is proposed that the KTU forms as a quick onset blister or abrasion, which deteriorates rapidly to a deeper stage III or IV pressure injury (Kennedy 1989; Kennedy-Evans 2009). The Trombley-Brennan Terminal Tissue Injury (TB-TTI) is a more recent addition to palliative care terminology and is defined as a pink, purple, or maroon ulcer that can occur over bony or non-bony tissues, including the extremities and trunk (Trombley et al. 2012). The lesions appear as non-blanchable, potentially white-centered, butterfly- or linear-shaped lesions, which do not progress to erosion or ulceration. They are reported to occur within hours to days of death (Carlsson and Gunningberg 2017).

Some authors describe these ambiguous lesions as unavoidable pressure injuries, while others propose that they are a distinctly different pathology and warrant a different nomenclature (Black et al. 2011; Steinberg 2016; Yastrub 2010). Regardless, the lack of consensus on what constitutes skin failure, a KTU, a TB-TTI, and unavoidable pressure injury, indicates a need for further research and quantifiable physiological and pathological criteria for assessment and diagnosis. In the meantime, comprehensive assessment of the patient and their wound should differentiate pressure injuries from wounds of other etiologies and guide the implementation of preventative strategies for those at risk.

5 Risk Factors for Pressure Injury

Predisposing risk factors for pressure injuries can be both intrinsic and extrinsic. Intrinsic factors (those that pertain to the person) alter the ability of the skin and underlying tissues to resist pressure, shear, and friction and they compromise recovery. Extrinsic factors (those that pertain to the external environment) increase the susceptibility of the tissues to damage. Palliative care patients especially in the terminal stage of disease are considered to be at high risk of pressure injury (Delmore et al. 2015; Langemo and Black 2010).

A structured approach to risk assessment of palliative care patients is a recommendation to be found in the International *Prevention and Treatment of Pressure Ulcers: Clinical Practice Guideline* (referred to hereon as the International Guideline), which was published in 2014 following a rigorous review of the evidence in the literature (NPUAP et al. 2014). The International Guideline ranks the strength of evidence presented as level A, B, and C as outlined in Table 1. In addition, the guideline provides strength of recommendations which are determined by the strength of internal or external evidence, clinical importance, potential to improve patient outcomes, feasibility, and cost-effectiveness of the recommendation.

Table 1 International Guideline strength of evidence (NPUAP et al. 2014)

Strength of evidence (SOE)	Recommendation
Level A	Recommendation supported by direct scientific evidence from properly designed and implemented controlled trials on PU in humans (level 1 studies)
Level B	Recommendation was supported by direct scientific evidence from properly designed and implemented clinical series on PU in humans (level 2, 3, 4, 5 studies)
Level C	Recommendation was supported by indirect evidence and/or expert opinion

A dedicated chapter for individuals receiving palliative care is to be found in the guideline, and the focus of this chapter is to build on the evidence for pressure injury prevention and management generally, with special consideration to optimizing comfort and patient preferences during active dying. A comprehensive health history and clinical assessment should be performed on admission and in accordance with changes in the patient's condition (NPUAP et al. 2014). Assessment of the palliative care patient should include: comorbid health problems, medications, nutritional status, risk factors, diagnostic test results, psychosocial implications, environmental resources, and the wishes and concerns of the individual and their significant others (NPUAP et al. 2014).

A structured approach to risk assessment can be directed by a number of pressure injury risk assessment tools such as the Braden Scale (Braden and Bergstrom 1992), Waterlow Score (Waterlow 1985), and Norton Score (Norton et al. 1962), which have been validated in different health settings and employed in palliative care. However, their validity and reliability in the palliative care setting lacks consensus. The Marie Curie Centre in Hunters Hill, Glasgow, devised and validated a risk tool specific to the needs of palliative patients and it is this tool that is proposed to have more utility in palliative care (Chaplin 2000). Comparative analysis was conducted between the numerical scores achieved with the use of the tool and the clinical judgment of experienced palliative care nurses. The seven risk parameters incorporated in the Marie Curie Centre Hunters Hill Risk Assessment Tool focus on the clinical changes evident in the tissues and activities of deteriorating palliative care patients and included: altered sensation, reduced mobility, excessive moisture, inactivity in bed, malnutrition, alterations in skin condition, and impacts of friction and shear on loose or cachectic tissues. Each risk factor is scored on an increasing four-point numerical scale and a minimum score of seven determines minimal risk and a maximum score of 28 determines very high risk (Chaplin 2000).

5.1 Altered Sensation

Altered sensation inhibits physiological responses to pain. Alterations in sensation are generally associated with loss of consciousness, analgesia, and neuropathy associated with malignant infiltration, surgical trauma, diabetes, or spinal cord injury (Chaplin 2000). Alterations in sensation impact significantly on patient mobility and activity.

5.2 Mobility and Activity

Immobility and inactivity results from neurological, cognitive, or physical dysfunction and impacts on the individual's ability to independently reposition and off-load mechanical forces (Carville 2017). Individuals who require assistance to reposition are susceptible to shear and friction due to dragging or sliding activities against support surfaces. Immobility impairs the blood flow to compressed tissues and retards the venous and lymphatic function, leading to edema which further compromises tissue oxygenation (Carville 2017).

The International Guideline discusses the need to reposition and turn the palliative patient at periodic intervals in accordance with their wishes, comfort, and tolerance (NPUAP et al. 2014). It is also recommended that premedication be offered 20 to 30 min prior to repositioning and that the patient be repositioned at least 4 h if on a reactive pressure redistributing mattress such as viscoelastic foam or 2 h on a regular mattress (NPUAP et al. 2014).

5.3 Nutrition and Hydration

Adequate hydration and a balanced diet containing essential nutrients is necessary for optimizing: tissue status, immune responses, a stable body mass index, and healing potential. Morbid obesity or cachexia will increase the individual's predisposition to pressure injuries. Individuals with morbid obesity have large amounts of poorly vascularized adipose tissue, and the capillaries in

adipose tissue are vulnerable to shear stress (Reger et al. 2010). Furthermore, morbid obesity compromises movement and activity and thus increases the risk of prolonged interface pressure. Alternatively, cachexia individuals have reduced adipose and muscle tissue, which reduces the tissues tolerance to pressure. Anorexia and nausea are common symptoms among palliative patients and nutritional protein and multivitamin supplements should be offered, especially when wound healing is the aim (NPUAP et al. 2014).

5.4 Alterations in Skin Condition

Skin assessment should be a component of the health agency's risk assessment screening policy (NPUAP et al. 2014). Alterations to skin perfusion, moisture, temperature, and pH can alter skin tolerance to pressure, shear, and friction (Carville 2017). Skin perfusion and oxygenation is compromised when blood vessels are compressed under pressure or damaged by shear or friction. Conditions such as ischemic heart disease, diabetes, peripheral arterial disease, cyanosis, hypotension, and smoking, as well as vasopressor medications can impair skin perfusion. In days or hours prior to death, skin failure as discussed earlier in this chapter may be demonstrated and the skin takes on a mottled, bluish appearance, which indicates hypoxia and ischemia (Curry et al. 2012; Kennedy-Evans 2009). Therefore, it is important to inform the patient or their significant others of potential skin changes at end of life (NPUAP et al. 2014).

5.5 Moisture

The tensile strength of the skin is impaired when there is frequent or excessive contact with moisture and the skin becomes macerated (Carville 2017). Moisture may result from incontinence of urine or faces, diaphoresis, uncontained wound exudate, dribbling of saliva and spilled food, drinks, or failure to maintain a stable microclimate. The latter term relates to the skin surface temperature and humidity or skin surface moisture when in contact with a support surface (Reger et al. 2010). The aim is to keep the skin clean and dry (NPUAP et al. 2014). Gentle skin cleansing practices and the use of tepid water will assist in preventing skin trauma, and the use of skin barrier creams, emollients, and protective barrier films can protect the skin from excessive moisture (NPUAP et al. 2014).

5.6 Temperature

An increase in body or skin temperature and ambient humidity increases the amount of skin moisture. Increases in skin temperature are closely aligned to changes in core body temperature (Carville 2017). However, local increases in skin temperature can occur due to contact with plastic or vinyl covered support surfaces or the use of excessive amounts of bed linen, clothing, or plastic-covered incontinence pads. An increased body temperature of 1 °C raises the metabolic demands of tissues by approximately 10% (Fisher et al. 1978). It has been proposed that individuals with pyrexia and associated increased tissue metabolic demands may be even more susceptible to pressure injuries when lesser amounts of pressure are applied or for shorter duration (Sae-Sia et al. 2005). Therefore, skin assessment should include assessment of skin temperature, edema, and change in surrounding tissue consistency (NPUAP et al. 2014).

5.7 Skin and Tissue pH

The skin pH averages 5.5 and is referred to as the acid mantle, which discourages bacterial colonization and reduces the risk of opportunistic infection (Carville 2017). Skin pH can best be maintained by avoidance of alkaline soaps and cleansers in favor of those that are perfume free and pH neutral. The use a pH balanced skin cleanser to maintain the normal acidic skin pH is highly recommended (NPUAP et al. 2014).

The pH of chronic wounds has been demonstrated to be alkaline with a pH range from 7.15 to 8.9 (Romanelli et al. 2002). Tsukada et al. (1992)

demonstrated increased alkalinity in deeper pressure injuries and wound healing to be associated with neutral or acidic pH. Stage I pressure injuries with intact skin were found to have an acidic pH of 5.4–5.6 which is aligned with normal skin pH, however, stage II injuries were found to have a pH of 6.9, and stage III injuries 7.6 (Tsukada et al. 1992). An acidic pH in the wound improves oxygen release and angiogenesis, impairs protease activity, and reduces toxicity and detrimental effects of bacterial end products such as ammonia and proteases (Geltin 2007).

6 Support Surfaces

The ability to off-load pressure and reduce shear impact is greatly aided by using appropriate support surfaces, which comprise: replacement mattresses, mattress overlays, or cushion support surfaces. The selection of these devices for prevention and management of pressure injuries is very much determined by the capability of the device to improve pressure redistribution and comfort (NPUAP et al. 2014). Support surfaces are broadly categorized as reactive and active devices, hybrid surfaces, or specialty beds. Reactive devices promote a constant low pressure principle that facilitates immersion and envelopment of the body (NPUAP et al. 2014). The devices can be powered or non-powered support surfaces and are comprised of high density, low resistance foams, polyester fiber, air or gel mediums that are covered with a two- or three-way stretch cover. These devices conform to the body contours on emersion which increases the load-bearing surface area.

Active support surfaces are powered air-filled devices that provide either constant low pressure or alternate pressure loading in cycles from one body part to another (NPUAP et al. 2014). Some alternating devices provide a one-in-two cycle (50% of the body is off-loaded at any time, others provide a one-in-three cycle (33% of the body is off-loaded at any time). Some active devices automatically adjust off-loading to support pressure on demand or movement. Active support surfaces can reduce the frequency of repositioning; however, extremely cachexia patients may find these devices afford less comfort than reactive mattresses or overlays that rely on emersion principles.

Hybrid support surfaces combine both reactive constant low-pressure foam support surface properties with active alternating air features when a pump is connected. Other hybrid support surfaces combine both reactive non-powered constant low-pressure foam and air cells that automatically respond to patient weight distribution and movement. Hybrid devices accommodate the need to "step-up" or "step-down" off-loading as pressure injury risk changes, without changing the support surface (Carville 2017).

Specialty beds combine a mattress and bed unit and incorporate low air loss systems, air fluidized systems, or pulsating or kinetic (continuous oscillation or rotation movement) therapies. These advanced technologies may convert from a bed to a chair position or combine repositioning capabilities, which makes repositioning easier for bariatric, cachexia, or immobile patients (Carville 2017).

7 Management of Pressure Injuries

Optimal management of a pressure injury involves comprehensive assessment and evidence-based interventions. See also ► Chap. 22, "Dealing with a Wound in Palliative Care." A comprehensive health assessment of the individual precedes a wound assessment which should include the following parameters:

- Pressure injury location and effectiveness of off-loading strategies and devices
- Clinical appearance of the wound bed or type and amount of tissue characteristics such as slough, necrosis, granulation, epithelium or exposed muscle, tendon, or bone
- Two- and three-dimensional measurement of depth, width, length, and circumference
- Amount, type, color, consistency, and odor of exudate

- Raised, rolled, undermined, colored, or macerated wound edges
- Surrounding skin characteristics identified on inspection and palpation which may include: blanching or non-blanching erythema, warmth, coolness, hemosiderin staining, edema, and induration
- Clinical signs of local or spreading infection
- Pain associated with wound or dressing procedure or removal (Carville 2017)

Assessment outcomes will guide evidence-based care plan decisions for the pressure injury and peri-wound, and these decisions should be consistent with the patient's wishes (NPUAP et al. 2014). However, wound healing may not be a realistic or achievable goal in the management of palliative care patients in the terminal stages of dying. This is especially so when the patient or family have made an informed decision to minimize repositioning or decline to use recommended support surfaces due to pain or patient decisions. However, this does not mean that the management of wound symptoms such as exudate, odor, infection, and wound pain are less deserving of the most diligent and informed assessment and best practice management. A collaborative and informed approach to care can do much to improve symptom management, quality of life, optimize comfort, and reduce patient and carer stress.

7.1 Exudate

Exudate is defined as the fluid that is produced and seeps from a wound (World Union Wound Healing Societies 2007).

Exudate is comprised of water, filtered red cells and platelets, electrolytes (sodium, potassium, chloride, bicarbonate), increased white cells (immune response), glucose (levels lower than those in blood), albumin, macrophages, cellular debris, proteolytic enzymes (elastase, collagenase, matrix metalloproteinases), high levels of lysosomes (antimicrobial agents), and growth factors (GF) (platelet-derived GF, basic fibroblast GF, epidermal GF) (Cutting 2003; Romanelli et al. 2010).

Exudate in acute wounds is usually initially sanguineous because of surgery or trauma, but in chronic wounds it tends to be produced in response to physiological changes in tissue pressures, inflammation, infection, and autolysis of necrotic tissue and can differ in type. Exudate has many purposes including wound cleansing, acts as a transport medium for white cells, proteases and growth factors, provides nutrients to cells, and promotes a moist wound healing environment (Cutting 2003; Winter 1962).

The amount of wound exudate depends on the wound etiology, the size of wound, the stage of wound healing (inflammatory or reconstruction phases), autolysis of necrotic tissue, and the presence of infection. A breach in the skin reduces the tissues' ability to maintain interstitial osmotic and hydrostatic pressures necessary to control normal fluid inflow from blood and outflow via lymph and the increased interstitial fluid leaks from the wound. Inflammatory responses and increased temperature results in capillary dilation and increased capillary permeability which in turn produces edema or increased interstitial fluid. Granulation deposition is an important aspect of the reconstruction phase of healing and granulation tissue has a high component of water-absorbing connective tissue components. Extensive granulation tissue or hypergranulation therefore influences the amount of exudate (Cutting 2003; Romanelli et al. 2010).

Autolysis is a physiological response to the presence of devitalized tissue and cellular debris which are denatured by phagocytic cells and endogenous proteolytic enzymes in the wound or wound fluid, which in turn adds to the moisture burden. Extremes in exudate volume can impact on the wound healing environment. Desiccation of the wound bed inhibits tissue reconstruction and epithelization, and an overly wet wound leads to maceration and impaired tensile strength in the tissues and subsequently can lead to peri-wound breakdown (Carville 2017). Excessive exudate can also increase the risk of infection.

Management of exudate in the management of palliative care patients with pressure injuries is determined by the short-term goal of care. Should

the goal of care be removal of eschar by promoting autolytic debridement, then this can be expedited if moisture donating hydrogels (for example: IntraSite®, SoloSite®, Flaminal®,) or moisture retention hydrocolloids (for example: Comfeel®, Duoderm®, Suprasorb H®), semipermeable films (for example: OpSite®, Tegaderm™, Hydrofilm®), or interactive wet dressings (HydroClean Plus®) dressings are used.

If exudate containment is the goal, then dressings are selected according to their moisture absorption and retention properties. Calcium alginate (for example: Kaltostat®, Biatain®, Urgosorb®), gelling fiber (for example: Aquacel®, Durafibre®, Exufibre®), foam (for example: Allevyn®, Biatain®, Tielle™) dressings are appropriate for low to moderate amounts of exudate while the super absorbent dressings (for example: Zetuvit Plus®, Relevo®, Vliwasorb®) are suitable for heavy exudate.

7.2 Odor

Odor can be a most distressing wound symptom and may be due to wound infection (especially anaerobic organisms), autolysis of necrotic tissue, or enteric or colonic fistula erosion into a pressure injury. Odor control is of paramount importance and involves regular wound cleansing, assessment, and management of infection and debridement of devitalized tissues with consideration to the individual's wishes and goals of care (NPUAP et al. 2014). Local wound infection usually responds to more frequent wound cleansing and the application of tissue-friendly antimicrobial cleansing solutions such as polyhexamethylene biguanide (Prontosan®), octenidine dihydrochloride (Octenilin®), or super-oxidized solution (Microdacyn®), and antimicrobial dressings (for example: silver, cadexomer iodine, wound honey). Spreading or systemic infection will require microbiological diagnostic investigations for appropriate antibiotic treatment. While fistula effluent within a pressure injury warrants containment in a wound or ostomy appliance. A variety of odor-absorbing dressings such as carbon-backed or impregnated dressings (for example: Carboflex®, Actisorb™, or Carbonet®) exist and should be considered if malodor is problematic.

Odor associated with autolysis of devitalized tissue may be curtailed with the assistance of faster debridement methods such as sharp or low-frequency ultrasound. However, noninfected dry eschar is nature's dressing, and it is usually considered prudent and more comfortable to leave it intact should the patient be close to death (Carville 2017).

7.3 Infection

Infection occurs when microorganisms multiply and host resistance is overcome. Host resistance is lowered when autoimmune status is impaired, immunosuppressant medications are prescribed, or chemotherapy and radiation therapy is involved. Infection adversely affects wound healing and can lead to life-threatening systemic infections. Assessment of the individual and their wound for clinical signs of infection should substantiate the need for microbiological assessment.

The classical signs of wound infection include: pain, heat, erythema, swelling, and purulence or increased exudate. Lymphangitis, crepitus, and wound deterioration or new breakdown may be indicative of spreading infection. However, signs and symptoms of local infection in chronic pressure injuries may be more subtle and involve:

- No signs of healing for 2 weeks
- Friable, bright red hypergranulation tissue
- New, increased, or altered pain
- Increased or altered exudate
- Malodor
- Increased necrosis
- Pocketing or bridging in the wound bed (International Wound Infection Institute (IWII) 2016).

These signs and symptoms of local infection are indicative of biofilm within the wound (IWII 2016). Biofilms are polymicrobial communities, which proliferate and are encased in a protective glycocalyx matrix also referred to as an extracellular polymeric substance (EPS). Microorganisms secrete the glycocalyx, which forms a biofilm that

protects the organisms from immune responses by phagocytes and from many topical and systemic antimicrobials (Phillips et al. 2010).

Biofilms evolve in the following sequence:

1. Planktonic attachment as free floating, single organisms attach to the surface of the wound (IWII 2016).
2. Irreversible attachment that is aided by the production of an extracellular polymeric substance (EPS), which protects against the host immune response. The EPS is comprised of polysaccharides, proteins, glycolipids, and bacterial DNA (Phillips et al. 2010).
3. Cell proliferation occurs as sessile (firmly attached) organisms communicate between microorganisms of same or different species via a process referred to as quorum sensing. Quorum sensing is responsible for phenotypic diversity and some of the genotypic diversity seen in wound biofilms, which enhances the community's nutrient-gathering capacity, defense, and reproductive abilities (IWII 2016).
4. Growth and maturation into a mature biofilm, which is immune to host defenses and many topical and systemic antimicrobials. Biofilms stimulate chronic inflammatory responses to dislodge biofilms, and there is a significant increase in neutrophils, pro-inflammatory cytokines, and proteases. Inflammatory cells secrete reactive oxygen species and proteases (matrix metalloproteases, elastase) to denature the biofilm; however, proteases can impair healing. Increased capillary permeability and tissue breakdown that occurs because of these host attempts to eradicate the biofilm produce nourishment for the biofilm (IWII 2016; Phillips et al. 2010).
5. Biofilm dispersal as the mature biofilm releases planktonic bacteria which attach to other parts of the wound and the cycle is repeated (IWII 2016; Phillips et al. 2010).

The International Guideline proposes that clinicians should suspect biofilm when:

- A pressure injury has been present for more than 4 weeks.
- Lack of healing progress in the previous 2 weeks.
- Clinical signs and symptoms of inflammation present.
- No response to antimicrobial therapy (NPUAP et al. 2014).

The management of biofilms replicates the principles of wound bed preparation, which involves: thorough cleansing, debridement, and the use of topical antiseptics to inhibit planktonic bacteria and the reformation of new biofilms. Some antimicrobial solutions and dressings such as polyhexamethylene biguanide (PHMB) with a surfactant (betaine) (Prontosan®) and cadexomer iodine (Iodosorb®), octenidine dihydrochloride (Octenilin®) and super-oxidized solution (Microdacyn®) have demonstrated ability to denature biofilms (IWII 2016; Phillips et al. 2010). While other antimicrobial dressings such as silver and medical-grade honey contribute bacteriostatic or bactericidal effects against planktonic microorganisms (Carville 2017; Phillips et al. 2010).

7.4 Wound Pain

Pain management is an important tenet of palliative care, whether the pain be associated with malignant infiltration or dressing procedure. Allodynia or pain at light touch may be experienced during wound cleansing or dressing removal and can be a significant issue for some. It is important to ascertain the pain etiology and patient preferences for management. Allodynia may be best managed by premedication and supporting the patient to undertake their own dressings if possible. The provision of simple directions for dressing removal and wound cleansing may prove beneficial. As is the use of silicone dressings that promote atraumatic removal or the use of highly absorbent dressings that require less frequent changing (NPUAP et al. 2014).

8 Conclusion

Pressure injury prevention and management is optimized when a collaborative approach, which involves the patient, their family, carers, and

health professionals is utilized. First and foremost, there is an utmost need to validate that the patient, their family, and care providers understand the goals and plan of care, and the palliative care patient's choices are acknowledged and accommodated if possible. At the end-of-life prevention of pressure injuries may not in every instance be a realistic goal due to the alterations in skin and tissues associated with active dying or conscious decisions made by the patient or their family to avoid regular repositioning or the use of recommended support surfaces. Should a pressure injury occur, palliative care principles for optimizing symptom management and patient comfort are employed.

Sleep Difficulties

24

Doris Howell

Contents

Abstract

Sleep disturbance is a prevalent and debilitating problem in palliative care that contributes to worse quality of life and adds to patient and caregiver suffering. Screening for this symptom in routine practice followed by a focused assessment and evaluation is essential given its consequences on daytime functioning and distress. The causes of disrupted sleep in palliative care populations are multifactorial and include disease physiology, uncontrolled physical symptoms, adverse effects of medications, and emotional distress or psychiatric disorders. Attention to reversible causative factors where possible, detection of specific sleep disorders

to ensure appropriate treatment, and development of a treatment plan individualized to the patient that takes into consideration prognosis are essential. Simple approaches such as sleep hygiene education may be helpful, but usually a combination of psychological and pharmacological agents is necessary for effective management. Cognitive behavioral therapy for insomnia (CBT-I) is considered first-line treatment for insomnia that targets the cognitive and behavioral factors that perpetuate this symptom but may require adaptation in the context of palliative care. Common medications used to manage insomnia include the benzodiazepine receptor agonists, benzodiazepines, and sedating antidepressants, but there is a lack of information about adverse effects of these drugs. High-quality research is needed to establish efficacy of psychological therapies and pharmacological agents for management of insomnia and other sleep disorders in palliative care. This chapter provides an overview of sleep disturbance, causative factors, and management of common sleep disorders of insomnia, sleep-wake cycle reversal, hypersomnia, and nightmares in palliative care.

1 Introduction

Sleep is a basic human need that is essential to physical and mental health. Sleep disturbance is a widespread and debilitating problem in the general population with rates of 20–41% reported in epidemiologic studies, whereas the prevalence of insomnia disorder defined by stringent diagnostic criteria ranges from 12 to 20% (Ohayon 2011; Buysse 2013). Sleep disturbance has profound consequences on physical and mental health including daytime fatigue, cognitive impairment, traffic and work site accidents, and work absences; increases the risk for cardiovascular disease, diabetes, obesity, and psychiatric disorders; and is associated with an increase in inflammatory processes, higher mortality, and healthcare costs (Garbarino et al. 2016).

Sleep disturbance is highly prevalent in patients with chronic diseases such as cancer and in advanced stages of disease but is often underrecognized and undertreated in clinical care. Patients and clinicians may both assume that little can be done to improve disruptions in sleep in the context of life-threatening or chronic disease. The estimated prevalence of sleep disturbance varies across studies due to differences in definitions of sleep disturbance and measurement, but rates of greater than 70% and as high as 95% have been noted in small and large observational studies in palliative care populations and in hospice and palliative care settings (Hugel et al. 2004; Renom-Guiteras et al. 2014; Mercadante et al. 2017).

A large body of research on insomnia has been conducted in the general population and cancer populations but less in advanced disease. Sleep disturbance is also a prevalent and serious symptom in cancer and other advanced disease populations. A systematic review across diverse advanced disease populations found sleep disturbance to be common in cancer, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), end-stage renal disease (ESRD), dementia (DD), acquired immunodeficiency syndrome (AIDS), Parkinson disease (PD), motor neuron disease (MND), and multiple sclerosis (MS) (Moens et al. 2014). The highest rates of insomnia were reported for ESRD (1–83%), followed by PD (40–74%), COPD (15–77%) and cancer (3–67%). Like sleep disturbance in the general population, insomnia as a comorbid problem with advanced disease has profound consequences on daytime functioning including cognitive impairment and interference with daily life activities and exacerbates severity of other physical symptoms such as pain, stress, psychological distress, and psychiatric disorders such as depression (Davidson 2002; Davis et al. 2014). Sleep disturbance may also be a problem for caregivers of palliative care patients with rates equivalent to those with the disease and contributes to caregiver burden, poor health, and hospitalization at the end-of-life (Maltby et al. 2017).

The causes of sleep disturbance in advanced disease are multifactorial and include biological, behavioral, and psychological factors and other contributors such as medications to manage other symptoms, adverse effects of medical treatments,

and environmental factors (Mystakidou et al. 2009; Berger 2009; Davis and Goforth 2014). Thus, sleep is a complex symptom that is challenging to manage in palliative care. Early identification and comprehensive evaluation of sleep disturbance are essential to determine the nature of the problem, causative factors, and impact on patients and caregivers and to detect the presence of specific sleep disorders that require appropriate treatment. The aim of treatment is to address reversible causes and enable restorative sleep through appropriate use of non-pharmacological and pharmacological interventions. Early intervention is extremely important in palliative care as this symptom can exacerbate symptom and psychological distress and has a negative impact on daily living, overall quality of life, and compounds suffering for patients and their caregivers. Poor sleep quality is a strong predictor of suicide in chronic disease and is associated with a desire to hasten death in palliative care (Rosenfeld et al. 2014).

The aim of this chapter is to provide an overview of normal sleep architecture and physiology, identify the factors associated with sleep disturbance, and discuss the comprehensive evaluation and management of this symptom and applicability of intervention approaches to palliative care. Specific sleep disorders in palliative care and management strategies will also be discussed in this chapter and include insomnia, hypersomnia, sleep-wake cycle reversal, and nightmares.

2 Definitions of Sleep Disturbance

A glossary of terms is shown in Table 1. Sleep health is defined as a multidimensional pattern of sleep-wakefulness, adapted to individual, social, and environmental demands, that promotes physical and mental well-being (Buysse 2014). Buysse defines good sleep health as subjective satisfaction, appropriate timing, adequate duration, high efficiency, and sustained alertness during waking hours.

The terms sleep disturbance (SD), sleep disorders, and insomnia or insomnia syndrome are often used interchangeably in the literature; however, there are distinctions between these problems. Sleep disturbance (also called sleep-wake disturbance) is an overarching term defined as perceived or actual alterations in nighttime sleep in terms of the quantity and quality of sleep with daytime impairment in the absence of a diagnostic label (Roscoe et al. 2007). Whereas, sleep disorders encompass diagnostic entities that are defined by the American Academy of Sleep Medicine (AASM) in the International Classification of Sleep Disorders manual third edition (ICSD-3, 2014) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-5, 2013). As shown in Table 2, common sleep disorders include the insomnias (initiating and maintaining sleep with daytime impairment), central disorders such as hypersomnolence (hypersomnia or excessive sleepiness), sleep-disordered breathing (e.g., obstructive sleep apnea), circadian rhythm disorders (e.g., sleep-wake reversal), sleep-related movement disorders (e.g., restless leg syndrome), and other dysfunctions associated with sleep stages or partial arousals or parasomnias, e.g., night terrors (Morin et al. 2015).

The sleep and arousal disorders most frequently encountered by the clinician are disorders of initiating and maintaining sleep, the insomnias. Insomnia is characterized as difficulty falling asleep (prolonged sleep latency) and maintaining asleep (waking up often with difficulty returning to sleep and/or early morning awakening), despite having the opportunity to sleep that is associated with a feeling of non-restorative sleep, daytime sleepiness, and impairment in daily functioning and activities. A clinical diagnosis of insomnia also called insomnia syndrome is confirmed on the presence of these subjective symptoms occurring on three nights or more per week for at least 1 month (ICSD-3 2014).

Insomnia can occur over a few days in response to stressful life events termed acute or adjustment insomnia or may be chronic (occurs three nights/week or more for 3 months). The diagnostic criteria for insomnia syndrome derived from the ICSD-3 and the DSM-5 are as follows:

- Difficulty initiating and/or maintaining sleep, whereby sleep onset latency is greater than

Table 1 Glossary of sleep disturbance terms

Term	Definition
Sleep disturbance	Termed sleep-wake disturbance and includes perceived or actual alterations in the quantity and quality of nighttime sleep with daytime impairment in the absence of a diagnostic label
Insomnia	Disruption in sleep, characterized by difficulty falling asleep (prolonged sleep latency), staying asleep (sleep maintenance), or a feeling of non-restorative sleep, associated with impairment in daytime functioning
Insomnia syndrome	Presence of insomnia symptoms on three nights or more per week for at least 1 month, accompanied by distress and impairment in daytime functioning
Acute insomnia	Termed adjustment or situational insomnia with insomnia symptoms experienced acutely in response to situational stressors; usually resolves when the stressful trigger has been resolved
Chronic insomnia	Presence of insomnia and insomnia syndrome symptoms on three nights or more per week for more than 3 months with daytime impairment in functioning and distress
Rapid eye movement (REM) sleep	Initial short phase of sleep characterized by random/rapid movement of the eyes, accompanied with low muscle tone throughout the body, and the propensity of the sleeper to dream vividly
Non-rapid eye movement (NREM) sleep	Four stages of NREM sleep (stages 1, 2, 3, and 4). Stage 1, lightest stage of sleep, characterized by slow eye movements. Stage 3 and 4 sleep is the deepest stage of sleep shown as slow-wave patterns on electroencephalography
Sleep disorders	Sleep disorders are a group of syndromes characterized by disturbance in the patient's amount of sleep, quality or timing of sleep, or behaviors or physiological conditions associated with sleep and a diagnostic entity identified by criteria in the International Classification of Sleep Disorders (ICSD-3) and the Diagnostic and Statistical Manual of Mental Disorders (DSM-5)
Sleep hygiene	Behavioral or environmental practices that positively or negatively affect sleep including avoiding stimulants such as caffeine or alcohol several hours before bedtime and other behaviors to enhance learned association of going to bed with sleep and includes attention to sleep environment (dark environment, quiet, and comfortable)

References: Ohayon (2011), Buysse (2013), Carskadon and Dement (2005), ICSD-3, DSM-5

30 minutes or frequent or prolonged nocturnal awakenings lasting greater than 30 minutes that is non-restorative.

- Sleep difficulty occurs despite adequate opportunity to sleep.
- Sleep efficiency (ratio of total sleep to time spent in bed) is lower than 85%.
- Difficulties occur at least three times per week.
- Difficulties occur for at least 1 month.
- Difficulties cause distress or daytime impairment in at least one of the following forms of daytime impairment:
  - Fatigue or malaise
  - Attention, concentration, or memory impairment
  - Social or vocational dysfunction or poor school performance
  - Mood disturbance or irritability
  - Daytime sleepiness
  - Motivation, energy, or initiative reduction
  - Proneness for errors/accidents at work or while driving
  - Tension, headaches, or gastrointestinal symptoms in response to sleep loss
  - Concerns or worries about sleep

Daytime impairment is a key feature of clinically relevant insomnia and can include fatigue, cognitive and memory impairment (changes in executive functioning, learning, and recall), and mood disturbances. Symptoms of insomnia can differ between older adults (>65) and younger populations. Older adults are more likely to report problems with waking after sleep onset (difficulty maintaining sleep) than problems with sleep onset latency (time to fall asleep) (Bloom et al. 2009).

Insomnia is differentiated into primary insomnia without comorbid illness or secondary insomnia

Table 2 Sleep disorders and characteristics

Disorder	Definition and characteristics
Insomnia disorder	Disorders of initiating and maintaining sleep with symptoms of difficulty initiating or maintaining sleep (early morning awakening and unable to resume sleep) occurring three nights/week for a month that is associated with distress and impairment in daytime functioning
Breathing-related sleep disorders	Conditions during which respiration pauses occur during sleep due to either complete or partial collapse of the person's airways lasting up to 10 seconds. Includes obstructive sleep apnea (OSA, in which no ventilation occurs) and hypopneas (reduced ventilation due to partial airway obstruction) with intermittent and abrupt reduction in blood oxygen levels. Symptoms include snorting, snoring, gasping, choking in one's sleep, and excessive daytime sleepiness. Includes OSA central sleep apnea, sleep-related hyperventilation
Restless legs syndrome (RLS)	A neurological disorder that causes achy, uncomfortable (and sometimes painful) tingling, tugging, or creepy crawly sensations in the legs associated with a need to move. Symptoms are worse in the evening and improve with walking or stretching
Narcolepsy	A hypersomnia characterized by profound sleep onset paralysis and vivid hallucinations that occur as a person is falling asleep. Excessive daytime sleepiness, cataplexy, hallucinations upon falling asleep or awakening. Narcolepsy with cataplexy also involves sudden loss of muscle control
Circadian rhythm sleep disorders	Disorders that involve an abnormal sleep-wake rhythm caused by a circadian clock that is not in phase with, and cannot be entrained to, the 24-hour light-dark cycle. Symptoms of habitually early sleep onset and wake times, compared with societal or preferred norms. Those with irregular sleep-wake disorder typically have three or more sleep episodes during a 24-hour period
Nightmare disorder	Disturbing mental experiences that generally occur during rapid eye movement (REM) sleep in the later portion of the night and often result in the person waking up. Occasional nightmares are normal; a nightmare disorder is diagnosed only if nightmares become more frequent and significantly affect daytime functioning and mood
Hypersomnolence disorder	Disorders of excessive daytime sleepiness (EDS) that interferes with functioning; can manifest itself as a tendency to fall asleep during normal waking hours when unstimulated. EDS and "hypersomnia" are currently used interchangeably. Although persons with hypersomnia chronically fall asleep when unstimulated, they do not necessarily require longer than average hours of sleep
Parasomnias	Parasomnias are a group of sleep disorders that involve unwanted events or experiences that occur, while you are falling asleep, sleeping, or waking up; may include abnormal movements, behaviors, emotions, perceptions, or dreams including sleep sex and night terrors

References: Gillette and Abbott (2005), Morin and Benca (2012), Morin et al. (2015), ICSD-3 and DSM-5

that is comorbid with a pre-existing medical condition. Primary insomnia can be divided into psychophysiologic and physiologic insomnia. Psychophysiologic primary insomnia is related to heightened arousal and learned sleep preventing behaviors. Physiologic primary insomnia is a confirmed sleep abnormality associated with abnormal polysomnography (PSG) indicating disruptions in non-rapid eye movement (NREM) sleep or rapid eye movement (REM) sleep (ISCD-3 2014). Palliative care populations may have a combination of a pre-existing primary sleep disorder and insomnia that occurs in response to diagnosis or treatment (acute or adjustment insomnia) but is usually chronic in cancer and other chronic or advanced diseases. In clinical practice, differentiating between sleep disturbance and insomnia is less important than detection of specific sleep disorders that require referral and evaluation by sleep specialists and appropriate treatment.

Later in this chapter, the assessment and management of common sleep disturbances in medical conditions and palliative care, defined in Table 2, including insomnia or insomnia syndrome, hypersomnia, circadian rhythm disturbance, specifically sleep-wake cycle reversal, and nightmares will be discussed.

3 Sleep Architecture and Physiology

Sleep influences the body's major physiological systems, including thermoregulatory, musculoskeletal, endocrine, respiratory, cardiovascular, gastrointestinal, and immune systems (Sateia and Pigeon 2004). These physiological systems are bi-directional and can be affected by disrupted sleep or influence an individual's sleep. Disruptions in sleep can all drastically change a person's thinking and behavior and negatively impact on physical, mental, and emotional health.

Sleep architecture (SA) refers to the basic structural organization of normal sleep, which is segmented into two types of sleep identified as non-rapid eye movement (NREM) and rapid eye movement (REM) sleep (Zepelin et al. 2005). NREM is associated with distinct brain activity and physiology and is divided into progressively deeper stages of sleep comprised of four stages (stage 1–4). Each stage has unique characteristics in brain wave patterns, eye movements, and muscle tone. During sleep, NREM and REM sleep alternate cyclically, and disruptions in either the cycling or stages are associated with sleep disorders. NREM stage 1 describes the transition between wake and sleep that occurs upon falling asleep and during brief arousal periods and represents 2–5% of total sleep time. Stage 2 represents 45–55% of sleep time and occurs throughout the sleep period. Stages 3 and 4 are referred to as slow-wave or deep sleep, most of which occurs during the first third of the night. Stage 4 lasts about 20–40 minutes and makes up about 10–15% of total sleep time. Both are shown on EEG as high-voltage and slow-wave activity. Whereas, REM sleep is shown on EEG as low-voltage and mixed frequency, muscle atonia, and bursts of REM and is most often associated with dreaming.

Physiological changes that occur during sleep, specifically during REM sleep, including cardiovascular (increases in blood pressure and heart rate, particularly in the morning), respiratory (ventilation and respiratory flow become increasingly faster and more erratic and less adaptive; cough reflexes are suppressed), and thermoregulatory processes. Changes also occur with NREM sleep and include reduced cerebral blood flow and metabolism, changes in renal blood flow, glomerular infiltration, hormone secretion, and sympathetic neural stimulation that is evidenced in decreased secretion of electrolytes and calcium, reduced urine flow and higher concentration of urine, and changes in endocrine functions such as secretion of growth hormone, thyroid hormone, and melatonin (influenced by light-dark cycle and suppressed by light).

Sleep-Wake Regulation The dominant model for sleep-wake regulation consists of two key processes including a homeostatic process that promotes sleep (process S) and a circadian process that maintains wakefulness (process C) (Borbely 1982). Process C is wake promoting and regulated by the circadian system, whereas process S counteracts process C to promote wakefulness and alertness in a cyclical process initiated during the day and night that is coordinated with environmental light-dark cycles. Sleep process S is regulated by neurons in the hypothalamus with transmission through molecules that shut down the arousal system, thus allowing the brain to fall asleep, the loss of which can cause profound insomnia. Inputs from other regions of the brain can also influence this sleep system such as the lower brainstem (communicates information about the state of the body, i.e., a full stomach) and emotional and cognitive areas in the forebrain.

Wakefulness is generated by two key pathways that originate in the ascending arousal system of the brainstem. The first pathway arises from cholinergic neurons in the upper pons, which activates parts of the thalamus that transmits sensory information to the cerebral cortex. The second pathway originates in cell groups in the upper brainstem that contain the monoamine transmitters (norepinephrine, serotonin, dopamine, and histamine), which enter the hypothalamus picking up inputs from nerve cells that contain peptides (orexin, hypocretin, and melanin-concentrating hormone) and from cells in the forebrain that contain acetylcholine and gamma-aminobutyric acid and are interpreted in the cerebral cortex through activation of nerve cells. Multiple factors,

alone or in combination, can impact processes C and S, disturbing the timing, duration, and architecture of sleep and potentially creating complaints of insomnia (Carskadon and Dement 2005). Additionally, there are inputs from the circadian system that enable the wake-sleep system to synchronize with the external day-night cycle or override the cycle to meet environmental needs (Waterhouse et al. 2012).

Circadian Rhythms Circadian rhythms (24-hour clock) control the sleep-wake cycle and other physiological processes such as body temperature, heart rate, muscle tone, and hormone secretion such as corticosteroids (Gillette and Abbott 2005). The rhythms are generated by neural structures in the hypothalamus that function as a biological clock and organize physiological rhythms in accord with environmental day-night cycles and through a disruption in gene products in a negative feedback loop that controls the 24-hour cycle time of circadian clocks and other body systems such as lipid metabolism. The suprachiasmatic nucleus (SCN) is responsible for regulating circadian rhythms through inputs from nerve cells in the retina that act as brightness detectors, which can reset the clock genes; these are transmitted to the brain and physiological processes in the body to bring about all the daily cycles synchronized with the day-night cycle. The SCN controls melatonin secretion, which further consolidates circadian rhythms.

Sleep Patterns The pattern of sleep changes across the life course including how sleep is initiated and maintained, the percentage of time spent in each stage of sleep, and overall sleep efficiency (i.e., how successfully sleep is initiated and maintained) (Bliwise 2005). Older individuals typically show an increase in sleep disturbance with difficulty in initiating and maintaining sleep particularly in the presence of depression, respiratory syndromes, and physical disability illness that is likely due to a gradual deterioration in the hypothalamic nuclei that drive circadian rhythms and melatonin production (Dijk et al. 2000). Decreasing sleep homeostasis can occur (time spent in stage 3 sleep decreases, increase in overnight arousals), which can be exacerbated by comorbid medical conditions such as musculoskeletal disorders and cardiopulmonary disease. Gender-based differences in sleep and circadian rhythms have also been shown. Adult men spend greater time in stage 1 NREM sleep and experience more awakenings, whereas women maintain slow-wave sleep (stage 3 and 4 NREM) longer than men and experience more difficulty falling asleep and mid-sleep awakenings.

4 Etiology and Risk Factors

Sleep disturbance specifically insomnia occurs as a comorbid problem with many medical conditions as shown in Table 3 (Schutte-Rodin et al. 2008). The causes of sleep disturbance comorbid with chronic illness and advanced disease are

Table 3 Comorbid conditions and insomnia

Body system	Comorbid condition
Neurological	Stroke, dementia, Parkinson disease, seizure disorders, headache disorders, traumatic brain injury, peripheral neuropathy, chronic pain disorders, neuromuscular disorders
Cardiovascular	Angina, congestive heart failure, dyspnea, dysrhythmias
Pulmonary	COPD, emphysema, asthma, laryngospasm
Digestive	Peptic ulcer disease, cholelithiasis, colitis, irritable bowel syndrome
Genitourinary	Incontinence, benign prostatic hypertrophy, nocturia, enuresis, interstitial cystitis
Endocrine	Hypothyroidism, hyperthyroidism, diabetes mellitus
Musculoskeletal	Rheumatoid arthritis, osteoarthritis, fibromyalgia, Sjögren syndrome, kyphosis
Reproductive	Pregnancy, menopause, menstrual cycle variations
Other	Allergies, rhinitis, sinusitis, bruxism, alcohol, and other substance use/dependence/withdrawal

Reference: Schutte and Rodin 2008

multifactorial, and both physical and psychological factors are clinically important. Differentiation of these factors into predisposing, precipitating, and perpetuating factors based on Speilman's three-factor conceptual framework is useful for guiding assessment of factors that contribute to insomnia (Spielman et al. 1996). This model known as the 3P model asserts that underlying biological or predisposing factors such as pre-existing traits interact with various situational (precipitating) factors, causing acute insomnia, whereas the detrimental beliefs, behaviors, and strategies (perpetuating factors) employed to cope with loss of sleep lead to the development of chronic insomnia. All types of insomnia, regardless of etiology, share the final common pathway of cognitive and physiologic hyperarousal, causing an individual to cross the insomnia threshold, i.e., the point at which sleeplessness occurs (Buysse 2013).

4.1 Predisposing Factors

The underlying risk or precipitating factors for insomnia vary but can include female sex; advanced age; lower levels of education; depressed mood; breathing disorders of sleep such as obstructive sleep apnea; low levels of physical activity; comorbid medical conditions, i.e., diabetes; nocturnal micturition; regular use of agents to aid sleep (i.e., hypnotics); previous history of insomnia; and high levels of perceived stress and/or anxiety (Morin and Benca 2012). Although higher rates of insomnia have been reported in younger cancer patients, this may be confounded with the high rates of psychosocial distress noted in those with life-threatening illness earlier in the life cycle (Palesh et al. 2010). Individuals presenting with insomnia syndrome usually exhibit premorbid psychological vulnerability to insomnia, characterized by higher depressive and anxiety symptoms, lower extraversion, higher arousability, and poorer self-rated mental health at baseline that pre-exists the diagnosis of a life-threatening or chronic illness (Morin and Benca 2012).

4.2 Precipitating Factors

A complex relationship exists between subjective events and neural events that can precipitate disruptions in sleep, and the biological mechanisms are not fully elucidated.

Adverse Disease or Treatment Effects Physiological response to disease or treatments such as brain radiotherapy, chemotherapy, or hormone therapies in cancer, thermoregulatory problems, or immunological changes are associated with insomnia (Berger 2009). Sleep disturbance is also common with diseases involving the central nervous system such as degenerative brain diseases, i.e., Alzheimer, or that disrupt the SCN and sleep processes such as REM sleep (e.g., dopaminergic deficit in Parkinson disease) or diseases affecting the liver, e.g., cirrhosis, and can include changes in liver function at the end-of-life that can disturb the sleep-wake cycle or the central nervous system, i.e., the brain (DeCruz et al. 2012). Shorter sleep time, increased lighter sleep with multiple arousals, and lower sleep efficiency have also been reported in those with chronic obstructive lung disease or congestive heart failure (McSharry et al. 2012).

Symptoms and Symptom Clusters In advanced disease, sleep disturbance is often associated with other symptoms, such as pain, fatigue, psychological distress, and psychiatric conditions (depression and anxiety). These symptoms are often interrelated likely due to similar underlying inflammatory mechanisms as part of a symptom cluster making this a complex symptom to manage in clinical practice (Berger 2009). Insomnia in palliative care populations is often identified as part of a symptom cluster of insomnia, pain, and depression or symptom clusters of pain, fatigue, and insomnia (Davis and Goforth 2014; Beck et al. 2005).

Other symptoms associated with chronic disease or adverse effects of treatments can also disrupt sleep (e.g., menopausal or other gastrointestinal, genitourinary, respiratory symptoms, co-

occurring symptoms, or symptom clusters) (Berger 2009). A small observational study of palliative care inpatients (n = 61) found that pain, medications to treat pain such as opiates, and respiratory symptoms of dyspnea and cough contributed to severe insomnia (Renom-Guiteras et al. 2014). Larger studies (n = 209) have also shown that physical symptoms such as pain and psychological distress particularly depression contribute to insomnia in palliative care populations (Akechi et al. 2007; Glynn et al. 2014).

Chronic Pain and Opiates Chronic pain is a strong predictor of sleep disturbance and attributed to disruptions in REM and slow-wave NREM sleep and characterized as symptoms of difficulty falling asleep and staying asleep, lack of restful sleep, frequent awakening, and daytime somnolence (Finan et al. 2013). Pain is highly prevalent in many chronic diseases and can be excruciating in advanced diseases such as cancer (Berger 2009). A vicious cycle of disturbed sleep due to pain followed by worsening of pain and resulting in more disruption in sleep has been noted. Of note, high pain intensity and insomnia have been shown to increase a desire for hastened death at the end-of-life (Rosenfeld et al. 2014).

Medications used to manage pain such as opiates may also disrupt sleep. Although the exact mechanism by which opioids disrupt sleep is unclear, morphine has been shown to reduce REM sleep via inhibition of acetylcholine release in the medial pontine reticular formation resulting in disruption of sleep architecture and affecting states of arousal during wakefulness (Brincat and Macleod 2007). The adverse effects of opiates on the central nervous system are complex but include a decrease in the level of consciousness (sedation, drowsiness), those affecting the thinking process and ability to react (cognitive impairment, delirium, hallucinations), and direct toxic effects on neurons (myoclonus, seizures, hyperalgesia, tolerance). The sedative effects of opioids can disrupt daytime arousal and disrupt circadian rhythms and lead to sleep-wake reversal and contribute to vivid dreams and nightmares. Many of these causes of sleep disturbance can be managed through optimization of pain management and with opioid dose reduction, opioid rotation, or use of a psychostimulant such as methylphenidate to counteract the sedating side effects of opioids to minimize sleep-wake reversal or hypersomnia (Mystakidou et al. 2009).

Psychological Distress A large body of evidence has shown associations between psychosocial distress, psychiatric conditions such as generalized anxiety disorder and depression, and insomnia. Psychological distress and psychiatric conditions such as depression is common in palliative care populations with high rates of moderate to severe depression reported (Wilson et al. 2007). Depression has been linked to disturbances in the continuity of sleep, decreased latency to the first REM sleep period, and diminished deep sleep (NREM, stage 3 and 4) (Ohayon 2011). Situational anxiety or pre-existing anxiety disorders can also contribute to nightmares and are found to be associated with sleep disturbance in palliative care populations through arousal of the primary adrenal axis (Davis et al. 2014). A recent review and meta-analysis of sleep and mental disorders showed alterations in sleep across a range of psychiatric conditions with noted changes in the arousal system, sleep depth, and REM processes with variation based on type of psychiatric disorder (Baglioni et al. 2011). Insomnia may also be a symptom of psychological distress, and effective treatment of this symptom may help to reduce sleep disturbances, although the interrelationship between these disorders is complex. Sleep disturbance is a hallmark symptom of major depression.

Medications to Manage Disease and Insomnia Any drugs that alter the balance of the neurotransmitters that regulate the sleep-wake cycle or the direct effects of disease on the central nervous symptom and other physiological systems can disrupt sleep. Drugs shown to contribute to insomnia include corticosteroids, diuretics, stimulant antidepressants, and other stimulants, such as antipsychotics, and a paradoxical response to hypnotics that can disrupt sleep has been shown (Davis

and Goforth 2014). A large systematic review of reviews with meta-analysis showed that drug classes such as DOPA agonists (for Parkinson disease and restless legs syndrome), acetylcholinesterase inhibitors (for Alzheimer disease, cognitive impairment, and dementia), SSRIs (for obsessive-compulsive disorder and premenstrual syndrome), serotonin-norepinephrine reuptake inhibitors (for generalized anxiety disorder), opioid receptor antagonists (for alcohol dependence), tricyclic antidepressants (TCAs) (for depression), COMTI (for Parkinson disease), nicotine receptor agonists (for smoking cessation), and systemic corticosteroids (for chronic obstructive pulmonary disease) are associated with impairment in sleep (Doufas et al. 2017). Moreover, psychotropic medications used to manage psychological distress or psychiatric conditions may worsen sleep disorders and may contribute to sedation and drug accumulation particularly in older individuals. As an example, mirtazapine commonly recommended in palliative care for management of psychological distress and symptoms of insomnia or insomnia syndrome has been shown to increase somnolence, sedation, and other symptoms that are associated with sleep disturbance such as hallucinations and delirium (Khoo and Quinlan 2016).

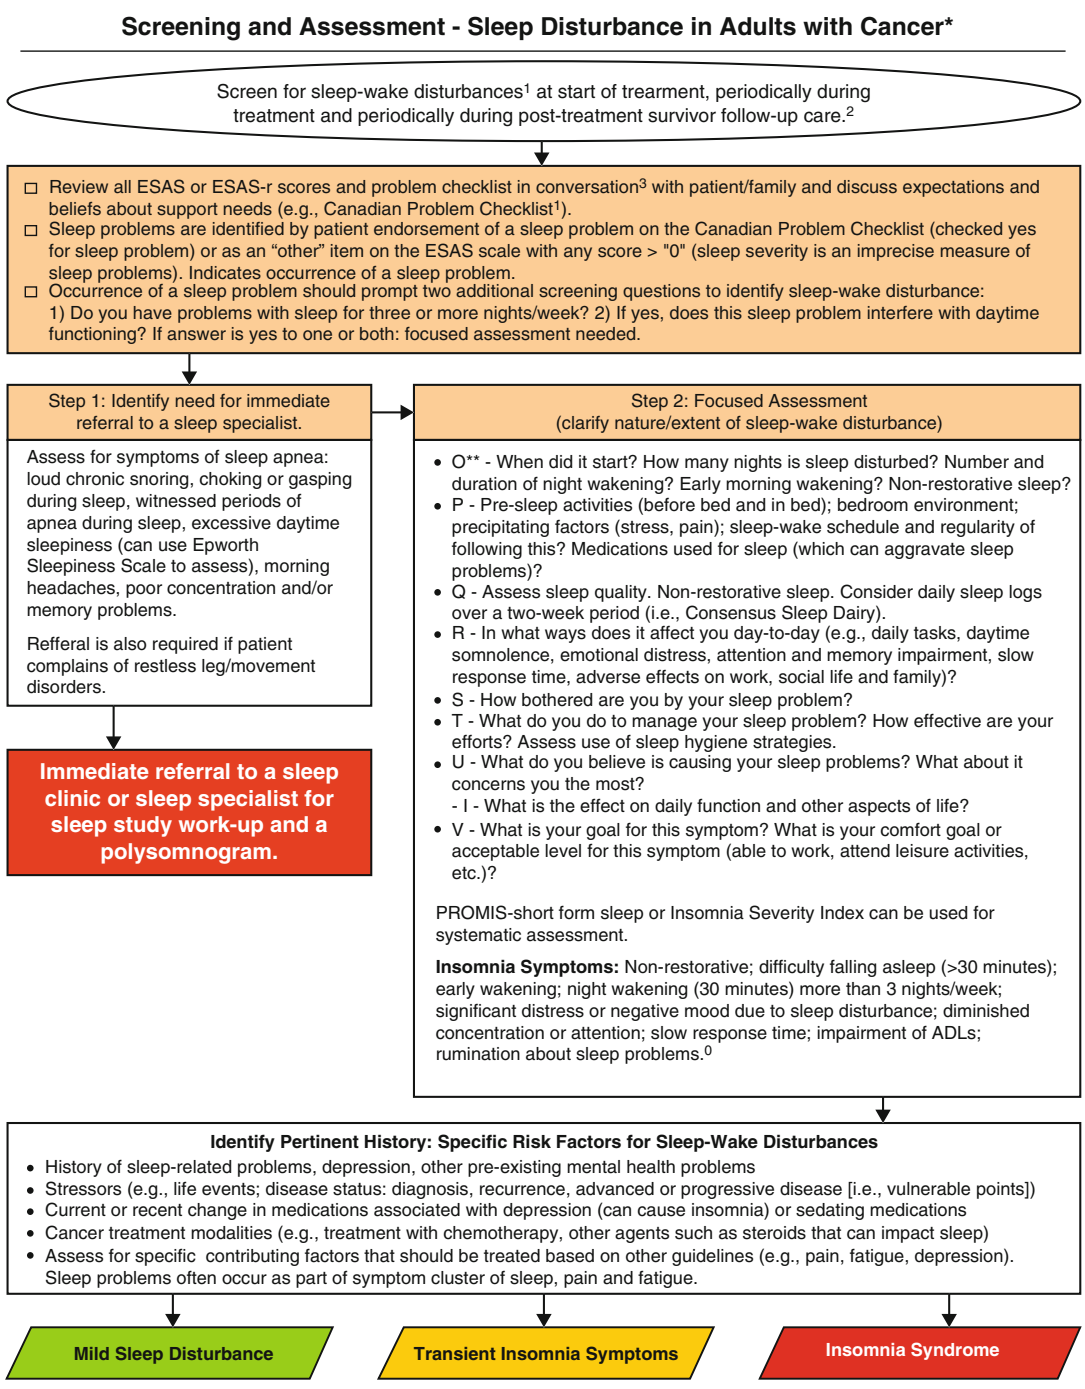
Environmental Factors Adequate levels of sleep are dependent on not only the physiological environment but also on behavioral and environmental factors. Excessive arousal in bed is a frequent cause of insomnia and may be particularly pronounced for patients with advanced disease. Nighttime rumination, fears, anxiety, and worry are profound for these patients and may contribute to hyperarousal. Environmental factors such as disruptive noise or interruption of sleep by caregivers, absence of usual light/dark cues, or temperature also play a role in sleep disruption. In PCUs, interruptions during the night by the nursing staff, noise coming from the ward or from another patient in the same room, have been shown to influence the sleep quality of palliative care patients (Hugel et al. 2004).

4.3 Perpetuating Factors

Beliefs, behaviors, or thoughts can maintain or exacerbate sleep disturbance (Buysse 2013). Behaviors including excessive time in bed, daytime napping, reduced daily activity, irregular sleep-wake times, stimulant consumption, and inappropriate use of sleep aids and beliefs including unrealistic sleep expectations, false perception of sleep time and quality, fear of sleeplessness, and difficulty discerning the cause of daytime fatigue can contribute to sleep disturbance. Negative cognitions such as uncertainty about the disease and prognosis, existential distress, and nighttime rumination accompanied by feelings of fear may all contribute to sleep disturbance in palliative care patients (Renom-Guiteras et al. 2014).

5 Clinical Assessment and Evaluation of Insomnia

Comprehensive assessment and evaluation of sleep disturbances as part of routine practice in palliative care populations is essential given its high prevalence and impact on symptom burden and psychological distress. As shown in Fig. 1, current practice guidelines recommend a three-step process for the assessment and evaluation of sleep disturbance (Howell et al. 2011, 2013; Qaseem et al. 2016). The initial step involves routine screening to identify sleep disturbance at scheduled clinic visits (Step 1). A positive screen for the presence of sleep disturbance should be followed by additional questions for detecting sleep disorders (Step 2). This step should be followed by a more focused assessment and evaluation to identify the specific parameters of sleep disturbance necessary to guide selection of interventions (Step 3). Routine screening in clinical care may be particularly important as palliative care patients may not complain of sleep disturbance. Moreover, an initial screening step can identify sleep disorders that require referral to a sleep specialist and can reduce the burden of a full assessment or completion of more lengthy sleep measures.



* Refer to the full technical guideline document for the disclaimer statement on the Canadian Association of Psychosocial Oncology website (www.capo.ca).

1 Use Screening for Distress Tool (SDT), which includes Edmonton Symptom Assessment System (ESAS-r) and Canadian Problem Checklist (CPC).

2 At initial diagnosis, start of treatment, regular intervals during treatment, end of treatment, post-treatment or at transition to survivorship, at recurrence or progression, advanced disease, when dying, and during times of personal transition or re-appraisal such as family crisis, during survivorship, when approaching death (CAPO/CPAC guideline: "Assessment of psychosocial Health Care Needs of the Adult Cancer Patient" by Howell et al., 2009).

3 The health care team for cancer patients may include surgeons, oncologists, family physicians, nurses, social workers, psychologists, radiation therapists, patient navigators and other health care professionals (HCPS).

Fig. 1 (continued)

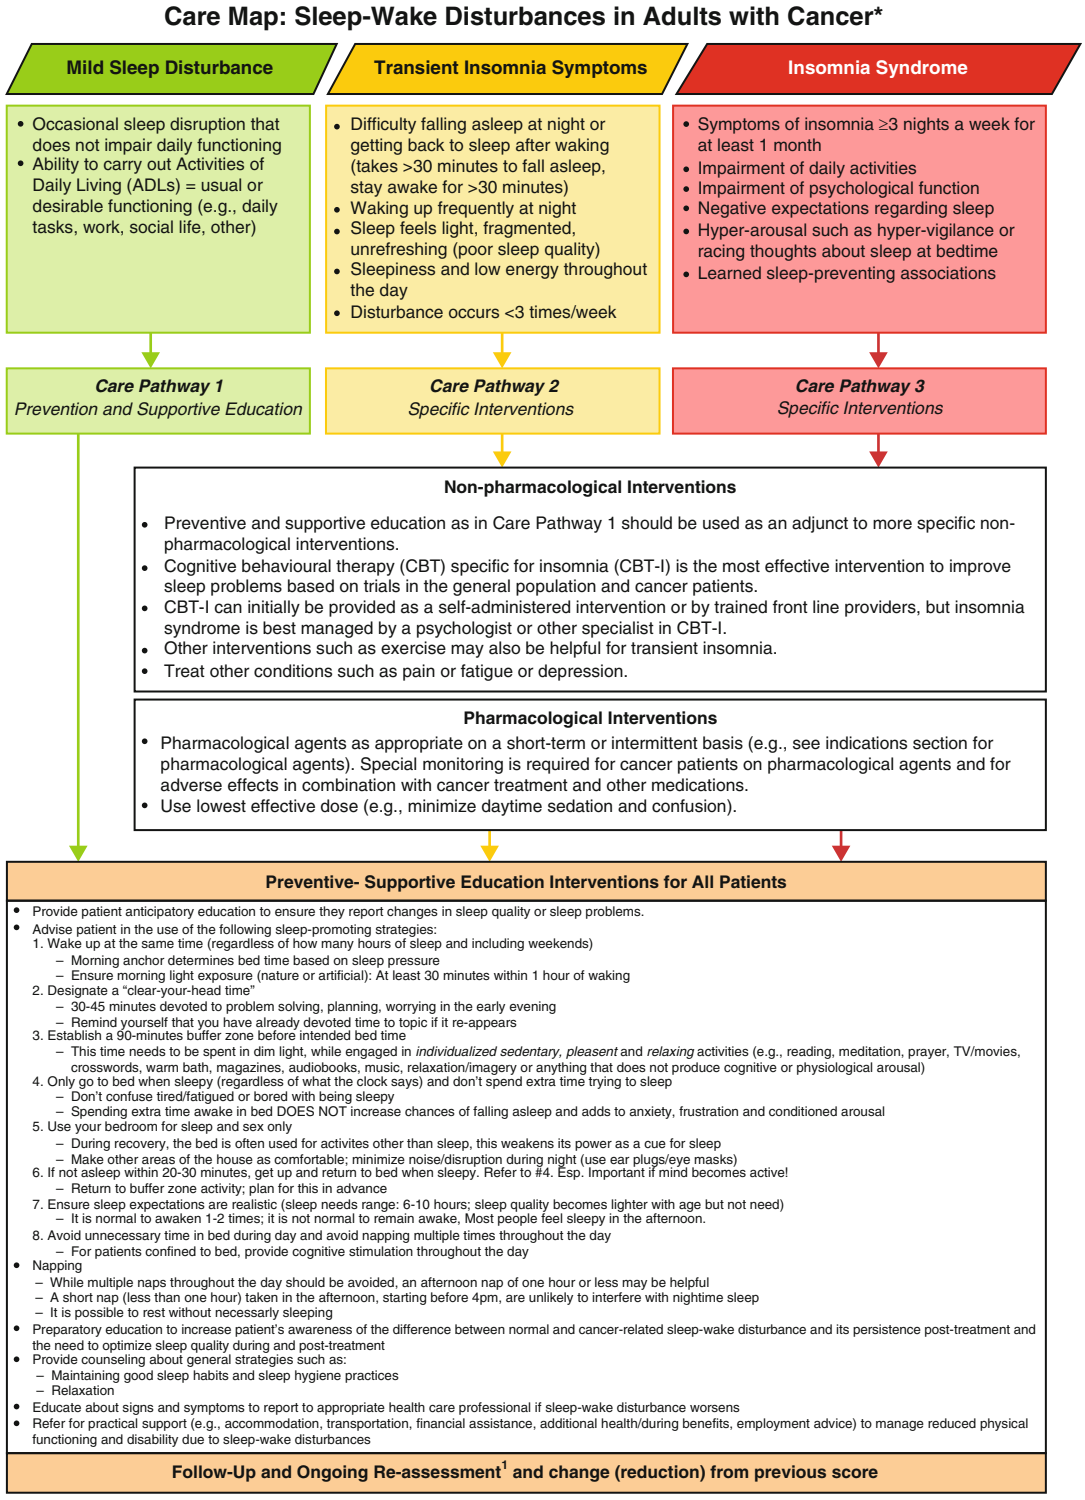

Fig. 1 Screening and assessment for insomnia in adults with cancer (Source: Howell et al. 2013)

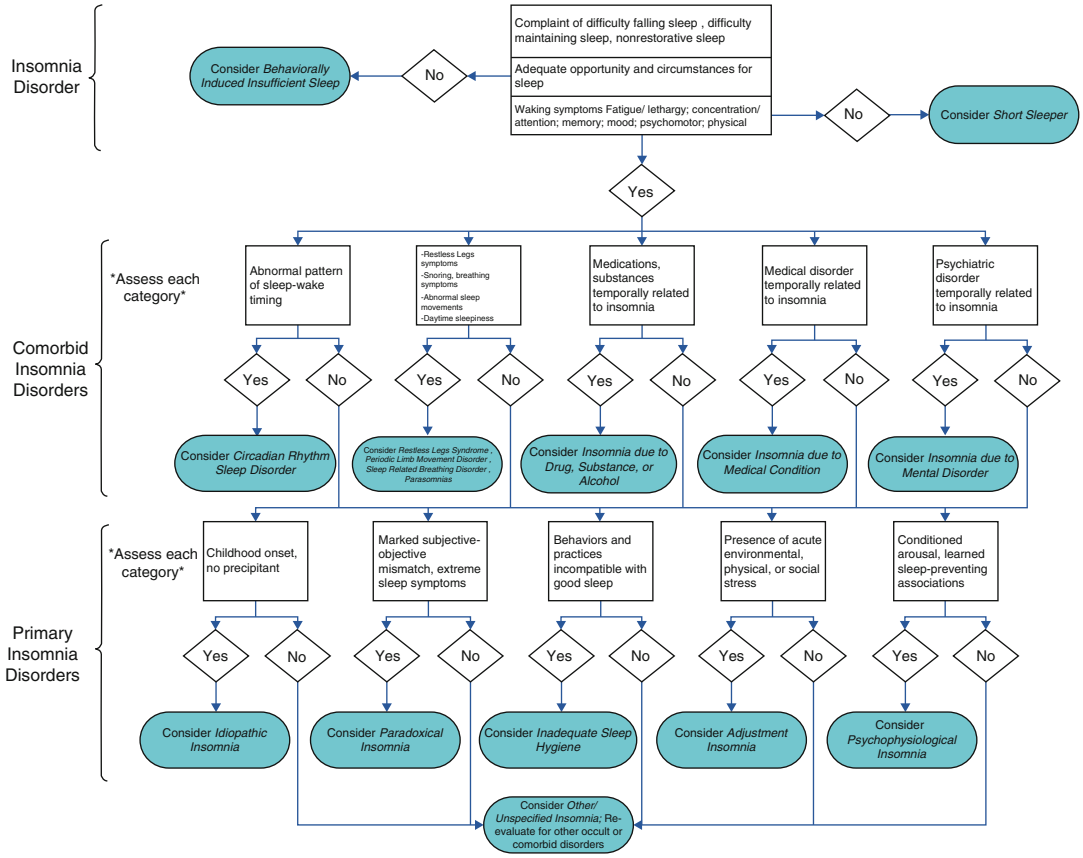

Fig. 2 Screening for sleep disorders (Reprinted with permission. Source: Schutte-Rodin et al. 2008)

Screening for Sleep Disturbance Screening for sleep disturbance (Step 1) typically involves several questions that can accurately detect the presence of sleep disorders. Although the specific questions or tools used for screening for sleep disturbance may differ across organizations, this step is useful to identify patients with the presence of sleep disturbance and to detect sleep disorders such as obstructive sleep apnea, narcolepsy, or restless leg syndrome that require more immediate referral for evaluation by a sleep specialist as shown in Fig. 2 (Schutte-Rodin et al. 2008).

Simple numerical rating scales (0, no sleep problem, to 10, worst sleep problem) may be sufficient such as the inclusion of sleep anchors on the "other" scale of the Edmonton Symptom Assessment System (ESAS) as an initial screen for sleep disturbance, particularly since ESAS is commonly used for symptom screening in cancer and palliative care (Gilbert et al. 2012). In a study of palliative care patients, exploratory and validation samples suggested that a cutoff value of ≥ 4 on an ESAS sleep item provides good sensitivity with reasonable specificity (Yennurajalingam et al. 2017). These authors suggested that all patients who score ≥ 4 on an ESAS sleep item should undergo a focused assessment for diagnosis of a sleep disorder. More recent research using the revised version of ESAS (ESASr) identified a score ≥ 2 on the ESAS-drowsiness item had a sensitivity of 61.5% and a specificity of 75.4% as a screen for sleep disturbance (Savard et al. 2016). When used in combination, the best option was scoring positively on a single question (endorsement of yes for problems with sleep) on a problem checklist and a score ≥ 2 on the ESAS-drowsiness item (sensitivity, 84.2%; specificity, 69.7%). Sleep

experts have recommended the use of two key questions to standardize the screening process for insomnia using items from the Patient-Reported Outcomes Measurement Information System (PROMIS) (Buysse et al. 2010) as follows:

1. Do you have problems with your sleep or sleep disturbance on average (routinely, in the past month, etc.) for three or more nights a week?
2. If yes, does the problem with your sleep negatively affect your daytime function or quality of life?

If the patient answers positive (yes) to both questions, a more focused assessment and comprehensive evaluation of sleep disturbance is recommended. The PROMIS short form 8A can also be used as a valid and reliable "sleep thermometer" to identify the presence of sleep disturbance.

Clinical practice guidelines have also recommended the use of a more comprehensive screening tool such as the Sleep Disorders Screening Checklist-25 (SDS-CL-25) that can be used to accurately screen for six sleep disorders including insomnia, obstructive sleep apnea, restless legs syndrome/periodic limb movement disorder, circadian rhythm sleep-wake disorders, narcolepsy, and parasomnias (Klingman et al. 2017). Ideally, screening in palliative care populations should also include screening measures for delirium and psychological distress given that insomnia is a key clinical marker for these conditions.

Focused Assessment and Evaluation Depending on the health status of the patient, a focused assessment of sleep disturbance should include specific parameters for identification of all sleep-related symptoms and disruptions in the sleep-wake cycle using self-reports of patients and their caregivers and clinician interviews. The underlying causes and comorbidities that can contribute to sleep disturbance, inclusive of recent stressors, can be assessed by taking a detailed history, doing a physical exam to identify physical conditions or comorbidities that contribute to insomnia, and taking a drug history (prescribed, recreational, caffeine, alcohol, nicotine). Identification of predisposing, precipitating causes, and perpetuating factors and the key parameters for assessment and evaluation are recommended as follows:

- Any underlying cause of insomnia or an associated comorbid condition, i.e., psychiatric or medical conditions such as COPD.
- Sleep history including patterns in the sleep-wake cycle.
- Previous treatments used and their effectiveness.
- Sleep hygiene practices and negative learned associations.
- Duration of symptoms.
- Emotional status and other symptoms.
- Person's beliefs and negative cognitions about sleep, perception of sleep quality, or other distortions about sleep (i.e., I will die in my sleep).
- Impact that insomnia has on the person's quality of life, cognition, ability to drive, employment, relationships and mood, and other daytime activities.
- Impact on caregivers particularly in the setting of home palliative care.
- Substance use (alcohol and drugs) and other medications including over-the-counter sleep aids.
- Consider the sleep requirements of the patient, variation with age, and normal pattern.
- Use a sleep log or diary covering 2 weeks to complement the history.

It is essential to characterize the complaint in terms of difficulty initiating sleep, recurrent nocturnal awakening, insufficient total sleep, nonrestorative sleep, advanced or delayed sleep onset, excessively long sleep, chronic drowsiness, and sleep attacks. At a minimum, a sleep history should capture domains of sleep including total sleep time, sleep latency, awakenings during sleep, wake time after sleep onset, napping during the day, excessive daytime sleepiness, quality of perceived sleep, circadian rhythm, and sleep efficiency (Woodward 2011). Patient-reported outcome measures (PROMs) that are psychometrically valid can help to standardize the assessment process, reduce the burden on the patient, and are a more efficient use of a clinician's time,

Table 4 Recommend domains and measures for sleep disturbance

Sleep efficiency (SE)	Ratio of actual sleep to time spent in bed × 100 reported as a percentage
Sleep latency (SL)	Time in minutes measured from intention to sleep (turn the lights out) to the actual onset of sleep
Waking after sleep onset (WASO)	The number of times a person wakes up during sleep, which increases with age
Pittsburgh Sleep Quality Index (PSQI)	PSQI is a 24-item self-report measure of sleep quality (global score > 5 is indicative of poor sleep quality (Buysse et al. 1989)
Insomnia severity index (ISI)	ISI is a seven-item rating scale to assess the patient's perception of insomnia and severity. Optimal cutoff score of 8 in cancer patients = optimal sensitivity and specificity (Bastien et al. 2001)
Epworth Sleepiness Scale (ESS)	ESS is an eight-item self-report questionnaire used to assess subjective sleepiness (score range 0–24, normal <10). Useful for measuring frequency of daytime sleepiness and associations between daytime sleepiness and insomnia (Johns 1991)
Sleep Disorders Screening Checklist-25	Screens for six categories of sleep disorders: insomnia, obstructive sleep apnea, restless legs syndrome/periodic limb movement disorder, circadian rhythm sleep-wake disorders, narcolepsy, and parasomnias. Takes 1–3 minutes to complete and is based on the ICSD criteria. Includes 17 statements clustered by disorder, summing responses in each subscale. Sensitivity and specificity for diagnosed sleep disorders (0.64 to 0.88) (Klingman et al. 2017)
Sleep diary	Useful in identifying circadian rhythm disorders and poor sleep hygiene. Self-reported record of a person's sleeping and waking times with related information, usually over a minimum of 2 weeks. It is self-reported or can be recorded by a caregiver (Carney et al. 2012)
Dysfunctional beliefs and attitudes about sleep questionnaire	A 28-item scale that evaluates sleep-related beliefs, respondents' expectations, and attitudes regarding the causes, consequences, and potential treatments of sleep issues (Morin et al. 1993)
Actigraphy	A small device that monitors and analyzes wrist movements during routine daily activities to estimate time spent in sleep vs. awake. Not used in diagnosis but can serve as a useful objective adjunct to routine evaluations of insomnia, circadian rhythm disorders, restless legs syndrome (RLS), or periodic limb movement disorder (PLMD) (Litner et al. 2003)
Polysomnogram (PSG)	Gold standard measure for assessments of sleep structure and for objective validation of the effects of treatments; not currently recommended for routine screening or diagnosis of insomnia in clinical practice (Pressman 2002)

References: Buysse et al. (1989), Bastien et al. (2011), Johns (1991), Klingman et al. (2017), Carney et al. (2012), Morin et al. (1993), Litner et al. (2003), Pressman (2002)

particularly in the context of palliative care (Howell et al. 2015). As shown in Table 4, several PROMs with valid cutoffs have been recommended for assessment of sleep disturbances such as the Pittsburgh Sleep Quality Index (Buysse et al. 1989) and the Insomnia Severity Index (Bastien et al. 2001) and for measurement of excessive daytime sleepiness using measures such as the Epworth Sleepiness Scale (Johns 1991). Objective measures for sleep are also summarized in Table 4. The Clinical Sleep Assessment for Adults (CSA) can also be a useful tool for guiding the clinical interview for sleep disturbance (Lee and Ward 2005).

Family and friends and particularly the patient's bed partner may also be an important source of assessment information, as they may be able to provide information about sleep and wake patterns, daytime napping, and frequency of symptoms (snoring or nocturnal limb movements). Daily sleep logs and sleep diaries are considered a "gold standard" for subjective sleep assessment and monitoring of response to treatment that is completed by individuals over several

days (e.g., 2-week period). Ideally, sleep diaries should be collected at baseline and throughout the course of insomnia treatment and for long-term evaluation in the case of relapse or reevaluation (Carney et al. 2012). A sleep diary should include information about sleep quality, sleep parameters (e.g., sleep duration, frequency and duration of nocturnal awakenings), napping, daytime impairment, medications, activities, time of evening meal, caffeine and alcohol consumption, and stress level before bedtime for each 24-hour period.

Sleep diaries can also provide data about sleep routines and may help identify environmental or behavioral factors contributing to insomnia. To achieve more consistency, a consensus sleep diary has been developed and proposed for use in insomnia research (Carney et al. 2012). There is agreement that such self-monitoring should yield information about relevant metrics including nightly sleep onset latency (SOL); wakefulness after initial sleep onset (WASO); total sleep time (TST); total time spent in bed (TIB); sleep efficiency (SE), defined as the percent of the time asleep out of amount of time spent in bed; and sleep quality or satisfaction, which includes a subjective global appraisal of each night's sleep from the perspective of the patient.

Objective Measures Findings from a physical exam and laboratory data may also be important to identify factors contributing to sleep disturbance. Polysomnography (PSG) is a major diagnostic tool and gold standard for identification of sleep disorders indicated in the evaluation of suspected sleep-related breathing disorders and periodic limb movement disorder and when the cause of insomnia is uncertain or when behavioral or pharmacologic therapy is unsuccessful (Pressman 2002). PSG assesses sleep parameters, stages, and architecture and is usually conducted in sleep medicine clinics overnight and supervised by sleep specialists. PSG includes the monitoring of electroencephalography, electrooculography, electromyography, effort of breathing and air flow, oxygen saturation, electrocardiography, and body position.

Actigraphy, which uses a small wrist or leg accelerometer to measure body movements, is also used to objectively evaluate activity-rest patterns and response to treatment of sleep disturbance (Littner et al. 2003). The use of objective measures in palliative care should take into consideration patient factors such as stage of illness, prognosis, and functioning as necessary to determine the specific type of sleep disorder and direct appropriate treatment.

6 Management of Sleep Disturbance

The goal of treatment for sleep disturbance and insomnia disorders is aligned with the principles of a palliative care approach, that is, to identify and treat any reversible or underlying cause(s) that are contributing to sleep disturbance. This includes optimizing the management of other symptoms, pain, and psychological distress (anxiety and depression) that can precipitate and exacerbate sleep disturbance.

The nature of the specific sleep disorder should also guide treatment approaches since each type of sleep disorder may require a different treatment approach. Primary sleep disorders such as insomnia and insomnia syndrome, sleep apnea, restless leg syndrome (RLS), and circadian rhythm disturbance may all require specific treatments, which have been shown to improve sleep quality. The algorithm developed for the identification and management of sleep disorders is shown in Fig. 2.

Given the multifactorial nature of sleep disturbances in palliative care, management strategies may require a combination of psychological interventions or non-pharmacological interventions and pharmacological treatment that is individualized to the patient and takes into consideration predisposing, precipitating, and perpetuating factors and illness severity and prognosis. The overall goal of treatment of insomnia is to improve sleep quality and minimize associated distress and daytime dysfunction if possible.

7 Non-pharmacological Management

As shown in Fig. 1, general treatment measures for management of insomnia include the treatment of comorbid medical and psychiatric conditions, modifying sleep-interfering medications and substances; changing sleep behaviors, i.e., sleep hygiene; and optimizing the sleep environment (Howell et al. 2013). Simple strategies such as changing the timing of medications such as corticosteroids, adjusting doses of opiates, or switching of opiates or antidepressants, sleep hygiene, and environmental manipulations may be an initial step in a tiered approach to management of insomnia and may be helpful in specific sleep disorders such as circadian rhythm disorders.

7.1 Sleep Hygiene Strategies

All patients should receive supportive education and information, including coaching in sleep hygiene strategies, as a health promotion approach for populations at risk for insomnia and as an adjunct to cognitive behavioral therapy. As summarized in Table 5, the patient should be advised and coached in the use of specific sleep hygiene behaviors to reduce insomnia, although the efficacy of sleep hygiene alone has not been established (Dietrich et al. 2016). Some aspects of sleep hygiene such as avoidance of daytime sleeping and increasing daytime activities may be difficult in very ill palliative care patients. If possible daytime napping should be kept short, and a prolonged uptime prior to bedtime and a focus on increasing tolerable daytime activities will be important.

7.2 Cognitive Behavioral Therapy for Insomnia (CBT-I)

CBT-I is now recommended as the standard of care and first-line treatment for primary insomnia and insomnia syndrome (Sateia et al. 2017). CBT-I is a multicomponent intervention that targets the behavioral and cognitive factors that are believed to perpetuate insomnia over time including poor sleep habits and negative thoughts, attitudes, and beliefs about sleep that contribute to hyperarousal (Savard and Savard 2017). The interrelated and most common components of CBT-I include stimulus control, sleep restriction, relaxation therapies, sleep hygiene, and cognitive restructuring are shown in Table 6. While a combination of these components has been shown to be most effective on sleep outcomes, single components such as relaxation therapy have also shown effects on insomnia and may be more feasible and acceptable to palliative care patients who may be too ill to participate in CBT-I programs.

A large body of evidence including systematic reviews and meta-analysis of CBT-I have demonstrated the short- and long-term efficacy of CBT-I for primary insomnia in general populations (Trauer et al. 2015) and cancer (Savard and Savard 2017). CBT-I has also been shown to be effective for distress and insomnia and other medical conditions including Parkinson disease (Humbert et al. 2017) and multiple sclerosis (Majendie et al. 2017). There is extensive review evidence for the efficacy of CBT-I in cancer with medium to large effect sizes shown and statistically and clinically significant gains on sleep measures (Johnson et al. 2016). CBT-I has been shown to improve sleep onset latency, wake after sleep onset, sleep efficiency, and sleep quality in the general population, and in cancer populations, improvements in SOL, WASO, and self-perceived severity (Johnson et al. 2016). CBT-I has produced larger effects than treatment as usual (TAU), compared to waitlist control groups, pharmacotherapy +/− medication placebo, relaxation therapy and behavioral placebo, and sleep hygiene education. Of the studies with long-term follow-ups, the effects of CBT-I have been remarkably durable lasting up to 2 years in a substantial proportion of participants, and, on several measures, patients continue to improve (if not reach remission) long after treatment is discontinued (Savard and Savard 2017). However, evidence in older adults (>60) is more mixed, and CBT-I may be less beneficial in older individuals versus younger patients with less durability of the long-term effects (Montgomery and Dennis 2003).

Table 5 Strategies for sleep hygiene

Behavior	Rationale
Wake up at the same time (regardless of how many hours of sleep and including weekends)	Sleeping in after a night of disrupted sleep, or on weekends, tends to perpetuate sleep problems by preventing the accumulation of sleep pressure, leading to more difficulty falling asleep or maintaining sleep
Ensure light exposure soon after waking	Exposure to natural or artificial light is an important regulator of sleep-wake rhythms. Light exposure can help "set" a patient's circadian clock, making it easier for them to continue with the same wake-up time
Designate a "clear-your-head time"	Establishing 30–45 minutes devoted to problem solving, planning, and worrying in the early evening can help patients deal with the concerns that may contribute to mental activity at night. It may be helpful for patients to write these concerns down to avoid mental rehearsal and remind themselves that they have already devoted time to a topic if it reappears
Establish a 90-minute buffer zone before intended bedtime	Implementing a designated time to unwind in the evening before bed allows patients to create an environment that is conducive to sleep. Dim lighting and a relaxing, pleasant, and sedentary activity promote sleep and activities that do not produce cognitive or physiological arousal, i.e., reading
Go to bed only when sleepy and don't spend extra time trying to sleep	Spending extra time awake in bed and trying to sleep does not increase the chances of falling asleep. In fact, this strategy can be counterproductive because it can contribute to performance anxiety, frustration, and eventually conditioned arousal
Use your bedroom for sleep and sex only	Preserve the bed as a strong environmental and psychological signal for sleep; and make the other areas where a patient spends time during the day as comfortable as their bed
If you are not asleep within 20–30 minutes, get out of bed and return when sleepy	If a patient is not asleep and their mind becomes active after being in bed for 20–30 minutes, it is recommended that they interrupt the tendency to try harder to sleep by getting out of bed and returning to their buffer zone activity. Returning to bed when sleep feels imminent. This may need to be planned for in advance or repeated several times until the disruptive sleep cycle is broken. The goal of this strategy is to reinforce the association between the bedroom and sleep
Ensure sleep expectations are realistic	Address inaccurate sleep beliefs that can contribute to increased patient anxiety surrounding sleep. One of the most common is that 8 hours of sleep is optimal for everyone; normal sleep needs range from 6 to 10 hours. Sleep quality changes with age, and it is normal to wake one to two times but not remain awake
Restrict napping	Patients should avoid multiple naps, especially in the evening; however, a short nap (less than 1 hour) in the afternoon, starting before 3:00 pm, may be helpful and is less likely to interfere with nighttime sleep. If resting, rather than sleeping, it should be done in a room other than the bedroom
Restful environment	Minimize noise and disruptions during night. Use earplugs and eye masks, cool temperature

References: Howell et al. (2013, 2015), Dietrich et al. (2016)

Positive benefits have been reported across various modes for delivering CBT-I, including face-to-face individual therapy, in-person group therapy, telephone-based modules, web-based or Internet modules, and self-help books (Zachariae et al. 2016). Web-based modules or self-help books may be particularly valuable in palliative care populations who can complete these strategies at their own pace. A recent review presented evidence from 15 trials, finding improvement in

Table 6 Cognitive behavioral therapy: insomnia components

Component	Definition	Approach
Stimulus control therapy	Promotion of a consistent sleep-wake schedule (sleep patterns) and behavioral strategies to reinforce association between bed and sleep	Go to bed early when sleepy, get out of bed if unable to sleep, use the bed for sleep only, arise at the same time of day, and avoid napping
Sleep restriction therapy	Limiting the time spent in bed as possible to actual sleep time to produce mild sleep deprivation and more consolidated sleep	The sleep window is gradually increased over a few days or weeks until optimal sleep duration is achieved
Sleep hygiene education	Behavioral or environmental practices that positively or negatively affect sleep including avoiding stimulants such as caffeine or alcohol several hours before bedtime and other behaviors and keeping the sleep environment dark, quiet, and comfortable	Manipulation of sleep environment and behaviors to promote sleep
Relaxation training	Strategies aimed at reduction of somatic tension, e.g., progressive muscle relaxation, or intrusive thoughts, e.g., imagery training or meditation	Usually require professional guidance initially and daily practice for a few weeks

References: Savard and Savard (2017)

the severity of insomnia and sleep efficiency, with the duration of treatment and the degree of support as moderators of sleep efficiency for web-based interventions (Seyffert et al. 2016). Larger effects have been shown for longer treatment duration and personal clinical support as part of web-based interventions. Self-administered CBT-I could be feasible in palliative care populations but with smaller treatment effects (Savard and Savard 2017).

The application and feasibility of CBT has emerged for the management of psychological distress (anxiety and/or depression) in advanced disease (Campbell and Campbell 2012). However, there is less research on CBT-I for management of insomnia in palliative care. CBT-I may be particularly beneficial in palliative care populations given that adverse effects are not reported for this approach. However, CBT-I involves a considerable time commitment and energy from the patient to acquire the new skills and behaviors that are emphasized. Some elements of CBT-I such as sleep restriction may also be difficult to achieve in palliative care patients who may be too ill to participate or experiencing hypersomnia due to adverse effects of disease or treatment and other disruptions in the sleep-wake cycle. Simple strategies such as environmental manipulation such as increased exposure to natural or artificial light during the days and reduced exposure during nighttime alongside behavioral strategies such as increased activity or engagement in pleasurable activities during the day if tolerable may be helpful. Another component of CBT-I, relaxation therapy, may also be difficult for a patient with severe weakness or pain from bony metastases. Adaptations of CBT to the palliative care setting have been suggested including offering guided assistance to patients in practicing skills such as talking an individual through the relaxation techniques; the use of pleasant activities as a sleep restriction strategy and brief CBT may be more tolerable.

Research is needed to establish the predictors of success with CBT-I and other psychological and behavioral interventions in palliative care populations. Kvale and Shuster (2006) recommended that CBT-I only be used with a patient whose prognosis exceeds the length of time required to benefit from this treatment, usually at least 4–6 weeks. Access to CBT-I may be problematic in palliative care, but there is emerging evidence that it can be delivered by appropriately trained and supervised community health nurses, primary care counselors, and primary care physicians. Ideally a clinician who is trained in

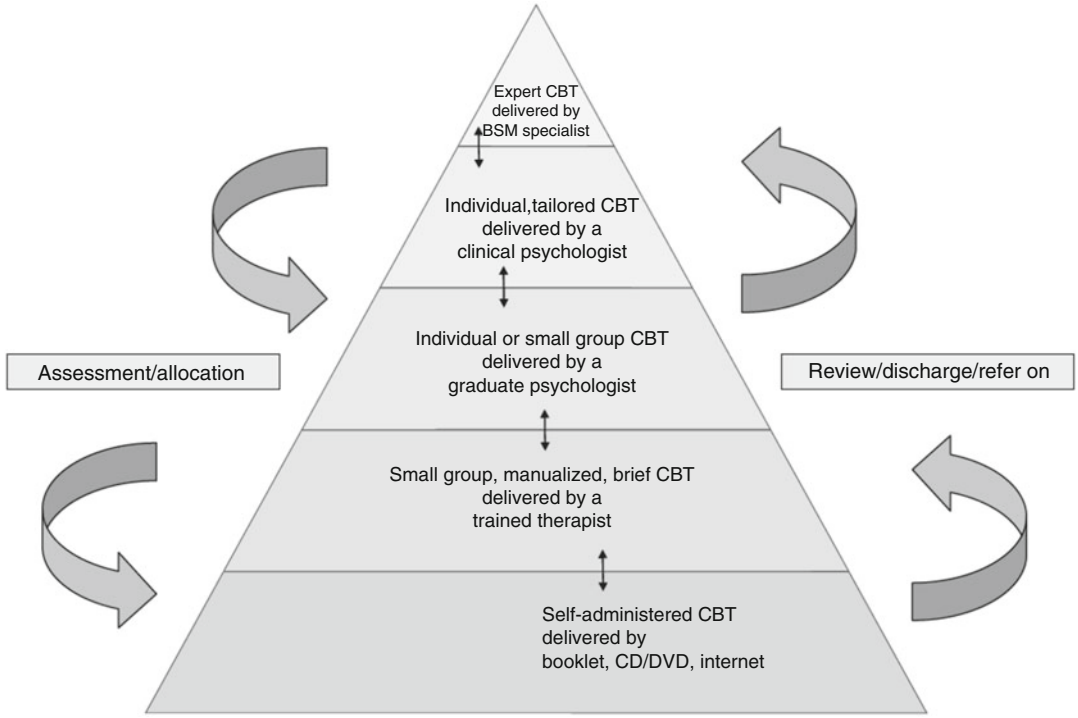

Fig. 3 Stepped care (Reprinted with permission. Source: Espie 2009)

psychological or behavioral therapies should deliver cognitive behavioral therapy; however when this level of care is not available, training of front-line staff guided by a manual has shown effectiveness (Espie 2009). To achieve best clinical care and utilize existing resources, an approach called stepped care has been proposed as shown in Fig. 3. Depending on the severity and complexity of the sleep disturbance, individuals could be allocated to different levels of psychological treatment with self-administered cognitive behavioral therapy (e.g., reading materials or bibliotherapy) as Step 1, brief cognitive behavioral therapy delivered by nurses following a manual as the next level (Step 2), and involvement of specialized health professionals such as psychologists experienced in delivering CBT-I in later steps (Step 3) in combination with pharmacological treatment on a short-term basis until CBT takes effect. Stepped care will still require practitioners to be trained, and implementation in routine practice may still not feasible based on available resources.

7.3 Mind and Body Therapies

Mind/body therapies such as yoga and Mindfulness-Based Stress Reduction (MBSR) may be helpful in reducing insomnia in medical illness and in palliative care populations (Neuendorf et al. 2015). A randomized non-inferiority trial comparing CBT-I with Mindfulness-Based Cancer Recovery (MBCR), an adaptation of Mindfulness-Based Stress Reduction (MBSR) in a heterogeneous sample of posttreatment cancer patients ($n = 111$), found this intervention to be inferior to CBT-I (Garland et al. 2014). CBT-I produced larger improvements in diary-measured sleep latency and sleep efficiency, but both interventions significantly reduced the amount of time spent awake after sleep onset and increased total sleep time. Significant improvements in symptoms of stress and psychological functioning were also reported, regardless of assigned treatment. MBCR/MBSR since it is focused on an acceptance-based treatment approach may be a viable alternative for palliative care patients.

8 Pharmacological Management

When behavioral approaches do not resolve sleep problems, the addition of medications is usually warranted, and a combination of these may be necessary in the context of palliative care. The goal of pharmacologic treatment is to improve sleep quality and quantity, to minimize impairment in daytime functioning and distress, to reduce sleep latency and wakefulness after sleep onset, and to increase total sleep time or sleep efficiency.

Numerous reviews and meta-analysis have been conducted on the effectiveness of pharmacological agents in the management of insomnia in adult populations with small to moderate effects shown with both benzodiazepines (BZDs) and non-benzodiazepine receptor agonists (BzRAs) (De Crescenzo et al. 2016). A recent systematic review and meta-analysis conducted to inform evidence-based recommendations in the American Academy of Sleep Medicine (AASM) 2017 guideline suggested the use of several medications for management of insomnia in adult populations, and recommendations from this guideline are summarized in Table 7 (Sateia et al. 2017). Small to moderate effects were shown for BZDs, BzRAs, anticonvulsants such as tiagabine, orexin receptor agonists, melatonin agonists, and heterocyclics in adult populations. Medications including diphenhydramine, melatonin, L-tryptophan, and Valerian were not recommended noting the harmful adverse effects of these drugs since their anticholinergic effects outweighed the benefits. It was also noted in the guideline that there was insufficient high-quality evidence regarding the overall efficacy of pharmacotherapy for insomnia and adverse effects that may preclude their use in some medical conditions and particularly in the elderly.

Drugs commonly used in the management of insomnia in palliative care include the benzodiazepine group of drugs, benzodiazepine receptor antagonists, sedating antidepressant drugs (Davis et al. 2014). The BZDs are commonly used in palliative care for their anticonvulsing properties and can reduce sleep latency, reduce nighttime awakenings, and increase total sleep time and a feeling of restorative sleep. However, they are recommended for short-term use, i.e., 4 weeks, and then should be tapered to discontinuation due to dependence. Intermediate-acting BZDs are preferred, but their active metabolites in the elderly and those with altered liver function can result in excessive drowsiness, sedation, and dizziness and need to be used cautiously when combined with opiates due to increased sedation and paradoxical agitation. Other drugs such as sedating antidepressants may be a useful option for depressed patients with insomnia, whereas some of the SSRI group of antidepressants are more stimulating and can increase insomnia and are not recommended as first-line treatment for insomnia in palliative care.

In the medically ill, it is recommended that medications should be prescribed at the lowest possible dose for the shortest amount of time and considered mainly in patients who are unable to participate in CBT-I, who still have symptoms despite participation in such treatments, or in select cases as an adjunct to CBT-I or as a short- term solution while waiting for CBT-I to take effect. This approach may not be feasible in patients with advanced disease, and these populations may require longer-term use and are unable to wait for CBT-I to take effect or may be unable to tolerate behavioral approaches given the number of sessions required depending on prognosis.

Little research has been conducted on the effectiveness of these drugs for insomnia in palliative care populations except in cancer. Sedating tricyclic antidepressants in lower doses that are recommended for depression have been used as adjuncts to treat insomnia in palliative care, but the daytime sedation and anticholinergic side effects can lead to adverse effects particularly in the elderly. Other medications such as trazadone may also be helpful to improve restorative sleep. Consensus recommendations to guide practice by the American Academy of Sleep Medicine (AASM) recommendations for prescribing medications for management recommend the following approach (Schutte-Rodin et al. 2008, p. 498).

- Short-intermediate-acting benzodiazepine receptor agonists (BZD or newer BzRAs) or

Table 7 Pharmacological agents recommended for insomnia

Agent	Type of agent	Dose (mg)	Onset of action-minutes/half-life hours	Effectiveness	Adverse effects/ caution
Recommended for treating sleep onset insomnia					
Eszopiclone (Lunesta)	BZD receptor antagonist	1–3 1 mg in elderly/ debilitated or hepatic impairment	10 minutes/ 5–7 hours	Doses of 2 mg and 3 mg reduced sleep latency by 14 minutes (SL), improved sleep quality (SQ)	Metallic taste in mouth, nausea and vomiting, dizziness, somnolence, rebound insomnia, low mood
Temazepam (Restoril)	BZD	7.5–30 7.5 mg elderly/ debilitated	30–60/8–15	Doses of 15 mg reduced SL by 37 minutes, small improvement in SQ	Somnolence, dizziness, hangover effect into next day, diarrhea
Ramelteon	Melatonin antagonist	8	45 minutes/ 2–5 hours	Doses of 8 mg reduced SL by 9 minutes; no improvement in SQ	Low mood (depression), anxiety, hallucinations, memory loss, nightmares, nausea and vomiting
Triazolam (Halcion)	BZD	0.125–0.25 0.125 in elderly/ debilitated	7–27 minutes/ 1 hour	Doses of 0.25 reduced SL by 9 minutes, improved SQ	Somnolence, dizziness, hangover effect into next day, diarrhea
Zaleplon (Sonata)	BZD receptor antagonist	5–20 5 mg in elderly/ debilitated	30 minutes/ 1 hour	Doses of 5–10 mg reduced SL by 10 minutes. No improvement in SQ	Not suitable for long-term use in elderly, similar to other BZD
Zolpidem (Ambien)	BZD receptor antagonist	5–10 5 mg in elderly/ debilitated	7–27 minutes/ 2–3 hours	Doses of 10 mg reduced SL by 5–12 minutes	Somnolence, fatigue, drugged state
Recommended for treating sleep maintenance insomnia					
Doxepin	Heterocyclic	3–6	3.5 hours/ 15 hours	Doses of 3 and 6 mg improved total sleep time 26–32 minutes longer, WASO reduced by 22 minutes, small improvement in SQ	Drowsiness, dizziness, dry mouth, blurred vision, constipation, or trouble urinating, sedating effects
Eszopiclone	BZD	1–3	10 minutes/ 5–7 hours	Doses of 15 mg improved total sleep time by 28–57 minutes, increased total sleep time, WASO not reported, small improvement in quality of sleep	Metallic taste in mouth, nausea and vomiting, dizziness, somnolence, rebound insomnia, low mood
Temazapam (Restoril)	BZD	7.5–30	30–60/8–15	Doses of 15 mg reduced SL by 37 minutes, small improvement in SQ	Somnolence, dizziness, hangover effect into next day, diarrhea
Suvorexant	Orexin receptor antagonist	5–20	60 minutes/ 12 hours	Doses of 10 to 20 mg improved total sleep time by 10 minutes, reduced WASO by 16–28 minutes, SQ not reported	Based on trials of 10–20 mg doses. Not used for narcolepsy. Hepatic insufficiency
Zolpidem	BZD receptor antagonist	5–10	7–27 minutes/ 2–3 hours	Doses of 10 mg improved total sleep time by 29 minutes, WASO reduction of 25 minutes, moderate improvement in SQ	Somnolence, fatigue, drugged state

References: Sateia et al. (2017), Schutte and Rodin (2008)

ramelteon: examples of these medications include zolpidem, eszopiclone, zaleplon, and temazepam.
- Alternate short-intermediate-acting BzRAs or ramelteon if the initial agent has been unsuccessful.
- Sedating antidepressants, especially when used in conjunction with treating comorbid depression/anxiety: examples of these include trazodone, amitriptyline, doxepin, and mirtazapine.
- Combined BzRA or ramelteon and sedating antidepressant.
- Other sedating agents: examples include antiepilepsy medications (gabapentin, tiagabine) and atypical antipsychotics (quetiapine and olanzapine). May only be suitable for patients with comorbid insomnia who would benefit from the primary action of these drugs.

Several factors should be considered in the use of medications for insomnia in palliative care specifically the differential diagnosis and etiology of sleep disturbance, short- and long-term effectiveness of the drug, its rate of absorption and metabolism, and potential risks and side effects. The elderly and seriously ill patients may be particularly at risk for adverse effects given the alterations in drug sensitivity and pharmacokinetics, and this must be taken into consideration in prescribing and weighing of the benefit to risks. Other drugs recommended in guidance documents for management of insomnia include hypnotic drugs such as lorazepam, temazapam, and zopiclone, but these should be used with caution particularly in combination with other medications (Davis and Goforth 2014). Discontinuation and rebound insomnia must be considered when pharmacological agents such as benzodiazepines such as lorazepam are discontinued.

When pharmacotherapy is utilized, the choice of a specific pharmacological agent within a class should be directed by (1) symptom pattern; (2) causative factors; (3) patient age, illness severity, and prognosis; (4) treatment goals; (5) past treatment responses; (6) patient preference; (7) cost; (8) availability of other treatments; (9) comorbid conditions; (10) contraindications; (11) concurrent medication or treatment interactions; and (12) side effects (Matheson and Hainer 2017). Additionally, absorption, time to maximum concentration, elimination half-life, receptor activity, ability to cross the blood-brain barrier, dose and frequency, and short-acting versus long-term formulation.

A goal of pharmacologic treatment is to achieve a favorable balance between therapeutic effects and potential adverse effects; and the use of one drug that may have a crossover effect for managing other palliative care symptoms such as psychological distress is an important principle. Pharmacological agents for patients with insomnia comorbid with other illnesses must consider the concomitant use of these agents with agents being used for disease management, as well as the type of condition (e.g., involvement of the central nervous system may preclude their use and aggravate insomnia). A large review of Cochrane Database of Systematic Reviews corresponding to 274 RCTs examined the effects of 109 drug and condition pairs and identified five drugs that were associated with a decrease in sleep disturbance including budesonide (inhaled corticosteroid), triazolam (benzodiazepine hypnotic), olanzapine (atypical antipsychotic), sulfasalazine (anti-inflammatory), and zopiclone (non-benzodiazepine hypnotic) with ORs of 0.50 or less (Doufas et al. 2017). Whereas many other drugs were associated with increased sleep disturbance or adverse effects, few of these were concordant with descriptions of adverse effects on sleep in drug formularies.

9 Management of Specific Sleep Disorders

Sleep disorders such as obstructive sleep apnea, restless leg syndromes, or narcolepsy require referral and management to sleep specialists and are beyond the scope of this chapter. Patients with advanced disease can have a single primary (premorbid) insomnia or other sleep disorder or secondary insomnia due to their medical or psychiatric condition. Common sleep disorders in

palliative care populations include hypersomnia, circadian rhythm disorder such as sleep-wake reversal or inversion of sleep-wake cycles, and nightmares. The characteristics of these disorders and strategies for management are described below. Sleep disorders are best managed in consultation with sleep specialists with strategies tailored to the specific sleep disturbance and causative factors.

Hypersomnia Hypersomnia (also labeled somnolence) is a neurological disorder and type of circadian rhythm disturbance that results in an abnormal increase in sleep duration (10 or more hours at a time) and difficulty staying awake during the day that is not relieved by daytime napping (Reynolds and O'Hara 2013). Hypersomnia is also characterized by symptoms of excessive daytime sleepiness, excessive amounts of deep sleep, trouble staying awake during the day, and sundowning which refers to agitation or a delirium-like state (wandering, agitation, aggression) mainly at night and is related to changes either in NREM or REM sleep or could be more central in origin. Hypersomnia can be due to brain and central nervous system tumors, cancer that has spread to the brain or other organs, and has been associated with some types of chemotherapy or radiotherapy (Berger 2009). Hypersomnia is frequently seen in elderly patients with Parkinson disease (PD), Lewy body dementia (DLB), or Parkinson disease dementia (PDD) and dementia (Weldemichael and Grossberg 2010).

Pain medications, anti-nausea medications and some antidepressants, sedatives and sleeping pills, and other medications to control agitation at night can also cause hypersomnia. Fluid and electrolyte disturbances (hypokalemia, hypothyroidism, or hypercalcemia) and hormonal disturbances in the endocrine system or superimposed delirium may also be causative factors. In addition, the use of anticonvulsants and anticholinergic drugs such as antihistamines, antidiarrheals, and drugs used to reduce bladder irritability can cause daytime sedation and sleepiness. Behavioral problems such as lack of participation in stimulating daytime activities can also lead to daytime sleepiness, and at times caregivers may promote daytime sleeping to ease the burden of caregiving.

Recommendations for measurement of hypersomnia include the Epworth Sleepiness Scale (Johns 1991) and the Stanford Sleepiness Scale (SSS) (Maclean et al. 1992) as subjective measures of sleepiness alongside PROMs for evaluating changes in insomnia parameters. Additionally, a complete medical examination and full evaluation for potential disorders such as sleep apnea should be excluded in the differential diagnosis.

Management of this condition may include adjustment in medications to reduce their toxic effects or interactions, behavioral/environmental approaches including sleep hygiene behaviors, and increase in physical activity or daytime activities. Pharmacological approaches are considered as a last resort and medications such as trazadone, zolpidem, mirtazapine; and the use of specific agents for behavioral dyscontrol such as carbamazepine or risperidone or mediations such as methylphenidate for excessive daytime sleepiness may be helpful but may be associated with other adverse effects and used with caution (Ouslander et al. 2006). Psychostimulants such as modafinil have proved clinically useful in the treatment of narcolepsy and other causes of excessive daytime sleepiness, such as idiopathic hypersomnolence (Ballon and Feifel 2006).

Caregiver burden should be carefully assessed with referral to home care resources or respite care in the context of hypersomnia and other sleep disturbances.

Nightmares Several studies have reported a significant relationship between nightmare frequency and sleep disturbances including insomnia, sleep onset latency, frequent nighttime awakenings, and restless or fitful sleep in adult populations (Hansen et al. 2013). Drugs which alter the normal synaptic activity of serotonin, norepinephrine, and dopamine may lead to nightmares. Opioids, beta-blockers, levodopa, ketamine, and BZDs have been found to the associated with nightmares. Nightmares typically occur during the first hours of stage 3–4 non-rapid eye movement (NREM) sleep and are differentiated from night terrors, which is a

type of primary sleep disorder that causes feelings of terror or dread and inconsolability like the experience of patients during a panic attack (Hochenbury and Hochenbury 2010).

Nightmares or disturbing dreams are reported in about a third of patients at the end-of-life and may occur independent of opioid analgesics (Davies et al. 2017).

Nightmares are often a symptom of trying to work through unresolved feelings and fears in palliative care. Nightmares may also be a symptom of post-traumatic disorders (Krakow and Zadra 2006). Nightmares occur as an outcome of almost any traumatic experience, and frequent nightmares are also reported by a sizable proportion of individuals without a trauma history. Nightmares are characterized by repeated awakenings, usually from late-night REM sleep, with clear recall of frightening dream content. On awakening from the disturbing dream, the person is quickly alert with little to no confusion or disorientation. The newer ICSD-3 criteria specify that although nightmares usually involve fear or anxiety, other dysphoric emotions may be implicated. The DSM-5 explicitly states that nightmares must cause "clinically significant distress or impairment in social, occupational, or other important areas of function" to be classified as a sleep disorder (DSM-3; ICSD-5).

In addition to adjustment of medications and attention to other causative factors that may be contributing to nightmares, simple behavioral measures such as sleep hygiene may be helpful in reducing the frequency of bad dreams alongside strategies such as mindfulness or imagery to promote more positive images prior to sleep.

Management of nightmares focuses on nightmares either as a learned sleep disorder or a learned behavior or considers nightmares as a symptom of a damaged imagery system. Sleep disturbance and nightmares are often associated with post-traumatic stress disorder, and mixed findings have been shown for CBT with reduction in nightmares noted (Krakow and Zadra 2014). Cognitive behavioral therapies, nightmare-focused CBT, desensitization, imagery rehearsal, and relaxation techniques have been reported as beneficial; however, large prospective studies are lacking (Krakow and Zadra 2014). The feasibility and efficacy of these approaches in palliative care has not been established, and the time required for these types of therapy to manage nightmares (8–9 hours of contact time) is substantive and must be taken into consideration. Medications such as Prazosin or propranolol have also been shown to be helpful for nightmares in PTSD (Krakow and Zadra 2014). Referral for psychotherapy should also be considered for treatment of PTSD, and treatment should be primarily aimed at managing psychological distress or psychiatric conditions such as PTSD.

Sleep-Wake Cycle Reversal Sleep-wake cycle reversal also called sleep-wake inversion is considered as sleep disorder that is characterized by involuntary reversal of sleeping tendencies, whereby patients exchange diurnal habits for nocturnal habits such that they are active at night and sleep during the day (Fitzgerald et al. 2017). The main reason for the alteration in sleep-wake cycle is related to alterations in the suprachiasmatic nucleus (SCN) and melatonin secretion.

Disturbances in the sleep-wake cycle are common in older medical inpatients with dementia and/or delirium and can be exacerbated by stress and psychiatric disorders such as depression that can impact on the circadian timing system, but the relationships between these conditions are not fully clarified. Disturbances in the sleep-wake rhythm are a hallmark symptom of depression and widely appreciated as a key symptom of delirium (Ryan et al. 2013).

Management of sleep-wake cycle reversal includes altering medications that may trigger this sleep disorder, behavioral treatment such as good sleep hygiene, incremental and gradual changes in sleep and wake times if appropriate, manipulation of the environment to promote circadian rhythms timed to external light and dark, and optimizing management of psychological distress and screening for delirium or other sleep disorders such as OSA. Exposure to bright light during the day and physical activity or other stimulating activities may be helpful. Pharmacological

treatment may be required. Light therapy has also been suggested as an option.

9.1 Conclusion and Summary

Sleep disturbance and sleep disorders such as insomnia and insomnia syndrome are common in palliative care populations with serious consequences on daytime functioning, quality of daily living, and overall quality of life. Early identification of sleep disturbance through routine screening in palliative care followed by more comprehensive evaluation is essential as this symptom is often poorly managed in clinical care. Palliative care patients may have a combination of a primary sleep disorder and comorbid insomnia with multiple causative factors including pain and psychological distress. Treatment should include identification of the specific sleep disorder and use of appropriate strategies in consultation with sleep specialists.

Simple strategies such as sleep hygiene may be helpful for improving sleep disturbances as part of a supportive care approach, but the strongest evidence for efficacy has been found for CBT-I for insomnia which may require adaptation for administration in palliative care. A combination of psychological and pharmacological interventions will likely be necessary to manage the multifactorial nature of sleep disruption in palliative care. The adage of using one medication to manage many symptoms in palliative care may be particularly relevant since insomnia is usually interrelated to other symptoms such as pain and psychological distress as part of a symptom cluster. Additionally, optimizing management of other symptoms may be helpful for reducing disruptions in sleep. The efficacy of medications to manage insomnia is not well established, particularly in advanced disease populations. Moreover, the harms of medications to treat insomnia may outweigh the benefits, and this must be considered in the context of palliative care. Considerations for pharmacological treatment include the nature of the insomnia; the expected duration of treatment; the potential side effects; the possibility for reactions with other medications, i.e., disease treatment or other symptom management medications; and the impact on daytime functioning and patient tolerance as well as prognosis. Insomnia and other sleep disorders are a serious symptom in palliative care that warrant impeccable assessment and management with treatment approaches tailored to the individual, causative factors and the specific sleep disorder that is identified such as insomnia, hypersomnia, sleep-wake reversal, and nightmares in the population. Sleep disturbances can worsen symptom burden and distress and the potential suffering for both palliative care patients and their caregivers. Thus, appropriate treatment of this neglected symptom is critical to reduce morbidity and maximize quality of life.

Psychological Symptoms

25

Gregory B. Crawford

Contents

Abstract

Psychological symptoms are highly prevalent in people requiring palliative care. They are much more challenging to elicit, and more controversy exists about what is normal and what might require intervention than physical symptoms. There are significant issues in determining what is normal and what is not. Sadness, distress, anxiety, and depression can coexist and require careful assessment.

Management of psychological symptoms and conditions can broadly be considered in terms of non-pharmacological and pharmacological therapies, "the talking and the drug therapies." These are not mutually exclusive, and for people with limited energy, failing cognition, and limited time, some pragmatic decisions may be necessary. To be distressed and immobilized by emotion is not normal. Depression is not a normal part of dying. There should be discussion about the nature of psychological issues and conditions,

explanation of common somatic symptoms, and a plan for intervention and support.

The burden on the carer, both professional and personal, in such situations should not be underestimated.

1 Psychological Symptoms

Symptom control is a significant part of the healthcare interventions provided by clinicians for people facing the end of their lives. Physical symptoms are generally well recognized and have a considerable prevalence (e.g., lack of energy (73.4%), pain (63.1%), nausea (44.7%), lack of appetite (44.5%), constipation (33.6%), cough (29.4%), and shortness of breath (22.9%)) (Portnoy et al. 1994). Psychological symptoms are much more challenging to elicit, and more controversy exists about what is normal and what might require intervention. Symptoms such as anxiety and depression may not be as easily acknowledged, diagnosed, or treated by patients, carers, or healthcare providers (Derogatis et al. 1983; Razavi et al. 1990; Barraclough 1997; Dein 2000; Henderson et al. 2000; Gilbody et al. 2001). For many the label of a "psychiatric" or "mental health" issue carries a strong stigma. Some would see serious risks associated with "unnecessary pathologizing" what are possibly normal reactions (Parker et al. 2012). This can inhibit full assessment and the consideration and implementation of appropriate interventions to provide relief.

2 What Is Normal: Sadness, Distress, Anxiety, and Depression

The diagnosis of an incurable illness is associated with an expected emotional response to the loss of well-being and to a potentially limited and altered future. Sadness, tearfulness, altered sleep, and change in appetite and eating habits are a normal response to receipt of this information and the impending loss it conveys (Zisook and Shear 2009). These symptoms constitute a grief reaction (Kübler-Ross 1969; Periyakoil 2015; Grunfeld et al. 2004). The symptoms of grief and sadness, as responses to such a situation, can be seen to be on a continuum with those of an anxiety and major depressive illness. Depression is not necessarily the inevitable response to such a situation. This raises the dilemma of defining thresholds (Chochinov et al. 1994; Robinson and Crawford 2005) at which a diagnosis is made and what might be considered to be the "normal" reaction to considering the possible end of one's own life. Emotions to death and dying and reactions to such information are modified by personal beliefs and cultural factors, particularly relating to what a person might believe occurs after they die. There are cross-cultural and historical attitudes to such complex issues including belief in an afterlife with perhaps heaven and hell, to a nihilism or sense of nothingness. Kübler-Ross introduced the concept of different types of depression – a reactive and a preparatory depression – the latter being seen as a normal part of the dying process and something that should not be interrupted (Kübler-Ross 1969). She believed that "an understanding person will have no difficulty in eliciting the cause [of the depression]." This is not as easy as she has suggested but may help to explain why some clinicians feel inhibited or may fail to intervene in distress, anxiety, or depression or even to assess systematically for psychological symptoms.

3 The Person Experience

It is always useful for healthcare providers to try to put themselves in the shoes of their patients or clients. It is all too easy to forget how foreign the environments are that we work within and how vulnerable our patients are. Not only are they being given bad news and potentially life-threatening information, but there are larger issues to consider. Not only are people trying to understand the problem and ask the obvious questions about what might be done to cure, control, or modify the process, but there are physical symptoms to manage and changes in body function. There are multiple demands for healthcare appointments and relationships to navigate with multiple providers.

The need for information, clear communication, and a sense of some control in what feels like the uncontrollable all are aspects of the experience for most.

It is not surprising that there will be impacts on work and leisure. There will be disruption of home, social, and financial arrangements. There are going to be changing roles and functions within the family. And in all of this most will be dealing with the understandable fear of loss of role, function, purpose, and death. And most would wish to maintain or find a new sense of meaning and purpose in life.

4 Distress

Psychological issues may present in many ways. Some people may express distress, depression, or anxiety in terms of unrelieved physical symptoms rather than emotion. It may be that there is only limited mild intermittent distress, or it may be a severe persistent distress that can become an overwhelming anxiety (National Comprehensive Cancer Network 2003). And there are questions about whether anxiety leads to depression or vice versa. And it is reasonable to consider that these issues are not simply binary, i.e., both can coexist and feed into the expression of psychological distress and vary over time. Exploring a person's experience of their illness and understanding the context and meaning ascribed to that illness and the physical, social, emotional, and spiritual influences and components of their distress are all vital to more fully assess and understand the person's experience (Clayton et al. 2007).

5 Demoralization

Within palliative care literature, demoralization as a syndrome has been proposed by Kissane et al. (2001) as having core features of hopelessness, loss of meaning, and existential distress. It is believed that this syndrome can be differentiated from depression and is recognizable in people facing the end of their lives. It is associated with chronic medical illness, disability, bodily disfigurement, fear of loss of dignity, social isolation, and feelings of greater dependency on others or the perception of being a burden.

Because of a sense of helplessness, those with the syndrome are thought to progress to a desire to die or to commit suicide. Treatment is aimed at relieving or alleviating the distress caused by this syndrome. The *Cambridge Dictionary* (Cambridge University Press 2018) describes demoralization as "having lost your confidence, enthusiasm, and hope" and also suggests feelings of sadness and unhappiness. Some alternative words and phrases have included "being down in the dumps, doleful, downhearted, miserable, morose and feeling wretched." These are powerful words and feelings.

6 Anxiety

Anxiety is a feeling of worry, nervousness, or unease about something with an uncertain outcome often with an associated strong concern that something unpleasant might happen (CareSearch 2017). For people facing the end of their lives, it would seem entirely reasonable that there is a fear or threat of separation and loss. It is common to hear people voice fears not only about death but also about the dying process, the manner of dying, the course of the illness, and the impact on their family. It is important to ask about suicidal thoughts or impulses in a patient experiencing significant anxiety or depressive symptoms (Hudson et al. 2006). Anxiety can accompany a depressive disorder.

The challenge is to be able to broach these difficult but important conversations. This requires a willingness to ask questions, to make connection, to have advanced communication skills, and be willing to listen. Some possible opening questions might be, "What do you feel about everything that is happening to you?"; "You seem (upset/anxious/depressed) today. Would you like to talk about how things are going?"

A full assessment requires specific questions about anxiety, depression, and likely symptoms. An exploration of physical symptoms such as palpitations, nausea, dizziness, shortness of

breath, trembling, sweating, and diarrhea is useful. Psychological symptoms may include feelings of apprehension, fear, and dread. You should also consider treatment-related factors; drug-induced anxiety; drug withdrawal including alcohol, tobacco, and other drugs; and disease-related factors, such as poor control of pain, nausea, dyspnea, and hypoxia (Palliative Care Expert Group et al. 2016).

It is important to assess for a depressive disorder as this may be the underlying condition when anxiety is severe, and it does not respond to supportive measures.

7 Depression

Depression is a major health issue in Australia (Wilhelm et al. 2003). There is a growing body of research about depression in palliative care populations and concern that it is a difficult and not particularly well-managed problem. This may relate to the inherent nature of depression but is possibly compounded by the difficulties of assessment and management in palliative populations, a group of people with many physical symptoms and the added burden of the existential issues associated with anticipating the end of life.

Depression has a significant and often unseen impact on the well-being and quality of life (Grassi et al. 1996; Goldney et al. 2000; Ruo et al. 2003; Smith et al. 2003) of the people it affects and on those around them. However, the construct and definition of depression is difficult. It is poorly understood. The general public and even health professionals may have quite different and divergent concepts, understandings, and beliefs about what depression is (Ng et al. 2013, 2015, 2014). The general public may consider crying, feeling sad, being melancholic, or feeling "upset" or "down and blue" to be depression. Palliative care professionals are often untrained in psychological health assessment and management. They are likely to have varied and possibly inaccurate concepts about psychological illness. A mental health professional diagnosis of a major depressive illness requires a constellation of specific symptoms that may include feelings of sadness and feeling "down and blue" that are pervasive and persistent (World Health Organization 1993; American Psychiatric Association 2013). Symptoms are on a spectrum of severity and can extend to a psychotic illness with loss of contact with reality and with loss of hope for the present or the future. Even the diagnostic systems proposed by specialist psychological authorities vary in the symptom constructs that are described to make a diagnosis, and the instructions and advice offered may be difficult to interpret and implement.

Depression is a prevalent problem in our society (Chochinov et al. 1994; Hotopf et al. 2002; Lloyd-Williams and Riddleston 2002; Durkin et al. 2003; Meyer et al. 2003). Depression is poorly recognized and poorly treated (Lloyd-Williams 1999; Wilson et al. 2000; Durkin et al. 2003; Lloyd-Williams et al. 2003a, b) within palliative care patients, causing increased suffering and hardship for these patients and their carers and families. Physical symptom control can be much more difficult to achieve in these patients (Dinan 1999). Carers' ability to support their depressed family member or friend may be diminished, at a time when there may be very little pleasure remaining in their lives. Interaction with and assistance from healthcare providers can be impeded, resulting in poorer health outcomes (Spiegel 1996; DiMatteo et al. 2000; Passik et al. 2002; Kelly et al. 2003; Lin et al. 2003). Depressed patients are less likely to attend appointments (DiMatteo et al. 2000). They are likely to feel bad about themselves and to make people around them feel uncomfortable, further perpetuating their isolation. They are more likely to be seen as "bad" or "difficult" patients, further reinforcing these negative feelings.

In Australia, the current 1-month prevalence of major depression in the general population is 3–5% (Wilhelm et al. 2003). This is similar to the reported prevalence in the United States and the United Kingdom (Wilhelm et al. 2003). Depression is reported to be more common in the unemployed, smokers, and those having a medical condition (Breitbart et al. 1995; Block 2000) as well as being in midlife (Fredman et al. 1988; Sorenson et al. 1991; Blazer et al. 1994), those previously married, and in females

Table 1 Comparison of symptoms assessed by DSM-5 and ICD-10

DSM-5		ICD-10	
Need one of these	Depressed affect	Depressed affect	Need two of these
	Anhedonia	Anhedonia	
Need four of these symptoms	Fatigue	Fatigue	
	Weight loss or change in appetite	Change in appetite	Need four of these symptoms
	Insomnia or hypersomnia	Sleep disturbance	
	Psychomotor agitation or retardation	Psychomotor agitation or retardation

	Concentration problems or indecisiveness	Concentration or thinking problems	
	Recurrent thoughts of death or suicide ideation	Recurrent thoughts of death or suicide	

(Goldberg and Huxley 1992; Weissman et al. 1996). Depression is predicted to be one of the leading contributors to the burden of disease into the future (Murray and Lopez 1996).

In the medically unwell, the assessment of depression is more problematic, and the prevalence is much more difficult to determine. In a systematic review of the prevalence of depression in patients with advanced disease, particularly advanced cancer, and among mixed hospice populations, i.e., palliative care populations, Hotopf et al. (2002) found that depression was a common problem; however, the quality of research was poor. The prevalence of depression varied between 1% and 50%. This variation is likely to be because of small sample size, and large attrition and exclusion rates, due to deteriorating physical and mental function and death and different definitions for making a diagnosis of depression. Many studies provided limited information about participants including demographic and clinical details and failed to provide "any data on the extent or severity of the participants' disease and their survival." The generally agreed prevalence of depression in the medically unwell and in palliative care populations is 25% (Barraclough 1999). Depression in this population is greater in the young (Blazer et al. 1994) and in some particular diseases (e.g., carcinoma of the pancreas) (Holland et al. 1986). There have been studies of the interaction between asthma and diabetes with depression, showing that with increased physical symptoms there is also an increase in depression (Goldney et al. 2003, 2004).

There are accepted systems for classifying the symptoms and signs required to make a diagnosis of depression (World Health Organization 1993; American Psychiatric Association 2013). There is however no single universally agreed system to confirm such a diagnosis and no one objective measure. The "gold standard" for making a diagnosis remains a systematic, structured clinical interview followed by the judgment of a mental health professional. The two widely accepted classifications of mental illnesses are the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association (2013) and the *International Classification of Diseases* (ICD) developed by the World Health Organization (1993). Many of the symptoms that might be considered may be on the continuum from normal variation to a clinical disease or condition. There is also possible overlap of symptom criteria with other known physical and psychological diseases and conditions. The diagnostic process requires the patient to have the physical, mental, and psychological capability to participate. There are clearly potential and real barriers to the assessment and diagnosis of depression, particularly in terminal illness. See Table 1.

A DSM-5 diagnosis of a major depressive episode requires that five symptoms, which may include both psychological and somatic symptoms, be present during the same period and that one of these is either depressed affect or

anhedonia (American Psychiatric Association 2013). DSM-5 diagnostic criteria for a major depressive episode include somatic symptoms that are common among medically ill patients, such as fatigue, change in weight, altered sleep patterns, and concentration. These somatic symptoms of depression may overlap with the symptoms of many medical illnesses. DSM-5 instructs doctors to exclude potential somatic symptoms of depression "when they are clearly attributable to another medical condition" (American Psychiatric Association 2013). But this advice creates practical problems (Peveler et al. 2006). For a population with a large number of "somatic symptoms," this instruction is not as easily translated into practice as might be suggested. It is often impossible to determine the etiology of symptoms. There is concern that including somatic symptoms of unknown etiology may lead to overdiagnosing depression (Ouslander 1982; Endicott 1984; Rapp and Vrana 1989; Kalichman et al. 2000). Alternatives to DSM-5 and ICD-10 classifications of depression have been proposed to differentiate depression from symptoms of a wide range of medical conditions, including cancer (Endicott 1984), Parkinson's disease (Marsh et al. 2006), dementia (Vida et al. 1994), chronic pain (Wilson et al. 2001) and generally for the elderly (Rapp and Vrana 1989; Gallo and Rabins 1999). They include three approaches: "etiological" (case-by-case or blanket exclusion from diagnostic criteria of symptoms judged likely to be due to medical illness or aging), "inclusive" (inclusion of all symptoms regardless of etiology), and "substitutive" (substitution of additional psychological symptoms for most or all somatic symptoms) (Endicott 1984; Cohen-Cole and Stoudemire 1987; Rapp and Vrana 1989; Kathol et al. 1990; Chochinov et al. 1994). Judging whether a symptom is "clearly and fully accounted for" by the patient's medical condition may be impractical.

Ellis et al. (2006) compared the two extreme approaches that do not require this judgment, i.e., the inclusion of somatic symptoms regardless of etiology (i.e., the DSM-5 guideline is ignored) and the exclusion of somatic symptoms which might be caused by the patient's medical condition or aging. Somatic symptoms regardless of their etiology did not adversely affect the identification of patients who showed evidence of psychological distress warranting follow-up. In contrast, the exclusion of somatic symptoms potentially due to disease or aging led to underrecognition of psychological distress (Ellis et al. 2006). Suggestions that somatic symptoms be excluded or substituted when assessing older and medically ill adults (Yesavage et al. 1982–1983; Bukberg et al. 1984; Rapp and Vrana 1989) were not supported. Whether somatic symptoms should be included, treated in a specific way, or be excluded is still unclear, and ultimately the decision must be left to the clinician and the individual situation.

There are barriers to effective management of depression in palliative care: recognition and diagnostic and treatment barriers related to patients, clinicians, and healthcare systems (Goldman et al. 1999). Patients create an important barrier to the recognition of depression by their failure to disclose psychological distress (Hinton 1994). Reasons may include a belief that talk about emotions is a waste of doctors' time (Maguire 1985), that they are responsible for their own distress (Maguire and Howell 1995), and that depression is too common to be noteworthy (Endicott 1984) and patient "stoicism" (Endicott 1984). Indeed, patients may actively deny their psychological distress in order to avoid the stigma associated with psychological disorders, because they believe depression is a sign of weakness, to avoid causing additional worry to their families, or because they fear being seen as ungrateful for the efforts of their family and clinicians (Endicott 1984). Patient disclosure is also influenced by clinicians' conscious or unconscious use of tactics that limit the expression of emotional distress (Maguire 1985).

Clinicians also directly contribute several barriers to the recognition and diagnosis of depression. Clinicians may have low motivation to identify patients with depression (Wilson et al. 2000). Depression can be difficult to detect accurately. It is a syndromic disorder: no biological markers can be used to identify it. Diagnosis relies on emotions, behaviors, and cognitions that overlap those reported by patients with

other psychological disorders and patients with no psychological disorder. As a result, it is known that symptoms of depression may not be recognized accurately by day care staff (McIntyre 1982), nurses (McDonald et al. 1999; Passik et al. 2000; Meyer et al. 2003; Pautex et al. 2003), or doctors (Passik et al. 1998, 2000; Durkin et al. 2003; Pautex et al. 2003) who do not have specialist mental health training. Nurses recruited to palliative care services are rarely required to have mental health training, and their continuing education generally fails to focus on these issues (Lloyd-Williams and Payne 2003).

8 Assessment

A careful and considered history is always the first step in assessment (Butow et al. 2015). The clinician should not be frightened of asking difficult questions. Not exploring a situation fully will lead to misunderstandings, assumptions, and ultimately poor management. A diagnosis of major depression is based on having a depressed mood that cannot be lightened; loss of pleasure or interest, even within the limitations of the illness; an excessive feeling of being a burden to others, accompanied by a sense of worthlessness or low self-esteem and of fearfulness and/or anxiety; and avoiding others or withdrawal. There may be brooding or excessive guilt and/or remorse, a pervasive sense of hopelessness or helplessness, a persistent desire for death, or suicidal ideation with prominent and persistent insomnia and excessive irritability.

Asking a person about their mood and exploring their thoughts including specifically asking about suicidal ideation or intent are not inherently dangerous. Indeed, it is indefensible to avoid these issues. It is unreasonable to fear that raising these issues might "give the person ideas." This is not true. It is important however to explore the person's thoughts about death and desire to actively end their life, the degree of planning, and access to means and intent to die (Hudson et al. 2006). Individual jurisdictions will have different thresholds and legal requirements for clinicians to ensure a person's safety. To deprive a person of their liberty is a serious responsibility, but at times this may be indicated and even more challenging when the person in consideration has a serious and potentially life-limiting illness.

There are many questionnaires and screening tools that have been proposed to assist in making the diagnosis of a psychological disorder or condition (Beck and Beck 1972; Chochinov et al. 1997; Kramer 1999; Hickie et al. 2001; Lloyd-Williams 2001; Akizuki et al. 2003; Arroll et al. 2003; Crawford and Robinson 2008). The gold standard is a structured clinical interview. Commonly used screening instruments may only be unidimensional considering "anxiety" as a single concept or "depression" or "depressed affect" such as using a visual analogue scale. That anxiety and depression are commonly coexistent is perhaps evidenced by the popularity of the Hospital Anxiety and Depression Scale (HADS) that is commonly used in clinical and research practice (Kramer 1999).

The impact of treatment-related factors; drug-induced depression; drug withdrawal including alcohol, tobacco, and other drugs (Passik and Theobald 2000); and disease-related factors, severe uncontrolled symptoms, or fear of symptoms such as pain should be part of the assessment. Important factors can include a past personal or family history of suicide attempt, cognitive problems (e.g., delirium), and any psychotic symptoms (e.g., hallucinations, delusions). An important part of the assessment should also include the person's level of isolation and social and family support.

9 Management

Management of psychological symptoms and conditions can broadly be considered in terms of non-pharmacological and pharmacological therapies, "the talking and the drug therapies." These are not mutually exclusive, and for people with limited energy, failing cognition, and limited time, some pragmatic decisions may be necessary.

The power of the clinician's and the clinical team's therapeutic relationship should never be underestimated (Marziali and Alexander 1991).

To provide clear information and explanation of what is happening physically and psychologically can be reassuring for many to assist in coping with the personal and social impact of disease. Supportive counselling and just being willing to explore the patient's distress, fears, and concerns and to promote a realistic hope should not be minimized. Dealing with physical symptoms and trying to address social and financial concerns can offer significant reduction of distress. Promoting communication with and support from others and by involving family and carers in care of the patient are useful strategies. Helping people to remember and gather the emotional resources that have sustained them through their lives before this crisis is a useful strategy for many. These are in essence attempts to try to reframe the situation and to consider strategies that assist in finding meaning and purpose.

Cognitive and other behavioral therapies can provide benefit (Coull and Morris 2011) but may not be readily accessible, or people may not have sufficient energy, time, and clear cognition to participate. Some of the nurturing therapies so well known in hospice care can provide a place of safety and relief as well. Life review and making meaning, whether in formal dignity therapy (Chochinov 2002), structured or informal biography services, or even reviewing the family photographs, may all be useful. Therapies to induce relaxation and some sense of peace should be considered. Some gain benefit with massage, aromatherapy, visualization, and music therapies (Hilliard 2001; Krout 2001; Demmer 2004; Kyle 2006; Ernst 2009).

Medication to moderate symptoms and to improve mood should be considered and if appropriate introduced early. Antidepressants have delay in maximum onset of therapeutic benefit. Many people are commenced on such medications when there is insufficient time to gain real and meaningful benefit (Lloyd-Williams et al. 1999). There is evidence that anything other than very short-term use of benzodiazepines is a useful strategy for the longer-term management of anxiety (Palliative Care Expert Group et al. 2016). Benzodiazepine medications with very short half-lives are particularly problematic particularly at the end of life. The clinical situation, the likely prognosis, and the intensity of the symptoms will all influence decisions. Antidepressants are likely to offer better long-term relief of anxiety. It is worth considering the full constellation of symptoms and trying to maximize benefit by employing medications that might assist other symptoms such as disturbed sleep and neuropathic pain. A trial of antidepressants for those with symptoms highly suggestive of a major depressive disorder should always be considered early. Choice about individual medicines will be guided by prescriber experience, confidence, route of administration, likely prognosis, and assessment of possible side effects and their likely impact on the person's quality of life.

And it can be argued that for the management of pain, most clinicians would initiate therapies even if there is incomplete understanding of the full etiology of the pathophysiology of the symptom. For psychological symptoms, it may be equally reasonable to commence interventions to assist in ameliorating the symptom, even in the absence of a full and clear diagnosis. The best way to support someone with a major psychological issue is to provide a coordinated interdisciplinary approach that is provided by professionals with different skills, working together to form a cohesive and consistent framework for the person and their family.

10 What Does It All Mean?

To be distressed and immobilized by emotion is not normal. Depression is not a normal part of dying. One must not ignore or avoid discussing these important issues, but help people to explore, if they wish, the meaning of what is happening and to assist in formulating a plan of support and intervention. To feel abandoned in such a situation would be unthinkable.

The management of psychological issues particularly for people facing the likely end of their life is complex. It may be quite daunting. But this should not allow any to avoid assessing and

commencing a therapeutic plan – be they inexperienced or experienced clinicians. Consider what resources are available within your network to provide advice, and consider what further assessment and interventions might be available to assist you and your patients.

It is important to try to provide continuity of care and emotional support, to understand the patient's concerns and needs and those of their family. There should be discussion about the nature of psychological issues and conditions, explanation of common somatic symptoms, and a plan for intervention and support. Medications are important but not the only "answer." Adverse effects on cognition, alertness, possibly mood, and behavior should be assessed. Antidepressants may assist both anxiety and depression, with or without judicious, short-term benzodiazepine use. If they are likely to provide benefit, then prescription is better earlier rather than later.

The burden on the carer, both professional and personal, in such situations should not be underestimated. Those providing personal care are likely to require extra support as well. Clinicians should not underestimate their own personal cost of supporting patients in these circumstances. The support of a team is useful and remembering to access the strategies for personal well-being is vital.

> Slowly, I learn about the importance of powerlessness. I experience it in my own life and live with it in my work. The secret is not to be afraid of it – not to run away. The dying know we are not God. . ..all they ask is that we do not desert them. (Cassidy 1991)

Abstract

This chapter outlines how health professionals may best prevent, recognize, assess, manage, and support people with palliative diagnoses who are at risk of delirium and their families, according to best evidence and the circumstances, needs, and wishes of the person. The chapter also presents evidence-practice gaps in delirium care in palliative contexts and briefly outlines future directions for research and clinical practice development.

1 Introduction

Delirium is a great source of suffering and perplexity for people receiving palliative care and the health professionals who care for them. The opportunities to appropriately respond to the needs of people with palliative diagnoses mirror other populations at risk of delirium; and there are similar challenges to delivering this care. Additional considerations relate to the burden, benefit, and goals of care in the context of living and dying with advanced illness.

Having optimal cognition, safety, and a sense of self and relationship with others at the end of life are highly valued by seriously ill people (Delgado-Guay et al. 2016; Spichiger 2008; Steinhauser et al. 2000). Equally, when a loved one has delirium, family carers want clinicians to give more information about what is happening and show respect and sensitivity for the person and their subjective experience (Namba et al. 2007; Brajtman 2003). Family feel supported when clinicians demonstrate respect and understanding of the person's needs and preferences and address suffering in ways which support them to communicate with each other (Bolton et al. 2016; Finucane et al. 2017).

This chapter outlines how health professionals can work to optimize care to achieve these important goals for people with palliative diagnoses and their families. Best evidence for delirium prevention, recognition, assessment, management, and support for people with advanced illness is presented. Where evidence is lacking for this population, we present evidence, guidelines, and standards for optimal delirium care of older hospitalized patients. We advocate for nuanced approaches to delirium care that are based on the individual needs and wishes of the person and informed by the intent of palliative care to prevent, recognize, and impeccably assess distressing symptoms and to relieve suffering. Ethical dilemmas, complexities, and uncertainties that clinicians and teams may encounter when caring for delirious people and their families in the last months, weeks, and days of life are discussed. Lastly, we propose how delirium outcomes for people receiving palliative care may be improved through research and clinical practice development.

2 Phenomenology

Delirium is an acute neurocognitive disorder, medical emergency, and serious healthcare complication. Delirium arises from physiological disturbances related to a medical condition, substance intoxication or withdrawal, and/or a toxin and manifests as acute disturbances to attention, awareness, and cognition (American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) 2013). Disturbances present variously in each patient, each delirium, and even during the course of one episode (Meagher et al. 2012a).

Cognitive changes include memory deficit; disorientation to time, place, and/or person; language and visuospatial disabilities; and perceptual disturbances, such as illusions, hallucinations, or delusions. Perceptual disturbances are almost always frightening for the person experiencing them, and this fear may cause him or her to become withdrawn, suspicious, and/or aggressive toward others, including family and clinicians (Breitbart and Alici 2008). Labile mood and altered sleep-wake cycle frequently occur but are not required for a diagnosis (Meagher et al. 2011). The intensity of delirium symptoms may range from mild to severe; and episodes may be brief (i.e., last for hours to days) or sometimes continue for weeks, even months (American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) 2013).

2.1 Diagnostic Criteria

Delirium was first included within the American Psychiatric Association Diagnostic and Statistical Manual (APA-DSM) in 1980. There have since been five iterations of delirium diagnostic criteria, reflecting evolving understanding of core features. Current criteria are:

1. Disturbed attention (i.e., reduced ability to focus, sustain, or shift attention) and awareness (reduced orientation to the environment).
2. Disturbance developed over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of the day.
3. An additional disturbance in cognition, e.g., memory deficit, disorientation, language, visuospatial ability, or perception.
4. The disturbances in criteria A and C are not better explained by another pre-existing, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma.
5. Evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication, or withdrawal (i.e., due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies (American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) 2013).

While classified as one disorder, delirium is further categorized as three subtypes according to the level of psychomotor activity:

(i) Hyperactive delirium: increased motor activity, agitation, and heightened states of arousal
(ii) Hypoactive delirium: decreased motor activity, delayed response, and drowsiness
(iii) Mixed delirium: fluctuation between hyperactive and hypoactive states in the 24-h period (American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), 2013; Gupta et al. 2008)

Whereas in a study of patients receiving palliative care, a small proportion (6%) experienced no particular subtype, and around 40% experienced a varied subtype, across the course of a delirium episode (Meagher et al. 2011).

3 Pathophysiology

The understanding of the pathophysiology of delirium is evolving. Hypotheses include those that primarily are theoretical and others that are being empirically investigated. The main theoretical models are as follows:

Neuronal Ageing: This model proposes that, with aging, central nervous system (CNS) immune cells undergo excessive production of pro-inflammatory cytokines in response to peripheral stimulation, providing a possible pathway for CNS dysfunction and consequent delirium. According to this model, elderly patients are

more at risk of developing delirium, because of age-related cerebral changes in stress-regulating pathways (Maldonado 2008, 2013).

Oxidative stress: In which physiologic insults, such as tissue damage, trauma, hypoxia, severe illness, and infections, cause decreased oxidative metabolism, leading to cerebral dysfunction with associated cognitive decline and behavioral symptoms seen in people with delirium (Berr 2000).

Neurotransmitter: Relates to deficits in central cholinergic functioning. This hypothesis suggests that excess release of dopamine, glutamate, and acetylcholine (Ach), as well as altered levels of serotonergic and gamma-aminobutyric acid (GABA) activity, may underlie clinical presentations of delirium (Maldonado 2008, 2013). It has further been proposed that decreased tryptophan and increased melatonin may result in decreased serotonin in people with delirium (Van Der Mast et al. 1991; Karlidag et al. 2006).

Circadian cycle: Disruptions to the 24-h circadian cycle and usual sleep-wake cycle have long been linked to development of delirium. This hypothesis suggests that alterations in the metabolism of melatonin (a hormone involved in the regulation of the sleep-wake cycle) may also play a role in the development of delirium (Maldonado 2008, 2013).

Neuroendocrine model: Suggests that sustained high levels of glucocorticoid levels occurring with acute stress can impair neurons in the brain and in turn may trigger and/or sustain delirium (Maldonado 2013; Olsson 1999).

The models with developing empirical evidence are

Neuroinflammatory: Altered neurotransmitter levels are commonly implicated in delirium. Higher serum levels of interleukin (IL)-6 and IL-8 (Van Munster et al. 2008) and raised S100 calcium-binding protein B (S100B) (van Munster et al. 2010) have been reported in people with delirium. Low levels of anti-inflammatory markers, such as insulin-like growth factor 1, are also reported (Adamis et al. 2009). As these studies report no correlation with clinical outcomes, with the exception of cognitive changes during delirium, it is therefore difficult to ascertain whether the altered levels are etiological or simply an epiphenomena (Caplan et al. 2010).

Glucose metabolism hypotheses: Lower cerebrospinal fluid (CSF) neuron-specific enolase (NSE) and higher CSF lactate are reported in people with delirium, suggesting the following hypotheses: (1) disrupted glycolysis, with switching from aerobic to anaerobic glucose metabolism by neuronal cells; (2) suppression of the glycolytic pathway in neurons; or (3) disrupted lactate uptake by neuronal cells (Caplan et al. 2010). Recent research further revealed widespread reduction in glucose metabolism in older inpatients with delirium and levels returning to baseline following delirium resolution (Haggstrom et al. 2017).

Most of these hypotheses are complementary and intersecting (Maldonado 2013). Ideally, further research into the complex neurochemical cascades leading to delirium will inform future development and testing of novel therapeutic approaches.

4 Epidemiology

4.1 Risk Factors

Epidemiological data indicates that people most at risk of developing delirium are those who are older, have advanced illness, and/or prior cognitive impairment (National Clinical Guideline Centre for Acute and Chronic Conditions 2010). Other predisposing factors are visual or hearing impairment, poor functional status, current hip fracture, and impaired nutrition. Yet any person – adult or child – can experience delirium when physiological insults are sufficiently great. Precipitants associated with illness, injury, and medical treatment are many and include (but are not limited to) polypharmacy, metabolic disturbance, presence of an indwelling catheter, dehydration, infection, and use of physical restraints. Additional precipitants related to advanced cancer are psychoactive medication (benzodiazepines, antipsychotics, and corticosteroids) and bone, liver, and brain metastases (Caraceni 2013) (Table 1). People receiving inpatient palliative care are

Table 1 Delirium risk factors

Predisposing factors	Precipitating factors	Additional risk factors in patients with cancer
Potentially modifiable • Sensory impairment (vision and hearing) • Diminished function/performance status • Malnutrition **Non-modifiable** • ≥65 years • Advanced illness • Prior cognitive impairment • Multiple comorbidities • Current hip fracture	**Potentially modifiable** • Polypharmacy • Anticholinergic load • Indwelling catheter • Use of physical restraints • Drug intoxication • Dehydration • Infection • Hypoxia • Pain • Anemia • Emotional stress • Prolonged hospital stay **Less modifiable** • Metabolic disturbance • Low albumin • Environment • Drug or alcohol withdrawal	**Potentially modifiable** • Benzodiazepines • Opioids • Corticosteroids • Other psychoactive medications **Non-modifiable** • Prior delirium • Bone metastases • Liver metastases • Hematological malignancies • Metastases to brain or meninges

National Clinical Guideline Centre for Acute and Chronic Conditions 2010, Caraceni 2013, Clinical Epidemiology and Health Service Evaluation Unit Melbourne Health 2006, Canadian Coalition for Seniors' Mental Health 2010, and Ahmed et al. 2014

likely to have multiple causes, up to as many as six (Meagher et al. 2011); a multimodal model of delirium risk proposes that predisposing and precipitating factors for delirium are cumulative (Inouye and Charpentier 1996).

4.2 Prevalence and Incidence

Delirium occurs frequently in palliative care contexts, where people are highly vulnerable through often having several predisposing and precipitating factors. Prevalence in studies conducted in adult palliative care units and hospices ranged from 13.3 to 42.3% at admission, 26% to 62% during admission, 58.8% in the weeks prior to death, and for almost all participants (88%) within six hours of death (Hosie et al. 2013; Rainsford et al. 2014). In the studies that screened participants at least once daily, incidence was 33–45%, compared to studies where daily screening did not take place (3–7%) (Hosie et al. 2013).

Hypoactive delirium is the most prevalent subtype, occurring in 68–86% of delirious inpatients in one study (Hosie et al. 2013) and in 58% in another of inpatients with advanced cancer (Uchida et al. 2015). Meagher et al. (2012b) reported a lower proportion of patients in a palliative care unit with hypoactive delirium (35%), likely because the study applied a different subtype categorization of motor behavior than that of the current APA-DSM 5 (American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) 2013) and these other studies.

There are no data on delirium prevalence or incidence in children receiving palliative care. A retrospective chart review of pediatric oncology admissions reported a 1-year incidence of 10%, which was likely an underestimate, as no prospective structured screening or diagnosis methods were used to detect cases (Combs et al. 2014). There are also minimal data on delirium prevalence or incidence in people having palliative care in their home or a residential aged care facility. One study reported an estimate of confusion occurring in 50% of US hospice patients in the previous week, measured by nurses' retrospective clinical report rather than a standardized tool (Nowels et al. 2002). Another reported delirium

prevalence of one in three people with pre-existing moderate to severe cognitive impairment in seven long-term care facilities in Canada (McCusker et al. 2011). Delirium is elsewhere reported to be present in almost one in five older people on arrival to the emergency department and almost half of people who reside in a nursing home (Inouye et al. 2014). The acute onset of delirium in an older person may be a key reason why emergency hospital care is sought.

4.3 Adverse Outcomes

Delirium adversely impacts on the individual, their family, clinicians, and the healthcare system.

During delirium, acute decline in attention and cognitive function reduces the person's capacity to make decisions and communicate with others, which suddenly and often unexpectedly compounds the other physical and functional losses of advanced illness. A delirious person may be reluctant or unable to verbally communicate his or her disturbed thinking, and feelings of fear, confusion, and isolation are common (O' Malley et al. 2008). While not always unpleasant, altered perception most often has a nightmarish, hellish quality, including visions of snakes, spiders, and ants crawling on walls and bedclothes, and beliefs that doctors and nurses plan to murder, experiment on, and sexually assault themselves and/or other patients (Boodman 2015). Being delirious also makes it harder for the person to verbally communicate other distressing symptoms, such pain or breathlessness, which may lead to inadequate management of those symptoms and greater discomfort and distress (Gagliese et al. 2016). In studies of people with advanced cancer who had experienced delirium in hospital, the majority remembered the experience (Breitbart et al. 2002; Bruera et al. 2009). Memories generated feelings of distress, embarrassment, humiliation, and ongoing fear, including that the delirium will return (Breitbart et al. 2002; Bruera et al. 2009; Teodorczuk et al. 2011).

Adverse effects of delirium are increased risk of falls, pressure areas, longer-term cognitive and functional decline, longer hospital stay, and mortality (National Clinical Guideline Centre for Acute and Chronic Conditions 2010; Australian Commission on Safety and Quality in Health Care 2013). An episode of delirium more than doubles the cost of an older patient's healthcare in the following year, due to spending a greater number of days in hospital or a nursing home (Leslie et al. 2008).

During delirium, family members experience high levels of distress (Breitbart et al. 2002). A review of 33 studies of family caregivers of patients with delirium in palliative care contexts found that they experienced anxiety, fear, helplessness, embarrassment, anger, disappointment, sadness, and guilt (Finucane et al. 2017). Delirium adversely impacted on relationships with the person, other family members, and health professionals. Caregivers wanted the person's suffering to be relieved, but did not want the possibility of communication to be thwarted because of sedation (Finucane et al. 2017).

Health professionals, particularly nurses, find identifying and appropriately responding to delirium challenging and experience uncertainty, strain, and distress (O' Malley et al. 2008; Leventhal et al. 2013). Nurses working in palliative care reported feeling compassion, distress, surprise, puzzlement, and frustration when delirium occurred (Agar et al. 2012; Hosie et al. 2014a). In one study, delirium severity and presence of perceptual disturbances were most significant predictors of nurse distress (Breitbart et al. 2002). In another of palliative care team members' experiences of caring for family of people dying with agitated secondary to delirium, participants felt the suffering of patients and family, tried to maintain control of the situation (usually through use of medication), felt ambivalent about the use of sedation, and valued communication to inform the family about the rationale of interventions and to reduce conflict (Brajtman 2005).

5 Prevention

There is growing evidence that the most effective way to improve delirium outcomes for people in hospital is to prevent it from occurring. Meeting

basic human needs, such as for physical and cognitive activity, sleep, hearing, vision, and hydration, significantly reduced delirium incidence in older hospitalized patients by up to 50% (Hshieh et al. 2015; Siddiqi et al. 2016). In contrast, a delirium prevention intervention for people with advanced cancer in seven Canadian specialist palliative care inpatient units reported a negative result (Gagnon et al. 2012), possibly because this intervention was not sufficiently targeted at these fundamental physical and cognitive needs. Instead, physicians were notified about delirium risk factors for each patient and asked to consider medication changes in response; while nurses orientated patients to time and place and gave patients and family information about early delirium symptoms. Despite almost 90% adherence to the study protocol, the intervention made no difference to delirium incidence, severity or duration, or dosage of psychotropic medication received by patients (Gagnon et al. 2012).

Psychoactive medications (Table 1) are commonly prescribed in palliative care to manage symptoms, such as pain, breathlessness, nausea, and fatigue, and may contribute to the increase risk of delirium (Gaudreau et al. 2005a; Clegg and Young 2011). It is important to discuss the potential risks with the person prior to commencing new psychoactive medication, so that they may make informed decisions about which means of symptom control are best for them. For example, some people would prefer to forgo some degree of pain relief to maintain optimal cognition. Choice of psychoactive medication should consider the side effect profile, pharmacokinetics and pharmacodynamics for the individual, and possible non-psychoactive alternative therapies and also pay close attention to drug-drug interactions. It is important to use the lowest effective dose and ensure ongoing regular review of the dose, necessity for ongoing treatment, and possible adverse effects.

Whether multicomponent delirium prevention interventions specifically targeted to risk factors and proven elsewhere are feasible and effective during receipt of palliative care is yet to be established. That the strategies address fundamental human needs does warrant that they are valued for all people in every care setting. Yet a potential barrier to routine implementation in palliative care is that people with advanced illness are frequently frail and fatigued and may be unable to fully participate in activities such as exercise. To make informed decisions about participating in these interventions, people first need to also understand the risks associated with delirium. They need accurate, timely, and sensitively delivered information about delirium and preventative strategies from clinicians at key points in the illness trajectory, such as on admission to a service and when deterioration occurs. Integrating delirium prevention into palliative care requires health professionals to view delirium as serious and potentially preventable in advanced illness, value this care, and offer and deliver preventative interventions in a safe, supportive, and informed way that is tailored to the individual.

6 Recognition

Early recognition of delirium risk and symptoms by all who are caring for the affected person, whether in primary care, the emergency department, or specialist palliative care settings, is essential so that his or her needs and those of their family can be assessed, a diagnosis or differential diagnosis made, and appropriate interdisciplinary care planned and implemented.

Historically, delirium is under-recognized and misdiagnosed across settings, including palliative care (National Clinical Guideline Centre for Acute and Chronic Conditions 2010; Barnes et al. 2010). Hypoactive delirium, which can easily be mistaken for depression or fatigue, is the least well-recognized subtype. One study in a palliative care unit reported a one-in-five detection rate of patients with hypoactive delirium by any member of the multidisciplinary team, significantly lower than detection of those with hyperactive and mixed delirium (Fang et al. 2008; Spiller and Keen 2006).

Poor recognition of delirium is due in part to it being a complex and fluctuating condition that manifests in various ways, even within one episode. Other reasons are health professionals' inadequate knowledge of delirium, particularly its

diagnostic criteria (Jenkin et al. 2016); attitudes that poor cognition is normal in older age and serious and advanced illness (McCarthy 2003); and lack of routine use of delirium screening, assessment, and diagnostic tools ("tools") and organizational direction (Hosie et al. 2014b). There are additional challenges to recognizing delirium in people with limited ability to speak, such as young children (Smith et al. 2013), those with an existing cognitive impairment (Morandi et al. 2016), and during intubation and sedation (Girard et al. 2008) and dying (Bush et al. 2014).

Timely recognition is supported by evidence-based knowledge of delirium as an abnormal condition, its seriousness, and who is most at risk (together denoting "awareness") and routine screening of those at risk using brief, validated tools and/or diagnostic criteria to confirm the diagnosis (National Clinical Guideline Centre for Acute and Chronic Conditions 2010; Australian Commission on Quality and Safety of Healthcare 2017).

Awareness requires evidence-based understanding of delirium that aligns with accepted diagnostic criteria, as in the APA-DSM-5, provided earlier. Across settings and time, numerous misnomers for delirium have been used in different areas of clinical practice and research, with examples being *ICU psychosis*, *sundowning*, and *confusion.* Increasingly these terms are being discouraged in the literature (Girard et al. 2008; Morandi et al. 2009) because they are imprecise, downplay the significance and severity of delirium, and contribute to under-recognition. Likewise, *terminal agitation* and *terminal restlessness* are widely used by palliative care practitioners to describe what may be delirium or other unspecified sources of distress (Hosie et al. 2014a; Brajtman 2005; Heyse-Moore 2003). Use of these terms has similarly contributed to under-recognition of delirium and delayed assessment and intervention for delirious patients in palliative care units (Hosie et al. 2014a), likely because the prefix 'terminal' implies that a delirious person is in the last days of life and communicates a presumption that interventions aimed at reversal are no longer the priority. Nurse participants in this study reported clinical incidents when they challenged their nurse colleagues' use of these terms, whereupon a more comprehensive assessment found that their delirious patients had reversible causes such as urinary retention and infection, which were successfully treated and these patients' delirium and distress resolved (Hosie et al. 2014a). To ensure an evidence-based approach to assessment and intervention when delirium symptoms occur, whatever the person's stage of illness trajectory or likelihood of reversal, it is recommended that use of *terminal agitation* and *terminal restlessness* be discontinued in palliative care practice and literature in preference for the more diagnostically precise "delirium."

Awareness also incorporates knowing the *general risk* of delirium to people with advanced illness, older age, and/or cognitive impairment (including the seriousness of its outcomes) and assessing the *specific risk* for an individual. General awareness is knowing that delirium is moderately to highly prevalent in people receiving palliative care, having "a high index of suspicion" that delirium is the cause of acute attentional and cognitive changes (LeGrand 2012), and understanding that all subtypes of delirium are a medical emergency that require urgent intervention (see ▶ Chap. 84, "Delirium as a Palliative Care Emergency"). While there is no tool to assess specific risk for people receiving palliative care, a simple and pragmatic approach outlined in evidence-based guidance is for any person with one or more risk factors (i.e., "age $\geq$ 65 years, known cognitive impairment/dementia, severe medical illness and current hip fracture" or any others) be asked, along with their family, on admission to hospital about any recent changes to behavior or thinking, undergo cognitive screening, and have preventative measures put in place (National Clinical Guideline Centre for Acute and Chronic Conditions 2010; Australian Commission on Quality and Safety of Healthcare 2017). Because by definition each person receiving palliative care has life-limiting illness, it is prudent to consider all to be at risk of delirium, with risk heightened for people who are older than 65 years, have an existing cognitive impairment, and one or more precipitants present (Table 1).

Screening patients for delirium requires routine and ongoing use of a structured tool by trained

clinicians. Delirium screening tools that are brief and low burden and/or include family observations include the:

- 4AT (McLullich 2015)
- Nursing Delirium Screening Scale (Nu-DESC) (Gaudreau et al. 2005b)
- Brief versions of the Confusion Assessment Method (CAM), such as the CAM-ICU (Ely et al. 2001) and short-, 3D-, or bCAM (Han et al. 2013; Hospital Elder Life Program 2015; Marcantonio et al. 2014)
- Single Question in Delirium (SQiD) (Sands et al. 2010)
- Recognizing Acute Delirium As part of your Routine tool (RADAR) (Voyer et al. 2015)

These tools were developed for various settings and users, and none have been tested or are routinely used in palliative care (Barnes et al. 2010; Irwin et al. 2008). Testing delirium tools and integrating them into current systems for symptom and problem screening (Palliative Care Outcomes Collaborative 2014; Cicely Saunders Institute 2012) is therefore an important area for palliative care practice development.

Confirmation (diagnosis) of delirium is best achieved by applying a validated confirmation tool, such as brief version of the CAM (as above) and/or diagnostic criteria (American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) 2013). Confirmation of delirium is not solely the responsibility of physicians; the process can be shared with other clinicians in the team who are trained in the use of the tool and have knowledge of the criteria (Australian Commission on Quality and Safety of Healthcare 2017). Potential differential and concurrent diagnoses, such as dementia or depression, need to be considered during the diagnostic process.

7 Comprehensive Assessment

Comprehensive assessment of a delirious patient is structured, multifaceted and interdisciplinary, and broader than a diagnostic assessment (Canadian Coalition for Seniors' Mental Health 2010; Australian Commission on Quality and Safety of Healthcare 2015). Given that delirium is a medical emergency, when symptoms are present and a diagnosis suspected, it is essential to determine likely causes through history taking, physical examination, and various investigations, aligned with the patient's goals of care. Understanding the experience from the patient's perspective, his or her level of distress, and need for information and reassurance are key components that are valued by patients and family (Day and Higgins 2015; O' Malley et al. 2008). Communicating the implications of delirium and the possible options for investigation and management and relative success rates expected helps people to make informed choices about the level of investigation. Understanding also informs any decisions for admission to hospital or a palliative care unit if the person is at home.

Elements of assessment of a person with suspected or confirmed delirium are several and include:

- History, including reported symptoms of delirium and precipitating medical conditions, baseline cognition, and previous episodes of delirium (some which may be from collateral history)
- Physical examination
- Likely causes and potential for reversibility
- Predicted prognosis
- Immediate, intermediate, and longer-term goals of care
- Decision-making capacity
- Level and cause of distress
- Safety: risk of falls, wandering, pressure areas, and injury to self or others
- Preference for location of care
- Social, psychological, cultural, or spiritual needs
- Family information and support needs
- The need for referral to appropriate psychiatric or geriatric specialists or specialist services if delirium is severe and/or persisting

Comprehensive assessment also involves the person and his or her family, and results in a plan of care that addresses identified needs, priorities, wishes, and short- and longer-term goals (National Clinical Guideline Centre for Acute and Chronic

Conditions 2010; Canadian Coalition for Seniors' Mental Health 2010; Australian Commission on Quality and Safety of Healthcare 2015).

8 Management

The goals of palliative care of a delirious person are to reduce distress, maintain function and physical and emotional safety, and resolve the delirium, wherever possible. These goals are best achieved through targeting the causes, effective communication, and practical strategies to meet patients and families' immediate needs.

While clinical decision-making about intervention to resolve delirium often contains elements of uncertainty about effectiveness, treating the identified causes is the most logical medical route to relieving distress. Potential for reversal of delirium remains even in far-advanced illness when modifiable precipitants, such as infection, dehydration, and psychoactive medication, are treated (Lawlor et al. 2000). Some people will have less modifiable causes of delirium, such as metabolic disturbances related to organ failure (Lawlor et al. 2000; Leonard et al. 2008). Ethical decision-making with the patient and family about treatment therefore requires consideration of and discussion about the likely success of the treatment (both for the precipitant and the delirium), where it would need to occur (e.g., hospital, home or palliative care unit), and the degree of invasiveness (e.g., oral versus intravenous antibiotics). As there are usually several precipitants for each episode of delirium (Meagher et al. 2011), treatment is often multifaceted.

Further details of the investigative and intervention approach to treat delirium are outlined in ▶ Chap. 84, "Delirium as a Palliative Care Emergency"

8.1 Pharmacological Treatment

There are no approved or proven pharmacological interventions that directly prevent or treat delirium. Rational pharmacological treatments for delirium are those which target the identified cause and any associated discomfort, for example, antibiotics to treat infection, rectifying polypharmacy, discontinuing or reducing the dose of suspected medication precipitants, paracetamol to relieve fever, and ensuring adequate analgesia for pain (Canadian Coalition for Seniors' Mental Health 2010).

Antipsychotics have for many years been recommended in clinical guidelines and commonly prescribed to relieve delirium symptoms within both palliative care and other settings, yet there is growing evidence that this medication is not effective. A recent systematic review and meta-analysis of 19 randomized controlled trials and cohort studies of antipsychotics to prevent or treat delirium found no association with reduction of delirium severity or duration (Neufeld et al. 2016). Clinical trials conducted in intensive care settings report that use of antipsychotics did not increase participants' number of days without delirium (Page et al. 2013; Girard et al. 2010). Most recently, the first adequately powered trial of antipsychotics (risperidone vs haloperidol vs placebo) in patients receiving palliative care found that, at three days, participants in the risperidone and haloperidol arms had delirium symptom scores significantly higher than those in the placebo arm. Participants in the active arms had significantly more extrapyramidal effects, while participants in the placebo arm received significantly lower doses of rescue midazolam and had the best overall survival (Agar et al. 2016).

Benzodiazepines, such as midazolam and lorazepam, are recommended and used as a second-line pharmacological palliative intervention for delirium when the patient is highly distressed (Palliative Care Expert Group 2016), with an absence of robust trials to evaluate efficacy and toxicity, and are also a class of medication which can contribute to or worsen delirium. A 2009 Cochrane review found no evidence that benzodiazepines improved delirium outcomes (Lonergan et al. 2009). The review authors highlighted that participants in the lorazepam arms had unacceptable side effects in two included studies, including severe sedation, which caused one randomized controlled trial to be prematurely discontinued (Breitbart et al. 1996).

A recent Cochrane review investigating the benefit of palliative sedation on quality of life, survival, and refractory symptoms in terminally ill adults in the last days of life examined 14 studies (12 in hospice and palliative care units and primarily of midazolam) and reported insufficient evidence that palliative sedation improved quality of life or symptom control (Beller et al. 2015). Of the eight included studies measuring sedation for delirium, none reported improved delirium symptom control, and four reported worsening of delirium symptoms; the one study measuring unintended adverse effects reported 6% of participants experienced drug-induced delirium (Beller et al. 2015).

Based on current evidence, antipsychotic and/or benzodiazepine medication should therefore be viewed as an emergency, last resort, and short-term intervention for a severely distressed or agitated delirious person, after all other therapeutic strategies to relieve distress and maintain safety have been trialled and when the immediate risks to the patient are assessed as greater than these pharmacological interventions. Wherever possible, the principle of informed consent requires that the affected person or their surrogate decision-maker be fully advised of the intent, potential for benefit, possible adverse effects, and plan for use of these medications, before they are prescribed and administered.

8.2 Communication

People with delirium value verbal and nonverbal language that communicates respect for them as a person and understanding of what they are experiencing, while family members feel supported when they are consulted and given timely information by health professionals (Finucane et al. 2017; O' Malley et al. 2008).

Delirium is usually frightening and alienating, and many people struggle to communicate its symptoms, even more so for those who speak a language other than English or have other pre-existing barriers to communication. Being alert to the person's fears and difficulties; using simple, concise, and slow-paced ways of speaking; sensitively asking about the experience; respectfully promoting orientation (e.g., using the person's name, introducing self, referring to the day and place in conversations) without directly contradicting the person's altered reality; and obtaining the help of interpreters where required are the recommended ways of communicating with a delirious person (Canadian Coalition for Seniors' Mental Health 2010).

People affected by delirium also appreciate knowing that it is common during medical illness, usually short in duration and often treatable. Highlighting that the causes are physiological clarifies that symptoms do not mean that the person is suddenly developing dementia or a mental illness, which is a common misunderstanding (Breitbart and Alici 2008). Naming symptoms as 'delirium' is therefore important. However, explaining that delirium is common should not be intended to communicate that it is normal, because delirium is always an abnormality for the person (Hosie et al. 2016). Communication instead seeks to understand the experience of delirium from the person's and family's perspective, identify the level of distress, and acknowledge the real impact. Informing family about delirium, including with written information, and involving them in practical and emotional care of the person are desired and acceptable to them and potentially beneficial for both (Finucane et al. 2017). As outlined above, communication with the person and family members includes discussion about treatment options and likely outcomes.

An episode of delirium, particularly subsequent episodes, may also signal that the person's prognosis is grave and death is near. At this time, interdisciplinary reassessment of the person's circumstances and needs, and honest, sensitive communication with the patient and family about the possible significance of delirium, enables a clear and agreed upon plan of care.

Effective team collaboration, communication and functioning improve processes and outcomes for people receiving palliative care (Tieman 2007; Abernethy et al. 2013). However, communication between team members, especially between

nurses and physicians, can be a barrier to optimal delirium care in palliative care contexts. Nurses do not always clearly report observed symptoms as delirium, and then perceive a lack of respect or listening from physicians and nursing managers (Hosie et al. 2014a). When delirium occurs, interdisciplinary communication is best enabled by shared use of diagnostic language, understanding of delirium and the rationale for a plan of care, established roles for each discipline, and more frequent and focused discussion at the bedside; in other words, informed, explicit, structured, and whole team consideration of delirium symptoms, with the person and family placed at the center of assessment, decision-making, and care (Vasilevskis et al. 2010).

8.3 Practical Strategies

There are numerous practical strategies recommended in clinical practice guidelines for care of a delirious person. Examples include:

- Continuation of care that helps the person maintain optimal movement, vision, hearing, cognition, hydration, and sleep.
- Optimizing the environment:
  - Natural day and night lighting, noise levels, and activity.
  - Avoid transfers and maintain familiar surroundings and belongings.
  - Orientating equipment such as clocks, calendars, and wall schedules.
- Assess and minimize risk of falls and injury while avoiding restraints and allowing the person to move as freely as possible.
- Supporting those who are familiar to and trusted by the person to remain with him or her, including family members, friends, and professional carers.

The reader is referred to relevant guidelines for more comprehensive details of these strategies (Canadian Coalition for Seniors' Mental Health 2010; Australian Commission on Safety and Quality in Health Care 2014).

8.4 Delirium in the Last Days of Life

Delirium is very common when someone is dying, although not inevitable. When delirium occurs in the last days and hours of life, there remains the need for a prompt and individualized response to the meticulously assessed needs of the person and his or her family.

Numerous studies have consistently reported what is most important to patients and family at the end of life. In the hospital setting, patients and family highly valued expert, respectful, and compassionate care, effective communication and shared decision-making, an adequate environment, involvement of family, support with financial affairs, and trust and confidence in clinicians (Virdun et al. 2015, 2016). Patients also wanted to maintain a sense of self and not be a burden to others; and family further valued preparation for death, the patient to be safe and enabled to make choices, and family care continuing past the death of the person (Virdun et al. 2016). A study of the end of life wishes of people with advanced cancer, conducted in the United States, reported the ten most important as being, in this order: to be at peace with God, pray, have family present, free of pain, not be a burden to family, trust in the doctor, maintain a sense of humor, say goodbye to those who were important to them, have family prepared for death, and be able to help others (Delgado-Guay et al. 2016). Studies in Japan with bereaved family members of people who had delirium when they were dying from cancer reported that family experienced high levels of distress; more than half believed clinicians should have shown more respect for the person, explained what was happening on a daily basis, helped to relieve the physical and psychological burden on family, and better prepared them for death (Namba et al. 2007; Morita et al. 2007).

Given the consistency of the descriptive data over time and setting, and the growing evidence for ineffectiveness of pharmacological interventions to reduce delirium duration, severity, or distress, it is clear that physical, emotional, and spiritual care to help people who are delirious in the last days of life to be seen as a person; connect and communicate with family, health

professionals, and God; and prepare for death ought to be the focus of both clinical practice and future interventional research.

Palliative care for a person who is delirious in the last days of life, and their family, therefore continues all appropriate strategies to relieve suffering, as outlined above. If agitation is present for a dying person, all potential contributors, such as pain, urinary retention, fecal impaction, and psychological and spiritual distress, should be assessed and managed accordingly. If any level of sedation is considered for a person who is suffering from refractory agitated delirium in the last days of life, or other symptoms, health professionals should be guided by the European Association for Palliative Care (EAPC) framework for palliative sedation (Bush et al. 2014; Cherny and Radbruch 2009). Briefly, this framework includes that the person is comprehensively assessed by experienced palliative care physicians and teams, and any other appropriate specialist; that patients and family members are fully informed and provide consent; that sedation is proportional to the person's needs and wishes, that the person's physical, hydration, nutrition, and concomitant medication needs are considered and met; that supportive care of the family continues; and that the views and well-being of team members with respect to decision-making and intervention are also considered (Cherny and Radbruch 2009). Care must also be taken that any sedating intervention is given primarily for the wellbeing of the person, and not for that of family or team members.

9 Future Approaches to Improving Palliative Care of People at Risk of Delirium

Improving delirium outcomes for people receiving palliative care requires greater empirical evidence in every domain: prevention, recognition, assessment, treatment, and support, including for family in bereavement (Lawlor et al. 2014). Numerous descriptive data exist, but proven interventions are lacking. Next steps to improving palliative care of people at risk of delirium are therefore to develop interventions that are based on the aspects of care that have consistently been reported as the most important to people at the end of life and test them in well-designed studies (Finucane et al. 2017). Interventions proven to be effective for other patient groups and settings, such as delirium prevention through meeting fundamental human needs, can also be tailored and tested in palliative care (Hshieh et al. 2015; Siddiqi et al. 2016). Novel therapeutic targets based on pathophysiological evidence of pathways to delirium ideally will guide future trials of pharmacological prevention and treatment therapies. Theories of grief and bereavement could be developed and tested as interventions to support family of people with delirium in advanced, life-limiting illness. For example, the theory of ambiguous loss acknowledges and addresses the loss experienced by family when a living person is physically present yet psychologically absent – as can occur during delirium – to find greater meaning, mastery, connection, hope, and resilience in the difficulty of the situation (Boss 2010; Day and Higgins 2016).

At the health system level, patients receiving palliative care require equitable access to organizational initiatives to improve delirium systems and practice. For example, in Australia, a new delirium clinical care standard will include people receiving palliative care in its remit (Australian Commission on Quality and Safety of Healthcare 2017).

Delirium education for health professionals should be based on those known to be most effective in changing attitudes, knowledge, and practice. Examples include interprofessional education (Sockalingam et al. 2014) and spaced education (Phillips et al. 2014).

10 Conclusion and Summary

This chapter has outlined how health professionals may best prevent, recognize, assess, manage, and support people with palliative diagnoses who are at risk of delirium, and their families, according to best evidence and the circumstances, needs, and wishes of the person. The chapter also

presented evidence-practice gaps in delirium care in palliative contexts and briefly outlined directions for future research and clinical practice development.

Abstract

Neurological disease is a major cause of disability and death across the world. There is increasing evidence that palliative care is effective in managing symptoms, maintaining and improving quality of life and helping patients

R. D. MacLeod, L. Van den Block (eds.), *Textbook of Palliative Care*,
https://doi.org/10.1007/978-3-319-77740-5_23

and families cope with the deterioration. As the disease progression varies, both between diseases and for individuals. palliative care may be involved for varying periods of time, and may need to be involved episodically throughout the disease progression. Careful assessment of all the issues – physical, psychosocial and spiritual – will allow appropriate management and support for patients and families. Carer support is very important as families face all the issues of coping with a progressive disease. Recognition of the later stages of life is helpful in enabling patients, families and professionals to be able to prepare for the dying phase and manage all the issues appropriately.

1 Introduction

The assessment of neurological symptoms may be particularly complex. It is essential that there is very careful assessment of the symptom, before any treatment, as for all palliative care. However there may be many interactions between the symptom and the psychosocial and spiritual aspects of care. Moreover there may be issues of communication and cognition, as many symptoms are experienced by people with complex progressive neurological diseases as well as other comorbidities.

The difficulty of communication – maybe due to severe dysarthria, dysphasia, or respiratory dysfunction reducing the power of speech – may make the assessment of the symptom more difficult as the patient may not be able to express themselves clearly or may not even be able to express the distress caused by the symptom. This may also be seen when there is cognitive change. The patients may be less able to express their concerns and to discuss their problems and the symptom. The assessment of the patient and symptoms may be by careful observation of the person, looking for signs of distress or evidence of symptoms, but may also include the assessment and comments from family and carers. This has been used widely for the assessment of pain, and the DisDAT assessment has been widely used for pain assessment in intellectual disability and PAINAD for pain assessment in dementia (Regard et al. 2007; Warden et al. 2003). For both of these assessments, there is close observation and discussion with the carers, and if distress is present, the cause is looked for. If there is evidence for pain, analgesia may be given, and careful reassessment will see if the distress has reduced and the diagnosis of pain has been correct.

Thus neurological symptoms may require even greater "impeccable assessment" (WHO 2002), as they may be part of a wider neurological disease, with variable progression. However the same symptoms may be seen in patients with other diseases, such as paraneoplastic syndromes in patients with cancer, autoimmune disease, or related to medication (Panzer and Dalmau 2011). It is important to differentiate the cause of the symptom, and to look at the comorbidities, if the management is to be the best for that particular patient.

2 Dizziness and Vertigo

Dizziness is a term that is used to explain different sensations, such as light-headedness and spinning (vertigo) accompanied by an involuntary, rapid, rhythmic eye movement (nystagmus); giddiness; and feeling as if one is going to faint (syncope) (MD Guidelines 2017). Vertigo, dizziness, and unsteadiness are often reported as similar symptoms even though they may have different causes involving different organs and pathophysiology (Bisdorff et al. 2013).

Dizziness is a general term for a sense of disequilibrium; vertigo is commonly due to the involvement of the vestibular system and is reported as the illusion of motion, usually rotational motion. Other causes of these symptoms can be due to lesions in the brain stem and cerebellum and can be associated or not with nystagmus, migraine, ataxia or nausea or vomiting, and falls. Systemic disorders, like vascular or neurovegetative (postural hypotension), can cause dizziness as well as psychological psychiatric conditions like anxiety and depression.

The most common causes of vertigo are benign paroxysmal positional vertigo, acute vestibular

neuronitis or labyrinthitis, Ménière's disease, migraine, and anxiety disorders. Less common causes include vertebrobasilar ischemia and retrocochlear tumors (Swartz and Longwell 2005). In cancer patients, dizziness is common in patients with a direct involvement of the brain (primary or secondary tumors), secondary to cancer complications like hypercalcemia, hypoglycemia, and general electrolyte disorders. This symptom is common in neurological disorders like multiple sclerosis, Parkinson's disease, or multisystem atrophy.

In palliative care dizziness is often a side effect of symptomatic drugs. The palliative care formulary (2016) reports dizziness as side effects in almost all drug categories used in palliative care, starting from opioids to anticonvulsants, benzodiazepines, mood stabilizers, dopaminergics, sedatives, and in general all drugs which can act in the central nervous system.

The evaluation of a patient with dizziness requires attention to the nature and the characteristics of the symptoms that can suggest a possible diagnosis (e.g., onset, triggers, duration) and clinical features (general and neurological examination, e.g., orthostatic blood pressure and cardiac rhythm, oculomotor function, and balance) (Kerber and Baloh 2011).

Management of dizziness and vertigo depends on the underlined primary cause. Drug treatments are not presently recommended for benign paroxysmal positional vertigo (BPPV), and bilateral vestibular paresis, but physical therapy treatment can be very useful in both (Hain and Uddin 2003). Non-pharmacological techniques are effective like vestibular physical therapy in vestibular neuritis or canalith repositioning procedure for BPPV.

Corticosteroids can be effective in inflammatory causes, and therapies to reduce intracranial hypertension can ease when cerebral edema is present in brain tumors. In Parkinson's disease dopaminergic doses, adjustments can improve this symptom. Therapies for specific electrolyte disorders can play a role. In migraine-associated dizziness, specific antimigraine drugs can be helpful (Neuhauser et al. 2003).

For vertigo in both Ménière's disease and vestibular neuritis, vestibular suppressants such as anticholinergics and benzodiazepines are used. In Ménière's disease, salt restriction and diuretics are used in an attempt to prevent flare-ups. In vestibular neuritis, only brief use of vestibular suppressants is now recommended (Hain and Uddin 2003).

Drug treatments are not presently recommended for BPPV and bilateral vestibular paresis, but physical therapy treatment can be very useful in both (Hain and Uddin 2003).

In palliative care it is very important to consider the role of palliative drugs throughout a cautious titration, attention to the drugs interaction (opioids and neuroleptics but antiemetic also), and possibly a reduction of futile treatments.

Since dizziness and vertigo can have anxious or mood disorders origin, a careful psychosocial assessment should be considered and proper treatment provided. Family carers are to be involved explaining the meaning of this symptom, reassuring them about the causes, and, when appropriate, involved in the daily assessment and treatment.

3 Hearing Loss

Hearing loss is an age-related condition affecting 80% of adults over age 80. It is often denied by patients, sometimes for sociocultural reasons, as they fear of being labeled deaf. The condition can appear slowly overtime, and patients can be unaware of their loss of hear. The prevalence of this disturbance is unknown in palliative care, even though it can be assumed higher of the general population, due to the high age, comorbidity, and the treatment received (Smith et al. 2015). Hearing can be affected by specific treatments, like antibiotics or anticancer drugs.

Promotion of communication, shared decision making, and empowerment, even in the case of people with mild cognitive impairment, can enhance patient autonomy and dignity, helping to improve the quality of remaining life (Feinberg 2014). Hearing loss can have emotional impact including social isolation, loss of self-esteem due to communication mistakes, and frustration at the difficulty with communication. People may withdraw and/or become depressed and may

experience anger and frustration at the effort it takes to communicate (Bade 2011). Hearing impairment therefore can be a barrier for many palliative care outcomes and interventions, if not recognized.

Often, in a medical consultation, hearing-impaired patients tend to look absentminded and inattentive, whereas they are only unable to follow the conversation. This happens frequently when more participants attend and the carers tend to attract the discourse and, finally, make decisions about the care process.

Audiologists can play a role in helping the palliative care team, through an accurate assessment and suggesting solutions to reduce the impact of hearing loss (Weinstein 2015). In order to assess a hearing impairment, some authors suggest a single-item question along with a whisper test (Bagai et al. 2006) or a finger rub test (Smith et al. 2015). If these tests are positive, an audiological and/or speech and language consultation should be performed. Since this can be difficult for patients in palliative care, some general approach can be adopted, like an ear inspection to see if cerumen is obstructing the ear.

The treatment in case of a defined hearing loss can involve hearing aids, which unfortunately do not resolve most of the problems in palliative care patients. These devices are expensive, their provision can take time, and patients are not always compliant. They are usually prescribed when patients' expected life span is higher than 3 months. In the literature tips and techniques to improve communication with persons with hearing loss are reported (Smith et al. 2015; Weinstein 2015) including attention to the setting, positioning, language, aids, and documentation.

Some patients can have acquired deafness from the infancy; in these situations, usually they are able to communicate via sign language. The lack of knowledge of this form of communication can be a barrier to palliative care for deaf patients (Maddalena et al. 2012). It can be useful to identify someone in the staff, or among the patient's family, able to perform with this language in order to be able to fully involve the patient in the clinical assessment and therapeutic decisions.

4 Visual Disturbance

Visual disturbance is not very often reported in palliative care papers as a prevalent condition. This does not mean that patients do not suffer of visual loss, but indicates that probably they tend to focus on other specific palliative care issues and professionals do not assess and consider visual problems in routine practice.

The literature shows that the main causes of sight disturbances are primary eye tumors, ocular metastases, and some paraneoplastic syndromes. Sight alteration can also be associated with asthenia, fatigue, anemia, and hypovitaminosis (Saita et al. 1999). A visual drop is frequent in other conditions related to palliative care such as multiple sclerosis as a consequence of optic neuritis, with blurred, double, or graying of vision, nystagmus, or blinding of one eye. HIV/AIDS patients can lose their capability to see for concurrent infections, mainly cytomegalovirus retinitis, but from other pathogens including varicella zoster virus and herpes simplex virus retinitis, ocular syphilis, ocular tuberculosis, cryptococcal meningitis, and HIV-related ischemic microvasculopathy, ocular toxic, or allergic drug reactions (Kestelyn and Cunningham 2001). Other common causes are glaucoma and the consequences of diabetes.

Hypoglycemia can be a cause of temporary visual loss in non-diabetic patients and in palliative care settings, but in this case the drop of vision is to be considered a symptom of the metabolic condition, potentially very risky for survival and therefore appropriately treated (Kok and Lee 2016).

Visual impairment can hinder people from accessing appropriate services, limit relationships, and increase the sense of social isolation. As the general conditions worsen, frail patients tend to have limited resources to communicate. In specific situation, the eye function remains the only possibility to express any personal need, for example, in the locked-in syndrome, but also in ALS/MND tracheostomized and mechanically ventilated patients using eye-controlled communicators, called "augmentative/alternative communication" (AAC).

Ophthalmologists can play a role in palliative care (Yorston 2004). Interventions range from assessment and diagnosis of eye-related disorders, local and systemic treatments, and other symptoms managements such as reducing painful eye pressure pain in glaucoma, even when a total visual loss has occurred. This can be obtained with a daily dose of a 1% solution of atropine, topical steroids, or topical nonsteroidal anti-inflammatory drugs. More invasive intervention are retrobulbar chlorpromazine and alcohol injections (Galindo-Ferreiro et al. 2016) up to the evisceration or enucleation of the eye bulb that is performed mostly after a trauma, but can play a role in glaucoma (Balta et al. 2016).

5 Anosmia

Smell disorders can markedly affect the quality of life. The four main causes of smell disorders are trauma, viral infections, nasal causes such as sinusitis or polyposis nasi, and smell disorders associated with aging or neurological illnesses such as Parkinson's disease (Hummel et al. 2011). Anosmia is a non-motor feature of PD that, with other smell dysfunction, occurs in 90–96% of cases (Doty et al. 1988; Haehner et al. 2009). This symptom can anticipate the motor signs of the disease and is more prevalent than tremor, usually considered as principal indicator of PD (Alves et al. 2008). The olfactory bulb is implicated in the dysfunction. Damage to the dopaminergic, cholinergic, serotonergic, and noradrenergic systems is likely involved, and the origin is multifactorial and includes the same determinants as those responsible for other non-motor symptoms of PD, such as dysautonomia and sleep disturbances (Doty 2012). Anosmia is associated with autonomic failure and constipation (Ramjit et al. 2010). Anosmia is present in atypical parkinsonian syndromes like MSA, where autonomic dysfunctions are pathognomonic, whereas normal olfaction seems present in PSP and CBD patients (Wenning et al. 1995).

MS can cause impairment of the olfactory system, since half of the patients can have a reduced sense of smell or hyposmia (Uecker et al. 2017). Dementia with Lewy bodies is another neurodegenerative condition associated with impaired odor detection (McShane et al. 2001). Moderate hyposmia is present in Huntington's disease (Nordin et al. 1995) and in ALS (Hawkes 2006).

There are only limited treatments available for smell disorders. A proven effective treatment is only available where nasal illnesses cause the smell disorder (Hummel et al. 2011).

Treatment of odor dysfunction secondary to neurological conditions is difficult due to the progressive nature of the disorders. Rasagiline showed a positive effect on the processing of olfactory information in early PD patients (Haehner et al. 2015).

6 Movement Disorders

Movement disorders include:

Tremor is an unintentional, rhythmic, oscillation of a body part in a fixed plane and results from contractions of agonist and antagonist muscles entrained by a signal pattern originating from an oscillator in the CNS (MD 2017). The commonest cause is Parkinson's disease, due to the degeneration of neuromelanin containing neurons in the brain stem and particularly the substantia nigari. Careful assessment and consideration of the other symptoms of PD – rigidity, akinesia, and changes in postural reflexes – support the diagnosis, and treatment is by the use of levodopa and dopamine receptor agonists.

Tremor may also be "physiological" and exacerbated by stress and may be eased by beta blockers; essential tremor may be seen and there is often a family history and beta blockers are often helpful; cerebellar damage from inflammation in multiple sclerosis tremor is mild at rest and increases on activity and may respond to propranolol or isoniazid.

The use of medication may be helpful, but there is also the need to help patients cope with their tremor and for families and carers to understand the disability and anxiety associated with tremor.

Chorea is an abnormal involuntary movement characterized by brief, abrupt, irregular, unpredictable, non-stereotyped movements (MD 2017). This may be seen in:

- Huntington's disease – a genetic neurological degenerative disease where there is increasing movement issues, swallowing problems, and cognitive change. The chorea may be reduced by tetrabenazine, a monoamine depletor, and amantadine and atypical psychotics may be helpful.
- Paraneoplastic chorea may be seen with small cell lung cancer and thymoma and is associated with antibodies to CRMP5. Treatment may be more for the underlying cancer.
- Sydenham's chorea may be seen. It follows an autoimmune response to group A beta-hemolytic streptococcal infection, and symptoms may continue for years, although they usually resolve in a few months. Benzodiazepines, valproic acid, and neuroleptics are used in management.

Spasticity may occur when there is upper motor neuron damage – due to degeneration, as in MND; damage, as in nerve compression; or damage by tumor, cortical damage in stroke, or cerebral palsy. The main management will be with physiotherapy and positioning, to maximize comfort, prevent contractures, maintain joint range of movement, and enable as much mobility as possible. Muscle relaxant medication can be useful, and there is little evidence of the effectiveness of any medication. It has been suggested that quinine sulfate may be used initially, monitoring cardiac function, followed by dantrolene, tizanidine, baclofen, and gabapentin (NICE 2016). Injections of botulinum toxin into spastic muscles can be helpful for severe spasticity.

Dystonia is characterized by sustained or intermittent muscle contractions causing abnormal, often repetitive, movements, postures, or both. The movements are typically patterned and twisting and may be tremulous, and they often initiated or worsened by voluntary action. Dystonia may be inherited but can be due to infection, including encephalitis and HIV; drug induced, including levodopa and neuroleptics; and vascular, with ischemia, brain tumors, or trauma (Albanese et al. 2013). Some people are particularly prone to dystonic reaction due to phenothiazine or metoclopramide and may require anticholinergic medication, such as benztropine.

Treatment of localized dystonia may be with injections of botulinum toxin. Medication can be helpful including levodopa, tetrabenazine, reserpine and benzhexol, or baclofen (Pall 1999).

A **tic** is an involuntary movement or vocalization which is usually of sudden onset, brief, repetitive, stereotyped, but nonrhythmical in character. This may frequently imitate normal behavior and often occurs against a background of normal activity (MDS). Tourette's syndrome is characterized by tics and is first seen in childhood. Tics may be related to intellectual disability and autism or be seen in degenerative disease, in particular HD (Shprecher and Kurlan 2009).

Management will include a behavioral approach or the use of alpha-2-agaonists, such as clonidine, or neuroleptic antipsychotics, such as haloperidol, risperidone, or aripiprazole (Shprecher and Kurlan 2009; Cuenca et al. 2015).

7 Seizures Including Myoclonus

A seizure is a transient occurrence of signs or symptoms due to abnormal excessive or synchronous neuronal activity in the brain (Fisher et al. 2005). They may occur in 13% of people, with cancer, receiving palliative care. They may be:

- Simple partial seizures – with normal consciousness but an area of the cortex is stimulated, and the corresponding functional area is affected.
- Complex partial seizures – focal symptoms with an altered state of consciousness. Although the person may seem to be awake, they cannot respond and they may show repetitive behavior and eye movements. Afterward they may be sleepy, have delirium, or complain of headache.
- Generalized tonic–clonic seizures with loss of consciousness and muscle rigidity. Afterward they may be in a deep sleep and recover slowly.

About 25–50% of people in palliative care who have a seizure have brain metastases and of people with primary brain tumors 20–45% will present with a seizure, and this is commoner in slow-growing tumors, such as oligodendroglioma (Tradounsky 2013). The common causes of seizures are damage to the brain, from tumor, abscess, and hemorrhage, and systemic causes include metabolic causes, such as hypoglycemia, uremia, hypercalcemia, hepatic failure, and hypo-, or hypernatremia. Medication may cause a seizure including ondansetron, antipsychotics, and some chemotherapy agents, either by a direct effect or lowering the seizure threshold (Tradounsky 2013).

Assessment should be to determine the cause, with careful physical examination to find focal neurological signs, and a review of the patient's medication and biochemistry may be helpful. If a brain tumor, primary or metastases, is suspected, radiological investigation, usually a MRI, is necessary. An electroencephalogram is only necessary if the diagnosis is not clear or there is only subtle seizure activity (Tradounsky 2013).

Medication will usually be needed but careful discussion with both the patient and their family is essential. There is a need for explanation of the possible implications of seizures – the need to stop driving and inform the relevant authorities; possible effects of cerebral damage and the psychological implications, particularly for children, of observing a seizure; the risks of aspiration; respiratory obstruction; and even death. Patients with a brain tumor may also feel that they are losing control of their body and face the risk of stigma and marginalization that may occur as society may still feel uneasy with the diagnosis of epilepsy (Maschio 2012). There is also the need to explain the benefits of medication – corticosteroids and anticonvulsants.

The management of seizures may include primary treatment of the causative factor – such as the correction of a metabolic abnormality or radiotherapy or chemotherapy for a cerebral tumor, although anticonvulsant should be prescribed prophylactically as there may be initial peri-tumor edema and a risk of seizures. For a single cerebral tumor, particularly more benign forms, local excision may stop the seizure activity. Any medication that may be lowering the seizure threshold should be carefully evaluated and the dose reduced or stopped, if appropriate.

For many patients with cerebral tumors, management is with corticosteroids and anticonvulsant medication. Corticosteroids will reduce peri-tumor edema and may be used to reduce raised intracranial pressure and ease symptoms. There may be a reduction in seizures. Careful titration of the dose is ended to ensure that side effects are minimized but the therapeutic effect is maintained (Malik et al. 2004). For a patient with a cerebral tumor, this may involve increasing the existing dose or commencing administration. The usual corticosteroid used is dexamethasone, at a dose of up to 16 mg daily, although higher doses are considered. There are many side effects and patients need to be counseled carefully to look for these, especially the symptoms of a raised blood sugar. There may need to be discussions of whether to continue or reduce the dose, as although there may be a reduction of seizures and headache, there are risks of continuing with increasing disability and poor quality of life. These issues may require very careful discussion with patient and family (Oliver 2004).

7.1 Anticonvulsant Medication

A patient who has a seizure and for whom there is no obvious remedial cause requires anticonvulsant medication. However there are side effects and interactions with other medication that need to be taken into account. The blood levels of medication may need to be monitored carefully and evaluation of all other medication – both prescribed and "over the counter" or "complementary" medication – to check for interactions.

The anticonvulsant will vary according to the seizure type:

	First line	Second line
Partial (with or without secondary generalized seizure)	Carbamazepine Phenytoin Valproic acid (for secondary generalized seizure)	Phenobarbital Clobazam Gabapentin Topiramate Lamotrigine Levetiracetam

(*continued*)

	First line	Second line
Generalized		
Absence	Sodium valproate Clonazepam	Clobazam Topiramate/ lamotrigine
Myoclonic	Sodium valproate Clonazepam	Clobazam Topiramate
Tonic/clonic	Carbamazepine Phenytoin Sodium valproate	Phenobarbital Topiramate

Taken from Tradounsky (2013)

If possible monotherapy should be used, but with complex seizures two or more anticonvulsants may be required.

It is essential that the reasons for the anticonvulsant treatment are discussed with the patient and family, and the importance of continuing on medication is emphasized. It is also important to discuss how to cope with a seizure, as families and carers may become frightened and very anxious if they witness a seizure. It can be helpful to discuss with the family and carers possible interventions that they could take – including consideration of providing rectal diazepam or buccal midazolam preparations, which can be given by family members if the seizure is prolonged (Tradounsky 2013).

Status epilepticus is usually defined as seizure activity over 30 min or 3 episodes without return of consciousness in 30 min. This can be as tonic–clonic seizure, epilepsy partialis continua with clonic jerking of distal muscles continuing for weeks, or complex nonconvulsive status, presenting as a confusional state without any obvious seizures. There is appreciable mortality of 11% to 34% and the risk of cerebral damage.

Treatment within a hospital setting is with intravenous benzodiazepines – lorazepam or diazepam. If this is not effective, sodium valproate, phenytoin levetiracetam, and phenobarbital can be used. Midazolam is effective intravenously or intramuscularly. In severe status propofol or phenobarbital may be used, but intensive care involvement may be necessary to allow intubation and ventilation if there is profound respiratory depression (Tradounsky 2013).

In palliative care the use of intravenous medication may be difficult within the home or hospice setting. Diazepam can be given rectally and is unlikely to cause respiratory depression. Midazolam can be given buccally or by intramuscular injection, and phenobarbital can be given subcutaneously. Careful consideration may need to be given before proceeding to more invasive treatment within the intensive care setting.

The support of family and carers is essential if a patient has status epilepticus and the continuous or continual seizures are distressing for all involved. Professional carers may also need support and debriefing afterward.

After an episode of status, careful reassessment of the patient, including reassessment of the anticonvulsant regime, is essential, so that the risk of recurrence is minimized.

When a patient deteriorates and maybe becomes unconscious at the end of life, oral medication may no longer be possible. Phenytoin and sodium valproate have long half-lives (22 and 20 h), and a therapeutic level may be maintained for 12–24 h, but it is essential to maintain anticonvulsant medication during this final phase, as a seizure at the end of life is very distressing for family and carers. Midazolam or phenobarbital may be continued as a continuous subcutaneous infusion or diazepam may be given rectally (Oliver 2004).

8 Restless Legs

Restless legs syndrome (RLS) is a neurological disorder that causes the urge to move the legs due uncomfortable sensations to the lower limbs, sometimes extended to other body parts. The symptomatology appears above all during the night, and therefore it is commonly considered a sleep disorder.

RLS is very common in the general population; its prevalence can be up to 15% in primary care (Nichols et al. 2003; Allen et al. 2003). Females suffer RLS rates twice as high as compared to males (Ohayon et al. 2012).

This condition can be classified in a primary RLS, which usually occurs earlier in life (before age 20 years), and it has a strong genetic component (Walters et al. 2001). Secondary RLS which appears

later in adult life and its symptoms are sporadic, but regression of symptoms is slower, and it is associated with other disorders such as peripheral neuropathy, iron deficiency, end-stage renal disease, Parkinson's disease, poor health status in general, and aging (Yeh et al. 2012; Fereshtehnejad et al. 2015). The use of drugs that interfere with dopaminergic system can also cause RLS.

The essential diagnostic criteria for restless legs syndrome were developed and approved by the executive committee of the International Restless Legs Syndrome Study Group. They include (a) an urge to move the legs, often accompanied by an unpleasant sensation in the legs or other body parts; (b) symptoms aggravated by rest; (c) symptoms alleviated by movement (such as walking); and (d) symptoms which must be worse in the evening or night, with an urge to move the legs, usually accompanied by an unpleasant sensation in the legs (other body parts may be involved, in addition to the legs) (Allen et al. 2003; Yeh et al. 2012).

Dopamine agonists are the treatment of choice for moderate to severe RLS. They lower the severity of RLS symptoms and reduce reoccurrence of symptoms or augmentation. Ropinirole and pramipexole alleviate RLS symptoms by providing the effects of dopamine and stimulating most D2 and D3 receptors (Yeh et al. 2012). Rotigotine patches, releasing the drug over 24 h, can ease the daily symptoms. Levodopa was also used in the past decades; however, long-term treatment with this drug and dopaminergic agents can lead to augmentation, an iatrogenic worsening of symptoms which may require a change in treatment strategy (Hogl and Comella 2015; Mackie and Winkelman 2015).

Among the symptoms, musculoskeletal pain is associated with RLS above all in young adults (Hoogwout et al. 2015), and opioids seem to be effective in treating RLS symptoms (de Oliveira et al. 2016). In particular oxycodone/naloxone and possibly low doses of methadone (above all for the action on the NMDA receptors) can play a role as non-dopaminergic drugs for RLS (Hogl and Comella 2015).

Benzodiazepines are often prescribed as a coadjuvant therapy to improve the quality of sleep, but their effectiveness is unclear, and side effects and long-term dependence are to be considered (Carlos et al. 2017). Other used drugs are anticonvulsants (carbamazepine and gabapentin), and also non-pharmacological strategies can be effective (Yeh et al. 2012).

RLS should be considered in palliative care because it can be related to poor health status, neurological and renal conditions, and age and can aggravate pain and suffering. The quality of life of untreated RLS patients is affected by poor sleep, daily somnolence, and pain. It is often underestimate and not recognized. Drug interaction can worsen the symptoms or cause severe side effects.

9 Muscle Weakness

Muscle weakness may occur due to:

- Changes within the muscle itself – from genetic or metabolic disturbance (including drugs such as corticosteroids).
- Altered transmission at the neuromuscular junction.
- Abnormalities of the nerve supply to muscles.
- Disuse atrophy occurs if there is immobility/the muscles are not used, due to pain or fracture.

The weakness may recover, such as in Guillain-Barre syndrome, where there is weakness over a period of time, usually with recovery, or permanent if there is nerve damage, in paraplegia or ALS. The weakness may also be generalized or localized – for instance, in a progressive neurological disease, there may be initial localized weakness that increases more widely as the disease progresses.

There are few specific treatments that improve weakness itself. However physiotherapy may help to maintain the movements that remain and help to prevent stiffness, joint changes, spasticity, or deformity. In ALS a Cochrane Review concluded that there was no evidence that strengthening exercises were helpful, but there was also no evidence of harm (Dal Bello-Haas et al. 2013).

Transcranial magnetic stimulation has been shown to be helpful in stroke rehabilitation (Hosomi et al. 2016). A Cochrane Review suggested that neuromuscular electrical stimulation may be an effective treatment for muscle weakness in advanced progressive disease and used within rehabilitation (Jones et al. 2016).

The main aim of management will be to maintain movement and mobility as much as possible, and physiotherapy and occupational therapy enable patients to maintain as good a quality of life as possible. This may involve exercises or passive physiotherapy to reduce stiffness, advising patient and carers on the most appropriate way of moving and being moved and providing aid to mobility such as a stick, crutches, or wheelchairs, and to reduce pain and enable function such as splints or supports.

As a person deteriorates and comes to the end of life phase, they may be less able to alter their position and will be at risk of pressure area damage and pain and discomfort. Special mattresses and aids to maintain movement may be helpful, together with careful assessment and management of pressure and continence. Analgesia may be needed if there is increasing pain, and benzodiazepines, such a diazepam or midazolam parenterally, may be helpful in reducing stiffness and providing comfort.

10 Ataxia

Ataxia is a syndrome of incoordination, with changes in balance, coordination of movement, and often speech and swallowing problems. It is often due to damage or changes in the cerebellum and the main causes are:

- Hereditary ataxia – the commonest being Friedreich's ataxia and ataxia telangiectasia
- Nonhereditary degenerative ataxia – multiple systems atrophy, cerebellar ataxia, multiple sclerosis
- Acquired ataxias due to neuronal damage – head injury, alcohol, vitamin efficiency, toxins, paraneoplastic syndrome, and immune mediated causes (Klockgether 2010)

Assessment requires a careful family history, physical examination, and often investigation of the cerebellum. Genetic testing may be necessary if a hereditary cause is suspected (Klockgether 2007). Management will depend on the cause – if there is a specific deficiency or toxic factor, it may be possible to reverse or lessen the nerve damage and reduce the symptoms.

For most people with ataxia, there is no specific treatment. Physiotherapy, including the decomposition, simplification, and slowing of activity, may help the person cope with ataxia. Speech and language therapy assessment will be necessary to help with speech and swallowing issues, and occupational therapy will help maintain movement and activity as far as possible. Emotional and psychological support of both patient and family may be needed.

11 Hiccup/Hiccough

A hiccup is involuntary, synchronous clonic spasm of the intercostal muscles and diaphragm leading to a sudden inspiration, flowed by a sudden closure of the glottis causing the characteristic sound (Calsina-Berna et al. 2012). They may occur for 2–60 times per minute, and in 80% there is unilateral contraction of the left hemidiaphragm. They are commoner in males.

Hiccups are seen in the fetus and neonates but reduce in adults. It has been postulated that there is an amorphous neural network coordinating afferent inputs which act as a "hiccup center" or an inbalance of the inspiratory and expiratory neuronal circuits, caused by stimulation or damage of the brain stem or vagus or phrenic nerves (Woelk 2011).

In advanced cancer 1% to 9% of people have hiccups, and in a large study of 362 patients 14 (3.86%) patients reported hiccup – 8 occasionally, 5 persisting, and 1 continuous (Mercadante et al. 2013). Persistent hiccups continue for 48 h and intractable for over 1 month (Calsina-Berna et al. 2012). The causes of hiccups may be:

- Gastrointestinal – distension, reflux, tumor mass
- CNS – intracranial tumor, trauma, MS, infection

- Thoracic – damage or irritation of the phrenic nerve, such as infection or tumor
- Metabolic – hypokalemia, hypocalcaemia, renal failure
- Ear/nose/throat – infection, tumor, foreign body
- Psychogenic – stress, conversion reaction, personality disorder
- Drugs – corticosteroids, benzodiazepines, opioids, antidopaminergics
- Chemotherapy- etoposide, cisplatinum

Assessment is important to ascertain the cause if possible, as this may affect management. There may be a specific cause which will allow appropriate treatment, such as gastric distension which may be eased by antacids and prokinetic medication. However usually there is no clear cause, or there is no treatment to remove the causative factor, such as an inoperable tumor causing phrenic nerve irritation. The management of hiccups is then complex, and there are many suggested treatments and medication, but most are from case reports and there are no controlled trials. The main treatments are:

- Folk remedies – which usually involve glottis stimulation, such as holding breath, drinking water upside down.
- If there is gastric distension/reflux prokinetics, such as metoclopramide, or antacids/proton pump inhibitors may be helpful.
- Baclofen.
- Gabapentin.
- Chlorpromazine or haloperidol – which may help via the dopaminergic pathways
- Amantadine, nifedipine, valproic acid, and midazolam have all been suggested (Calsina-Berna et al. 2012; Woelk 2011).
- Surgery – including cervical phrenic nerve block for severe intractable hiccups (Smith and Busracamwongs 2003).

Support for the patient and family is important in helping them cope with the difficult symptom, which can adversely affect quality of life, as well as affecting sleep, eating and drinking, and speech and causing pain, fatigue, and depression (Calsina-Berna et al. 2012).

12 Delirium

Delirium is a complex syndrome with disturbance of cognition, arousal and attention of acute onset, and with fluctuation of symptoms. Factors include attention deficit, abnormalities of thought processing, disorientation, memory deficit, sleep–wake disturbance, behavioral changes, and language disturbance, but there may also be disturbance of perception, delusions, and affective change. This is usually related to physiological disturbance and may be reversible.

Delirium is common in palliative care with estimates of 13–42% of patients on admission to a unit showing evidence of delirium and 3–45% developing changes after admission (Hosie et al. 2013). It is also increasingly common bear to death, with estimates up to 88%.

Many neuronal pathways have been implicated in the causation of delirium, and it would appear to be a response to both an insult to the brain and stress reactions. A full assessment is essential to exclude a reversible cause – such as infection, alcohol/drug withdrawal, metabolic changes (such as hypercalcemia), hypoxia, and medication – including opioids and corticosteroids. There may be predisposing factors, such as deafness, visual loss, frailty, and comorbidities, including dementia, particularly in the elderly. Regular assessment of patients may be helpful, to detect early evidence of delirium, and allow treatment before severe symptoms develop, such as the regular monitoring using the Memorial Delirium Assessment Scale. Over 33% of people with advanced cancer on admission to a palliative care unit were found to have a raised score, and this reduced with careful assessment and treatment, with reduced cognitive change and symptoms (Mercadante et al. 2017).

The effects of delirium can be severe, with increased morbidity and mortality, longer hospitalization, longer-term cognitive decline, and distress for both the patient and family. Families may find the changes particularly distressing and explanation of the causation and management is important. The family may need support in helping to reduce the symptoms and in coping with the changes (Finucane et al. 2017).

Management of delirium includes:

- Non-pharmacological interventions – correcting any causes, ensuring the patient is in a well-lit room with a clock and calendar and supported by family and friends
- Pharmacological intervention – low-dose haloperidol, lorazepam, and atypical antipsychotics, such as olanzapine or risperidone, have been suggested. There may be pronounced sedation and side effects and possible increased mortality. Moreover a trial of risperidone and haloperidol showed that symptoms were reduced and improvement quicker with individualized management (Agar et al. 2017).
- Sedation may be necessary if there is severe distress at the end of life – see ▶ Chap. 87, "Palliative Sedation: A Medical-Ethical Exploration"

Further details are in ▶ Chap. 26, "Delirium."

13 Cord Compression

Malignant cord compression is spinal cord or cauda equine compression by direct pressure and/or induction of vertebral collapse or instability by metastatic spread or direct extension of malignancy that threatens or causes neurological disability (NICE 2008). It may occur in up to 2.5% of people with advanced cancer, most commonly breast, prostate, lung, or renal cancer. Sixty percent are in the thoracic spine, 30% in lumbosacral spine, and 10% in cervical spine (Pi et al. 2016).

The main symptoms are of pain (83–95%), motor deficit (60–95%), sensory deficit (40–90%), ataxia, and bowel and bladder dysfunction (Pi et al. 2016). Pain may be localized or radicular and may increase over a period of several weeks. Up to 80% may be unable to walk or only walk with assistance at the time of diagnosis (Levack et al. 2002), and they had suffered backache for an average of 3 months.

There is a need for suspicion of cord compression for all patients with bone metastases, particularly if there is back pain (NICE 2008). There is a need for urgent investigation and treatment. Careful neurological assessment and a MRI of the whole spine should be undertaken as soon as possible (NICE 2008).

Treatment should be started urgently to help control pain, minimize complications, and preserve or improve neurological function. The options include:

- Corticosteroids – there is limited evidence for the use of steroids, and an intravenous dose of 10 mg, followed by 16 mg daily orally, has been suggested, with proton pump inhibitors to reduce the risks and the dose reducing as soon as possible (Kumar et al. 2017).
- Surgery is the only treatment that will immediately improve the symptoms, but there are increased risks of morbidity and mortality. Surgery may be considered if it is felt that irradiation will be ineffective; the spine is unstable, an unknown primary, where diagnosis at surgery can be made by biopsy and previous radiotherapy (Pi et al. 2016; NICE 2008).
- Radiotherapy – should be offered, if the patient is well enough to cope with this, and will be effective in controlling pain in over 70% (Pi et al. 2016).
- Analgesia should be provided at all times.

The effectiveness of treatment will depend on the state at diagnosis – with 95% of patient mobilizing independently remaining independent or requiring only a stick but 51% of patients who were bedbound at diagnosis remaining independent (Savage et al. 2014). Careful rehabilitation, monitoring of the general physical state, ensuring thromboprophylaxis, and preventing bed sores are all essential (NICE 2008). Survival is low after cord compression – with bedbound patients having a median survival of 1.9 months and mobile patients only 11 months (Savage et al. 2014).

14 Coma

Coma is a state of prolonged unresponsiveness and unconsciousness from which the patient cannot be aroused. Impaired consciousness refers to similar, less severe disturbances of consciousness. A state of coma can be caused by a variety of

problems – traumatic head injury, stroke, brain tumors, drug or alcohol intoxication, or even an underlying illness, such as diabetes or an infection. To distinguish coma from brief transient states of unconsciousness (syncope or concussion), it is required a state of loss of arousal of at least 1 h.

Diagnosis is mainly clinical whereas the identification of the causes needs laboratory tests and neuroimaging techniques. The Glasgow Coma Scale (GCS) grades coma severity according to three categories of responsiveness: eye opening, motor, and verbal responses. It is not used for the diagnosis of coma, and its use is limited by intubation and use of sedating drugs that interfere with its utility (Bryan Young 2015). The GCS was developed to assess patients with head trauma and is scored between 3 and 15, 3 being the worst and 15 the best. It is composed of three parameters: best eye response (E), best verbal response (V), and best motor response (M). The components of the GCS should be recorded individually. A score of 13 or higher correlates with mild brain injury, a score of 9 to 12 correlates with moderate injury, and a score of 8 or less represents severe brain injury. The FOUR score provides greater neurological detail than the GCS, recognizes a locked-in syndrome, and is superior to the GCS due to the availability of brain stem reflexes, breathing patterns, and the ability to recognize different stages of herniation (Wijdicks et al. 2005).

Coma is different from vegetative state which happens when a person is able to be awake, but is totally unaware. A person in a vegetative state can no longer "think," reason, relate meaningfully with his/her environment, recognize the presence of loved ones, or "feel" emotions or discomfort. The higher levels of the brain are no longer functional. A vegetative state is called "persistent" if it lasts for more than 4 weeks. Patients in persistent vegetative state (PVS) have sleep–wake cycle and can cough, sneeze, scratch, and even cry or smile at times and be responsible to touch. However, all of these are automatic behaviors that do not require any functioning of the thinking part of the brain (Arenella 2017).

A state of coma is frequent in palliative care. It can be confused with the therapeutic or palliative sedation, which is the result of an active intervention adopted in those cases where patients develop intolerable pain and suffering despite excellent palliative care. In such patients, sedation is used to treat pain, dyspnea, nausea and vomiting, delirium, and myoclonus in order to relieve symptoms while the patient is to dying and to ensure the appropriate management of distress, so that the patient may die comfortably. In other cases coma is secondary to the disease progression or due to the progressive increase of drugs, like pain killers or neuroleptics, aimed at controlling symptoms, but not intended to explicitly suppress the consciousness.

There is not a specific treatment for coma. If the loss of consciousness is secondary to an endocranial hypertension, an attempt with steroids and/or osmotic diuretics can be used. If the cause is metabolic (e.g., hypercalcemia), parenteral hydration or the use of bisphosphonates can be attempted; in case of suspect of drug accumulation (opioids or other neuroactive drugs), a dose reduction can be done, but the aim must be clearly balanced with the possible outcome: will the result be transient and temporary? will the quality of life be better? and will a distressing symptom reappear?

In general patients in coma do not appear to suffer. There is no indication to force the arousal of a patient affected by a terminal condition, since it could trigger agitation or delirium and would not improve the quality of life. When a patient loses the capability to maintain attention, the focus of care must be kept on comfort care, prevention of bedsores, and symptoms. Time is required to talk to the family and explain that the person is not experiencing any suffering and is probably going to die soon.

Often family member ask if patient can hear, see, or perceive their presence. A reassuring approach can be to discuss the fact that even though the odds are that the patient does not feel or perceive external input, in case he or she could feel something a positive if someone close to them is present and talking to them. This means, for example, saying at bedside just the words one would have said if the patient were awake and avoid those that would not be appropriate. At the same time, encourage to give caress or kisses as if

he or she could feel it. It is also important to reassure that the patient does not feel hunger or thirst and will not starve to death even though he/she cannot swallow.

15 Locked-In Syndrome

The locked-in syndrome (LIS) is a rare neurological condition characterized by a complete paralysis of the voluntary muscles and intact state of consciousness and the sensory system. Usually some eye movements are spared, like vertical gaze and upper lid control. There are also incomplete form where some other muscular areas remain functional and a total form where even the eyes and lids are fully paralyzed (Bauer et al. 1979).

The most common cause is a stroke of the basilar artery and consequent bilateral damage of the pons, which may cause this catastrophic clinical state. A famous example of this condition is described in the book "The Diving Bell and the Butterfly" (original French title: Le Scaphandre et le Papillon) by the French journalist Jean-Dominique Bauby. It describes what his life is like after suffering a massive stroke that left him with locked-in syndrome. The patient was able to communicate blinking his left eyelid and created a code, shared with the speech and language therapist, that allowed him to write the book.

Life expectancy in LIS is usually not longer than few months (Thadani et al. 1991), but in rare cases can be of some decades (Haig et al. 1987).

Possible causes of LIS are poisoning (curare, snake bites, and neurotoxins) or trauma. LIS can occur as a complication of other progressive neurological conditions such as in severe Guillain-Barre syndromes or neuromuscular disorders like amyotrophic lateral sclerosis. In the latter LIS can be the consequence of the disease progression after that the patient is tracheostomized and mechanically ventilated. If the eye movement remains spared, it is possible to communicate through electronic computer-based alternative communication aids, but if the progression leads to a total LIS (Schnakers et al. 2009), it can be impossible to detect the consciousness of the patient and assess symptoms and sensations, since there are no commercially devices available for this purpose.

One important challenge is to differentiate between the coma, the persistent vegetative state (PVS), and the LIS. Clinically coma state is when a patient has a complete abolition of consciousness and awareness; in the PVS the upper functions of the brain are compromised, but the lower are spared; therefore patients are in an apparent state of arousal, but their consciousness is lost. In LIS the upper brain functions are intact, patients remain conscious and awake, but the lower brain functions are damaged and patients lose movements and communication.

No specific treatments for LIS are available. The literature shows examples of recovering from acute forms of this syndrome (McCusker et al. 1982; Silver et al. 2006; Heckmann and Dinkel 2013).

The quality of life of patients in LIS was studied, and results are surprising, since authors conclude that no difference was found between totally dependent and paralyzed LIS patients and healthy adults (Rousseau et al. 2013). Several factors may have an impact on QOL in LIS patients, such as family support and patient–computer communication devices. The QoL tends to remain stable over a long period of time (Rousseau et al. 2015).

However patients in LIS are totally dependent and their care is very challenging. Most of them are institutionalized in long-term care facilities. This is very costly because patients need tube feeding via PEG, mechanical ventilation via tracheostomy, and the communication devices. Being quadriplegic they are exposed to an increased risk of bedsores and need special beds and mattress. The corneas of the patients are at risk of ulceration if blinking is reduced. Patients are often affected by cramps and spasms that can be painful. Respiratory complications, like pneumonia, are frequent and can lead to death (Lahrmann and Grisold 2004).

Carers need long-term support. Home care is very hard to organize for patients with such a degree of physical impairment. This can be arranged with the involvement of paid carers which makes the care even more expensive.

Patients are totally dependent on their carers. As shown in previous studies on other severely impaired neurological patients, the QoL of the carers can be severely impaired, sometimes even worse than the patients (Kaub-Wittemer et al. 2003). Although being very distressed by the burden of care, discussion about end of life is often hard to tolerate for families (Anderson et al. 2010).

LIS can raise difficult ethical dilemmas about withdrawing or withholding life sustaining procedures (Kuehlmeyer et al. 2012). Some patients can ask for euthanasia (Kompanje 2010), but most patients can find a peaceful adaptation to the situation and do not request hastened death (Laureys et al. 2005).

16 Neuropathic Pain

Neuropathic pain (NP) is a type of chronic pain that occurs when nerves in the central nervous system become injured or damaged. It is a complex, chronic pain state caused by damaged, dysfunctional, or injured nerve fibers. The result is a painful sensation at the nerve site or in the surrounding area.

In terms of painful sensations, it can be described as an excruciating pain when clothes touch the skin, spontaneous burning, bursts of "pins and needles," and a band of searing pain around the body at the level of a spinal cord injury (Costigan et al. 2009).

Multiple mechanisms are responsible for neuropathic pain. It can be caused by a peripheral or by a central nervous system damage and can be secondary to mechanical trauma, metabolic diseases, neurotoxic chemicals, infection, tumor invasion or spinal cord injury, stroke, Parkinson's disease, or multiple sclerosis (Dworkin et al. 2003, 2007; Ducreux et al. 2006; Buhmann et al. 2017).

Assessing NP requires attention and practice. An accurate neurological examination can provide invaluable information about the localization, triggers, and clinical features of pain. A number of questionnaires can help in the diagnosis of NP: the neuropathic pain questionnaire (NPQ), ID Pain, and PainDETECT rely on interview questions; the Leeds assessment of neuropathic symptoms and signs (LANSS) (Bennett 2001) and *Douleur Neuropathique en 4 Questions* (DN4) (Bouhassira et al. 2005) as well as the Standardized Evaluation of Pain (StEP) (Scholz et al. 2009) integrate questions and physical tests aiming at identifying pain subtypes and therefore leading to a more appropriate choice of treatment (Cruccu and Truini 2009).

For the treatment of chronic neuropathic pain, recommendations are available (Dworkin et al. 2010). Authors list first-line pharmacological treatments including antidepressants (Saarto and Wiffen 2010) like tricyclic antidepressants (TCAs) like amitriptyline, selective serotonin–-norepinephrine reuptake inhibitors (SSNRIs) like duloxetine and venlafaxine, calcium channel α2-δ ligands (gabapentin and pregabalin), and topical lidocaine (see ▶ Chap. 10, "Pain and Pain Management").

As second-line medications, they propose opioids (tramadol and strong opioids). For those patients who cannot use or do not tolerate first- or second-line medications, third-line drugs can be offered like bupropion, citalopram, paroxetine, certain antiepileptic medications (e.g., carbamazepine, lamotrigine, oxcarbazepine, topiramate, and valproic acid), topical low-concentration capsaicin, dextromethorphan, memantine, and mexiletine (Dworkin et al. 2007, 2010).

17 Conclusion

The careful assessment – including history, examination, and investigation – is essential in the management of neurological symptoms. These may be related to acute or progressive neurological disease or other disease processes. The ongoing management will depend on the causation.

Abstract

Genitourinary symptoms may significantly impact on quality of life. Identifying the underlying cause will help guide management. In the palliative setting, understanding the goals of treatment, the prognosis of the patient, and

R. D. MacLeod, L. Van den Block (eds.), *Textbook of Palliative Care*,
https://doi.org/10.1007/978-3-319-77740-5_24

their wishes will help with decisions regarding the various treatments that may be available.

1 Introduction

Genitourinary symptoms are common in patients with pelvic malignancies. These include gynecological, urological, and colorectal malignancies as well as metastases from other neoplasms. Nonmalignant conditions occurring in patients with malignancy may require management in the palliative care context.

Genitourinary symptoms may not be readily volunteered by patients to medical and nursing personnel. Patients may be embarrassed to discuss symptoms such as urinary frequency and/or incontinence. Identifying patients who may be at risk of developing these symptoms may enable early investigation and management. Specific questions should be asked at the time of consultation or scheduled nurse reviews. The use of questionnaires may help measure the subjective grade of symptoms (e.g., Lent-Soma patient questionnaire; Livsey et al. 2002).

The history of the diagnosis, staging, surgery, and treatment, together with the posttreatment symptoms, may indicate the likely pathophysiology. New onset symptoms including fevers, evidence of inflammation, infection, or self-detected masses may lead to the diagnosis. The severity of symptoms may be graded using scales such as CTCAE (National Cancer Institute 2009).

A careful general, speculum, pelvic, and/or rectal examination in the clinic is mandatory. Urine or high vaginal swabs for culture or collection of urine or smears for cytology may be helpful. Biopsy in the clinic should be undertaken with caution.

An examination under anesthesia with consideration of cystoscopy, sigmoidoscopy, and biopsy may be indicated. Biopsy within the radiation field should be undertaken with extreme caution as healing may be impaired and new fistula formation can occur.

Renal ultrasound or CT pyelogram may be helpful with renal tract abnormalities. Magnetic resonance imaging (MRI) and FDG positron emission tomography (PET) may be required to differentiate recurrent disease from posttreatment complications. Interpretation of PET scans can be difficult as both recurrent tumor and inflammation will result in increased uptake of radiolabeled glucose.

Good communication with the patient regarding the cause of symptoms, potential treatment/management options, and the anticipated outcome of proposed treatment with the revised long-term prognosis may reduce anxiety and help manage patient expectation. For example, urinary symptom flare may occur a year after SBRT for prostate cancer and resolve to baseline by 2 years (Woo et al. 2014). Patients undergoing permanent implant prostate brachytherapy may expect resolution of urinary symptoms by 12 months, but there may be a symptom flare shortly after the implant (Ryuta et al. 2012; Talcott et al. 2003).

Ongoing follow-up at three monthly intervals with monitoring of the nature and severity of symptoms in the patient record will aid assessment. More frequent assessment may be required.

2 Vaginal Dryness

Itching, burning, irritation of genital skin, vaginal discharge, and pain may accompany this symptom. Associated urinary symptoms of frequency and urgency may also be present. Radiotherapy-related vaginal dryness may be associated with vaginal narrowing and shortening.

Atrophic vaginitis due to reduction in systemic estrogen may be physiological or treatment-related secondary to chemotherapy, endocrine therapy, or radiotherapy. Approximately 40% of women experience vaginal dryness following pelvic radiotherapy (mostly grade 1–2) (Kirchheiner et al. 2014).

Endocrine therapy such as tamoxifen or aromatase inhibitors may be associated with severe or very severe vaginal dryness in 48% of patients (Chin et al. 2009).

Pelvic, speculum, and vaginal examination will generally reveal dry, atrophic, and thinning vaginal mucosa with areas of inflammation. Petechial hemorrhages and contact bleeding may be

present. A thick white discharge may indicate yeast infection. A gray-yellow discharge is often present with bacterial vaginosis. Microscopy and culture of specimens will guide management.

Vaginal yeast infections should be treated with topical application of antifungal cream or antifungal tablets. Treatment of the gastrointestinal reservoir with single dose of oral fluconazole at the time of topical treatment will reduce the risk of recurrent candidiasis.

Bacterial vaginosis can be treated with antibiotics after collection of a high vaginal swab for culture and antibiotic sensitivity.

Treatment of non-infective vaginitis should start with water-based vaginal moisturizers or lubricants such as Replens or KY gel which are available "over the counter." They may be effective in short-term relief of symptoms.

Hormonal treatment may be considered if there is no relief with the use of vaginal moisturizers and lubricants. Hormonal treatment may be given in the form of creams, pessaries, or tablets, applied directly into the vagina three to four times weekly.

In certain endocrine-responsive breast and endometrial cancers, hormonal replacement therapy is contraindicated. However, in a patient with severe vaginal dryness, the benefits of topical low-dose estrogen in alleviating symptoms adversely impacting on quality of life may outweigh the risks. Systemic absorption is low, but discussion with informed consent regarding possible low-dose absorption of estrogen which may potentially exacerbate or reactivate cancers is mandatory. In the palliative setting with limited life expectancy, quality of life considerations may override any potential exacerbation of hormone-responsive cancers.

3 Vaginal Discharge

Vaginal discharge may be normal physiological, infective, malignant, or treatment-related. Atrophic vaginitis will usually respond to topical estrogen. Collection of a high vaginal swab for microscopy and culture using a speculum will facilitate treatment of infective causes. Rarely, retained foreign bodies such as tampons will be identified with a speculum examination. Side effects of endocrine therapy such as tamoxifen may include vaginal discharge (Jones et al. 2007).

Malignant tumors require investigation and treatment in their own right, which may include surgery, radiotherapy, or chemotherapy. Formation of a differential diagnosis will include previous gynecological history, diagnosis, and treatment of pelvic malignancy and current treatment. Examination should include a general physical examination, speculum, colposcopic, and pelvirectal examination.

Previously treated pelvic tumors require palliative measures. Tranexamic acid (1 g tds po) may be used for bleeding, while metronidazole douches can reduce the offensive discharge of infected pelvic masses.

4 Vaginal Bleeding

This may be normal physiological (menstrual) or pathological. Menstrual bleeding may be regular or irregular. Intermenstrual bleeding requires gynecological assessment as it may be secondary to gynecological pathology.

Benign causes include hormonal or hematologic abnormalities, benign tumors such as polyp or fibroids, local trauma, pregnancy-related bleeding, or medications (e.g., warfarin). The presence of foreign bodies should be excluded. In the setting of malignancy, common causes are primary or recurrent carcinoma of the uterus, cervix, or vagina, local invasion from a pelvic malignancy such as colorectal cancer, metastases from other sites, or treatment-related bleeding (primarily from surgery or radiotherapy).

History and examination, including examination under anesthetic, will usually confirm the diagnosis. An urgent gynecological review may be helpful.

Investigations include full blood count, coagulation profile, and directed biochemistry. Pelvic ultrasound should include transvaginal imaging for adequate resolution where possible. A CT and/or MRI can clarify the diagnosis. Histology from an appropriate biopsy will assist in confirming the etiology.

In the presence of active hemorrhage, the patient may need urgent support with intravenous fluids and transfusion if anemic. The underlying cause should be treated. In the case of heavy bleeding, tranexamic acid (1 g tds, oral or intravenous) may be used. Vaginal packing can temporarily slow vaginal or cervical bleeding. After insertion of a urethral catheter, a speculum is passed and the vagina packed with wide ribbon gauze coated with antibacterial cream. The packing should be removed after 24 h due to the risk of infection. For malignancy, radiotherapy should be started as soon as possible and is effective in reducing bleeding due to cancer (Kim et al. 2013). Treatment may be given with relatively low risks of toxicity using 3D CRT, IMRT, or brachytherapy. Depending on the prognosis of the patient, a "standard" fractionation regime or a hypofractionated regime may be used.

5 Vaginal Stenosis

This is defined as shortening and or narrowing of the vagina and may be graded using CTCAE. It may cause difficulty with sexual function and medical examinations. Vaginal stenosis may progress with time with chronic and irreversible tissue changes (Kirchheiner et al. 2014). It may have psychosexual impact on the patient and decrease the quality of life (Mirabeau-Beale et al. 2014) with attendant difficulties with clinical physical examination of the patient. Complete obliteration of the vagina may occur and this is difficult to remedy. Prevention with regular use of vaginal dilators is optimal.

The most common cause is pelvic radiotherapy (external beam radiotherapy to the pelvic region and/or brachytherapy). The risk may be related to the total dose delivered and the volume of vagina treated (Park et al. 2014). Stenosis is exacerbated by estrogen deprivation which may occur due to previous surgery involving oophorectomy or pelvic radiotherapy-induced menopause. Vaginal stenosis due to radiotherapy may be associated with other symptoms such as vaginal bleeding, ulceration, and pain.

6 Pelvic Pain

Pelvic pain is a common symptom in patients with malignancy and in otherwise well patients (see ▶ Chap. 10, "Pain and Pain Management"). In the acute situation, narcotic and nonnarcotic pain relief may be required until other measures can relieve the pain.

For acute pelvic pain in the setting of malignancy (primary or metastatic), radiotherapy is an effective treatment (Kim et al. 2013). As radiotherapy may take 1–2 weeks to improve pain, medical management of pain with analgesics will usually be required. Modern radiotherapy techniques (3D CRT, IMRT) are effective in relieving pain due to bone metastases (with overall RR of 58–91% with short-course radiotherapy) with acceptable toxicity (Chow et al. 2007; Caravatta et al. 2012).

7 Urinary Problems

Urinary frequency and urgency may be distressing for patients who may be coping with other symptoms related to their condition such as pain and nausea. Irritating urinary symptoms may cause sleep disturbances and depression in addition to their effect on the patient's quality of life (see ▶ Chap. 24, "Sleep Difficulties"). Severe incontinence and problems such as vesicovaginal fistula may result in total social isolation.

8 Dysuria

Dysuria may occur due to nonmalignant causes such as urinary tract infection, inflammation or trauma or malignant causes such as tumor invasion of the urinary tract or its nerve supply or from pressure effects from extrinsic bladder compression. Bladder outlet obstruction may be secondary to tumor infiltration or to inflammatory or fibrotic sequelae of treatment.

Exposure of inflamed or irritated skin to urine in the perineal region (e.g., from radiotherapy or infection) can cause dysuria. It is important to identify the cause of the symptoms to deliver appropriate management (Table 1).

Table 1 Urinary problems in palliative care

Symptom	Potential cause	Investigation	Treatment
Dysuria	Infection (UTI)	MSSU	Change catheter if present Antibiotics as per sensitivities
	Inflammation		Urinary alkalinizer
Urinary urgency	Bladder instability Infection	Urodynamics Urine culture	Behavioral modification, antimuscarinic drugs, botulinum toxin, neurostimulatory devices
Urinary frequency	UTI Bladder instability Bladder inflammation (post RT) Bladder contracture/ partial cystectomy	MSSU Bladder diary Bladder diary	Antibiotics Bladder training
Nocturia	Nocturnal fluid intake	Fluid diary	Restrict fluids after 1700
	Bladder instability	Urodynamics	As per urinary urgency
Continuous urine loss per vagina	Vesicovaginal fistula Ureterovaginal fistula	Cystogram CT intravenous pyelogram	IDC/SPC Cystoscopy and trial of ureteric stent Reimplantation of ureter if feasible
Urinary retention	Dystonic bladder	Ultrasound for residual volumes	IDC or intermittent self-catheterization
	Outlet obstruction	Examination +/− cystoscopy	Self-catheterization or IDC/SPC
	Neurogenic bladder	US for pre-voiding and residual volumes	Trial of oxybutynin IDC or self-catheterization

UTI urinary tract infection, *MSSU* midstream specimen urine, *RT* radiotherapy, *IDC* indwelling catheter, *SPC* suprapubic catheter, US ultrasound

Combined treatment modalities, such as surgery and radiotherapy, may increase the risks of urinary complications (Erekson et al. 2009). Partial cystectomy may be required during surgical treatment and the residual bladder capacity further compromised by subsequent radiotherapy or chemotherapy (especially cyclophosphamide).

9 Urinary Tract Infections/Urinary Frequency

Urinary tract infections should be treated on the basis of antibiotic sensitivities. Long-term urinary catheters should be changed every 3–6 months during treatment. Urinary alkalinizers may improve urgency symptoms. In patients with recurrent urinary tract infections, prophylactic low-dose antibiotics or antibacterial agents such as hexamine hippurate (Hiprex) may be useful.

Management of fluid intake, including avoidance of caffeine, diuretics, and fluids in the evening, should be advised. Bladder training and pelvic floor exercises should be recommended.

Botulinum toxin type A (Botox) injections may be useful in overactive bladder causing urinary frequency, urgency, and urge incontinence. In rare circumstances, nerve stimulation devices implanted under the skin may be required.

Ring pessaries may be used for uterovaginal prolapse. Topical estrogen and vaginal moisturizers such as Replens are indicated for urogenital atrophy. As above, consideration of potential systemic absorption of estrogen may need to be balanced against the patient's quality of life in the patient with endocrine-responsive cancer.

Anticholinergics together with urinary alkalinizers may help relieve symptoms of dysuria. Surgery for stress incontinence should be considered very carefully, particularly in the

post-radiotherapy pelvis. Urodynamic pressure/flow profiling prior to any surgical intervention is mandatory.

10 Urinary Incontinence

Urinary Incontinence is the involuntary leakage of urine. Urinary incontinence reduces mental and physical quality of life with attendant anxiety, reduced sense of well-being, self-esteem, ability to socialize, sleep disturbances, falls, and skin breakdown (Avery et al. 2013; Smith 2016) as well as impacting on caregivers. Urinary incontinence is more common in women (23–55%) (Botlero et al. 2009; Hunskaar et al. 2004), with increasing frequency with age, and may be temporary or chronic.

Stress incontinence is provoked by increased abdominal pressure (coughing, exertion etc.), while urge incontinence is caused by bladder instability and is marked by involuntary loss of urine after a sudden and strong urge to void. Patients may have mixed urge and stress incontinence. Overflow incontinence occurs when the bladder becomes overfull due to outlet obstruction, poor bladder tone, medication or neurological issues.

Causes of incontinence may be multifactorial, and genetic factors may increase the susceptibility to incontinence (Richter et al. 2015; Campeau et al. 2011) (Table 2).

A careful clinical history is required. A medication list may also aid the diagnosis. A physical assessment including mental status, mobility, obesity, abdominal, pelvic, perineal, and neurological examination will aid treatment. Lower limb edema suggests a component of cardiac failure. Pelvic examination may reveal a palpable bladder, uterovaginal prolapse, pelvic masses, and poor pelvic floor muscle tone. Rectal examination, including prostate examination in a male, can also assist in evaluating pelvic pathology including loss of anal sphincter tone with neurologic pathology. Examination should include urinalysis and measurement of post voiding residual bladder volumes, either with a catheter and measuring device or by ultrasound. Semiautomatic devices may give an inaccurate measurement of residual volumes in the context of obesity and where other pelvic pathology is present.

Table 2 Urinary incontinence

Type	Cause	Treatment
Stress	Urogenital atrophy	Vaginal estrogen
	Urethral sphincter incompetence	Suburethral sling procedure Suburethral bulking agents
	Excessive intra-abdominal pressure	Cough suppressants, avoid straining
Urge	Urinary tract infection	Antibiotics
	Bladder instability	Oxybutynin
Overflow	Neurogenic	Intermittent self-catheterization SPC/IDC
	Pharmacologic	Review medication
	Outlet obstruction (e.g., stricture/prostatic)	SPC/IDC Consider urethral dilatation

Incontinence may be exacerbated by extrinsic compression of the bladder, intravesical tumor, or tumor involvement of autonomic and/or somatic innervation of the bladder. The presence of a ureterovaginal or vesicovaginal fistula may be interpreted by the patient as incontinence but is intractable to conventional management. A careful history will usually provide a tentative diagnosis of fistula, and this can be confirmed with a careful speculum and/or imaging with a CT IVP or cystogram.

In women with urinary incontinence, treatment will depend on the underlying etiology. In stress incontinence (triggered by increased intra-abdominal pressure due to coughing, sneezing, Valsalva maneuver, etc.), pelvic floor muscle training may improve continence (Dumoulin et al. 2015). Bladder training and/or anticholinergic agents may also help urge incontinence.

Urodynamic studies (bladder pressure profiles obtained during bladder filling) will demonstrate bladder irritability, which can be improved with muscarinic receptor antagonists. These studies require insertion of a urinary catheter for measurement of flow/pressure profiles and bladder

stability at different filling volumes. A Cochrane review showed that urodynamic studies changed clinical decision-making but may not lead to higher continence rates. It found that there was no statistical significant difference in continence rates between women receiving treatment guided by urodynamic studies compared with women assessed by history and clinical findings (Clement et al. 2013).

Cystoscopy/imaging may be indicated if the presence of a fistula is suspected.

Conservative treatment should be used before considering more invasive treatments. Absorbent incontinence pads may be sufficient for small volume incontinence. Behavioral therapy including timed voiding, modification of high fluid intake, and bladder training (delaying voiding to increase bladder capacity where small frequent voids have become established) may be helpful.

Pelvic floor muscle training requires prolonged effort with some benefit after some months of training. Physiotherapist-directed pelvic floor exercises can augment voluntary muscle control. Benefit is not sustained without continuing use. Topical vaginal estrogen may improve mucosal integrity in postmenopausal women with vulvovaginal atrophy.

Pharmacologic methods for bladder instability include anticholinergics which may be administered orally or transdermally. The lowest effective dose should be used, and full benefit may take 4 weeks to achieve. Troublesome side effects include dry mouth, impaired gastric emptying, and constipation. They should not be used in patients with a history of urinary retention or narrow-angle glaucoma.

Surgical options require careful assessment, taking the underlying pathophysiology, previous treatment including surgery and radiotherapy, and disease prognosis into account.

Botulinum toxin type A (Botox) injections can reduce bladder instability with improved continence rates. The duration of response is limited and repeated administration is necessary (Owen et al. 2016). Neuromodulation, in which leads from a nerve stimulation device are tunneled through the S3 foramen, has been shown to provide a 28–63% cure rate for urge incontinence (National Institute for Care and Excellence Guidelines 2013). Potential complications of this surgical procedure include pain, lead migration, and bowel dysfunction. Symptoms recur on stopping treatment.

In women, injection of silicone into the external urethral sphincter can augment continence. Suburethral sling procedures should be reserved for women with severe stress incontinence as recurrence rates are significant and their efficacy is limited in the postradiation pelvis (Tommaselli et al. 2015; Habashy et al. 2017).

More invasive surgical procedures such as augmentation cystoplasty or creation of a urinary diversion stoma should only be considered in very limited circumstances in the palliative care setting.

Severe intractable urinary incontinence may be sufficiently socially isolating that catheterization is warranted. Women may be taught to self-catheterize up to eight times per day. Silicone urethral catheters with collection bags strapped to the leg can be worn under clothing. These catheters should be changed every 3 months and the catheter bags changed at least weekly.

Where a urethral catheter is not feasible, a suprapubic catheter can be inserted into the bladder through the skin above the pubic symphysis. They are available with introducer kits and can be inserted into a full bladder with local anesthetic under aseptic conditions. Care is needed to ensure adequate bladder filling prior to insertion, and ultrasound may be used to guide placement.

Suprapubic catheters may cause less pain than urethral catheters, but care should be taken to avoid infection, hemorrhage, or bowel injury. The catheter will need to be changed at intervals, depending on the type of catheter. Patients with suprapubic catheters may still leak from the urethra. Bladder spasms can be an issue.

11 Bladder Spasms

Spasms occur when the bladder muscle (detrusor) contracts suddenly and severely, causing the patient to feel the urge to urinate. Severe bladder spasms may cause urinary incontinence by

forcing urine from the bladder. Bladder spasms may cause cramping pain which may be severe, and some patients experience a burning sensation.

Causes of bladder spasm include infection, indwelling catheters, previous bladder surgery or pelvic radiotherapy, and bladder cancer. Certain foods such as caffeine, alcohol, spicy foods, and preservatives can exacerbate this symptom. Neurological causes include multiple sclerosis, strokes, spinal cord injury, and degenerative neurological conditions.

Immediate relief of severe spams can be achieved with hyoscine butylbromide injection 20 mg intramuscularly. Underlying causes should be addressed. Antibiotics should be given for UTI and anti-inflammatory agents for radiation-induced bladder spasms. Oral medications to reduce spasm include oxybutynin, tolterodine, solifenacin, and tricyclic antidepressants such as imipramine hydrochloride, alpha-blockers, terazosin, and doxazosin.

The patient should practice timed voiding (e.g., every 1.5–2 h) and avoid trigger foods or drinks. Pelvic floor exercises can be helpful as can regular analgesics.

Invasive techniques include the use of TENS devices which provide electrical stimulation through the skin. Injection of Botox into the bladder wall at cystoscopy may provide relief for 2–3 months. Patients then require a second injection which may be effective for 6 months (National Institute for Care and Excellence Guidelines 2013). Side effects include urinary retention requiring a catheter and increased frequency of urinary tract infections. Onset of relief takes approximately 1 week.

12 Macroscopic Hematuria

Hematuria may originate in the upper or lower urinary tract. Causes include urinary infections, urinary calculi, renal tract neoplasms, and surgical trauma (e.g., following instrumentation or injury to the renal tract). Infections require antibiotic use (usually oral) with change of catheter. Renal calculi may require lithotripsy or surgery. Postsurgical hematuria will often settle with conservative management including use of a large three-way indwelling catheter with the capacity for bladder irrigation. Tranexamic acid (1 g tds orally or i.v. will usually reduce blood loss).

Hemorrhagic cystitis may follow chemotherapy (especially cyclophosphamide). Radiation may cause an acute cystitis with hematuria, urinary frequency, and bladder spasms. Late radiation cystitis may occur many years after radiotherapy and is related to the dose and volume of bladder irradiated. Anticoagulation may increase the risk of hematuria.

Gross hematuria is psychologically distressing for patients. Clot-induced acute urinary retention is an emergency and may require emergency department presentation for insertion of urinary catheter to relieve the obstruction and for bladder irrigation. Patients may require blood transfusion for anemia if there is significant blood loss.

Assessment should include a history and examination including vital signs, abdominal/pelvic masses, rectal/prostate examination in males, and gynecological examination in females.

Suspected renal parenchyma disease should result in referral to a nephrologist or urologist. Urinary microscopy, culture, and cytology with a full blood count are mandatory. Urinary tract ultrasound and cystoscopy may be required. CT and MRI imaging should be performed with care due to potential toxicity of contrast agents.

Treatment should be directed to the underlying cause. Palliative radiotherapy for renal tract tumors is effective in achieving hemostasis in 75–80% of patients (Mohamed et al. 2015; Cameron et al. 2015). Gogna et al. reported on patients with locoregionally progressive hormone-refractory prostate cancer treated with palliative split-course radiotherapy (Gogna et al. 2012) with gross hematuria resolving in seven out of nine patients, five out of seven patients being able to have their urinary catheters removed, and four out of four patients had their ureteric stents removed.

Tranexamic acid can reduce severe hematuria. Dose reduction is recommended in the presence of renal impairment. Tranexamic acid has been reported to cause ureteric obstruction due to

clots where bleeding originates from the kidneys (Vujkovac 2006).

13 Urinary Retention

Inability to empty the bladder completely may be chronic or acute.

Acute urinary retention causes severe pain and is a medical emergency. Chronic urinary retention causes mild discomfort or pain, lower abdominal distension, difficulty initiating the flow of urine, weak urinary flow, and feeling of incomplete bladder emptying. Chronic unrelieved obstruction may cause distension of the urinary tract proximal to the site of obstruction with injury to the kidneys or bladder musculature and innervation. It may also predispose to urinary tract infections. Lower abdominal pain and distension may or may not be accompanied by a sensation of a need to urinate. Chronic urinary retention may result in constant discomfort, slow urinary flow, urinary frequency, and a sensation of incomplete bladder emptying.

Causes include tumor masses causing obstruction (e.g., prostatic hypertrophy or cancers of the prostate, cervix, vagina, or vulva cancers obstructing the urethra). Surgical denervation may occur during radical hysterectomy or prostatectomy.

On examination, the patient may be distressed and agitated. The bladder may be palpable superior to the pubic symphysis. Insertion of a catheter (urethral or suprapubic) will provide a measurement of the residual volume, a specimen for urinalysis, and relief of discomfort. Urinary tract ultrasound should not delay treatment of the symptomatic patient but can provide imaging of the upper renal tract after correction of the acute problem.

While acute urinary retention is most appropriately treated with a temporary catheter, chronic retention may require either a long-term urethral or suprapubic catheter or intermittent self-catheterization. The frequency of self-catheterization is determined by the degree of retention (residual volume after voiding) and will generally be one to six times per day. Residual volumes under 100 ml do not require self-catheterization.

14 Ureteric Obstruction

Obstruction may be unilateral or bilateral. Unilateral obstruction may lead to impairment of renal function or renal failure if bilateral obstruction is present.

Causes include extrinsic obstruction by tumor (e.g., prostate, cervix, ovarian, colon), nodal metastases, retroperitoneal fibrosis, and postsurgical or radiotherapy strictures.

Intrinsic obstruction may be due to tumor or calculi.

Unrelieved bilateral obstruction (or unilateral obstruction with impaired renal function of the contralateral kidney) may cause rapidly progressive renal failure, drowsiness, loss of consciousness, and death.

Patients with ureteric obstruction may be asymptomatic or may present with classical loin to groin pain. They may show signs of sepsis and renal impairment/renal failure. Symptoms include nausea and vomiting, poor urine output, and hematuria. Patients may develop dehydration due to nausea and vomiting.

Examination may reveal signs of dehydration and reduced consciousness. Abdominal examination will often reveal unilateral or bilateral renal angle tenderness. Ultrasound may confirm a dilated renal collecting system. A CT nephrogram will confirm the obstruction and the transition point.

Renal cortical thinning on CT imaging may reflect chronic obstruction. Creatinine levels should be checked prior to imaging as contrast is not usually used in the presence of raised creatinine to avoid worsening of renal function. In some circumstances, aggressive prehydration may reduce the potential for damage to renal parenchyma (Sadat 2014).

Management will depend on the underlying condition, treatment history, and the patient's life expectancy. Electrolyte disturbances such as raised potassium may need to be treated urgently

with resonium given orally or rectally. Fluid balance will require careful management. Antibiotics may be given for infection where appropriate. Analgesia may be prescribed for pain (care must be taken with nonsteroidal anti-inflammatory agents and dose adjustment of narcotic analgesia in the setting of impaired renal function/renal failure may be necessary).

Treatment to relieve obstruction should be carefully considered in the context of the patient's prognosis. If the prognosis is poor and relieving the obstruction will not improve the patient's quality of life, the option of not relieving the obstruction should be considered. This option should be discussed with the patient, together with a description of what the procedure for relieving obstruction involves, the potential toxicities, and complications weighed against the benefits that may be achieved by relieving the obstruction in the context of the patient's remaining lifetime.

If the decision is made to relieve the obstruction, cystoscopy with insertion of a ureteric stent to relieve the blockage may provide short-term benefit. If a retrograde ureteric stent(s) cannot be passed, unilateral or bilateral percutaneous nephrostomy tubes may be inserted by an interventional radiologist to relieve obstruction until the underlying cause is treated. Antegrade stents may be passed percutaneously. Complications associated with percutaneous nephrostomies and those of stent placement include retroperitoneal hemorrhage, hydrothorax, pneumothorax, and intraperitoneal urinomas. Patients find percutaneous stents cumbersome to manage with the attendant skin irritation, urine leakage, and risk of dislodgement. Complications such as infection, irritation with urinary frequency, dysuria, hematuria, urinary incontinence, and pain may also occur. They may require repositioning and may migrate. Stents will require changing at 3–6 monthly intervals if left in situ.

Ureteric stenting is reasonable in newly diagnosed patients, in whom there is a reasonable likelihood of tumor regression with either radiotherapy, chemotherapy, or surgery.

Targeted radiotherapy may be considered if there is an obstructing malignant lesion that can be identified. The use of image-guided radiotherapy and modern radiotherapy techniques enables accurate targeting of the obstructing lesion with less toxicity to surrounding normal tissues. As with ureteric stenting, patients need to be informed of the potential toxicities and the benefits of relieving the obstruction.

More invasive procedures such as urinary diversion have a limited role in the palliative setting, except in the occasional patient who would be anticipated to have a significant life expectancy with treatment of the underlying condition.

15 Ureterovaginal Fistula and Vesicovaginal Fistula

These are abnormal tracts between the ureter or bladder and the vagina, causing uncontrolled discharge of urine through the vagina. They may be associated with other symptoms such as pelvic pain, vaginal bleeding, and infection. Constant urine exposure to the skin may cause skin irritation. As the patient is incontinent, this is a cause of significant morbidity. As well as impacting on the patient's emotional and psychological well-being, it may result in total social isolation.

Prolonged obstructed labor is the most common cause worldwide. Tumor-related causes include direct invasion of the urinary tract together with complications of surgery and/or pelvic irradiation. Patients with bladder invasion by tumor are more likely to develop a fistula following radiotherapy. Surgery-related fistulas usually present within 7–30 days postoperatively. Those related to radiotherapy (rare with modern radiotherapy techniques) are usually a late complication, occurring 30 days to 30 years post-treatment. These may be associated with other signs of radiation-induced injury such as bladder contracture or hematuria. The risk is increased with combined modality treatment (e.g., surgery and radiotherapy).

Careful speculum examination may reveal the site and nature of fistula, but it may be difficult to

distinguish clinically between induration from radiotherapy or from tumor. Examination may also reveal a concomitant rectovaginal fistula or other fistulas. Indigo carmine dye given intravenously will appear in the vagina within 30 min if a fistula is present. It may require several tampons placed in the vagina to differentiate leakage per urethra from a fistula. An MRI scan may show the site of the fistula and confirm the cause as tumor recurrence or treatment complication.

Urine should be collected for culture via a catheter and infection treated. Biopsy of the fistula tract may be performed to confirm malignancy. An intravenous urogram or retrograde pyelogram should be performed to assess the upper urinary tract before cystoscopy is be performed to examine the urethra and bladder for a potential site and evaluate the condition of the bladder for possible surgical management.

Malignant fistulas are complex conditions which should be managed in the multidisciplinary setting within a specialized unit.

Radiotherapy to the pelvis to control the tumor may allow the bladder mucosa to heal. Continuous drainage of the bladder with an indwelling catheter will facilitate healing of the bladder musculature and mucosa. Where conservative management fails, urinary diversion may be considered depending on the prognosis. This is a major surgical procedure with considerable risk of morbidity.

Vesicovaginal fistulas secondary to surgical complication should initially be treated conservatively with placement of a urinary catheter for 7–30 days to allow healing of the fistula. Similarly, placement of a retrograde or antegrade ureteric stent or a temporary percutaneous nephrostomy will facilitate healing of a ureteric defect. A major ureteric leak into the abdomen may require placement of peritoneal drain under radiological guidance. A CT intravenous pyelogram (for ureteric defects) or cystogram (for bladder defects) prior to catheter removal will confirm integrity of the renal collecting system.

Minimally invasive surgical techniques may be appropriate for intraperitoneal bladder defects if conservative management has failed.

16 Rectovaginal Fistula

Rectovaginal fistula occurs when an abnormal tract develops between the rectum and vagina (Champagne and McGee 2010). This causes uncontrolled leakage of stool and gas into the vagina. Symptoms may also include purulent vaginal discharge and pain in the pelvic region. Because of the incontinence of stool and gas through the vagina, rectovaginal fistulas have a significant impact on the patient's quality of life and socialization.

Malignant or nonmalignant fistulae are a major cause of morbidity, either as a result of malignancy or as a complication of treatment.

The history will suggest passage of flatus or feces per vaginam. A careful speculum examination may reveal the site of leakage. Vaginal and rectal examination may also reveal the site of the fistulous opening, but small defects may be difficult to locate, particularly in the presence of induration from radiotherapy or active malignancy. A flexible sigmoidoscopy or colonoscopy should be performed. Gastrografin CT scan may show the fistula and demonstrate the cause such as a tumor. MRI scans should be performed by a radiologist with expertise in pelvic imaging and may show linear gas tracking along the fistula.

The distance from the external anal sphincter, the current disease process, and prior treatment will dictate potential treatment. Fecal diversion with a laparoscopic end colostomy is relatively low-impact surgery in patients with a reasonable prospect of medium-term survival.

Resection of the area of affected rectum with stapled reanastomosis and a protective temporary ileostomy is a more invasive option and one reserved for patients with likely survival beyond the medium term. It requires careful discussion with the patient who may have unrealistic expectations of the physical impact of major surgery.

17 Conclusion and Summary

Genitourinary symptoms are common in palliative care and may significantly impact on patients' quality of life. Careful assessment including

history and directed investigation will usually provide a diagnosis. Decisions on treatment must be made in the context of the severity of the problem, medium- and long-term prognosis, and the wishes of the patient. While many treatment options are available, good clinical judgment, multidisciplinary care and patient input are imperative in the decision pathway toward relieving symptoms.

End-of-Life Symptoms

Contents

Abstract

Safe care at the end of life involves much more than just prescribing for end-of-life symptoms. An approach of whole person care is one in which respect for the individuality of the dying person is fundamental, and this can sometimes present real challenges for clinicians. Diagnosis of dying is a key clinical skill, and the use of triggers can assist clinicians to recognize patients who are likely to enter the terminal phase soon. Early recognition creates the opportunity to plan care and to share decision-making about goals of care with patients, allowing more choices about how and where the dying person may wish to be cared for. Common symptoms at the end of life include pain, nausea, respiratory secretions, dyspnea, agitation, and delirium. Prescribing for the end of life involves, on the one hand,

ceasing unnecessary medications and interventions and, on the other, providing and using comfort medications appropriately and effectively. Psychosocial care of the dying person focuses on their personal and spiritual needs at the end of life. Decision-making about what interventions are appropriate at the end of life is based on weighing up the likely benefit versus the burden of such interventions, assessing this in the context of the patient's prognosis. Decision-making at every stage must include the dying person as much as they are able and wish to, as well as their family and close supporters. It is therefore essential that clinicians are able to communicate comfortably and empathically about end-of-life concerns.

1 Introduction

So come, my friends, be not afraid. We are so lightly here.
It is in love that we are made. In love we disappear.
Though all the maps of blood and flesh are posted on the door,
There's no-one who has told us yet what Boogie Street is for.

From "Boogie Street," Leonard Cohen. *The Book of Longing*. Harper Collins, New York. 2006

Care for dying people at the end of life is a core role of palliative care. It is also a responsibility that is shared with every domain of medicine, and as such it is "everyone's business." The palliative care approach acknowledges that death is a normal, inevitable, mysterious, and natural phenomenon in which the focus of care should be to comfort and support. Palliative care practitioners have played a very significant part in putting the care of dying people onto the health-care agenda as a domain requiring evidence, skills, and appropriate models of care. Being able to die a natural death with distressing symptoms treated, to have choices wherever possible about where death occurs and who is present, and to be given culturally appropriate care that supports one's individuality and dignity and is responsive to psychological and spiritual needs – these are appropriate outcomes for end-of-life care and are indicators of quality care for the dying. An example of a statement of the principles associated with safe dying (Box 1) is contained in the Australian Commission on Safety and Quality in Health Care *National Consensus Statement* (ACSQHC 2015).

Box 1 Guiding Principles for Safe and High-Quality End-of-Life Care. Australian Commission on Safety and Quality in Health Care. National Consensus Statement: Essential Elements for Safe and High-Quality End-of-Life Care (ACSQHC 2015)

1. Dying is a normal part of life and a human experience, not just a biological or medical event.
2. Patients must be empowered to direct their own care, whenever possible. A patient's needs, goals and wishes at the end of life may change over time.
3. Providing for the cultural, spiritual and psychosocial needs of patients, and their families and carers is as important as meeting their physical needs.
4. Recognising when a patient is approaching the end of their life is essential to delivering appropriate, compassionate and timely end-of-life care.
5. The prognosis and the way that people respond to medical treatment will vary between individuals. This means that there is potential for ambiguity and uncertainty at the end of life. This must be honestly and openly acknowledged, and discussed with patients, substitute decision- makers, families and carers.
6. Safe and high-quality end-of-life care is patient and family-centred. Whenever possible, it should be aligned with the values, needs and wishes of the individual, and their family or carers. Such care should consider the patient's expressed wishes regarding the

(*continued*)

Box 1 (continued)

circumstances, environment and place in which they wish to die.

7. Safe and high-quality end-of-life care requires the availability of appropriately qualified, skilled and experienced interdisciplinary teams.
8. Safe and high-quality end-of-life care requires effective communication, collaboration and teamwork to ensure continuity and coordination between teams, within and between settings, and across multiple episodes of care.
9. Care of the dying is urgent care. Timely recognition of a patient's transition to the terminal phase of life must be documented and communicated to patients, families, carers and other health professionals by the interdisciplinary team. The care plan must be specifically revised to meet the unique needs of the patient, family and carers during this phase.
10. End-of-life decision-making should be shared between the interdisciplinary team and the patient. Substitute decision-makers, families and carers should be involved, in accordance with the patient's expressed wishes and/or jurisdictional legislation.

Nonetheless, in developed countries many people die in hospitals while receiving care that is burdensome and non-beneficial, with continuing investigation, monitoring and treatment, and lack of good symptom management, and the goals of care do not shift toward comfort and palliation of symptoms until quite close to the patient's death (O'Brien et al. 2006; Wright et al. 2014; West et al. 2014; Swerrisen and Duckett 2014; Henson et al. 2016). Other settings of care (home, residential aged care facility) may allow an experience of death which is less interventional, but these present different challenges in order to ensure that care and symptom management are adequate and responsive to the patient's and family's needs. This chapter will discuss care of dying people and explore the practical implementation of principles of safe end-of-life care.

2 Whole Person Care: The Dying Person and Their World

The aim of palliative care for dying patients is to promote their comfort and dignity. However, it is important for clinicians to be aware that what is meant by comfort and dignity may be very different for different people. Their life experiences; their networks of relationships; their values and beliefs; their strategies for coping; the experience of and meaning given to their symptoms, illness, and death; their perception of death as a tragedy, as meaningless, or as the completion of life; and the story of how their illness has brought them to be dying at this particular time and place – all of these things go into the individual's own construction of what is meant by comfort and dignity. This is what clinicians must try to respond to.

Clinicians who work in palliative care inevitably become very familiar with the appearances and symptomatology of dying people. This very familiarity, however, may dull them to the mystery of this once-only process for the dying person her- or himself and for all those who care about them. Clinicians need to be able to treat each person as an individual, but meeting the very individual wishes and needs of dying people may require considerable creativity and flexibility. Sometimes this is in tension with other goals of providing good palliative care, with their focus on the provision of evidence-based care and protocol-based care planning. Negotiating processes of care with the dying person and their network of supporters requires some space to be left within protocols, guidelines, and pathways to enable clinicians to individualize their responses. This is a very fundamental tension within palliative care and particularly in inpatient settings may sometimes create ethical, clinical, and human dilemmas.

When clinicians care for patients, a degree of medicalization is inevitable. Assessment and care processes allow us to define and manage problems

within a clinical framework, but this can sometimes be experienced as an intrusion within the world of the dying person. Even when patients are cared for in their own home, this medicalizing process still occurs, changing the home environment into something more institutional, intruding on people's privacy, and taking some of the decisions about how to care for the dying person away from family and friends, putting them instead in the hands of clinicians. Great gulfs of mutual misunderstanding can sometimes arise from differences in culture or when caring for those in stigmatized or socially marginalized groups. Difficulties in relating to health-care providers which may have been present throughout the illness trajectory will often intensify at the end of life. Care for dying people ultimately requires great trust from them and from their friends and families, and this trust is needed most at the time when distress and care needs are peaking. Some dying people and their supporters may struggle with conflicting concerns – their intensifying needs for help, care, and information on the one hand, versus distress at being caught within a health-care system that is experienced as intrusive or threatening on the other (Luckett et al. 2011; Hanssen and Pedersen 2013; Francois et al. 2017).

In the intimate space of the dying person's world, clinicians have to be mindful of how their own anxieties and judgements, and the language in which these are expressed, can make people feel more or less safe and accepted. A whole person care approach requires acknowledgment of different worldviews – views that may potentially be very challenging during the intensity of the final days and hours of life, which is a time when these things matter very much to people. There may not always be a way to resolve the resulting tensions; however, care is able to be more authentic and honest if any differences are acknowledged and respected. That in itself helps to build trust. Individual and team clinical processes such as case reviews, mentoring, and debriefing are important in creating a culture of whole person care and may help clinicians to meet each dying person as a person with a new story, afresh, and still thrive while doing this work.

3 Planning for Expected Death

For most palliative care patients, death can be regarded as expected, based on the nature of their condition and the lack of curative treatment options available for them. Expectedness creates the opportunity for planning and choices about care and treatment and for dying people to focus on their own priorities in the last period of their life. However, this opportunity is largely dependent on clinicians being willing to talk clearly about prognosis, being comfortable to discuss dying with patients and their families in a timely way, and being aware of the options that are available in their own community to allow choices for people who are dying, such as referral to palliative care services (Clayton et al. 2007). Many patients and families are still shocked and unprepared for the dying process, even when this is thought by clinicians to be expected (Sanderson et al. 2013; Kehl 2015; Ek et al. 2015; Lamden et al. 2016).

For those people who would prefer to die at home, careful planning for an expected death is needed to ensure that end-of-life symptoms are able to be treated appropriately. Strategies such as the Gold Standards Framework (http://www.goldstandardsframework.org.uk/home) provide a model of care that can guide provision of end-of-life care in a primary care setting. Preemptive prescribing for end-of-life symptoms is important to allow prompt initiation of treatment in the event of a sudden deterioration, and this involves ensuring that there is ready, safe access to needed comfort medications, which is especially critical when a home death is planned (NICE 2015). Documenting an advance care plan to ensure that transitions of care (between home and hospital, or between different settings of care) can be made safely if required is another essential element in planning for an expected death. Such documentation is needed to protect dying people from unwanted and burdensome interventions such as cardiopulmonary resuscitation. Preparation of family carers to look after a dying person at home is also essential, and ongoing support and access to advice will be needed.

4 Diagnosing Dying

In order to be able to provide appropriate care and to cease treatments that are no longer beneficial, it is essential to be able to diagnose dying – yet it is not always easy to identify the point at which a patient who is approaching death makes the transition to being a dying patient (Haga et al. 2012).

Symptoms associated with the onset of the terminal phase have been identified in a number of studies. A systematic review identified the most common symptoms found in patients who are dying as dyspnea (56.7%), pain (52.4%), respiratory secretions/death rattle (51.4%), and confusion (50.1%) (Kehl and Kowalkowski 2013). Functional changes, particularly the inability to swallow, reduced oral intake, reduced level of consciousness, and becoming bedbound, have traditionally been used as criteria to identify dying patients in end-of-life care pathways, but these have not been prospectively validated in robust studies (Chan and Webster 2011; Phillips et al. 2011; Watts 2012). However, a large cohort study based on the use of standardized assessment tools for symptom burden and functional state confirmed that at the time of entering the terminal phase, more than 90% of patients were bedbound and 50% were either comatose or barely rousable. The majority (73.6%) of the patients who were identified as being in the terminal phase in this study survived no longer than 2 days, 23.2% of them dying on the same day that they were assessed as being in the terminal phase (Clark et al. 2016).

The terminal phase therefore presents with a fairly recognizable syndrome, and in acute care settings, the onset of the terminal phase is very often the main trigger for ceasing active treatments and for changing goals of care (Cardona-Morrell et al. 2016). However, given the features of this syndrome, the associated alterations in the level of consciousness, and how rapidly it may progress to death, it is important to understand that the onset of the terminal phase is far too late for many of the social, spiritual, and relational tasks that are important to dying people (Steinhauser et al. 2000, 2014; Virdun et al. 2015). In particular, for families who may wish to care for their dying family member at home, earlier planning and decision-making is absolutely essential. The diagnosis of dying is a clinical assessment, and it is important that this should be a positive diagnosis made in a timely way, rather than happening at the last hour. No single diagnostic tool or measure has been identified that can support clinicians in identifying the dying patient, particularly across different diagnostic groups and in varied settings. One evolving strategy is the use of "trigger tools" or identification of sentinel events that can prompt clinicians to consider whether a patient may be at risk of dying soon (Hussain et al. 2014) and if so to reassess their goals of care accordingly (Box 2). This allows preemptive prescribing for end-of-life symptoms and encourages earlier discussions with the patient and their family, so that they can participate in decision-making and make informed choices about their wishes for treatment and care.

Box 2 Triggers and Sentinel Events Indicating Patient Is Approaching End of Life (Adapted from ACSQHC 2015)

- Diagnosis of life-limiting conditions
- Poor or incomplete response to medical treatment, continued deterioration despite medical treatment, and/or development of new clinical problems during inpatient admission
- Repeated calls to the rapid response team, particularly if the patient has been admitted for more than 1 week
- Advanced age with increased frailty, reduced mobility and increased dependence on others to assist in performing activities of daily living
- Moderate to severe dementia
- Multisystem comorbidities (cardiovascular, pulmonary, endocrine, etc.)
- Maximal medical therapies already in place
- Decline in the patient's condition, or a clinical determination that they will not

(*continued*)

Box 2 (continued)
benefit from interventions such as surgery, dialysis or treatment in intensive care
- Multiple recent admissions to hospital for exacerbation of a chronic condition
- Unexpected or inappropriately prolonged stays in hospital
- Request by patient or family or family to review goals of care, or for palliative care input

Deciding that a patient is at risk of dying soon requires an assessment of the person's overall condition, illness trajectory, performance state and level of functioning, their past responses to treatment and the likely outcome of treatment now, and their wishes. Understanding when a patient's problems are no longer likely to be reversible, or when multiple problems have additively overwhelmed a person's ability to recover, is an important clinical skill which is rarely formally taught. Factors that impede the identification of the dying patient have been studied (Kennedy et al. 2014), and many relate to the "treatment orientation" of health-care providers. The presence of clinical uncertainty often leads health-care providers to default to continuing active management while neglecting the dying person's comfort and their human needs. The process of assessing the potential reversibility of a patient's problems may in itself lead to a cascade of burdensome treatments and investigations, particularly if a holistic assessment of the patient's overall condition and wishes has not been made. The clinical cascade in response to uncertainty often results in postponing important conversations and decisions until very late – indeed these may not happen until the patient themselves can no longer participate. Even when a situation is clinically challenging, particularly when there is a degree of clinical uncertainty, sharing decision-making processes with the patient and their family can sometimes provide a path through the available options. If it is possible to have a conversation focusing on what is important to the person now, in the context of having a short time to live, that can be extremely helpful in coming to agreement about goals of care and the tradeoffs that may be involved in different options.

5 Symptoms at the End of Life

5.1 Fundamentals of Physical Care

As death approaches, it becomes ever more important to actively and regularly assess all aspects of a dying person's physical comfort and to prescribe preemptively for the common symptoms that can be expected. Assessment of a person who is not able to respond verbally requires careful observation for signs of discomfort or pain and regular focused examination related to comfort. Frequent attention to skin and mouth care, to the eyes (e.g., by providing lubricating eye drops), to the sleeping patterns, and to the person's mental state (whether the person is aware and able to communicate, whether they appear relaxed or distressed or fearful, whether there is any evidence of hallucinations) is part of the routine of caring for patients entering the terminal phase.

Supporting bladder and bowel function should be individualized according to the person's physical needs and functional state and are essential for comfort. For many patients, the capacity to toilet themselves independently is a fundamental component of dignity, and so any intervention needs to be offered with sensitivity. Unidentified urinary retention or fecal impaction is a significant cause of distress in dying patients and should always be checked for when a dying patient is restless and agitated. In-dwelling catheters have a place – they may be required if there is urinary retention, to protect the skin of an incontinent patient, or to prevent unnecessary moves for a patient in significant pain or other distress. However, a person with minimal urinary output and none of these problems may not necessarily require a catheter. Management for the bowels changes as patients approach death. Once they are no longer able to take oral aperients, gentle and judicious rectal intervention may sometimes be needed for comfort.

The most common symptoms that need to be looked for and addressed at the end of life are pain, nausea, respiratory secretions and respiratory distress, and delirium/agitation (NICE 2015; Blinderman et al. 2015). When a person is able to communicate, it is important to check with them about these and any other symptoms regularly. When a person is unable to communicate, the assessment is based on behaviors, for example, wincing, vocalizing, or stiffening when moved. Other assessments that are important relate to adverse effects of medications and treatments, for example, the presence of frequent fleeting myoclonic jerks, particularly associated with confusion, suggests opioid metabolite accumulation, while worsening edema while fluids are being administered suggests a need to cease parenteral fluids.

Pain is a feared problem and all dying patients require access to pain medications. Being bedbound, unable to move independently, and cachexic will produce a level of discomfort in many people even if there are no specific sites of pain. As needed opioids are the most appropriate choice to deal with this and should generally be given prior to turning the person or doing other personal care. Those previously on regular pain medications should have these continued in a parenteral form to maintain pain control and prevent withdrawal, possibly with some dose reduction to adjust for the changed metabolic parameters of the dying process, but with rapid access to as needed doses for any episodes of extra pain. Regular review of pain medication use and adjustment of doses are essential. Good explanations for families are also incredibly important, as the use of opioids in dying patients can be misinterpreted. Each breakthrough dose of any medication should be explained to the family, if they are present, and families should be encouraged to help assess the person's symptoms and response to medications if they are able to do so (NICE 2015).

Nausea is often not easy to identify in a patient who is not alert. Reduced oral intake, including reduction in the number of oral medications, may reduce nausea for some patients. However, patients for whom nausea has been an ongoing problem, or who have a partial or complete bowel obstruction, should have regular parenteral antiemetics continued. When rationalizing a patient's medications at the end of life, it is helpful to be aware that a range of medications may have antiemetic properties via different mechanisms, for instance, dexamethasone, antipsychotics, and antihistamines are all reasonably effective against some types of nausea. Patients on some or all of these agents may not require an additional regular antiemetic. All patients should, however, have an as needed antiemetic available, and wherever possible this should be selected on the basis that it is an agent which has been previously effective (Glare et al. 2011).

Respiratory secretions occur commonly in dying patients, usually in association with reduced level of consciousness and consequent loss of the normal ability to manage upper respiratory tract secretions. However, lower respiratory tract secretions secondary to edema or infection may also contribute. In general, it is thought that this problem is not distressing for patients, as it occurs most often when people are minimally conscious; however, some families may find these secretions (often called "death rattles") very disturbing indeed. There is little evidence to support the use of antisecretory medications (Wee and Hillier 2008), and the preferred treatment involves frequent repositioning. Many medications used traditionally are strongly anticholinergic (e.g., atropine or hyoscine hydrobromide) and have a side effect profile that is associated with adverse effects in patients who are aware, such as dry mouth, urinary retention, and delirium. If antisecretory agents are used, they should be trialled soon after symptoms are noticed, and agents that do not enter the central nervous system are preferred (hyoscine butyl bromide, or glycopyrrolate).

Gentle suction may be appropriate if secretions are copious and visible, if the patient tolerates this. Discussion with the family is an essential part of care in relation to this problem (Wee et al. 2006) as some people will be left with distressing and traumatic memories of the person's death that are connected to this symptom.

Respiratory distress may be suggested by increased respiratory rate and/or visible effort of breathing. Abnormal respiratory patterns such as Cheyne-Stokes or Kussmaul's respirations are caused by significant dysregulation of normal breathing physiology, and families should be counselled to expect these changes. If there is any suggestion of increased respiratory drive or air hunger, opioids can be titrated to reduce the respiratory rate. The goal of oxygen therapy is comfort, not normalization of oximetry. It is not without adverse effects, such as pressure injuries from tubing or drying of mucous membranes. A patient who is dying of predominantly respiratory causes, such as upper airway obstruction or lymphangitis carcinomatosis, may sometimes require palliative sedation to relieve their respiratory distress. Any patient with risk of respiratory failure who is still aware and is afraid that they may die with severe breathlessness should be reassured that sedation can be offered to reduce their awareness, and this information will often be gratefully received. Sedation, when given, should be at an effective dose, taking into account prior medication exposure, and levels of sedation should be reviewed regularly and titrated to effect. Midazolam is often the initial agent of choice due to its rapidity of onset, and in a distressed patient commencement of an infusion of midazolam and an opioid (usually morphine, which has the strongest evidence for relief of dyspnea) should be accompanied by an appropriate loading dose so that sedation is achieved rapidly (Vargas-Bermudez et al. 2015; Barnes et al. 2016; Simon et al. 2016).

Agitation is often multifactorial. Sources of pain, distress, and discomfort should be looked for and treated. Possible causes such as severe hypoxia, seizures, or akathisia should be considered. However, agitated delirium is extremely common at the end of life, most likely due to the progressive biochemical and physiological changes associated with the dying process, and if it is due to these causes, reversal is not expected (Bush et al. 2014a). As such it should be managed as a refractory delirium. In the past this syndrome has been referred to as terminal restlessness, but this term is best avoided as it reduces the likelihood that a proper assessment of the symptom will be made. Often the picture is of a dying person who is confused and disoriented, and is struggling to get out of bed, throwing off bedclothes or needing to move continuously, and who will only settle for very short times. Another common presentation is that of a person with reduced awareness who is plucking at the bedclothes, or performing other repetitive motor activities, who may be hallucinating and calling out or vocalizing. For the imminently dying patient diagnosed with a refractory delirium, the goal of treatment is to provide enough sedation that they can be calm and safe. Sedation at an effective dose with antipsychotics and/or benzodiazepines, or with sedating antipsychotics such as levomepromazine, is appropriate to obtain that goal, and – as in all symptom management at this stage – the discussion of this plan with families is essential (Bush et al. 2014b).

5.2 Preemptive Prescribing and Crisis Medications

As needed medications should be charted for comfort, including as a minimum adequate doses for pain, nausea, and agitation or delirium. Preemptive prescribing of comfort medications that can be given parenterally, along with good documentation of when they should be given, is a hallmark of good end-of-life care (NICE 2015). They minimize the problem of distressing delays in getting symptoms under control if a dying patient deteriorates more quickly than anticipated. Providing regular background medications is also important to maintain good symptom control, especially for pain. Rationalization of medications and ensuring that comfort medications can be given by an alternative route, if a patient is not able to swallow, are important.

Most often in palliative care the subcutaneous route is used for medications (NICE 2015) because this is a minimally burdensome parenteral route of delivery. Intramuscular and intravenous routes should generally be avoided due to the associated trauma for the patient. Subcutaneous lines can be maintained at home and have a low

risk of infection. Syringe drivers can reduce the need for frequent bolus doses to be given and allow steady state to be achieved. However, occasionally an alternative route needs to be considered, for instance, in a patient who is profoundly edematous or whose subcutaneous sites break down very quickly. In these patients intravenous access might be needed, but other options might be to use sublingual, topical, or rectal medications if appropriate.

Crisis medications are usually charted for patients who are at risk of specific end-of-life emergencies, e.g., major bleeding, airway obstruction, seizure, and so on. In the hospital setting, prescribing such medications is intended to ensure that there can be a rapid and appropriate response, allowing the person to be sedated quickly to minimize distress. Doses of opioid and midazolam are most often prescribed, and they should be adjusted according to whether the person is opioid and/or benzodiazepine naïve or not. It is important to individualize and provide an effective dose to achieve sedation. Crisis medications should only be used for likely preterminal events. Prescribing crisis medications in residential aged care or for patients dying at home is more complex, as they may not be able to be rapidly administered and may take carers' attention away from the dying person at the time they most need someone with them.

5.3 Review of Medications and Proportionate Dosing

Regular review and, if necessary, titration of medications is essential. Even when a patient is dying, medication doses need to be proportionate and defensible. Good palliative care involves careful choice of both drug and dose, according to the symptoms that are being experienced, and assessment of the benefits and any adverse effects (NICE 2015). Goals of treatment should be explicit, negotiated, and documented, for example, if sedation is the goal of care wherever possible that should be offered to and discussed with the patient (if they are able to communicate) and the family. Conflicting agendas may cause difficulties. For instance, patients and families may have concerns about euthanasia, or may be seeking assistance to hasten the person's death, or alternatively may be fearful that inappropriate prescribing is causing the deterioration of their family member. Addressing these concerns is important in the palliative care context. As euthanasia and assisted death are being very widely discussed and are available in some jurisdictions, it is ever more important to be absolutely clear about the intent of all palliative treatments, particularly where they involve opioids or sedation.

5.4 Fundamentals of Psychosocial Care

A person who is aware that they are deteriorating or dying may have fears, worries, or concerns that they wish to discuss. It is important to ask about this and to identify who it is that they would most like to discuss any issues with. Another helpful question is to ask if the person has any important goals that they need assistance with. The general need for companionship and conversation varies greatly, and this should be explored, without making assumptions. Not everyone will be distressed or in need of companionship.

Supporting dying people may also involve conveying their wishes back to their family and other visitors and helping them to manage who and how many people visit and for how long. Some patients do not wish to be a burden on their family and friends and may seek to minimize time with them for that reason. It can sometimes be helpful in that situation to explain that for people who are likely to be grieving their loss, time spent now can be extremely precious and can help them to recover better during their bereavement. Some patients wish for spiritual support (Best et al. 2016) – whether it be from a minister or chaplain from their own faith community or simply a chance to discuss what is on their mind with a good listener. However, it is also quite common for dying people to have no spiritual concerns or needs.

Be aware that in among all the end-of-life concerns, what many dying people greatly

appreciate is to be treated more or less normally – to talk about what is going on in the world, in their family, to discuss the weather, or just to share a joke. As well as helping to normalize what is happening to them, such interactions can reconnect a person to their threatened sense of themselves, in a situation where much of their previous life and identity is vanishing. Many palliative care services have volunteers, pastoral care workers, or other team members who can support patients in this way, when the family struggling with their impending loss and the changes in the dying person may find it difficult to do so. Appropriately modified gym activities and diversional therapies that have the goal of supporting function are often not considered for dying patients, yet they can have great psychological value at this time, as patients may sometimes feel that they are "just waiting to die." Dignity therapy (Ostlund et al. 2012; Guo and Jacelon 2014) at the end of life can be of particular benefit for dying patients whose sense of loss of personhood might otherwise overwhelm them. Even without such a specialized response, when a person is dying in an inpatient setting, every person that steps into their room has the opportunity to recognize and behave toward them in a way that supports their personhood. This is possibly one of the most therapeutic and under-recognized "interventions" in palliative care.

6 Management Decisions

Care for dying patients is anchored in the simplest principle of all. It is helpful to return regularly to the question of whether a given treatment, investigation, or procedure contributes anything to the comfort of the dying patient: any treatment or activity that does not add to the person's comfort can be ceased. However, for many patients and families, such decisions may be difficult and confronting. Misunderstandings may cause conflict, for instance, related to a perception that a dying person is not being given the care that they need. Thus, part of the difficulty for many clinicians at this stage is how to work through these decisions with the patient and their family.

6.1 Stopping Medications and Investigations

When the irreversibility of the dying process is clear, then most long-term medications for comorbid conditions offer no benefit and indeed may create harm in terms of cost, burden of tablets, drug interactions, and greater risk of adverse effects as the dying patient becomes less and less able to eliminate medications (Stevenson et al. 2004; Currow et al. 2007). Once patients are no longer able to swallow, many of these decisions "make themselves." However, discussion with patients and families is still very important, as ceasing medications can sometimes be seen as clinical fatalism or abandonment or may act as a confronting reminder of the imminence of death. When decision-making is individualized and explained, and when the rationale is the dying person's comfort and well-being, it will usually be accepted.

Routine observations such as checking of blood pressure and pulse, or routine blood tests, also contribute nothing to the care of the dying patient, whose physiological parameters are likely to be abnormal. Investigations and observations at this time are only useful to answer specific clinical questions, and even then only if the answer that is yielded will be appropriate to act on for that patient. However, routine assessments of patients' comfort, including of their pain, mental state, and other symptoms, and of how the person's family are coping, should now become the focus of the daily care of the patient, replacing those clinical priorities which are no longer important. Some hospitals have attempted to address this shift in care processes by replacing standard patient charts with a specific "comfort chart" for dying patients.

For some medications, withdrawal or inability to take via an oral route can be associated with problems or symptoms which may need to be carefully considered, and sometimes replacement with alternative treatments may be appropriate. Common examples of medications requiring some consideration are included in Table 1.

Table 1 Alternatives to some common long-term medications which can be used in end-of-life care

Oral medication	Alternative management strategy for end-of-life care
Antineuropathic agents	Monitor for worsening of pain and titrate opioids to compensate
Anti-inflammatories or gout medications	Dexamethasone given subcutaneously may provide anti-inflammatory cover if clinically required
Anticonvulsants	A patient who is on anticonvulsants after having had seizures should be converted to a long-acting benzodiazepine such as clonazepam. If anticonvulsants were prophylactic only, as needed doses of clonazepam should be made available, but the patient may not require regular doses
Anti-parkinsonian medications	Subcutaneous apomorphine or topical rotigotine may be appropriate for patients with severe Parkinson's disease even in the terminal phase, to prevent them becoming locked-in by immobility
Oral laxative	Consider treatment per rectum if clinically indicated
Anticoagulants	It is usually appropriate to cease anticoagulants, particularly if they are prescribed for prophylaxis. However, if deep venous thrombosis is a cause of distressing pain, it may be appropriate to cautiously continue parenteral anticoagulants such as low molecular weight heparin, depending on the clinical situation
Oral hypoglycemics, long-acting insulin, or other diabetic medications	When oral intake is minimal, regular oral hypoglycemics and long-acting insulins should cease. Frequent testing of blood sugar is not required. Hypoglycemia presents a more significant risk than hyperglycemia. Check blood sugar if symptomatic, and treat with short-acting insulin for symptom control if required

6.2 Food and Fluids

Issues related to giving food and fluids in the last days of life can be extremely contentious to deal with. Families may be greatly distressed by the perception that a patient is not receiving enough nutrition, believing that this is the reason for the symptoms that the person is experiencing. The human and relational significance of food and drink should never be underestimated by clinicians, who need to be able to talk comfortably and empathetically with families and about this issue. In the past, there has been a tendency to routinely cease hydration in dying patients, and indeed this was institutionalized within some end-of-life care pathways and became one of the aspects of the Liverpool Care Pathway that caused much difficulty when poorly or inflexibly implemented (NICE 2015). Requests for parenteral hydration by families of dying patients are common (Gent et al. 2015). Little evidence exists to support any benefit of such treatment; there is some low-level evidence to suggest that it may improve nausea, but it may worsen ascites, without improving delirium or thirst or survival (Raijmakers et al. 2011). Artificial nutrition for dying patients has also not been shown to prolong life or improve quality of life (Chow et al. 2016).

As with everything else in the terminal stage, the patient's comfort is the best guide wherever possible. Most families can be helped to understand that eating is no longer a biological necessity for a dying person, but that small amounts of food and drink, when able to be tolerated, and if the patient wants them, may give some pleasure – which at this time is the main goal. Lack of appetite, nausea, swallowing difficulties, dyspnea, or fatigue may all be limiting factors in how much oral intake a dying patient will want. Families can be helped to make this assessment, recognizing that pushing a person to eat may cause them distress. Likewise fluids are for comfort for the patient. When dry mouth is a problem for palliative care patients, which it commonly is because it is such a common side effect of many palliative medications, the best treatments are good, frequent mouth care and safely offering oral fluids. Parenteral hydration does little to help with this

subjective experience (Raijmakers et al. 2011), but regular small sips of fluid, ice, mouth sprays, or topical administration of artificial saliva may be much more beneficial. Wherever appropriate, families can be encouraged to offer these, which can alleviate some of their own distress. However, it is also important to give some instruction about how to offer food and fluids safely, as many family members are unaware of the risks of aspiration for seriously ill patients. The idea of pleasure from oral intake can be further explored, encouraging the family to think about what the person might enjoy, for example, a frozen fruit or some ice cream, a sip of alcohol, or some soda water or lemonade.

Frequently in hospital, dying patients have been identified as being at high risk of aspiration and have been made "nil by mouth." In the palliative care context, this is usually inappropriate; however, some institutions have policies that are quite rigid once such an assessment has been documented in the medical record. The alternative is to allow and assist the patient and family to make an informed decision about what oral intake they wish to have, including whether and when they wish to use thickened fluids and modified texture foods or not. For patients who want to eat or drink specific things, wherever possible they should be allowed to do so with safety precautions, which include careful positioning, ensuring that the patient is alert when eating or drinking, and offering only very small amounts at a time (Pollens 2004).

6.3 Appropriate and Inappropriate Interventions for Dying Patients

Stopping treatments is often much harder than starting them. Clinicians should carefully consider clinical endpoints and prognosis whenever they offer any active interventions at the end of life. When interventions are given for non-reversible problems, it is likely that those treatments will need to be withdrawn subsequently. Consideration of how to manage that is as important as initiating the treatment itself; for example, withdrawal of ventilation can itself be regarded as a palliative intervention (Huynh et al. 2013).

Many problems are not reversible in the terminal phase, for example:

- Fatigue and weakness in the terminal phase cannot be relieved by transfusion of red cells or correction of iron deficiency.
- Metabolic derangements in patients dying of renal or liver disease are not correctable.
- Severe cachexia and hypoalbuminemia are not able to be reversed by artificial nutrition.

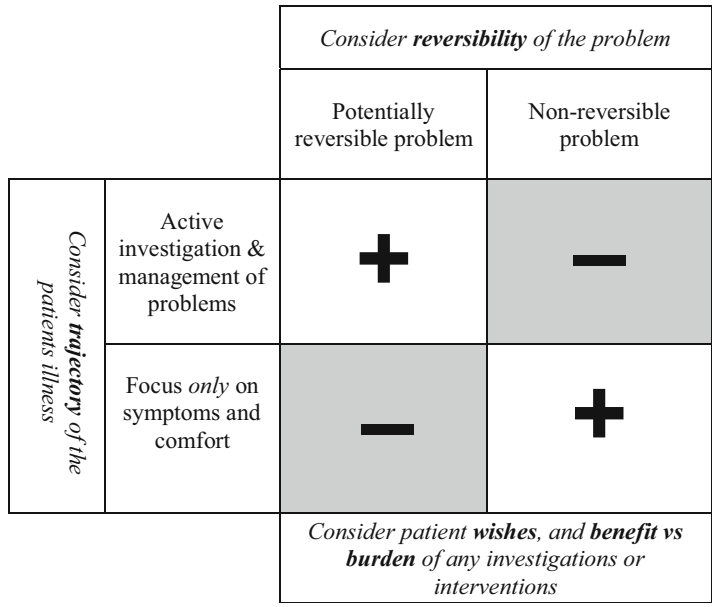
Even when it is possible to correct biochemical or hematological abnormalities, this almost invariably does not produce any meaningful clinical benefit for the patient and is not able to be sustained.

Some potentially reversible problems may be considered for treatment if they improve the comfort of the patient and treatment is not too burdensome, for example:

- Hypercalcemia causing confusion.
- Respiratory tract infection causing coughing of purulent sputum.
- Seizures affecting mental state.
- Acute intercurrent conditions – for instance, gout, atrial fibrillation, cellulitis – can all be treated for the comfort of the patient rather than to prolong their life.

Some potentially reversible problems could potentially require a significant intervention, such as spinal cord compression, or obstructive processes that may be able to be relieved by stenting. The value of any such treatment, however, will completely depend on the life expectancy of the person and their ability to tolerate the procedure itself. For the dying patient, ongoing anticancer treatment – whether with chemotherapy, immunotherapy, or radiotherapy – is only of value in the rare case that there is a defined symptom with likelihood of responding in the timeframe of the patient's life expectancy, for example, SVC obstruction that can be treated with radiotherapy (Table 2).

Table 2 A clinical approach to patient problems in end of life care



6.4 Trials of Therapy

When there is uncertainty around the reversibility of a problem, for example, a patient with sepsis or delirium, and particularly when this problem makes it unclear whether the patient is in the terminal phase or not, it may sometimes be appropriate to offer a trial of therapy. The other context in which a trial of therapy can be appropriate is when a patient or family are absolutely insistent on receiving more active treatment which is unlikely to be of benefit. A trial of therapy involves a time-limited course of treatment, and an appropriate therapeutic outcome, specified in advance. In this context, functional outcomes that are meaningful to the patient are the most helpful, for example, "to be able to comfortably spend the day out of bed." It may be important also to specify possible adverse effects of a treatment that would lead to stopping the trial. Discussing a trial of therapy for a patient who is approaching the terminal phase allows the clinician to be very clear about the context – which is that of very grave clinical concern – and thus can also help to prepare the patient and family for the possibility that death may happen soon. Often setting such clear goals gives patients and families a chance to adjust to their changing situation and can avert conflict about treatment, ultimately allowing them to be part of the decisions for a more palliative approach to care rather than fighting against them. Working through such a process carefully can help to maintain a strong therapeutic relationship, even where there is initial disbelief or great unreadiness for death.

7 Conclusion and Summary

Caring for patients at the end of life demands both clinical and human responses. This chapter has emphasized that none of the management approaches described should be allowed to become a rigid framework for care. Excellent care must always be grounded in evidence, but pathways and protocols are only ever a guide and on their own will not ensure that patients' profound human needs are met. This was an important lesson from

the implementation of the Liverpool Care Pathway (Neuberger 2013). The challenges of caring for dying people lie in how we respond to each circumstance, how we understand both the disease and the meaning of the disease, and in learning what dignity and comfort mean for each individual. Palliative care also cares for the family and loved ones of the dying person, during and after the death. This is a wide net and a serious responsibility. They too must be included in our care processes and decision-making to the very best of our ability.

Ultimately, our regular contact with death and dying should help us to be in safe hands for our dying patients, but never forgetful of the great human mystery we are witnessing. At the very end, we take them to that door, and stay with them, in order to see that they go through it safely. They depend on us to be their guide through a process that they have never experienced, but which we know familiarly.

Contents

Abstract

This chapter considers the development of generalist and specialist palliative care practice and the emerging understanding of respective competences, roles, and responsibilities. Evidence relating to the effectiveness of partnership working and factors promoting (or hindering) collaboration are reviewed. Specialist and generalist palliative care practice are critically appraised through the lens of models of care. The question of whether research to date has adequately examined areas of commonality, separation, and overlap is posed, and the resultant implications for optimal palliative care practice are studied. An overview of research in the field of integrated care is provided, and it is suggested that consideration of integrated care frameworks offers opportunity

for greater conceptual and methodological clarity in the design and implementation of palliative care interventions and models of care. Worldwide ranking systems of specialist and generalist palliative care are reviewed, and variability in developmental stage between countries is highlighted. The chapter concludes that research in palliative care practice arguable remains largely siloed, considering either generalist or specialist palliative care interventions separately and failing to move to a space where consideration of the "whole" might be more advantageous than considering the sum of the parts.

1 Introduction

The ancient Greeks recognized the need to consider the respective places of both healing and treatment in healthcare. "To cure sometimes, to relieve often, to comfort always" is a phrase attributed to Hippocrates, among others. It reminds us that there has always been a need to care for the seriously ill and dying in medicine. However, the importance of comfort care was increasingly marginalized from mainstream medicine until the mid-twentieth century and the work of Cicely Saunders. When Saunders founded St Christopher's Hospice in South London in 1967, it quickly became a source of inspiration to others, and the palliative care movement spread globally. As the first "modern" hospice, it uniquely combined three key principles: education, research, and excellent clinical care that encompassed physical, psychosocial, and spiritual domains of need.

The role of specialist practitioners in the modern hospice movement was clear from the outset. Saunders explained the benefits of having skilled and experienced staff working in hospices, stating that "those working in them are specialists and from experience know how to deal with pain, fungating and eroding growths, mental distress, fear and resentment" (Saunders 1958: 40). The importance of nonspecialists in providing palliative care was also clear; indeed, Saunders said that one of the main aims of work at St Christopher's was that "... basic principles in teaching and research [should be] fed back into the health service" (Clark 2002). However, articulation of the exact role of nonspecialists and their relationship with specialists was more ambiguous. Ongoing definitional problems regarding palliative care contributed to lack of clarity over subsequent years.

As hospice and palliative care developed in the United Kingdom, interest in formally establishing it as a specialty grew. In 1987, palliative medicine became a sub-specialty of general medicine, initially on a 7-year "novitiate." Once this was successfully concluded, the specialty was established (Doyle 2005). The journey to specialty status was not without its opponents, however. Many arguments focused on whether palliative medicine was really a specialist territory and not more properly the domain of the primary care physician or treating specialist and whether specialty status would lead to further over-medicalization and marginalization of dying (Doyle 1994). Nevertheless, by 2014, 18 European countries had followed the UK's lead in establishing certification programs in palliative medicine (Bolognesi et al. 2014). The growth of palliative medicine was not confined to Europe, for example, the Royal Australasian College of Physicians created a pathway for sub-specialty training in palliative medicine with the first trainees starting supervised training in 1991. In 2006, the American Board of Medical Specialties approved the creation of Hospice and Palliative Medicine as a sub-specialty of ten participating boards.

To date, certification programs remain heterogeneous in content and structure, however, and the most appropriate certification system, not only for palliative medicine specialists but also for other disciplines, has not yet been agreed.

To a certain degree, the historic arguments about the advantages and disadvantages of specialty palliative medicine have been addressed by the model proposed by Quill and Abernethy (2013) where contributions from both specialists and nonspecialists in palliative care are valued. Quill and Abernethy argue that a care model is needed that distinguishes primary palliative care

skills (skills that all clinicians should have) from specialist palliative care skills (skills for managing more complex and difficult cases) so that they can coexist and support each other. In this "coordinated palliative care model," the primary care physician or treating specialist can manage many palliative care problems and initiates a specialist palliative care consultation for more complex or refractory problems. Patients may be returned to the sole care of the referring specialist or primary care physician once this is felt appropriate by all involved.

The authors argue that the advantages of this model offers are that it recognizes the important role of the primary (also known as "generalist" or "nonspecialist") palliative care clinician, allows increased access to specialist palliative care for those who need it, reinforces existing relationships, increases satisfaction and enhances the skills of all clinicians in palliative care, and potentially contributes to cost control by reducing the number of specialists routinely co-managing cases. On their own, specialist palliative care clinicians will never be able to care for all patients with palliative care needs, and increasing demand is already outpacing capacity. The fragmentation of the healthcare system is well recognized, and the addition of another layer of expert care, such as specialist palliative care, should only be considered when benefits outweigh disadvantages.

2 Defining Levels of Palliative Care Provision

The coordinated care model of Quill and Abernethy fits well with the thinking of the revised definition of palliative care published by the World Health Organization (WHO) in 2002 (Sepúlveda et al. 2002) and of the three-tier framework of the European Association for Palliative Care (EAPC) (Gamondi et al. 2013). The WHO description of palliative care as an "approach" to care and a core component of universal healthcare underscores the importance of weaving palliative care into the fabric of healthcare provision and making palliative care accessible to all that need it. The EAPC provides greater depth to the distinction between generalist and specialist practice by describing three recommended levels of education in palliative care for healthcare professionals (Table 1).

Table 1 Agreed levels of education currently adopted by the EAPC to reflect the scope and focus of professionals involved in the delivery of palliative care

Palliative care approach
A way to integrate palliative care methods and procedures in settings not specialized in palliative care. Should be made available to general practitioners and staff in general hospitals, as well as to nursing services and nursing home staff. May be taught through undergraduate learning or through continuing professional development
General palliative care
Provided by primary care professionals and specialists treating patients with life-threatening diseases who have good basic palliative care skills and knowledge. Should be made available to professionals who are involved more frequently in palliative care, such as oncologists or geriatric specialists, but do not provide palliative care as the main focus of their work. Depending on discipline, may be taught at an undergraduate or postgraduate level or through continuing professional development
Specialist palliative care
Provided in services whose main activity is the provision of palliative care. These services generally care for patients with complex and difficult needs and therefore require a higher level of education, staff, and other resources. Specialist palliative care is provided by specialized services for patients with complex problems not adequately covered by other treatment options. Usually taught at a postgraduate level and reinforced through continuing professional development

Reproduced from Gamondi et al. (2013)

Internationally, several policy and strategy documents recognize the place of these levels of palliative care provision and core competencies; however, variation does exist. In some documents, palliative care approach and general palliative care levels are collapsed into the one category of "generalist palliative care," while other documents provide further subdivisions of three EAPC levels. Notably, these documents do not address the core competencies or training needed by informal carers and volunteers, despite the significant contribution they make toward supporting people with both generalist and specialist palliative care needs.

The different levels should not be regarded as descriptors that value the contributions of one group over another; in fact, the opposite is true. The value of recognizing different levels of palliative care provision is as follows. First, recognition of different levels of competence and service provision emphasizes that many palliative care needs can be met by generalists without the need for referral to specialist services. Second, it can inform the development of palliative care training programs for generalists and specialists. Third, distinctions based on healthcare professionals' skills and training and patient complexity address ambiguity about the nature and scope of generalist and specialist palliative care and help clarify and value respective roles. Finally, defining levels of palliative care and their corresponding core activities facilitate measurement of the extent to which generalists and specialists are, respectively, addressing palliative care needs.

3 Respective Roles and Responsibilities of Generalist and Specialist Palliative Care Practitioners

As previously discussed, the coordinated care model proposed by Quill and Abernethy (2013) acknowledges the skills and expertise of both generalist and specialist practitioners. Indeed, the distinct advantages of supporting primary care providers to deliver palliative care were recently highlighted in a publication by the EAPC Taskforce in Primary Palliative Care (Murray et al. 2015). The Taskforce noted that primary care providers:

- Use their detailed knowledge of patients and families and strong relationships with them to reach all people with life-threatening illnesses and begin providing a palliative care approach immediately following diagnosis with a life-limiting illness.
- Address the various domains of palliative care needs including physical, social, psychological, and spiritual.
- Deliver care directly to patients in all relevant settings including home, clinics, and nursing or care homes.
- Support family caregivers and provide bereavement care.

The role of specialist palliative care providers then is to provide holistic care to patients and families with complex palliative care needs; support complex end-of-life decision-making; provide bereavement care; act as a resource for other healthcare professionals by providing education, training, and support; and demonstrate leadership in advancing the field of palliative care through research, practice, and policy development.

Rather than viewing the roles and responsibilities of generalist and specialist providers as discrete skill sets, some authors have suggested that palliative care input should be divided between generalists and specialists on a continuum (Ryan et al. 2014; Carroll and Quill 2015). "Core" competences are regarded as those attitudes, knowledge, and behaviors that are common to the care provided by all health and social care professionals. Discipline-specific competencies are described in ascending expertise of palliative care practice. There is broad agreement between bodies on what the core competences are that are common to all clinicians (Table 2).

Distinct groups of patients with varying levels of palliative care need may be identified as existing within the population of people with life-limiting or life-threatening conditions. A needs-based approach to palliative care provision advocates that services are provided based on need. For example, people who experience relatively uncomplicated (though potentially troubling) trajectories of illness should be cared for by generalist providers, while people who experience complex palliative care needs will require the input of a specialist palliative care team. Quality palliative care is best realized when strong networks exist between generalist and specialist providers and when clinicians work together to meet the needs of all people.

Table 2 Core competences for generalist and specialist palliative care

European Association for Palliative Care – ten core competencies in palliative care (Gamondi et al. 2013)	National competence framework for palliative care, Health Service Executive, Ireland – six domains of competence (Ryan et al. 2014)
Apply the core constituents of palliative care in the setting where patients and families are based	Principles of palliative care
	Communication
	Optimizing comfort and quality of life
Enhance physical comfort throughout patients' disease trajectories	Care planning and collaborative practice
	Loss, grief, and bereavement
Meet patients' psychological needs	Professional and ethical practice in the context of palliative care
Meet patients' social needs	
Meet patients' spiritual needs	
Respond to the needs of family carers in relation to short-, medium- and long-term patient care goals	
Respond to the challenges of clinical and ethical decision-making in palliative care	
Practice comprehensive care coordination and interdisciplinary teamwork across all settings where palliative care is offered	
Develop interpersonal and communication skills appropriate to palliative care	
Practice self-awareness and undergo continuing professional development	

4 Factors Supporting Collaboration Between Generalist and Specialist Palliative Care Providers

Working in teams is an essential feature of palliative care delivery (Sepúlveda et al. 2002), and the need for partnership working and collaboration between generalist and specialist palliative care providers is at the center of international palliative care policy and guidelines. The emphasis on coordination within palliative care policy as a means for improving access and outcomes is supported by studies reporting the benefits of team working for both patients and healthcare professionals. A systematic review by Gardiner et al. (2012) found that for patients receiving palliative care, these benefits include increased likelihood of dying in most preferred location, improved symptom management, and greater opportunity for patient education. Generalists reported improved confidence in providing palliative care and increasingly positive attitudes toward specialist palliative care providers.

Given the critical role of effective collaboration in ensuring access to palliative care support for all patients living with a life-limiting illness, it is important to understand the factors that promote and sustain working relationships between generalists and specialists. Overall, studies examining the topic have drawn broadly similar conclusions about the factors influencing collaboration across all care settings. These center around three themes: characteristics and views of generalists, the nature of interpersonal and interprofessional relationships and communication, and organizational factors.

Factors related to generalist providers themselves influence the extent to which they engage in collaborative practice. Their preferences for collaboration with specialist palliative care are often shaped by their own perceptions about the necessity or value of team working. Limited knowledge about the nature or scope of palliative care may also serve as a barrier to collaboration. Similarly, professional judgments about specialists' skill set also influence generalists' willingness to collaborate and the types of issues they seek input for. For instance, while generalists widely believe that specialist palliative care services provide a level of support that requires additional training and expertise, some have reported concerns that specialists have limited knowledge about disease-specific issues. Firn et al. (2016) report that these perceived gaps in proficiency directly

impact on generalists' willingness to collaborate with specialists.

The nature of interpersonal and interprofessional relationships between generalists and specialists, and the quality of their communication, also influences partnership working. Good communication is central to collaboration but requires considerable time and effort, while working relationships are being established and often develop through personal interactions between generalists and specialists rather than any type of formal process or procedure (Gardiner et al. 2012). Studies have found that successful collaboration between generalists and specialist providers is often characterized as being built upon respect, trust, and expertise (Walshe et al. 2008; Firn et al. 2016). Specifically, generalists trust that specialist palliative care providers will respect the hierarchy of decision-making by continuing to consult with the referring team around the patient's care. This approach to communication and negotiation ensures that generalists and specialists are both acknowledging and supporting the expertise of the other and sharing decision-making responsibilities. Moreover, without this clear delineation in roles and responsibilities, the working partnership between generalist and specialist palliative care providers can break down (Brueckner et al. 2009).

Organizational factors also impact on collaboration. Often cited is generalists' need for efficiency and ease of access to specialist palliative care services in hospital or the community. Good partnership is fostered through specialist palliative care services being flexible, visible, and available to provide advice and support round-the-clock. With most patients accessing care across several settings, IT infrastructure is also crucial in supporting efficient communication between healthcare professionals.

To date, the factors supporting collaboration tend to be ad hoc and driven by informal interactions rather than formal structures. There is also limited evidence about outcomes associated with or methods for evaluating various formal models of partnership working to guide practice and policy.

5 Specialist and Generalist Palliative Care Practice and Models of Care

A model of care broadly describes a framework that brings together regulatory, organizational, financial, and clinical aspects of service provision to outline best practice in patient care delivery. The concept is an important one because of the link between adoption of best practices (as described in a model of care) and improved patient outcomes. Viewing palliative care through the lens of a model of care demands that stakeholders consider how best health services can best utilize the skills of generalist and specialist palliative care professionals. It offers opportunity to critically appraise areas of commonality, separation, and overlap in generalist and specialist palliative care practice and to ensure that organization of practice is optimally configured to meet the needs of patients and their families.

In the traditional model of medical care, palliative care was only provided when curative or disease-modifying treatment was no longer felt to be appropriate. This is gradually being supplanted by an integrated model where palliative care, when needed, is provided at the same time as curative or life-prolonging treatments. To date, a range of different models of palliative care provision have been developed and implemented to meet the requirements of this paradigm shift. Many reviews have been published that have tried to identify the effectiveness and cost-effectiveness of these different models (Luckett et al. 2014; Kavalieratos et al. 2016; Brereton et al. 2017). The reviews acknowledge that palliative care offers benefits to patients and their families but conclude that the evidence base for effectiveness of individual models of care remains limited by heterogeneity, methodological limitations, poor reporting, and a lack of consensus about outcome measures.

Much of the evidence that has been produced relates to models that predominantly focus on specialist rather than generalist palliative care provision. Moreover, within the models there has been relatively little explicit consideration of the interface between specialist and generalist palliative care and how that might optimally

function. While this may in part be due to ambiguous terminology, methodological challenges, and poor reporting of components of the intervention, it contrasts with a growing focus in the general healthcare literature on the integration of primary and specialty care. Instead, research in palliative care arguably remains largely siloed, considering either generalist or specialist interventions separately and failing to move to a space where consideration of the "whole" might be more advantageous than considering the sum of the parts.

What has been learnt from the studies that have been conducted on models of palliative care? Kavalieratos et al. (2016) conducted a systematic review and meta-analysis of palliative care randomized clinical trials (RCTs). RCTs were included if the intervention comprised at least two of the eight possible domains of palliative care as defined by the National Consensus Project for Quality Palliative Care. Interestingly, interventions addressed a median of five (range two to seven) of eight palliative care components. The 43 randomized clinical trials included data on 12,731 patients (mean age, 67 years) and 2479 caregivers. In the meta-analysis, palliative care was associated with statistically and clinically significant improvements in patient QOL at the 1- to 3-month follow-up and symptom burden at the 1- to 3-month follow-up. Findings for caregiver outcomes were inconsistent. When analyses were limited to trials at low risk of bias ($n = 5$), the association between palliative care and QOL was attenuated but remained statistically significant, whereas the association with symptom burden was not statistically significant. Evidence of associations with other outcomes was mixed.

Due to the diversity and lack of standardization of models studied, it is difficult to classify or group the interventions studied in these reviews. Models of specialist palliative care studied included services provided by unidisciplinary and multidisciplinary teams in hospital (inpatient and outpatient) and community settings. Models of generalist palliative care were similarly conducted across a range of settings, often focusing on communication, advance care planning, or improvements in needs assessment, psychosocial support, and symptom management. Notably, of the five RCTs focused on quality of life at 1- to 3-month follow-up that were judged by Kavalieratos et al. to be at low risk of bias, three comprised a specialist palliative care intervention (Bakitas et al. 2009; Temel et al. 2010; Zimmermann et al. 2014), one was generalist in nature (Rummans et al. 2006), and one comprised both specialist and generalist components (Higginson et al. 2014) (Table 3).

Luckett et al. (2014) adopted a different approach in their rapid review and aimed to identify the elements of effective palliative care models. They concluded that models of palliative care should integrate specialist expertise with primary and community care services and enable transitions across settings, including residential aged care. They considered the following elements to be essential to effective care: case management, shared care, specialist outreach services, managed clinical networks and/or health networks (clinical networks), integrated care, and the use of volunteers. Luckett also encountered the problems of heterogeneity of

Table 3 Generalist and specialist palliative care interventions

Bakitas et al. (2009)	A multicomponent, psychoeducational intervention (Project ENABLE [Educate, Nurture, Advise, Before Life Ends]) conducted by advanced practice nurses with palliative care specialty training consisting of 4-weekly educational sessions and monthly follow-up sessions until death or study completion versus usual care for patients with advanced cancer
Temel et al. (2010)	Early outpatient specialist palliative care for patients with advanced cancer
Zimmermann et al. (2014)	Early hospital, community, or outpatient specialist palliative care for patients with advanced cancer
Rummans et al. (2006)	Structured multidisciplinary intervention comprising eight 90-min sessions over 3 weeks for patients with advanced cancer scheduled to undergo radiotherapy
Higginson et al. (2014)	Short-term, single point of access breathlessness support service integrating specialist palliative care, respiratory medicine, physiotherapy, and occupational therapy

studies; methodological issues; problems mapping between evidence at the outcome levels of the patient, caregiver, provider, and service; and variable findings.

Indeed, the importance of the trials with negative or equivocal findings should not be overlooked in the search for understanding effective components of specialist and generalist practice. Negative studies highlight methodological issues that need to be addressed in future work and help us understand the "active ingredients" in palliative care interventions. For example, in their study of early specialist palliative care among advanced cancer patients, Groenvold et al. (2017) hypothesized that their negative result might be attributable to a failure to provide more specific guidance on the frequency and nature of the input of the specialist palliative care team, a relatively short intervention period, some degree of crossover, and contamination of control groups (as this was not a cluster RCT). Similarly, in Carson et al.'s (2016) RCT of the effect of palliative care-led meetings for families of patients with chronic critical illness, it has been hypothesized that the negative result was attributable to a highly structured study protocol that solely aimed to provide informational support with little regard to what makes this process meaningful to many patients, families, and clinicians: frequent and longitudinal follow-up, close involvement with the primary clinical team, and a focus on relief of physical and psychosocial distress (Malani and Widera 2016).

It is important to recognize that much of the research evidence on specialist and generalist palliative care originates from high-income countries where more is spent on healthcare and research. Generalizability of findings to low- and middle-income countries cannot be assured, and there is a lack of research on models of generalist or specialist care set in these countries. Lowther's et al. (2015) high-quality RCT that studied nurse-led palliative care for HIV-positive patients taking antiretroviral therapy in Kenya is a standout example of what can be achieved outside of high-income countries. It serves as an encouragement for further research to be undertaken to ensure that models of care are fit for each country's purpose.

6 Specialist and Generalist Practice and Integrated Care

"Integrated care" is a complex and still evolving concept. Integration (from the Latin integer, meaning whole, complete, entire) generally means combining parts so that they either work together or form a whole, although its definition in healthcare is somewhat more complex and multidimensional. The technical brief prepared for WHO's Department of Health System Governance and Service Delivery in 2008 (World Health Organization 2008) describes integration as "the organisation and management of health services so that people get the care they need, when they need it, in ways that are user-friendly, achieve the desired results and provide value for money." The purpose of integrated care is to reduce fragmentation of healthcare, duplication of health services, and missed opportunities for appropriate healthcare and instead improve the user experience and outcomes of care.

As previously discussed, the term "integrated palliative care" is commonly used to distinguish between the traditional dichotomous model of provision of palliative care at the end-of-life only and the model where palliative care is provided at the same time as curative or life-prolonging treatments. However, as the range of models of palliative care provision demonstrates, organizations have demonstrated considerable diversity in the structures and processes that they have used to achieve integration. While there is no single agreed conceptual model for health systems integration, arguably efforts to integrate palliative care in the mainstream of health provision would benefit from a more considered application of organizational theory and management science. This would help policy makers, planners, managers, clinicians, and researchers study, promote, and implement integrated palliative care and consider the optimal place and relationship of generalist and specialist palliative care practice in achieving integration with the wider health system.

While a detailed review of integrated care is outside of the scope of this chapter, several key points about integration may be made. Fulop et al.

(2005) describe five types of integration occurring within the system:

1. Organizational integration (where organizations are brought together through legal instruments or agreements such as mergers, collectives, or networks)
2. Functional integration (where back-office and support functions are integrated)
3. Service integration (where different clinical services are integrated at an organizational level such as through multidisciplinary teams)
4. Clinical (professional) integration (where care by professionals and providers to patients is integrated into a single coherent process within and between professionals and their organizations, such as the use of one care plan, shared clinical guidelines and protocols, devolved shared decision-making, etc.)
5. Normative integration (where an ethos of shared organizational and professional values enables trust and collaboration in delivering healthcare within and across organizations)

Levels and breadth of integration have also been described as important dimensions of integration in the literature. Authors variously describe three levels of integration as macro (regulation, policy, and strategic planning), meso (organizational and professional or physician), and micro levels (clinical) (Stevenson Rowan et al. 2007; Curry and Ham 2010). Breadth of integration is described as horizontal or vertical (Shortell et al. 1996). Horizontal integration refers to the combination of two organizations who are at the same level (e.g., two residential care units), whereas vertical integration refers to the combination of organizations who are at different levels (e.g., hospital, nursing home, and home care provider).

The general healthcare literature has used these frameworks of integrated care provision to explore real-life experiences of integration (Lasker and Committee on Medicine and Public Health 1997), categorize collaborations (Martin-Misener and Valaitis 2008) and outcomes (Ramsay et al. 2009), and identify and describe determinants of successful collaboration (Humphries and Curry 2011). For example, Powell Davies et al. (2008) reported on nine types of strategy used to coordinate care within primary healthcare and among primary healthcare, health services, and health-related services (Table 4). The potential application of similar work in generalist and specialist palliative care is clear. Explicit consideration of integrated care frameworks offers opportunity for greater conceptual and methodological clarity in the design and implementation of palliative care interventions and models of care.

Table 4 Types of strategies used to coordinate care. (Adapted from Powell Davies et al. 2008)

Types of strategies used to coordinate care
Patient and provider level
1. Arrangements to improve communication between service providers e.g. case conferencing
2. Using systems to support care coordination e.g. patient held or shared records
3. Structured arrangements for coordinating service provision between providers e.g. joint consultations
4. Providing support for service providers e.g. training
5. Structuring the relationships between service providers and with patients e.g. case management
6. Providing support for patients e.g. education
Organizational level
7. Joint planning, funding, and/or management of a program or service
8. Formal agreements between organizations
System level
9. Changes to funding arrangements

7 Ranking or Rating Systems for Palliative Care

Despite the difficulties inherent in describing and comparing models of specialist and generalist palliative care, several ranking systems have been devised for palliative care systems in Europe and across the world. The best known of these are the Global Atlas of Palliative Care Development at the End of Life (Lynch et al. 2013), the EAPC Taskforce on the Development of Palliative Care in Europe (Martin-Moreno et al. 2008), and the Global Quality of Death Index (The Economist Intelligence Unit 2015). Global categorizations of palliative care development are correlated with

Table 5 Global atlas of palliative care typology (Lynch et al. 2013)

Group 1:
Countries with no known hospice-palliative care activity, i.e., best efforts have been unable to identify any palliative care activity in this group of countries
Group 2:
Countries with capacity-building activity, i.e., there is evidence of wide-ranging initiatives designed to create the organizational, workforce, and policy capacity for hospice-palliative care services to develop. Activities include attendance at, or organization of, key conferences, personnel undertaking external training in palliative care, lobbying of policy makers and health ministries, and an incipient service development, usually building on existing home care programs
Group 3 countries:
(3a) Isolated palliative care provision, i.e., countries characterized by the development of palliative care activism that is patchy in scope and not well-supported, sourcing of funding that is often heavily donor-dependent, limited availability of morphine, and a small number of hospice-palliative care services that are often home-based in nature and limited in relation to the size of the population
(3b) Generalized palliative care provision, i.e., countries characterized by the development of palliative care activism in a number of locations with the growth of local support in those areas, multiple sources of funding, the availability of morphine, a number of hospice-palliative care services from a community of providers that are independent of the healthcare system, and the provision of some training and education initiatives by the hospice organizations
Group 4 countries:
(4a) Countries where hospice-palliative care services are at a stage of preliminary integration into mainstream service provision. This group of countries is characterized by the development of a critical mass of palliative care activism in a number of locations, a variety of palliative care providers and types of services, awareness of palliative care on the part of health professionals and local communities, the availability of morphine and some other strong pain-relieving drugs, limited impact of palliative care upon policy, the provision of a substantial number of training and education initiatives by a range of organizations, and existence of (or at least an interest in the concept of) a national palliative care association
(4b) Countries where hospice-palliative care services are at a stage of advanced integration into mainstream service provision. This group of countries is characterized by the development of a critical mass of palliative care activism in a wide range of locations; comprehensive provision of all types of palliative care by multiple service providers; broad awareness of palliative care on the part of health professionals, local communities, and society in general; unrestricted availability of morphine and most strong pain-relieving drugs; and substantial impact of palliative care upon policy, in particular upon public health

the state of palliative care as a field of specialization in each system, although the relative weight given to specialist and generalist practice varies significantly between systems.

The Global Atlas uses a six-part typology to describe levels of hospice and palliative care development (Table 5). As can be seen from the descriptors, aspects of both generalist and specialist palliative care provision are considered in each typology.

The EAPC Taskforce describes the development of palliative care in the context of processes, structures, policies, and resources that support the delivery of palliative care. Data is gathered from multiple sources including qualitative data by means of the Eurobarometer survey, quantitative data by means of the FACTS Questionnaire, bibliographic review, and interview of key informants. Both generalist and specialist palliative care data are collected, although it is arguable that the focus on specialist palliative care provision is greater than in other rating systems.

The Quality of Death Index is scored on 24 indicators in 4 categories, each with a separate weighting, as follows:

1. Basic end-of-life healthcare environment (20%)
2. Availability of end-of-life care (25%)
3. Cost of end-of-life care (15%)
4. Quality of end-of-life (40%)

Eleven of the Index's 24 indicators are based on quantitative data, such as life expectancy and healthcare spending as a percentage of GDP. Ten of the indicators are qualitative assessments of end-of-life care in individual countries, for example, "Public awareness of end-of-life care," which

is assessed on a scale of 1–5 where 1 equates to "little or no awareness" and 5 to "high awareness." Three of the indicators describe whether something is or is not the case, for example, "Existence of a government-led national palliative care strategy," for which the available answers are Yes, No, and In Progress. Only one indicator (availability of hospices and palliative care services per million population aged 65 and over) refers specifically and solely to specialist palliative care.

Despite the different methodologies, the different systems show broad agreement, with the United Kingdom, Australia, New Zealand, and Ireland ranking highly. The rating systems should be used and interpreted with caution, however, as they are associated with both advantages and disadvantages. As should be clear from the preceding discussions on the evidence base for models of palliative care, the methodology underpinning the scoring systems is far from an exact science. Moreover, despite best efforts, data may be unreliable or unverifiable. While the systems provide some absolute measure of development as well as change over time and can be used to advocate for development in specific countries, they can also prove to be demotivating for some countries where areas of achievement are not given adequate recognition or weighting.

8 Access to Generalist and Specialist Palliative Care

The way in which palliative care is delivered is determined by the nature of patients' and families' needs. The majority can have these addressed by generalists providing a palliative care approach, with referral for specialist input required only for more complex needs. As previously discussed, a growing body of evidence demonstrates that receiving palliative care support is associated with several positive benefits. Nevertheless, access to both generalist and specialist palliative care is less than optimal. Many who would benefit from a palliative care approach are never identified, and referrals to specialist palliative care services are often delayed or poorly managed. Access is also inequitable for those with non-malignant disease. Overall, current evidence suggests that only a minority of those who need specialist palliative care, approximately 14%, ever receives it (Connor and Bermedo 2014). Further to this, projected increases in the number of annual deaths and disease burden indicate that the need for palliative care will continue to grow.

Meeting this demand is a serious challenge for healthcare systems. However, returning to the coordinated palliative care model outlined by Quill and Abernethy, health systems need to ensure that they do not simply focus on ensuring access to specialist palliative care – rather they must also consider issues of access to generalist palliative care. To date, evaluations of access to palliative care have focused primarily on patients' utilization of specialist palliative services. However, if many patients can, and do, have their palliative care needs adequately addressed by generalists, it follows that using specialty as a proxy for measuring access to palliative care systematically underestimates how much palliative care people are receiving. Indeed, future research activities should also seek to define what a palliative care approach is and develop methods for measuring and evaluating its delivery. Such exercises would allow for more informed discussion around how best to respond to the growing need for palliative care.

8.1 Timing the Introduction of Generalist and Specialist Palliative Care

Related to concerns about access to palliative care services is the issue of timing. Uncertainty about the nature or scope of palliative care can make it difficult for generalists to identify patients and families with multiple unmet needs who would benefit from a palliative care approach or specialist palliative care in a timely manner. This late identification is one of the main reasons people do not receive palliative care. Education and training has been cited as crucial for helping generalists develop the skills required to identify and address needs and the confidence to introduce a

palliative care approach or seek specialist input, thus ensuring patients have timely access to the appropriate level of support.

It is worth noting that the literature on introducing palliative care tends to reflect concerns around appropriate timing of referral to specialist services. This development is understandable as referrals to specialist palliative care late in the disease trajectory are common and can have serious consequences for patients, families, and healthcare professionals including perceived poor coordination of care, unexpected death, and lower satisfaction with palliative care services (Gardiner et al. 2012). Hui et al. (2012) found the median interval between referral to specialist palliative care and death in patients with advanced cancer was 42 days. Delays can be significantly longer for patients with a non-malignant disease, as demonstrated by Bakitas et al.'s (2013) chart review of access to specialist services among a cohort of patients with advanced heart failure which reported a median time between consultation and death of only 21 days. These delays in referral to specialist services are often attributed to difficulties with prognostication and predicting disease trajectory, particularly for those with a diagnosis other than cancer.

Several tools have been developed to help generalists identify patients with palliative care needs. Some use prognostic estimates and clinical indicators to gauge when palliative care should be introduced. One example is the Gold Standards Framework Prognostic Indicator Guidance (GSF), a tool originally developed to improve quality of care for patients near the end-of-life. The GSF uses multidimensional criteria to assess need including the "surprise question" (*Would you be surprised if this person dies within the next 6–12 months?*), if they voice preference for comfort care only and clinical indicators relevant to the patient's diagnosis (Department of Health 2008). Alternatively, some tools, such as the Supportive and Palliative Care Indicators Tool (SPICT), focus on helping generalists identify patients who are *at risk* of deterioration or dying (Highet et al. 2014) for palliative care needs assessment and future care planning. The SPICT includes six general indicators suggesting increasing need or deteriorating health status and other indicators of advanced disease, depending on the patient's diagnosis. The SPICT also advises on assessment and review of current and future care needs, including considering referral to specialist palliative care. Like the GSF, the SPICT may be used in all adult patients with life-limiting conditions.

9 Conclusion

It is essential that policy makers, service providers, and service users all recognize that the provision of palliative care is the responsibility of the whole healthcare system and not just specialist providers. Patients with life-limiting or life-threatening illness must be able to engage easily with the level of expertise most appropriate to their needs regardless of care setting or diagnosis. Quality service provision is best realized when generalist and specialists work together in an integrated and coordinated way to respond to, and meet, those needs. However, worldwide, there is significant variation in the level of specialist and generalist palliative care service provision.

The success of generalist and specialist partnerships can be critically affected by lack of clarity and agreement regarding roles and responsibilities. Ideally, models of care should be developed that describe the optimal structures and processes of specialist and generalist practice so that patients and their families experience the best possible outcomes of care. To date, while palliative care has been shown to improve patient and family outcomes, research has largely focused on specific generalist or specialist interventions. As a result, the evidence base is not yet able to describe universal models of comprehensive, evidence-based palliative care that span services and settings. There are methodological and practical challenges to conducting clinical and cost-effectiveness work in palliative care, but these are not insurmountable and should not delay further study. Transferable learning from the fields of integrated care and implementation science may be of help in achieving the goal of designing

whole system approaches to care and in ensuring that palliative care is an integral part of universal healthcare provision.

Access to Palliative Care

Contents

Abstract

Access to palliative services is currently an important issue facing policy makers around the globe. Much of this discussion is centerd on the significant challenges facing the developing nations and how health care leaders are seeking to integrate high-quality palliative care. But inequality of access is also apparent within developed health care economies. This chapter addresses some of these challenges as they are experienced by those suffering from nonmalignant conditions. Using two case-studies, the chapter highlights evidence that draws attention to the ways in which people with dementia and those experiencing Chronic Obstructive Pulmonary Disorder (COPD) are often excluded from palliative provision.

1 Introduction

The World Health Organization now regards access to palliative and supportive care at the end of life as a human rights (World Health Organization 2014). While much has happened in policy terms to facilitate the development of such services, particularly in developed nations, the reality for many means that they will experience an end of life where access to palliative care is

denied (Brennan 2007). Evidence from the UK suggests that every year over 100,000 people who demonstrate high levels of palliative need will die without the benefit of such care, and poor access continues to be experienced by particular groups of patients via persistent inequalities (Dixon et al. 2015). In the past, inequity has been demonstrated as a result of socioeconomic status (Lewis et al. 2011), while others have noted inequality of access to palliative care on the grounds of sexual orientation (Harding et al. 2012) and age (Gardiner et al. 2013). However, a key theme of much of the literature relating to inequality of access to palliative care focuses on the importance of the patient's condition. The experience of cancer patients has for some time, at least within developed healthcare systems, continually demonstrated elevated palliative service usage and improved outcomes for those diagnosed with a form of cancer (Boland and Johnson 2013). In contrast, nonmalignant conditions have been the subject of relatively slow progress and poor access. For example, US citizens living with nonmalignant chronic lung disease are less likely to access palliative services (Brown et al. 2016). Similarly, people suffering from heart failure also demonstrate poor access to palliative care (Gadoud et al. 2013). Readers of this book will be well aware of what we mean when talking about such care, but how this is accessed or indeed denied and what shape or form palliative care takes is not so clear cut. This chapter will explore the literature which centers upon access to palliative care. It will explore what we mean by access via the more contested notion of transition. Furthermore, the chapter will look at inequity of access across the globe and across particular condition groups. Using two case "exemplars," the chapter addresses sources of barriers to access and attempts to provide a way forward in policy and practice fields.

2 Palliative Care: Access to What?

Across the globe, a great variety of forms of palliative care exists. Wiencek and Coyne (2014) point to four models: ambulatory; home-based; hospital-based specialist units; hospital-based specialist services (consultation). A global perspective of the scope and reach of palliative care services suggests that, although patchy, the pervasiveness of such provisions is increasing (Lynch et al. 2013). Add to this the growing potential for palliative and supportive care to be provided in residential and nursing home facilities for older people and a fairly complex web of services and types of provision exists. Measuring access to specialist palliative care services, such as those listed, provides a relatively straightforward means to exploring patterns of service usage across and within populations. In doing so, we are able to observe patterns of service usage, inequalities, and unmet need. But measuring how patients access palliative *regimes* of care is less straightforward. Kaufman (2015) talks of the process of crossing a threshold at the end of life when care turns from a curative form to palliative, readers will also be familiar with wedge and wave models of shifting approaches to the care of patients. The notion of transition has emerged as an important notion in the process of these changes in the emphasis of care and treatment. Two reviews looking at the nature of transition from curative to palliative care have been undertaken in the past (Gardiner et al. 2011; Marsella 2009). Both reviews point to the importance of understanding the nature of transition, partly as a result of the relationship between the introduction of palliative care and outcomes for patients. But addressing transition is important because of the increasing focus upon inequality of access and the attention that this brings to the investigation of barriers to palliative care experiences. Those writing about transition have noted that it is often not clear cut, particularly in the absence of a specific referral or physical admission to a specialist service. In other words, transitions can often occur while patients remain within the same place of care, such as a hospital or ward setting, often under the treatment of the same team of clinicians. This is partly an outcome of more recent approaches to palliative care, which firstly may be undertaken by generalist staff, but secondly as a result of the use of curative approaches which coexist with palliative care. The timing of

transition is of critical concern to those undertaking research in the field, but more importantly to the medical and nursing staff providing care, patients, and their families. One of the key challenges remains the culture and environment of care where transitions are experienced. Kaufman (2015) in her classic ethnography of end of life care on the United States points to this as one of the key challenges in making the transition, and something we will return to later in this chapter. But equally challenging remains the issue of prognostication. As increasingly experience death as a result of noncommunicable disease and long-term chronic conditions, the nature of end of life trajectories has shifted toward protracted and unpredictable clinical states thee ways in which medicine can prognosticate effectively (Murray et al. 2005).

Notwithstanding the problems associated with observing and measuring its prevalence, there remains a great deal of evidence to suggest that there exists inequality in relation to the experience of accessing services and making the transition to palliative and supportive care is problematic for some groups of people. This chapter will use two case exemplars to highlight such inequality.

2.1 Case Exemplar One: Dementia and Failure to Make Transition

There are almost 40 million people living with dementia across the world (Prince et al. 2013). Recent global policy has placed emphasis upon early diagnosis, better information and support, as well as enhanced end-of-life care throughout the condition trajectory. Indeed the improvement of access to palliative care and high quality end of life care has become an important policy objective across the globe. Palliative care and improved end of life experiences for people with dementia is emerging as a critical area of concern and debate, with national dementia strategies across the globe focusing attention upon the issue of access (Nakanishi et al. 2015).

The evidence to support claims that people with dementia do not access palliative and supportive care comes from a range of sources. For a long time, access to hospices was more or less denied to people with dementia, with less than 1% of the hospice population of Europe being diagnosed with a neurological condition (Sampson 2010). This failure to access a key front line palliative care service having implications for referral to other specialist end of life services. Recent research undertaken in the UK would further support these observations. Based upon census research carried out within two large hospitals, identifying the range and prevalence of symptoms which might indicate palliative needs (Gardiner et al. 2013), people with dementia were identified as experiencing heightened levels of physical burden (pain, fatigue, poor function) and psychological burden (anxiety, depression, mood) when compared to other patient groups, such as those with cancer. Despite this heightened degree of burden, people with dementia were less likely to have made the transition to palliative forms of care, especially in the form of a referral to specialist services (Ryan et al. 2013). Furthermore, a number of reviews have highlighted the lack of transition to more palliative forms of care for people with dementia at the end of life, with the continued use of regimes of care which favor an aggressive approach. Paradoxically, it is claimed that throughout their illness people with dementia often receive "*too little*" care, whereas end of life care is often characterized by "*too much*" (Small et al. 2007). A failure to access palliative care for people with dementia has, it might be argued, led to poor quality end of life experiences. In the past, a tendency to rely upon aggressive forms of medical care (feeding tubes for example) have been emphasized, denying people with dementia the opportunity for more palliative approaches at the end of life, with little or no evidence suggesting this form of care contributed to improved outcome (Sampson et al. 2009). More recently evidence from the Netherlands has highlighted similar unequal access to palliative approaches to end of life care. For a long time, the systematic use of antibiotics has been viewed as a means of extending life, often at the cost of quality of life. Hendriks et al. (2015) identified increased prevalence their use among people with dementia, when compared to cancer patients. There is also

continued evidence that enteral tube feeding is more prevalent amongst hospital patients with dementia at the end of life, a practice which might be considered contrary to palliative principles.

2.2 Case Exemplar Two: Chronic Obstructive Pulmonary Disease (COPD)

COPD is the umbrella term given to represent a range of chronic lung disease, including emphysema, chronic bronchitis, and chronic asthma. It is characterized by increasing chronic breathlessness. There are estimated to be around 380 million people living with COPD worldwide (Adeloye et al. 2015). As is the case with dementia, the end of life care experience for people with COPD continues to be blighted by unequal access to palliative services. Furthermore, there is evidence that patients with COPD often fail to make the transition to palliative regimes of care, especially compared to other conditions. A recent major US study highlighted a lack of access to palliative care for patients with COPD after hospitalization (Rush et al. 2017), noting unfavorable comparisons with patients with cancer. Szekendi et al. (2016), also reporting research carried out in the US, observed high levels of unmet palliative care need and identified COPD patients as being less likely to be referred to such services. Furthermore, Ahmadi et al. (2015) identified a reduced proportion of patients with COPD receiving a referral to palliative services (including home-based), increased hospital admission, and few opportunities for end of life discussions.

As is the case in dementia, there is also evidence that, use of specialist services aside, people with COPD also fail to make appropriate transitions to high quality end of life care when compared to other patient groups. The Ahmadi et al. study (2015) is also interesting in this respect. The team was able to collect data on symptoms at the end of life, noting higher levels of uncontrolled breathlessness, nausea, and confusion at the end of life for COPD patients, when compared with cancer patients at a similar point in the disease trajectory. Invasive procedures are also likely to persist within the end stage COPD population, with mechanical ventilation being difficult to withdraw once established and indicating a high level of burden on the patient and family (Hajizadeh et al. 2015). One important element of palliative and end of life care is to have open discussions with those caring for the person. A great deal of the literature within the field of COPD and palliative care relates to this issue, with some evidence that the opportunities for discussion are limited for COPD patients, again when compared to those with cancer (Rocker et al. 2008).

3 Explanations for Inequity of Access

The reasons for this inequality of access for people experiencing dementia and or COPD and reluctance for providers to facilitate transition are now well established and barriers to palliative care for people with dementia are known to take a number of forms.

3.1 Prognostication

Note has already been made within this chapter about the nature of the end of life experience for people suffering from long-term chronic conditions. The implication for transitions to palliative forms of care is centered on the timing of changes in treatment or indeed the decisions to refer to a specialist service. Some argue that the failure to prognosticate effectively is, however, a product of a culture of care which is more readily focused upon life sustaining treatment as opposed to palliative care. Coupled with a rise in the use of life sustaining technologies, prognostication is increasingly delayed (Seymour and Gott 2011). Nonetheless, prognostication is difficult within the context of dementia and several authors have therefore chosen to cite this issue as a particular reason for this failure (Birch and Draper 2008). Typically a person with dementia will live for around 5 years after diagnosis, but this varies and the trajectory of experience is unique to each person. This is made more complex when the

person experiences comorbidities or death as a result of an additional condition (Lee and Chodosh 2009). Similarly, prognostication in the context of COPD is problematic, leading to challenges in transition to palliative forms of care.

Despite the challenges in the field of prognostication in dementia, some attempts have been made to identify markers which might be indicative of the last 6 months of life. Van der Steen et al. (2014) argue that professionals should be able to use clinical judgement alongside such tools to help in the process. Importantly, they add that communication with the family on the issue of prognostication is critical to help in the preparation of shared decisions making. Efforts to develop prognostication tools within the field of COPD have similarly taken place. The PRO-LONG tool uses 11 indicators to assess mortality postdischarge and has shown promise within early field trials (Duenk et al. 2017).

3.2 End of Life or Advance Care Planning Discussions

Open discussion about end of life treatment is thought to enhance decision making and provide preferential regimes of care in the late stage chronic conditions. The most prominent form of discussion is termed Advance Care Planning (ACP), defined by the World Health Organization as: *"planning in advance for decisions that may have to be made prior to incapability or at the end of life. People may choose to do this planning formally, by means of advance directives, or informally, through discussions with family members, friends and health care and social service providers, or a combination of both methods"* (World Health Organization 2004). ACP is felt to improve end of life outcomes for people experiencing a range of conditions (Brinkman-Stoppelenburg et al. 2014). In both dementia and COPD contexts, however, the prevalence of active engagement with ACP is thought to be low (Lovell and Yates 2014) and a number of explanations have been put forward. In the context of dementia, it is thought that the idea of planning for the end of one's life is both actively and passively avoided. A recent review of the qualitative literature on the subject suggests a number of explanations which alongside avoidance of the matter include: lack of support from services; carer burden; living for today; a lack of confidence in professionals being able to deliver choice (Ryan 2017). In the case of COPD, a similar line of exploration has taken place. Patel et al. (2012) note that patients lack an awareness of ACP options, they do not have well established lines of communication with professionals, fear of abandonment, and an assumption that conversations will occur when they are needed. Additionally, the authors note delays in diagnosis and concerns among physicians that initiating ACP will take away the patient's hope.

It is difficult to assess the significance of the absence of ACP on the quality of end of life care or transition to preferred forms of palliative care. Nonetheless some suggestions are provided to help facilitate the ACP process within both a dementia and COPD context. Ryan suggests that the skills within professional groups need to be enhanced so that initiation of future planning conversations may take place (Ryan 2017). Furthermore, the importance of sharing the responsibility of planning is stressed to help lift the burden of responsibility from the individual and family. Patel et al. (2012) also stress the skills involved are complex and subtle, pointing to the importance of appropriate timing of the conversation and relaxed environment. They also highlight the evidence relating to decisions aids as a potential route to improved prevalence of ACP within the COPD population.

3.3 Organizations and Cultural Factors

Kaufman's classic ethnography of US hospitals focuses very much on the environmental and cultural features of institutions and professional groups in their influence on end of life care (Kaufman 2015). This study is important as it helps us to gain insight into the values, concerns, financial, and policy drivers which shape decision making. She notes a great deal, but among these valuable insights, Kaufman highlights the ways in which

discussion about death is delayed, partly as a product of the medical profession's attention to life sustaining treatments and a failure to see it as a possibility. The literature around the failure of people with dementia or COPD to gain access to palliative care via transitions or the accessing of services rings true here. Within both conditions, there is a reluctance to view end of life as a possibility. In a paper which engaged the views of medical and nursing staff about access to palliative care services for people with dementia, the notion of candidacy is used (Ryan et al. 2012). This describes the idea that dementia is not viewed as a cause of death and as such people with the condition are not viewed as candidates for palliative services.

The nature of the exploration of end of life care for people with dementia in the book by Small et al. (2007) chimes also with Kaufman's work. This study focuses on what is called the distinction between the *"life world"* of the person, their sense of self, wishes, and preferences and the *"system world"* a culture of care which denies preference, choice, and autonomy, consequently leading to overuse of technology and life sustaining interventions. Organizational issues have also been identified as a barrier to the accessing of palliative services, particularly in the form of generalist provision in the field of COPD. Hynes et al. (2015) working in acute environments in Ireland draw attention to the episodic nature of hospital care which focus on the short term management of exacerbations. This, they argue, is at odds with a long-term approach to understanding the physical, emotional, and spiritual challenges faced by people with long-term conditions such as COPD. Specifically, they state that rather than a person-centered approach, acute environments address these challenges with a "disease-centered" focus.

3.4 Systems and Resources

Many have noted the problems faced by people with dementia or COPD in relation to access to palliative services or end of life care as a result of systemic failings or resource limitations. Recent research in the United States demonstrates relatively poor access to hospice care for patients diagnosed with COPD and neurodegenerative disorders when compared with cancer patients (Riggs et al. 2016). Problems in gaining access to services such as hospices in the field of COPD are also noted. Vermlyn et al. (2015) describe access problems in the UK as a result of hospices being viewed as a resource for cancer patients. In the USA, the issue of access to hospice care is made more complex by Medicare regulations, with eligibility restricted to those in the last 6 months of life and who forgo curative treatment resourced via Medicare (Part A) funding. Given the problems associated with prognostication for people with COPD or dementia, it is not difficult to see how these access problems may persist. Referral and communication issues of a systemic nature have also been shown to restrict access for particular groups of patients, including those diagnosed with dementia. Illife et al. (2013) have conducted pan-European research to highlight the problems associated with a failure of community-based medical practitioners in identifying people with dementia as candidates for specialist services, noting that in some cases fewer than one in five were recorded on palliative care registers.

Palliative provision outside of specialist services is often undertaken by generalist staff working either in community- or hospital-based settings. For some time now, the challenges in generalist staff being able to provide palliative forms of care have been noted, especially in acute settings. Gott et al. (2012) note in their work in hospitals that resources were often identified as the reason that generalist staff were unable to provide what they saw as high quality palliative care. Specific examples from the field of COPD highlight this issue. During fieldwork, Hynes et al. (2015) note that COPD specialist nurses in Ireland were being expected to carry significantly higher workloads when compare to specialist palliative practitioners within the same organization. Ryan et al. (2012) note that specialist palliative care providers often viewed eligibility for access to hospices as being limited to those diagnosed with cancer. In particular, they report already stretched resources and limited capacity in

dealing with the specific needs of people with dementia as a means of rationing access.

4 Implications for Future Policy and Practice

This chapter has highlighted the inequity which is evident in accessing palliative care for two specific populations of patients: people with dementia and those diagnosed with COPD. This is not to say that inequality does not occur for other patient populations or indeed along other lines, such as socioeconomic or between developed and developing nations. Rather the two case studies used here exemplify condition specific inequality and the sources of inequity. A number of potential explanations have been offered and it now may be pertinent to offer a way forward. Firstly, specific guidance should be made available where problems of access or palliative care practice deficits are identified. This has already occurred in the case of dementia to some extent. The EAPC White Paper on optimal care for older people with dementia has helped to clarify consensus on this issue in a European context (van der Steen et al. 2014). A number of key features were identified, including access to palliative care, promotion of advance care planning, avoidance of overly aggressive approaches at the end of life, and education and training for key health and social care professionals. Guidelines do, however, need to be developed to meet the needs of national populations and embedded within organizational practices and cultures of care. Secondly, a critical perspective around the relative importance placed upon prognostication is required. It is well established that prognostication is challenging within the context of some conditions. But prognostication is only relevant to end of life decision making. Palliation is much broader than end of life care and needs to be embedded within pathways of care from a much earlier time point. Placing less emphasis on prognostication and more on the introduction of the palliative principles of care would allow for the introduction of such approaches in a timely and appropriate manner and would have the benefit of improving end of life experiences. Thirdly, it is clear that established methodology around ACP is failing populations of people who suffer from long-term chronic conditions. Work is required in enabling more informal approaches to ACP to be established, where a focus on relational practices and collective responsibilities are central themes. Health and social care professionals need to be provided with the capacity (skills and resources) to be able to introduce the notion of ACP at a timely manner for all.

5 Conclusion

This chapter has drawn attention to some of the key challenges facing policy makers and practitioners in addressing some of the inequalities in palliative care provision. Using two distinct case studies, the chapter demonstrates that while access to palliative care in developed countries remains relatively unproblematic for some patients, especially those with malignant disorders, the route for others is more fraught. A number of explanations are considered and these have implications for professional groupings, policy makers, organizational leaders, and legislative bodies. Evidence surrounding the issue of inequality in the developed world remains insubstantial compared to those global concerns about access to palliative care for all. If access for all is to be realized and the goal of palliative care as a human right is to be achieved, then there remains a great deal of work to be done.

Interprofessional Practice in Palliative Care

32

Marion Jones and Jill Thistlethwaite

Contents

Abstract

Interprofessional practice informed by and developed through interprofessional education is critical for working within modern healthcare contexts and particularly within healthcare teams. Palliative care is a complex area of healthcare delivery, and interprofessional practice is a way of working together learning from, with, and about other health professionals. This chapter

explores the terminology used within the interprofessional working and learning contexts. The challenges, opportunities, and barriers to interprofessional practice are explored in relation to what they are and how they can be constructive instead of creating conflict. One model of interprofessional practice is discussed, and the stages health professionals need to work through are outlined. The importance of interprofessional teamwork and collaborative practice is recognized as being critical to develop in settings such as palliative care where the focus is on the patient and their family.

1 Introduction

Palliative care is typically provided by a range of healthcare professionals, frequently with a core multidisciplinary team (MDT) or primary healthcare team (if the patient is being cared for at home). Members of the core team are also likely to collaborate with other health- and social care professionals for specific purposes such as for advice about particular aspects of management, financial issues, or family support. Palliative care is a complex area of health care delivery. It may be ethically challenging and, in our experience, for optimal outcomes requires values-based and patient-centered approaches. In this chapter, we consider the nature of this teamwork and collaborative practice through the lens of interprofessionality. We discuss the definitions of concepts related to interprofessional practice (IPP) and explore the rationale for IPP while acknowledging the challenges. Conflict may arise when there is diversity among team members in relation to personal, professional, and/or organizational values. Such conflicts may be prevented or they may need to be addressed, through a process of negotiation to reach consensus. Indeed conflict may be ultimately constructive if managed well, whereas avoiding conflict at all costs may be deleterious (Tekleab et al. 2009). One model to develop interprofessional practice is outlined and rationalized as being a process of cultural change as well as interprofessional learning and working.

There are multiple definitions being used locally and globally, and this can be confusing. In the following section, we discuss the definitions we use in this chapter.

2 Definitions

2.1 Interprofessional Practice

Interprofessional practice (IPP) implies that boundaries and territories are broken down, and the professionals work together with intent, mutual respect, commitment, and a common objective (Jones 2000). IPP is fostered through interprofessional education (IPE) which is "when two or more professions learn from, with and about each other to improve collaboration and the quality of care" (CAIPE 2002). IPP breaks through the boundaries of role specialization of a discipline. Ideally, IPP should involve shared education and practice opportunities that assist health professionals to work together more effectively with the interests of the clients being the focus from admission to discharge from care or death (though support will carry on for carers and the family). Therefore the word "interprofessional" when applied to practice implies a way of working together above and beyond a group of professionals interacting with the same patient and family.

The interest in interprofessional practice in healthcare has increased, and, over many years, "interprofessional" has become a key word in practice development. In 2009, the World Health Organization's (WHO) global consultation on primary healthcare and the global health agenda listed two objectives as building effective partnerships and fostering interprofessional collaboration (World Health Organization 2009). It has been a focus of the WHO's health plans and is the subject of growing research globally. In addition, there has been the development of worldwide networks devoted to IPE and IPP, for example, in the United Kingdom, Sweden, Canada, Australia, New Zealand, the United States, and more

recently in Sub-Saharan Africa, Japan, India, and South America.

One might talk of a semantic debate with the terms of interprofessional, multiprofessional, multidisciplinary, and interdisciplinary carrying a variety of meanings depending on the perception of the interpreter within a specific context. This reinforces that all perceptions could be thought of as socially constructed. In addition, the prefixes "multi" and "inter" may be considered as value-laden. They focus the interpretation on the ways that team members predominantly interact. Multiprofessional has been defined as two or more professionals working side by side (in parallel), with little interaction, as "multi" suggests "many" (Thistlethwaite 2012a). In contrast, "inter" implies "between," "among," and "mutually," leading to interprofessional approaches (with the global consensus now being to spell the word without the hyphen) with the nuances of cooperation, coordination, and frequent communication.

In order to clarify further the concepts used in practice and the literature, and to distinguish between terms that are often used synonymously, the following additional terms are outlined to clarify how language can be confusing as well as helpful:

Multidisciplinary implies that more than one profession/discipline may be involved in the particular scenario being described, but discipline-specific solutions evolve which denotes that working is primarily in parallel and health professionals only come together when there is a problem to solve.

Interdisciplinary pertains to a situation or group between more than one branch of learning and that members meet to look at areas of common interest and knowledge (Jones 2000). Coyle et al. (2011) believed that when inter- was used, confusion existed from working together to working separately. Boon et al. (2004) tried to overcome this and had seven different team-oriented models ranging from parallel to integrative. The interprofessional approach to patient care involves practitioners from different professional backgrounds delivering services and coordinating care programs to achieve different and often disparate needs. Ideally goals are set collaboratively, including with the patient, through consensual decision-making, and this results in an individualized care plan, which may be delivered by one or more professionals. This level of collaborative practice may be difficult to achieve but does maximize the value of shared expertise.

2.2 Interprofessional

Practicing interprofessionally means crossing occupational boundaries – setting aside our own professional view of healthcare as being the only right one and actively listening to what our colleagues have to say (Jones 2000). Interprofessional practice needs to involve the patient, family, and health professionals in planning the care together with a shared vision and direction, taking into consideration that it is critical to consider the cultural, social, economic, and personal needs and preferences of the patient, carers, and family.

2.3 Interprofessionality

D'Amour and Oandasan (2005, p. 9) defined interprofessionality as "the development of a cohesive practice between professionals from different disciplines." It may also be thought of as being characterized by "the transformation in practice which may result from combining and blending specialist knowledge and expertise" (Brooks and Thistlethwaite 2012, p. 405). Brooks and Thistlethwaite (2012) have asked some critical questions about the transformation in identity that may be associated with working and learning across professional boundaries, such as in the context of palliative care, and the challenges due to the synergy and possible disjunctions between multiple professional identities. The term "interprofessionalism" also appears in the literature and has all the nuances and controversies associated with professionalism (Thistlethwaite et al. 2016). The US-based Interprofessional

Education Collaborative Expert Panel (IPEC) defines "interprofessional professionalism" as a "consistent demonstration of core values evidenced by professionals working together, aspiring to and wisely applying principles of altruism, excellence, caring, ethics, respect, communication, [and] accountability to achieve optimal health and wellness in individuals and communities" (IPEC 2011, p. 17). Interprofessional practice is integral to the health reform changes worldwide, and those involved in this approach to practice have joint goals and break down their professional boundaries to allow for interactive learning between professions to take place (Jones 2000).

Recognizing opportunities rather than identifying barriers is the thinking that is required to move past the traditional ways of working and how the preconceived ideas of professions and professionals influence the culture of teams and the language used. Curriculum structures for continuing education are influenced by staff attitudes, administrative structures, and lack of resources which in turn impact on palliative care and practice (Jones 2000). When health professionals successfully work together from assessment through to intervention, they have a shared goal toward the patient's best interests.

Interprofessional collaboration is the process of developing and maintaining effective interprofessional working relationships with learners, practitioners, patients/clients/families, and communities to enable optimal health outcomes (CIHC 2010).

2.4 Discipline

Grossman and Hooten (1993) talk of the broad aims of a discipline being to specify its proper place in society along with defining the knowledge framework for practice. They expand that by saying a professional discipline must explicate its historical, social, philosophical, and learning traditions in order to understand its connectedness to others in the field of epistemology and to provide a meaningful context for its method of inquiry and its content areas for practice (p. 867).

2.5 Discipline Culture

Each discipline has a specific culture or health profession. Culture means different things to different people and is seen as a set of definitions of reality held in common by a group of individuals who share a distinctive way of life (Strasen 1992). Within this view are the crucial elements of shared values, beliefs, expectations, attitudes, assumptions, norms, and social relevancies which are often not explicit, discussed, or recognized as they are lived and internalized as norms that provide social signposts for behavior (Jones 1993). A health professional's discipline will therefore have shared practices, beliefs, knowledge, language, and resources which are specific to them along with how they influence and relate to other health professionals (Sohier 1992; Jones 1993).

Therefore understanding the professional culture provides direction, interpretation and meaning, energy for action, and the map for "how we do things around here." Culture in the context of interprofessional practice relates to each discipline and what each one brings to a specific team. This in turn could surface the cultural gaps that may be perceived as conflict or just being difficult. This has the potential to influence interprofessional practice and the actual professional development that occurs within the discipline and the team itself. How disciplines influence interprofessional practice is what is important to consider.

3 Barriers to Interprofessional Practice

There are a number of barriers evident that prevent interprofessional relationships developing and include "problematic power dynamics, poor communication patterns, lack of understanding of one's own and others' roles and responsibilities and conflicts due to varied approaches to patient care" (Zwarenstein et al. 2009, p. 2).

Gilbert (2005, p. 90) overviewed the barriers to working and learning interprofessionally and

emphasizes one of the barriers as how "the use of language varies considerably across social groups – the language used by health disciplines is no exception." He goes on to explore how disciplines have developed a culture of communication including gender-related differences which then mix with institutional dialogue and the professional associations' way of working. Complexity reigns and these aspects need to be made very transparent in the development of interprofessional working and learning.

Alongside the use of language, specific health professional barriers with the differences evident inhibit an interprofessional curriculum being developed. Over time a curriculum can change; however to work together to develop interprofessional learning and working is what helps all health professions take ownership of the process. Then there are the scheduling issues both from an individual and institutional perspective including no time to develop interprofessionally, lack of confidence to change, lack of funding and resources to change, and lack of knowledge to name a few.

Health professional regulations are developed in isolation from each other with separate Councils and Boards, and this in itself prevents IPE and IPP being transparent in the competencies required for practice. In some countries, evidence of integration and working with other health professionals is evident in codes of practice. Examples include having the terms integration, team development, interdisciplinary, and occasionally interprofessional.

Therefore institutional barriers can be within legislation, registration, and accreditation processes. However Gilbert (2005, p. 98) recognizes that there "are clearly clinical (or care) settings for which it is highly desirable to have three or more professionals engaged in teaching about that setting," for example, palliative care. Oishi and Murtagh (2014) emphasize that fragmentation of healthcare and delayed referrals to palliative care result in some patients not receiving the palliative care when they need it.

4 Team Development

Despite the importance of team development and interprofessional practice, many health professionals continue to practice and educate disciplines in isolation. The challenge for palliative care health professionals is to examine where and how they value skills in relation to team decision-making, customer service, and quality of care within an interprofessional framework. Interprofessional collaboration is the message being given in all practice settings, and palliative care settings are no exception.

Working effectively together is facilitated by health professionals understanding each other's disciplines, identities, and diversities and how these impact on day-to-day practice to work together (Jones 2000). It is also important to consider that breakdowns in communication can jeopardize the team development and individual practice itself recognizing the person who is disadvantaged is the patient. Interprofessional practice demands collaboration and organizational structures to support it (Walby et al. 1994; Soothill et al. 1995). It is well documented that organizational efficiency is more vulnerable if interprofessional communication is not effective (Henry and LeClair 1987; Farley 1989; Shortell and Kaluzny 1994; Clinton and Scheiwe 1995; Jones 2000). Literature from the 1990s is purposely used to emphasize that interprofessional practice has long been considered as best practice although many areas of practice still struggle with it holding on tightly to only their disciplined ways of working, thinking they will lose their identity (Jones 2000). Instead to work interprofessionally, health professionals need to identify explicitly disciplined ways of learning and in doing so actually strengthen their discipline.

Given the above perspectives, it is important to examine how any diversity of professional discipline may impact on interprofessional practice, along with recognizing that culture encompasses practice, beliefs, knowledge, language, and resources all of which are relevant to health professional practice and the strategic directions in healthcare (Jones 2000). The main consideration

here is the patient and the patient outcome, not the discipline.

Some may ask what is new as there have always been teams in healthcare. However, how the concept of team is interpreted is important for setting the context for interprofessional practice. Each profession in finding its own identity appears to have become territorial in setting the boundaries of what makes it a unique group. This, in turn, can set up power and authority interplay in the process of legitimating the separate entity of the specific profession (Jones 2000).

Alongside this, the leaders of interprofessional practice within a supportive infrastructure provide the context for practice to be strengthened (Jones 2000). Therefore there needs to be a balance between developing the team, each discipline or health profession, and interprofessional learning and working.

As mentioned earlier, Boon et al. (2004) identified a range of team development from parallel to integrative with the process of growing to interprofessional working developing through seven stages. From parallel to consultative teams, Boon et al. believed these were part of the biomedical model of health; whereas the development progressed to collaborative, coordinated, and multidisciplinary, the emphasis increases to patient-centered care models. Finally with the development to interdisciplinary and integrative models, changes occur in philosophical underpinnings, structure, process, and outcomes. The important part of the development was that the practice model chosen depended on the patient needs not the health professionals (Coyle et al. 2011).

5 Types of Teamwork and Collaboration

Interprofessional practice is not solely about "teamwork," and in this section we consider the nature of teamwork, the relationship between teamwork and wider collaborative practice, and the implications for palliative care.

There is an extensive literature on teamwork spanning many disciplines such as business, organization theory, sociology, psychology, and the health professions. For example, "*a team is a set of interpersonal relationships structured to achieve established goals*" (Johnson and Johnson 2006 p. 5, p. 595), while the following adds in values from a business perspective: "*Teamwork represents a set of values that encourage behaviors such as listening and constructively responding to points of view expressed by others, giving others the benefit of the doubt, providing support to those who need it, and recognizing the interests and achievements of others*" (Katzenbach and Smith 1993, p. 15). There is an implication here of a small number of people – the core palliative care team, for example.

A common theme of definitions of teams is of such a small number of people with a common purpose. Indeed, research indicates that optimal team functioning is dependent on common goal settings, together with regular meetings and reflection on performance. For example, a study from the UK found that health professionals, who had identified themselves as working in teams, reported less job satisfaction and more burnout if they did not meet frequently (or at all) to review performance in relation to their goals. There was also a greater probability of patient safety issues (Dawson et al. 2007). Reeves et al. (2010), from their extensive review of the teamwork literature, and through empirical research in healthcare settings, also conclude that for teams to be effective they need to have clear team goals, shared commitment, role clarity, interdependence, and integration between members. Additional attributes of functional healthcare teams include democratic approaches; agreement on ground rules for working together; active participation by all members; mutual role understanding; good communication; the development of joint protocols, training, and work practices; and good performance management (West and Slater 1996; Hammick et al. 2009; Reeves et al. 2010). In addition, emphasizing the need for a workable number of members, teams need to have a single shared work location and regular time to develop team working away from practice (Reeves et al. 2010).

To achieve a common good or aim, a team has to have a specific structure and organization

process in order to present a cooperative accountable outcome. Manion et al. (1996) differentiate between a working group and a team in the responsibility, authority, and accountability of each. In order to accomplish a task as a successful team, it is important to recognize that the different skills, knowledge, and expertise each team member brings needs to be combined to meet the patient needs: this translates into interprofessional working. This should be achieved through an agreed formal decision-making process and a valuing of differences that is seen as a collective strength that develops trust and confidence that results in a highly productive, effective, creative group of people (Ovretveit 1995).

6 Collaborative Practice in Action

In healthcare practice, however, many health and social care professionals are not together in bounded "official" teams even though they may interact at times with the same patients, families, and carers. The palliative care team, whose core membership may include nurses, a palliative care specialist, a cancer specialist, a physiotherapist, and a psychologist, may also work in collaboration with others including social workers, occupational therapists, and pharmacists. There are also likely to be hierarchical lines of authority within each profession together with varying levels of professional autonomy. Multi- rather than interprofessional collaboration may mean that health professionals interact individually with patients, setting their own goals and management plans without consultation with others who are involved – a situation that is not helped if patient records are not shared (even with the patient) (Thistlethwaite 2012a). Collaborative working is a skill that needs to be learnt and involves negotiation and often conflict resolution. As mentioned earlier health and social care professionals work within strict boundaries set by their professional bodies, and this can be frustrating for others who prefer greater flexibility in patient care. Having interprofessional practice within their codes of practice could loosen these boundaries and provide a more integrated approach to care.

While we have given one definition of collaboration, this word is yet another term with multiple meanings. Another useful definition is that of Thomson et al. (2009), formulated following their review of the literature and through interviews with stakeholders:

> Collaboration is a process in which autonomous or semi-autonomous actors interact through formal and informal negotiation, jointly creating rules and structures governing their relationships and ways to act or decide on the issues that brought them together; it is a process involving shared norms and mutually beneficial interactions. (p. 25)

The World Health Organization has stated that there is now sufficient evidence to show that collaborative practice enhances health services and improves health outcomes, particularly for patients with chronic diseases (WHO 2010).

Reeves et al. (2010) have conceptualized interprofessional relationships as a series of widening circles. Their work was based on a critical assessment of published works relating to interprofessional practice in a variety of settings and national contexts. In the smallest circle is interprofessional teamwork defined as "the most 'focused' of health professional practice with high levels of interdependence, integration and shared responsibility" (p. 44). Collaboration, coordination, and networking then ripple out as more people and interactions become involved. Collaboration is therefore envisaged as a looser form of IPP – health professionals work together but with reduced levels of interdependence, integration, and shared responsibility. While a healthcare team may involve three to ten people, collaboration assumes many more than this. Coordination involves a shared identity, but integration and interdependence are much less important, while networking may relate to virtual working with asynchronous meetings across wider distances and many institutions.

This work of Reeves et al. (2010) has been expanded more recently through a further critical review on interprofessional interventions culminating in the development of the InterProfessional Activity Classification Tool (InterPACT) (Xyrichis et al. 2017). New subcategories are

added to the four previously defined, under collaboration, consultative collaboration and collaborative partnerships, and under coordination, coordinated collaboration, delegative coordination, and consultative coordination. Each category and subcategory is categorized by the relative importance of the following six dimensions: (1) shared commitment; (2) shared team identity; (3) clear goals; (4) clear team roles and responsibilities; (5) interdependence between team members; and (6) integration between work practices.

How is this classification useful in relation to palliative care? By categorizing the type of interprofessional work undertaken within any given setting and the health professionals involved, it is hoped that it will be easier to evaluate performance, plan training, and compare research studies into the impact of interprofessional practice. For example, palliative care by the core team directly with involvement of the patient is teamwork with very high levels of each of the six dimensions required. Consultative collaboration, such as when a specialist is required for advice about a particular patient care problem, requires a lower level of interdependence. Networking features "networks" of clinicians who share best practice, clinical guidelines, and innovations in care across a number of organizations with little integration across work practices at the level of individual patients. Orchard et al. (2005) emphasized that the development of an interprofessional culture that supports collaborative practice is critical, and this is supported by Gilbert (2005) as well.

7 Collaborative Decision-Making

Within any MDT, including palliative care teams, members make clinical decisions informed by several factors unique to the health professionals, and the patient and family, involved. Clinical guidelines, professional and organizational rules, and national regulations help provide the infrastructure to any action, but these are interpreted in relation to the views of the clinician and patient preferences that help direct decisions. Such views and values are central to the function of the MDT (Thistlethwaite and Hawksworth 2014).

Adopting a patient-centered approach facilitates the process by which the perspective of the patient is paramount in shared decision-making. Shared decision-making is informed by collective values and the sharing of different views. It is important to ensure that the patient (and carer/family as appropriate) is regarded as part of the team. Thus, a "new" team is formed for every patient (Thistlethwaite and Hawksworth 2014).

The first step in the collaborative decision-making process is to invite and listen to the patient's perspective and experiences. The patient's needs, ideas, concerns, values, and expectations are explored using a biopsychosocial approach without solely focusing on the biomedical or reverse view (Fulford 1989). "The biopsychosocial model enables the physician to extend application of the scientific method to aspects of everyday practice and patient care previously not deemed accessible to a scientific approach" (Engel 1981, p. 102).

Of course adopting a patient-centered approach and eliciting the patient's perspective may be difficult. Impeding factors may include such factors as a professional's concept of their duty of care, organizational values based on efficiency, medical paternalism and professional hierarchies, as well as power imbalances between professional and client (Fulford 1989). The team needs to bear these factors in mind and their influence on professional decisions. The team needs to reflect, analyze, and challenge members' views within an ethos of trust and respect.

8 Dysfunctional Teams

Coming back to considering practice at the level of the palliative care team, challenges arise when teams become dysfunctional. A common problem is that team members start to work as a group of individuals with each team member identifying more with their own profession and their own professional colleagues than with their team members from other professions. Some teams manage to avoid conflict, yet working through conflict

rather than burying and ignoring it can make a team stronger and more productive. Alternatively there is the indecisive team. Prioritization of tasks becomes difficult, perhaps when workload increases or leadership changes.

Lencioni (2002) identified five common characteristics of dysfunctional teams: absence of trust, fear of conflict, lack of commitment, avoidance of accountability, and inattention to results. Trust between team members is imperative: trust is required for people to be able to work together and implies a certain level of vulnerability. Trust may be lost for many reasons: personal experience with an individual or members of a particular profession, lack of confidentiality in relation to team or personal conversations, dislike between team members, etc. Lack of trust may also be due to team members not fully understanding each other's roles and responsibilities, what each has been trained to do and is competent at doing. Regular team meetings and discussion of values, patient cases, near misses, and significant events are necessary to build and maintain trust (Thistlethwaite 2012a). Self-awareness is required to diagnose that the team is dysfunctioning and needs help. Team members always need to remind themselves that the focus is on improving quality of life for the patient and their families.

9 Team Conflict

Dysfunction may lead to conflict within the team, while unacknowledged and unattended conflict may lead to dysfunction. Conflict, however, does not necessarily have to be a negative experience with a negative outcome. Conflict has been described as occurring when "behaviour is intended to obstruct the achievement of some other person's goals" (NHS Institution for Innovation and Improvement 2010, p. 297). It is a feature of human life and thus of healthcare. It may take place in teams, between teams, between teams and their organization, and, indeed, between patients and health professionals. One of the core underpinnings of working in palliative care is that health professionals will focus on total patient care. Like a family, teams do have conflict at times and is probably inevitable. However the key to resolution is that it will be effectively managed. Conflict in itself can be a positive and healthy process in that there will always be differences, and the diversity can become a strength of a high functioning team. Competencies required for interprofessional practice include those relating to conflict resolution, through awareness, negotiation, and compromise (see, e.g., CIHC 2010; IPEC 2011).

Reasons why conflict occurs include poor and miscommunication, personal dislikes, lack of understanding of roles and responsibilities of team members, poor leadership, hierarchies within the health system, diverse values, maldistribution of workload, etc. Within an interprofessional practice framework conflict may also arise from leadership (principally if medical) restricting healthcare delivery to a predominantly medical model. Brown et al. (2011) found three main sources of team conflict – role boundary issues, lack of understanding of scope of practice, and accountability. True interprofessional practice is based on full participation by all health and social care professionals and the patient: teams need to put aside traditional authority relationships and adopt an egalitarian philosophy (Shaw 1990).

To help prevent conflict, teams need to share their feelings and values regularly and feel safe to do so. There should be frequent updates about individual's roles and responsibilities and the boundaries of their professional scope. It is helpful to agree guidelines for dealing with conflict. Good leaders monitor the psychological safety of the team and its members: psychological safety constitutes a shared belief that the team is safe for interpersonal risk taking (Edmondson 1999).

Orchard et al. (2005) offer a model for "Creating a culture for Collaborative Practice" and emphasize the importance of managing power imbalances between professions when developing power sharing in collaborative practice. In this model, Orchard et al. (2005) identify the main barriers to working with, from, and about health professionals are organizational structures, power imbalances, and role socialization. Gilbert (2005)

reinforces the barriers to collaborative practice in that he identifies institutional and professional barriers hinder progress, whereas Orchard et al. (2005, p. 4) stress that "organisations need to shift from their rigid bureaucratic structures to facilitate health professionals providing patient centred care." The World Health Organization (2010) agrees with these influences in that the barriers are seen as opportunities to change the institutional structures, collaborative practice teams, and a power with culture in that over time collaborative practice strengthens and transforms the education and health systems.

10 Interprofessional Education

In order to develop this further interprofessional education is required for all the palliative care team members so they work together with a common vision as well as recognizing the differences each brings to care. Historically health professional education was developed in silos keeping each profession separate in its education and in many areas this is unchnaged. Interprofessional education (IPE) is informed by educational, psychological, and sociological theories for its rationale and delivery, including but not limited to sociocultural and activity theory, social identity theory, situated learning, and organizational change (Thistlethwaite 2012b). It involves integration and shared learning throughout the continuum of professional education, training, and practice. Interprofessional education needs to be both at undergraduate and postgraduate levels as well as onward into continuing professional development (CPD) or in this case continuing interprofessional development (CIPD). Effective interprofessional education (IPE) enables effective collaborative practice, and effective collaborative practice strengthens health (and social care) systems and improves health outcomes (WHO 2010, p. 5). Interprofessional collaboration in palliative care is an opportune context for the team working together to "learn from, with, and about" each other for optimal patient care (CAIPE 2002) and well-planned, committed work for patients.

The opportunity for interprofessional working and learning and decision-making extends beyond interprofessional learning in palliative care and end of life care. Therefore to share some models that can assist in the development of interprofessional collaboration will follow.

CIPD should be based on adult learning principles and the identification of specific interprofessional learning outcomes of relevance for all participants (Thistlethwaite 2015). It may be delivered through seminars, short courses, and certificate programs that give different health professionals the opportunity to develop teamworking and collaborative skills together through case study analysis, role-play, storytelling, and perhaps problem-based learning to name a few strategies.

In order to create change and transform the systems, Orchard et al. (2005) identified four phases of change including sensitization, exploration, intervention, and evaluation (Fig. 1).

Sensitization identifies the barriers; exploration clarifies and values the roles; and throughout the implementation trusting relationships develop through power sharing within teams and valuing each other's roles. As this development process

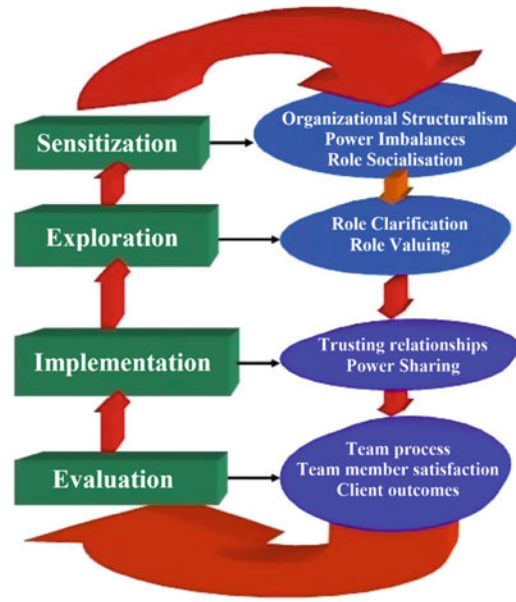

Fig. 1 Change process during team development. (With permission from the authors)

evolves and becomes the way of working, evaluation (4th phase) is undertaken with the team including the patient.

However opportunities for teams to work together once clarification of roles is transparent involve diversity being valued and power sharing occurring. It's moving through the four phases along with valuing, trusting, and respecting each other's role through working together for the best outcome for the patient and family – thus developing a cultural change to interprofessional working which includes a shared vision. Gilbert (2005) summarizes this well by saying "we not only need to build a culture of interprofessional education collaboration but at the same time as we build that culture, we need to be able to access a wide range of resources that can build new knowledge, new skills, respect and esteem for all collaborating partners along with the development of trust" (p. 102).

Consideration for transforming the barriers needs to include the structure of the organization along with the power imbalances and clarification of roles along with developing trust. The total process is shown in Fig. 2.

Ho et al. (2015) found that EOC (end-of-care) discussions with patients and families are challenging and that there are "additional ethical, emotional and practical concerns compared to other forms of healthcare decisions" (p. 798). The barriers of discomfort with death and dying, role responsibility, and uniprofessional working impact further on the health professional working outside a team. There needs to be a move from uniprofessionalism to interprofessionalism (Jones et al. 2015). Orchard et al. (2005) is one model that can guide that change. Given the global workplace crisis, the WHO supports collaborative practice (WHO 2010). Ho et al. (p. 801) emphasize "modern health care is increasingly interprofessional, and patients with complex situations may spend more time" with the team of health professionals.

11 Conclusion: Moving Forward

Understanding each other's profession, crossing the boundaries, valuing the diversity that is uncovered, and learning to practice together bring a collegiality that is interprofessional practice. Careful planning and working together are needed to build successful interprofessional practice. So decide on the team's work, a team development that works for the organization within which it sits, and work together to learn from each other as you work with each other, having learned about each other's profession. Interprofessional practice

needs palliative care teams to work together, meet challenges, and overcome any barriers to patient care.

Nursing and Palliative Care

33

Contents

Abstract

Nursing is integral to meeting the growing demand for palliative care which is being driven by population aging and the increasing burden of chronic, noncommunicable disease. Palliative nursing and nursing in general share many of the same principles and practices. Both are committed to addressing the holistic domains of health (physical, psychological, emotional, cultural, social, practical, spiritual, and informational aspects of a person's health and well-being) (Fitch, Hosp Q 3(4):39–46, 1999). This chapter provides an overview of the role of nursing in the context of contemporary interdisciplinary specialist and primary palliative care, key constructs underpinning palliative nursing, the core competencies of specialist and primary palliative care nursing, and how these competencies can be applied to provide best evidence-based person-centered palliative care, regardless of the care setting.

1 Introduction

Nursing care is central to all hospice and/or palliative care ("palliative care") service delivery and is underpinned by the World Health Organization definition of palliative care (World Health Organization 2003). Having emerged from its informal religious roots, palliative nursing has evolved into a dynamic discipline that works with other interdisciplinary team members to improve care outcomes for people living with and dying from

R. D. MacLeod, L. Van den Block (eds.), *Textbook of Palliative Care*,
https://doi.org/10.1007/978-3-319-77740-5_43

progressive illness and their families. Palliative nursing, along with palliative care, has evolved rapidly since the late 1970s and has largely been driven by a social movement designed to improve the care of people dying from cancer (Phillips et al. 2015). Dame Cicely Saunders (1918–2005), a nurse, social worker, and physician, responded to this need and established St Christopher's Hospice in North London, where care was focused on the physical, psychological, and spiritual needs of dying patients (Pace and Lunsford 2011). This holistic care model was rapidly translated to other high income countries such as Canada and Australia, while the uptake of palliative care in the United States of America occurred much later, partially in response to the landmark "SUPPORT study" (Connors et al. 1995). This large randomized controlled trial conducted at five US teaching hospitals lent considerable support to the need to improve palliative care in the world's largest economy. The subsequent release of the Institute of Medicine's "Approaching death: improving care at the end-of-life" (Institute of Medicine 1997) strengthened this call to action. Emerging from these developments has been the establishment of specialist palliative care nursing and recognition of the increasing importance of primary palliative care (Box 1) (Quill and Abernethy 2013).

The purpose of this chapter is to provide an overview of the role of nursing in the context of contemporary interdisciplinary palliative care.

Box 1 Key Definitions

Nurses – Regulated health professionals who work across all care settings (acute care, aged care, primary care) and in doing so provide care for people with palliative care needs and their families. These nurses provide primary palliative care.

Palliative nurses – Nurses who work specifically in the care of people with palliative care needs and their families. These nurses might work in specialist inpatient services (e.g. hospices, palliative care units) or in a consultative role working alongside nursing and interdisciplinary colleagues. These nurses provide specialist palliative care.

Palliative care – The definition provided by the World Health Organization has been adopted for this chapter: http://www.who.int/cancer/palliative/definition/en/. This definition refers to people who are affected by a life-limiting illness and advocates for the nursing role (generalist and specialist) to enable those affected to live as well as possible with their complex healthcare needs managed as well as possible.

1.1 Key Constructs Underpinning Palliative Care Nursing

Palliative care demands a skilled interdisciplinary response, with nurses playing a central role. Several constructs underpin contemporary palliative care nursing practice, including domains of nursing practice, evidence-based practice, person-centered care, and a population-based approach to palliative care. Each is essential to providing best palliative care, at the right time, every time, as detailed below.

1.1.1 Evidence-Based Practice

The notion that health service evaluation must be guided by scientific evidence, not clinical impression, was first suggested in the 1970s (Rosenberg and Donald 1995). Since then, evidence-based healthcare has become a guiding force in clinical practice and gradually embedded across various disciplines, including nursing. Evidence-based nursing care extends beyond mere reliance on research evidence, with nurses required to concurrently assess the risks, benefits, costs, inconveniences, and patient preferences in relation to proposed care (Scott and McSherry 2009). In the palliative care setting, these considerations are even more crucial due to the complex interplay of a patient's

vulnerability, diagnosis, prognosis, goals of care (Owens 2009), and a rapidly evolving evidence base (Tieman et al. 2008).

In order to exercise astute clinical judgment, nurses need prerequisite capabilities to successfully integrate evidence with their clinical expertise and patient preference(s) (Scott and McSherry 2009). Despite having positive attitudes toward evidence-based practice (Mehrdad et al. 2012; Stokke et al. 2014), recent research suggests that many nurses minimally engage in providing evidence-based care (Stokke et al. 2014). Keeping abreast of new evidence is challenging (Phillips 2015), which has led to the development of various publicly available websites, including: CareSearch (www.caresearch.com.au); Cochrane Library; Joanna Briggs Institute; and eviQ, which all host specialized evidence-based resources relevant to palliative care.

Having located the evidence, the next challenge is to critically appraise this in a rigorous way. At a minimum, all nurses need to be able to evaluate a study's methodological strengths and weaknesses before carefully considering its results, relevance, and applicability to their own practice. Critical appraisal tools such as those electronically hosted in the Critical Appraisal Skills Program (CASP) and Joanna Briggs Institute website provide nurses with a framework to systematically analyze research evidence for their trustworthiness and relevance.

Notwithstanding, the step up from "best evidence" to "best practice" requires concerted system level efforts, and nurses have ample opportunities to integrate best evidence to practice in day-to-day decision-making and care delivery. As nurses continue to shape palliative care practice through their diverse roles, from providing bedside care in an institutional setting to working as advanced nurse practitioners, every nurse needs to consider how they can integrate and promote evidence-based care into all healthcare decisions.

1.1.2 Ethical Behavior and Consumer Rights

The responsibility of providing palliative nursing care to vulnerable patients is often associated with ethical challenges that need to be addressed judiciously. An understanding of beneficence, non-maleficence, autonomy, and justice (Webb 2005) helps nurses uphold high standards of ethical conduct while addressing the unique issues pertaining to a patient's end-of-life care needs. Some of the common ethical issues that nurses' encounter are determining competency to consent, advocacy, and withholding and/or withdrawing treatment. Determining a patient's competency to consent is critical to striking a balance between respecting their autonomy to making informed decisions and protecting them if they are unable to do so.

When a patient lacks the competence to make a decision about treatment, substitute decision makers must be sought. Nurses have a responsibility to ensure that competent patients are provided with relevant information to assist them in making informed choices about the goals of care, proposed treatments, and burdens and benefits of participating in clinical trials (Anyfantakis and Symvoulakis 2011). Vulnerable palliative patients may be easily persuaded to make choices that they would not normally make. In such situations, nurses have a responsibility to act as patients' advocates ensuring that the patient's voice is heard and their choices are respected (Webb 2005). As the discipline that spends the most time with patients, nurses are best placed to advocate for the patient's preference and goals of care, symptom management, and cultural and spiritual needs (Earp et al. 2008). Advocacy in palliative care is not limited to speaking up "on behalf" of the patient but also involves providing patients with the support and information they require to speak for themselves regardless of their level of dependency (Webb 2005). The strengths of the nurse-patient relationship provide nurses with unique access to the perspectives, preferences, wishes, and concerns of the patient living with and dying from progressive illness.

Nurses play a central role in ensuring that the patient's voice is heard, especially when decisions about forgoing and/or starting a medical treatment are made (Albers et al. 2014). Careful consideration of the benefits versus the burden of proposed treatment and its impact on the patient's quality of life ought to inform all decision-making processes.

While physicians are more often responsible for such decision-making, the involvement of nurses in this process is essential (Albers et al. 2014). It is also crucial for nurses to be able to differentiate between withholding and withdrawing treatment, and provision of effective symptom relief and euthanasia. While the former is carried out with an intent to minimize treatment burden and improve patient's quality of life, the latter is intended to end a patient's life (New South Wales Department of Health 2005). Nurses may receive requests from families asking for "something" to bring an end to the suffering of their loved ones in the last days of their life. Such requests demand the utmost care to identify why such a request is being made at this time and to determine alternative actions that could address the patient's and/or family's concerns (Caresearch 2017).

1.1.3 Person-Centered Care

Person-centered care is a fundamental component of effective palliative care and underscores the importance of interdisciplinary care for people living with and dying from progressive illness. There are many definitions of person-centered care; however, two are of specific relevance to palliative care nursing, namely: (1) dimensions of patient-centered care as articulated by the Picker Institute (Picker Institute Europe 2017) and (2) constructs articulated in a person-centered practice framework developed by McCormack and McCance (2017). The Picker Institute identified eight characteristics of care that are most important to patients and their families (Barry and Edgman-Levitan 2012) and has since detailed these as the principles of person-centered care, namely: (1) fast access to reliable healthcare advice; (2) effective treatment delivered by trusted professionals; (3) continuity of care and smooth transitions; (4) involvement of, and support for, family and carers; (5) clear, comprehensible information, and support for self-care; (6) involvement in decisions and respect for patient's preferences; (7) emotional support, empathy, and respect; and (8) attention to physical and environmental needs (Picker Institute Europe 2017). In the McCormack person-centered practice framework, four constructs are considered essential for the provision of person-centered nursing care: (1) prerequisites and/or nursing attributes; (2) care environment and/or context of care; (3) person-centered processes of care; and (4) person-centered outcomes (Fig. 1) (McCormack and McCance 2017).

Nurses are in a unique position to both lead and innovate in relation to provision of person-centered care especially as they are the only health professional available 24 hours a day in most care settings. This exposure to patients and families provides nurses with a unique opportunity to establish and develop therapeutic relationships that address the principles of person-centered care. Understanding how to achieve person-centered care is fundamentally important for all nurses but particularly for those providing palliative care given the complexity of patient and family needs. Indeed, a synthesis of a large body of research conducted over the past 25 years has identified the elements of care inpatients and their families considered to be most important at the end-of-life (Fig. 2) (Virdun et al. 2015, 2017). These areas of importance align with the principles and constructs of person-centered care. It is these elements of importance that ought to inform the provision of optimal person-centered palliative nursing.

1.1.4 A Population-Based Model of Palliative Nursing

The demand for palliative nursing continues to grow in response to changing epidemiology, population aging, the recognition of the value of early palliative care, and the need to extend timely palliative care to populations beyond cancer (Morrison et al. 2011; Temel et al. 2010). Meeting this increased demand will be challenging for specialist palliative care services, especially, if people with palliative care needs are to have access to a comprehensive and holistic service. There is now recognition of the importance of developing interdisciplinary population-based models that are designed to improve access to palliative care in accordance with need (Luckett et al. 2014).

A population-based approach to palliative care service planning focuses on strengthening the delivery of palliative care provided by the patient's usual care team ("primary palliative care") in the acute care, community, and aged care settings (Quill and Abernethy 2013).

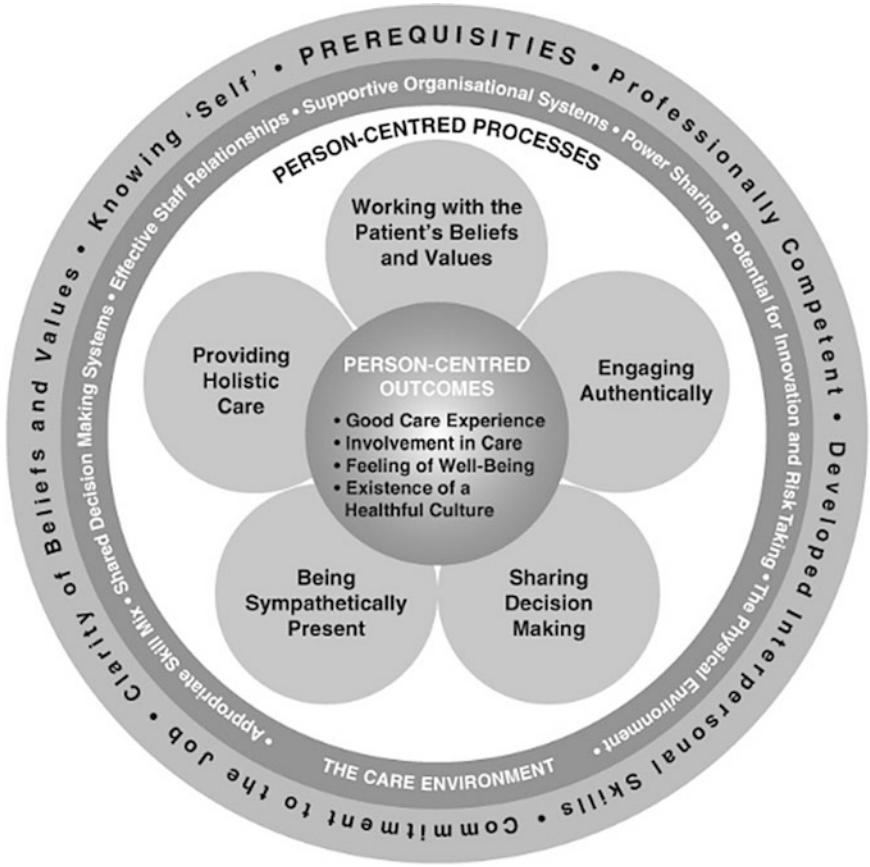

Fig. 1 The person-centered practice framework (McCormack and McCance 2017, p. 63) (Source: Permission obtained to use the figure)

Adopting a population-based approach helps to facilitate a responsive and inclusive method of addressing the particular geographical, social and cultural needs of people with a progressive illness (Palliative Care Competence Framework Steering Group 2014). It helps to ensure that palliative care is more accessible for Aboriginal-first nation peoples, socially disadvantaged people, people living with nonmalignant illness, and people living in rural and remote areas, all of whom often have more limited access to palliative care (Palliative Care Competence Framework Steering Group 2014). For example, a population-based model of care is key to improving the provision of palliative care to older people in nursing homes who have unmet palliative care needs. In this care setting, the primary palliative care ought to be provided by the older person's usual care team (care assistants, registered nurses, and general practitioner) and be augmented with specialist palliative care input and active patient and primary care engagement (Candy et al. 2011; Hall et al. 2011; Davies et al. 2011). Implementing this type of model would do much to address poor symptom control, unnecessary hospitalizations, suboptimal communication, inadequate advance care planning, and families who are dissatisfied with palliative care (Phillips et al. 2006).

Comprehensive interdisciplinary specialist palliative care services are central to operationalizing a population-based model of care. Providing direct care and/or consultative services in the tertiary, secondary and/or primary care settings, these specialist palliative care services (including specialist nurses) are ideally placed to provide local leadership, training, mentorship,

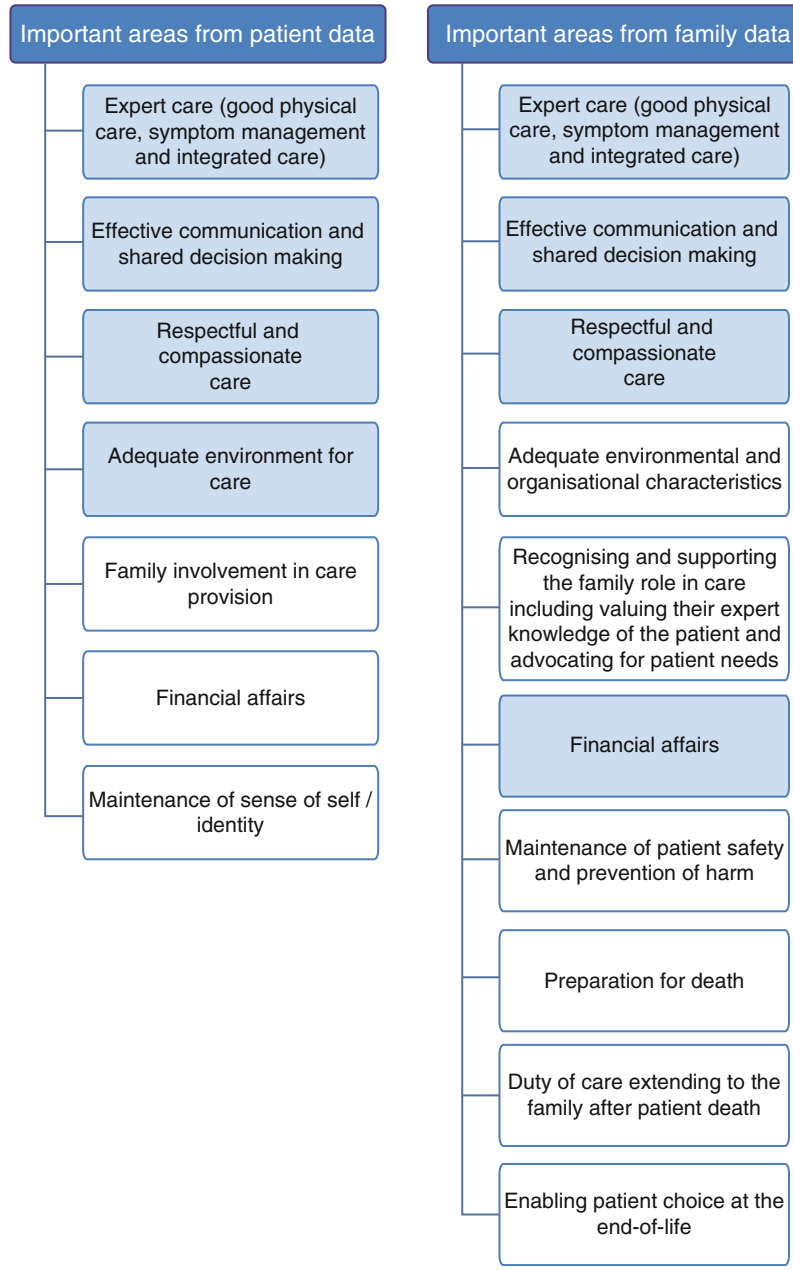

Fig. 2 Area of importance for optimal end-of-life care in hospitals: patient and family perspectives (Virdun et al. 2015)

and supervision to support the delivery of primary palliative care by other health professionals and to undertake research and/or quality initiatives (García-Pérez et al. 2009; Higginson and Evans 2010). Implementing a population-based approach requires that all nurses, regardless of specialty training, are able to provide primary palliative care to the patients and families they service. It also requires specialist palliative nurses to operate alongside nurses providing primary palliative care. Furthermore, a commitment to building collaborative care partnerships and the palliative care capabilities within the broader interdisciplinary care team is vital. By making better use of scarce resources, specialist palliative nursing is then reserved for patients and families with the most complex needs (Palliative Care Australia 2005).

1.1.5 Domains of Nursing Practice

Regardless of the care setting or population, all nurses are required to practice in accordance with the relevant legislation affecting nursing practice in healthcare. Nurses function within several key domains of practice, and while these may vary across countries and/or jurisdictions, they largely focus on (1) critical thinking and analysis; (2) engagement in therapeutic and professional relationships; (3) maintenance of the capability to practice; (4) comprehensive assessments; (5) development of a plan for nursing practice; (6) provision of safe, appropriate, and responsive quality nursing practice; and (7) evaluation of outcomes to inform nursing practice (Nursing and Midwifery Board of Australia 2016). In Australia, these standards are conceptualized as a matrix, with interrelated Standards 1–3 forming the y-axis, while Standards 4–7 describe the dimensions of practice and form the x-axis. Each standard has criteria that specify how that standard is demonstrated within the context of each registered nurse's practices (Nursing and Midwifery Board of Australia 2016).

Nurses are also required to operate within a professional and ethical nursing framework. Practicing within an evidence-based framework, participating in ongoing professional development, and systematically developing the capabilities of others are considered core competencies necessary for critical thinking and analysis. The provision of coordinated and effective care requires nurses to have the capabilities to conduct a comprehensive and systematic nursing assessment, plan care in consultation with other members of the interdisciplinary team and in accordance with patient preference, implement comprehensive safe and effective evidence-based nursing care, and evaluate the care. Establishing and/or maintaining therapeutic relationships as well as appropriately concluding them and collaborating with other members of the interdisciplinary team underpins all collaborative and therapeutic practices (Nursing and Midwifery Board of Australia 2016). The competency standards for registered nurses are the foundation upon which specialist competencies are built.

1.1.6 Palliative Care Competencies

Preparing the nursing workforce to operate within a population-based model requires consideration of the competencies required to fulfill the different levels of specialization and defined scope of practice. While there is considerable debate about the most appropriate definitions and methods of assessments, nursing competencies are generally considered to represent a dynamic combination of knowledge (basic or specialized), skills (assessment, communication, critical thinking, time management, customer services, technical skills, and teaching), and abilities (caring, character, and professional presentation) which contribute to understanding (Aranda and Yates 2009). In preparing the nursing workforce to provide palliative care, it is important to consider the competencies required for each of the four levels of nursing practice across the six domains of palliative care, namely: (1) principles of palliative care; (2) communication; (3) optimizing comfort and quality of life; (4) care planning and collaborative practice; (5) loss, grief, and bereavement; and (6) professional ethical practice in the context of palliative care (Palliative Care Competence Framework Steering Group 2014). The European Association for Palliative Care has identified the following ten core interdisciplinary palliative care competencies considered necessary for optimizing patient and family outcomes (European Association for Palliative Care 2013) (Box 2).

Box 2 Ten Core Interdisciplinary Palliative Care Competencies (European Association for Palliative Care 2013)

1. Apply the core constituents of palliative care in the setting where patients and families are based.
2. Enhance physical comfort throughout patient's disease trajectory.
3. Meet patient psychological needs.
4. Meet patient social needs.
5. Meet patient spiritual needs.
6. Respond to the needs of family carers in relationship to short, medium, and long-term patient care goals.

(*continued*)

Box 2 (continued)

7. Respond to the challenges of clinical and ethical decision-making in palliative care.
8. Practice comprehensive care coordination and interdisciplinary teamwork across all settings where palliative care is offered.
9. Develop interpersonal and communication skills appropriate to palliative care.
10. Practice self-awareness and undergo continuing professional development.

As the provision of high-quality palliative care is an essential responsibility of the whole healthcare system, many countries, jurisdictions, and/or professional bodies have developed palliative care competency frameworks (Palliative Care Competence Framework Steering Group 2014; Aranda and Yates 2009; Palliative Care Nurses New Zealand 2014). Competencies have been variously defined but generally refer to ". . .a cluster of related knowledge, skills and attitudes that affects a major part of one's role (a role or responsibility) that correlates with performance on the job, that can be measured against well–accepted standards, and that can be improved by training and development" (Parry 1996).

Recognition of the different levels of palliative care nursing specialization is central to developing a competency framework, with four different levels of palliative care nursing specialization evident across the healthcare system, including primary palliative care nurses ("all"), palliative care nurses' champions ("many"), specialist palliative care nurses ("some"), and palliative care advanced practice or nurse practitioners ("few") (Table 1) (Palliative Care Competence Framework Steering Group 2014; Aranda and Yates 2009; Palliative Care Nurses New Zealand 2014).

The palliative care nursing capabilities required for each of these four levels increases in intensity as the role becomes more focused on the specialty. At a minimum, all nurses require the capabilities to provide basic pain and symptom management, including managing anxiety and depression, and initiating conversations about prognosis, suffering, and goals of care and patient preferences, especially around resuscitation status (Quill and Abernethy 2013). Specialist palliative care nurses are required to have more advanced skills and the capabilities to manage refractory pain and other symptoms, including complex depression anxiety and existential distress; and assist with resolving goals of care, treatment, and/or family conflicts as they arise (Palliative Care Australia 2005). Palliative care nurse practitioners have a broader scope of practice and operate in accordance with the values, guidelines, and principles set out by their governing regulatory and professional bodies (Aranda and Yates 2009). All nurses will need to continue to learn throughout their professional life as new evidence emerges within this field.

As developing a sustainable nursing workforce capable of providing high-quality care requires a targeted response, several countries have established national professional development frameworks for cancer and/or palliative care nursing (Palliative Care Competence Framework Steering Group 2014; Aranda and Yates 2009; Palliative Care Nurses New Zealand 2014). Underpinned by a population-based approach, these professional development frameworks define nursing's contribution to palliative care and highlight the contribution all nurses make, irrespective of their role (Palliative Care Nurses New Zealand 2014). As previously described, four broad levels of palliative care nursing practice have been identified (Refer Table 1) to reflect the different levels of competencies required of nurses working in different contexts (Palliative Care Nurses New Zealand 2014). The level of palliative care competencies required at each of the four levels of practice reflects the number of palliative patients cared for by nurses and is best conceptualized as the "all, many, some, and few" competency framework as depicted in Fig. 3 (Aranda and Yates 2009; Palliative Care Nurses New Zealand 2014). Within each of the four levels, nurses will be functioning at differing levels of competencies from beginning through to advanced levels. This progression is reflected

Table 1 Levels of palliative care specialization (Palliative Care Competence Framework Steering Group 2014; Aranda and Yates 2009)

Level of specialization	Guiding principles
Level I – *ALL* Primary palliative nurses	Palliative care principles or a palliative approach needs to be practiced by all nurses working in the acute, community, or nursing home settings. Many people with progressive life-limiting illnesses will have their care needs met comprehensively by their usual healthcare team and not require referral to specialist palliative care units or personnel
Level II – *MANY* Palliative nurses champions	As an intermediate level, a proportion of individuals and families will benefit from the expertise of local palliative nursing champions who, though not engaged full time in palliative care, have undertaken additional palliative care training (i.e., graduate certificate and/or diploma levels) and/or intensive palliative care clinical internships and training. With this training and their networks, they are able to act as a palliative care resource within their organization. Many of these nurses will work in cancer, renal and/or respiratory care, intensive care, acute care, domiciliary care, and/or aged care
Level III – *SOME* Specialist palliative nurses	Specialist palliative nurses are focused entirely on the provision of palliative care. These nurses are involved in the care of patients and families with more complex and demanding palliative care needs. As a consequence these nurses require higher level palliative care training at the masters level in order to develop the competencies and specialist skills required for managing complex problems
Level IV - *FEW* Palliative care nurse practitioners/ advance practice nurses	Palliative care nurse practitioners or advanced practice nurses are able to work as independent nurses and in many countries have prescribing rights

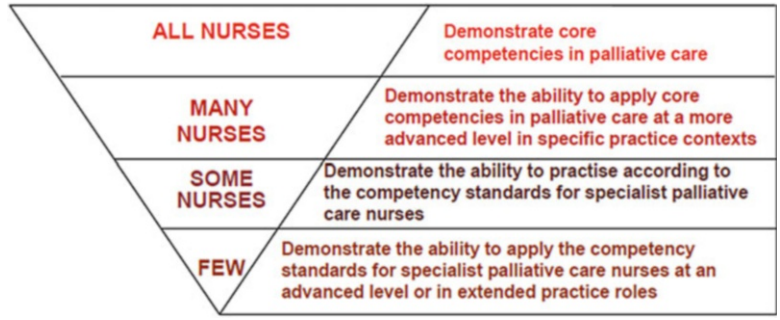

Fig. 3 A professional development model for palliative care nurses (Palliative Care Nurses New Zealand 2014, p. 6)

in their capacity to integrate theory, practice, and experience (Palliative Care Nurses New Zealand 2014). Increasing degrees of autonomy in judgment and interventions is evident as nurses become more specialized (Palliative Care Nurses New Zealand 2014).

1.1.7 Certification and Credentialing

In addition to the competency framework, some organizations have moved to introduce certification and/or credentialing processes. Certification is generally undertaken by professional bodies (i.e., Palliative Care Nurses Australia) on behalf of its members. Certification processes are designed to publicly acknowledge the achievements of nurses working in specialized areas against a predefined set of requirements (Aranda and Yates 2009). A major limitation of most certification processes is they lack the detail necessary to guide employers as to whether a particular nurse can function effectively in all areas of practice (Aranda and Yates 2009), whereas credentialing is a more comprehensive process that is normally undertaken by an employing organization. Credentialing clearly documents the scope of practice of a particular nurse in a specific practice setting and is often locally defined (Aranda and Yates 2009).

Table 2 Applying palliative care competencies to ensure the provision of person-centered palliative nursing (McCormack and McCance 2017)

Person-centered care (McCormack and McCance 2017)	Translation to palliative nursing	Opportunities for improvement/innovation
1. Prerequisites		
Professionally competent	Relevant registration requirements confirmed Implementation of palliative care nursing competencies for "all, many, some, and few" nurses Annual appraisal of competencies and identified areas for growth Ability to think critically, problem solve, predict outcomes, and use judgment and wisdom to devise optimal palliative care interventions and evaluation of care	Validation of competency frameworks for palliative nursing and competency indicators for each level of palliative care nursing Aligning nurses' continuing professional development (CPD) opportunities with their required competencies
Developed interpersonal skills	Interpersonal communication capabilities (managing workplace conflict, challenging conversations) clearly defined and measured in accordance with level of competencies Builds therapeutic relationship with patients and families Develops interpersonal and communication skills appropriate to palliative care	Partnering with universities and/or communication experts to build nurse's interpersonal skills Integrates communication into CPD opportunities Evaluates patient and family experience in relation to care received to drive improvement efforts
Commitment to the job	Rewards commitment with professional development and advancement opportunities Acts as a resource to others in the interdisciplinary team	Organizational efforts to value, develop, and reward excellence in care provision accessible to staff Evaluation and/or research of what fosters commitment to one's role to drive organizational strategies for staff development and retention
Clarity of beliefs and values	Shares a common philosophy of care Alignment of organization and individual beliefs and values Acts in accordance with national, international, legal frameworks and patient's wishes and values	Creates a values-driven workplace Development of and linkage to accessible CPD opportunities to provide information about legal frameworks with particular reference to advance care planning, directives, effective palliative care, and euthanasia to support staff understanding about the clear differences between palliative care and euthanasia
Knowing "self"	Engages with clinical supervision to support development of self-awareness and how this may impact on palliative care Practices self-awareness and undergoes CPD Implements self-care strategies to prevent burnout Recognizes early sign of burn out and seeks appropriate help	Builds the evidence on effective self-care and sustainability strategies for palliative care Identifies ways to strengthen resilience and prevent burnout Validates clinical supervision models to understand best practices Develops tools for nurses to use for self-care, based within emerging technologies Ensures integration of learning about strategies to prevent burnout and maintain health within undergraduate and postgraduate education
2. The care environment		
Appropriate skill mix	Provides the correct nursing and interdisciplinary skill mix requirements for optimal palliative care	Develops and tests innovative models of care Researches the unique contributions made by nursing within palliative care provision to enhance understanding of such roles in both

(*continued*)

Table 2 (continued)

Person-centered care (McCormack and McCance 2017)	Translation to palliative nursing	Opportunities for improvement/innovation
	Balanced skill mix to optimize patient outcomes	primary and specialist roles Identifies optimal skill mix models to drive policy support for best care across all settings (aged care, acute care, primary care). Such work could inform structural quality indicators for service commissioners to align with
Shared decision-making systems	Enables patients and families to participate, in accordance with their wishes, in consultations, case conferences, bedside handovers, articulation of goals and plans for care Supports patients and families to participate in daily planning sessions for their care to enable changes in priorities to be identified, over time Champion nurses' unique position to advocate for the patient and family voice in care planning and provision	Considers the role of emerging technologies to assist in shared decision-making Develops and tests new models that deliver integrated and coordinated care Evaluates patient and family experience in relation to shared decision-making
Effective staff relationships	Supports and fosters collaborative interdisciplinary relationships and effective communication Supports and mentors new graduates or staff new to a clinical area Palliative nurses actively support colleagues providing primary palliative care	Develops new models to promote interdisciplinary collaboration both within the specialist and primary palliative care teams Develops, utilizes, and evaluates explicit supports for new graduate staff and staff new to a clinical area which align with the constructs of a person-centered practice framework Evaluates current practice to identify areas for improvement
Supportive organizational systems	Creates an environment that actively implements the existing evidence and supports the delivery of best evidence-based nursing care Values and rewards the provision of excellent person-centered care at all times	Enables regular staff feedback in relation to supports provided and improvements required to allow optimal person-centered care Evident organizational support for identification and management of key areas for improvement Evident no blame culture – respect for staff reporting concern so as change can occur
Power sharing	Actively engage patients and families in organizational and patient level decision-making processes Understand and respect practice and disciplinary boundaries	Prioritizes consumer involvement (patients and their families) in organizational decision-making processes Considers use of technological feedback systems for staff to use in reviewing working relationships
Potential for innovation and risk-taking	Implements the existing palliative nursing evidence base Critically considers all aspects of care, questions appropriately, and fosters opportunities to develop new evidence Engages consumers in all change initiatives and/or new developments Displays agility in professional practice to	Builds the palliative nursing evidence base Develops and test new models of care and non-pharmacological strategies to improve care outcomes Seeks philanthropic funding to build palliative nursing research Specialist palliative care nurses to lead in the

(*continued*)

Table 2 (continued)

Person-centered care (McCormack and McCance 2017)	Translation to palliative nursing	Opportunities for improvement/innovation
	enable creative care options (based within the evidence) for people with complex care needs	adoption of new evidence for people with chronic and complex healthcare needs
The physical environment	Consider the needs of people living with and dying from progressive illness within each care environment Identify areas within each environment that can be improved and where possible, do so (e.g., visiting hours, supported parking fees, privacy for families) Work with each patient to understand their needs as these vary with each individual (e.g., single room, home setting, remote locations)	Self-assess a care environment to identify areas for improvement, some of which can be fixed much more easily than others Work with consumers to understand their areas of importance in relation to the care environment Consider partnerships with designers and architects to assist in altering clinical environments to enable best palliative care
3. Person-centered processes		
Providing holistic care	Provides optimal palliative care at all times, in accordance with patient wishes and preferences and best available evidence Applies the core constituents of palliative care in the setting where patients and families are based Enhances physical comfort throughout the patient's disease trajectory Meets patient psychological, social, and spiritual needs	Builds the evidence base to support palliative nursing interventions that, in conjunction with interdisciplinary care, drive optimal palliative care
Working with the patient's beliefs and values	Conscious and respectful of the patient's boundaries in terms of cultural taboos, values, and choices Ensuring the translation of unique patient's beliefs and values to the interdisciplinary team to inform care Provision of creative solutions where needed to enable person-centered care, irrespective of care environment (e.g., Enabling spiritual practices to occur; working to enable identified goals be achieved; considering opportunities to allow pets to visit)	Creates agile and adaptable organizational systems that accommodate the patient's beliefs and values Works closely with consumers to understand what aspects of care need improving in relation to care provision, organizational practices, or physical environment
Engaging authentically	Effectively engages patients and their families, clinicians providing primary palliative care, and other members of the interdisciplinary team	Creation of networked palliative care models Effective use of technology to optimize engagement Assessment of patient and family experience in relation to this aspect of care to drive improvement efforts
Shared decision-making	Optimizes patient and family engagement in decision-making Ensures patient and family information accurately translates into the care plan Understands when and how to refer for expert specialist advice	Researches patient and family requirements for shared decision-making in palliative care – What level of "shared" is of most support? Investigates the impacts of effective shared decision-making for families in relation to their bereavement needs Considers, designs, and evaluates educational needs for health professionals in relation to enabling effective shared decision-making
Being sympathetically present	Responds appropriately to the needs of patients and families and other members of the interdisciplinary palliative care team	Evaluates this aspect of care experience for patients and their families to highlight areas for improvement

(*continued*)

Table 2 (continued)

Person-centered care (McCormack and McCance 2017)	Translation to palliative nursing	Opportunities for improvement/innovation
	Recognizes the uniqueness and value of each patient and works to maximize their coping abilities Understands the meaning and impact of life-limiting illnesses on patients and their families Adheres to evidence-based guidelines for breaking bad news	Works with universities to create simulated opportunities for skill development for students at both undergraduate and postgraduate levels
4. Person-centered outcomes		
Good care experience	Utilizes patient reported outcome measures to drive practice assessment and change	Develops and tests novel approaches for understanding real-time patient and family experience Embeds real-time experience data into systems that drive opportunities for improvement and uture research
Involvement in care	Actively involves patients and their family in care planning and delivery Supports patients to receive palliative care in their setting of choice Enables patients to manage their personal affairs Actively promotes comprehensive care coordination	Develops mechanisms to regularly assess patient and family experience in relation to this aspect of care Considers novel technologies that enable real-time feedback for care teams in relation to patient and family experiences of care delivery
Feeling of well-being	Values the patient and works to provide a positive care experience Acknowledges patient's emotions and provides sensitive support Prevents suffering and unnecessary distress Promotes patients' and families' coping mechanisms Understands patients' and families' social context and how this may impact on their palliative care experiences Paces the provision of information according to patient preferences and cognitive capacity Identifies complex bereavement needs and refers accordingly Prioritizes work environments that are supportive and staff feel valued for their work and positive about their role	Develops and tests novel approaches for understanding patient and family experience in relation to this aspect of care Enhances the evidence base informing how to work and foster patients' and families' coping mechanisms Works with available evidence in relation to bereavement assessment and care to implement where possible and/or identify new research questions Considers unique population needs and allows consumers to drive service design in accordance with these
Existence of a healthful culture	Responds to the challenges of clinical and ethical decision-making Supports colleagues throughout emotionally challenging work Positively responds to opportunities for change and improvement Utilizes supportive and empowering leadership approaches based in mutual respect for colleagues and a willingness to continually work for excellence in care delivery	Considers novel technologies to support interdisciplinary staff feedback in relation to this aspect of organizational culture Clear management support for a positive organizational culture based in respect for staff and a shared vision for care delivery Development of CPD resources to shape understanding about leadership and change management

1.2 Policy and Practice

Operationalizing a population-based approach to palliative care requires consideration of the competencies required by all nurses working within the healthcare system and strategies to ensure the provision of best evidence-based person-centered care. Integrating the person-centered practice framework to palliative nursing in accordance with the EAPC's ten core palliative care competencies allows for the identification of systems, education, clinical service delivery, and research improvements and/or innovation opportunities to improve care outcomes for patients and their families with palliative care needs (Table 2). All such areas have implications for global palliative care nursing policy and practice.

1.3 Conclusions

Nurses globally are central to addressing the palliative care needs of people living with a progressive life-limiting illness and their families. In partnership with other members of the interdisciplinary team, nurses are responsive to palliative populations' needs within the context of the governing values, guidelines, and principles set out by the relevant regulatory and professional nursing bodies' and governments' priorities. The adoption of a population-based approach to planning offers opportunities to increase the access patients and families have to timely and best evidence-based palliative nursing care. Continuing to evolve and integrate new evidence into practice while building palliative care nurses' capabilities within their scope of practice will ensure that more patients have access to optimal palliative care. In order to improve outcomes for populations with palliative care needs, nurses need to develop new knowledge in partnership with their practice, education, and research colleagues.
