9. Summary

A thorough chemical and physical understanding of DNA recognition by transcription factors requires a combination of structural and thermodynamic studies. The precise recognition of a defined DNA sequence by a given transcription factor necessitates an optimal shape complementarity between the interacting species. The binding reactions are, thereby, characterized through the formation of large complementary surfaces at the interface between the DNA and the protein. While rigid body association has been observed, significant conformational changes of both the DNA and the protein often occur on complex formation to ensure an optimal fit. It is, therefore, important to understand both the intrinsic and the induced properties of the reactants.

While most prokaryotic transcriptional regulators bind to DNA with high specificity, many eukaryotic transcription factors display only modest DNA-binding specificity. The amount of DNA-binding specificity of a protein depends on the conformational flexibility of its DNA recognition element. The recognition helix of the prokaryotic HTH motifs, for instance, is stabilized through the interaction with other parts of the protein (indeed, the HTH motif adopts a stable conformation only in the structural context of the whole protein). The recognition helices of the eukaryotic BHLH and BZ motifs, on the other hand, adopt well-defined structures only upon binding to DNA. However, even in the complexes, large parts of the recognition helices face the solvent. The conformational flexibility of such open recognition elements can be reduced and their DNA-binding specificity altered through the interaction with other components of the transcriptional machinery. Therefore, transcriptional regulation in eukaryotes relies to a large part on multiprotein complexes with the potential for combinatorial interactions.

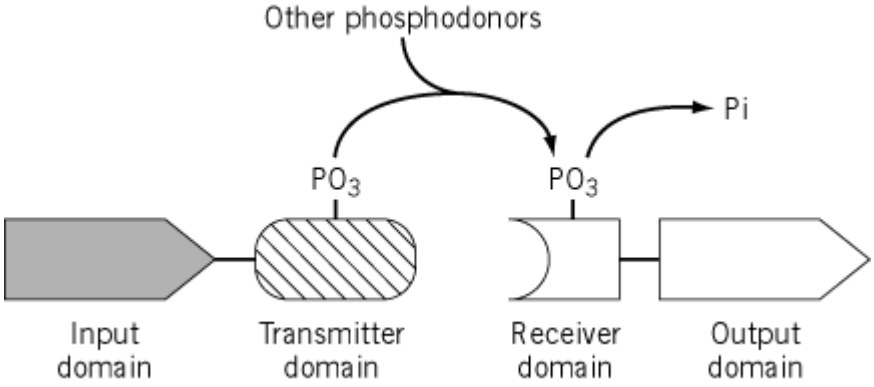
Transducer Proteins

The transducer proteins are proteins that receive and help process information so that proper action by the cell ensues. This article emphasizes transducer proteins that bind ligands on the outside of **bacterial cells** and, consequently, cause changes within the cell to optimize cell survival in the particular environment. Two particular types of transducers are described, the sensor kinase of the two-component signal transduction system and the methylated receptors of chemotaxis in bacteria. Both have ectodomains responsible for interacting with environmental factors, which induce conformational changes in the receptor to regulate the cytoplasmic coupled kinase activity.

An important means by which bacteria sense changes in their environment is by a signal transduction strategy known as the two-component system. It consists of a membrane-spanning sensor kinase and a cognate cytoplasmic response regulator. A sensor kinase with two **domains**, an input domain usually outside the plasma membrane and a cytoplasmic transmitter domain, autophosphorylates its transmitter domain on a histidine residue at a rate that depends on the input domain's conformation. The response regulator usually also has two domains, a receiver domain and an output domain. Using the phosphorylated sensor kinase as a substrate, the receiver domain catalyzes the transfer of the phosphate to an aspartate residue within itself, so that inhibition is relieved on the ouput domain (Fig. 1). The output domain becomes altered, usually resulting in activation of the transcription of an appropriate operon.

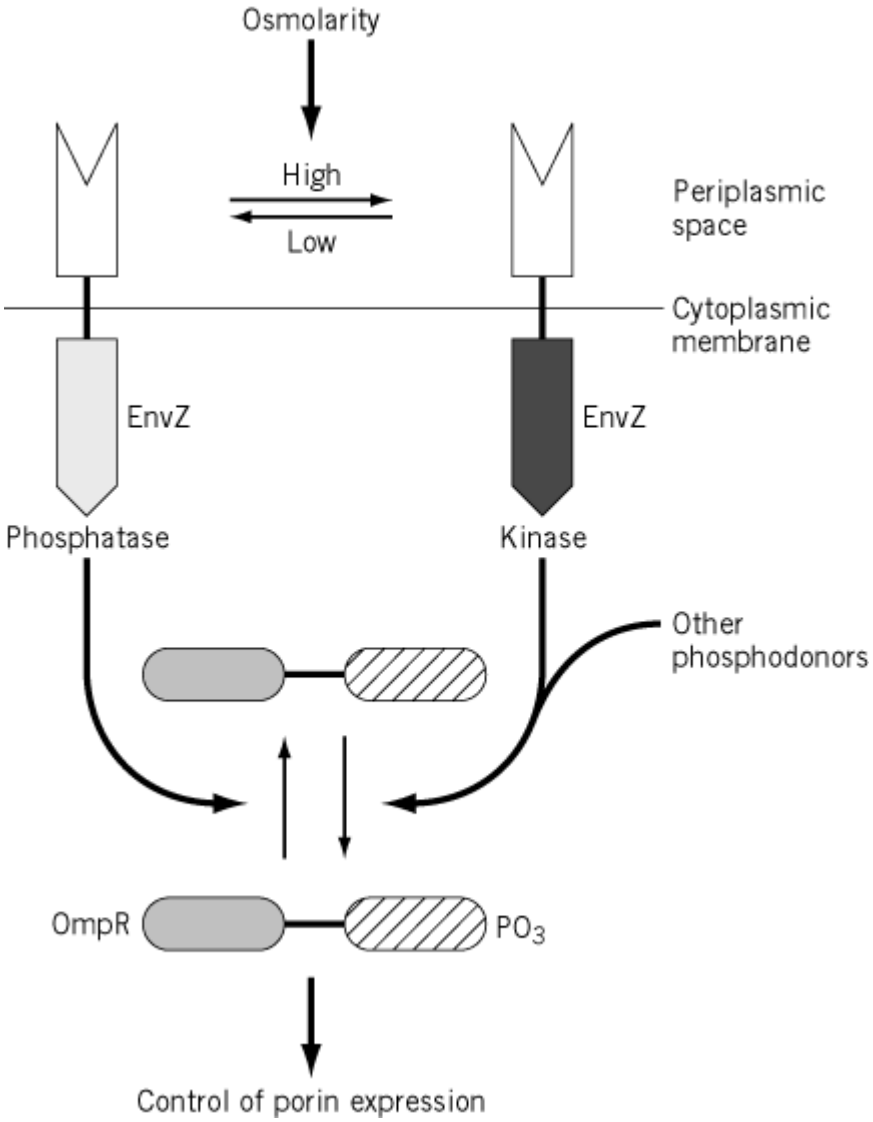
Figure 1. Prototypical two-component system in bacteria.



One particularly interesting instance of this is from the osmoregulation circuit in *Escherichia coli*. The sensor kinase EnvZ has an input domain in the **periplasmic** space beyond the membrane and a cytoplasmic output domain that phosphorylates OmpR, the controller of porin expression. In an

unknown way, high osmolarity makes EnvZ act as a kinase, leading to high concentrations of phosphorylated OmpR (OmpR-P), and low osmolarity makes EnvZ act as a phosphatase, leading to low concentrations of OmpR-P (1) (Fig. 2).

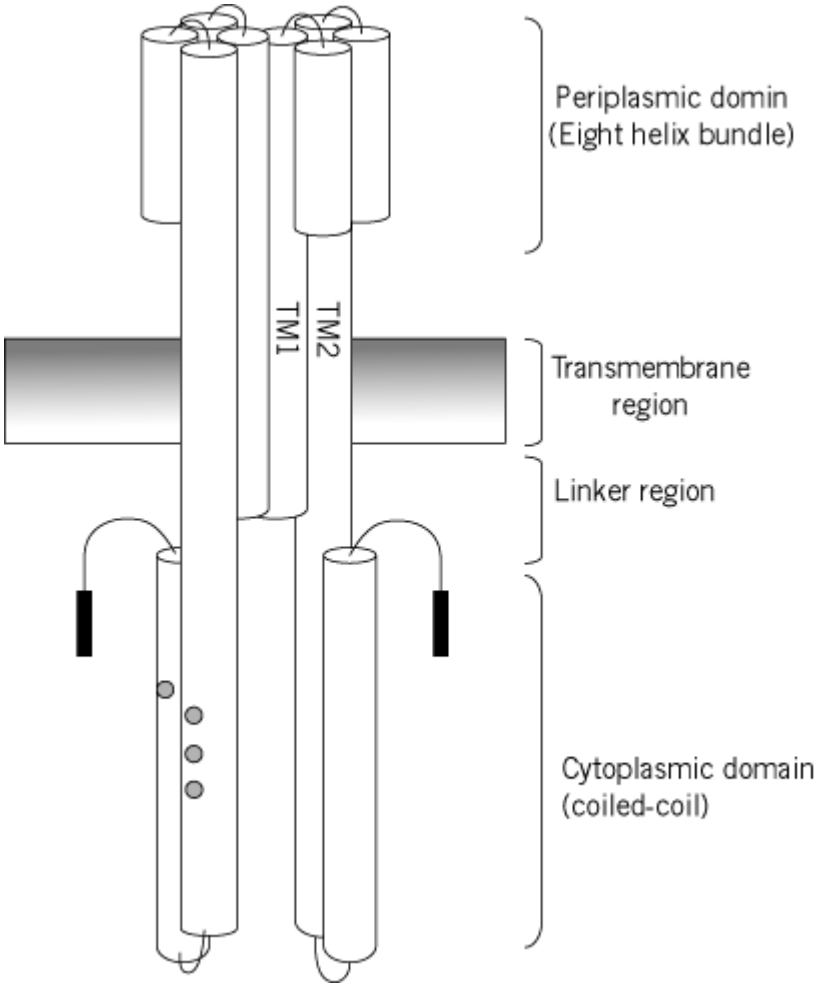
Figure 2. Sensor kinase of the two-component system that senses osmolarity in bacteria. Open arrows indicate control of the designated signaling step. EnvZ is transducer protein that senses the osmolarity of the external medium, with effects on its opposite activities as a kinase or a phosphatase of OmpR. In turn, the phosphorylation state of OmpR controls the expression of the gene for porin.



The primary means by which bacteria sense changes in concentration of chemotactic attractant or repellents is through chemoreceptors. Chemoreceptor proteins exist *in vivo* as stable dimer molecules that are entirely a-helical throughout. The extracellular domain organization of the *E. coli* Tar dimer consists of an eight-helix bundle, and the cytoplasmic domain consists mostly of a four-helix coiled-coil (Fig. 3)(3). The chemoreceptors may bind attractants and repellents directly, like Tar binding aspartate, or indirectly, by interaction with ligand-binding proteins like Tar-binding maltose-binding protein, associated with maltose. Evidence indicates that Tar-binding aspartate produces a piston-like shift in transmembrane helix 2 toward the cytoplasm. This conformational change results in a reduction in CheA kinase activity, the kinase of the chemotaxis system. Reduction in CheA-P levels in turn reduces levels of CheY-P (see Chemotaxis), causing a change in direction of flagellar

rotation.

Figure 3. Dimeric structure of the chemoreceptors in bacteria. The cylinders represent a-helical regions of each monomer. Attractants bind between the monomers causing a downward shift of transmembrane helix 2 of one of the monomers.



Chemotaxis transducers are unique, because they contain conserved, reversibly methylated glutamate residues in the cytoplasmic four-helix coiled-coil domain. These conserved glutamate residues are the substrates for the methyltransferase enzyme, CheR, which uses S-adenosyl methionine as a methyl donor (see Methyltransferase). Methyl glutamate residues are substrates for the methylesterase enzyme, CheB. CheB is a response regulator protein like CheY, which also uses CheA as a phospho-donor, and is activated by phosphorylation to demethylate the chemoreceptors. The methylation system serves as an adaptational mechanism to make the chemotactic receptors phasic (on for a short period) rather than tonic (always on when ligand is bound), a unique feature among two component systems. The methylation region is located between the signaling region, where the CheA kinase binds, and the cell exterior, where the chemoeffectors bind, and is thus strategically located to compensate for the movement caused by chemoeffector binding. These taxis transducer proteins are found among both the **eubacteria** and **archaea**, and thus probably antedate the separation of these two domains of life. In all known cases, these transducer proteins control a sensor CheA kinase. In *E. coli*, they operate as chemoreceptors, as described before. In two instances in the archeon *Halobacterium salinarium*, the transducer protein complexes with a sensory rhodopsin, which senses light by using a retinal chromophore and interacts with the methylated transducer protein to control the CheA kinase (4).

Transducin

Transducin, also known as G_t by the standard GTP-binding protein nomenclature, is the major heterotrimeric G protein of photoreceptor cells of the vertebrate retina, comprised of a, b, and g subunits. Activation of G_t is initiated by the photoactivated form of rhodopsin (known as "bleached," meta II), and it in turn activates the effector protein cyclic GMP phosphodiesterase (PDE). By hydrolyzing cyclic GMP in response to light, this signaling pathway leads to the closure of cyclic GMP-activated cation channels in photoreceptor cells. The resultant hyperpolarization of the photoreceptor cell is conveyed synaptically to organizational interneurons in the retina, which ultimately send the visual information to the brain.

Transducin's mechanism of action is typical for a G protein. Bleached rhodopsin catalyzes the release of GDP from Ga_t, and the binding of GTP in its place, in an extremely rapid and efficient reaction. Several hundred G_t molecules can be activated in 1 s, and a single bleached rhodopsin molecule can catalyze the activation of 2000 G_t molecules in a mammalian photoreceptor cell (1). Without rhodopsin, the rate of GDP/GTP exchange by G_t is extremely slow; noncatalyzed stoichiometric exchange has not been observed *in vitro* (see Guanine Nucleotide Exchange Factors). Such slow spontaneous activation is needed to minimize background signaling in the dark, which is in turn needed to allow photoreceptor signaling to operate over a huge range of light intensities.

Activated Ga_t-GTP binds and sequesters the two inhibitory PDE g subunits from the inactive abg_2 PDE heterotetramer, thus activating the catalytic PDE ab subunits. Although Gbg is presumably released upon G_t activation, no regulatory role for Gbg in photoreceptor cells has been clearly established. Signaling is terminated by hydrolysis of Ga_t-bound GTP and the consequent release of PDE g. In photoreceptor cells, GTP hydrolysis and its consequent deactivation are much faster than is observed with isolated G_t (~$1s^{-1}$ rather than $0.02s^{-1}$). Deactivation is accelerated in photoreceptors by RGS9, a GTPase-activating protein (GAP) whose activity is potentiated by PDEg

subunits (2) (see RGS Proteins).

There are two Ga_t polypeptide chains, Ga_{t1} and Ga_{t2}, encoded by two closely related **genes** in the two classes of photoreceptor cells. Both are members of the Ga_i family and are typically sensitive to pertussis toxin. In rod cells, which are responsible for vision in dim light, G_t is composed of Ga_{t1}, b_1, and g_1 subunits. Its great abundance, ~15% of total protein in the photoreceptor membranes of rod outer segments (3), made rod transducin one of the two experimental prototypes in the elucidation of G-protein signaling mechanisms. Transducin in cone photoreceptor cells (there is one cone cell each for red-, green-, and blue-sensitive opsins) contains Ga_{t2}. These two Ga_t polypeptide chains are also found at low abundance in a few other places in the brain.

Transducin is unusual among G proteins in several respects. First, it is relatively more water-soluble than other G proteins, despite the addition of a **farnesyl group** to Gg_1 and a **myristoyl group** to Ga_t (which has no **palmitoyl groups**). It can be solubilized from photoreceptor membranes by high ionic strength in the absence of detergent, and Ga_t can be solubilized quantitatively by dissociating it from Gbg after activation with a nonhydrolyzable GTP analog. Its mode of regulating its effector by chelation of inhibitory subunits is also unique. Last, basal GDP/GTP exchange on Ga_t is at least 10-fold slower than that on other G proteins.

Transfection

Transfection is the introduction of foreign **DNA** into the **nuclei** of **eukaryotic** cells, a fundamental technology in molecular and cellular biology. There are many reasons for transfecting cells (Table 1). Most often, cells are transfected to characterize the function and control of **genes**. More recently, economic (see Transgenic Technology) or therapeutic (human gene therapy) purposes have become increasingly important. After transfection, the foreign DNA, which is also referred to as the *transgene*, is usually neither integrated into cellular chromosomes nor replicating as an **episome**. In mitotically active cells, the transgene persists for only a few days, with a peak of expression observed within the first 24–48 h after exposure to DNA (transient transfection). Stable transfection results only if the transgene is integrated into the cellular genome. This is a random event, facilitated by chromosomal strand breaks and involving cellular recombinases and DNA repair pathways in an as yet poorly defined manner. The frequency of stable integration after transient transfection is dependent on the target cell population and on the method and protocol used; it usually occurs in 10^{-}

^{2} to 10^{-6} of transiently transfected cells. Therefore, dominant selectable marker genes encoding drug resistance or cell surface or cytoplasmic markers are used for the identification of stable clones. Regulatory elements of stably inserted foreign DNA are subject to environmental influences from neighboring chromosomal sequences. This can result in either support or extinction (silencing) of transgene expression, leading to a broad clonal variability, depending on the integration site. Semistable transfection can be accomplished by introducing episomally replicating **plasmids** that are inherited by random distribution in mitosis. Usually, foreign DNA is more autonomously expressed in the episomal form, but can easily be lost if not conferring a selective advantage.

Table 1. Reasons for Transfecting Eukaryotic Cells

Study *cis*-active elementsof DNA (control regions of genes)
Study coding sequences of DNA (function of genes)
Overexpress genes for protein purification (including industrial production)
Alter cellular genotype or phenotype for fate-mapping in complex organisms
Alter cellular genotype or phenotype for diagnosis or therapy in humans
Alter characteristics of cells or organisms for scientific or economical purposes

Starting from the original description of calcium phosphate precipitation as the first transfection method in 1973 (1), a great variety of methods and protocols have been developed to date that, in principle, allow transfection of any cell. However, with the increasing sophistication of the scientific goals, efficacy is no longer the only parameter to be considered (Table 2). Equally important criteria for choosing a method are the impact of the transfection procedure on cellular **stress responses** and viability, plus the fate of DNA and transfection vehicles inside the cell. This includes the potential degradation of DNA in **lysosomes**, the copy number of transgenes in the nucleus, the type and loci of transgene integration, and the potential of rearranging the cellular genome during or after transfection.

Table 2. Criteria for Evaluating Transfection Methods

Stress and toxicity of method (side effects for cellular genotype or phenotype)
General applicability (cell numbers and amount of DNA required, accessibility of target cells)
Selectivity (possibility of targeted delivery when approaching complex cell systems or organs)
Potential of lysosomal degradation (might generate unwanted side products)
Duration of transfection (transient, stable, semistable)
Quality of stable transfection (nuclear copy number and rearrangement potential)
Efficacy (percentage of transfected cells, level of gene expression)

These parameters are well understood in the natural ways of introducing genetic information into cells, such as **virus infection** pathways, some of which were exploited for developing very efficient, yet often laborious, viral transfection systems. The description of viral methods for introducing DNA into eukaryotic cells is covered elsewhere (see Adenovirus, Baculovirus, Polyomavirus, Retroviruses, Rous Sarcoma Virus (RSV), and Vaccinia Virus). As is evident from these articles, viruses have evolved using diverse strategies to overcome the most important hurdles to introducing foreign DNA successfully into cells. These are the cellular membrane barrier, lysosomal degradation of endocytosed nucleic acids, nuclear transport of DNA, and, most importantly, replication and persistence of DNA in episomal moieties or integrated into the cellular genome. Some properties of viral replication pathways have been exploited in the design of physicochemical transfection methods. These have the general advantage of using biochemically defined material for transfection of cells. In many physicochemical strategies, however, the quality parameters discussed above and listed in Table 2 are still not entirely investigated. Despite this lack of basic knowledge, one encounters an ever increasing diversity of protocols and recommendations, whose variety is due to the use of different types of transfection materials or instruments and varying DNA, targets (cells or even organs), culture conditions, experimental scales and scientific goals.

This article provides an overview of the physicochemical techniques most commonly used for transfecting cells. Some transfection methods rely on physical forces to enhance the uptake of DNA into cells; these include injection, biolistics, and electroporation . Chemical and biological carrier-mediated transfection methods include calcium phosphate precipitation, complexation with DEAE-dextran, polybrene or activated dendrimers, lipofection , and, finally, receptor-mediated methods. Description of protocols is beyond the scope of this *Encyclopedia*. For this, the reader should refer to the literature cited and, where possible, to experienced scientists.

1. Transfection by Feeding

The simplest way of offering DNA to cells is feeding. In hematopoietic cells, a lineage-restricted cellular **receptor** for nucleic acids has been described (2); this is a heparin-binding integrin. Similar receptors that trigger uptake of nucleic acids by endocytosis might also exist in other tissues. However, the biological significance of DNA receptor-mediated endocytosis of nucleic acids remains to be investigated. The endosome eventually fuses with lysosomes, after which the DNA is subjected to an acidic milieu and cellular **nucleases**. A surprising result has been obtained by feeding mice with not more than 50 μg of bacteriophage M13 DNA: fragments of M13 of size of up to 1.6 kbp have been detected by **PCR** in blood cells after feeding (3). This indicates that feeding can be quite successful for transferring small pieces of nucleic acids, such as oligonucleotides. However, it is—fortunately—not applicable for transfecting cells with genetically defined, biologically active genes.

2. Injection of DNA in Organs

To bypass the membrane barrier, physical methods have been developed. The simplest procedure is injection of DNA. Discovered surprisingly late, injection of DNA into postmitotic striated muscle tissue results in persistence and expression over prolonged periods of time (weeks to months) (4). In contrast to microinjection employed in the process of developing transgenic animals, injection does not directly target the nuclei. Because no carrier is used for the DNA, this implies that uptake and nuclear transport of foreign DNA occurs solely by cellular factors, thus representing a natural pathway. The preferred application of injecting DNA into tissues is DNA vaccination, which has turned out to be a most potent, versatile, and cost-effective way of immunization that is applicable to a large number of diseases, including viral and bacterial infections and possibly also cancer (4). More recently, instillation of DNA in hypertonic fluids has led to successful transfection of hepatocytes, indicating that hypertonic exposure to naked DNA after intravascular delivery might be applicable to other parenchymal organs (5).

3. Biolistics

More elaborate than injection using syringes is the method of biolistics. The principle of this method is to coat heavy-metal (preferably gold) particles (size about 1 μm) with DNA which thereafter are accelerated in a high voltage electric discharge or gas-pressure-driven apparatus (the so-called gene gun). Biolistics, also known as particle bombardment, is sufficiently versatile, efficient and flexible to be applied successfully in a wide range of cell types and cell environments, importantly also including organ slices *in vitro* and many types of solid tissues or organs *in vivo* (6-9). The method requires a fairly small amount of DNA and, compared to other transfection procedures, a small number of cells. Transfection results in high nuclear copy numbers (usually >20). When two or more different DNA are simultaneously coated on the metallic bead, almost 100% cotransfection is observed. Stable transduction is reported to occur at relatively high frequency (in the range of 1% of transiently transfected cells) and apparently results in integration of multiple arrays of transgenes. This may lead to inaccuracies when analyzing regulatory elements of transgenes and, moreover, might render the cellular genome unstable. Biolistics has found wide acceptance for applications in almost any eukaryotic cell and in cell environments not accessible by other transfection procedures. Unfortunately, the potential drawbacks have not been systematically addressed, although some enthusiasm has already been raised regarding therapeutic applications (preferentially for DNA vaccination) in humans.

4. Electroporation and Iontophoresis

Electroporation also employs physical forces to bypass the membrane barrier. Cells suspended at high densities (2×10^{6}–10^{7} mL^{-1}) in a buffer are subject to a short electric pulse lasting microseconds to a few milliseconds (10-12). The pulse is generated by discharging an electrical field of high voltage through the cell suspension kept in a cuvette. Alternatively, cells can be grown on microporous membranes for transfection *in situ*. Electroporation has also been proposed for improving delivery of drugs or nucleic acids by transdermal *iontophoresis* (13, 14), a technique using an electrical potential gradient for facilitating the movement of solute ions across membranes. Electroporation is highly stressful, with best transfection efficiencies obtained under conditions resulting in more than 50% mortality. Surviving cells are expected to reorganize the membrane immediately after being pulsed. Careful examination, however, reveals membrane instabilities even hours after transfection. Parameters influencing the transfection efficacy and mortality are those defining the pulse length (condenser capacity and voltage; electrode gap distance; volume, resistance, and temperature of the cell suspension), the amount of DNA and, generally, the fitness of cells. Further variations result from the use of machines generating different types of pulse waveforms (exponential decay, rectangular plateau, and radiofrequency) or pulse repetitions (single pulse vs double pulse). Thus, almost any cell can be transfected using electroporation, but the definition of a suitable protocol can be cumbersome. Fortunately, some conditions seem to be more widely applicable (15, 16). An advantage of electroporation is that stable integrations of transfected DNA often occur as single copies, rendering electroporation the method of choice for gene trap or gene knockout studies in developmental biology (see Gene Targeting). Not sufficiently analyzed is whether the procedure of electroporation can induce chromosomal rearrangements. Moreover, it can be envisaged that the stress exerted by electroporation interferes with some transient transfection studies where the results of the experiment are monitored within 24–48 h after transfection.

5. Calcium Phosphate Transfection

Calcium phosphate transfection was developed in 1973 to introduce Adenovirus DNA into mammalian cells (1). This actually represents the first description of a transfection method, made possible by carefully evaluating the parameters leading to a fine DNA–salt precipitate that can be applied to cells for endocytotic uptake. The method works well for most adherent cells *in vitro* and has the general advantage of being exceptionally cheap (17). However, the efficacy of the method is

heavily dependent on the pH of the media and calcium phosphate buffers, explaining the low reproducibility in the hands of researchers not precisely controlling this factor. Stable transformants occur at a frequency of @ 10^{-5}, often containing multiple copies of transfected DNA. This might be a result of previous complexation, as in biolistics, which would imply that the complete DNA–salt precipitate is transported into the nucleus. Using a special buffer allowing complex formation on cells in culture dishes, stable transfection frequencies can be improved 10–100-fold (18). Calcium phosphate transfection is not applicable *in vivo* or to suspension cells *in vitro*.

6. DEAE–Dextran Transfection

DEAE–dextran transfection is another simple and cheap method based on chemical complexation of DNA, which works well in transient expression experiments and can also be applied to some suspension cells (19). The mechanisms involved in DNA uptake and nuclear delivery in this method are poorly understood. The transfected DNA is present as minichromosomes and somehow excluded from stable integration. Parameters that need to be optimized for each given cell type are the concentrations and ratio of DEAE–dextran to DNA, the duration of transfection, and the time course of expression of the transfected gene. A DMSO (dimethylsulfoxide) or glycerol shock of cells after exposure to DEAE–dextran/DNA complexes can improve their uptake by chemical permeabilization of the membrane.

7. Polybrene/DMSO-Assisted Transfection

In this method, DNA is bound to the amorphous polycation polybrene, which is adsorbed electrostatically by negatively charged residues of **glycoproteins** located on the cell surface. Uptake is accomplished by chemically disrupting the membrane with a short exposure (in the region of 5 min) of cells to DMSO (20, 21). Toxicity is low to moderate, once the amount of polybrene and, more importantly, the conditions for the DMSO shock have been adjusted. Polybrene might protect the DNA from nuclease attack, perhaps similar to the lysosomal neutralization and disruption pathway described for activated dendrimers (see discussion below). Inside the nucleus, the DNA presumably dissociates from polybrene to facilitate transcription and integration. The method works best in adherent cell layers where high transient, as well as stable, transfection rates can be achieved; in suspension cells, it is not so efficacious. Integration can occur both as multiple copies arranged in tandem links at single sites and as single copies at distinct sites.

8. Activated Dendrimer Technology

More recently, so called activated dendrimers (22, 23) have been proposed for complex-mediated transfection. In this technique, DNA is bound electrostatically to tiny spherical cationic polyamidoamine polymers (dendrimers). Activated dendrimers with higher transfection efficacy are produced by partially degrading dendrimers on exposure to heat and solvents before binding of DNA. Uptake is mediated by endocytosis. No chemical permeabilization is required. Degradation of DNA is presumably blocked by neutralizing the acidic pH of lysosomes with an excess of positive charges of the dendrimer. Lysosomal escape might also involve osmotic swelling and subsequent disruption of the organelle. The subsequent fate of the dendrimer is yet unknown, as is the mechanism for nuclear translocation of transfected DNA. This relatively nontoxic method is applicable with good reproducibility for transient and stable transfection of adherent and suspension cells *in vitro*. *In vivo* applications have not been reported thus far. The copy number and integrity of stably transfected DNA still need to be investigated.

9. Lipofection

A method offering Trojan Horses for transfection is lipofection. The DNA is coated in surrogate membranes known as liposomes, which are then added to cells in order to fuse with the cellular membrane for releasing their content into the cytoplasm (24, 25). Fusion of liposomes with cellular

membranes is a rare event, however; uptake occurs preferentially by endocytosis. Liposomes are artificial spherical or cochleae-like vesicles consisting of lipid bilayers covering small volumes of aqueous solution. Many different neutral or cationic lipids are utilized by many different companies for the commercial formulation of liposomes. The rationale for using cationic lipids is an improved interaction with negatively charged DNA and cellular membranes. Almost any formulation is reported to yield excellent transient transfection rates in selected target cells. In fact, different cell types need different lipid formulations to achieve good transfection rates. Therefore, several formulations need to be tested in a given experimental setting. Once the lipid of choice and the optimal DNA:lipid ratio is defined, lipofection works in a highly reproducible manner, for both transient and stable transfection. Of special interest is the reproducibly good stable transfection efficiency achieved with lipofection of large pieces of DNA, such as **yeast artificial chromosomes** (26). Lipofection is also employed for transfecting cells in complex organisms *in vivo*, including applications in gene therapy. However, not every formulation withstands inactivation by serum or membrane surfactants (27). Moreover, in poorly adjusted experimental conditions, lipofection can be hampered by a profound toxicity. Interesting prospects of lipofection are the introduction of membrane components (glycoproteins) of viruses in order to increase the potential for membrane fusion or lysosomal escape (28) and the combination with specific ligands for targeted delivery in specialized cell types (see the following paragraph). Furthermore, proteins can be codelivered with DNA, offering novel perspectives for nuclear and genomic targeting.

10. Receptor-Mediated Transfection

All methods described thus far are nonspecific with respect to the target cell population. Receptor-mediated transfection has been developed to overcome this limitation. In the archetypal form known as transferrinfection, DNA is electrostatically bound to polylysine that is coupled to transferrin (29). Uptake by endocytosis predominantly occurs in cells expressing the cognate transferrin receptor. High transfection efficiencies were reported when lysosomal degradation was blocked by treatment with **chloroquine**, or, even better, when the complexes had been coupled with pH-controlled membrane-disruption activities derived from adenovirus or influenza virus (30). This observation has led researchers to design multiple types of artificial DNA shuttles, consisting of a ligand for cell-type specific uptake (eg, for the asialoglycoprotein receptor exclusively expressed in liver epithelium (30)), a DNA-binding moiety (polylysine, DNA-binding domains of transcription factors, liposomes, possibly dendrimers in the future) and, optionally, the lysosome-disruption activity. The primary goal is to design biochemically defined pseudoviruses for applications in gene therapy. Criteria for the usefulness of these systems include (*1*) the specificity and efficacy of transduction, (*2*) the resistance to serum or other natural barriers such as membrane surfactants, and (*3*) the potential mutagenicity of randomly integrated DNA.

11. Summary and Outlook

In summary, enormous progress has been made in developing defined physicochemical procedures for transfecting cells *in vitro* and *in vivo* (summarized in Fig. 1 and Table 3). To date, the challenge is no longer whether a cell can be transfected, but rather what the consequences of the transfection method are for the genotype and phenotype of the transfected cells. The primary choice to be made is the method, a decision that should be influenced by a basic understanding of its technological background and its possible consequences for the efficiency and quality of the experiment. Important parameters in this regard are the stress (for the cell, of course, not so much for the researcher) and toxicity of the method, the copy number of uptaken DNA and its fate inside the cell, and the consequences of the newly-introduced DNA for the cellular phenotype. The secondary but still critical choice is that of the protocol, which has profound impact on the outcome of the experiment and often will have to be adapted according to the individual setting under investigation.

Figure 1. Schematic overview of physicochemical transfection methods. The transgene is represented as a horizontal

bar. Injection (A); biolistics (B); electroporation (C); feeding—possibly involving a cellular receptor for nucleic acids (D); chemical complex-mediated methods including calcium phosphate transfection, DEAE/dextran-transfection, activated dendrimers, and polybrene/DMSO transfection, the latter requiring chemical permeabilization of the membrane (E); lipofection (F); receptor-mediated transfection (G). The first step in transfection is to bypass the membrane barrier, requiring either endocytosis, fusion with, or forced disruption of the membrane (1). Endocytosed nucleic acids can be subject to nuclease attack in lysosomes (2); lysosomal escape is a prerequisite for successful transfection with defined transgenes. After nuclear transport, which is mediated by yet unknown cellular cofactors, the transgene is present in episomal form (3). Integration in the cellular genome occurs randomly, and rarely (4). The transgene is transcribed to RNA from its episomal or integrated form (5). The cellular phenotype is altered according to the coding sequence and expression levels of the transgene (6).

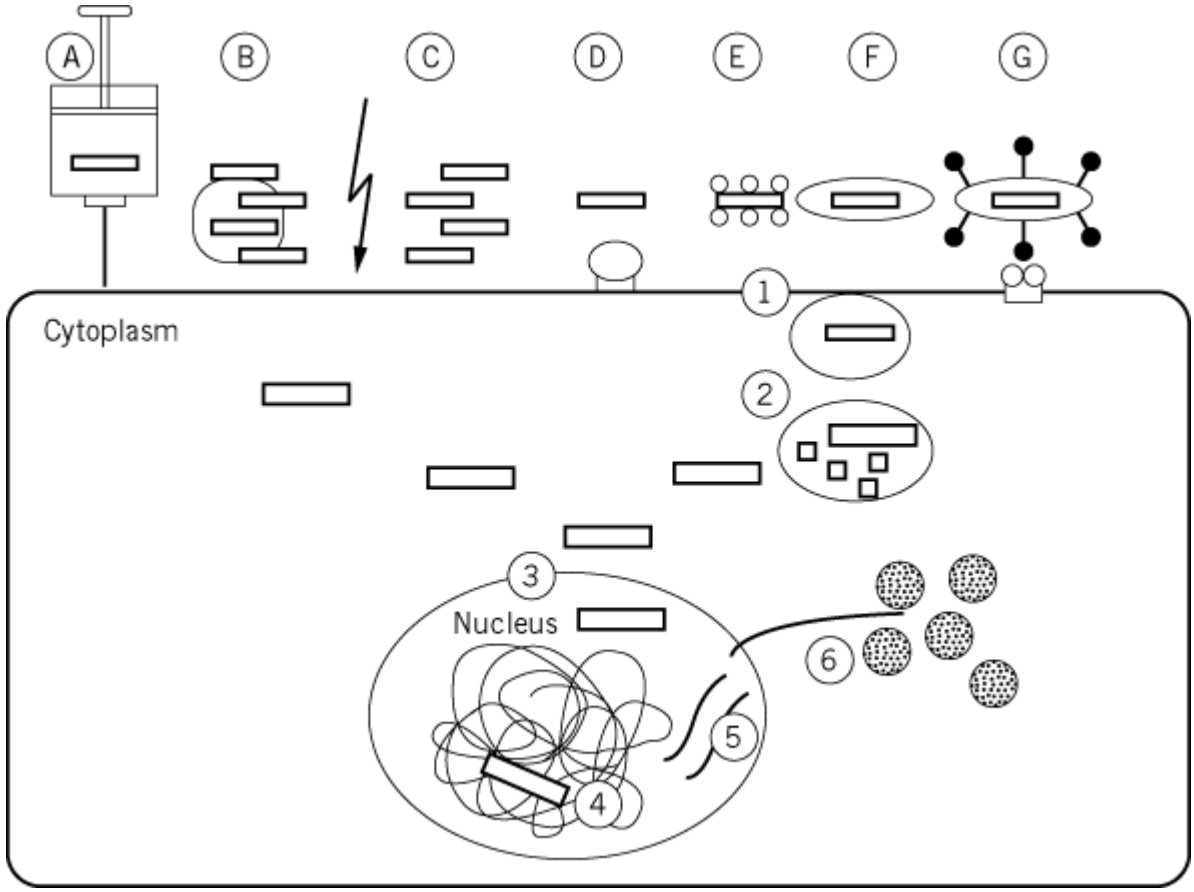

Table 3. Overview of Transfection Methods

Method	Principle	Uptake	Transient Transfection	Stable Transfection
Feeding	Exposure to DNA in aqueous solution	Endocytosis	Yes (degraded DNA)	Unclear
Injection	DNA in aqueous	Unknown[a]	*In vivo* only	Not carefully

	solution injected in tissue			analyzed
Biolistics	Bombardment with DNA coated on gold particles	Forced disruption of membrane	*In vitro* and *in vivo*	In multiple copies, rate $\approx 10^{-2}$
Electroporation	Disruption of membrane barrier in electric field	Forced disruption of membrane	Preferentially *in vitro*	In single copies, rate $\approx 10^{-5}$
Calcium phosphate transfection	Complexation of DNA by salt precipitation	Endocytosis	*In vitro* only	In multiple copies, rate $\approx 10^{-2}$
DEAE-dextrantransfection	Complexation of DNA with large sugars	Endocytosis or chemical permeabilization	*In vitro* only	No
Polybrene/DMSO transfection	Complexation of DNA on cationic amorphous salt	Chemical permeabilization	*In vitro* only	Single or multiple copies, rate $\approx 10^{-4}$
Activated dendrimers	Complexation of DNA on cationic particles	Endocytosis	*In vitro*	Possibly in multiple copies
Lipofection	Coating of DNA in aqueous solution in lipid bilayers	Membrane fusion or endocytosis	*In vitro* and *in vivo*	Single copy possible, rate $\approx 10^{-4}$
Receptor-mediated transfection	DNA bound to ligand-displaying carrier	Endocytosis	*In vitro* and *in vivo*	Yes, copy number presumably carrier-dependent

[a] Possibly involving forced membrane disruption by locally increased pressure or nucleic acid receptor-mediated endocytosis.

In future, we will encounter an increasing diversity of materials and methods proposed for transfection. Special attention will be paid to developing selective and efficient systems that allow safe and controlled transduction of primary cells *in vitro* and *in vivo* . With an improved knowledge of the underlying mechanisms, continuous elaboration of transfection methods will thus raise the quality of basic research, as well as the economical or even therapeutic applications of molecular genetics.

Transfer Free Energy

The transfer free energy $Dm_{pr,tr}$, of a protein is the increment in **free energy** of transferring the protein from water into a solvent of a given composition (eg, 1*M* sucrose, 8*M* urea, 6*M* **guanidinium chloride**). This means that it is the free energy of interaction of the protein with the solvent of the given composition, in other words, the free energy of binding of the cosolvent to the protein, DG_b. The transfer free energy defines quantitatively the effect of a cosolvent on protein stability (see Stabilization And Destabilization By Co-Solvents, solubility), and self-assembly (such as the formation of **organelles**, eg, microtubules).

The transfer free energy is obtained directly by integration over ligand concentration of the preferential binding measured by equilibrium dialysis, when that parameter is expressed by the perturbation of the chemical potential of the protein, m_{pr}, by the ligand (1):

$$(\partial\mu_{pr}/\partial m_L)_{T,P,m_{pr}} = -(\partial m_L/\partial m_{pr})_{T,P,\mu_L}(\partial\mu_L/\partial m_L)_{T,P,m_{pr}} \quad (1)$$

and

$$\Delta\mu_{pr,tr} = \int_0^L (\partial\mu_{pr}/\partial m_L)_{T,P,m_{pr}} dm_L = \Delta G_b \quad (2)$$

The term $(\partial\mu_L/\partial m_L)_{T,P,m_{pr}}$ is the expression of the nonideality of the ligand, ie, cosolvent, and is equal to $RT\,(1/m_L + \partial \ln g_L/dm_L)$ where R is the gas constant, T the temperature, and g_L is the *activity coefficient* of the ligand, eg, sucrose, urea, the values of which can be found in many standard tables.

The variation with the cosolvent concentration of the three fundamental interaction parameters, namely, preferential binding, chemical potential perturbation, and transfer free energy, is illustrated in Figure 1 for two cosolvent systems. It is clear that their mutual variation is complex and a single point does not give much information. It is also clear that positive values of preferential binding correspond to negative values of the chemical potential perturbation, ie, the interactions are favorable, and vice versa. There is no such direct relation with the transfer free energy (free energy of binding). For example, in the 2-chlorethanol system, $Dm_{pr,tr}$ is negative at all cosolvent concentrations, even though the preferential binding goes through a maximum and becomes negative. Just the converse is true for the b-lactoglobulin-$MgCl_2$ system, where $Dm_{pr,tr}$ is always positive (increasingly unfavorable interactions relative to water), whereas preferential binding starts with negative values, passes through a minimum, and finally becomes positive. This reflects the difference in the reference states and illustrates the vast amount of information that may be obtained from equilibrium dialysis measurements, if these are fully interpreted.

Figure 1. Variation of the the thermodynamic interaction parameters with cosolvent concentration: preferential binding (interaction parameter (f), and transfer free energy $Dm_{pr,tr}$ ($\triangle$). (*a*) **b-Lactoglobulin** in aqueous 2-chloroethanol; (*b*) b-la pH 3.0. Note that $Dm_{pr,tr}$ is at its peak (minimal for the favorably interacting 2-chloroethanol and maximal for the unfav where the binding measured by equilibrium dialysis is zero. Transfer RNA

Transfer RNAs, usually usually abbreviated tRNAs, are small, well-characterized RNA molecules with a key role in **protein biosynthesis**. They must interact with a number of proteins, including specific aminoacyl-tRNA synthetases, **initiation** and elongation factors, and components of ribosomes. Specific interaction between a region of the tRNA called the anticodon and **codons** of the messenger RNA (mRNA) guarantees that the nucleotide information in the mRNA is translated correctly into protein. The concept of an adapter to provide the interface between nucleic acid language and protein language was introduced by Crick in 1955 (1). tRNA (the abbreviation for transfer ribonucleic acid) was, however, not discovered until 3 years later (2). tRNAs also participate in nonprotein synthetic capacities. They prime **reverse transcription** in retrovirus life cycles and serve as amino acid donors during synthesis of the cell wall, chlorophyll, and heme. Structural variants of tRNA, the tRNA-like molecules, are probably of distinct evolutionary origin but share some tRNA properties. These tRNA mimics are present in some messenger RNA and in a number of viral RNA, where they contribute to **translational** control and viral replication, respectively. One other small RNA, 10 S RNA, will also be considered here because it has aminoacylation properties like tRNA. Interestingly, it also has mRNA-like properties and is an important component in a process that eliminates defective proteins from **prokaryotic** cells.

1. Structural Properties

tRNAs are single RNA chains of 75–93 nucleotides, present in the cytosol and organelles of all living cells. Holley and his co-workers determined the first tRNA sequence in 1965 (3); today more than 2700 sequences are known either from direct sequencing of tRNA or by sequencing of their genes (4). Direct sequencing of tRNA reveals a high level of modified versions of the classic nucleotides. More than 80 different modifications have been characterized (5). All occur posttranscriptionally and may be modifications of the base (methylation, thiolations, etc) or of the ribose (methylations). Dictated by their primary sequence, tRNA fold into cloverleaf-like secondary structures with well-defined stems and loops that make up the acceptor arm, D arm and loop, anticodon arm and loop, and the T arm and loop (Fig. 1a). Regardless of the length of the tRNA, the numbering of conserved nucleotides remains constant. The acceptor stem always has 7 base pairs and 4 single-stranded nucleotides, including an absolutely conserved CCA sequence. The D stem and loop are of variable length, whereas the anticodon stem has 5 nucleotides and the anticodon loop has 7 nucleotides. The variable region usually has 4–5 nucleotides but can contain up to 24 nucleotides. Finally, the T stem always has 5 base pairs and the T loop has 7 nucleotides. High-resolution crystal structures of yeast tRNAPhe and yeast tRNAAsp revealed a three-dimensional (3D) L-shaped structure. The two domains of this structure correspond to the acceptor branch (stacking of the acceptor arm and the T arm) and the anticodon branch (anticodon arm, D arm) (Fig. 1). The angle between both branches is about 90°, and the distance between the extremities of the branches, that is, between the acceptor end and the anticodon triplet, is 75–80 Å. This 3D structure forms through a number of interactions between conserved or semiconserved nucleotides distant in the covalent structure, but close in the folded conformation, especially those in the D and T loops and within the core of the molecule (Fig. 1). Among the nine tertiary interactions present in classic tRNA, three involve triple interactions between three nucleotides (between residues 8-14-21, 9-12-23, 10-25-45, and 13-22-46).

tRNA are classified according to the length of their variable region, which can be 4 or 5 nucleotides (class I tRNA) or 10–24 nucleotides (class II tRNA). Only tRNALeu, tRNASer, and eubacterial—as well as some organelle—tRNATyr are class II tRNA. A new class II tRNA, discovered more recently in many organisms, serves as the adapter for selenocysteine, the "21st amino acid" (6). Some tRNA from mitochondria present peculiar structural features, such as the absence of one or more stems and loops within the secondary structure (7) and/or the absence of conserved nucleotides. Nonetheless, these tRNA are thought to fold into the L-shaped 3D structures necessary to fulfill their functions (8).

In each cell or organelle, there are 20 families of tRNA, one per each amino acid. Isoacceptor tRNAs belong to the same family and are charged with the same amino acid during protein synthesis. It is critical that the amino acid be appropriate to the sequence of the anticodon triplet, which, in turn, is complementary to a specific codon. Charging of tRNA with an amino acid is governed by specific aminoacyl-tRNA synthetases (aatRS). These enzymes esterify an amino acid to either the 2′- or 3′-hydroxyl group of the 3′-terminal ribose, a mechanistic aspect of the aminoacylation reaction that is used to classify aatRS into two classes (9, 10). The reaction occurs in two steps: (1) activation of the amino acid to an adenylate and (2) transfer of the activated amino acid to the tRNA. Both reactions are magnesium-dependent. Some aatRS require the presence of the homologous tRNA for recognition of the cognate amino acid (11).

1.1. Charging with Amino Acids

The accuracy of protein synthesis is dependent on the accuracy of aminoacylation, so the elements that dictate the recognition of tRNA by aatRS have been referred to as the second genetic code (12). Specific aminoacylation of tRNA by their cognate aatRS is governed by identity determinants present within the tRNA. These include both positive signals allowing recognition by the cognate aatRS and negative signals hindering recognition by noncognate enzymes (13-16). Positive elements continue to be identified using two similar approaches. The *in vivo* approach exploits suppressor tRNA, tRNA with anticodon triplets that are altered for complementarity to codons that do not correspond to an amino acid and are referred to as stop codons. Mutations that alter the specificity of aminoacylation identify "identity elements". The *in vitro* approach examines aminoacylation properties of purified tRNAs produced by *in vitro* transcription. Alterations in the nucleotide sequence of these tRNAs that lead to significant decreases in aminoacylation efficiency are referred to as recognition elements. Both approaches reveal a similar set of nucleotides important for aminoacylation identity, which are referred to as identity determinants .

Positive identity elements are limited in number (a single nucleotide and up to 13 nucleotides). Thus, histidine identity requires a single base added at the 5′ end of the tRNA, (G1); specific alanylation is governed by a single base pair (G3-U70) in the acceptor stem; only five nucleotides within yeast $tRNA^{Phe}$ dictate specific phenylalanylation (A20, G34, A35, A36, and A72). Identity elements are concentrated mostly in the anticodon loop and the 3′ end of the acceptor stem, including the discriminator base, first recognized in the early 1970s. Identity elements have, however, also been found in the D loop or the anticodon stem. The preferential location of identity elements at the extremities of tRNA led investigators to design minihelices , small RNAs that are missing substantial portions of the original tRNA. These minihelices contain complete or partial identity sets (17-19). Minihelices as small as the acceptor stem can be specific substrates for aminoacyl-tRNA synthetases. Anticodon-like minihelices, containing major identity elements, stimulate the aminoacylation capacity of the partner acceptor stem minihelix in yeast valine and *Escherichia coli* isoleucine systems (20, 21).

Identity sets transplanted into an unrelated host tRNA confer a new identity on the host. A simple anticodon switch changes the identity of methionine and valine tRNA (22). Insertion of the 5-nucleotide phenylalanine identity set into yeast $tRNA^{Arg}$, $tRNA^{Tyr}$, and $tRNA^{Met}$ converts these tRNA to very efficient phenylalanine acceptors. A leucine tRNA can be transformed into a serine

tRNA by changing 12 nucleotides (23). Interestingly, nonoverlapping identity sets allow the design of some tRNAs with multiple identities (24). Identity sets have been investigated for all *E. coli* tRNAs, as well as for a number of eukaryotic tRNAs. Although there are some exceptions, identity sets are usually conserved throughout different kingdoms (16).

That identity elements are usually in direct contact with the aatRS is revealed by X-ray structures of complexes of the *E. coli* glutamine (25) and yeast aspartate (26, 27) tRNA and their respective synthetases. All chemical groups of an identity nucleotide are not involved in specificity. Specific recognition of alanine tRNA by its cognate synthetase is dictated by the exocyclic NH_2 group of guanosine G3 (28). Specificity of isoleucylation is governed by modification of the 5′-anticodon nucleotide, C34. When modified with a lysine, to become "lysidine" 34, the tRNA is efficiently recognized by isoleucyl-tRNA synthetase. In the absence of the lysidine modification, the isoleucine identity is lost and the tRNA becomes a substrate for methionyl-tRNA synthetase (29).

Optimal expression of aminoacylation identity also depends on higher order structural features, and disruption of tertiary interactions leads to dramatic losses in aminoacylation efficiencies. Some aminoacyl-tRNA synthetases are sensitive to local subtle conformational changes in their cognate tRNA. Contribution of the structure to efficient aminoacylation has been demonstrated for alanine-specific tRNA. A local distortion in the acceptor stem helix caused by the G-U base-pair identity element contributes to specificity (30). In *E. coli* $tRNA^{Arg}$, identity is dependent on the presence of a "variable" pocket, formed by nucleotides from the D and T loops, which are in close vicinity in the 3D structure (31). Similarly, *E. coli* $tRNA^{Glu}$ has major structural identity determinants within the "augmented D helix" (32). In *E. coli* $tRNA^{Cys}$, the tertiary G15-C48 pair is a structural element required for specific aminoacylation (33).

The higher-order structure necessary during the recognition step is not maintained following the initial interaction between synthetase and tRNA. Significant conformational changes do occur after synthetases bind to tRNA. During the aspartate tRNA synthetase interaction, the tRNA anticodon loop nucleotides are spread out to reach pockets in the complementary protein environment of the aspartyl-tRNA synthetase (27). Dramatic changes are also observed in the anticodon loop during the glutamine tRNA synthetase interaction, as well as at the acceptor stem, where the CCA end folds back on the acceptor stem helix (25).

Negative elements also contribute to specificity by hindering tRNA recognition by noncognate aminoacyl-tRNA synthetases. Thus, lysidine, present at position 34 of *E. coli* $tRNA^{Ile}$ (see discussion above), prevents recognition of this tRNA by methionyl-tRNA synthetase (29). A single methyl group present on G37 of yeast $tRNA^{Asp}$ hinders its recognition by the noncognate arginyl-tRNA synthetase (34).

In three cases (Arg, Glu, Gln), the tRNA not only is a substrate in the aminoacylation reaction but also plays an important role as a cofactor in allowing correct recognition of the amino acid by aatRS. Interaction between tRNA identity nucleotides and their recognition sites in glutaminyl-tRNA synthetase determines the affinity of the enzyme for the cognate amino acid (11, 35). This participation of tRNA in optimizing amino acid recognition reveals a novel mechanism for maintaining translational fidelity and also provides a strong basis for the coevolution of tRNA and their cognate synthetases.

In rare instances, production of a correctly charged tRNA depends on more than a correct aminoacyl-tRNA synthetase interaction. To produce Gln-$tRNA^{Gln}$ in *E. coli* and in yeast mitochondria, the tRNA is first "mischarged" with glutamic acid (Glu-$tRNA^{Gln}$) and then the esterified glutamic acid is converted into glutamine. Synthesis of Asn-$tRNA^{Asn}$ in *Halofax volcanii* occurs in a similar fashion; aspartate is charged on $tRNA^{Asn}$ and subsequently converted to asparagine by

transamidation (36). Synthesis of selenocysteine (Sec)-charged $tRNA^{Sec}$ also requires two steps. The tRNA is aminoacylated by seryl-tRNA synthetase with serine, and in a second step, selenium is inserted into the serine by selenocysteine synthase to produce selenocysteine (6, 37).

2. Amino Acid Transfer

After specific aminoacylation, tRNAs arrive at the ribosome where their amino acids are connected together as peptide bonds are formed by peptidyl transferase. A particular $tRNA^{Met}$, $tRNA^{iMet}$, the initiator tRNA, recognizes the initiation codon AUG. Methionine residues located internally are provided by the elongator $tRNA^{Met}$, $tRNA^{eMet}$. Both tRNA are charged with methionine; in prokaryotes and in mitochondria, the methionine charged to the initiator tRNA is subsequently modified by formylation. Initiator tRNA bear particular structural features that allow their discrimination from elongator tRNA by initiation factors. These include the formylated amino acid, if present (38), and three consecutive G:C base pairs, conserved in the anticodon stem of virtually all initiator tRNA from eubacteria, eukaryotes, and archaebacteria (39).

All aminoacylated elongator tRNA form ternary complexes with a GTP-activated elongation factor, which is necessary for binding to the ribosomal A site. The major elements required for recognition by prokaryotic elongation factor EF-Tu-GTP are the a-NH_2 group of the bound amino acid and nucleotide A76. Additional direct contacts between the tRNA and the protein occur via riboses and phosphates contained within the amino acid acceptor stem, as revealed by the X-ray crystallography structure of the ternary complex formed by yeast $tRNA^{Phe}$, elongator factor EF-Tu from *Thermus aquaticus*, and a structural analog of GTP (40). Neither conserved nucleotides nor modified bases within this domain are necessary.

Negative elements allow elongation factors to discriminate initiator from elongator tRNA. For prokaryotic $tRNA^{fMet}$, the formyl group present specifically on the a-amino group of methionine is the negative element. A modification at the 2′ carbon of the ribose at position 64 in plant and fungi $tRNA^{iMet}$ provides this function. An additional signal that distinguishes initiator from elongator tRNA is the absence of a base pair between residues 1 and 72.

Interaction of aminoacylated tRNA with the ribosome depends on initiation or elongation factors. Initiator tRNA enters the ribosomal P (peptidyl-) site. Elongator tRNAs enter the A (aminoacyl) site, matching the anticodon with the mRNA codon, and acquire the growing peptide chain attached to the tRNA in the P site. The peptidyl-transferase activity of the large ribosomal subunit catalyzes a nucleophilic attack by the amino acid of the A site tRNA on the carboxy-terminal amino acid of the growing peptide chain. The tRNA carrying the peptide chain then moves to the P site by translocation. Uncharged tRNAs leave the ribosome via the E (exit) site. Many studies, including footprinting and crosslinking, seek to define detailed information about the interactions between tRNA and the ribosome (41-44). It is known that the anticodon of the tRNA interacts with the small ribosomal subunit, whereas the acceptor stem, especially the -CCA-amino acid end, interacts with the large ribosomal subunit. Direct contacts with *E. coli* 23 S RNA have been observed. Recently, three tRNAs bound to *E. coli* 70 S ribosomes were directly visualized with cryoelectron microscopy (45). The detailed arrangement of A- and P-site tRNA inferred from this study by 3D reconstruction allowed localization of the ribosome sites for anticodon interaction and peptide bond formation.

3. Other Functions

tRNAs have several functions in addition to ribosomal-dependent protein biosynthesis. Specific host tRNA are used to prime minus-strand DNA synthesis during the replication cycle of retroviruses. $tRNA^{Trp}$, $tRNA^{Pro}$, $tRNA^{Lys}$, and $tRNA^{iMet}$ are most widely used as primers. They are specifically encapsidated in viral particles. Reverse transcription of the genomic RNA of human immunodeficiency type 1 virus (**HIV**-1) is primed by $tRNA3^{Lys}$. Primer tRNA bind to the primer

binding site (PBS) of the viral genome via hybridization of 18 or more (31 nucleotides of $tRNA3^{Lys}$) 3′-terminal nucleotides, leaving the 3′-OH accessible for initiation of reverse transcription. In some cases, additional interactions take place between the primer tRNA and the retro-RNA outside the PBS. Modified nucleosides of the tRNA contribute to the efficiency and accuracy of the different steps of the process. Since tRNA secondary and tertiary structures are very stable, hybridization to the viral RNA requires assistance from nucleocapsid protein and reverse transcriptase (46).

$tRNA^{Glu}$ is involved in the formation of d-aminolevulinic acid, a precursor for heme and chlorophyll synthesis. In this process, $tRNA^{Glu}$, charged with glutamate, is the substrate for Glu-tRNA reductase, which reduces Glu-$tRNA^{Glu}$ to glutamate 1-semi-aldehyde and releases free $tRNA^{Glu}$. Glutamate semialdehyde is further converted to d-aminolevulinic acid by glutamate-1-semialdehyde-2, 1-aminomutase in a reaction that is independent of tRNA (47).

tRNA-like domains are present at the 3′ end of some RNA genomes of some plant viruses (48). These domains fold into simple L shapes or more complex conformations that include an L shape (49). These structures are recognized by **nucleotidyltransferases**, are efficiently aminoacylated by host or heterologous aminoacyl-tRNA synthetases, and interact with elongation factors. Tymoviruses are typically charged with tRNA for valine, tobamoviruses with histidine, and bromoviruses with tyrosine. Rules for aminoacylation are the same as those for classic tRNA. Despite their functional and structural similarities to classic tRNA, these tRNA-like domains are not involved in protein synthesis. They serve as initiation sites for viral replication, and also play a role similar to that of telomeres by protecting the viral RNA against degradation (50). In bromoviruses, aminoacylation is not required for replication. In tymoviruses, the presence of an amino acid is necessary for replication (51). tRNA-like structures are present in the upstream leader sequences of some *E. coli* mRNA that code for aminoacyl-tRNA synthetases and are involved in translational regulation of aatRS synthesis (52). The tRNA-like structure of the threonyl-tRNA synthetase mRNA is the best characterized. The leader folds into two anticodon-like arms. When the level of cellular $tRNA^{Thr}$ is low, free ThrRS binds to the leader sequence instead. This hinders binding of the ribosome to the Shine–Dalgarno sequence and prevents use of the initiation codon. Alternatively, high levels of $tRNA^{Thr}$ engage all the available ThrRS, and translation from the mRNA proceeds (53).

4. 10SaRNA/tmRNA

10SaRNA or tmRNA, a 350-nucleotide RNA, has a dual role as both tRNA and mRNA and is present in a wide variety of prokaryotes (54). Its has features within its secondary structure that mimic canonical tRNA arms (55). Aminoacylated with alanine, it enters the A site of ribosomes that are stalled on mRNA and thus cannot terminate protein synthesis properly. Peptidyl transferase catalyzes the transfer of the nascent peptide to the alanine, and the ribosome transfers to the 10Sa/tmRNA; it continues to translate the 10Sa/tmRNA, until a stop codon is reached and the ribosome, the protein, and the last tRNA are released normally. All proteins released by this process have the same carboxy-terminal amino acid sequence, since 10Sa/tmRNA directs its synthesis. This carboxy-terminal tag is a signal for directing the truncated, defective proteins to specific cellular proteinases. Thus, 10Sa/tmRNA protects the cell from defective proteins and allows ribosome cycling by directing ribosome switching from one mRNA to another (56).

5. Neuromuscular Diseases

A large number of human neuromuscular genetic diseases resulting in severe oxidative phosphorylation deficiencies correlate with the occurrence of point mutations in mitochondrial tRNA genes (57, 58). Mitochondrial DNA in individuals suffering from these diseases is heteroplasmic, and the severity of the symptoms generally relates to the ratio of wild-type to mutant DNA. To date, 32 independent mutations have been found in 13 tRNA genes. Among the most widely studied are mutation 3243 in $tRNA^{Leu}$ (UUR) gene, responsible for mitochondrial myopathy with lactic acidosis

and stroke-like episodes (MELAS) and for diabetes mellitus, and mutation 8344 in the gene of tRNA ^{Lys}, responsible for myoclonic epilepsy with ragged red fibers (MERRF). The molecular mechanisms by which mutations in the genes cause the associated phenotypes are not yet clear.

Transferase

Transferases are a diverse group of enzymes with respect to the identity of the groups that they transfer and the structure of the acceptor molecules.

1. The transfer of one-carbon groups is catalyzed by methyltransferases; hydroxymethyl-, formyl-, and related transferases; carboxyl- and carbamoyltransferases; and amidinotransferases.
2. Acyl groups are transferred by the acyltransferases, with the formation of esters or amides, and the donor is usually the corresponding coenzyme A (CoA) derivative. Aminoacyl group transfer also occurs.
3. Glycosyltransferases form a major subdivision within the transferase group of enzymes; the general reaction is the transfer of a sugar moiety from oligosaccharides or a high-energy compound, such as UDP-galactose, to another carbohydrate molecule. They can catalyze hydrolytic and phosphorolytic reactions by transfer of a glycosyl group to water and inorganic phosphate, respectively.
4. *Aminotransferases* catalyze the transfer of an amino group from an amino acid to a keto acid through the involvement of pyridoxal phosphate (see Coenzyme, Cofactor).
5. The enzymes concerned with the transfer of phosphorus-containing groups include the phosphotransferases (see above), diphosphotransferases, nucleotidyltransferases, and the transferases that utilize CDP, GDP, and UDP derivatives.
6. There are also the sulfurtransferses, the sulfotransferases, and the CoA transferases.

Transferrin

No other metal surpasses iron in versatility of uses to which it is put by nature. Iron is essential for the transport of oxygen by hemoglobin and hemerythrin; it has critical functions in the energy-transducing pathways of electron transport; it is indispensable in the DNA-synthesizing activity of mammalian ribonucleotide reductase; it participates in the catalysis of biological oxidations and oxygenations by dioxygen and hydrogen peroxide, as well as in protection against oxidative stress induced by these sometimes noxious species; it has a central function in nitrogen fixation; it engages in a rich variety of reactions entailing hydration-dehydration or hydrolytic cleavage; it is a magnetosensor for orienting organisms as diverse as magnetotactic bacteria, honey bees, and pigeons; and it is even used for mineralization of teeth by invertebrates of the limpet family.

The need for iron is accompanied by a corresponding need for iron carriers. In an aerobic environment at physiological pH the stable state of iron is the ferric, Fe^{3+}, but hydrolysis of ferric

iron to form insoluble polynuclear complexes of ferric hydroxide limits the concentration of simple aquated Fe^{3+} to 10^{-17} M. Iron carriers are needed to overcome the solubility problem and to keep iron from catalyzing the generation of noxious and reactive oxygen species — an event prone to occur when iron is surrounded by reductants of metabolism — the pyridine nucleotides or reduced flavins, for example. Iron carriers are as indispensable to life as iron. Derangements of iron metabolism, whether hereditary as in hemochromatosis, or acquired as in transfusion-dependent or nutritional iron-deficiency anemias, are among the most common, ubiquitous and dangerous of human maladies.

1. Transferrins: General Descriptions

In the universe of multicellular organisms with circulatory systems, including species at least as ancient as the cockroach and tobacco hornworm (1-3), iron transport is often managed by the transferrins, a class of single-chain, two-sited, iron-binding proteins. The human transferrin molecule is a bilobar structure of 769 amino acids and two multiantennary glycans, with a molecular weight of near 80,000 depending on the branching of its two glycans (4, 5). A 45% identity in amino acid sequences of the two lobes, with conservative equivalence of most of the nonidentical residues, and a nearly exact homology in intron/exon organization of corresponding halves of the human transferrin gene (6), establish that the modern transferrin structure arose from duplication and fusion of an ancestral gene specifying a single-sited transferrin precursor. No species is known in which a verified single-sited half-transferrin persists, nor is the evolutionary advantage enjoyed by a two-sited protein clearly understood.

The transferrins are customarily divided into three major subclasses: serum transferrin, ovotransferrin (formerly called conalbumin), and lactoferrin or lactotransferrin, depending on the source from which each is isolated. Iron-binding ligands are identical among these subclasses, as is the general organization of the protein molecules. Each lobe of a transferrin molecule is divided into two domains, designated N1 or C1 and N2 or C2, depending on location in B- or C-lobes, respectively. Thus, the protein molecule consists of two lobes and four domains. The lobes are joined by a short connecting b-strand in human transferrin, by a loop structure in hen ovotransferrin (7), and by a three-turn helix in human lactoferrin (8). Slight differences in arrangements of lobes and domains help account for the sometimes striking differences in iron-binding and functional properties among the transferrins.

Serum transferrin is, under normal circumstances, the major or sole source of iron for the metabolic needs of most cells. In man, the half-life of circulating transferrin is about 7.5 days, whereas that of transferrin-borne iron is about 1.7 h (9), implying that a transferrin molecule experiences over 100 cycles of iron transport during its lifetime. Understanding mechanisms of iron binding and release is therefore central to understanding the biological function of transferrin. Like mammalian transferrin, ovotransferrin, the product of the same gene in the chicken as serum transferrin and differing from the serum protein only in its glycosylation, also can serve as an iron source for developing chick embryo red cells (10). Its primary function, however, may be in sequestering iron, thereby defending the egg against microbial invasion. In contrast to these proteins, the principal role of lactoferrin appears to be in conferring bacteriostatic activity to the milk and other physiological fluids in which it is found. Such activity originates not only from the strong iron-binding properties of the protein, but in a basic sequence of its N-lobe that has been termed lactoferricin (11). Lactoferrin sequesters iron much more tenaciously than do serum transferrin and ovotransferrin, so that release of iron to cells probably entails intracellular degradation of the protein. The concentration of lactoferrin in blood plasma is less than 1 mg/ml, but its turnover, primarily the result of uptake by hepatocytes (12), is sufficiently rapid so that lactoferrin may serve a true transport function for iron, complementing that of serum transferrin.

2. Regulation of Transferrin Expression

The human transferrin gene lies on chromosome 3 (4), as do the genes for the transferrin receptor and ceruloplasmin. Transferrin is expressed by many cells largely in a constitutive manner, the liver being by far the most important source of the circulating protein (13). Secretion is promoted by cytokines (14); expression is enhanced by estrogen, hypoxia, iron deficiency anemia, inflammation, and other factors, but seldom to a pronounced degree. Regulation may be at transcriptional and post-transcriptional levels, with tissue-specific transcriptional factors identified in Sertoli cells and hepatocytes (15).

3. Structure of Serum Transferrin

Human serum transferrin consists of 679 amino acids disposed in a single polypeptide chain divided into two highly homologous lobes (46% identity of amino acid residues, and a much higher degree of conservative structure) roughly equal in size. Domain 1 of each lobe is formed by the first 90 or so amino acids of that lobe. The main chain then crosses to form the full second domain comprising some 150 residues, before returning to complete the first domain. Thus, the two domains are connected by a pair of antiparallel strands; the two lobes are joined by a single short b-strand of some seven residues. Each domain and each interdomain connecting strand provides a ligand for the iron-binding site: Asp 63 (392) from domain 1 of N-lobe (or C-lobe), Tyr 95 (426) from the first strand connecting domain 1 to domain 2, Tyr 188 (517) from domain 2, and His 249 (485) from the connecting strand returning from domain 2 to complete domain 1. Thus, the protein contributes four ligands to each of its specific sites; the remaining two coordination requirements of Fe^{3+} are satisfied by a carbonate anion bound in bidentate manner to the metal ion and further joined to the protein in a complex network of hydrogen and electrostatic bonds.

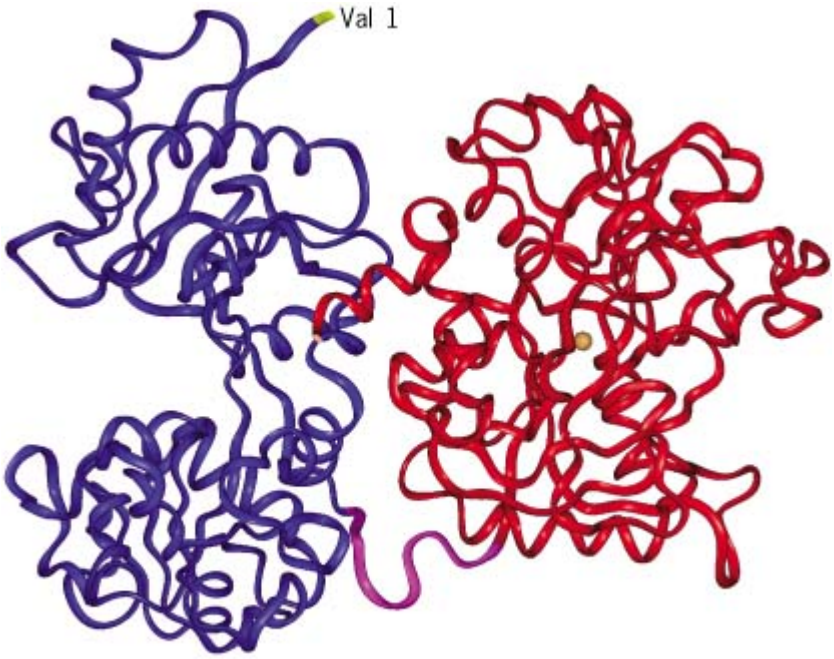
4. Carbonate and the Binding of Iron to Transferrin

Binding of iron and carbonate are highly cooperative, neither being strongly bound in the absence of the other. This interdependence of iron and carbonate binding may be taken as the unique and defining characteristic of all transferrins. A variety of studies suggest that carbonate binding precedes iron binding, perhaps by introducing negative charge at the binding site in preparation for receiving positively charged iron (16, 17). For this reason, carbonate (or, in its absence, other bifunctional anion capable of occupying the anion-binding site) is often referred to as the synergistic anion (18). Iron is always bound in the ferric state, Fe^{3+}, the binding of the ferrous form, Fe^{2+}, being much too weak to be of practical significance.

5. Conformational Changes Associated with Binding and Release of Iron

Each lobe of transferrin, when devoid of iron, assumes an open-jaw configuration of its two component domains. Binding of iron is accompanied by a rotation of the domains with respect to each other, thereby closing the cleft bearing the iron-binding site to secure the metal and shield it from hydrolysis and formation of insoluble ferric hydroxide (Fig. 1). Interdomain interactions, and to a lesser extent interlobe interactions, contribute to stabilization of bound iron (19-21).

Figure 1. Crystal structure at 3.3 Å resolution of monoferric transferrin bearing iron in the C-terminal lobe. Residue Val 1 in the empty N-lobe is labeled, and the iron atom in the C-lobe is depicted as a pale pink ball. The N-lobe is in blue, the C-lobe in red, and the interlobe connecting strand in violet.



Human monoferric (C) transferrin

6. Binding and Release of Iron by Transferrin

Transferrin will accept iron in a variety of forms, ranging from free Fe^{2+} to Fe^{3+} bound to a large variety of chelators. A recently described iron transporter, IREG1 (also known as ferroportin1 and MTP1) (22-24), probably acting in concert with hephaestin, a multicopper oxidase (25), has been implicated in the export of iron from duodenum and reticuloendothelial cells. Very likely, therefore, iron experiences a sequence of intracellular redox reactions before it is presented to circulating transferrin as Fe^{3+}.

Under physiological conditions, the effective stability constants for the binding of iron by transferrin exceed 10^{21} M^{-1}. Despite this great affinity for Fe^{3+}, the transferrin molecule can deliver its iron to erythroid cells within a minute or two without damage to its structure. How this is accomplished is still only dimly understood, but recent studies, reinforcing old conjectures, have offered insights into the mechanisms of reversible iron release. Protonation of the synergistic carbonate anion as pH is lowered, with consequent disruption of its coordination to iron, undoubtedly contributes to release of iron from transferrin within acidified endosomes (26-28). A further effect of low pH is seen in the N-lobe, where two lysine residues on opposite domains lie in close apposition to each other (29). At the pH of the circulation, 7.4, both lysines cannot be positively charged by protonation. As pH is lowered in the endosome, however, both lysines become protonated and mutually repulsive, thereby helping force the domains into the open configuration from which release is facile (30). Other protonations, of iron ligands or remote residues, as well as ligand exchange reactions, are likely to be involved in iron release as well (31, 32). Binding of transferrin to its receptor also modulates iron release, impeding at extracellular pH, 7.4, but facilitating at endosomal pH, 5.6 (33). Even at endosomal pH, iron sequestering agents are required to achieve release of iron in physiologically reasonable times. The chemical nature and concentration of such agents and the ionic strength of the solution in which release occurs markedly affects release rates (34), with differing effects on the two lobes of transferrin, but the physiological roles of these variables are not known. At the cellular level, binding of the hemochromatosis protein, HFE, to receptor interferes with concomitant binding of transferrin and uptake of its iron (35, 36).

Because the endosomal iron transporter DMT1 requires Fe^{2+} (37), a reductive event during iron release from transferrin and its export to the cytoplasm must occur, but where and how this takes place is unknown. Intestinal absorption of iron also involves reduction of Fe^{3+}, again emphasizing the role of redox reactions in iron meabolism (38). The many concerted interactions among transferrin and its partner proteins of iron metabolism are still incompletely understood and subjects of active investigation by many laboratories.

7. Acknowledgments

Preparation of this article was supported, in part, by Grant DK15056 from the National Institutes of Health, U.S. Public Health Service.

The author thanks Dr. Harmon Zuccola for the crystal structure coordinates of human monoferric transferrin bearing iron in the C-terminal lobe.

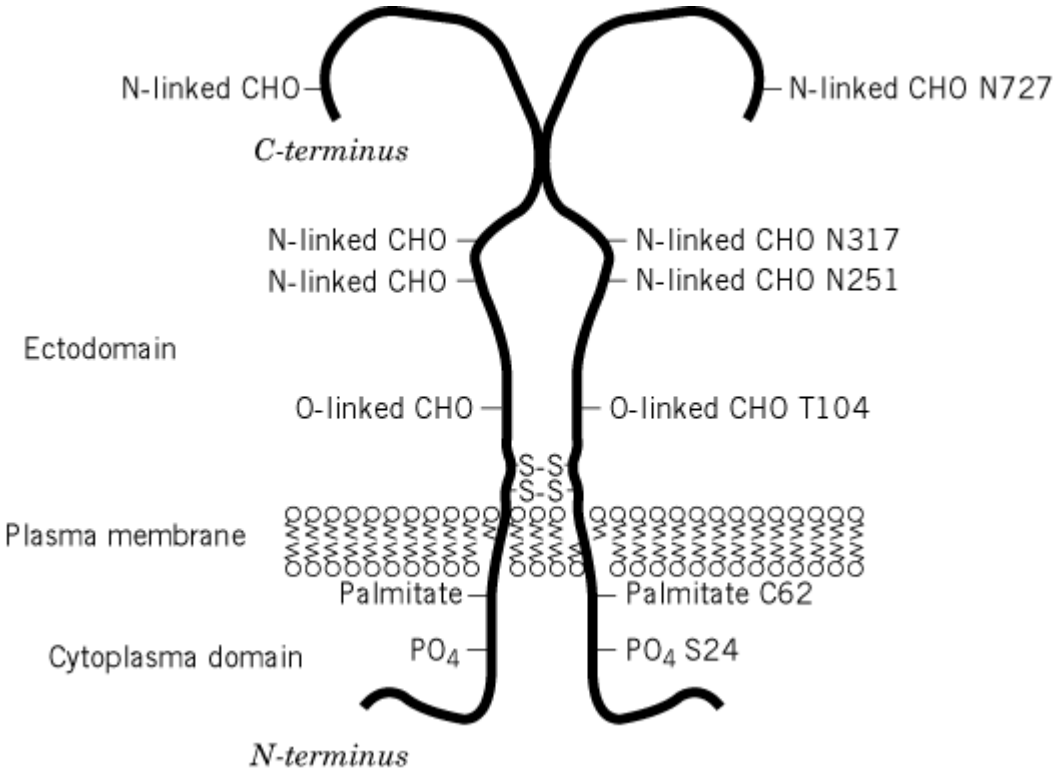
Transferrin Receptor

Most cells acquire iron from transferrin by a **receptor**-mediated process, and the transferrin receptor controls iron uptake. The transferrin receptor is a glycosylated homodimer membrane protein of 90-kDa subunits, linked by two intramembranous disulfide bonds (1). The receptor spans the plasma membrane once (Fig. 1), with the transmembrane portion of the receptor serving as its own **signal sequence** for membrane insertion (2). Insertion is stabilized by covalently bound fatty acid in or near the intramembranous portion of the protein (1). Most of the receptor, including the transferrin-recognition sequence in its *C*-terminal region (3), lies outside the membrane. The extracellular portion of the receptor contains three sites for N-glycosylation and one for O-glycosylation; **glycosylation** is critical in the proper folding and function of the molecule (4, 5). A soluble 85-kDa form of the receptor, resulting from cleavage at an extracellular site adjacent to the region of the membrane insertion site, is found in the circulation and correlates with iron deficiency and enhanced erythropoiesis (6).

Figure 1. Model of the transferrin receptor showing post-translational modification sites. (Figure generously provided by Dr. Caroline Enns.)



1. Cell Biology

Distribution of the transferrin receptor between plasma membrane and intracellular locations is variable among different cell types, with as much as 75% located within cells and therefore inaccessible to extracellular transferrin (7, 8). Endocytosis of receptor is triggered by binding of transferrin, but the receptor is continually shuttled between plasma membrane and intracellular sites even in the absence of its ligand (9). **Phosphorylation** of the receptor enhances its rate of internalization, without altering its cellular distribution (10). Microtubule inhibitors retard internalization but exert little effect on exocytosis (11, 12); conversely, inhibitors of phosphoinositide kinase inhibit exocytosis without affecting endocytosis (13). A tetrapeptide tight-turn sequence, –Tyr–X–Arg–Phe– (or YXRF), within the cytoplasmic domain of the receptor has been incriminated as the recognition signal for high efficiency endocytosis (14).

2. Regulation of Transferrin Receptor Gene Expression

Expression of the transferrin receptor gene is enhanced by iron demand or deficiency and suppressed, even to the point of nondetectability, by iron overload (15). Regulation of expression is primarily at the stage of translation. Hairpin **stem-loop structures** in the 3′-untranslated region of the receptor messenger RNA, termed iron-responsive elements, (IRE) bind trans-acting proteins known as iron regulatory proteins (IRPs) (formerly designated IRE-binding proteins). Five IRE motifs are found in the receptor mRNA. Occupancy of these regulatory sequences by IRPs stabilizes and substantially prolongs the lifetime of the mRNA. Two classes of IRP have been identified. The first of these, IRP-1, displays high homology with mitochondrial *aconitase*, an **iron–sulfur** enzyme with a 4Fe–4S cluster. When depleted of iron by cellular iron deficiency, iron chelators, or reducing agents, IRP-1 binds avidly to the IREs, protecting their mRNA from endonucleolytic attack. Conversely, IRP-1 loses IRE-binding activity when loaded with iron, with consequent loss of such protection. In contrast, IRP-2 is not definitely known to bind iron; instead, iron effects a threefold increase in its degradation rate by proteasomes (16) as well as increased *de novo* synthesis (17). The IRE targets of the two IRP may not be identical (17, 18), but each responds to the iron status of the

cell, increasing receptor mRNA levels in iron deficiency and decreasing mRNA in iron-replete states.

3. Receptor-Dependent Uptake of Iron from Transferrin by Cells

At the pH of the extracellular space, 7.4, where transferrin and the transferrin receptor meet, iron-bearing transferrin is preferentially bound by receptor (19). The effect of this preference is to keep the cell from useless internalization of transferrin molecules devoid of iron, which predominate in iron-deficient and normal states, when transferrin saturation is 30% or less. Binding of transferrin to its receptor is rapidly followed by internalization of the transferrin–transferrin receptor complex to a membrane-bounded **clathrin**-coated vesicle, which soon matures to an ATP-driven proton-pumping endosome. As the pH is lowered to about 5.6 (the final value varies in different cell types), iron is lost from transferrin, a reaction driven in part by the receptor, which now binds apotransferrin more tightly than iron-bearing transferrin. In addition to the lowered pH of the endosome and the accelerating effect of receptor on iron release (20), an iron-sequestering agent is required to effect release; this requirement may be met by physiological iron chelators such as ATP, citrate, and oxalate.

Released iron must now escape the endosome; details of how this is accomplished remain elusive. One attractive suggestion is that reduction of released iron to the ferrous state enables it to traverse the endosomal membrane (21). In **yeast**, reduction of iron is an essential step for uptake (22), and ferrous iron is capable of crossing reticulocyte membranes for incorporation into hemoglobin (23). The endosome bearing iron-depleted transferrin still bound to its receptor is now returned to the cell surface, where fusion with the plasma membrane again exposes transferrin to the extracellular pH, 7.4. At this pH, apotransferrin dissociates from receptor to reenter the circulation for another cycle of iron transport ((24, 25)

4. Receptor-Independent Pathways of Iron Uptake from Transferrin

In addition to the receptor-mediated pathway for iron uptake from transferrin, at least two other routes are available for acquisition of transferrin-borne iron by cells. The hepatocyte may secure as much or more iron from transferrin by a receptor-independent pathway as by the receptor-mediated process (26, 27). The ultimate fate of iron acquired by the receptor-independent path is indistinguishable from that of iron taken up by the receptor-dependent mechanism, but the details of receptor-independent are still to be elucidated.

Melanoma cells can manage uptake of iron from transferrin by yet another mechanism. These malignant cells express a membrane transferrin appropriately named *melanotransferrin*, which can function as a shuttle for transferring iron from transferrin to the cell interiors (28). The mechanism of iron exchange between proteins, and the physiological importance of melanotransferrin as a vehicle for iron uptake, like so many other intricacies of iron metabolism, are not known.

Transformation

Many bacteria can bind naked **DNA** to their surface, transport it through the cell wall, and

incorporate it into their genomes. This phenomenon is called *transformation*. Typically, transforming DNA substitutes for a **homologous** segment of the host chromosome by recombination, although **plasmids** usually resume their autonomous existence. The term *transformation* originally referred only to the alteration in behavior and appearance of one pneumococcal strain upon mixing with heat-killed cells of another (1), but it has since come to signify the entire DNA-uptake process.

To import DNA, bacteria must be in a particular physiological state, usually transitory, termed competence. Only then are the **genes** that code for the DNA uptake apparatus turned on. Competence occurs naturally in many species, but far from all. However, the capacity for DNA uptake can often be induced by laboratory manipulation of bacteria that do not display natural competence. Two examples of competence, one natural and one artificial, transformed biology itself: Natural transformation of *Pneumococcus* (now *Streptococcus pneumoniae*) was the experimental procedure used by Avery and his colleagues to demonstrate that DNA is the genetic material (2), and calcium treatment of normally noncompetent *Escherichia coli* was crucial to the emergence of recombinant DNA technology (3, 4). Our intention here is less ambitious: to show how transformation takes place and to consider its function in nature.

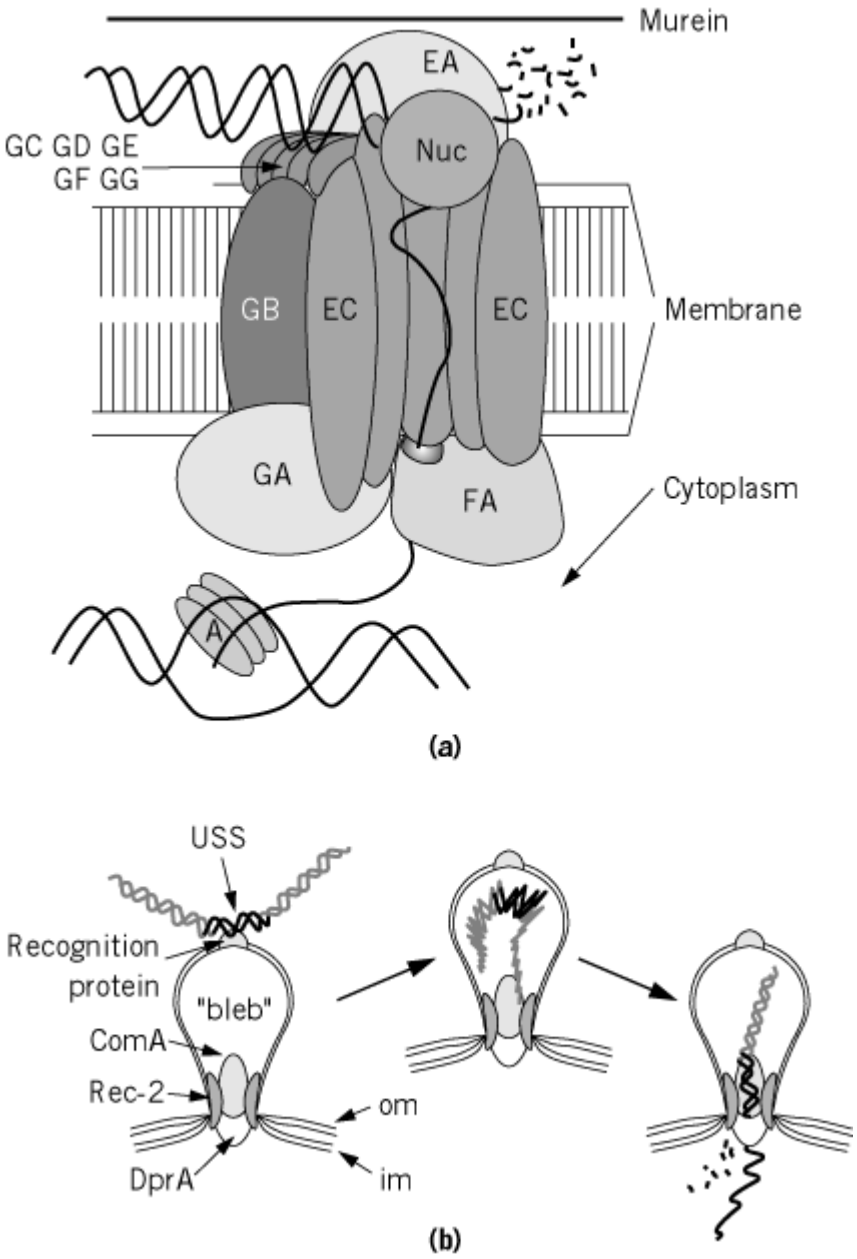
1. The Basic Process

Nearly everything we know about transformation and competence comes from experiments carried out on four species: *S. pneumoniae*, *Bacillus subtilis*, *Haemophilus influenzae*, and *Neisseria gonorrhoeae*. These studies suggest that whereas induction of competence is idiosyncratic, possibly reflecting the diversity of natural habitats in which naked DNA is encountered (see Competence), the basic mechanisms of transformation are similar in all naturally transformable bacteria. Thus we can view the process of transformation as passing through four stages: (i) Competent cells sporting a limited number of DNA-binding receptors attach duplex DNA to the cell surface. (ii) The DNA is processed by endonucleolytic cleavage and, usually, by exonucleolytic removal of one of the strands. (iii) The other strand is drawn through a pore into the cytoplasm, possibly in concert with the exonucleolytic degradation. (iv) The entering single strand of DNA undergoes homologous recombination with the chromosome, creating a new recombinant if the recombining partners carry different **alleles**. We shall look at how each of the four bacterial species works its variations on this theme.

1.1. *B. Subtilis*

As cells become competent, transcription of the “late” competence genes begins. One of these transcription units, *comG*, specifies five small proteins (ComGC to GG) that appear to form external **receptors** for DNA, as well as two larger proteins (ComGA, GB) that probably anchor the receptors to the membrane (Fig. 1). Each competent cell has about 50 of these receptors, as measured by saturation of binding capacity for radioactively labeled DNA (5, 6). When transforming DNA is added, the receptors bind it rapidly and without regard to sequence (unlike *H. influenzae* and *N. gonorrhoeae*; see text below), and for about 30 seconds the DNA remains on the surface, susceptible to added **nucleases** but not removable by washing.

Figure 1. The apparatus of DNA uptake during transformation of (**a**) *B. subtilis* (modified from Ref. 8, with permission of the publisher) and (**b**) *H. influenzae*. The locations and presumed roles of several of the proteins shown are partly speculative, but the overall mechanisms depicted are based on good evidence. The *B. subtilis* Com proteins are described in the text; Nuc denotes nucleases that cut bound DNA and degrade the 5′-ended strand; A shows RecA protein, mediating invasion of the resident chromosome. The appearance of the *H. influenzae* bleb is based on the electron micrograph shown in Ref. 34. The pore location of the *H. influenzae* proteins is based on their presumed function (see text).



Processing of the DNA then begins, initiated by double-strand cleavage. The length distribution of the resulting fragments is consistent with the DNA being cut once at each of the sites to which it is bound (7). This cleavage provides the free ends used for transport across the membrane. Within 1–2 minutes, one strand of each molecule becomes immune to added nuclease, reflecting transport, while the other is degraded. Of the known competence functions, the ComE proteins are the most intimately involved in transport. ComEC is needed only for transport, not for DNA binding, and its properties suggest that it may form a transmembrane pore through which the DNA passes (8). ComEA appears to be involved in both binding and transport: Its C-terminus, which projects from the membrane to the exterior, carries **DNA-binding** motifs, suggesting a role in processing of DNA (9). However, neither ComEA nor any of the other proteins has been proven to exhibit the nuclease activities associated with processing. The 17-kDa ComI protein, which forms part of a complex obtained from competent cells, was found to have endonuclease activity (10), but a *comI* null mutant is fully transformable (11). Perhaps there is more than one transformation endonuclease.

The entering single strand appears to be driven into the cytoplasm by the inner-membrane protein, ComFA, using the energy of ATP hydrolysis to translocate the DNA, rather like the PriA protein of

E. coli that it resembles (12, 13). ComFA mutations that abolish ATP binding diminish rather than eliminate transformation, suggesting that the DNA can sometimes find its way in by simple diffusion.

Upon entering the cell, the single-stranded DNA encounters a recombination system primed by induction of competence: an increased frequency of single-strand gaps in the recipient chromosome (14) and major increases in the concentrations of **RecA** and the nuclease/DNA helicase, AddAB (15, 16). Incorporation of DNA into the homologous chromosomal region is thus very efficient; about 70% of it is integrated (11), and the overall probability of integration is greater than 0.5 per molecule initially bound at the cell surface. Although sequence differences between the added and host DNA cause the transformation frequency to drop (17), apparently because of reduced duplex stability, the DNA metabolism of *B. subtilis* is otherwise well-adapted for incorporation of new alleles. Restriction-modification systems do not seem to limit transformation in interspecific crosses (18), and mismatch repair following transformation has not been reported, although genes analogous to the *hex* mismatch correction system of *S. pneumoniae* (see text below) appear in the *B. subtilis* genome sequence.

1.2. *S. Pneumoniae*

The individual components of the DNA binding and uptake process are not as well known as for *B. subtilis*, but the process appears to be very similar. There are 30–80 duplex-DNA binding sites per cell, at which DNA is cut to initiate transport of a single strand into the cytoplasm. In this bacterium, however, more is known of the nuclease activities. A specific membrane-bound endonuclease, EndA, introduces double-strand breaks into the DNA, thus providing free ends for entry (19, 20). Although introduction of an *endA* null mutation reduces transformation frequency over a thousandfold, transformants are still obtained in such an *endA* strain (21), possibly because a single-strand nicking activity that accompanies binding can also create free ends (19). The mere presence of ends is insufficient, however; ongoing transport is curtailed when the mechanism encounters a nick in the entering strand (22). A particular geometry of the DNA end and the transport initiator seems to be needed.

Unlike *B. subtilis*, *S. pneumoniae* transports DNA in an oriented manner. The entering strand goes in 3′ first, while the other strand is degraded from its 5′ end to acid-soluble oligonucleotides (22, 23). The identical kinetics of uptake and degradation suggest that these processes are concerted (22), although there is as yet no direct evidence for such coupling.

Other proteins involved in DNA processing or the assembly of transmembrane pores have not been identified, although it is possible that a 19.5-kDa peptide found associated with the single strand in the cytoplasm is one such example (24), because by complexing with the DNA it confers on it resistance to nucleases. Evidence that DNA uptake is energy-dependent has been presented, with the suggestion that an ATP-driven import protein translocates the entering single strand (25).

The DNA is released from the nuclease-resistant complex to recombine with the homologous chromosomal region via RecA-mediated strand invasion. A function that probably catalyzes branch migration, MmsA, is also needed to complete transformation (26). Genetic transformation must run the gauntlet of the Hex repair system, which recognizes and removes mismatched bases, reducing transformation frequencies (27). The Hex system is of limited capacity, however, being readily overwhelmed by related but divergent DNA (28). The way is therefore open to recombination with DNA of other *Streptococci*, with obvious evolutionary consequences.

1.3. *H. Influenzae*

Initial DNA binding by this Gram-negative bacterium contrasts sharply with that of *B. subtilis* and *S. pneumoniae*, in that only the DNA of *H. influenzae* itself can participate (29). The binding apparatus specifically recognizes a 9-bp sequence (5′-AAGTGCGGT), termed an *uptake signal sequence* (USS), within an extended consensus region of 29 bp that is rich in adenine and thymine. *H. influenzae* contains 1465 of these USS's, nearly 200 times more than expected by chance, and they

are distributed more or less randomly within its genome (30, 31), accounting for the species-specific binding observed. A further difference is the appearance on the surface of competent cells of about four to eight physically discrete membranous vesicles, termed *transformasomes* (or "blebs"), which bind DNA and protect it from nucleases (Fig. 1**b**) (32-34). The blebs are necessary for transformation; certain transformation-deficient mutants form the blebs, but shed them prematurely (32, 35).

Transformation in *H. influenzae* begins when a transformasome packages a double-stranded USS-containing DNA molecule. Both linear and circular (or closed-end) DNA is readily taken up by transformasomes, but only linear DNA is conducted out again (36); there appears to be no endonuclease to create ends in bound DNA. The transformasome extrudes DNA with a free end through a pore into the cytoplasm; electron microscopic images suggest that the two cell-wall membranes are fused where the bleb attaches (34). As with *S. pneumoniae*, the 5′-ended strand is degraded, while the 3′-ended strand enters the cell (36), apparently by a translocation process that involves the products of the following genes: *rec-2*, which is probably a pore protein (37), *dprA*, which is possibly a translocase (38), and *comA*. Unlike *S. pneumoniae*, however, the entering strand is not protected and suffers partial degradation, prior to being incorporated by recombination into the chromosome (36). Rec-1 protein mediates the recombination, with a recipient chromosome rendered 5% single-stranded during competence development (39).

Although the catalogue of proteins that participate in *H. influenzae* transformation is far from complete, the availability of the entire *H. influenzae* sequence (40) will accelerate identification of proteins with functions similar to those in other transformable species.

1.4. *N. Gonorrheae*

This gram-negative species inhabits the human genital tract, attaching itself to the epithelia by filamentous pili. It is another bacterium that selects for transformation by its own DNA, or that of close relatives, through USS recognition. In this case, the USS is the 10-bp sequence 5′-GCCGTCTGAA, of which there are several hundred examples in the genome (41, 42).

DNA uptake depends strictly on the major component of the pilus, PilE, as well as a protein involved in pilus assembly, PilC (43-45), but not on the pilus itself. Nonpiliated mutants can still be transformed (46), as can strains that make normal PilE in quantities insufficient for pilus formation (45). *Pil C*$^{-}$ strains that have reacquired the ability to make pili are normally not transformable, but become so upon addition of a PilC protein fraction to the cells, indicating that PilC and PilE act at the cell exterior. Nonpiliated *pilC*$^{-}$ strains cannot be so complemented, suggesting that PilC and PilE act as a complex to promote DNA uptake (45). They do not, however, specifically recognize DNA containing the *Neisseria* USS (47); the protein that does so remains to be identified. Deficiencies in other proteins involved in pilus formation, such as PilT, can impair transformation (48), leading to the suggestion that these proteins also mediate the reverse reaction, pilus depolymerization, thus pulling bound DNA across the outer membrane (47).

Bound DNA is subjected to limited double-strand cleavage (48), but enters the **periplasm** otherwise intact. The available data (49) suggest that it then crosses the murein layer with the aid of two proteins involved in cell shape and division, ComL and Tpc, and finally passes through the cytoplasmic membrane aided by ComA, a protein with similarities to the pore-forming proteins of *B. subtilis* and *H. influenzae*. Uniquely among the organisms studied, *Neisseria* does not generate single-stranded DNA during uptake. Even the further processing that occurs in the cytoplasm appears to consist of double-strand exonucleolysis (49). Strand separation is presumably concerted with the other steps of homologous recombination mediated by RecA (50). Nevertheless, efficient transformation with single-stranded DNA has been observed (51), indicating a degree of versatility in the transport machinery.

Transformation of *Neisseria* has revealed some striking relationships. First is the intimacy of the

connection between DNA transformation and the pili. The pilus is the point of both attachment to the host and attack by it; it expands the former and limits the latter by binding related DNA containing alternative pilus gene alleles. Second is the economy of the 10-bp USS's, which serve not only as the recognition elements for DNA binding but also, in the form of pairs of inverted sequences, as transcriptional terminators (41). [Although the examples of *H. influenzae* and *N. gonorrhoeae* had suggested that sequence-specific binding was a feature of all gram-negative bacteria, this is not the case; *Acinetobacter calcoaceticus* binds any DNA (52).] Third is the extensive homology of the PilE protein and proteins involved in pilus assembly with a large family of proteins responsible for transporting macromolecules across membranes: the DNA-binding proteins of competent *B. subtilis* and *H. influenzae*, the type IV pilus proteins of a variety of pathogenic bacteria, and proteins involved in filamentous **phage** assembly, DNA transfer during **conjugation** in *E. coli* and ***Agrobacterium*** *tumefaciens*, and protein secretion (53).

2. Artificial Transformation

The discovery that *E. coli* could be induced to take up DNA by treatment with Ca^{2+} ions (3) led to the realization that transformation need not be limited to species that attain competence naturally. The need for genetic manipulation of an expanding range of bacterial species motivated the search for new methods of transformation. These fall into three general classes: chemical treatment, protoplasting, and electroporation. These methods nearly always have as their goal the uptake of intact double-stranded DNA, and the physical mechanisms, insofar as they are known, appear to bear little relation to those of natural transformation.

1. Chemical treatment is typified by the suspension of *E. coli* cells in cold $CaCl_2$ solution, and the ensuing membrane changes that might be responsible for allowing DNA uptake are discussed in the entry Competence. This type of method has been most successful with gram-negative bacteria, especially when variations such as the use of other divalent cations or the addition of a freeze-thaw step, which presumably makes the membrane fragile, are included (54, 55). Nevertheless, addition of **polyethylene glycol** to the cell–DNA mixture has permitted transformation of certain gram-positive species (56).
2. Protoplast transformation involves mild digestion of the murein layer with lysozyme, incubation of the resulting protoplasts with DNA in the presence of polyethylene glycol, and regeneration of the treated cells to restore the cell wall, followed by selection of transformants (57). Although more laborious than other methods, protoplast transformation has proven particularly useful for strains that cannot be rendered competent otherwise. Most of these are gram-positive bacteria, such as *Streptomyces*, *Corynebacterium*, and *Lactobacillus*, suggesting that the main barrier to DNA entry is the thick murein layer, which is removed during formation of protoplasts. For some species, deoxyribonucleases associated with the protoplasts hinder transformation, but this problem has been circumvented in certain cases by enclosing the DNA in phospholipid **vesicles** called liposomes (58). These presumably fuse with protoplast membranes to deliver the DNA, rather like the blebs of competent *H. influenzae*.
3. Electroporation works by delivering a brief pulse of current to cells in the presence of DNA, producing temporary holes in the membranes that allow DNA uptake (59, 60). It is fast and simple and is probably the method of choice for a bacterium of unknown transformability. It does not work with every species, however: Some (eg, *S. pneumoniae*), although transformable naturally, are not transformed by electroporation, because only cells in which competence has developed contain adequate levels of recombination enzymes. For this method, as for the others, the mechanisms underlying DNA uptake are not fully understood.

3. Biological Significance

Until recently, it was not unreasonable to question whether transformability is biologically important

or just a by-product of the altered metabolism with which it is associated. It has, however, become increasingly difficult to sustain this skepticism. Perhaps the strongest argument for the biological significance of transformation is the existence of mosaic genes in transformable species isolated from nature after exposure to antibiotics or host defenses. This phenomenon implies a role for transformation in generating the variability that has allowed fitter populations to emerge from threatened ones. Nevertheless, other functions for uptake of DNA have been advanced.

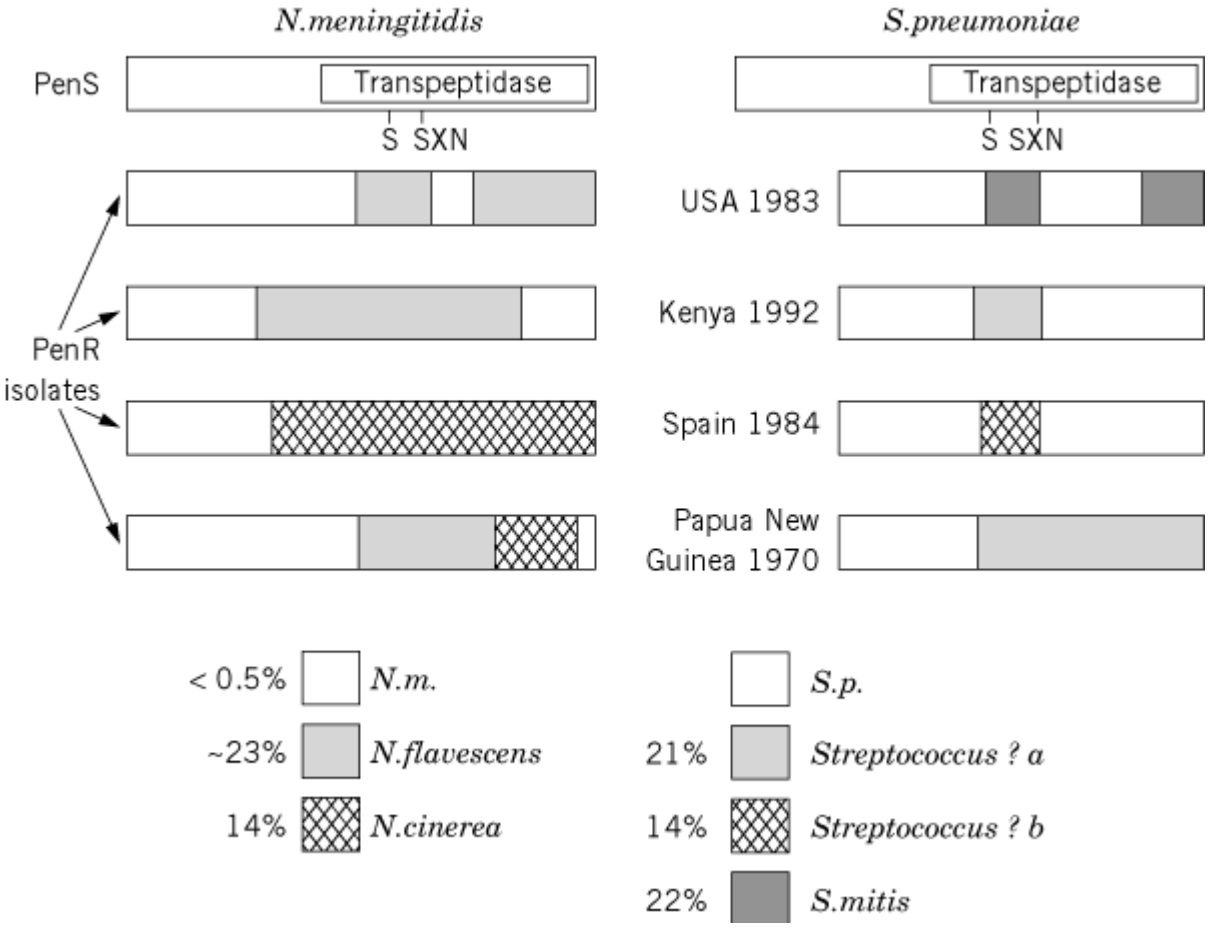
3.1. Restauration?

The induction of competence by nutrient deprivation suggested that transformation might be a form of scavenging, in which cells increased their chances of survival by eating DNA released from their dead cohabitants (61, 62). There is, however, no direct evidence that transformed cells use DNA in this way. Moreover, the wastage of one strand by degradation during transport, the lack of extensive degradation of the incoming strand, and the elaborate nature of the uptake apparatus render a general nutritional role unlikely. Another suggested function for transformation is the use of the imported DNA as a template to repair damaged chromosomes: Addition of homologous DNA increased the survival of UV-irradiated *B. subtilis* and *H. influenzae* cells (63, 64). However, in *H. influenzae* a sequence constituting only 1% of the chromosome was just as effective as the whole genome, indicating that transforming DNA enhances survival indirectly, rather than by simply providing undamaged copies (64). Furthermore, DNA damage failed to enhance competence in either species (65). Thus, although transformation might serve in nature as one means of correcting errors, DNA repair does not appear to be its major role.

3.2. Mosaic Genes

The clearest indication that transformation might increase the fitness of bacterial populations comes from the analysis of **penicillin** -resistant isolates of *Neisseria* and *Streptococcus* (66). Penicillin acts as a substrate analogue, binding to the transpeptidases that cross-link murein chains. Resistance arises by alterations in these penicillin-binding proteins (PBPs) that reduce their affinity for penicillin. Comparison of the PBP2 genes in various *Neisseria* species revealed that those in penicillin-sensitive isolates of each species have a very uniform sequence, whereas those in resistant isolates of the same species have a composite structure (Fig. 2). The resistant PBP2s of *N. gonorrhoeae* and *N. meningitidis* consist of regions nearly identical to those in sensitive strains, interrupted by islands of divergent sequence corresponding to the PBP2 genes of *N. flavescens* and *N. cinerea* (67). Similar gene structures are found in the PBP2B genes of diverse isolates of *S. pneumoniae*, where it has also been possible in some cases to trace the origin of the divergent regions (68, 69). It is unlikely that these mosaic genes result from successive point mutations. The subtle changes in protein structure needed to reduce affinity for penicillin, while continuing to allow recognition of substrate, can in general only be achieved through multiple amino acid changes. Because the probability that any single one of these changes provides selective advantage is low, all or most of the changes are most likely to have been introduced simultaneously. Only recombination can bring this about. Because **phage**-mediated and **plasmid** mobilization-mediated mobilization of chromosomal DNA are unknown in *Neisseria* and *Streptococcus*, transformation by DNA released from related species almost certainly generates the resistant PBPs.

Figure 2. Mosaic composition of the PBP2 and PBP2B genes in penicillin-resistant isolates of *N. meningitidis* and *S. pneumoniae*, respectively. The figure is an abbreviated composite of Figures 1 and 2 in Ref. 66. The domain responsible for the transpeptidase activity of these homologous proteins is shown, together with the active site serine (S) and a shared sequence motif, -Ser- X-Asn- (SXN), that is probably important for activity. The percentages indicate the degree of sequence dissimilarity of each divergent region with the equivalent sequence in the penicillin-sensitive strains. For *S. pneumoniae*, only the sequenced portion (~70%) is shown. The source of two of the divergent PBP2B regions is unknown (?a and?b). (Modified from Ref. 66, with permission from the author.)



Alteration of the major *N. gonorrhoeae* pilus protein, PilE, provided the first evidence for the involvement of transformation in the creation of mosaic genes (70). The pili are a target of immune attack, but frequent switching of the expressed *pilE* allele helps the bacterium evade it. This switching occurs in cultured cells, either by recombination with endogenous silent *pil* genes or by transformation with DNA from cells expressing a different allele. Because *Neisseria* are constitutively competent and continually release DNA by autolysis, it is likely that recombination with transforming DNA is also a major source of pilus switching *in vivo*. Evidence for mosaic gene formation in nature comes from the structure of IgA1 proteinase (*iga*) genes, virulence determinants thought to act by cleaving the antibody and using the **Fab** fragment to mask the pilus. Genes from independent *N. gonorrhoeae* isolates contained a pattern of related segments (71). A more extensive analysis has uncovered evidence of interspecies recombination between *iga* genes of *N. gonorrhoeae* and *N. meningitidis*, as well as indications of composite gene formation in *H. influenzae* (72).

3.3. Microcosms

Transformation has often been demonstrated in pseudonatural habitats (“microcosms”). *H. influenzae* cells contained in diffusion chambers and implanted in rat peritoneum quickly acquired competence and were transformed with coimplanted DNA (73); differently marked *B. subtilis* strains inoculated into sterile soil were replaced by populations of cells carrying markers from both parents (74); and transformation of *Pseudomonas stutzeri* has been observed in a sterile marine water and sediment environment (75). Even with this evidence that transformation can play an important part in adapting natural populations to environmental challenge, we cannot yet assess its extent in nature. Future studies aimed at determining how transformation contributes to the evolution of natural populations and the virulence of pathogenic bacteria will be of particular interest. Indications that naked DNA can be fed to an animal with whose genome it shares no sequence homology, and yet become integrated in the chromosomes of several tissues of the animal (76), provocatively suggest

that we might have underestimated the wider significance of transformation.

Transformation Of Fungi

Transformation systems for filamentous fungi came into their own during the 1980s. The first DNA-mediated transformation into a filamentous fungus was demonstrated for *Neurospora crassa* (1). Since then, procedures have been developed for all of the major fungal classes (2-8); similar transformation frequencies, stabilities of transformants, and multiple heterologous integration events have been observed for most of the species commonly studied (see Refs. 9 and 10 for review).

1. Getting DNA into Cells

Most fungal transformation techniques involve either the formation of protoplasts or some method to remove cell-wall components. Cells without walls are further incubated with DNA in the presence of calcium ions and **polyethylene glycol**, followed by regeneration of the cell wall and appropriate selection. Protoplasts are usually formed using young cultures and may be stabilized with either sorbitol or sucrose. In certain instances, transformation efficiencies were reported to be increased with a brief **heat shock** step before recovery and plating. The following partial list of fungi have been successfully transformed by protoplasts: *Candida, Aspergillus, Podospora, Ascobolus, Coprinus* (5, 11, 12). Intact *Neurospora* has been reported to be transformed with lithium acetate ions (13), but this methodology does not appear to be in general use for other fungi. In a few instances, fungal cells have been reported to be transformed using electroporation techniques, although efficiencies are considerably lower than those using protoplasts (14, 15).

The efficiency of transformation varies with the type of fungal cell being manipulated, the age of the

culture, and the quality of the DNA preparation. In addition, the efficiency varies with the type of transformation that occurs—replicative versus integrative (discussed in greater detail below).

1.1. Vectors

Vectors for transformation of filamentous fungi are not that different from those used for transformation of the yeasts. They contain a selectable marker and bacterial sequences for propagation and selection (usually in *E. coli*). They may also contain multiple cloning sites (MCS) for easy directed cloning at unique sites within the vector. In some instances, DNA fragments are included in the vector that permit autonomous replication in the host fungus (16, 17). Nuclear plasmids analogous to 2 μ in *Saccharomyces* have not been found in other filamentous fungi, and the dearth of naturally occurring plasmids has made constructing replicative vectors in the filamentous fungi difficult. More recently, cosmid vectors have been described for *M. grisea* and *U. maydis* (18).

Recently, a sequence of DNA from *A. nidulans*, *AMA1*, has been found that substantially increases transformation frequencies concomitant with a decrease in stability of the vector and an elevation in copy number (10–30 copies/haploid genome in *A. nidulans*); all properties of autonomously replicating sequences (ARS). From a practical standpoint, this same sequence confers similar properties on other species (19, 20), but it has been observed that these plasmids are lost during conidiation (N. Coleman, personal commununication). In another series of experiments, a portion of the 2 μ of *Saccharomyces* was shown both to stabilize and to decrease the copy number of two *Hansenula polymorpha* plasmids (21). The mechanism by which this occurs is thought to be through mitotic partitioning of proteins bound to the 62-bp repeated sequence of the STB locus on 2 μ. Whether or not these effects can be extended to other model fungal systems remains to be determined.

2. Selectable Markers

For many of the fungi, auxotrophic mutants exist that permit the isolation of wild-type genes using a simple selection scheme (ability to grow on medium lacking a particular amino acid or nutrient). For example, mutants in orotidylic acid pyrophosphorylase (OMPppase) have been isolated from nearly every microorganism in which they have been screened for; and either the host gene has been isolated and cloned, or sufficient functional homology exists between the OMPppase genes of different organisms that one OMPppase has been used successfully to transform another species. For example, the first successful transformation in *A. nidulans* used the *pyr-4* gene of *N. crassa* (11). In fact, this gene is so conserved that some fungal genes have been isolated by complementing the defects in an *E. coli pyrE* mutant (22).

Other auxotrophic markers include *trp-1* and *arg12* of *N. crassa* [encoding a trifunctional enzyme for tryptophan biosynthesis (see TRP Operon) and ornithine carbamoyl transferase, respectively]; and *amdS* and *niaD* of *A. nidulans* (encoding acetamidase and nitrate reductase, respectively). In many instances, these genes are conserved so that their selective use in heterologous hosts is widely known. For example, *trpC* gene and *pyrG* gene of *A. nidulans* correspond to the *trp-1* and *pyr-4* of *N. crassa* . Many, many more auxotrophic markers are known than are listed here and have been used in a wide variety of fungi.

Auxotrophic markers are an excellent source of selectivity in fungi because a single copy of the gene is usually suitable for complementation. Second, the marker itself may be used to direct a chromosomal integration event at its homologous site. And third, selections against the auxotrophy usually give low backgrounds so that false positives are kept to a minimum. However, the disadvantage of using an auxotrophy as a selectable marker is that one requires a starting mutant strain. While some mutations may be directly selected for, such as ura3 using 5-FOA (5-fluoroorotic acid), or screened visually using color pigmentation, such as *ade2* (23), most auxotrophies require screening thousands of mutants.

If a suitable auxotrophic marker does not exist, a number of "antibiotic"-resistance genes have been

cloned from a variety of organisms that function in heterologous hosts and have been used successfully in cloning strategies. For example, resistance to the anti-tubulin drug benomyl is provided by the *Bml* gene of *Neurospora* and the *BenAR* gene of *Aspergillus nidulans* (24, 25). Many antibiotic resistance genes from bacteria also function suitably as selective markers in fungal transformations: phleomycin, hygrogmycinB, and methotrexate (7, 26-28). **Drug-resistance** markers have the advantage that one does not require a recessive mutant strain as a host. In addition, drug resistance markers provide a simple means of multiply transforming a strain without the necessity of genetic crosses or other manipulations required to make a strain multiply mutant. On the other hand, unlike markers where there is homology between the gene present on the plasmid and the gene in the chromosome, these heterologous markers cannot be used to direct integration events within the host genome. That very property maybe used to advantage when one desires to lower background integration events by using heterologous marker selection. One caution is noted here: Selection for drug resistance tends to cause high backgrounds, because single-gene mutations (common during transformation procedures) often lead to elevated levels of resistance.

3. Integrative Transformation

The characteristics of transformation systems developed for the majority of filamentous fungi are very similar to one another. In most instances, for example, transformation with circular double-stranded plasmids leads to integrative transformation at both nonhomologous and homologous sites, although nonhomologous or ectopic integration events exceed homologous events in most systems (12). The integrations may be single or multiple events and are often accompanied by plasmid rearrangement. This is in contrast to events that most often occur in yeasts, in which homologous integrations are favored and plasmid rearrangements are rare. Even in mammals, where nonhomologous integrations far exceed homologous events, plasmid integrity is favored. In both *Podospora anserina* and *Ascobolus immersus*, nonhomologous integrations are more frequent than homologous ones, although during a homologous integration in *Podopsora* an integration/duplication event is the more likely outcome, whereas in *Ascobolus* gene substitution is more likely to occur (29).

Increasing relative rates of homologous versus nonhomologous integrations has been achieved in several ways: First, increasing the length of homology increased homologous integration events by up to 50–95% in *P. anserina* (30). However, the extent of the homology in these experiments was generated by using cosmids and reached 30 to 50 kbp in some instances, generally impractical for routine laboratory use. Using single-stranded DNA or double-strand cutting within the region of homology was observed to increase the proportion of homologous gene substitutions in *A. immersus* up to 65–70% of the events (31) and for the phytopathogenic filamentous fungus, *Ashbya gossypii* (32). Both of these methodologies have been well documented in *S. cerevisiae* system as well. A further modification of this procedure called restriction enzyme-mediated integration (REMI) has been highly successful in increasing transformation frequencies in most filamentous fungi (see text below).

4. Nonintegrative or Replicative Transformation

This is the exception in most filamentous fungi (12). Most filamentous fungal vectors are not maintained extrachromosomally. While this may be due to a failure to obtain host autonomously replicative sequences (ARSs), it is difficult to reconcile that in those instances where large fragments of chromosomes have been cloned successfully, origins of replication are not present. It is possible that centromeres or telomeres or both are needed to stabilize plasmids in filamentous fungi. In *Podospora*, linear plasmids containing *Tetrahymena* telomeres were shown to be self-replicating; however, they were observed to be unstable when placed on nonselective media (33).

The advantage of having a nonintegrative system available is that it often imparts a very high transformation efficiency upon the host strain. In addition, because extrachromosomally maintained plasmids usually have elevated copy numbers, questions concerning function of extra copies of

proteins produced in a transformed strain may be addressed without prior knowledge of inducible promoters. However, a certain level of risk also occurs in that overexpression of certain proteins is known to cause lethality in some instances.

5. Methods of Gene Cloning and Manipulation

The tools that one uses can provide a wealth of information about a wide variety of fungi—even those with intractable genetic systems. Clearly, isolating fungal genes by complementation of previously characterized mutations is a highly successful strategy. However, it may be impractical in some systems to generate suitable mutations. In those instances, one can take advantage of the ectopic nature of fungal transformation in the filamentous fungi in order to introduce mutations that may be in the form of duplication, disruption, or activation of a gene. Less obvious is the ability to clone genes by insertional mutagenesis, in which the transformation results in the creation of a mutant **allele** that is marked by a molecular tag. Vectors containing bacterial transposons have been constructed that have been used for gene disruption in *A. nidulans* or *M. grisea* strains auxotrophic for arginine or sensitive to hygromycin, respectively (34). The use of transposons has proven useful in many systems, but it has not been heavily pursued in the filamentous fungi. Nevertheless, putative transposons have been identified from *A. fumigatus* (35), *N. crassa* (36), and *M. grisea* (37) that may be adaptable to this problem.

Restriction enzyme-mediated integration (REMI) is a recent development in which the addition of a restriction enzyme to the DNA solution is used to enhance significantly the frequency of integrative events. It has been widely used in the fungal field (38-49). A modification of this approach, in which the transforming DNA solution also contains an inducible promoter along with a selectable markers, permits the random insertion of DNA sequences upstream from open reading frames, which may then be controlled by the ectopic promoter (T. Adams, personal communication). Identification of genes by activation may, of course, be achieved by creating transcription or translation fusion libraries *in vitro* and then introducing them into suitable hosts.

Other strategies for gene identification and cloning in fungi are widely known and practiced in other systems (42). Genes may be cloned by heterologous complementation in a related mutant host [such as the *pyr4* gene of *N. crassa*, or the *cdc10* gene of *Candida albicans* (43)]; or they may be identified by homology during sequencing projects (see the WEB sites for the various genome projects described below) and identified either by degenerate **PCR** or short homologous regions in cloned libraries. Furthermore, reporter genes such as *lacZ* (encoding b-**galactosidase**), *uidA* (encoding b-glucuronidase of GUS), and green fluorescent protein from *Aequeoria victoria* (44-49) have all been shown to be functional in one or more of the fungi. Thus, the fundamental tools available for molecular analysis of the yeasts are, by and large, available for the filamentous fungi. These tools have bridged the gap between the few fungi studied by geneticists for decades and those fungi whose genetic systems had remained largely undeveloped, but whose biology nevertheless compels us to understand their unique place in the biological world.

Transforming Growth Factors

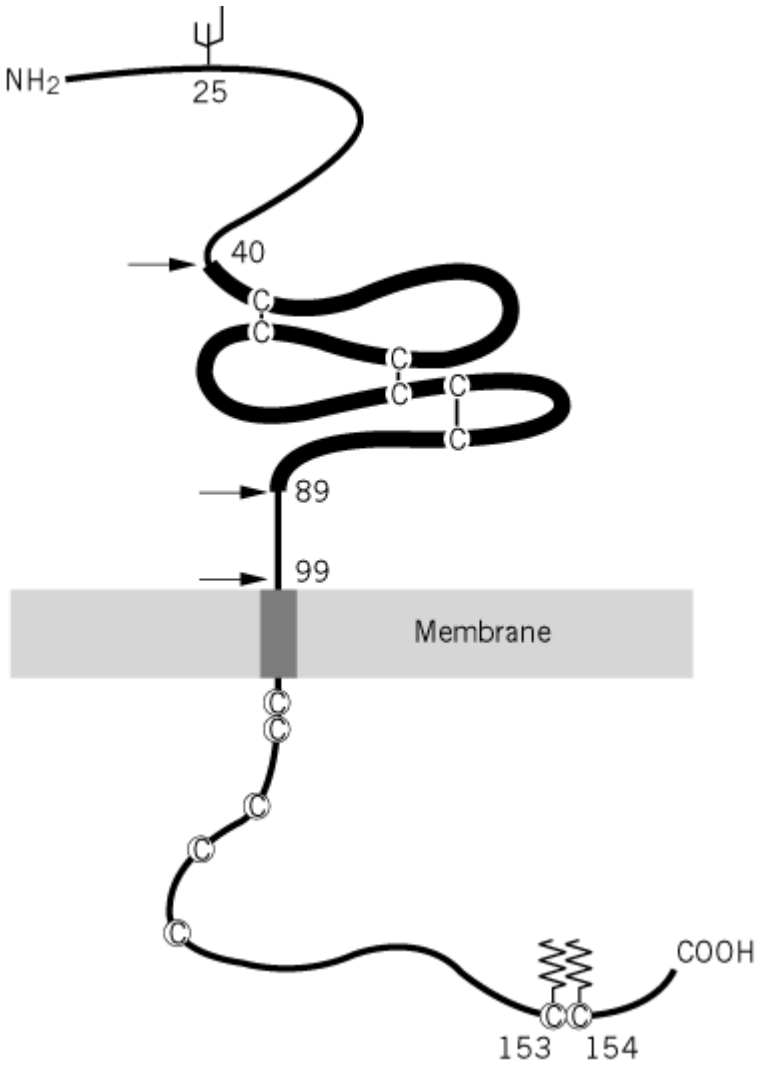
The biological activity of transforming growth factor (TGF) was first described in 1978 by De Larco and Todaro (1). The addition of supernatant of Rous-sarcoma virus-transformed fibroblasts to normal rat kidney cells or mouse fibroblasts enabled these cells to form colonies under anchorage-independent growth conditions in agarose. This growth property is limited to transformed and neoplastic cells and therefore the activity was called TGF. Further studies have shown that the transforming capacity was mediated by two unrelated proteins that have been termed TGFa and TGFb, respectively. Their coidentification in this particular assay was rather accidentally as both have little sequence homology and display distinct biological activities. TGFs are now known to regulate a number of processes during normal development. The activity originally described as TGFb has developed into a superfamily of numerous related molecules. They bind to a heterocomplex of receptor molecules with Ser/Thr kinase activity. Only recently a new family of molecules has been identified that serve as intracellular targets for these kinases and function as signal transducers to the nucleus.

1. Transforming Growth Factor a (TGFa)

1.1. Structural Properties of the TGFa Protein

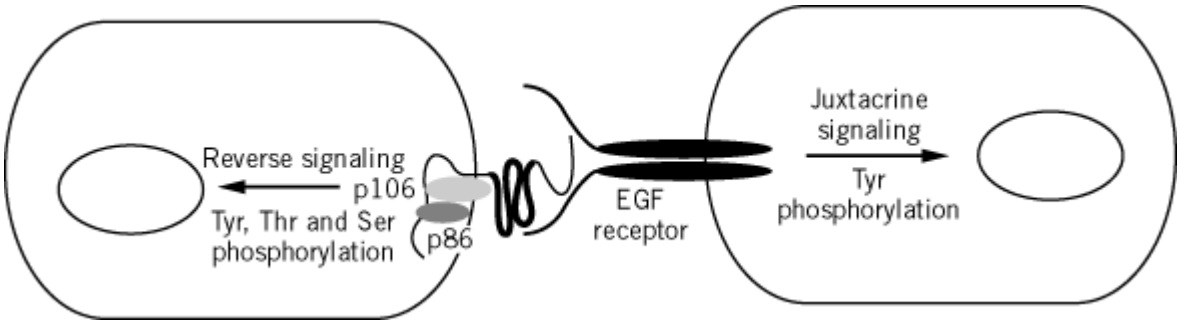
The TGFa gene spans a region of about 100 kb and includes 6 exons that encode a membrane-anchored precursor molecule (proTGFa) of 160 amino acids (2) (Fig. 1). The mature 50–amino acid polypeptide is released from the precursor by cleavage of Ala/Val bonds at both termini by an elastase-like protease. Cleavage at the N-terminus occurs rapidly while the release of mature TGFa by proteolysis of the C-terminal site is slow and tightly regulated (3). Many cell types secrete larger TGFa species due to differential cleavage at the C-terminus and heterogeneous glycosylation of the extracellular domain.

Figure 1. Schematic representation of the TGFa precursor molecule. The bold line indicates the mature TGFa molecule. Proteolytic cleavage sites are indicated by arrows. N-linked carbohydrates (position Asn 25) and palmitoylation sites (positions Cys 153 and Cys 154) are indicated. Cys residues are marked by ©.



The highly conserved epidermal growth factor (EGF)-domain, characterized by six Cys residues, is essential for proper interaction of soluble TGFa with the EGF receptor. This binding results in receptor dimerization. In addition to autocrine and paracrine stimulation of EGF receptors by soluble TGFa, activation of EGF receptors may also occur through proTGFa. By means of site-directed mutagenesis the cleavage sites were altered yielding noncleavable proTGFa precursors. Coculture experiments confirmed that the membrane-bound proTGFa was biologically active and could activate the EGF receptor in a similar way as the soluble ligand (4, 5), a phenomenon called juxtacrine signaling (Fig. 2). Two cellular proteins (p106 and p86) associate with the transmembrane and cytoplasmic part of proTGFa and this complex can phosphorylate exogenous substrates on Tyr, Ser and Thr residues. The 39–amino acid long and highly conserved cytoplasmic part itself does not possess any enzymatic activity. However, experiments that introduced deletions and mutations revealed its critical role for complex formation and kinase activity. Two palmitoylated Cys residues at the C-terminus are necessary for association with p86 and truncation of the cytoplasmic tail almost completely abrogated kinase activity (6). Complex formation between the transmembrane growth factor and a kinase activity could therefore lead to a two-directional signaling creating a situation in which proTGFa would serve both as a ligand and a receptor: the extracellular domain would elicit a signal in neighboring cells through juxtacrine mechanisms while the complex between cytoplasmic region and kinase would signal into the opposite direction (Fig. 2).

Figure 2. Two-directional signal transduction of membrane TGFa. The extracellular domain of proTGFa can trigger signal transduction after interaction with EGF receptors on neighboring cells. Cellular proteins that associate with the intracellular domain attribute kinase activity to proTGFa and allow reverse signaling in the TGFa-producing cell.



1.2. Biological Activities of TGFa

TGFa is widely expressed in developing embryos and in a number of adult mammalian tissues. Important functions have been attributed to TGFa in wound healing and the homeostasis of several tissues. In addition, TGFa is thought to effectively drive the proliferation of different cell types, especially those of epithelial origin and to regulate normal development at various stages (7). Therefore, it was rather surprising that mice in which both TGFa alleles had been inactivated developed normally and were generally healthy and fertile. Such mice show two major phenotypic changes: curly hair as a consequence of a dramatic disorganization of hair follicles and abnormal eye development of variable incidence and severity (8, 9). The lack of more dramatic changes might, however, reflect a compensation of TGFa by other members of the EGF-superfamily that also can serve as a ligand for the EGF receptor.

Probably all epithelial cells synthesize TGFa under normal conditions. They coexpress the EGF receptor thereby being able to respond to TGFa in an autocrine fashion. The overexpression of TGFa in mice has underlined its mitogenic activity for epithelial and mesenchymal cells in vivo. Deregulation of the ligand might, therefore, lead to impaired growth properties. In fact, the pathological hyperproliferation of skin keratinocytes that is characteristic for psoriasis could be explained by locally increased production of TGFa (10). It is well established that numerous neoplastic and transformed cell lines express TGFa, quite often to a higher extent than their normal counterparts. Transfection of a weakly tumorigenic carcinoma cell line with TGFa enhanced its tumorigenicity in nude mice (11) suggesting a role of TGFa during certain stages of carcinogenesis. This question has been investigated in transgenic mice where TGFa was overexpressed under the control of different promoters. The results suggest that the effects of TGFa overexpression are pleiotropic and tissue-specific. Several tissues and organs displayed hyperplasia of epithelial cells while the tissue architecture remained largely intact. However, in certain tissues such as liver and mammary glands TGFa overexpression induced neoplastic transformation (12-14). This process may occur preferentially in predisposed cells that have undergone other changes such as overexpression of the EGF receptor or dysregulated oncogenes (7) though the overexpression of TGFa might substitute for some of these events (15). Thus, besides being a physiological ligand that is important for cell proliferation and development, TGFa might also act as an oncoprotein in vivo under certain circumstances.

2. Transforming Growth Factor b (TGFb)

2.1. The TGFb Superfamily

The TGFb superfamily is a group of polypeptide molecules that affect cell proliferation and differentiation in numerous ways. The first report describing a biological activity of a member of the TGFb superfamily appeared in 1981 (16). The prototype molecule of the family is TGFb1 which shows sequence homology to all family members. In vertebrates, five genes encoding distinct TGFb-

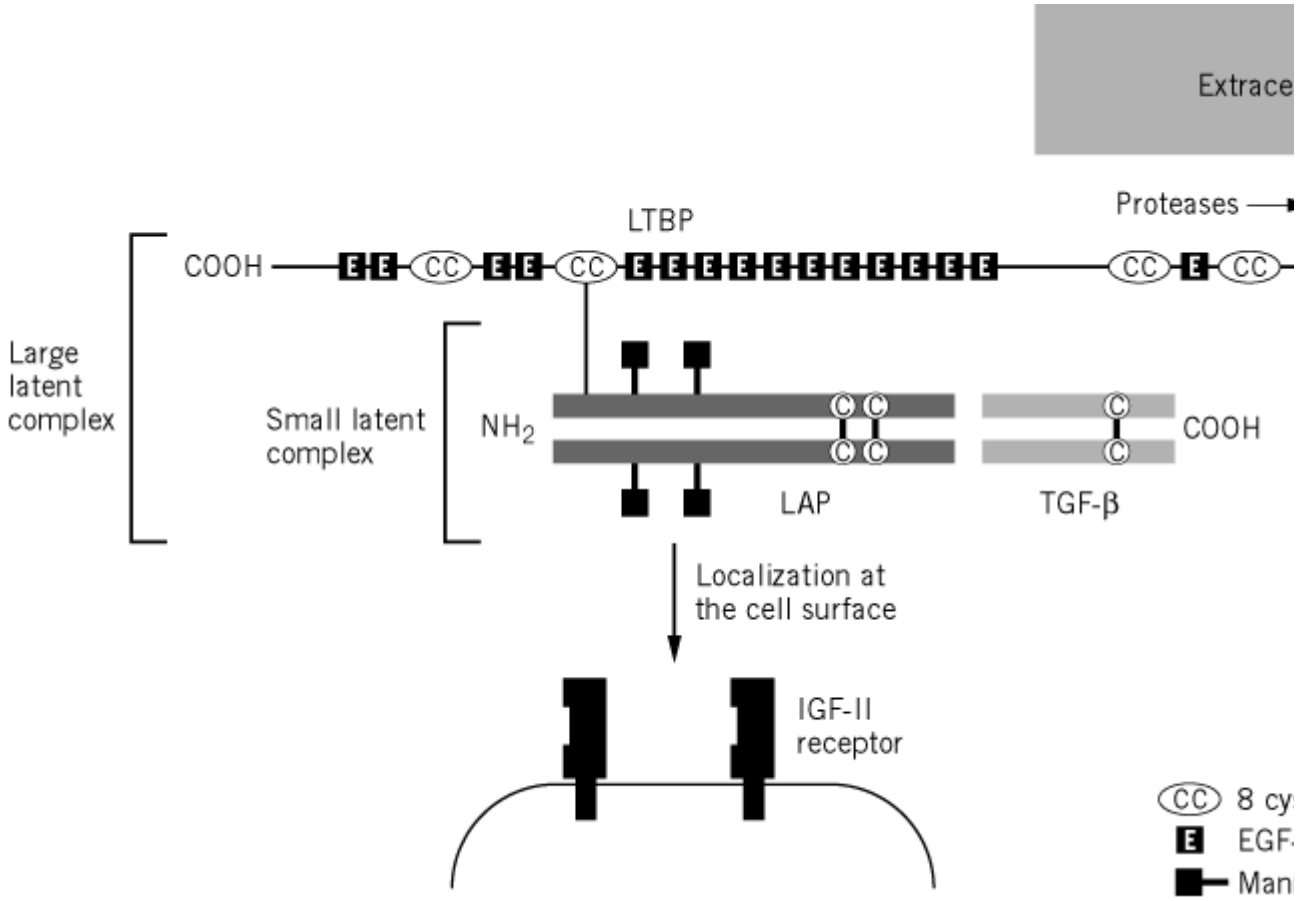
isoforms have been identified. Each gene spans more than 100 kb and contains seven exons. Mammalian cells express three differentially regulated isoforms (TGFb1, TGFb2 and TGFb3). Additional isoforms have been identified from chicken (TGFb4) and *Xenopus laevis* (TGFb5). The peptides are synthesized as large precursor molecules. The amino-terminal part contains a leader sequence (15–25 amino acids) and a prodomain of variable size (50–375 amino acids) which is poorly conserved. The biological activity is located in the C-terminal region which shares 70 to 80% sequence homology between different isoforms. The interspecies homology of TGFb isoforms is extremely high: mature human TGFb1 is identical to porcine, simian and bovine TGFb1 while the murine isoform differs by a single amino acid. The most characteristic structure of mature proteins is the so-called cysteine knot. Crystallographic studies of TGFb2 revealed that this motif is a ring of eight amino acids that are held together by two disulfide bonds while a third one passes through the middle of it (17). A similar three-dimensional structure has also been identified in members of the nerve growth factor and platelet-derived growth factor (PDGF) families. The seventh conserved cysteine forms an intermolecular disulfide bond between two monomers to form a dimer. Increasing information on the structural properties of TGFb-isoforms has enabled the identification of further related molecules. In humans and mice these new members include activins, Müllerian inhibitory substance, bone morphogenic proteins, nodal, growth differentiation factors and others. Further members of the TGFb-superfamily have been identified in nonmammalian organisms: the decapentaplegic gene (*dpp*) plays an essential role during several stages of development in *Drosophila*, *dorsalin* appears to be important for the neural patterning in chicken while the *Vg1* gene participates in embryonic axis formation of *Xenopus laevis* (18, 19). Presently, the TGFb-superfamily comprises more than 30 members.

2.2. Activation of Latent TGFb

The bioactive form of TGFb1 is a 25-kDa molecule that is usually composed of two identical disulfide-linked monomers though heterodimeric forms have also been described (20, 21). However, TGFb is not directly secreted as a bioactive molecule but is released in a latent form (Fig. 3) that is biologically inactive and cannot interact with cell surface receptors (22). The precursor is cleaved into the N-terminal latency associated protein (LAP) and the mature TGFb peptide. Both molecules form homodimers that interact via electrostatic interactions to form the tetrameric small latent complex (SLC). LAP is thought to be essential for the proper folding and transport of the complex. In addition, it contains mannose-6-phosphate (M6P) residues that allow interaction with the M6P/IGF-II receptor. Thereby TGFb could be localized at the cell surface and this interaction has been shown to be necessary for the activation of latent TGFb (23). Additional proteins are frequently associated with the SLC to yield the large latent complex. The latent TGFb-binding protein (LTBP) is a glycoprotein of 125 to 190 kDa that is covalently bound to LAP through its third eight cysteine region. LTBP appears to have a function in determining TGFb-bioavailability through targeting the latent complex to the extracellular matrix (ECM). LTBP apparently is covalently linked to the ECM as only proteases release it. Experimentally, latent TGFb can be activated by denaturing conditions (heat, acidification, chaotropes, detergents) and by radiation though such mechanisms are unlikely to be of general physiological relevance. Mechanisms that are more likely to represent physiological mechanisms include nonproteolytic activation, enzymatic deglycosylation of LAP and activation by different proteases (22). A central role in TGFb activation has been attributed to the thrombospondins (TSPs), a family comprising five extracellular proteins (24). The best characterized member is TSP-1 which interacts with a number of membrane-bound molecules but also with growth factors such as PDGF and TGFb. TSP-1 is composed of globular domains at the N- and C-terminus, a domain homologous to procollagen and three repetitive motifs, designated TSP type 1, 2, and 3 repeats (TSRs). The WSHWSPW sequence in the second TSR interacts with TGFb while an ^{412}RFK^{415} motif located at the C-terminus of TSR-1 mediates the activation of TGFb1 upon interaction with the ^{54}SKL^{57} sequence at the amino terminus of LAP. This mechanism of activation appears to be conserved among TGFb-isoforms as TGFb2 can be activated in a similar way (25). There is strong evidence that activation of TGFb by TSP-1 also occurs in vivo: TSP-1 deficient mice first develop normally but acquire histologic abnormalities in several organs similar to those recorded in TGFb1 knockout mice. Treatment of these mice with synthetic KRFK peptides resulted

in a marked improvement of lung abnormalities (26). In striking contrast are results which indicate that TSP-1 fails to activate TGFb produced by platelets (27). Apparently further requirements such as posttranslational modifications of TSP-1 or the presence of additional cofactors are needed in these cells suggesting the existence of tissue- and/or cell type-specific mechanisms for the activation of TGFb.

Figure 3. Schematic representation of latent TGFb. The disulfide bond between the latent TGFb-binding protein (LTBP) protein (LAP) is indicated by a thin line. Covalent bonds link latent TGFb through LTBP to the extracellular matrix whil mannose-6-phosphate and the IGF-II receptor allow localization at the cell surface. Reproduced with modifications from



2.3. TGFb Receptors

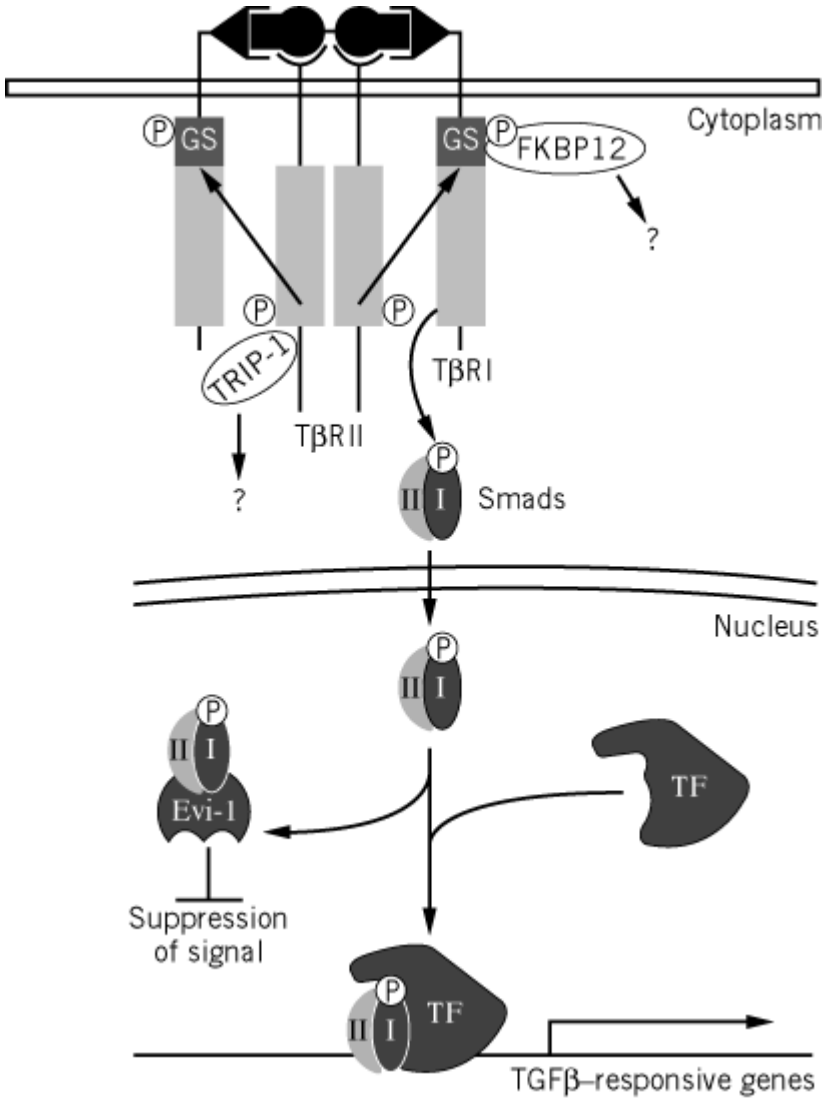
Affinity crosslinking studies using iodinated TGFb have identified at least nine different surface molecules that can interact with TGFb. However, subsequent studies revealed that sole interaction does not necessarily trigger a biological signal in every case. The major TGFb-binding proteins are molecules of 53, 70 to 85, and 200 to 400 kDa, which are termed TGFb-receptors type I, II and III (TbRI, TbRII, TbRIII), respectively. Meanwhile it is clear that only TbRI and TbRII are directly involved in signaling. The importance of both receptors for signaling was shown by chemically induced TGFb-resistant mutants of epithelial cells which either failed to bind TGFb to TbRI (R mutants) or to both TbRI and TbRII (DR mutants). Fusion of R and DR cells resulted in normal expression of TbRI and TbRII and a completely restored TGFb-responsiveness of these cells (28). The puzzling fact that TbRI were present in hybrids despite its absence in both R and DR mutants was explained by a model in which TbRI required TbRII for ligand binding and the necessity of both receptors for signaling. This model has been confirmed upon cloning of the receptors.

The cloning of TbRI (29) and TbRII (30) revealed that both receptors lack a tyrosine kinase domain

but instead are transmembrane Ser/Thr kinases. The overall structure of both receptors is similar, comprising cysteine-rich extracellular domains, a single transmembrane region and the intracellular tail containing the kinase domain. However, each receptor has characteristic and unique structural features. TbRII possess a C-terminal tail rich in Ser and Thr and bind TGFb when expressed alone possibly through a site formed by several Cys residues. Besides this cysteine box ligand specificity appears to be determined by the distribution of Cys residues in the extracellular domain. The TbRIII (beta-glycan) appears to modulate TGFb-binding in positive and negative ways. In the absence of TbRIII relatively few TbRII bind TGFb isoforms, especially TGFb2, with high affinity. However, TGFb presented by TbRIII results in high affinity binding of all three isoforms to TbRII (31). In contrast, in its soluble form TbRIII can effectively antagonize the action of TGFb by sequestration of free ligand (32). The TbRI does not bind ligand when expressed alone and contains a characteristic conserved 29–amino acid sequence (GS domain) located at the N-terminal of the kinase domain.

The kinase of TbRII is constitutively active and autophosphorylates Ser and Thr residues. Neither its activity nor the phosphorylation sites are altered upon binding of TGFb. However, upon ligand-binding a heterocomplex is formed with TbRI which is phosphorylated on Ser and Thr in the GS domain. This transphosphorylation activates the kinase of TbRI which then in turn delivers the signal to further cellular targets (33). Recent evidence suggests that the functional receptor complex is a heterotetramer that consists of two TbRI and TbRII molecules (34) (Fig. 4).

Figure 4. Signal transduction by TGFb receptors. Binding of TGFb to TbRII leads to formation of a heterocomplex with TbRI. The kinase (indicated in gray) of TbRII transphosphorylates the GS-domain of TbRI which activates the kinase of TbRI. The signal is transmitted to the nucleus by Smad proteins that associate with transcription factors (TF) and finally activate TGFb-responsive genes. R = R-Smads, Co = Co-Smads.



2.4. Smad Proteins–Key Molecules of TGFb Signaling

Using the yeast two hybrid system several proteins have been identified that interact with the cytoplasmic part of TbRI or TbRII. FKBP12 interferes with TGFb signaling by inhibition of TbRI phosphorylation (35). TRIP-1 associates with the TbRII and decreases TGFb mediated induction of transcription from the plasminogen activator inhibitor-1 promoter (36). Recently, a closely related homolog has been identified in breast cancer cells suggesting a role for these molecules in tumor progression (37).

The fact that TbR possess Ser/Thr kinase activity lead to the speculation that the intracellular downstream targets would be different than those used by tyrosine kinases. The first protein identified was the *Mad* (*Mothers against dpp*) gene product of *Drosophila* (38) followed by the discovery of three genes (*sma*-2, *sma*-3, *sma*-4) that share mutant phenotypes with *daf*-4, a TbRII in *C. elegans* (39). Meanwhile nine related vertebrate genes have been described and this novel family has been termed Smads, for *sma*- and M*ad*-related proteins. Except for Smad6 these proteins contain an N-terminal DNA-binding domain termed MH-1 (*Mad*-homology domain 1) and a C-terminal MH-2 domain involved in transcriptional activation, Smad-oligomerization and interaction with receptor serine kinases. According to their structural and functional properties three classes of Smad proteins have been defined (40). R-Smads (‘receptor-regulated’ Smads) are phosphorylated at the C-terminal SSXS motif by the serine kinase of TbRI and activin type I (Smads-2 and -3) or BMP type I receptors (Smads-1, -5 and -8). Upon phosphorylation, R-Smads physically associate with a second

group termed Co-Smads ('common' Smads). Co-Smads which include Smad-4 and -4b appear to be required for the formation of a functional transcriptional complex. The third group of so-called Anti-Smads (Smads-6 and -7) function as inhibitors of TGFb signaling by interference with the phosphorylation of R-Smads.

A network of regulators influences activation of TbR and Smad proteins (40). Antagonists of activation include the immunophilin FKPB12 (35), the pseudoreceptor BAMBI (41) and Anti-Smads (42, 43). SARA (Smad anchor for receptor activation) binds to R-Smads thereby directing them to TbRs (44). Phosphorylation of R-Smads reduces their affinity to SARA. Phosphorylated R-Smads associate with Co-Smads in the cytoplasm and move to the nucleus. Both R- and Co-Smads are able to directly activate transcription via their MH-2 domain or they act in concert with other transcription factors (40) (Fig. 4). In addition, R-Smads may initiate transcription by interference with transcriptional repressors (45).

2.5. Biological Activities of TGFbs

A prominent biological activity of TGFbs is growth inhibition of most normal cells, especially those of epithelial origin. TGFb prevents the progression into the S phase of the cell cycle by maintaining the retinoblastoma (Rb) protein in a hypophosphorylated form that arrests the cells in late G_1 (46). Complexes of cyclins and cyclin-dependent kinases (cdk) are involved in hyperphosphorylation of Rb. TGFb can inhibit the kinase activity of this complex by downregulation of cdks or induction of cdk inhibitors (47). In some cells of mesenchymal origin TGFb induces growth stimulation. This activity has been reported to be mediated by PDGF which is induced by TGFb (48). TGFbs are also important molecules in wound healing. At the site of tissue injury platelets release high amounts of TGFb which acts as a chemoattractant for monocytes, neutrophiles and T lymphocytes. After the early phase TGFb exerts immunosuppressive effects that counteract the inflammatory process. T lymphocytes acquire TGFb-responsiveness and are growth-inhibited primarily by the interference of TGFb with interleukin-2-mediated growth stimulation. The potential physiological immunosuppressive role of TGFb is strengthened by results obtained with TGFb1-knockout mice which are born normally but die within 20 days of a wasting syndrome that is accompanied by multifocal inflammatory responses in several organs and elevated levels of inflammatory cells and cytokines (49). In contrast, homozygous TGFb3 null mutants are not viable and die within 24 hours after birth. They display a defective palatogenesis and exhibit histopathological abnormalities in the pulmonary system (50, 51). Certain developmental processes appear to be strictly controlled by one isoform of TGFb. Its absence can not be compensated by other isoforms though the biological activity of TGFb peptides is often quite similar in vitro. Excess of TGFb may equally have dramatic consequences. Animals in which TGFb1 was overexpressed under the control of an epidermal-specific promoter displayed a heavily disturbed skin development and died within 24 hours (52). Targeted expression of TGFb2 in osteoblasts resulted in a dramatic loss of bone mass and the appearance of an osteoporosis-like phenotype (53). Inactivation of components of the TbRI signaling cascade caused severe early developmental abnormalities and embryonic lethality in homozygous animals (54, 55). As a single Smad protein is used by different ligands these dramatic effects might be explained by the simultaneous inactivation of multiple signal pathways of TGFb-related factors.

2.6. TGFb and Cancer

The majority of neoplastic cells is resistant to the growth inhibitory activity of TGFb suggesting that TGFb-unresponsiveness may attribute a growth advantage to the malignant cell. However, only recently some of the responsible mechanisms have been unraveled on a molecular level. In colorectal carcinoma frameshift mutations have been detected that introduce stop codons on the N-terminal site of the transmembrane domain of TbRII. This mutation leads to the synthesis of truncated receptor proteins that are functionally inactive. Unexpectedly, these lesions occur exclusively in a subpopulation of colon cancer cells that are characterized by mismatch repair deficiencies and demonstrate microsatellite instability (56). Meanwhile the same mutational inactivation of the TbRII has been detected in a variety of human tumors. Transfection of wild type TbRII into tumor cells that express no or only mutated TbRII suppressed anchorage-independent growth in soft agar and abolished tumor formation in nude mice (57, 58). These experiments provide a direct proof that

TbRII can function as a tumor suppressor gene. Some of the intracellular target molecules may have similar activities. Functional mutations and loss of heterozygosity have been discovered in DPC4 (Smad4) and Smad2 (59, 60) which are both essential for the signaling of TGFb to the nucleus. Finally, the ligand itself and molecules upstream of TGFb such as the IGF-II receptor are candidate tumor suppressor genes (61). Future experiments will have to confirm the functional activity of these components to suppress tumor growth. Furthermore, mutational inactivation of the TGFb signaling pathway entitles neoplastic cells to use endogenously produced TGFb as an effective weapon against attacking immune cells. TGFb is certainly the most potent immunosuppressive cytokine that can influence almost every cell type and reaction of the immune system (62, 63). Through TGFb-mediated suppression of immune responses tumor cells may escape from immune surveillance and gain further growth advantage.

3. Conclusion

Since the discovery of TGFs more than twenty years ago our knowledge on their molecular structure and their biological activities has tremendously increased. While this progress has answered many questions it has also created new ones. It even holds true for the ligands that are well-known for quite some time on the molecular level. Though the activation of mature TGFb has been unraveled in some tissues it remains still unclear how the cytokine is activated in other cell types. To date neither the physiological importance of membrane-bound TGFa nor the reverse signaling pathway are fully understood. The Smad family has been identified as a key player in TGFb-mediated signal transduction and a number of cellular proteins have been discovered which modulate their activity. Additional partners may reveal completely new functions of these molecules and open yet unidentified connections to other pathways. Likewise, the understanding of the transcriptional control of Smad proteins is just at the beginning. The investigation of these complex interactions may open novel possibilities in different fields of research enabling us to generate the next round of interesting questions.

Transgenic Technology

Transgenic technology consists of the introduction of a defined genetic material into the **germline** of mice or other animals. This technique has attracted considerable attention, because it has been found to be a very powerful approach for different experimental fields, including molecular and **developmental** biology as well as medical research. Using different experimental strategies, it allows the *in vivo* analysis of **gene** function, the mechanisms controlling **gene expression**, and the generation of specific animal models for human diseases. This has resulted in new insights into normal and pathological processes, thus improving our knowledge and tools in diagnostic and therapeutic fields.

This review focuses on the use of transgenic mice for different purposes including a) **promoter** analysis, and gain- and loss-of-function mutations: and b) their application in molecular and developmental biology. Further aspects will be discussed in the generation of animal models and their use in diagnostic and therapeutic approaches.

1. Experimental Approaches

Three basic methods are widely used for the generation of transgenic animals:

1. Microinjection of DNA into the male **pronucleus** of one-cell embryo.
2. Infection of pre- and postimplantation embryos by retroviruses (which will not be discussed here)
3. Transfer of the desired genetic material using embryonic stem cells.

2. Pronuclear Injection of Genetic Material

The pronuclear injection of linearized DNA is the technique most used for generating transgenic animals including transgenic mice (1, 2). Female mice are superovulated by hormonal treatment and mated to produce one-cell stage embryos in which the two **pronuclei** are still visible (2). The linearized DNA devoid of vector sequences, known as the *transgene*, is injected by micromanipulation into the male pronucleus, which is larger (2). The following day, the two-cell stage embryos are transferred to a pseudopregnant female. Pseudopregnancy is achieved by mating

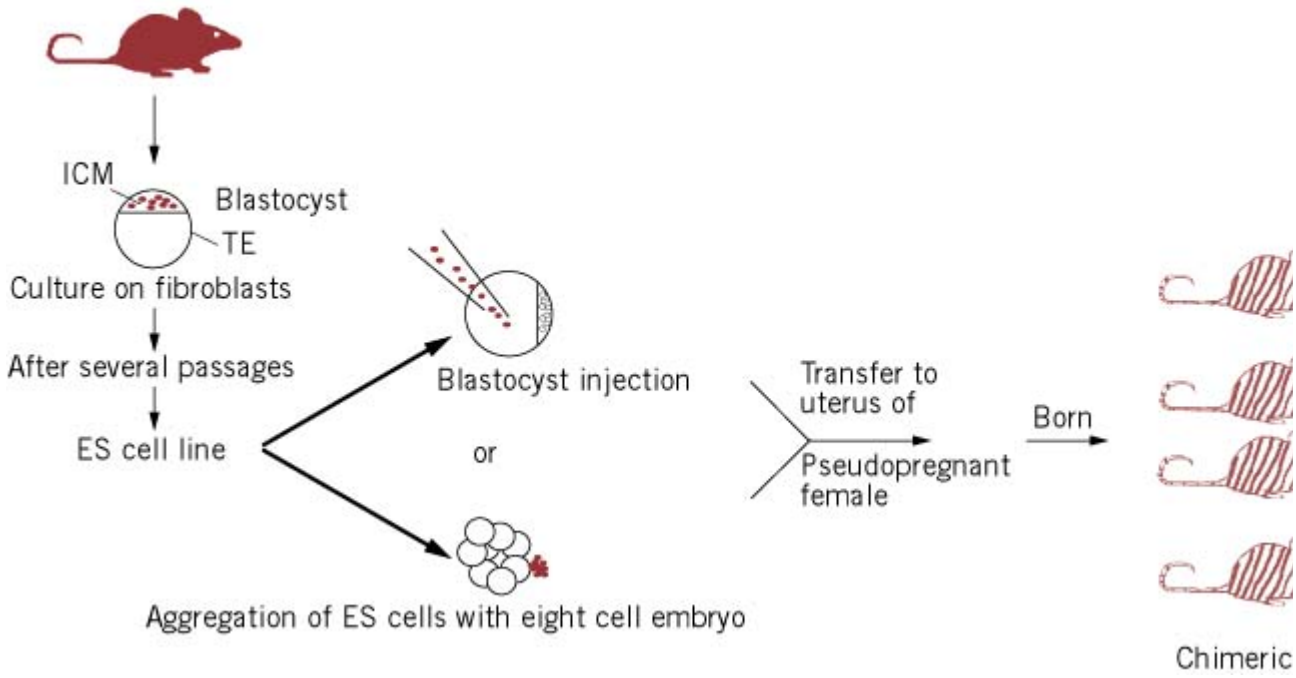
females with vasectomized males. Integration of the introduced DNA normally occurs randomly at the one-cell stage, resulting in a multicopy tandem of head to tail array of the transgene into the host genome. After the manipulations, the newborn animals are tested using standard procedures, such as Southern blot or polymerase chain reaction (**PCR**) for transgenesis, using DNA derived from tail biopsies. Animals that carry the transgene are called *founders*. Founder mice are crossed with wild-type animals to establish a transgenic line, which carried a stably integrated transgene in the germline. Sometimes the integration of the introduced DNA occurs at later embryonic stages, rather than at the one-cell stage, resulting in a mosaic integration of the transgene into the animals. Consequently, further mating may not transmit the transgene to the germline.

3. Embryonic Stem Cell Techniques

Embryonic stem (ES) cell technology is usually used for the establishment of loss-of-function mutations (3). As it becomes more effective, it may in the future replace the pronuclear injection technique.

Embryonic stem cells are derived from the inner cell mass of the mouse blastocyst (Fig. 1) (4, 5). The blastocyst is cultured on a feeder layer of primary embryonic fibroblasts. After a few days, the blastocyst attaches to the feeder and the inner cell mass starts to grow. From an inner cell mass that is picked selectively, a homogenous population of embryonic stem cells can be established (Fig. 1). The ES cells, when cultured on embryonic fibroblasts and/or in the presence of leukemia inhibitory factor (LIF), can be propagated *in vitro* and retain their undifferentiated state and pluripotency. When ES cells are introduced into the mouse embryo, they contribute to all tissues, including the germline (5, 6). They have bene shown to be the ideal vehicle for the introduction of exogenous DNA sequences into the mouse genome, because they can be genetically manipulated *in vitro* before starting *in vivo* procedures (7). Thus, more precise DNA manipulation such as site-specific integration by homologous recombination can be carried out. ES cells with stably integrated exogenous DNA are introduced into the embryo by blastocyst injections or by aggregation with eight cell embryos (5), and these manipulated embryos are then transferred to foster mothers. Animals derived from both host and ES cells are termed *chimeric*. The extent of ES cell contribution to the chimera can be assessed by coat color (Fig. 1). These chimeras can transmit the introduced genetic sequences to the mouse germline by mating with wild-type animals, resulting in the establishment of transgenic lines. The advantage of ES technology over pronuclear injection lies in the more controllable introduction of the DNA in ES cells. Stable ES cell lines may be analyzed for expression, copy number of the transgene, and so on, prior to proceeding to the mouse germline. However, the ES cell procedure is more time-consuming. Exogenous DNA, when introduced into cells, normally integrates randomly within the genome. However, specific targeting of exogenous DNA to a defined locus in the cellular genome is now possible by the means of homologous recombination. Mammalian somatic cells possess the basic machinery to mediate homologous recombination between endogenous chromosomal loci and exogenous DNA molecules (8, 9). In conjunction with ES cell technology, homologous recombination provides a powerful tool to study gene function through the generation of transgenic mice harboring specific mutations for any gene of interest.

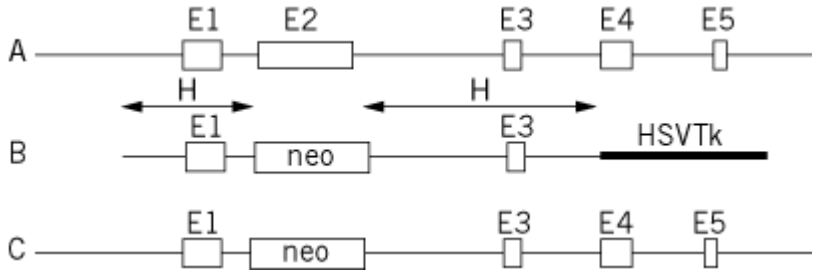
Figure 1. **Establishment of embryonic stem cells (ES)**. Blastocysts are collected from mice (with agouti coat) and cult on a feeder layer of embryonic fibroblasts. After further passages ES cell lines can be established. Introduction of ES cel mouse embryos by blastocyst injection or aggregation to eight cell embryos and subsequent transfer to foster mothers gi to chimeric mice. Chimeric mice are schematically shown with brown stripes.



There are two types of targeting vectors in common use. Both consist of a selection marker flanked by sequences that are homologous to the gene of interest. Usually, neomycin (Neo) is the selection marker of choice and confers resistance to Geneticin (G418). In the first type of vector, the targeting construct is linearized in such a way that it remains collinear with the endogenous sequences of the gene to be targeted.

During homologous recombination events, the endogenous sequences are replaced by the targeting vector, and sequences that lie outside the domains of homology are excluded from the integration. This kind of vector is termed *replacement vector* (10, 11). The second type of vector is linearized so that the pairing of the targeting vector with the endogenous sequences of the target gene results in the insertion of the whole targeting construct, including plasmid sequences. The result is a partial duplication of the target gene. This kind of vector is termed *insertion vector* (12). Both types of vectors have been successfully used, and they exhibit similar targeting frequencies (3). In most cases, however, replacement vectors are used, due to their easier handling and construction. The targeting vector used for homologous recombination experiments consists of two domains with homology to the gene to be targeted, one at the 5′ end and the other on the 3′ end of the targeting construct (Fig. 2). The selection marker, usually the Neo gene, or less usually that for hygromycin resistance or the **hypoxanthine–guanine phosphoribosyl transferase** (HPRT) minigene (13), is usually inserted between the 5′ end and the 3′ end homologous segments. The Neo gene is used first to monitor the presence of introduced DNA and second to interrupt, or **knock out**, the function of the gene. Therefore, the Neo gene is introduced into one exon, or it may replace a deleted coding sequence (Fig. 2). A typical knock out experiment will start by **electroporating** the targeting construct into ES cells. Subsequent selection (24 h after electroporation) using geneticin (G418) kills all the cells that have not integrated the construct. After 8 to 10 days of selection, the G418-resistant colonies are screened by PCR or Southern blot for homologous recombination events. Homologous recombinant clones are further used to generate germline chimeras via aggregation or blastocyst injection (Fig. 1). ES cells are in most cases derived from 129Sv agouti strain, and chimerism is identified by the coat color of agouti in contrast to the black or albino, of the host embryo (C57B1/6, NMRI, or CD1 strains).

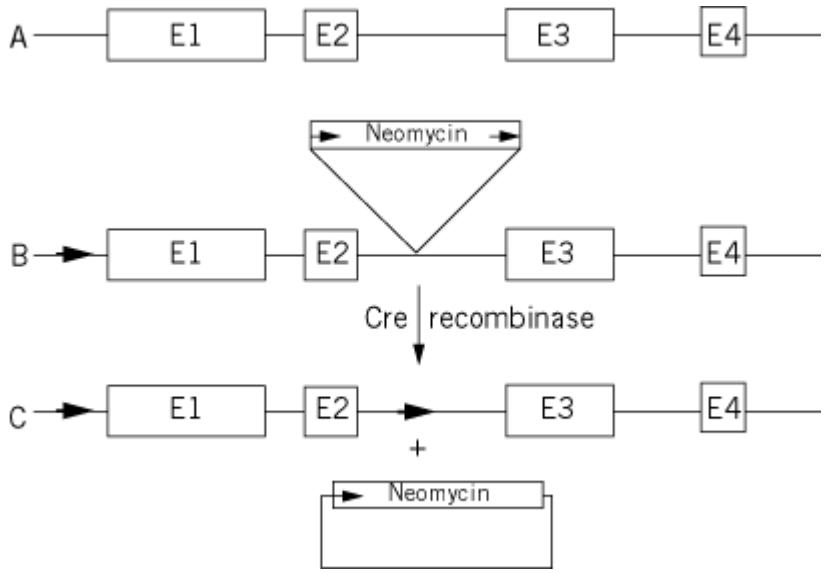
Figure 2. **Constructs for homologous recombination**. (**a**) The genomic organization normal gene to be targeted. Boxes represent exons (coding sequences E). (**b**) The targeting construct using the positive–negative selection procedure. The second exon of the gene was replaced by the PGKNeo. HSV-Tk is the thymidine kinase gene for the selection with gancyclovir, and lies outside of the segments of homologous DNA (indicated with H). (**c**) genomic organization of the targeted allele after homologous recombination.



The frequency of homologous recombination in mammalian cells is normally a rare event, in contrast to **yeast**. Two factors influence the frequency of homologous recombination: 1) the length of the homologous segments used for the construct and 2) the origin of the genomic DNA (14, 15). Increased targeting frequencies are obtained if using isogenic DNA (from the strain of mice from which the ES cells are derived) and if more than 10 kb of homologous DNA is included in the construct. One strategy to enhance the targeting frequency is the promoter-less construct. If the gene of interest is expressed in undifferentiated ES cells, a promoter-less Neo gene can be introduced into the construct. Basically, the Neo gene coding sequence is fused in frame to one exon or may replace the first exon containing the start site for translation. Upon introduction of the construct into ES cells, the Neo gene is only active if it integrates in the vicinity of a promoter or is inserted into the target locus (16). The number of clones to be screened is low, so consequently the targeting frequency is highly enriched (about 100-fold). Most of the genes are not expressed in undifferentiated ES cells, however, and the targeting frequency for most genes remains very low. Capecchi and colleagues (17) have developed a technique that allows enrichment of homologous recombinant events when targeting genes that are not expressed in ES cells. In addition to the insertion of the Neo into one exon to disrupt gene function, a **thymidine kinase** (TK) gene from the Herpes simplex virus is placed outside of the homologous regions. Two selection drugs are now applied to the medium. The G418 kills all the cells that have not integrated the Neo gene (random and homologous recombinant clones), whereas Gancyclovir kills all the cells that have retained the TK gene (random integrations); the TK gene is lost during homologous recombination events. This method is called the *positive–negative selection* (PNS) procedure (17) and provides an enrichment factor of between four- and 10-fold (Fig. 2). The PNS procedure can also used to achieve point mutations in the *hit-and-run* technique, in which a variation of homologous recombination is used to introduce deletions or point mutations in two steps (18). HPRT has been successfully introduced as a selection marker. The *in–out* targeting strategy is similar, but uses in the first step and *hprt* minigene for selection, rather than neomycin resistance and thymidine kinase (13). It is also suitable for the generation of point mutation or subtle deletions. The selection system requires HPRT-negative ES cells. Recently, more sophisticated strategies have been developed, based on the Cre-*Lox* recombination system of **bacteriophage** P1 or Flp recombinase system from yeast (19). The Cre recombinase perform recombination at *Lox* sites (locus of X-ing-over) in **bacteria** and eukaryotic cells and is the most widely used system (20, 21). DNA that is flanked by 34-bp *LoxP* sequences is excised by the Cre recombinase. This system allows the removal of specific DNA segments, such as selection markers, and only the desired point mutations or deletions will be retained (Fig. 3). This strategy can be used to perform so called *knock-in* experiments and *temporal* knockouts (22). Genes are then altered in certain tissues and at determined times of embryonic development (23). In fact, because the inactivation of several genes led to early lethal phenotype, the Cre-*LoxP* system is now used to design knockouts in such a way that tissue-specific inactivation of the targeted locus is

performed. In principle, in a first targeting experiment the gene of interest is specifically modified so that some of the coding sequences (exons) are flanked by two *LoxP*-sites in cis (Fig. 3). The *LoxP* sites, which are introduced into introns, should not affect the function of the gene. The thus modified allele is termed floxed allele. The *LoxP* sites are now recognized by Cre-recombinase to perform the excision of the coding sequences flanked by them (Fig. 3). Practically, floxed mice are generated from ES cells, which carry the floxed allele. The floxed mice are then crossed with transgenic mice expressing the Cre-recombinase under a specific promoter in a defined tissue or cell type. There are now several transgenic mice expressing the Cre-recombinase in specific tissues (so-called Cre-mice).

Figure 3. **LoxP-Cre recombinase system**. Scheme for the site-specific recombination of the *LoxP*-Cre system of the phage P1 in mammalian cells. A typical construct for the generation of so-called floxed allele is schematically shown. The Neo gene inserted into intron 2 is flanked by two *LoxP* sites shown as arrowheads. A third *LoxP* site is introduced in front of exon 1. In a first knockout experiment the gene shown in (**a**) is targeted and replaced by the targeting construct (**b**). After addition of the Cre recombinase, the neo gene is excised and from Neo only one *LoxP* site is left. The floxed allele (**b**) exhibits two LoxP sites flanking exon 1 and 2. The floxed allele is not the only product, which appears after addition of the Cre recombinase. The addition of the Cre recombinase may be performed after homologous recombination by transfecting ES cells (carrying allele B) with Cre-expressing DNA or by crossing transgenic mice expressing Cre with mice having the knockout allele B, where the neomycin gene is still present. (**a**) Normal allele; (**b**) targeting construct; (**c**) floxed allele. Exons (coding sequences are labeled with E).



During the generation of the floxed allele the selection marker (usually neomycin also flanked by *LoxP* sites in cis) is removed by Cre. This is of special interest, because it has been reported that the neomycin promoter/enhancer may affect the expression of neighboring genes. In gene clusters, where this may occur, a bias of the phenotype is induced. The first knockout mice of the Myf5 gene, which show a rib cage defect, illustrate clearly this phenomenon. In the newly targeted allele, however, where Cre excised the neomycin gene, Myf5-deficient embryos exhibit a normal rib cage (24). One of the experiments illustrating the use of *LoxP* sites is the tissue-specific inactivation of the *Pax6* gene in the eye. Mutation of the *Pax6* normally induces several defects in the eye, nose, spinal cord, and brain tissues. The tissue-specific inactivation of *Pax6* in the lens primordium indicates that it is required for lens formation and for correct placement of a single retina in the eye (25).

In addition, the *LoxP* system is now widely used to generate so called temporal knockouts in mice by using inducible site-specific recombination. For example, the engineering of a fusion protein between the Cre recombinase and the ligand-binding domain of a modified steroid receptor provides a functional inducible site-specific recombination system in mice (26, 27). The application of the

drug tamoxifen, which is still recognized by the mutant form of the estrogen receptor, efficiently induces the activation of the Cre fusion protein at the desired time of development. An alternative strategy is using a tetracycline controlled gene activation or repression protocol.

Finally, the Cre-recombinase system may be used to generate transgenic mice expressing a certain protein in a certain tissue and at a defined time of development. This is in fact necessary, when the expression of the desired gene may induce lethal defects at early stages of development.

4. Potential of Transgenic Technologies

In recent years a large number of genes and gene families have been cloned. Most of them exhibit a restricted temporal and spatial expression pattern during murine development. To study the function of these genes during development, *in vitro* experiments are not sufficient, because they cannot reproduce the complex cell–cell communications and interactions of the intact organism. Transgenic technology is therefore the method of choice to analyze the various mechanisms of gene regulation and gene function. Functional analysis of the gene can be carried out in the intact animal, and new insights may be gained into such processes as tumorgenesis and disorders of cardiovascular, immune, inflammatory, and neurodegenerative natures. Furthermore, animal models may be generated for each gene suspected of having a role in disease.

4.1. Gene Regulation Analysis

The analysis of gene regulation and the search for elements necessary and sufficient to reproduce the *in vivo* expression pattern of genes has profited from the pronuclear injection technology. Generally, the bacterial **b-galactosidase** gene (*LacZ*; see *lac* Operon) is inserted in the construct under the control of different DNA elements of the gene to be analyzed, and transgenic embryos are generated. The activity of the elements is followed by staining the embryos for the *LacZ* gene product using **X-gal** as a substrate, to produce a blue color. Normally, several deletion constructs and corresponding transgenic lines are necessary to determine the regulatory elements of a gene (28, 29). *LacZ* is a valuable marker that can also be inserted in the knockout construct, so that the expression of the targeted gene can be followed during the analysis of the phenotype (30)(Fig. 4).

Figure 4. **Expression pattern of the *Pax7* gene at E11 of development**. The *Pax7* gene has been inactivated by homologous recombination by inserting the b-galactoidase gene in frame to the first exon of the paired box. Mice carrying the mutation express the b-gacatosidase gene under the promoter of *Pax7*, and the blue staining reflects the expression of the gene during development.

A recent technique takes the advantage of *LacZ* as a reporter gene to search for new genes involved in development. This approach has been first described using pronuclear injection. The *LacZ* gene lacking active cis-acting elements is microinjected into mouse embryos. If the *LacZ* happens to integrate at a site controlled by a strong promoter or enhancer that is active in specific cells, it will be also expressed in these cells (31). A modified technique has been designed for ES cells. Again *LacZ* is inserted between a splice acceptor site at the 5′ end, and a neomycin-resistance gene at the 3′ end. Upon electroporation into ES cells, the construct may happen to integrate into a gene, when b-galactosidase may be fused to the endogenous protein. This enzyme is the expressed under the trapped promoter, and reflects the expression pattern of the endogenous gene. The corresponding ES cells are introduced into the embryo, and the expression pattern can be followed in chimeras or in mouse transgenic lines. At the same time, the trapped gene can cloned using RACE-technique (**R**apid **A**mplification of **c**DNA **E**nds using PCR). In this way, a new gene is identified by its expression pattern. The insertion of the *LacZ* leads to the inactivation of the trapped gene. Thus this method, known as *gene trap*, allows the cloning of new genes and their targeted inactivation in ES cells and mice (32, 33).

4.2. Functional Analysis

One of the classical methods to analyze the function of a gene is to modify its expression pattern *in vivo*, by increasing the activity of the gene product by its overexpression in transgenic mice and thus disturbing its physiological activity. The addition of genetic information, from mouse, rat, or human may result in alterations in the **phenotype**, and consequently help to define the role of the gene of interest. It may also lead to the generation of animal models for human disease, such as hypertension, arthritis, atherosclerosis, inflammatory disease, and neurodegenerative disorders (34, 35). One of the earliest transgenic mice generated by microinjection arose from the classical experiment of Palmiter et al (36). They used the metallothionein promoter to achieve widespread expression of the human growth hormone in mice. The transgenic mice were significantly larger than normal mice, confirming the role of the hormone in body growth. A related type of experiment was the use of the b-actin promoter upstream of the *HoxA7* coding region to express *HoxA7* at ectopic sites. Several founder animals were generated. The transgenic offspring died soon after birth and exhibited craniofacial abnormalities reminiscent of the effect of retinoic acid application during pregnancy. Also a posterior transformation of the cranial vertebrae has been observed, thus consistent with a homeotic function for this gene (37).

Expression of a certain gene in a target tissue requires the regulatory elements specific for the desired site. Promoter analysis is very time-consuming, however, and only a few genes have been analyzed in detail. The recent use of large DNA fragments to generate transgenic mice is of general interest. **Yeast artificial chromosomes** (YACs) are now used for the analysis of gene regulation and function. Such large DNA fragments are able to contain all regulatory elements, thereby ensuring expression in an integration-site–independent manner (38). The overexpression of *Pax6* using YAC transgenic technology led to a phenotype similar to that observed in a loss of function mutant and confirmed the dosage effect of this **paired-box** gene during eye development (39). The use of YAC transgenics provides a unique opportunity to analyze several basic questions in biological research. In a number of diseases where large DNA fragments are involved, YAC transgenics may now be generated. This may be used to test the hypothesis of the involvement of the amyloid precursor protein in Alzheimer's disease. Additionally, the molecular bases of diseases (such as Down syndrome) resulting from trisomy or other chromosomal translocations are now able to be dissected. This would be done by inserting large consecutive fragments of DNA from regions near the site of translocation to form transgenic mouse lines. Furthermore, mouse lines can be developed to express human **antibodies** for therapeutic and diagnostic purposes (40).

Before the development of homologous recombination in ES cells, dominant-negative mutations have been achieved by means of classical transgenic mice. The purpose is to alter one of the subunits by mutation so as to disrupt the function of the entire protein. One of the earliest experiments was the introduction of a transgene containing a point mutation into the pro-a (I) collagen gene. The mutation is identical to the one found in human corresponding gene. The transgenic mice developed a dominant-lethal phenotype similar to the human disease osteogenesis imperfecta (41).

Some investigators have utilized some toxic genes and performed some cell ablation experiments *in vivo*. The toxic genes generate a toxic product in the cell where they are expressed, or they may produce a substance that first becomes toxic after it is metabolized (42). Examples are the A-chain of the diphtheria toxin (DT-A) (43) and the Herpes simplex thymidine kinase gene TK mentioned above (17). In this way, cell-specific regulatory elements like the d-crystalline promoter can be used for the ablation of a specific cell type or cell population.

Homologous recombination remains the method of choice, however, to generate loss of function mutations. Several genes have been inactivated and many of them have been found to be necessary for embryonic development (44). In gene families, redundant functions have been confirmed by single and double mutants. This was clearly illustrated with the MyoD family of transcription factors. The inactivation of MyoD, Myf5, and myogenin revealed that although muscle is normally produced in mice lacking MyoD or Myf5 (45, 46), mice with null alleles for both genes produce no muscle, and no myogenin is transcribed (47). In further experiments the myogenin complementary DNA was inserted into the Myf5 locus by homologous recombination, disrupting its function. This knock-in of myogenin into the Myf5 locus leads to viable mice with normal rib cage. Myf5-deficient mice die prenatally and exhibit a rib cage defect (22). The knock-in experiment clearly demonstrates the functional redundancy of Myf5 and myogenin for rib formation. This kind of redundancy is also found for the **engrailed** protein (48).

Among other gene families involved in embryonic development, the *Pax* (49) and the *Hox* gene families (50) are notable. The generation of loss of function for these genes confirmed their crucial role in embryonic development. Analysis of some of the *Hox* mutants indicated that the expression of these genes is required to establish the anterior posterior axis (51-53). Analysis of the *Pax* loss of function mutants revealed not only their important function in establishing certain brain territories of the nervous system, but also that they have an essential role for the generation of different organs of the body (54). These experiments indicate that *Pax* genes are necessary for the development of the eye, the nose, the inner ear, the heart, the kidney, the pancreas, and the thyroid gland (54).

4.3. Animal Models for Human Diseases

A number of spontaneous mouse mutants have been described that can be used as animal models for

human genetic disorders (55). Because the number of these mutants is limited, the homologous recombination technique provides a powerful tool to generate animal models for known human genetic disease, where it allows the inactivation of each gene in the mouse. Although transgenic mouse models are not always suitable (some neurological and vascular disorders are better studied in the rat), some already existing models are encouraging. The first animal model engineered in mice was the HPRT-negative mouse as an animal model for the Lesh–Nyhan syndrome. Unfortunately, these mice exhibit none of the neurological symptoms characteristic of that syndrome (56, 57). However, the administration of an adenine phosphoribosyltransferase (APRT) inhibitor to the HPRT-deficient mice leads to the development of the typical symptoms of the syndrome, including compulsive self-injurious behavior (58).

Cystic fibrosis (CF) is an autosomal recessive disorder affecting about one in every 2500 newborn individuals in Caucasian populations, and is caused by a defect in the chloride transport in epithelial cells. The gene encodes a protein called *Cystic fibrosis transmembrane conductance regulator* (CFTR). Several animal models have been generated in mice. Two generated by replacement vectors have identical phenotypes, and mice die perinatally of intestinal obstructions (59, 60). In contrast, a much greater percentage of the mice generated by an insertional type vector survive, and they developed pathological changes in the lung that are characteristic for human CF (61). Whitsett and colleagues (62) prevented premature death of CF mice by introducing a transgene encoding human CFTR expressed under a gut-specific promoter. Now the CF mice survive and do not exhibit intestinal obstructions, but they develop similar symptoms to the human CF. These models are useful to establish proper conditions for aerosol-based gene therapy.

The HD gene responsible for the development of the neurodegenerative disorder Huntington's disease has been knocked out to generate an animal model. The loss of function mutation is lethal, however, and the phenotype observed in heterozygotes does not reflect the expected animal model (63, 64). However, a valuable animal model was generated by the microinjection of constructs containing a portion of the mutated HD gene in humans carrying variable CAG repeat expansions into the first exon (65). This suggests that if the real cause of the disorder is unknown, it may be suitable in some cases to generate transgenic mice by the classical procedure.

In the field of cancer research, homologous recombination has permitted the generation of mice lacking the p53 protein. Mice deficient in this protein are normal but develop cancer within 6 months after birth; consequently, they represent an animal model of carcinogenesis (66). Analysis of the mutated mice revealed that the p53 gene is necessary for the programmed cell death (**apoptosis**) of cells that are proliferating abnormally. Mice deficient for the **proto-oncogene** Mdm2 gene die early in development (67, 68). The Mdm2 oncoprotein forms a complex with the p53 tumor-suppressor protein, and inhibits p53-mediated transregulation of expression. Mice deficient for both the Mdm2 and the p53 proteins develop normally and are viable, supporting the hypothesis that the critical role of Mdm2 during development is regulation of p53 function (67, 68). Mdm2-deficient mice die because the p53 function cannot be down-regulated in early stages of development. Furthermore, some of the p53-negative embryos die *in utero*, exhibiting an exencephaly. These neural tube defects are associated predominantly with female mice, and a similar sex bias is also observed in human embryos with neural tube defects (69-71). This indicates that the p53 may also have some crucial role in the closure of the neural tube. Two other tumor suppressor genes have been inactivated in mice, but the phenotype was different from that observed in humans; mice with the inactivated **retinoblastoma** or Wilms' tumor gene do not develop tumors (72). These results may emphasize some differences in the pathogenesis of tumors in mice and man.

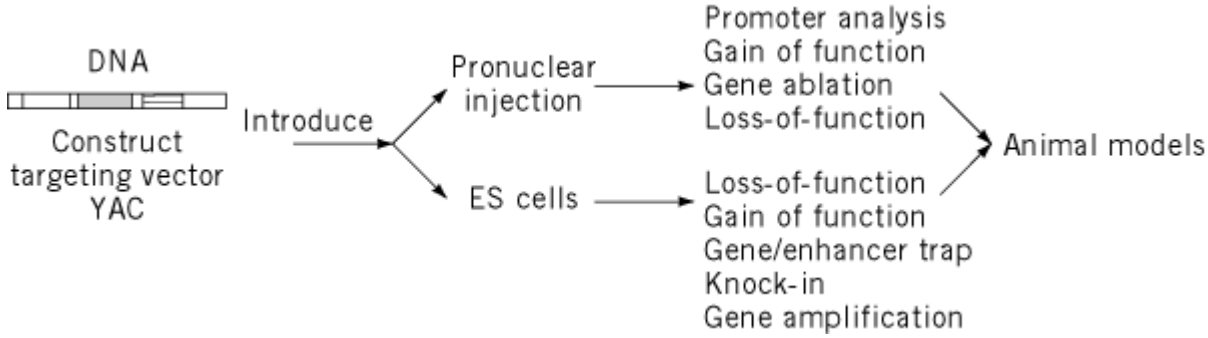
It has long been debated whether DNA **methylation** plays an important role during carcinogenesis. The generation of mice deficient in the gene for DNA methyltransferase, Dnmt (which is responsible for methylation of newly synthesized CpG dinucleotides) (73) can be used to test this possibility. In fact, APC^{Min} mice carrying a point mutation for multiple intestinal neoplasia (Min) in the mouse homologue of the APC gene have been used for this purpose. Inheritance of mutations of the APC

gene in man is the cause of familial adenomatous polyposis coli. A small proportion of cases develops to a malignant state. Mice heterozygous for the APC^{Min} allele exhibit a similar phenotype, so this represents a suitable animal model (72). Mice heterozygous for both APC^{Min} and Dnmt deficiency show a significant reduction in the number of intestinal polyps when compared to those heterozygous for solely APC^{Min} (74). Furthermore, the use of 5-aza-2′ deoxycytidine, an inhibitor of DNA methylation, leads to a more drastic reduction of the polyp number in these double heterozygous mice (72). These results indicate how useful transgenic mice may be for the elucidation of debated hypotheses, and they may also give us new insights for the development of new concepts for cancer therapy. The efficacy of the homologous recombination technique has been recently shown by the production of a **fusion protein** that normally occurs by chromosomal translocation in humans, to produce an oncogenic protein Mll-AF9 causing acute leukemia (75).

4.4. Future Perspectives

Transgenic technology has opened new possibilities in studying gene regulation and function (Fig. 5). It provides us with animal models for human diseases. Furthermore, it may give us new insights into the molecular basis of known human disorders. One such a disease is inflammatory dowel disease, called *ulcerative colitis*, which has previously been proposed to originate from an *autoimmune* response. Mice lacking interleukin-2 function develop a similar bowel inflammation, suggesting that interleukin-2 deficiency may be involved in this process (76). The site-specific recombination system and the use of YAC transgenics have opened new possibilities. Animal models can now be produced using the Cre/lox system to design subtle mutations, deletions, or even translocations (77). Temporal knockout experiments are opening new avenues in the analysis of mouse development.

Figure 5. **General scheme for the potential of the transgenic mice**. Using pronuclear injection or ES cell technology, transgenic mice can be generated. Constructs are variable and may include also YACs. Gain and loss of function mutants help to analyze gene regulation and function and provide animal models for human diseases.



Finally, the establishment of embryonic stem cells from different species including livestock has been reported. However, so far none could pass the germline, as in the mouse. The recent production of a gene-targeted sheep by nuclear transfer from cultured somatic cells (fibroblasts) provides a new tool for the introduction of a defined genetic material to create transgenic animals (78). It has opened a new field for the generation of transgenic animals from different species to use for transplantation and useful biofactories.

5. Acknowledgments

The author thanks Prof. Peter Gruss for constant support and encouragement, Jens Krull for excellent technical assistance, and Prof. Peter Gruss, Dr. Kenneth Ewan and Dieter Treichel for critically reading the manuscript. I apologize that it was not possible to cite a number of colleagues due to the

limited scope of this review. This work is supported by the Max-Society.

Transit Peptides

Cells contain distinct subcellular compartments, such as the nucleus, the endoplasmic reticulum (ER), the Golgi apparatus, **peroxisomes**, mitochondria, and, in plants, chloroplasts. Each of these compartments has a well-defined morphology and is surrounded by one or more limiting membranes. The various functions of the different compartments depend critically on an array of diverse proteins. Because the majority of the organellar proteins are encoded in nuclear DNA and synthesized on cytosolic ribosomes, efficient mechanisms must exist to transport proteins to their final destinations.

1. Export and Import Systems Operate in Intracellular Protein Trafficking

Two types of protein transport systems have been classified: export and import systems (1). Export systems operate in the transport of proteins from the cytosol into extracytosolic compartments. *Extracytosolic* means that the final destination of a given protein is a noncytoplasmic space, such as the lumen of the ER or the chloroplast thylakoid lumen, or a distinctive membrane, such as the peroxisomal membrane or the inner membranes of mitochondria and chloroplasts, respectively. Import systems, by contrast, transport proteins from the cytosol into an environment that is either functionally equivalent to, or evolutionarily derived from, the cytosol. Among such cytosolic-equivalent compartments are the internal compartments of mitochondria (called the *mitochondrial*

matrix), chloroplasts (stroma), and peroxisomes (peroxisomal matrix). The nucleoplasm of the eukaryotic cell nucleus is cytosolic as well, but transport of proteins through the nuclear pores does not obey the common principles governing protein translocation in export and import systems. Consequently, nuclear protein transport will not be discussed here (but see Ref. 2 for review and also see Nuclear Import, Export).

2. The Principal Features of transit Peptides

Export and import systems operate by similar mechanisms (1). A given polypeptide chain has to contain a molecular "stamp," a topogenic signal (3) that dictates its proper compartmentation. Topogenic signals can reside either in the polypeptide itself (internal targeting signals, as found in almost all nuclear and peroxisomal proteins and some proteins destined to the inner membranes of mitochondria and chloroplasts) or in NH_2-terminal cleavable extensions known as **signal sequences**, leader sequences, or presequences (1, 3) (see Signal Peptide). These sequences, which are rather short and therefore often collectively referred to as transit peptides, display a remarkable variability in terms of structure and function. However, powerful methods have been developed to identify and characterize transit peptides and to predict to which compartment a transit peptide will direct a protein (4, 5).

Proteins destined for the ER contain **hydrophobic** signal peptides (see Ref. 1 and references cited therein). These are remarkably different in length and overall amino acid composition, as found in different secretory proteins. Present evidence suggests, however, that there might be common **secondary structure** motifs that are essential for proper signal peptide function. As shown for the prepro-a-factor, the signal peptide consists of a hydrophobic core and two to three turns of a-**helix** (6). Other signal peptides might contain similar helical structures, in which the minimal length of the hydrophobic core could be determined by the requirement to build subsequent turns of the helix (6 to 7 residues)(6).

Proteins destined to the matrix of mitochondria contain mitochondrial transit peptides of about 20 to 60 amino acid residues in length (see Ref. 7). Mitochondrial transit peptides are rich in positively charged amino acids but usually lack negative charges. Furthermore, mitochondrial transit peptides have the potential to form amphipathic a-helices in nonaqueous environments, such as membranes. Both the basic and the amphipathic characters of mitochondrial transit peptides are essential for their function.

Proteins destined to chloroplasts contain chloroplast transit peptides. These are variable in length and amino acid composition (8). They are characterized by an uncharged NH_2-terminus and a high content of hydroxylated amino acids (Ser, Thr). Chloroplast transit peptides are neither strongly basic nor amphiphilic, and their nature remains mysterious (1).

All presequences have in common that they are removed **proteolytically** during or upon transport of the higher-molecular-weight precursors to their final destinations (see Ref. 1 and literature cited therein). The actual cleavage sites are conserved in proteins destined to the same compartment, but they differ for secretory proteins and mitochondrial and chloroplast precursors. This reflects the different specificities of the signal, mitochondrial matrix, and chloroplast stroma processing peptidases.

3. Transit Sequences Mediate Protein Export and Import, Sometimes Both

Transit peptides are operative in the transport of proteins along the export pathway (eg, precursors destined to the ER or the chloroplast thylakoid lumen) and the import pathway (eg, precursors destined to the mitochondrial matrix and the chloroplast stroma). Import signals are generally hydrophilic, whereas export signals appear to be hydrophobic (1).

Most transit peptides are simple in terms of structure and function: They just direct the precursor across one or two lipid bilayers (1). Some transit peptides, however, display a more complex molecular architecture. They represent bipartite presequences that contain both *import signals*, directing the precursor across the limiting outer and inner membranes of mitochondria and chloroplasts, and *export signals*, which determine the final intraorganellar protein sorting (1). For example, the import domains of mitochondrial and chloroplast precursors reside in the NH_2-terminal halves of their transit peptides and are removed by the matrix and stroma processing peptidases, respectively (1). The export domains located in the carboxy-terminal halves of the transit peptides then direct the intermediate-sized proteins to their final destinations—for example, the mitochondrial inner membrane and the thylakoid lumen (1). At either place, the export domains are removed proteolytically, giving rise to the mature, properly localized protein.

4. Transit Peptides Interact with Cytosolic Targeting Factors and Membrane-Bound Receptor/Translocase Complexes During Transport

4.1. Cytosolic Factors with Presumed Targeting Functions

How can the targeting information, specifying to which compartment a given precursor must be transported, be decoded? There are at least two crucial elements in this decoding process. These are provided by precursor-specific targeting factors and presequence-specific receptors in the target membranes. A nascent polypeptide chain just emerging from the ribosome binds sequentially to these proteins. However, the very first partner of a nascent chain is a heteromeric protein that forms a nascent-chain-associated complex (NAC) (9-11). As shown for mammals, NAC sits on the surface of the ribosome just at the site where the nascent polypeptide chain appears. NAC binds to the chain and thereby prevents the signal recognition particle, a supramolecular protein/RNA complex involved in cotranslational transport of proteins into the ER (see text below), from associating with polypeptide chains that do not contain ER-specific signal sequences. If such proteins do, however, contain such NH_2-terminal signals, SRP displaces NAC from the nascent polypeptide chain and initiates co-translational protein secretion into the ER. In addition, NAC prevents spontaneous contacts between the ER and vacant ribosomes (9-11).

Remarkably, NAC of yeast has recently been demonstrated to operate also in protein transport to mitochondria (12). NAC was shown to protect nascent polypeptide chains from all cytosolic proteins until 30 to 50 amino acids have been translated. Subsequently, the mitochondrial presequence was found to become accessible to a cytosolic protein, Mft52 (13), and to the **molecular chaperone** Hsp70 that, together with DnaJ (a co-chaperone; see DnaK/DnaJ Proteins), delivers the precursor to the cytosolic face of the mitochondrial outer membrane (12).

From rabbit reticulocyte lysates, two other targeting factors have been purified. These are the presequence binding factor (14) and the targeting factor (15). They interact with typical mitochondrial transit peptides (see text above). Rat liver cytosol contains another such factor, the mitochondrial import stimulating factor (MSF) (16, 17), that recognizes and targets mitochondrial precursors to their final destination (18, 19). In addition to the aforementioned factors, a cytosolic Hsp70 molecular chaperone was suggested to operate in mitochondrial protein import (20, 21).

The relative degrees to which the different cytosolic factors determine the various targeting pathways in a cell has not been investigated. This is due in part to the fact that not all factors have been purified to homogeneity from one and the same source. On the other hand, complex regulatory circuits might exist that regulate intracellular protein trafficking at the level of targeting factor expression and interaction (see Ref. 22 for review). A general involvement of NAC in intracellular protein trafficking is likely but has not been proven in all cases (eg, for chloroplasts).

4.2. Membrane-Bound Receptor/Translocase Complexes Decode Export and Import Signals

Although transit peptides per se are able to interact with their respective target membranes, the aforementioned factors promote proper binding and/or translocation. In the case of the ER (see Refs.

23 and 24 for review), signal recognition particle (SRP) binding to the signal peptide of nascent secretory proteins causes an arrest of elongation of translation. Simultaneously, SRP pilots the ribosome-nascent chain–SRP complex to the ER membrane. At this place, a heterodimeric SRP receptor (SR) mediates docking, after which SRP transfers the signal sequence to the translocon and then cycles back to the cytosol. GTP hydrolysis appears to be involved in the regulation of targeting: SRP and SR reciprocally stimulate GTP hydrolysis. As a final step, the signal sequence inserts into the actual translocation channel formed by the Sec61p complex so that co-translational transport can begin. Recent studies have shown that Sec61p constitutes both the signal peptide receptor and the actual translocation channel (25).

The post-translational transport of secretory proteins into the ER, found in yeast, is independent of SRP but requires a signal sequence (6) and involves the same Sec61p complex as reported before, as well as an additional complex, named Sec62 / 63p (26).

Co- and post-translational protein transport into the ER differ functionally in their driving forces (26, 27). In the co-translational pathway, the major energy source appears to be provided by the ribosome itself. In the post-translational pathway, a luminal member of the Hsp70 family, called BiP, operates as an ATP-powered ratchet and/or import motor and pulls the precursor in Ref. 27. Despite this major difference, co- and post-translational translocation converge at one important point; in each case the signal sequence is presumed to cause opening of the translocation channel (6, 25).

In the case of mitochondria, two different receptor subcomplexes have been characterized on the outer mitochondrial membrane (see Refs. 7 and 28 for review). Translocon outer membrane protein Tom70 (the number indicates the apparent molecular mass in kilodaltons) and Tom37 form one subcomplex (29) that is involved in binding of MSF-complexed precursors, as mentioned before. Upon binding MSFs, an ATPase is activated and, after ATP hydrolysis, MSF is released. The precursor bound to Tom70/Tom37 is then transferred via another Tom, Tom5 (30), to the Tom20/Tom22 subcomplex (31, 32). In turn, the precursor interacts with Tom40 that, presumably together with three small Tom components, forms the actual translocation site (33). Precursors that do not need MSF for binding bypass Tom70/Tom37 and interact either directly or in a Hsp70-complexed form with the Tom22/Tom20 subcomplex (19, 21).

Transport of cytosolic precursors across the mitochondrial outer membrane is indeed a remarkable process. The positive charges in the basic transit peptides appear to interact sequentially with the negatively charged cytosolic domains of the different Tom proteins (34). Presumably by electrostatic interactions, the precursors pass Tom20, perhaps Tom5, and Tom22. After translocation across the outer membrane, the transit peptide reaches Tim23 (35), which represents a key component of one of the two principal protein import machineries in the mitochondrial inner membrane (see Ref. 7 for further details). Whether the intermembrane space-exposed domain of Tom22 associates with Tim23 or forms a binding site for the positively charged or other, yet to be identified, amino acid residues of the transit peptide has not been ultimately answered (36-39). Nevertheless, once the intermembrane space-exposed domain of Tim23 has been approached, the transit peptide binds to and triggers dissociation of the Tim23 dimer (35). As a result of a presumed conformational change, the preprotein-conducting channel, which is constituted by Tim23 and Tim17 and presumably other, as-yet-undetermined components, opens (40). Then, the presequence is transferred through this Tim complex into the matrix so that it may interact with mitochondrial Hsp70 (mHsp70)(41, 42). To accomplish its function, Hsp70 interacts with Tim44, which is associated with the Tim23/Tim17 channel (see Ref. 40 for details), and the soluble nucleotide exchange factor MGE (43). Initial precursor translocation requires a membrane potential DY, but in an equilibrium reaction that is later biased toward inward movement by the binding of mHsp70 (44, 45). Subsequent rounds of mHsp70 binding require hydrolysis of matrix ATP and pull the precursor in.

The proper function of mitochondrial import (matrix-targeting) signals can be counteracted by hydrophobic regions immediately following the transit peptide (46). The precursor then arrests its movement and may leave the translocation channel of the inner membrane laterally into the

membrane. In addition to such a stop-transfer mechanism, reexport from the matrix has been reported for some inner membrane proteins (47). Furthermore, numerous other mechanisms have been identified in recent years that give rise to an abundance of different protein topologies (48-53). Remarkably, these various mechanisms involve transport across the common Tom machinery but diverge at the intermembrane space and/or inner membrane (48-51). While some mitochondrial inner membrane proteins are synthesized with NH_2-terminal cleavable transit peptides [eg, D-lactate dehydrogenase (52)], others are targeted via internal signals [eg, carrier proteins (48-50) and the BCS1 protein (53)].

5. A Common Scheme of Transit Peptide Function

Transit peptides are crucial elements in the targeting pathways of cytosolic precursors to their final destinations. They can operate as either export or import signals. In either case, they interact sequentially with cytosolic proteins with presumed targeting function, cytosolically exposed receptors on their respective target membranes, and translocation channel components embedded into these membranes. The presequence initiates translocation. The driving force for the actual translocation across the membrane may be provided by the ribosome itself (co-translational import of secretory proteins into the ER) or ATP-powered molecular chaperones on the *trans* side of the target membrane (post-translational transport into the ER, mitochondria, and chloroplasts). During or upon completion of translocation, the NH_2-terminal presequences are cleaved proteolytically. In case of bipartite transit peptides, the remaining part directs the intermediate-sized protein along its final targeting pathway. Recent studies have shown that thylakoid lumenal proteins of chloroplasts can follow two different pathways: a DpH-dependent route (54) and a chloroplast SecA-dependent route (55); both display amazing similarities to the protein export pathways operating in bacteria (see Refs. 56 and 57 for review). Pathway specificity is determined by information residing in the carboxy-terminal halves of the transit peptides, which function as export signals (58, 59).

6. Exceptions to the Rules: Transit Peptides with Regulatory Functions

Another interesting facet of transit peptide function was recently discovered: Porphyrins such as heme, which is found ubiquitously in all living organisms, can regulate mitochondrial protein import (60). A conserved heme-binding site was identified in the presequence of 5-aminolevulinic acid synthase, which represents a key enzyme of heme biosynthesis. Binding of heme to this motif blocked import of the cytosolic precursor of this enzyme, and this is assumed to be a key element through which heme biosynthesis is controlled in mitochondria (60). Just the opposite mode of regulation was discovered in case of a key enzyme of chlorophyll biosynthesis of higher plants, the NADPH:protochlorophyllide oxidoreductase (PORA). One of the enzyme's two substrates, protochlorophyllide, bound to a yet unidentified porphyrin binding site in the transit peptide and triggered the import of the cytosolic precursor into chloroplasts (61).

Transition Mutation

A transition mutation is a base-pair-substitution point mutation that substitutes a **purine** for the other purine or a **pyrimidine** for the other pyrimidine, so that the purine/pyrimidine axis of the DNA molecule is maintained. The four possible transitions are

$$G \rightarrow A \quad A \rightarrow G \qquad \textit{Purine/purine}$$
$$C \rightarrow T \quad T \rightarrow C \qquad \textit{Pyrimidine/pyrimidine}$$

The term transition was first defined by Ernst Freese in 1959 (1). By studying mutations induced by the **mutagenic** base analog 5-bromouracil or 2-aminopurine, he showed that there are two types of mutagenesis, those that undergo **reversion** by the base analogues, called transitions, and those that do not, called **transversions** . Transitions result from base mispairing due to the ambiguous base-pairing properties of base analogues. 2–Aminopurine mispaired with a thymine results in the insertion of an adenine in the next round of DNA replication, creating a G to A transition. Because these mutations were due to mispairing by the base analog, it was reasoned that the mutations would be revertible with another base analogue.

Transitions are the errors that occur most frequently during DNA replication. **DNA polymerases** are far more likely to misinsert the wrong purine or pyrimidine than to insert a purine instead of a pyrimidine or vice versa. Transitions are also induced by a number of exogenous and endogenous DNA-damaging agents that behave like base analog *in vivo*. Such mutagens include alkylating and some oxidative agents.

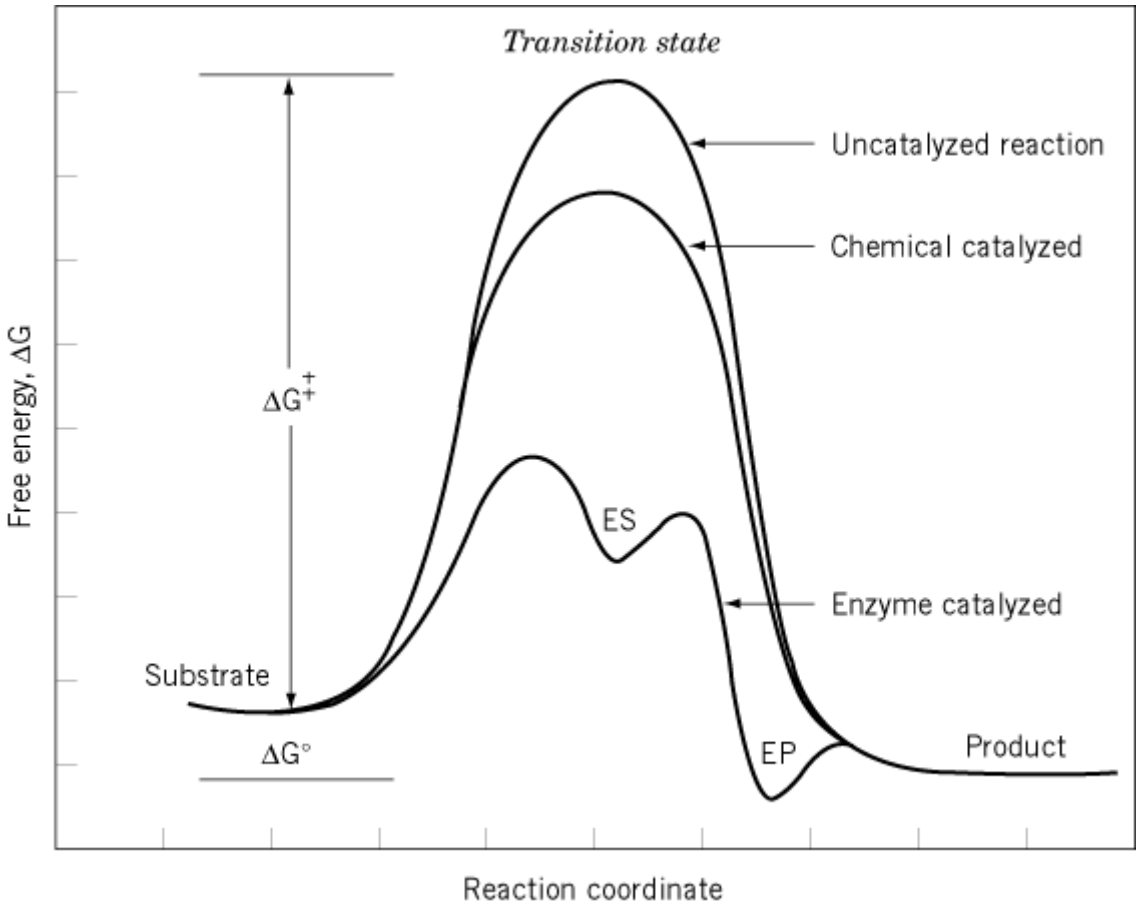
Transition State

There is no necessary connection between how much and how fast a reaction occurs (see Kinetics). The more stable the products are relative to the starting reactants, the more complete is the reaction. A **free energy** diagram of the reaction indicates why this is so (Fig. 1). The difference in free energy between the reactant and the product determines the equilibrium constant for the reaction. A large and favorable free energy difference does not, however, ensure that the reaction will occur rapidly. The rate of a reaction is determined by an independent variable, the free energy of the transition state, which is the least stable species occurring during the reaction. If the transition state has a low free energy, the reaction occurs rapidly. The higher the free energy, the slower the reaction. Within the transition state for chemical reactions, covalent bonds are being broken and made.

Figure 1. An example of a reaction coordinate diagram. The reaction coordinate is a measure of the extent to which a chemical reaction has occurred in a molecule. The starting molecule is on the left, the product on the right. The free energy of the molecule is given by the solid line. The species with the highest free energy is the transition state for the reaction. The higher its free energy, the slower the reaction. Chemical catalysis is depicted as occurring because the transition state is stablized. Such stabilization shown for enzymatic catalysis is caused by binding of the reactants to the enzyme.



According to the simplest form of transition-state theory, the rate constant k_r for a reaction is defined by the free energy DG‡ of the transition state, in the following equation:

$$k_r = \left(\frac{k_B T}{h}\right) exp(-\Delta G\ddagger / RT) \qquad (1)$$

where k_B is the Boltzmann constant, T is the absolute temperature, h is Planck's constant, and R is the gas constant. This equation was derived by assuming that the transition state is in equilibrium with the reactants and that molecules reaching the transition state are converted to products by the most rapid process in which covalent bonds can be broken and made, given by k_BT/h; it has a value of $6\times10^{12}s^{-1}$ at 25°C.

A related concept is the activation energy, which corresponds to the enthalpy of the transition state. Enzymes and other catalysts can be imagined to increase the rates of reactions by lowering the free energy of the transition state, generally by interacting with it and stabilizing it.

Because they are the least stable species during a reaction, transition states are populated for the least amount of time and are not detectable directly. Their natures can be inferred only by studying the effects of systematically varying the conditions of a reaction or the reactants and examining their effects on the rate of the reaction, i.e., the free energy of the transition state (see Free Energy Relationships).

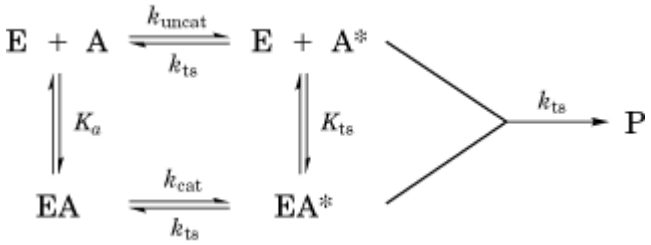
Transition State Analogue

Like all **catalysts**, enzymes increase the rate of chemical reactions by lowering the activation energy. The result is that the substrate molecules pass through the activated or transition state at a greater rate than would be the case if the reaction were uncatalyzed (see Catalysis). The features of an enzyme-catalyzed reaction and the corresponding nonenzymic reaction can be described in terms of transition kinetic theory (1) by the following scheme:



In this model, the enzyme (E) has only a single substrate, which is converted to a single product (P), and the release of P from the enzyme is not rate-limiting. The rates of formation of the transition state, designated as A*, when bound to the enzyme and when in solution, are given by k_{cat} and k_{uncat}, respectively. A transition state breaks down to the original ground state or to the product at the same intrinsic rate, independent of the enzyme. In classical transition state theory, these rates are represented by the rate constant k_{ts}, which is equal to kT/h, where k is Boltzmann's constant, h Planck's constant, and T the absolute temperature. K_a and K_{ts} denote **dissociation constants** for the EA and EA* complexes, respectively. From the kinetic scheme, it follows that the rate of the reaction on the enzyme, relative to the rate of the reaction in solution, is given by k_{cat}/K_a, which must be equal to k_{uncat}/K_{ts}, as these are **linked functions** and the **free energy** must not change in a

cyclic series of reactions. To the extent that k_{cat} is greater than k_{uncat}, the value of K_{ts} must be less than K_a; ie, the transition state should have a correspondingly higher affinity for the enzyme than the substrate. As enzymes speed up the rate of reactions by as much as 10^{12}-fold, the binding of the transition state by the enzyme should be very much tighter than the binding of the substrate in the ground state. The above relationship can be expressed as $K_{ts} = (k_{uncat}/k_{cat})\ K_a$, so that, for an enzyme that increases 10^{12}-fold the rate of reaction of a substrate with a K_a value of 10^{-5}M, the value for K_{ts} would be 10^{-17}M. Such a low value for K_{ts} would ensure that the transition state is not released from the enzyme. The enhanced binding of the transition state would be due to the additional and favorable interactions between it and the enzyme that are not available to the ground state substrate.

The idea of tight-binding of the transition state prompted the development of *transition state analogues* with structural features approaching those of the transition state. It was expected that such compounds would be highly specific and potent inhibitors of enzymes. But it would be difficult, if not impossible, to prepare a good stable analogue of an extremely unstable transition state, which must have an unusual covalent structure with partial and extended bonds and unusual bond angles. Most of the compounds referred to as transition state analogues are, in effect, *intermediate state analogues* , as they are analogues of actual intermediates, such as carbanions and tetrahedral adducts (2, 3). An enzyme would not be expected to bind an intermediate state as tightly as it would a transition state. Examples of intermediate state analogues that bind strongly to enzymes are listed in Table 1.

Table 1. Selected Examples of Intermediate State Analogues

Enzyme	Inhibitor	*K*	Reference
Aconitase	1-hydroxy-2-nitro-1,3-propanedicarboxylate	0.7 nM	(5)
Adenosine deaminase	2′-deoxycoformycin	0.22 nM	(6)
Adenylate deaminase	Coformycin-5′-phosphate	55 pM	(6)
Cytidine deaminase	Phosphapyrimidine nucleoside	0.9 nM	(7)
Enolase	(3-hydroxy-2-nitropropyl)-phosphonate	6.0 nM	(8)
Isocitrate lyase	3-nitropropionate	1.5 nM	(2)
Pepsin	Pepstatin	46 pM	(9)
Ribulose bisphosphate carboxylase	4-carboxy-D-arabinitol-1,5-bisphosphate	5 pM	(10)
Thermolysin	Phosphonoamidate peptide	9.1 nM	(11)

Finding an intermediate state analogue that functions as a potent inhibitor and has been developed on the basis of the postulated chemical mechanism for the reaction could be taken as evidence for the proposed mechanism. It is possible however, that the strong interaction is due simply to fortuitous interactions. Methotrexate, an analogue of dihydrofolate, is a potent inhibitor of dihydrofolate reductase from *Escherichia coli* (see Aminopterin, Methotrexate, Trimethoprim, and Folic Acid) and shows other characteristics of the behavior of intermediate state analogues (see below). But the strong inhibition of dihydrofolate reductase by methotrexate occurs not because it behaves as an

intermediate state analogue, for it is bound upside down relative to the binding of dihydrofolate, but because there are more interactions between the inhibitor and the enzyme than between the enzyme and the substrate.

A feature of intermediate state analogues is that they often exhibit slow-binding characteristics (4) (see Slow-Binding Enzyme Inhibition). This time-dependent behavior is often due to the rapid formation of an enzyme-inhibitor complex that subsequently undergoes a slow conformational change, leading to marked enhancement of the binding of the inhibitor. This behavior could well be analogous to the conformational change that an enzyme-substrate complex is believed to undergo in the formation of the transition state complex. It could be considered that, in both instances, the conformational changes are responsible for the stronger interactions and tighter binding.

Translation

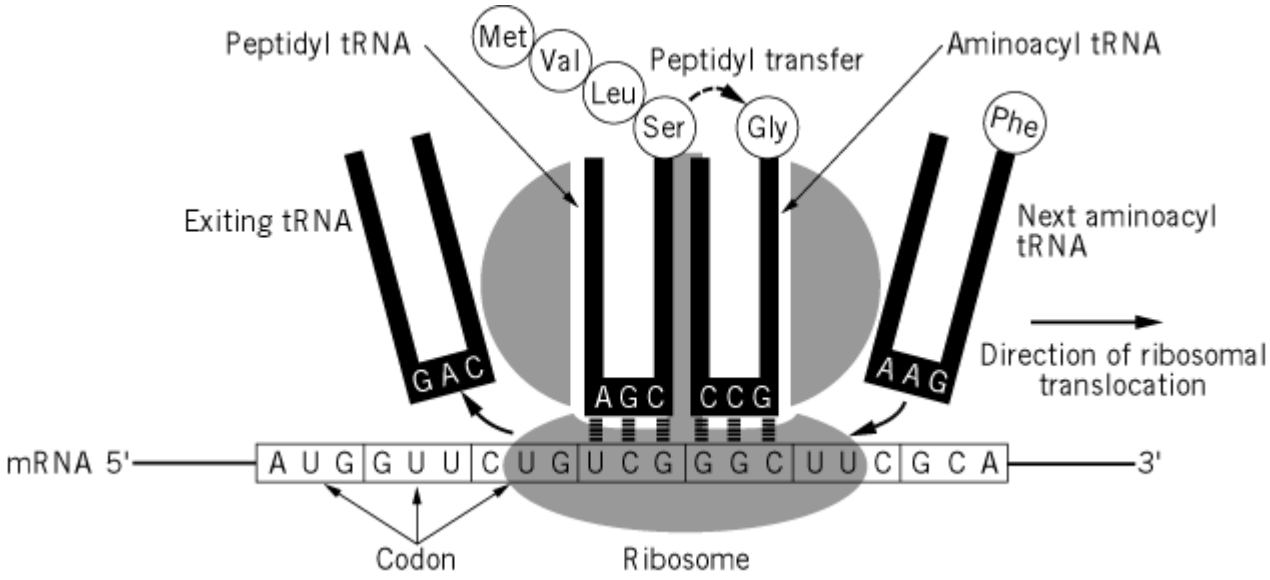
Translation is the synthesis of a protein according to the genetic information. It is the second step of **gene** expression, following transcription, and is a universal and essential step for life. The process is called translation because it converts the genetic information of nucleic acid sequences, composed of four distinct nucleotides, to the polypeptide sequence composed of 20 distinct amino acids. A unit of the genetic code consisting of three nucleotides (triplet), named a **codon**, corresponds to one amino acid, except for the final stop codon. The conversion of information is often referred to as "decoding." Being highly accurate (with an error rate of only 5×10^{-4} per amino acid residue) and fast (15 amino acids incorporated per second at 37 °C), translation is one of the most complex biological processes; it involves a number of factors in a coordinate manner and consumes a vast proportion (about 80%) of energy that cells produce. That translation of all the contemporary genomes uses a common basic mechanism is a strong indication that all organisms originated from a single evolutionary ancestor.

The template for translation is a messenger RNA that encodes the genetic code as a sequence of 64 ($= 4^3$) different codons. The linear order of codons aligned on the mRNA from the 5′ end to the 3′ end in a nonoverlapping and nongapped manner specifies the amino acid sequence of the polypeptide chain from the *N*-terminus to the *C*-terminus. The principal reaction of translation is the polymerization (by peptide bonds) of amino acids arrayed according to the codons. The amino acids

are not lined up by direct interaction with the codons, however, but each of them is first bound to an adapter molecule, transfer RNA, and aligned by the interaction between the anticodon of the tRNA and the codon of the mRNA. Aminoacyl-tRNA synthetases catalyze the covalent attachment of the a-**carboxyl group** of the amino acid to the 3′ terminus of the appropriate tRNA, to form aminoacyl tRNA. This reaction couples the hydrolysis of ATP to AMP to charge the amino acid with the chemical energy for peptide bond formation. The accuracy of the aminoacyl–tRNA synthetase is one of the determinant factors for the translational fidelity. The polymerization of amino acid proceeds from the *N*-terminus to the *C*-terminus. For each step in the reaction, the substrates are the elongating peptide and a new amino acid, both of which are attached to tRNAs. The actual polymerization is, therefore, transfer of the elongating peptide from one tRNA to the amino group of the new amino acid–tRNA complex, referred to as **peptidyl transfer**.

Translation is carried out on the intracellular particles called ribosomes (Fig. 1). Each ribosome consists of three distinct molecules of ribosomal RNAs and many proteins and is made up of two subunits, namely the large and small subunits (see Ribosomes). The ribosome has two major functions. It binds to mRNA and tRNAs, providing the sites of specific codon–anticodon interaction. It also catalyzes the peptidyl transfer. There are three tRNA-binding sites on the ribosome; two of them, called the A site and the P site, are directly involved in decoding of mRNA, while the remaining one, called the E site, is used as an exit site after the decoding and peptidyl transfer reaction. The P site of the ribosome accommodates the tRNA with the elongating peptide (peptidyl-tRNA), and the A site accepts the aminoacyl-tRNA that correctly base-pairs with the corresponding codon. Binding of the aminoacyl-tRNA is followed by peptidyl transfer. The catalytic center of the reaction is in the large subunit of the ribosome and likely to be a **ribozyme** encoded by domain V of the large rRNA (see Peptidyl Transferase). The 3′ termini of the two tRNAs at the P- and A-sites come to face the catalytic center. The peptidyl transfer reaction leaves deacylated-tRNA at the P site and leaves the newly elongated peptidyl–tRNA at the A site. The ribosome then proceeds toward the 3′ end of the mRNA by 3 nucleotides. This translocation is concomitant with the simultaneous shifts of the peptidyl-tRNA from the A site to the P site and of the deacylated-tRNA from the P site to the E site (see Translocation). On binding of a new aminoacyl-tRNA to the A site, the deacylated-tRNA dissociates from the E site of the ribosome.

Figure 1. Schematic representation of protein synthesis on the ribosome.



The translation process is divided into three steps, namely initiation, elongation, and termination. Initiation not only refers to decoding of the initiation codon (which is normally the AUG codon of mRNA), but also includes all the processes prerequisite for the first peptide bond formation. It is more diverse between prokaryotes and eukaryotes than the other two steps. The small subunit of the ribosome is bound to mRNA with the assistance of protein factors named initiation factors. In bacteria, binding occurs near the initiation codon through interaction between the small subunit (16 S) rRNA and a specific short sequence of mRNA, the Shine–Dalgarno sequence. For most of the eukaryotic mRNAs, however, the initial binding site of the translational apparatus is the Cap structure of the 5′ terminus of mRNA (see Cap), and the whole 5′-untranslated region is scanned by the small subunit (see Scanning Hypothesis). In both cases, the small subunit is associated with the large subunit at the initiation codon (see Initiation Complex). The tRNA that decodes the initiation codon is not used for elongation. Bacterial initiator tRNA is $tRNA^{f}$ bound to *N*-formyl methionine, and eukaryotic initiator tRNA is referred as $tRNA^{iMet}$ (see fMET (N-Formyl Methionine)). The *N*-formyl groups of mature bacterial peptides, as well as the *N*-terminal methionine residues of many bacterial and eukaryotic peptides, are removed co-translationally. Initiation of protein synthesis constitutes a rate-limiting step in translation and hence provides a main target of regulation in many genes of prokaryotes and eukaryotes (see Initiation Complex).

Elongation is a reaction cycle that repeats the three processes for each amino acid: (i) decoding of aminoacyl-tRNA at the A site of ribosome, (ii) peptidyl transfer, and (iii) translocation of the ribosome. Two indispensable GTP-binding proteins, called elongation factors, are involved in these processes. Only the aminoacyl-tRNA associated with EF-Tu (in bacteria) or EF-1a (in eukaryotes) and with GTP, in a ternary complex, can bind to the A site of the ribosome. When aminoacyl-tRNA correctly base-pairs with the codon, hydrolysis of GTP to GDP occurs, and the GDP form of EF-Tu and EF-1a dissociates the ribosome, leaving the aminoacyl-tRNA at the A site for the subsequent peptidyl transfer reaction. After peptidyl transfer, the GTP form of EF-G (for bacteria) or EF-2 (for eukaryotes) then binds to the ribosome and translocates the peptidyl-tRNA from the A site to the P site, making the A site vacant for the next round of protein elongation. Apparently, hydrolysis of GTP to GDP serves as an energy source for translocation. Mutually exclusive binding of EF-Tu (EF-1a) and EF-G (EF-2) ensures orderliness of the elongation cycle. Recycling of the GDP forms of EF-Tu and EF-1a are catalyzed by the GDP-GTP exchange factors, EF-Ts (in bacteria) and EF-1b EF-1g (in eukaryotes). They are also classified as elongation factors.

Termination of protein synthesis takes place on the ribosome in response to a stop, rather than a sense, codon in the “decoding” site. Translation termination requires two classes of polypeptide release factors: (i) a class I factor, codon-specific release factors (RF-1 and RF-2 in prokaryotes; eRF-1 in eukaryotes), and (ii) a class II factor, nonspecific release factors (RF-3 in prokaryotes; eRF-3 in eukaryotes), that binds guanine nucleotides (see Release Factor). Release factors seem to mimic tRNA and recognize directly the stop codon. When release factors correctly recognize the stop codon on the ribosome, the ribosomal peptidyl transferase center (domain V of the large rRNA) changes the catalytic mode and hydrolyzes the peptidyl-tRNA, releasing the polypeptide chain. After polypeptide release, the final dissociation of the termination complex takes place by the action of the ribosome-recycling factor (called RRF in bacteria) (see Termination Factor), allowing reuse of the ribosome, release factors, and tRNAs for the next round of protein synthesis.

Translation can be studied *in vitro*. Supernatants of low-speed centrifugation of cell lysates show translation activity dependent on exogenously added mRNAs and upon energy supplementation. Products from endogenous mRNAs can be reduced by a ribonuclease treatment. Widely used *in vitro* translation system are rabbit reticulocyte lysates, wheat germ extracts, and the S30 fraction of *Escherichia coli* extracts. Individual steps of translation may be examined in a reconstitution system with purified ribosomes and other components.

Translation Repressors

Translation of messenger RNA into protein represents an important regulatory step in **gene** expression. **Protein biosynthesis** involves three distinct stages: initiation, elongation, and termination. In eukaryotes, formation of the mRNA–ribosome initiation complex represents the most critical step for control of translation (1). The translation machinery is responsive to a wide range of intracellular and extracellular signals. For example, under certain conditions, such as **virus infection** or **heat shock**, there is preferential translation of viral and heat-shock mRNAs, respectively, while translation of most **5′-capped**, cellular mRNAs is inhibited (2, 3). Maternal mRNA during early development, and certain newly synthesized mRNA transcripts in somatic cells, are transported to the cytoplasm, where they are sequestered from the translational machinery and remain untranslated until the encoded proteins are needed (4).

Translation repressors encompass both cis-acting mRNA regulatory sequences and trans-acting protein factors. The best characterized repressors act at the level of translation initiation and fall into four classes: (*1*) repressor molecules that target the eukaryotic initiation factors (eIFs) required to assemble mRNA–ribosome initiation complexes, (*2*) specific ribonucleotide sequences and structural motifs within the mRNA template that interfere with the translational machinery, (*3*) specific and nonspecific mRNA-binding proteins, and (*4*) complementary RNAs that inhibit translation through the formation of heteroduplexes with the mRNA template.

1. Inhibition of Translation Initiation Factors

Translation is dependent on the productive association of mRNA with ribosomes. Recruitment of the 40 S ribosomal subunit to mRNA requires ATP and involves the participation of several translation initiation factors (1). Functional inactivation of these initiation factors disrupts this process. This can occur by a variety of mechanisms, including **phosphorylation**, interaction with inhibitory polypeptides, and **proteolytic** cleavage.

eIF-2 participates in the formation of the ternary complex involving the initiator methionine transfer RNA and GTP. eIF2 is required for the delivery of the ternary complex eIF2:tRNA(Met)i:GTP to the 40 S ribosome subunit before mRNA is bound. eIF-2 contains three subunits. Phosphorylation of the a-subunit of eIF-2 blocks the exchange of GDP for GTP required for the catalytic utilization of eIF2. Three protein kinases, hemin-regulated initiation factor-2 kinase (HRI), double-stranded RNA-dependent kinase (PKR), and yeast protein kinase GCN2, specifically phosphorylate eIF-2a under certain physiological conditions (5-7). Viral infection induces PKR autophosphorylation and kinase

activation, which lead to phosphorylation of eIF-2a and subsequent repression of host cell protein synthesis (8). On heat shock, eIF-2a is initially phosphorylated by HRI, resulting in a general inhibition of protein synthesis and preferential translation of heat-shock protein mRNAs. During heat shock recovery, the level of eIF-2a phosphorylation decreases as cellular protein synthesis is restored (3). In yeast, GCN2 phosphorylates eIF-2a in response to amino acid starvation, resulting in a decrease in the synthesis of total cellular proteins, but a specific increase in the translation of GCN4 mRNA (9).

eIF-4E and eIF-4G are important components of the eIF-4F complex. eIF-4E binds directly to the 5′ cap and plays a critical role in the formation of 48 S mRNA–ribosome preinitiation complex. eIF-4E is present in the cell in limiting amounts relative to other initiation factors. The phosphorylation state of eIF-4E correlates well with the rate of translation in the cell, and overexpression of eIF-4E has been shown to affect cell growth (10). A family of inhibitory proteins have been shown to inhibit translation by interacting with eIF-4E to prevent assembly of the eIF-4F complex. These proteins are called eIF-4E-binding proteins (4E-BPs) (11). The activity of 4E-BPs are also regulated by phosphorylation. Viral infection induces the dephosphorylation of 4E-BPs, resulting in the enhanced association of 4E-BPs with eIF-4E and inhibition of host mRNA translation. In contrast, exposure to growth factors promotes phosphorylation of 4E-BPs, resulting in dissociation from eIF-4E and translational activation (11).

Following poliovirus infection, eIF-4G is proteolytically cleaved by the virus-encoded proteinase $2A^{pro}$. As a result, translation of most capped cellular mRNA is inhibited, while translation of uncapped viral mRNAs is stimulated (12).

2. *Cis*-Acting Regulatory RNA Sequences

Most eukaryotic mRNAs are composed of a 5′ cap, a 5′-untranslated region (5′-UTR), a central amino acid coding region, and a 3′ untranslated region (3′-UTR), followed by a **poly(A)** tail. Translational initiation of most capped mRNAs follows the scanning hypothesis that was originally proposed by Kozak and Shatkin (13). In this model, the translation initiation complex forms at or near the 5′ cap and scans the mRNA toward the 3′ end in search of the first initiation codon that is situated within an appropriate sequence context. The efficiency of translation varies markedly for different mRNAs and is influenced in large part by specific sequences and structural motifs in the mRNA. The presence of upstream translation initiation codons and associated open reading frames (uORFs) in the 5′-UTR, plus specific sequences and secondary structures in the two untranslated regions, have been shown to repress translation of the protein coding region.

The inhibitory effect of uORFs can be explained by the inability of ribosomes to reinitiate translation at the downstream initiator AUG after completion of translation of the uORF (1, 13). The suppressive effect of uORFs can be overcome by several mechanisms, including the removal of upstream AUG codons by alternative splicing or through the use of alternative **promoters** to initiate transcription. An uORF can be bypassed either through a “leaky scanning” mechanism (13), or through the use of an internal ribosome entry site to initiate translation (14). In addition, under certain conditions, ribosomes may acquire competence to bind to the ternary complex to reinitiate translation after having completed translation of the uORF (9).

During cap-dependent translation initiation, the formation of the 48 S preinitiation complex near the 5′-cap structure and the subsequent ribosome scanning process can be inhibited by the presence of mRNA secondary structures in the 5′-untranslated regions. The effect of an mRNA 5′-UTR secondary structure on the rate of translational initiation is determined by both the stability and the position of the secondary structure (15, 16). Secondary structures located close to the 5′ end of the mRNA may prevent assembly of the preinitiation complex; when distant from the cap, a stem-loop structure with moderate stability may be easily unwound by the scanning 40 S ribosomal subunit and its associated initiation factors. For example, a hairpin structure with a stability of –30kcal/mol

located 12 nucleotides downstream of the 5′ cap completely inhibits the translation of preproinsulin mRNA, but has no effect on translation when it is located 52 nucleotides downstream of the cap structure (16).

3. RNA-Binding Proteins

RNA-binding proteins can be recruited to specific sites or to secondary structures on the mRNA to repress translation. The activity and/or expression of these RNA-binding proteins may determine the translational efficiency of specific mRNAs. The iron-response element (IRE) located at the cap-proximal regions of ferritin mRNA contains a 35-nucleotide sequence that folds into a specific stem-loop structure. The IRE is recognized by a repressor protein, IRE-BP. Under iron-starvation conditions, the IRE-BP binds to the IRE with high affinity, blocking recruitment of the 40 S ribosome subunit to ferritin mRNA and preventing its translation. As iron levels increase, IRE-BP dissociates from the IRE, and the translation repression of ferritin mRNA is relieved. The inhibitory effect of IRE-BP on ferritin mRNA translation is also position-dependent, requiring that the IRE be located within 40 nucleotides of the 5′ cap (17). This suggests that formation of the cap-proximal IRE:IRE-BP complex may disrupt the interaction between the cap structure and the 40 S ribosome subunit.

In recent years, a growing number of *cis*-acting sequence elements have been identified in the 3′ UTRs of mRNAs from various species. These 3′-UTR regulatory sequences have been shown to influence mRNA translation, stability, and localization (4, 18). In general, the 3′ *cis*-acting regulatory elements involved in translational regulation interact with specific binding proteins to repress translation. One intriguing proposition is that RNA-binding proteins acting on the 3′ end of mRNA disrupt the association between the 3′ and 5′ ends of mRNA that normally facilitate translation initiation.

During mouse spermatogenesis, protamine mRNAs are stored in the cytoplasm for 7 days prior to translation. A conserved sequence in the 3′-UTR of protamine mRNA is responsible for the appropriate temporal control of translation. The inhibitory function of this conserved sequence element is dependent on binding to an 18-kDa protein; translation is facilitated on dissociation of the factor (19). Erythroid 15-lipoxygenase (LOX) is a key enzyme during erythroid cell differentiation and is required for the breakdown of internal membranes during the late stages of erythrocyte maturation. LOX mRNA is synthesized in bone marrow erythroid precursor cells, but is not translated until the final steps of reticulocyte maturation. The 3′-UTR of LOX mRNA contains a 10-fold repeat of a CU-rich 19 nucleotide sequence that has been shown to mediate translational repression. Two proteins, hnRNP E1 and hnRNP K, bind to the CU-rich motif and mediate repression by disrupting the association of ribosomes with LOX mRNA (20).

Y-box proteins are transcription factors that bind specifically to Y-box sequences on DNA. In addition, these proteins are components of RNPs that bind non-specifically to stored mRNA molecules in germline cells. Binding of Y-box proteins to mRNA sequences, both *in vitro* and *in vivo*, has been shown to repress translation (21, 22).

4. Complementary Antisense RNAs

Small, stable RNA species have been shown to repress translation by pairing with specific sequences on target mRNA molecules. One of the best characterized examples occurs during early development in *Caenorhabditis elegans*, where the small, noncoding *lin-4* RNA binds to a complementary and repeated sequence element present in the 3′-UTR of *lin-14* mRNA. *lin-14* gene mutations, in which the complementary sequences in the 3′-UTR are partially or completely deleted, result in inappropriately high levels of LIN-14 protein expression at late stages of development. It is believed that *lin-4* regulates *lin-14* translation via an **antisense** RNA–RNA interaction (23). Alternatively, a repressor protein may bind to the bulged cytosine residue in the RNA/RNA hybrid structure and

block translation (24).

Translational Editing

The genetic code is an algorithm that relates 20 specific amino acids used in protein synthesis to individual trinucleotide sequences, the **codons** . Because of degeneracy in the code, there are 61 triplet codons for the 20 amino acids. The relationship between these 20 amino acids and the 61 triplets is established in the aminoacylation reactions catalyzed by aminoacyl tRNA synthetases. In these reactions, an amino acid is covalently attached to the 3′ end of the transfer RNA (tRNA) that contains the anticodon triplet that is **cognate** to that amino acid.

Once an amino acid is attached to a tRNA, the position of the amino acid in a growing polypeptide chain is determined by the interaction between the anticodon of the tRNA and the matching, complementary codon of mRNA. This conclusion followed from early experiments that showed that, when alanine was attached to a cysteinyl-tRNA ($tRNA^{Cys}$), alanine was incorporated into positions in a growing polypeptide that normally were occupied by cysteine (1) (this experiment, by Lipmann, Benzer, and co-workers, was done by reaction of Raney nickel with Cys-$tRNA^{Cys}$, which converted Cys to Ala *in situ*). The conclusion from these experiments has since been confirmed by other means (2).

Errors in protein synthesis are relatively rare, having a frequency of perhaps 10^{-4} *in vivo* (3-5). They would be much higher, except for translational editing mechanisms that specifically correct particular errors that occur at a much higher frequency. These errors occur because of limitations to molecular recognition at two critical points in translation. First, certain amino acids are difficult for synthetases to discriminate from each other and, for that reason, can be misactivated and potentially attached to the tRNA cognate to the synthetase but noncognate to the amino acid. Second, the anticodon–codon interaction on the ribosome is determined by base pairing between the complementary triplets, and this interaction is prone to mistakes because, for example, pairing of two rather than three bases, although less probable, is still possible.

In the case of misactivation of amino acids by synthetases, the energy cost for proofreading is in the form of extra hydrolysis of ATP. For the ribosome-dependent system, the cost of proofreading is in an additional hydrolysis of GTP. Errors also occur in DNA replication, and here, as in translation, nucleoside triphosphate hydrolysis is required to correct errors of replication. The general requirement for triphosphate hydrolysis in error-correcting mechanisms was recognized early by Hopfield (6) and Nino (7).

Translational editing by tRNA synthetases requires the presence of the cognate tRNA. This system of proofreading is an example of RNA-dependent amino acid recognition (8). The tRNA synthetases were perhaps among the first proteins to emerge from an RNA world in connection with the development of the genetic code. Possibly, the present-day RNA-dependent recognition of amino acids in translational editing developed out of an early system in which RNA played a more prominent role in aminoacylation activity in general.

1. RNA-Dependent Amino Acid Discrimination in Translational Editing

1.1. Misactivation of Amino Acids

Most tRNA synthetases can activate amino acids in the absence or presence of tRNA. The activated amino acid then reacts with the 3′ end of the tRNA cognate to the amino acid:

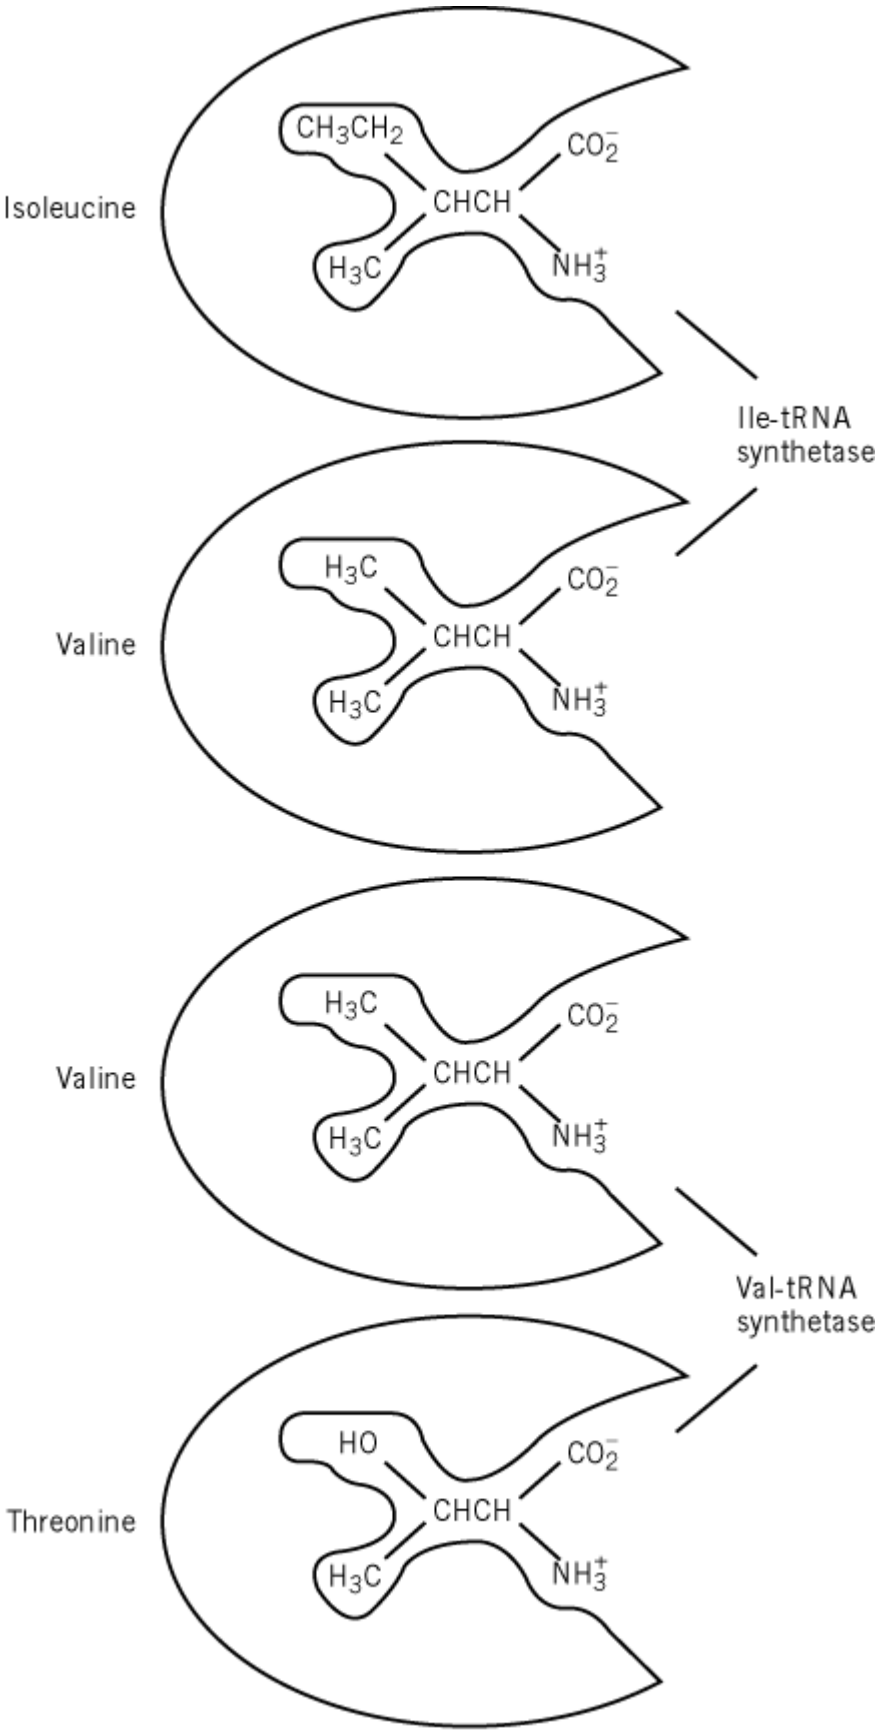
$$\mathrm{E} + \mathrm{AA} + \mathrm{ATP} \leftrightarrow \mathrm{E(AA\text{-}AMP)} + \mathrm{PP_i} \qquad (1)$$

$$\mathrm{E(AA\text{-}AMP) + tRNA \leftrightarrow AA\text{-}tRNA + AMP + E} \quad (2)$$

In reaction (1), E, AA, AA-AMP, and PP_i denote enzyme, amino acid, aminoacyladenylate, and inorganic pyrophosphate, respectively. In reaction (2), AA-tRNA represents aminoacyl-tRNA. The first step is referred to as amino acid activation , while the second step is a transfer reaction where the aminoacyl moiety is transferred from the adenylate to the 3′ end of the tRNA (see Aminoacyl tRNA Synthetases). In general, the transfer reaction is the rate-determining step in aminoacylation.

Potential errors of aminoacylation occur because of inherent difficulties in molecular recognition associated with step 1 (5, 9, 10). In particular, Pauling pointed out that closely similar amino acids such as valine and isoleucine, which are both branched at the b-carbon and differ by one methylene group, are difficult for isoleucyl-tRNA synthetase to discriminate on the basis of binding interactions alone (11) (Fig. 1). For example, a pocket that can accommodate the isobutyl side chain of isoleucine should also be able to accommodate the isopropyl group of valine. The loss of van der Waals interactions associated with the missing methylene group of valine should be calculable from measurements of the transfer of a methylene group from a hydrophobic solvent to water (see Hydrophobicity). Similarly, valyl-tRNA synthetase is confronted with distinguishing between valine and the nearly isosteric threonine. These expectations are fulfilled, because valine is misactivated by isoleucyl-tRNA synthetase and threonine is misactivated by valyl-tRNA synthetase.

Figure 1. Schematic illustration of the binding of isoleucine and valine to IleRS and of valine and threonine to ValRS. The isopropyl side chain of valine can fit easily into the pocket in IleRS that binds the isobutyl side chain of isoleucine. In the case of threonine and valine, the side chains are also isosteric, thus making it possible for threonine to fit into the pocket in ValRS for valine. (Adapted from Ref. 9.)



1.2. Translational Editing as an ATPase Activity

The overall translational editing activity was discovered with the isoleucine system (12). Valine was

observed to be misactivated by isoleucyl-tRNA synthetase (IleRS). When challenged with $tRNA^{Ile}$, the misactivated adenylate was hydrolyzed to AMP and valine in the overall reactions:

$$\text{IleRS} + \text{valine} + \text{ATP} \leftrightarrow \text{IleRS(Val-AMP)} + \text{PP}_i \quad (3)$$

$$\text{IleRS(Val- AMP)} + \text{tRNA}^{\text{Ile}} \rightarrow \text{IleRS} + \text{valine} + \text{AMP} + \text{tRNA}^{\text{Ile}} \quad (4)$$

The sum of reactions (3) and (4) is simple ATP hydrolysis:

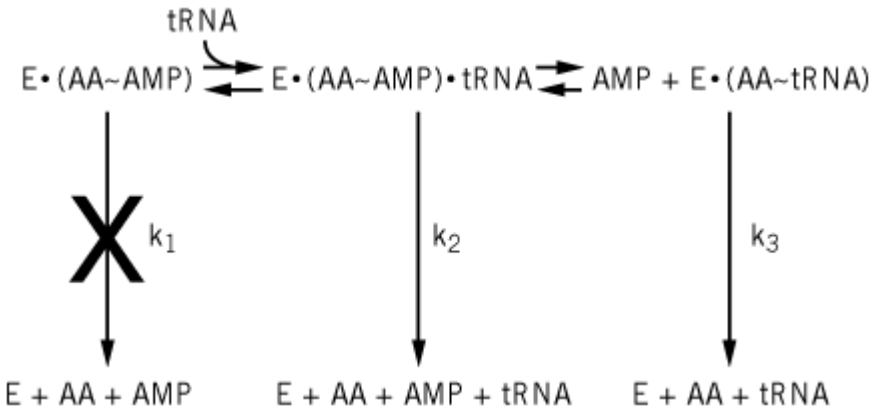
$$\text{ATP} \rightarrow \text{AMP} + \text{PP}_i \quad (5)$$

Thus, translational editing can be measured as a $tRNA^{Ile}$-dependent ATPase activity of IleRS, where the enzyme discriminates between isoleucine and valine in a reaction that depends on $tRNA^{Ile}$.

1.3. Two Steps to Translational Editing by tRNA Synthetases

When the ATPase activity associated with RNA-dependent amino acid discrimination was discovered, no details of the mechanism were understood. Now it is known that, when valine is misactivated by isoleucyl-tRNA synthetase, the misactivated amino acid can, in principle, be attached in step 2 to $tRNA^{Ile}$ to yield Val-$tRNA^{Ile}$. The species Thr-$tRNA^{Val}$ can similarly be generated when threonine is misactivated by valyl-tRNA synthetase. At this point, three potential reactions can occur (Fig. 2). First, the misactivated amino acid can be spontaneously hydrolyzed while bound to the enzyme (k_1 step). This reaction is inconsequential because, in the absence of added tRNA, even the misactivated amino acid is stably bound to the enzyme. Second, the misactivated species can be "induced" to hydrolyze in the presence of the tRNA (k_2 step), or it can be transferred onto the tRNA to give a mischarged species. This mischarged amino acid is subsequently hydrolyzed from the tRNA by the action of an esterase activity of the synthetase that is directed toward the mischarged tRNA (k_3 step) (13-15).

Figure 2. Schematic of editing pathways. In this illustration, a misactivated aminoacyl adenylate (AA-AMP) is stably bound to a tRNA synthetase enzyme, E. No hydrolysis to AA + AMP occurs (k_1 step) in the absence of tRNA. Addition of tRNA causes breakdown of the adenylate by one of two steps. In the k_2 step, the adenylate is hydrolyzed before the amino acid is transferred to the tRNA (pretransfer editing). In the k_3 step, the mischarged aminoacyl tRNA species is formed and an esterase activity of the enzyme catalyzes removal of the misactivated amino acid from the tRNA.



The k_2 and k_3 steps represent tRNA-dependent amino acid discrimination in translational editing. They occur only when the mischarged amino acid is first bound and then activated to an adenylate that is located at the active site of the enzyme (9, 16) . In contrast, activation of the correct amino acid leads to stable attachment of the amino acid to its cognate tRNA. Thus, in the context of its tRNA, a synthetase can distinguish two closely similar amino acids through these hydrolytic editing reactions.

1.4. Elucidation of the Two Steps in RNA-Dependent Amino Acid Discrimination

The k_3 step of translational editing was demonstrated directly. The mischarged Val-tRNA^{Ile} was generated by a special procedure. When IleRS was added, an esterase activity of the enzyme removed valine from tRNA^{Ile}:

$$\text{IleRS} + \text{Val-tRNA}^{\text{Ile}} \rightarrow \text{IleRS} + \text{valine} + \text{tRNA}^{\text{Ile}} \quad (6)$$

This esterase activity was first seen as a weak activity that synthetases had toward their cognate, properly charged, aminoacyl tRNA, such as Ile-tRNA^{Ile} (13). This activity was then observed to be greatly enhanced when the mischarged species was presented to the enzyme (14).

The k_2 step indicates that the misactivated adenylate is hydrolytically removed before transfer to the tRNA. This step was first inferred from kinetic studies that were able to distinguish two steps to the overall editing reaction, one of which occurred before transfer of the aminoacyl group to tRNA (9). Thus, the k_2 and k_3 steps can be referred to as pretransfer and posttransfer editing reactions, respectively. In the pretransfer reaction, the tRNA is imagined to act as an effector and not as an amino acid–accepting substrate.

1.5. DNA-Aptamer-Induced Translational Editing

If the amino acid acceptor function of tRNA^{Ile} were still necessary for the k_2 step, then that step might be thought of as closely related or similar to the k_3 step, where a mischarged species is deacylated. For example, the acceptor hydroxyl groups of the tRNA itself might participate in the hydrolytic reaction. Independent demonstration of the pretransfer step was accomplished by searching for a surrogate effector that was incapable of accepting an amino acid. A DNA **aptamer** was selected from a pool of more than 10^{14} molecules. DNA lacks a 2′-OH, which is the initial site of amino acid attachment by the isoleucine enzyme (17). The selected aptamer replaces tRNA^{Ile} in reaction (4), inducing the hydrolysis of Val-AMP bound to IleRS. In contrast, the aptamer had no effect on the stability of Ile-AMP bound to the isoleucine enzyme. As expected, the aptamer was not an acceptor for isoleucine. These data show that a constellation of nucleotides per se can act as a surrogate effector for RNA-induced translational editing, without requirement for amino acid acceptance activity. They provide strong support for the existence of the k_2 step of translational editing.

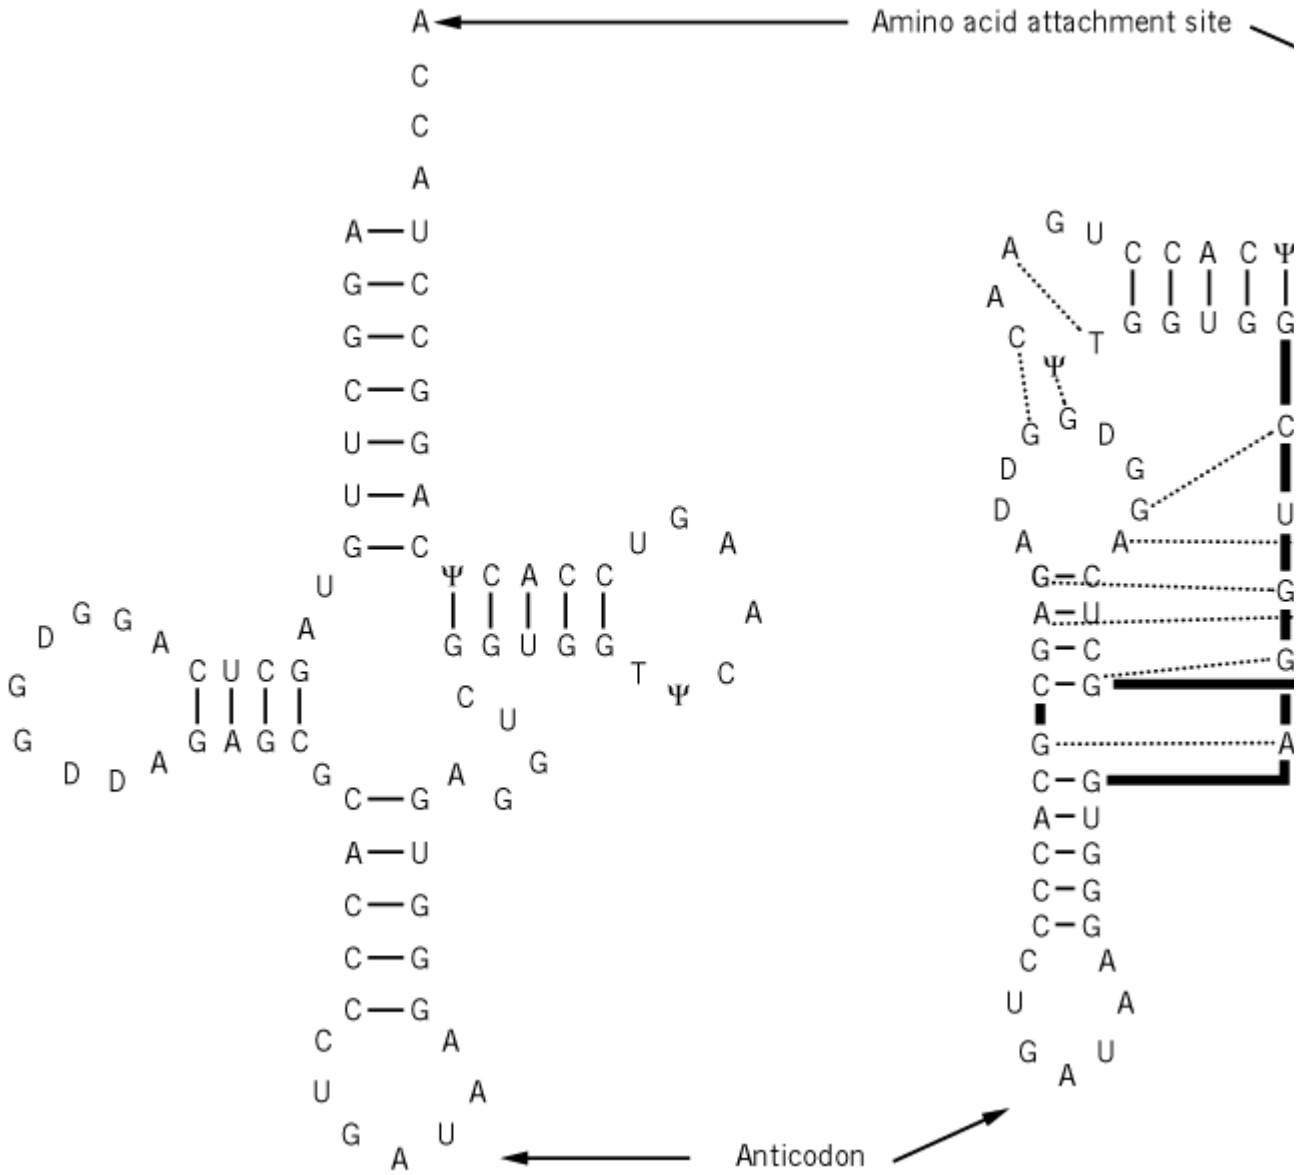
1.6. tRNA Nucleotides for Translational Editing Are Distinct from Those for Aminoacylation

The idea that a constellation of nucleotides per se can elicit the ATPase activity (Eqs. 3-5) motivated experiments to identify the location of those nucleotides in a tRNA. Actually, tRNA^{Val} does not substitute for tRNA^{Ile} as the effector in equation (4); that is, addition of tRNA^{Val} to IleRS(Val-AMP) results in no hydrolytic breakdown of Val-AMP. Thus, some of the nucleotides that distinguish tRNA^{Ile} from tRNA^{Val} must account for the difference in translational editing activity. Because nucleotide differences also must explain why one is charged with isoleucine and the other is not, the possibility that nucleotides needed for charging are also needed for editing has to be considered.

Nucleotides needed for aminoacylation of tRNA are typically located within the acceptor stems and, in many instances, within the anticodon trinucleotides as well (see Aminoacyl tRNA Synthetases). Transplantation of the GAU anticodon of $tRNA^{Ile}$ into $tRNA^{Val}$ converts the latter to an isoleucine acceptor that is designated as $tRNA^{Val/GAU}$. Isoleucine acceptance is further enhanced if the acceptor stem of $tRNA^{Ile}$ is introduced into $tRNA^{Val/GAU}$. Yet neither of these "chimerized" valine tRNAs is active in stimulating the ATPase activity that is characteristic of the editing reactions (eqs. 3-5) (18). These results showed that nucleotides sufficient for charging a tRNA do not in themselves confer editing.

Instead, nucleotides at the corner of the L-shaped tRNA molecule trigger the editing response (Fig. 3). The editing function of $tRNA^{Ile}$ or of $tRNA^{Val/GAU}$ can be turned off or on by simple manipulation of just three nucleotides. These nucleotides are part of a highly differentiated region of the molecule where two loops of the tRNA cloverleaf are brought together. When the three-dimensional structure of tRNA was first determined, this highly differentiated corner was suggested to be a potential protein discrimination site (19). Possibly it is a discrimination site used for triggering the editing response. Additionally or alternatively, this part of the molecule may be involved in transducing a signal between the two domains of the tRNA structure. This signal would be part of a system to ensure that the trinucleotide anticodon and the attached amino acid were matched according to the rules of the genetic code.

Figure 3. Nucleotides in a tRNA that trigger the editing response. The L shape of the tRNA structure is depicted. Nuclec tertiary interactions are joined by dotted lines. The nucleotides that are needed for the editing response are shown in bold



1.7. Editing Site on a Synthetase Is Distinct from That for Aminoacylation

The editing activity is directed toward an adenylate and an aminoacyl-tRNA, species that are also fo cognate amino acid. Early work suggested, however, that the editing activity occurred at a site that w the active site (13). To address the question of whether the two sites can be separated, mutational ana directed mutagenesis of IleRS found several mutations that severely reduced the catalytic activity by cognate amino acid by more than two orders of magnitude. One mutation was obtained that eliminat valine and isoleucine in the initial amino acid activation step (20) (Eq. 1). In contrast, when challeng enzyme efficiently discriminated against misactivated Val-AMP in the hydrolytic editing reaction (E was mutationally isolated from the active site.

In another set of experiments, mutations were made in ValRS that severely affected amino acid activ for valine. In an analysis of aminoacylation error correction, the deacylation activity of two of the mu Thr-tRNA^{Val}) was studied. In each instance, this activity was unaffected by the mutations (21). This of a design for at least some tRNA synthetases that separates the catalytic site for aminoacylation fro acid discrimination.

1.8. Cloned Insertions from Two tRNA Synthetases Destroy Errors of Aminoacylation
Isoleucyl- and valyl-tRNA synthetases are examples of class I enzymes. These enzymes have a core

constructed from alternating b-strands and a-helices in an alternating b–a–b pattern (see Aminoacyl t

2. RNA-Independent Amino Acid Recognition in Translational Editing

Methionyl-tRNA synthetase is a special example that uses a tRNA-independent pathway to reject the
homocysteine (5). This amino acid is generated by transfer of the active methyl group from *S*-**adenos**
acceptor to give *S*-adenosylhomocysteine, followed by hydrolysis of *S*-adenosylhomocysteine to ade

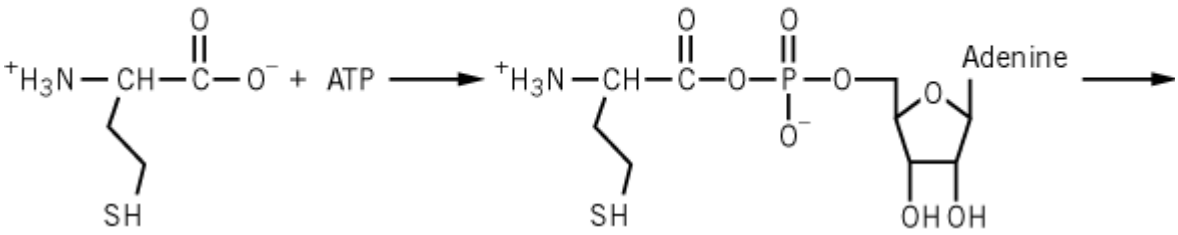
The activated homocysteinyl adenylate is subsequently converted to the thiolactone and re consequence, homocysteine is not attached to methionyl tRNA and is not incorporated into proteins.



3. Translational Editing on the Ribosome

Aminoacylated tRNA binds to the A site on the ribosome; specificity is determined by the codon–an Translation). The specificity of the codon-anticodon interaction is enhanced by an editing mechanisr GTP to GDP and P_i. The source of the GTP in this hydrolytic reaction is that which is bound to elon member of the G-factor superfamily, EF-Tu has two form—one that is "active" (GTP-bound) and an bound). The active form binds aminoacyl-tRNA while the inactive form does not.

After aminoacylation, the charged tRNA is bound to the GTP complex of EF-Tu and carried to the ri bound to the A site. With a perfect codon–anticodon match, the GTP is hydrolyzed and the aminoacy to the A site, where the aminoacyl moiety can react with the peptide group of the peptidyl tRNA in t anticodon match, some data showed that two molecules of GTP are hydrolyzed per aminoacyl tRNA interaction is imperfect (eg, two base pairs rather than three are complementary), then the imperfectl rejected from the A site in a reaction that also results in hydrolysis of the GTP that is bound to EF-Tu mismatched aminoacyl tRNA is also released from EF-Tu (as an EF-Tu-GDP complex). Thus, in orc aminoacyl-tRNA to bind again at the A site, it must rebind to a new molecule of EF-Tu-GTP and rep consequence, an abortive cycle is established in which GTP hydrolysis accompanies the successive h mismatched aminoacyl-tRNA.

4. Conclusions

The translational editing reactions described above share in common the use of nucleoside triphosph prevent errors in protein synthesis. In both the RNA-dependent amino acid discrimination by tRNA s for codon–anticodon fidelity on the ribosome, RNA plays a critical role as an effector in the editing r effector function is not clear, but the tRNA synthetase system shows clearly that specific nucleotides nucleotides (at the corner of the L-shaped structure) actually affect the editing response is not known system, the slight difference, for example, in a perfect three-out-of-three match *versus* an imperfect t Whether specific nucleotides (other than the anticodon triplet) in a particular part of the tRNA struct response is also a question that requires more investigation. These RNA-dependent events may have of life forms, when RNA may have had even more roles in protein synthesis than it does in contemp

Translocation

Translation of a messenger RNA during protein biosynthesis requires a coupled movement of mRNA and transfer RNAs throughout the elongation stage. Each new amino acid is recruited to the ribosome as an aminoacyl-tRNA:EF-Tu:GTP ternary complex. Elongation factor EF-G catalyzes a precise movement of the tRNA–mRNA complex within the ribosome after **peptidyl transfer** to empty the A site for the next aminoacyl–tRNA (see Elongation Factors (EFs)). During each translocation step, the elbow of tRNA moves on the order of 50 Å. Although the elongation cycle under physiological conditions requires the two G proteins EF-Tu and EF-G, it has been shown that polypeptide synthesis can be carried out by the ribosome itself, in the absence of factors or GTP under certain *in vitro* conditions [such as poly(U)-dependent polyphenylalanine synthesis]. Thus, the ability to move mRNA and tRNA is an inherent property of the ribosome; the factors serve to increase the speed and accuracy of elongation in a GTP-dependent manner.

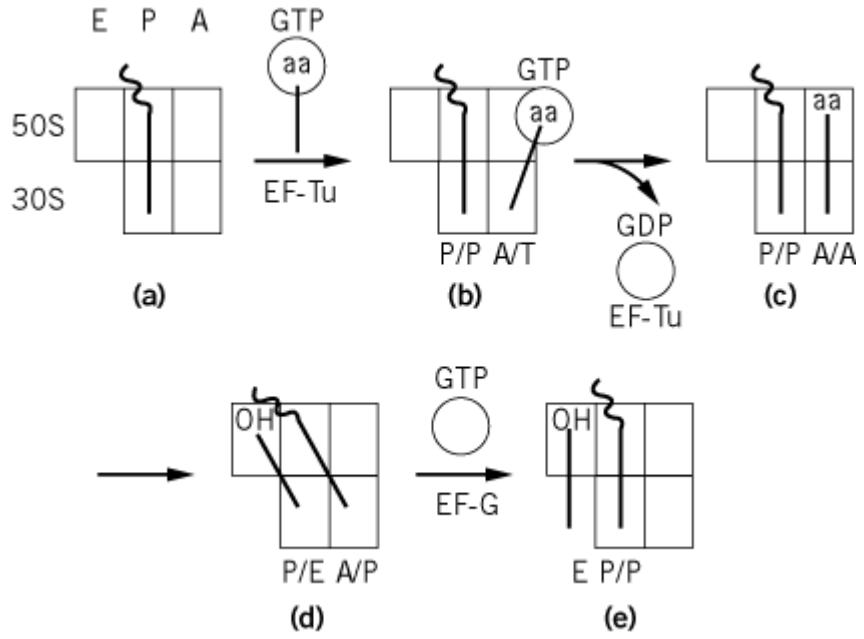
Eukaryotic and prokaryotic ribosomes are composed of one large subunit and one small subunit that fit together to form a complete ribosome with mass of several millions daltons (see Ribosomes). The small subunit matches the tRNA to the **codons** of the mRNA, while the large subunit catalyzes formation of the peptide bonds that link the amino acids together into a polypeptide chain. The

ribosome contains more then 50 different proteins and three rRNA molecules, provides specific binding sites for mRNA, tRNA, and the various initiation, elongation, and termination factors, and catalyzes peptide bond formation. The ribosome also stabilizes codon–anticodon interactions and preserves the reading frame.

How does the ribosome choreograph the movements required for translation? There are two major tRNA-binding sites on the ribosome: one incoming site, called the A site for aminoacyl–tRNA, and the P site for peptidyl-tRNA, where new peptide bonds are formed. A third site, the E site, is transiently occupied by the deacylated end of the tRNA that has completed amino acid transfer and is about to be ejected. According to the three-site version of the classical model, beginning with an initiator or peptidyl-tRNA in the P site, a new aminoacyl tRNA, with an anticodon complementary to the mRNA codon positioned at the A site, is introduced as an aminoacyl-tRNA:EF-Tu:GTP ternary complex. Upon correct binding of the aminoacyl-tRNA, GTP is hydrolyzed, and the GDP form of EF-Tu is released from the ribosome, along with inorganic phosphate. The anticodon ends of both tRNAs interact with the small 30 S subunit, and their acceptor ends interact with the large 50 S subunit. The ribosome is now ready for formation of the next peptide bond. This step is catalyzed by the peptidyl transferase activity of the large ribosomal subunit, and the growing peptide chain carried by the tRNA at the P site links to the amino acid carried by the tRNA at the A site. Movement of the newly created peptidyl-tRNA from the A to the P site is accomplished by EF-G in a GTP-dependent reaction. At the same time, the deacylated tRNA moves to the E site. The E site is most likely located on the 50 S subunit; this would mean that the elongation cycle is really a two-and-a-half-site, rather than a three-site, model. Deacylated tRNA, bound weakly to the E site, dissociates from the ribosome to complete the cycle of elongation.

Chemical footprinting studies in certain intermediate states of elongation showed that the two ends of a tRNA could be in different states on the two ribosomal subunits; for example, a tRNA could simultaneously occupy the 30 S A site and the 50 S P site. Interpretation of these experiments resulted in the hybrid states model for the elongation cycle (1, 2). According to this model, translocation of tRNAs on the ribosome occurs in two separable steps (Fig. 1). In the first step, the movement of the acceptor ends of tRNAs relative to the 50 S ribosomal subunit occurs spontaneously following peptide bond formation, independent of EF-G and GTP (Fig. 1). The peptidyl–tRNA is in the A/P state, in which its anticodon is in the 30 S A site, while its acceptor end is in the 50 S P site. The deacylated tRNA is in the P/E site, in which its anticodon is in the 30 S P site and its acceptor end in the 50 S E site. The second step, which is EF-G and GTP-dependent, results in translocation of the anticodon arms of the two tRNAs, together with their associated mRNA, relative to the 30 S subunit. The peptidyl-tRNA moves into the P/P state and deacylated tRNA into the E site (Fig. 1). Independent movement of tRNAs relative to the two ribosomal subunits suggests that tRNA translocation could involve relative movement of the subunits, providing an explanation for the universal two-subunit structure of ribosomes.

Figure 1. Hybrid states model for the translational elongation cycle (2). The tRNA binding sites on the 50 S and 30 S subunits are represented schematically by the upper and lower rectangles, respectively. The 50 S subunit is subdivided into A, P, and E sites; the 30 S subunit is subdivided into A and P sites. The tRNAs are represented by vertical bars, and the nascent polypeptide chain is represented by a wavy line; circles represent EF-Tu and EF-G, respectively. Binding states, indicated at the bottom of each panel, indicate the state of each tRNA relative to each ribosomal subunit; A/P indicates interaction of the anticodon end to a tRNA with the 30 S A site and its acceptor end to the 50 S P site.



The discovery of factor-independent translocation established that it is fundamentally a ribosomal mechanism. Equally significant is the finding that translocation can take place in the absence of mRNA. Under certain *in vitro* conditions, lysyl-tRNA can be polymerized by the ribosome into polylysine. Thus, the translocation machine acts directly on tRNA and the movement of mRNA is passive, driven by its association with tRNA.

Recent studies have provided evidence for further insight into the hybrid states model. First, initial binding of the EF-Tu ternary complex is rapid and reversible and does not involve codon recognition (3). This initial complex can form even if the A site is blocked with another aminoacyl-tRNA. A series of conformational changes follow the initial binding to lead to codon recognition and GTP hydrolysis. Upon dissociation of EF-Tu:GDP, the aminoacyl-tRNA enters the 50 S site, leading to peptide bond formation. Second, until recently, binding of EF-G:GTP to the ribosome was thought to induce translocation, followed by GTP hydrolysis and release of EF-G:GDP from the ribosome. However, recent pre-steady-state kinetic experiments show that GTP hydrolysis occurs before translocation and accelerates translocation more than 50-fold relative to that observed with nonhydrolyzable GTP analogues. It reevaluates the role of GTP hydrolysis in translocation, suggesting that a conformational transition in EF-G itself is coupled to translocation (4).

The structures of EF-G and its GDP-complex that have been solved by X-ray crystallography resemble the aminoacyl–tRNA:EF-Tu:GTP ternary complex (see Elongation Factors (EFs)). The tRNA anticodon stem mimicry by domains IV of EF-G is essential for its translocase activity to fit the A site of the ribosome. Superficially, EF-Tu and EF-G appear to be involved in translational steps that seem mechanistically unrelated; EF-G catalyzes translocation, while EF-Tu introduces aminoacyl-tRNA to the ribosome. Their fundamental mechanism, however, may be to catalyze the two very similar sets of rotational steps, which may themselves be innate properties of ribosomal mechanics.

Translocation, Chromosomal

Chromosomal translocations occur when segments of one chromosome are relocated to another. They result from chromosome breakage and fusion (Fig. 1). Three breaks in a single chromosome lead to an intrachromosomal translocation, in which the translocated segment might be inverted. Single breaks lead to other chromosomal changes (Fig. 1). Reciprocal translocations occur when two nonhomologous chromosomes exchange segments. Translocations of chromosomal segments to the end of the chromosome also occur. This type of terminal translocation might account for the existence of **telomeric** repeats within the chromosomal arms. Finally, Robertsonian events are an extreme form of translocation when two acrocentric chromosomes fuse to generate a **metacentric**.

Figure 1. Examples of chromosomal translocations. (**a**) Chromosomal translocation leading to the insertion (intercalation) of one chromosomal segment into a distinct position in the same chromosome. (**b**) Chromosomal translocation leading to the intercalation of one chromosomal segment into a non homologous chromosome. (**c**) Reciprocal chromosomal translocation between nonhomologous chromosomes. Two possible outcomes are shown: a balanced pair of chromosomes or a combination of a dicentric and acentric chromosome.

Transmembrane a-Helix

In most membrane proteins, the transmembrane regions are composed of **a-helices**. Each helix

typically consists of 20 to 30 consecutive **hydrophobic** amino acid residues, although single polar or potentially charged residues are occasionally inserted into the membrane-spanning sequence. Helical **secondary structure** is a natural way of embedding a polypeptide chain into lipid. Hydrogen bonding between the peptide groups is satisfied by the network that forms along the helical axis between residues that are close in the sequence.

Structural analysis of the photosynthetic reaction center (1) and the mitochondrial cytochrome *c* oxidase (2), which contain a total of 39 transmembrane a-helices, suggests the following general features of transmembrane helices:

1. The helices are about 40 Å long when they penetrate the bilayer as straight rods. In most cases, however, they are slightly tilted relative to the membrane normal.
2. The ends of the a-helices have polar residues.
3. The hydrophobic core of a helix spans about 20 Å and is composed of hydrophobic residues, such as phenylalanine, valine, leucine, methionine, and isoleucine.
4. Polar aromatic residues (tyrosine, tryptophan) are found on both sides of the core. Close to the hydrophobic core, aromatic residues are exposed to the lipid headgroup region, whereas the buried tyrosine and tryptophan residues are slightly further from the core.
5. The latter region is also populated by asparagine and glutamine residues that are either exposed to the surface or buried in the protein structure.
6. The occurrence of proline residues peaks around 25 Å from the core, just outside the ends of the helices. Proline and glycine residues are buried in the structure when they occur in the hydrophobic core.

Transposable Elements

Transposable elements are discrete pieces of DNA that can move between nonhomologous positions in the genome. Within a single cell, they may translocate between positions within a chromosome, between chromosomes, or between chromosomes and extrachromosomal DNAs such as plasmids. Such elements have been found in virtually every organism examined and can take a variety of forms. In some cases, they encode only functions to promote their own movement—that is, a recombinase called a transposase (or integrase, when the transposable element is a **virus** that integrates into the host genome) and special recombination sequences at the tips of the element that are the recombination substrates on which the transposase acts. In other cases, transposable elements additionally encode other information, such as antibiotic-resistance genes or viral genomes.

All transposable elements, whether they encode only transposase or also additional genes, have an "activity": Their movement to new insertion sites is very often accompanied by changes in host gene expression. If the element inserts into a **gene**, that gene is disrupted and usually inactivated; such

inactivation could, for example, lead to cell death if the gene product is essential. Alternatively, the expression of a host gene adjacent to the point of element insertion may come under the influence of the transposon, for example by element-embedded enhancers, thereby disrupting the usual host-specified expression pattern. Thus transposable elements can influence their host by altering genomic DNA upon insertion; that is, the translocation and insertion of transposable elements can cause mutations. Indeed, in some organisms they are the predominant form of spontaneous mutagenesis. Probably because of this potential for lethal mutagenesis of the host, transposition frequency is generally very low, often less than one translocation per thousands of cell divisions. One strategy for controlling transposition is to highly regulate and limit the expression of the transposase; indeed, in some elements, transposase expression is limited at virtually every level of gene expression. Host factors that participate in or influence transposition may also play roles in controlling transposition.

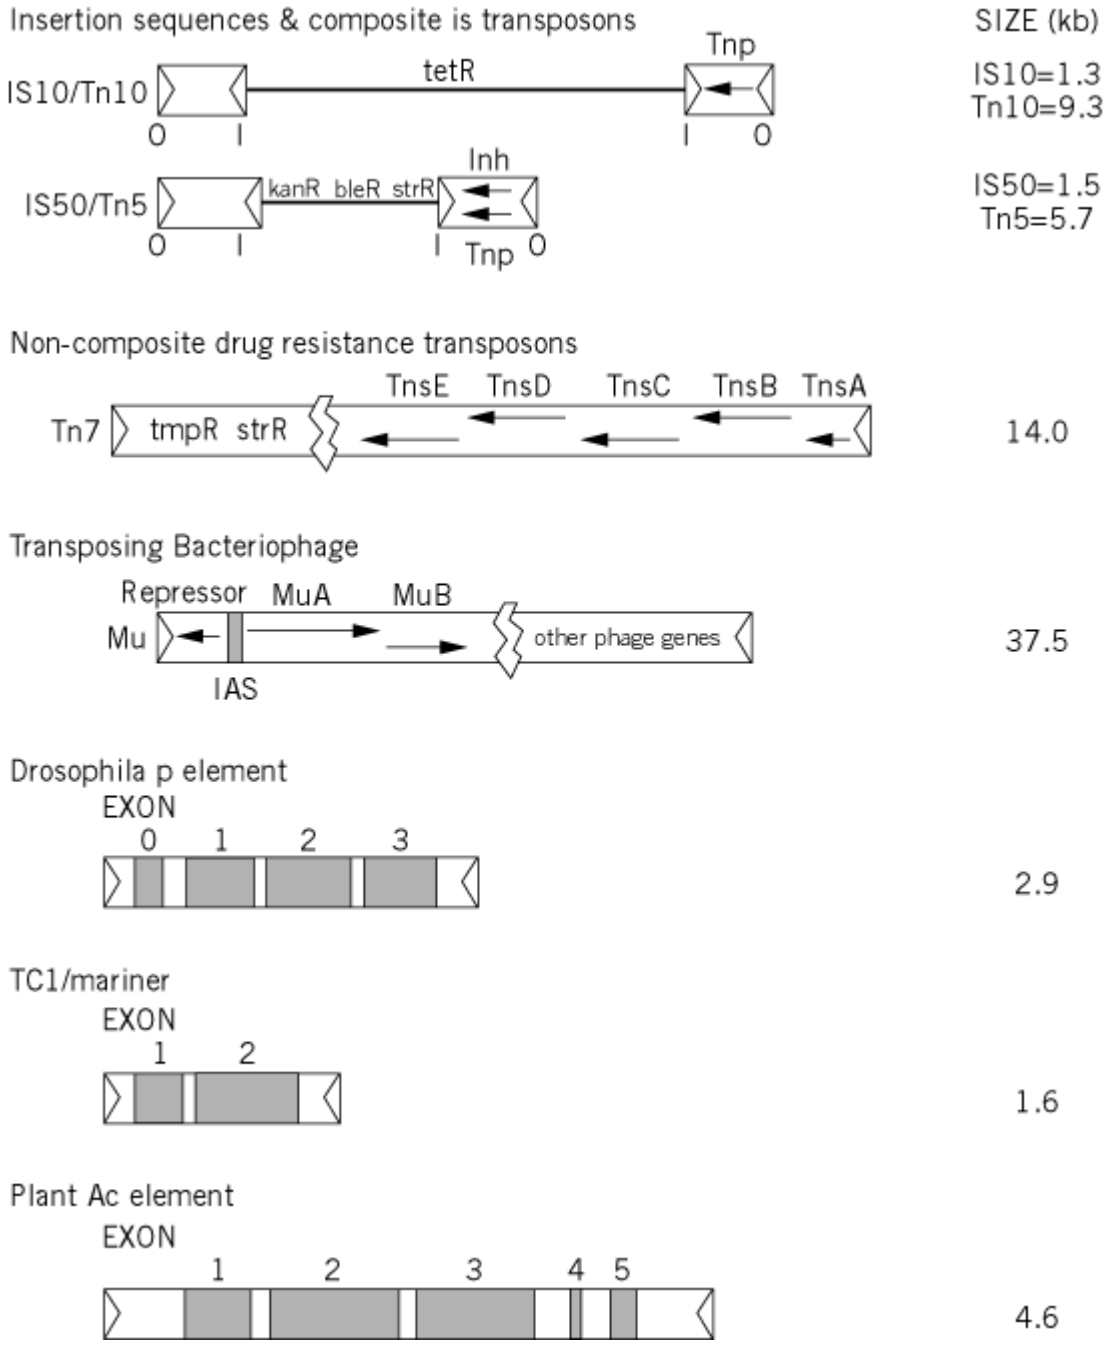
Transposable elements were discovered in maize in the 1940s by Barbara McClintock (1). While looking for deletions of certain regions of genomic DNA, she observed a large number of "unstable mutations"; that is, although the mutant phenotype was present in early cells of developing kernels, the mutation "reverted" to wild-type during the later stages of growth. We now know that this instability results from the insertion of a transposable element to cause the mutation and then the excision of the element to restore it to wild-type; chromosome breakage can also result from the excision of the element.

McClintock's great insight was to realize that there were discrete genetic elements that could both influence the expression of host genes, including causing unstable mutations, and move from place to place in the genome. She found such elements at the sites of certain unstable mutations she examined. One such element, which she called Ds (for dissociation, because she also found it to be associated with chromosome breaks), we now know is a deleted transposable element that has recombination sequences at its tips but does not encode a transposase. She deduced that this Ds element was activated by another discrete element elsewhere in the genome that she called Ac (for activator); we now know that activator is an intact transposable element that makes a transposase that can act both on both Ac and Ds because they have highly related terminal recombination sequences. She determined that these elements could both affect gene expression and move from place to place; both were novel and remarkable properties. To emphasize the effect that these elements could have on host gene expression, she called them "controlling elements." She also believed that the effects of controlling elements on gene expression were critical to development (2). These mobile controlling elements are now generally referred to as *transposable elements*, emphasizing their ability to translocate from place to place.

McClintock discovered and described these mobile elements in genetic terms. It was not until the late 1960s, when transposable elements were discovered in bacteria, that mobile elements acquired a molecular description. Several groups isolated unusual mutations in bacterial operons that were highly polar on downstream gene expression (3, 4). These mutations could be analyzed physically because they could be located on bacteriophage DNA, which is far, far smaller than the maize genome. Such molecular analysis revealed that these polar mutations resulted from the insertion of small discrete pieces of DNA that contained transcription terminators. Mobile DNA in bacteria was also discovered by the analysis of antibiotic resistance genes that could translocate between plasmids. Subsequently, transposable elements have been discovered and described in many organisms; particularly well-studied elements are the P element of *Drosophila* and the Tc1 element of nematodes and its close relative mariner, found in *Drosophila* (5) (Fig. 1). Another important step in the study of transposable elements was the realization that retroviruses, such as human immunodeficiency virus (HIV), and some nonviral elements similar to retroviruses, such as the Ty elements of yeast, are also transposable elements (6).

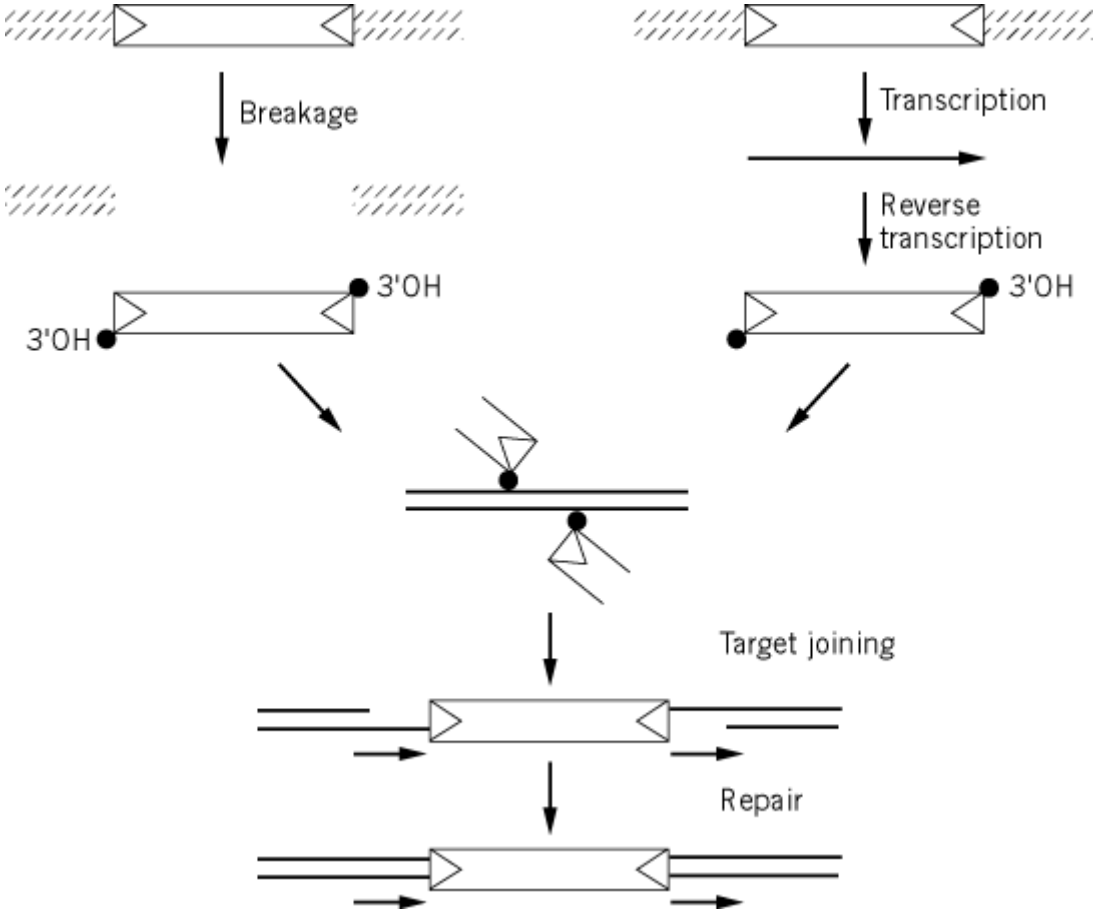
Figure 1. Examples of transposable elements. Well-studied transposable elements from a variety of organisms are

shown. The special recombination sequences present as inverted at the ends of the elements are indicated by triangles. All the elements encode proteins for transposition as indicated by arrows (top three sections) or gray boxes (exons of eukaryotic elements). Some elements encode other determinants; for example, IS50 encodes a transposition inhibitor, many elements encode antibiotic resistance determinants, and Mu encodes a viral genome.



The mechanism of transposition has been studied intensively, facilitated by the development of *in vitro* transposition systems for a number of elements. Many elements transpose via a “cut and paste” mechanism, in which the transposase binds specifically to the ends of the element and introduces double-strand breaks that excise the element from the donor backbone (7); a key feature of this step is that the 3′OH ends of the element are exposed (Fig. 2). The 3′OH ends of the element then join to the target DNA at staggered positions, one end on each strand; these positions have a spacing characteristic of each element. Thus the newly inserted element is flanked by short gaps that are repaired by the host DNA repair machinery; this repair results in target sequence duplications that flank the newly inserted element.

Figure 2. The mechanism of transposition. Reaction pathways for both DNA-only elements (left path) and RNA + DNA elements (right path) are shown. The key first step is to expose to the 3′OH ends of the element, usually by transposase cleavage, although in some retrotransposons the 3′OH ends are generated by cDNA synthesis. The 3′ OHs at each end of the element join to staggered positions of the target, often 5 or 9 bp apart. In the strand transfer product, the transposon and target DNAs are covalently linked through the 3′ ends of the element. The 5′ ends of the transposon are flanked by short gaps (determined by the spacing of the staggered positions of joining). These gaps are filled in by the host repair machinery.



The transposition of a retrovirus involves the same DNA breakage and joining steps (7). Although one form of the retrovirus is RNA, the actual substrate for transposition is a DNA copy of this RNA generated by **reverse transcription**. In some cases, reverse transcription leaves the 3′OH ends of the element exposed, and in other cases DNA cleavages are necessary to expose them. As with DNA-only elements, the 3′OH ends of the retroviral DNA attack the target DNA at staggered positions, generating an insertion product flanked by small gaps that are subsequently repaired by the host.

All transposable elements that have been examined use this basic chemical scheme of exposing 3′ OHs and using them to attack the target DNA. It is also likely that the transposases that execute these reactions from bacteria to yeast to *Drosophila* to humans are fundamentally related.

Transposase

Transposase is the recombinase that promotes the movement of its cognate transposable element from place to place in a genome. The transposase binds to special specific inverted terminal repeat sequences at the ends of a transposable element and executes the DNA breakage and joining reactions that underlie transposition . Recognition of these specific sequences is the basis of recognition of a cognate element by a transposase.

Transposase executes multiple steps in recombination . It specifically recognizes an element by binding to particular sequences at the element termini. These special sequences are usually arranged as inverted repeats, so the interaction of transposase with these sequences positions a transposase molecule at each end of the element in identical fashion. For the elements in which mutagenesis has been used to evaluate the functions of these inverted repeats (1, 2), it has been determined that the internal side of an inverted repeat consists of specific sequences that are the actual transposase binding site. This binding sequence itself is separated from specific sequences at the extreme tips of the element by “spacer” base pairs, whose actual sequence is less critical to recombination. The tip base pairs are the key in specifying the positions for cleavage and joining. In some cases, there are other transposase binding sites internal to the inverted repeats that assist the assembly of appropriate transposase–transposon end complexes and in mediating the DNA breakage and joining reactions. The active form of transposase in the systems that have been examined is a multimer; for example, IS10 transposase functions as a dimer, with one transposase acting at each element end (3).

Transposase also interacts with the target DNA and is often intimately involved in choosing a target site (4). Some elements recognize specific features in the target DNA [for example, retroviral transposases (integrases) interact preferentially with bent DNA (5)], while other transposases recognize particular sequences in the target DNA [for example, the bacterial element Tn10 preferentially recognizes sequences related to a 9-bp **consensus sequence** (6, 7)]. Following end recognition, transposase then mediates the synapsis of the element ends with each other, thus

identifying a transposable element with two ends and juxtaposing the ends so they can act coordinately.

The transposase then executes the breakage reactions at the ends of the element that disconnect it from the donor backbone (8). In many cases, these are double-strand breaks that completely sever the element from the donor DNA; in some other cases, breaks happen only at the 3′ ends. In some elements, these cleavages occur only upon end synapsis; for other elements, interaction of the ends with the target DNA is also required for the initiation of DNA breakage (9, 10). Once the 3′ ends of the transposon are exposed by these transposase cleavage reactions, transposase then promotes the attack of the 3′OH ends on the target DNA at staggered positions, often separated by 5 or 9 bp. Thus the transposon becomes covalently linked to the target DNA.

The *in vitro* analysis of transposable elements from bacteria to yeast to nematodes to humans has revealed that all of these reactions occur by a fundamentally similar mechanism (8): in all cases, recombination is Mg^{2+}-dependent and involves cleavages to expose the 3′ ends of the elements and the attack of these 3′OH ends at staggered positions on the target DNA; for some elements, cleavages at the 5′ ends of the transposon can also occur, completely disconnecting the element from the donor backbone. Recent **X-ray crystallographic** studies of transposases from bacteria [the Mu phage transposase (11)] and humans [the HIV integrase (12)] have revealed that although there is little sequence homology between these proteins, the same global three-dimensional structure exists in the catalytic regions. Most strikingly, in each recombinase there is a cluster of acidic residues (the D,D,E motif) that forms a Mg^{2+} binding site that is likely the key to the active site for DNA breakage and joining. Although displaced from each other in the primary sequence, the folding of both recombinases closely juxtaposes these acidic residues in space. This D,D,E motif has been observed in many transposases (13, 14), and it is likely that many other transposes are also members of the retroviral integrase superfamily.

The activity of the transposase may also require or be influenced by other proteins. For example, some systems require accessory host DNA-bending proteins that also interact with the element termini to facilitate the assembly of particular transposase–transposon end structures (15-17). Proteins other than transposase can also play a key role. These other regulatory proteins can also play a key role in target-site selection (4).

Transposition

Transposable elements are discrete DNA segments that can move between nonhomologous positions within a genome and have been found in virtually all organisms examined. The recombination pathway by which such elements move is called *transposition*. Most elements encode a transposase, that is, the recombinase that executes the DNA breakage and joining reactions that underlie transposition, as well as special recombination sequences at the ends of the transposon arranged as inverted terminal repeats that include transposase binding sites; elements lacking a transposase can often be mobilized by the transposase from another cognate element. The insertion of a transposable element into a new insertion site alters the host DNA at that point and often results in a mutation through gene disruption.

Transposition requires the binding of transposase to both ends of the transposable element and subsequent synapsis of the ends. This requirement for synapsis prior to DNA breakage and joining ensures that an intact two-ended element is present. Many elements—from bacteria to *Drosophila* to fish—transpose by a "cut and paste" mechanism, in which Mg^{2+}-dependent double-strand breaks at the ends of the element separate the transposon from the donor backbone; that is, the transposable element is excised from the donor site (1) (see Fig. 2 in Transposable Elements). The cleavages that expose the 3′OH ends are key, because these reactions expose the transposon ends that transposase will join to the target DNA. Cleavage of the other strand at the 5′ ends of the element can occur by a variety of means, including simple endonucleolytic cleavage by the transposase or using an alternative transposase subunit specific for 5′ ends cleavage (2).

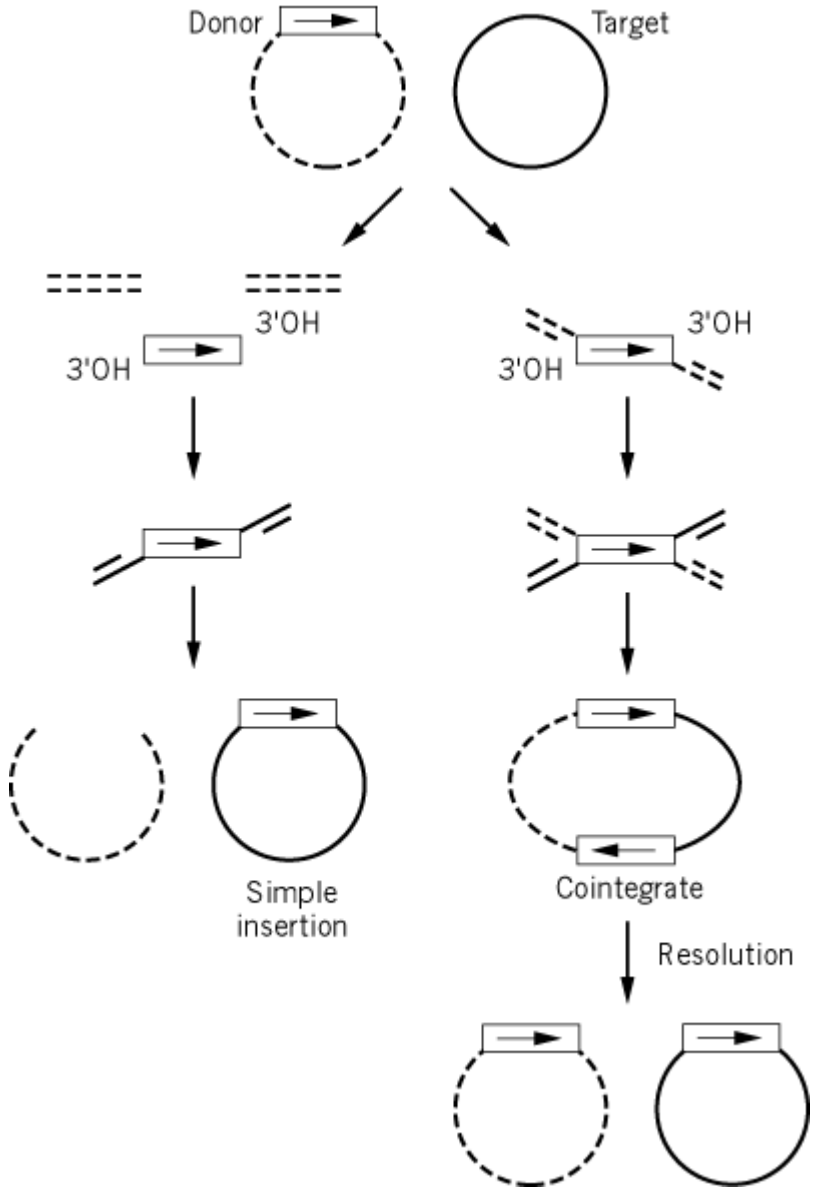
In the subsequent target-joining step, the exposed 3′OH ends of the transposon directly attack the target DNA. It is important to appreciate that this excision and insertion cycle occurs in the absence of any covalent protein–DNA intermediates; instead, these steps occur via simple one-step transesterification reactions in which H_2O attacks the transposon end to disconnect it from the donor DNA, and the transposon end joins to the target DNA by the direct attack of the 3′OH transposon end (1). This attack of the transposon ends occurs at staggered positions on the target DNA—that is, the positions of end joining displaced from each other by several nucleotides. Because of these staggered positions of attack, a small gap the size of the stagger flanks each end of the newly inserted element. Repair of this gap occurs by the host DNA repair functions to generate intact duplex DNA, in which the newly inserted transposon is flanked by a target sequence duplication.

The transposition of retroviruses and retroviral-like transposons occurs by making a messenger RNA copy from the DNA provirus present in a genome, which is then turned into a DNA copy of the element by **reverse transcriptase** (3). The actual DNA breakage and joining steps that underlie the insertion of this DNA copy into a target DNA are very similar to the mechanisms described above for bacterial elements and for elements from *C. elegans* and *Drosophila*. The ends of the viral DNA are often trimmed to expose the actual 3′OH ends of the transposon, and the resulting 3′OH ends the attack the target DNA at staggered positions. As with the excision–insertion elements described

above, the newly inserted transposon is flanked by target-sequence duplications resulting from the repair of these gaps.

For some bacterial elements, in particular Mu phage and probably also Tn3, transposition involves 3′ end cleavage and joining of the ends to the target DNA, but no 5′ end cleavage. The products of these transposition reactions are different than the simple insertions that arise by the cut-and-paste pathway (Fig. 1). Transposon end cleavage occurs only at the 3′ ends of Mu; the 5′ ends of Mu remain attached to the donor DNA. Thus, when the 3′ ends attack the target DNA, the transposon is still linked to the donor DNA via its 5′ ends and is now also linked to the target DNA. This structure is variably called a *fusion product*, a *strand transfer product*, or a *Shapiro intermediate*. The exposed target ends that flank the newly inserted transposon have 3′OH ends that can serve as primers for DNA replication. Such replication results in a structure called a *cointegrate*, which contains two transposon copies linked by the donor backbone and the target DNA. In this reaction, as opposed to a simple cut-and-paste reaction, the transposon is copied during recombination; thus this type of reaction is called *replicative transposition*.

Figure 1. Simple insertion and cointegrate products of transposition. Some elements transpose through a cut-and-paste mechanism in which the transposon is completely excised from the donor site and is then inserted into the target DNA. Other elements, such as phage Mu and Tn3-like elements, carry out replicative transposition in which an additional copy of the element is made by DNA replication. In this pathway, recombination begins with cleavage to expose the 3′ ends of the element and the resulting 3′OH termini attack the target DNA. Replication of the resulting joint structure from 3′OHs in the target DNA that flank the newly inserted element results in a molecule called a cointegrate in which two copies of the transposon link the donor and target replicons. Recombination between the directly repeated copies of the element can generate two species, one which looks like an intact donor molecule and the other which looks like a simple insertion. Tn3-like elements encode a special resolvase enzyme and recombination site within the element that very efficiently promote resolution.



For Mu, the final product is a cointegrate; Tn3 cointegrates are, however, processed further. Tn3 encodes both a transposase and a **resolvase**, an enzyme that can act at special sites to exchange DNA duplexes. Resolvase action on the cointegrates results in a target molecule that contains a copy of the transposon and regeneration of a donor molecule containing the transposon. It should be noted that different transposition reactions can both give rise to simple insertion products; for example, both cut-and-paste elements and Tn3-like elements yield similar insertions as their final product, but are generated by distinct mechanisms. It is very difficult to infer the recombination mechanism from *in vivo* studies, because the products observed may have undergone other recombination reactions prior to or after the actual transposition event.

Another feature that affects whether transposition appears replicative or not is how the gapped donor DNA is dealt with after translocation of an element to a new site. In some cases, the gapped backbone is repaired by double-strand gap repair using a sister chromosome as a template (4-6); in this case, the donor can be restored to its transposon-containing state. When such repair occurs, transposition appears replicative; that is, there is one transposon copy at the donor site and one at the target site, although transposition itself occurred by a nonreplicative cut-and-paste mechanism, and the transposition copy at the donor site was generated by homologous recombination. In other cases, the gapped donor is repaired by an end-joining reaction, generally without restoration of the donor to

the original pre-transposon state. Thus transposition can leave “footprints” that may alter gene expression at the insertion site, even though the transposable element itself is no longer present (4, 6, 7). With retroviruses and retrotransposons, the “donor” provirus site is not altered, because the translocation substrate is a DNA copy of the element made by reverse transcription of an RNA copy.

Transposon

Transposon is another word for a transposable element—that is, a DNA segment that can move between nonhomologous positions in a genome via a type of recombination called transposition. A transposable element generally encodes a recombinase, a transposase that executes the DNA breakage and joining reactions that underlie transposition, by acting on special recombination sequences, inverted terminal repeats, at the ends of the element. Transposable elements are present in Eubacteria, Archea, and Eucaryotes—indeed, in virtually every organism that has been examined. The term “transposon” is often, but certainly not exclusively, used in conjunction with bacterial transposable elements that encode, in addition to their transposition functions, other determinants such as antibiotic-resistance genes. The structure of a number of bacterial transposons comprises special recombination sequences up to perhaps 150 bp in length at the termini of the element, and the interior of the element encodes a transposase (and possibly other transposition proteins) and a gene (s) for another determinant, for example, an antibiotic-resistance gene. Small elements that lack determinants other than transposase are usually called **insertion sequences**.

Some transposons are actually composite elements in which two insertion sequence (IS) elements flank a determinant such as an antibiotic-resistance gene. One IS element may move independently of the other, and both IS elements can collaborate to move the entire IS–drug resistance–IS segment. For example, the transposon Tn10 is composed to two IS10 elements flanking a segment encoding a tetracycline-resistance determinant. The transposon Tn5 consists of 2 IS50 elements flanking a **kanamycin**-resistance determinant. Transposase supplied by both (or sometimes one) of the IS elements acts on the outside ends of the composite element to move them from place to place.

Despite the custom of using the terms *insertion sequences* and *transposons* to describe certain bacterial elements, it is important to remember that both types of DNA segments are actually transposable elements, highly related to many eukaryotic transposable elements in structure and transposition mechanism. However, some types of transposable elements have, to date, been identified in bacteria. For example, composite transposons with two internal individually transposable elements (IS elements) have not been identified to date in eukaryotes. Furthermore,

elements that execute replicative transposition such as elements bacteriophage Mu and Tn3 have also not been identified in eukaryotes.

Transposon Tagging

Transposons are mobile genetic elements that move (transpose) from one region of the genome to another. Transposons are used as tools for gene cloning because insertion of a transposon into a **gene** disrupts its function, often producing a visible mutant **phenotype**. When the **DNA** sequence of the transposon is known, it is possible to clone the disrupted gene by using the transposable element as a "tag" to identify the segment of DNA harboring the element. Transposon tagging involves inducing transposition, screening for mutations caused by transposon insertion, identifying the element causing the mutation, and cloning the tagged gene.

Transposons are found in almost all organisms where they have been looked for, including **bacteria**, **yeast**, **plants**, and mammals. Transposons from one organism often also transpose in heterologous systems. Therefore it is possible to use transposon-tagging methods to clone genes in a wide variety of organisms, including those where there are few other tools available for gene isolation.

1. Characteristics of Transposons Relevant to Tagging

There are many families of transposons, and they are generally divided into two classes. Class I is the retrotransposons, and Class II is the DNA-based transposons. Class I transposons are used for tagging in mammals and yeast, and class II transposons are those used most frequently in tagging schemes for bacteria, plants, *Drosophila*, and **Caenorhabditis elegans**. Class II elements have inverted repeats at their ends and produce the products needed for their own excision and insertion, termed transposase.

1.1. Regulation of Transposition

It is important to have some method for regulating the frequency of transposition. Certain families of transposable elements contain-**"nonautonomous" controlling elements** that cannot produce transposase but move in the presence of the transposase produced by an "autonomous" family member. A similar "two-element" system is often employed in transposon-tagging schemes where a stable transposase source (eg, a transposon immobile due to deletion of one of its direct repeats) is used to mobilize nonautonomous elements. This system has the advantage that, once new insertions have been generated by combining the two types of elements, the transposase source can be segregated. This stabilizes the new insertions and thus stabilizes any mutant phenotypes generated. Transposase can be reintroduced later to remobilize the element to revert the mutant phenotype or to create new alleles of the tagged gene.

In some organisms, the frequency of transposition is regulated by environmental factors, such as temperature. For example, in *Antirrhinum*, the transposition frequency of Tam3 is increased 1000-fold in plants grown at 15°C rather than 25°C (1). In *Saccharomyces cerevisiae*, transposition of Ty1 is also fairly high at low temperatures but decreases 20-fold at 30°C (2).

1.2. Obtaining the Sequence of the Transposon "Tag"

To use a transposon as a molecular "tag" for gene cloning, it is necessary to use a transposon with a known DNA sequence. Many transposons have already been well characterized. New transposons can be "trapped" by first mobilizing transposition and then identifying transposon insertions into known genes (generally by looking for unstable **alleles** of the gene). Then the mutant allele is sequenced, thus determining the sequence of the inserted transposon.

1.3. Integration Site Preference

The efficiency of transposon tagging any particular gene depends on a number of factors. The perfect transposon for tagging purposes would have no preference for the integration site in the host genome, but many, if not most, transposons show some type of site preference. Preferences range from that of the *C. elegans* Tc1 element, which has a TA dinucleotide target site (3), to that of the *Drosophila* P element which preferentially inserts at the 5′-ends of transcription units (4). Such target site preferences explain why transposon-tagged alleles are never recovered for some genes, whereas many tagged alleles have been discovered for other genes.

1.4. Transposition to Linked Sites

A feature of many transposons is their tendency to transpose to linked sites. This is useful for some types of screens (see "Directed tagging" later) but makes random transposon mutagenesis more difficult. In some cases, methods have been devised to select for transposition to unlinked sites. An *Arabidopsis* Ds element carrying a positive selectable marker was linked to IAAH (a marker that can be selected against). The Ds element was mobilized, and by selecting for the Ds marker and selecting against IAAH, lines were identified in which the transposon had moved to a position unlinked to IAAH (5).

1.5. Endogenous Versus Heterologous Transposons

Another consideration in transposon-tagging experiments is whether to use endogenous unmarked transposons, which are plentiful in some backgrounds, or whether to construct transposons specifically for transposon tagging and to mobilize a single transposon or a few transposons per genome. The greater the number of mobile transposons and the higher the transposition frequency, the greater the chance of tagging any particular gene. A large number of background transposons, however, complicates the linkage studies that must be done to identify the specific transposon inserted into the gene of interest. High rates of transposition also result in unstable mutations, making it difficult to link a transposon with a mutant phenotype. The use of only one or a few transposons per genome greatly facilitates identification of the transposon inserted into the gene of interest and thus speeds up cloning of the gene. The trade-off is that more individuals must be screened to obtain insertions into the gene of interest. Using a heterologous two-element, transposon-tagging system is one way of ensuring that only a few elements are mobilized in the genome in the presence of the transposase and allows removing the transposase by segregation to prevent further transposition.

1.6. Transposon and Transposase Engineering

It is useful to have transposons designed so that (1) they carry selectable markers and (1) they carry part of a **plasmid** that can be selected for in *E. coli* to facilitate cloning of flanking DNA by plasmid rescue. A marker linked to the transposase source facilitates removal of the transposase later by segregation from the tagged gene. It is also sometimes possible to increase transposition frequencies by deleting or altering part of the transposase gene, by using a powerful constitutive **promoter** to drive transposase, or by altering transposon size (6-8).

2. Transposon Tagging Strategies: Obtaining Insertions into Genes

2.1. Random Mutagenesis

In random mutagenesis, transposons are mobilized to create a **library** of individuals with different transposon insertions. Then the library of insertions is screened for mutant phenotypes of interest. In a two-element system, transposons are mobilized by putting stable transposase into the background of the nonautonomous transposons, either by genetic crosses or, in the case of the *Drosophila* P element, by **microinjecting** the transposase into an embryo containing nonautonomous elements (9). In other organisms, growth at low temperature mobilizes transposition. Dominant visible mutations are seen in the M1 generation, and recessive visible mutations are seen segregating in the M2 progeny of M1 individuals. Individuals containing a transposed element are often termed "transposants".

2.2. Directed Mutagenesis

There are two types of directed tagging schemes. In both cases, the target gene has been identified previously by its mutant phenotype. In the first type of directed mutagenetic scheme, insertion into a specific gene is selected for by crossing an individual homozygous for the previously identified recessive mutation with a wild-type individual carrying an autonomous transposon (alternatively, an individual carrying both a stable transposase source and the mutation of interest is crossed with a wild-type individual carrying a nonautonomous transposon). The next generation, the M1, is screened for individuals exhibiting the mutant phenotype. These individuals carry both the original mutation and a new transposon-induced allele of the same gene.

The second type of directed mutagenetic experiment is useful in systems where the transposon is known to move preferentially to linked sites on the chromosome. A mapped transposable element that is known to be linked to the gene of interest is mobilized. Insertions into the gene of interest are identified in the M1 by the strategy outlined previously, or the linked transposon is mobilized in a wild-type background, and the M2 is screened for mutations. In either case, if there is a strong preference for transposition to linked sites, the frequency of mutations induced in the specific gene should increase relative to a random tagging procedure (10).

2.3. Enhancer and Gene Traps

Enhancer traps are transposons designed to identify genes on the basis of their expression patterns. The transposon carries a reporter gene under the control of a weak or minimal promoter. Insertion of the transposon near an enhancer causes the reporter gene to be expressed in a pattern governed by that enhancer. In this way, it is possible to identify genes having interesting tissue-specific or developmentally regulated patterns. Enhancer-trap screens should identify genes not usually found in regular tagging screens, such as those having no obvious phenotype when disrupted. They can also be used to suggest new roles for genes. For example, nearby insertion of an enhancer trap could reveal interesting adult expression patterns in a gene that, when disrupted, is lethal in an embryo. Enhancer-trap lines also provide useful tissue, cell-type, and developmentally specific markers that can be analyzed in different mutant backgrounds or under different conditions. Enhancer-trap screens are successfully used to identify interesting gene expression patterns in a number of different organisms, including *Arabidopsis* (5) and *Drosophila* (11).

Gene traps are similar to enhancer traps, except that the transposon used for tagging carries a reporter gene lacking a promoter. Thus, for reporter gene expression, the transposon must insert downstream of the promoter of an expressed gene. RNA **splicing** -acceptor sequences are introduced upstream of the coding region of the reporter gene to permit fusion of the reporter gene to the tagged gene if the transposon inserts into an **intron** (5).

Cloning genes identified by a gene-trap transposon is often easier than cloning enhancer-trapped genes, because gene traps must insert in the correct orientation downstream of a promoter to allow reporter gene expression. Enhancers act at a distance, and it is possible that the gene normally regulated by the “trapped” enhancer is at some distance from the enhancer-trap insertion. To clone the endogenous enhancer-regulated gene, it is sometimes necessary to initiate a **chromosome walk** from the site of the transposon insertion.

3. Cloning tagged genes: from insertion to sequence

The first step in cloning a tagged gene is to identify a transposon linked to the mutation. This is done by Southern blotting DNA from progeny obtained from the putatively tagged mutant. A transposon-specific probe probes the blot to identify a band present in the homozygous mutant progeny and absent in wild-type progeny that do not segregate for the mutant phenotype. If many transposons segregate in the background, finding a transposon linked to the mutant phenotype is difficult. A large number of progeny need to be examined, or the mutant must back-crossed to a strain lacking transposons to segregate background transposons. Once a linked transposon is identified, there are a number of different ways to clone the gene in which a transposon has inserted. Three commonly

used methods are described here.

1. **Plasmid rescue**. If the transposon used for tagging contains part of a selectable plasmid (eg, pBR322) at one end of the transposon, plasmid rescue is used to isolate a fragment of flanking host DNA. Genomic DNA from the tagged individual is digested with a restriction enzyme that releases the selectable plasmid from the transposon but does not cut within the plasmid itself. This creates a linear piece of DNA containing the plasmid sequence and a small fragment of flanking host DNA. The products of the digestion are religated at a high dilution to ensure intramolecular ligation products. The ligation products are **transformed** into *E. coli*, and then the cloned flanking DNA is isolated.
2. **Inverse polymerase chain reaction** (IPCR). IPCR is another method for isolating host sequences flanking a transposon insertion. As for plasmid rescue, genomic DNA from a tagged individual is isolated and digested with a restriction enzyme that releases the end of the transposon and a piece of adjoining host DNA. Ligation is used to circularize the linear host DNA–transposon fragment. PCR using two transposon-specific oligonucleotide primers, each reading outward from the ends of the transposon sequence into the flanking DNA, are used to amplify the flanking host DNA. Then the amplified product is cloned.
3. **Library screening.** A third option is to make a library using genomic DNA from the tagged mutant that has been digested with an enzyme that does not cut within the inserted transposon. The recombinant vector containing the transposon also contains some flanking host DNA. A transposon-specific probe is used to screen the library and identify clones containing the transposon and the flanking DNA.

4. Confirmation

Once the flanking host DNA is cloned, it should be used to probe Southern blots of DNA extracted from homozygous mutant and wild-type plants to look for a band difference, indicating transposon insertion into the complementary sequences in the mutant. This is done to prove that the cloned DNA actually represents the host DNA flanking the transposon and is not an artifact of cloning. Then the cloned flanking sequences are sequenced directly or used as probes to obtain full-length sequences for further analysis. If the transposon has not inserted into the coding sequence of the disrupted gene itself (or in the case of an enhancer trap, if the transposon is not in a gene), it is necessary to use the flanking sequences for initiating chromosome walk to identify the gene of interest.

The most convincing way to prove that a mutant phenotype results from transposon disruption of the cloned gene is to rescue the mutant phenotype by transforming the cloned gene back into the mutant. It is also possible to isolate and analyze different alleles of the gene from independently derived mutants. If all of the mutant alleles harbor mutations in the cloned gene, it is good evidence that the correct gene has been identified. Phenotypic revertants that show a loss of the transposon from the cloned sequence, when they are examined by sequencing or Southern blotting techniques, also confirm the identity of the tagged gene. In the case of enhancer-trapped genes, where there is no mutant phenotype associated with the insertion, expression analysis of the cloned gene should closely mimic that of the enhancer-trap reporter gene.

5. Transposon Tagging Strategies: From Gene to Mutant

5.1. Site-Selected Mutagenesis

Often a gene is identified based on the basis of its expression pattern or its homology to another gene, but its phenotype is unknown. The goal of site-selected mutagenesis is to obtain a transposon insertion into a gene of known sequence to obtain an idea of the null phenotype of the gene.

To obtain a site-selected mutation in a gene of interest, a large population of transposants is generated and divided into pools. Two types of primers are needed for the **PCR** reaction: (1) primers

specific to the gene of interest and (2) transposon-specific primers, one reading "out" from each end of the transposon into the host DNA flanking the insertion. PCR is performed using one gene-specific primer, one transposon-specific primer, and DNA obtained from a pool of transposants. If an individual has an insertion in or near the gene of interest, the gene-specific primer and the transposon-specific primer are positioned so that a PCR product is amplified. Nested primers are often used to ensure specificity of the amplified band. Then pools of transposants from which a product is amplified are subdivided and rescreened until a single individual harboring the insert is obtained. Because the original individuals are often dead by the time tagged individuals are identified, it is necessary to maintain viable siblings of the original transposants for further studies. In the case of plants, this is simple because seeds from the transposants can be maintained for reasonable periods of time. In the case of *C. elegans*, a frozen "transposon insertion mutant bank" has been developed (10).

In some cases, the original insertion does not disrupt gene function sufficiently to generate a visible phenotype. Then, it is often necessary to remobilize the transposon and select for excision/reinsertion events that fully disrupt the gene.

6. Conclusion

Transposon tagging methods are valuable for several reasons. They are used to identify and clone numerous genes having visible phenotypes, and enhancer-trap and gene-trap methods are used to identify genes based on their expression patterns. Possession of a tagged allele of a gene is often a shortcut to cloning, compared with traditional methods, such as chromosome walking. Now, development of site-selected tagging screens allows identifying transposon insertions into genes of known sequence. Such insertions result in null alleles or are used to produce null alleles of genes for which no previous mutation is identified. Null alleles are extremely useful for identifying the functional roles of the gene under study. They are used in genetic studies, such as analyzing double-mutant interactions, and they provide null backgrounds for mutational analysis of a gene. Transposon-induced alleles are also used to produce an allelic series by remobilizing the transposon and selecting for reinsertion elsewhere in the gene or coding sequence. Multiple alleles of a gene can provide insights into its function. Somatic excision events are also used to analyze the role of a gene in different tissues or at different times during development. For all of these reasons, transposon tagging is and will continue to be a useful tool for gene cloning and gene analysis.

Transverse Gradient Gel Electrophoresis (Tgge)

Electrophoresis through polyacrylamide gels (**PAGE**) is one of the most commonly used techniques for characterizing proteins and nucleic acids. It is especially useful to monitor changes in their conformations because the size and shape of a molecules are two of the main determinants of electrophoretic mobility through sieving gels (the other is the net charge). Electrophoresis, however, is primarily a comparative technique because little information is obtained solely from the mobility of a macromolecule under any single set of conditions. It is most informative when a change in mobility is observed. For example, unfolding of a **protein** or **nucleic acid** is apparent by a dramatic decrease in electrophoretic mobility. Phenomena whose conformation is induced to change under the influence of some agent, such as a **denaturant**, are readily studied by electrophoresis in transverse gradient gels. In such gels, the perturbing agent is included in the gel in a continuous gradient, perpendicular to the direction of electrophoretic mobility. In a sample applied uniformly across the top of such a gel, each molecule migrates under constant conditions but different from those adjacent to it on the gel. The population of molecules migrates under continuously varying conditions. Changes in the macromolecular structure at any point within the gradient are apparent from the change in mobility and give a characteristic shape to the electrophoretic band after electrophoresis. Such changes are most apparent if they occur abruptly, such as a cooperative change from form A to form B over a small part of the transverse gradient, when form A predominates at one extreme of the gradient and form B at the other extreme.

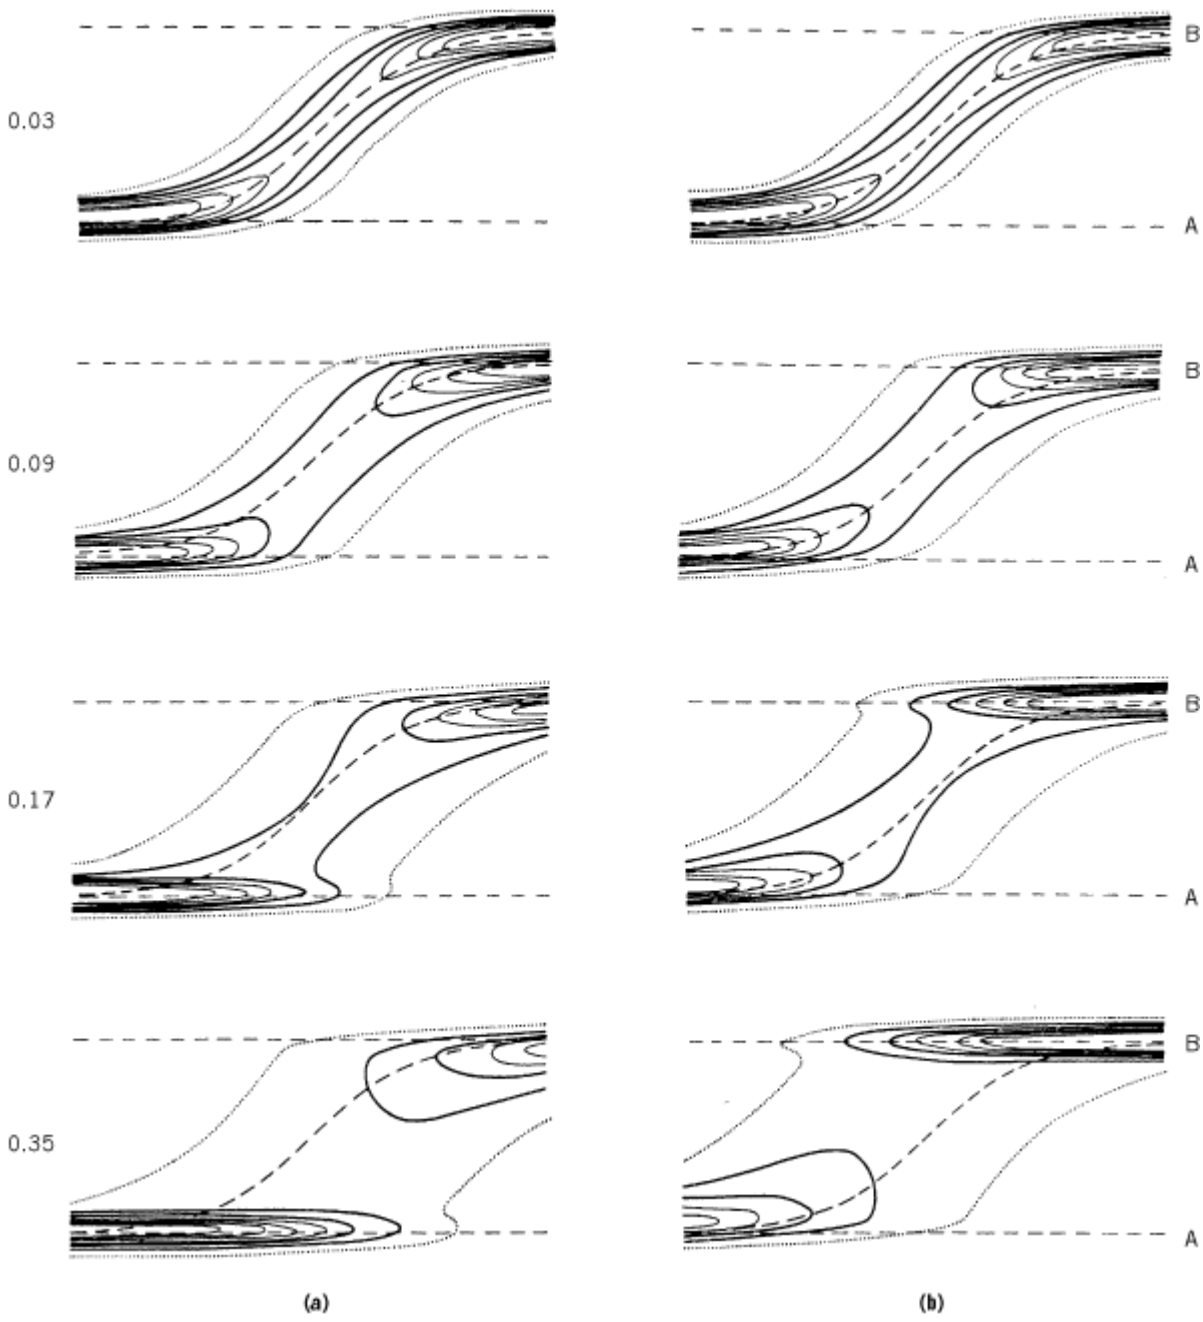
TGGE has the many advantages of electrophoretic techniques. The method is simple, rapid, and

requires no expensive equipment, only small quantities of sample are required, and the sample need not necessarily be homogeneous. Although only semiquantitative, TGGE has the advantage that close comparisons can be made of different macromolecules by running them on the same gel. Even small differences in their electrophoretic mobilities are detected.

When a macromolecule interconverts between two forms, say A↔B, as a result of the transverse gradient, a major question is whether one or two electrophoretic bands are observed at positions where the two species coexist. Numerical simulations indicate that this depends almost exclusively on the rate at which the two states are interconverted, relative to the duration of the electrophoretic separation (Fig. 1). If their interconversion is very slow, individual bands corresponding to both A and B are present to the extent that they were both present in the original sample. At the other extreme, with very rapid rates of interconversion and a **half-time** less than about 0.1 the duration of the electrophoretic separation, a single band will be present that has an intermediate electrophoretic mobility at the weighted average of the two. In this case, a change from one state to another at some point in a transverse gradient gel is apparent after the electrophoresis as a sigmoidal change in the mobility of a single, continuous band across the gradient. Then the final pattern describes the equilibrium between the two forms as a function of the variable in the gradient. With intermediate rates of interconversion, the electrophoretic patterns are smeared between the two positions of the two states A and B as various molecules convert to the other state at various times during the separation.

Figure 1. Simulated TGGE patterns expected for a macromolecule undergoing a two-state transition between forms A and B at four different rates and starting with the sample initially as either all A (left) or all B (right.) The transverse gradient was imagined to favor the A state on the left and the B state on the right, and the apparent equilibrium constant [A]/[B] varies logarithmically across the gradient from 10^2 to 10^{-2}. It was assumed that both the forward and reverse rate constants vary inversely across the gradient by a factor of 10^2. The rate of the interconversion is at a minimum at the middle of the transverse gradient, and the half-time is $t_{1/2}$. The rate there is expressed on the left as the ratio of $t_{1/2}$ to the duration of the electrophoretic separation (t_{elect}). Electrophoretic migration is from top to bottom, and state A has greater mobility. The distribution of the macromolecule in the final gel is given by the contours.

With the most rapid interconversion (top), the final pattern is a single, continuous band that describes the equilibrium between A and B across the gradient (dashed sigmoidal curve). The patterns are the same, irrespective of whether form A or B is applied to the gel. With a slower transition, where the interconversion takes place with a half-time comparable to the duration of the electrophoretic separation, the continuous band is replaced by a smear because the initial molecules convert to the other form only once and at various times during the electrophoresis. The form applied to the gel persists increasingly with a slower transition. In the limit of a very slow transition, only the form applied to the gel would be present after the electrophoretic separation. Adapted from Ref. 1.



If the starting macromolecule is homogeneous and all in one state, only one band should be apparent finally at each point in the gradient. Its mobility should be either that of the original state, if its interconversion is slow, or, if the interconversion is fast, of the final equilibrium mixture. The rates of such transitions can also be investigated more directly by comparing patterns obtained starting with the sample in either of the two states. Identical patterns are observed with rapid interconversions, but the original form persists if the interconversion is slow. If more than two states are possible, the resulting patterns may be more complex, but the same rules should apply to the interconversion of each pair of states.

The transverse gradient can be of any parameter that does not unduly affect the electrophoresis. Unfortunately, high concentrations of ionic species, such as **guanidinium chloride**, have a drastic effect on electrophoretic mobility and therefore cannot be included in electrophoretic gels. Small concentrations of other charged molecules making up the gradient are altered by their electrophoresis within the gel. Therefore reagents with a net charge are not ideal for TGGE, but any other agent that

does not interfere with electrophoresis may be used in the transverse gradient.

For example, the size and shape of a molecule can be inferred from its electrophoretic mobility as a function of acrylamide and bisacrylamide concentrations (see Ferguson Plot). These electrophoretic measurements are usually carried out in a number of gels with different acrylamide concentrations, but they are more readily performed in a single transverse gradient gel in which the acrylamide concentration varies across the gel.

The most common agents used to alter the structures and conformations of proteins and nucleic acids are the denaturant urea and temperature. Their use in TGGE is described in the entries **urea gradient electrophoresis** and temperature gradient gel electrophoresis, where they give information about the folding and unfolding of proteins and nucleic acids.

Transversion Mutation

A transversion mutation is a mutation that substitutes a **purine** for a **pyrimidine** or a pyrimidine for a purine, inverting the purine/pyrimidine axis of the **DNA** molecule. These are

$$G \to C \quad G \to T \quad A \to C \quad A \to T \quad Purine \to Pyrimidine$$

$$C \to G \quad C \to A \quad T \to G \quad T \to A \quad Pyrimidine \to Purine$$

Transversions may result form the mispairing of a purine with a second purine, then replication of a nascent strand completes the transversion mutation by pairing that purine with a pyrimidine. Transversions were named by Freese (1) as a class of mutations that are not easily subject to **reversion** by base analogs (see Transition Mutation). However, transversions typically result when a nucleotide is altered by a bulky DNA adduct so that the base-pairing capacity is lost.

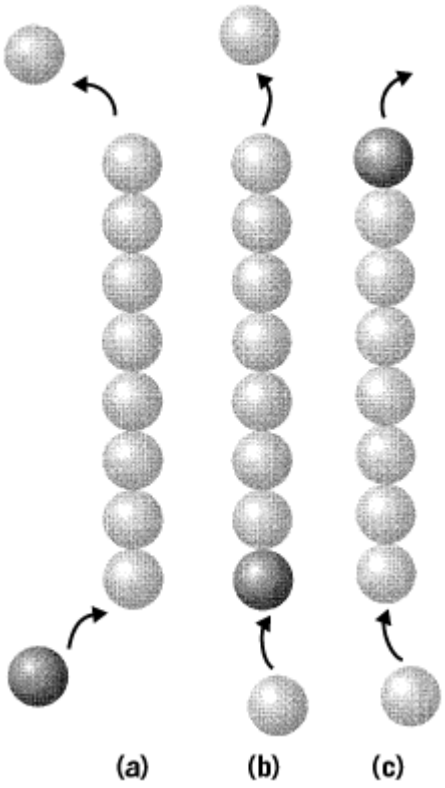
Treadmilling

In the absence of an energy source, a polymer will exist in equilibrium with a pool of monomers. In such an equilibrium, monomers will randomly associate and dissociate from the polymer, with no net change in length. Since many protein polymers (such as actin, tubulin, and **RecA**) bind and hydrolyze a nucleotide cofactor, the possibility exists that this energy source can be used by the polymer to drive a flux of subunits through the filament. This will result in a steady state where the polymer is maintaining a constant length but moving subunits vectorially, a process known as treadmilling.

With no energy source, a polymer may have a "fast" growing end and a "slow" growing end, but the equilibrium constant (the ratio of the rate constants for subunit addition and loss) must be the same at both ends of the filament. Thus, if the rate of addition is tenfold greater at one end of the filament than at the other, the rate of subunit loss at this fast-growing end must be tenfold greater than at the slow-growing end. The critical concentration of the monomer (the concentration at which the monomer will be in equilibrium with the polymer, with no net growth or depolymerization) must be the same at both ends of the filament at equilibrium. In the presence of an energy source, it was first realized for actin (1) that ATP hydrolysis could lead to a situation where the critical concentrations are different at the two ends. There could thus exist a state where the monomer concentration leads to depolymerization at one end, but polymerization at the opposite end. Under these steady-state conditions, the filament length could remain constant, but there would be a net flux of subunits travelling through the polymer (Fig. 1).

Figure 1. In a polymer where subunits add preferentially at one end (bottom, a) and depolymerize from the opposite end (top, a), a treadmilling phenomenon will exist, with a flux of subunits passing through a polymer that maintains a constant length. In (b) a "labeled" subunit adds at the bottom, and this subunit would travel the length of the polymer before exiting, as in (c). This flux of subunits would require an energy source (such as ATP hydrolysis).



A direct *in vitro* demonstration of the existence of treadmilling was shown for microtubules (2), but the role of treadmilling *in vivo* for both actin and microtubules has remained controversial for many

years. Recent observations, however, have shown the existence of *in vivo* treadmilling for both actin (3) and microtubules (4, 5). The resulting vectorial movement of subunits through a polymer could be an important mechanism for motility and intracellular transport.

Trifluoroethanol

Trifluoroethanol (2,2,2-trifluoroethanol, CF_3CH_2OH, often abbreviated TFE) is a substituted organic alcohol often used as a co-solvent. It is a liquid at room temperature and miscible with water. The property that makes it of interest in molecular biology is its ability to stabilize noncovalent structure in peptides. The a-helix is a common **secondary structure** motif in proteins, but it is only slightly stable in most short peptides (see Alpha-Helix Formation). TFE stabilizes helical structure in some peptides (1-3). Several proteins have been split into peptide fragments, and these peptide fragments have shown a tendency to form helices in TFE (4-6), even if they are unstructured in water. This tendency is particularly strong for peptides corresponding to helical regions in the intact protein, but it has also been present even in fragments that contained no helix in the intact protein. Relatively high concentrations of TFE are needed to get the full stabilization, and the amount of a-helical structure generally reaches a maximum around 40% to 60% (v/v) TFE. TFE has also been shown in certain instances to stabilize b-sheet secondary structure (3, 7).

Because TFE weakens **hydrophobic** interactions, it is a protein **denaturant**. However, the denatured state induced by TFE is usually structured. For example, the denatured state of the protein hen egg-white lysozyme in 70% TFE consists of regions of high helical content (8), corresponding to regions that were helical in the native protein, although this denatured state does lack tertiary structure interactions. Study of proteins denatured in TFE can give an idea of the local structure-forming tendencies of regions of the polypeptide chain and may suggest sites at which the folding of the protein is initiated.

The mechanism by which TFE stabilizes structure is unclear. One suggestion is that TFE interferes with the ability of water to solvate peptide groups that make up part of the peptide backbone (2, 9). Therefore the unstructured conformation of a peptide, whose backbone peptide groups are exposed to water, is less favored in TFE solution than the same conformation in pure water. Thus, structures featuring these groups hydrogen-bonded to other groups in the peptide (as in the a-helix) are favored.

Trigger Factor

Trigger factor is an abundant **cytosolic** protein of **bacteria**, first discovered in *Escherichia coli* by Wickner and co-workers in 1987 (1). They searched in a biochemical screen for cytosolic components involved in protein secretion of the precursor of **OmpA protein**, proOmpA, and identified a protein with an apparent molecular weight of 60 kDa that had the ability to form 1–1 stoichiometric complexes with proOmpA; this stabilized the precursor and facilitated its translocation into membrane **vesicles**. The protein was termed “trigger factor” because of its ability to trigger the folding of proOmpA into a membrane assembly-competent form *in vitro*.

Recent investigations revealed new interesting features of trigger factor. That from *E. coli* has peptidyl-prolyl-cis/trans isomerase (PPIase) activity and is capable of catalyzing **protein folding** *in vitro* much more efficiently than all other PPIases tested so far (2). In addition, trigger factor binds to the large subunit of ribosomes (3) and associates with cytosolic and secretory nascent polypeptide

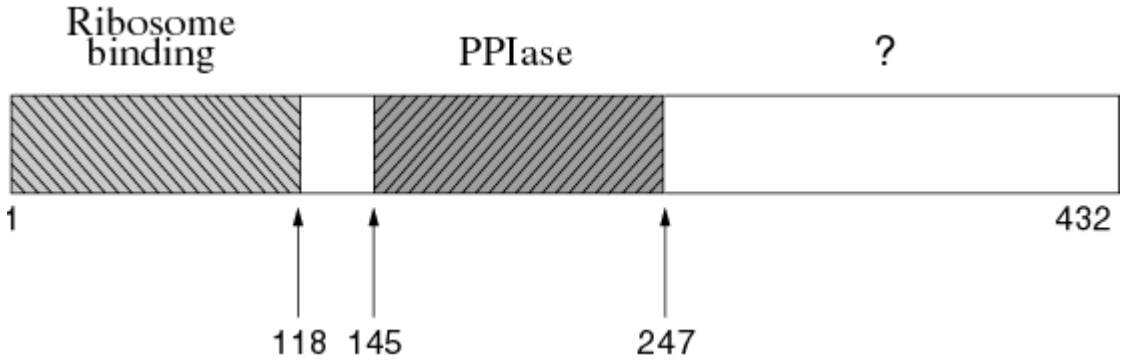
chains *in vitro* (4, 5). These findings led to the hypothesis that trigger factor acts as a cotranslational folding catalyst for newly synthesized polypeptides. Trigger factor was also described to cooperate with the chaperonin GroEL in stimulating **protein degradation** of an unstable protein, apparently by enhancing the interaction of GroEL with the substrate (6). Together, these findings suggest an involvement of trigger factor in processes related to cellular protein folding and metabolism. However, *in vivo* functions of trigger factor have not yet been demonstrated.

Genes encoding homologous trigger factor proteins were recently identified in other **eubacteria**, including *Bacillus subtilis*, *Campylobacter jejuni*, *Haemophilus influenzae*, *Haemophilus actinomycetemcomitans*, *Mycoplasma pneumoniae*, *Mycoplasma genitalium*, and *Synechocystis PCC6803*, whereas no homologous protein has been described so far in **archaebacteria** and **eukaryotic** cells. This review will focus mainly on the *E. coli* trigger factor, since most mechanistic analyses were performed with this homologue.

1. A peptidyl-prolyl-*cis/trans* Isomerase

Peptidyl-prolyl-*cis/trans* isomerases (PPIases) are enzymes that catalyze the ***cis–trans* isomerization** of **peptide bonds** preceding **proline** residues (Xaa-Pro peptide bonds) (see Peptidyl Prolyl Cis/Trans Isomerases). This isomerization can be rate-limiting in the folding of a polypeptide chain into its native structure (see **Protein folding**). Trigger factor is proposed to represent a new member of the family of FK506 binding (FKBP)-type PPIases on the basis of the following findings. Stoller et al. (2) identified trigger factor as a ribosome-bound PPIase. Using series of tetrapeptides of the sequence Suc-Ala-Xaa-Pro-Phe- *p*-nitroanilide to monitor PPIase activity, trigger factor resembled in its Xaa-Pro substrate specificity PPIases of the FKBP-family (2). Independently, two groups reported on a significant sequence homology of trigger factor with PPIases of the FKBP-family (5, 7). In particular, **hydrophobic** and **aromatic** residues forming the substrate-binding pocket in the well-known structure of the human FKBP12 homologue are found in trigger factor as well. A puzzling finding, however, is that the *E. coli* trigger factor is not inhibited by FK506 at concentrations of up to 100 m*M* (2), while the *B. subtilis* homologue is half maximally inhibited by 0.5 μ*M* FK506 (8). Confirmation of the FKBP-domain as a structural and functional element of trigger factor was achieved by limited **proteolysis** of the native protein, which generated a stable fragment of 12 kDa constituting the predicted FKBP domain (Fig. 1) When assayed for PPIase activity toward tetrapeptides, this fragment displayed the same specific activity as the full-length protein (9, 10).

Figure 1. Schematic representation of the domain structure of *E. coli* trigger factor. Hatched boxes show the domains for which activities have been assigned. Arrows with numbers indicate the residues at the domain boundaries.



Alignment of the sequences of trigger factor proteins from different prokaryotic species revealed that the central parts of the proteins representing the FKBP domain exhibit a strikingly higher degree of conservation than do their *N*- or *C*-terminal parts, suggesting that the PPIase activity is a particularly

conserved feature of the trigger factor proteins (10).

2. Chaperone activity

The ability of trigger factor to form 1–1 stoichiometric complexes with unfolded proOmpA and to stabilize the translocation-competent form of this precursor is reminiscent of **molecular chaperones**. A chaperone-like activity is further indicated by the trigger factor ability to associate with high affinity (apparent dissociation constant ~0.7 μM) with the unfolded form of a mutant **ribonuclease T1** (11), and this high affinity binding is a prerequisite for trigger factor's excellent catalysis of refolding of the same protein *in vitro* (2, 11). Refolding of this protein is rate-limited by the *cis–trans* isomerization of a single proline peptide bond. Because of the high affinity of trigger factor for the unfolded substrate, it outscores all other PPIases in its efficiency of catalyzing the prolyl isomerization, although the catalytic constant is low (k_{cat}~1.3 μM) (11). The activity of the isolated central PPIase **domain** of trigger factor is reduced 800-fold, whereas its PPIase activity toward tetrapeptide substrates is comparable to that of full-length trigger factor (11).

These findings indicate distinct sites on trigger factor for high affinity substrate binding and prolyl-isomerization and suggest that the exceptional catalytic efficiency of trigger factor originates from a cooperation of its PPIase and chaperone-like activities (11). Tight substrate binding may position the stretch of the protein substrate that contains the critical proline residue close to the active site of the PPIase.

3. Association with Nascent Polypeptide Chains

Two research groups independently demonstrated that *E. coli* trigger factor can associate with nascent polypeptide chains. Luirink and coworkers discovered that trigger factor can be efficiently **crosslinked** to all nascent chains arrested on the ribosome (4). Trigger factor competes with P48, a component of the *E. coli* signal recognition particle (SRP), for crosslinking to nascent chains of precursors of secretory proteins. In contrast to P48, however, trigger factor also crosslinks efficiently to nascent chains of cytoplasmic polypeptides (4). Bukau and co-workers identified trigger factor as the main component that associates with ribosomes translating **b-galactosidase** (5). This association was resistant to high salt but was disrupted by puromycin treatment, which leads to premature termination of translation, suggesting an association of trigger factor with b-galactosidase nascent chains (5). Further evidence for an association of trigger factor with nascent chains was provided by its photocrosslinking to nascent chains of secretory as well as nonsecretory derivatives of preprolactin (5).

The ability of trigger factor to associate with nascent chains emerging from the ribosome suggests that this protein has a binding site on the ribosome that positions it near the exit site for nascent chains. Trigger factor is indeed exclusively associated with the large ribosomal subunit, which harbors this site (3), and trigger factor cannot be **crosslinked** to nascent polypeptides after their puromycin-mediated release from the ribosome (4, 5). Interestingly, trigger factor also associates with eukaryotic **wheat germ** ribosomes, suggesting conservation in evolution of its binding site on the ribosome (5).

4. Role with GroEL in Binding and Degradation of Proteins

A further role for trigger factor in protein metabolism is indicated by the finding that trigger factor stimulates the degradation of CRAG, an artificial protein composed of fragments of the l **cro repressor**, b-galactosidase, and protein A that has been used as a model unfolded substrate for studies of **protein degradation** in *E. coli*. Proteolysis of CRAG by the ClpP proteinase depends on the interaction of CRAG with the chaperonin GroEL, and formation of this complex was the **rate-limiting step** in degradation. Trigger factor accelerates the chaperone-dependent degradation of CRAG by promoting its binding to GroEL. A ternary complex of CRAG, GroEL, and trigger factor

was demonstrated by affinity chromatography. Addition of ATP causes dissociation of the complex of GroEL and trigger factor from the substrate (6). Trigger factor interacts directly with GroEL prior to association with CRAG. This interaction differs from that of GroEL with denatured substrates in that addition of ATP and GroES, which causes substrate release from GroEL, does not dissociate the complex (12). Trigger factor also enhances the binding of GroEL to unfolded proteins other than CRAG (12). This indicates that trigger factor is involved in both degradation and folding of denatured substrates by stimulating their binding to the chaperonin (12).

5. Domain Organization

The *E. coli* trigger factor consists of 432 amino acids with a molecular weight of 48 kDa. Limited proteolysis of the full-length protein with proteinases revealed a compactly folded proteinase-resistant central domain comprising residues 145–247 (Fig. 1) (9, 10). This domain has homology to FKBPs and displays PPIase activity, and thus represents the catalytic core of the protein.

The *N*-terminal part of trigger factor forms another structural and functional module. The *N*-terminal 144 residues are necessary and sufficient for specific binding of trigger factor to the large ribosomal subunit, both *in vitro* and *in vivo* (13). This fragment contains a compactly folded domain comprising the amino-terminal 118 amino acids (Fig. 1). It copurifies with *E. coli* ribosomes from cell extracts and is capable of associating with isolated ribosomes *in vitro*; therefore, it represents the ribosome-binding domain of trigger factor (13).

Intriguingly, the *N*-terminal fragment alone, or with the adjacent PPIase domain, is unable to form complexes with translating ribosomes that are resistant to high salt concentrations. Furthermore, the association of both fragments with ribosomes was not altered by puromycin, suggesting that the sensing of the translational status requires the C-terminus of trigger factor (13). It is conceivable that the *C*-terminus mediates the tight association with nascent polypeptide chains or with the translating ribosomes, which consequently leads to the formation of high salt-resistant complexes of trigger factor with the translating ribosome.

6. Cellular Function

Despite the considerable progress made in the biochemical dissection of trigger factor *in vitro*, the role of this protein in *E. coli* remains unclear. The known properties of trigger factor strongly suggest an important biological function in folding of newly synthesized proteins and raises the attractive hypothesis that trigger factor acts as a cotranslational folding catalyst. Interestingly, expression of the *tig* gene encoding trigger factor is growth-phase-controlled and coregulated with genes encoding ribosomal components (14). A possible role of trigger factor in GroEL-assisted protein metabolism (12) is not yet established.

Although a **knockout** mutation of the *tig* gene is not available yet, the available data indicate that trigger factor is not essential for *E. coli* growth at 37°C. Depletion of trigger factor to less than 5% of the cellular wild-type levels causes formation of short filaments, indicating cell division defects. Trigger factor–depleted cells remain fully viable at 37°C, however, and have no additional cellular defects (14). For example, although trigger factor enhances translocation of proOmpA into vesicles *in vitro* (1), trigger factor–depleted cells have no defect in translocation of the precursor, even in a *secB* mutant background that lacks activity of the secretion-specific chaperone SecB (14). It is unclear whether the activities of other chaperones or PPIases existing in the *E. coli* cytosol can compensate at 37°C for the missing activity of trigger factor in the depleted cells.

The only detected phenotype of trigger factor-depleted cells was observed at low temperature. Depleted cells stored at 4°C die faster than do normal cells, while cells overproducing trigger factor show enhanced viability at this temperature (15). This suggests an involvement of trigger factor in cell survival at temperatures below the growth temperature limit. Trigger factor may be particularly important at low temperatures for folding of proteins requiring prolyl-bond isomerization. This

isomerization is slower at low temperature, so there is an increased requirement for catalysis. Furthermore, the cellular level of trigger factor is about twofold higher at 16°C and 4°C than at 37°C (15).

The importance of trigger factor for metabolism of bacteria is also indicated by the discovery of a *tig* gene in ***Mycoplasma*** *genitalium*. This bacterium is believed to be free from genetic redundancy and thus contains only the minimal set of genes required for life. Trigger factor appears to be the only PPIase of this organism (16). Identification of the *in vivo* functions of trigger factor thus seems to be of importance for understanding the fundamental process of protein folding in the bacterial cytosol.

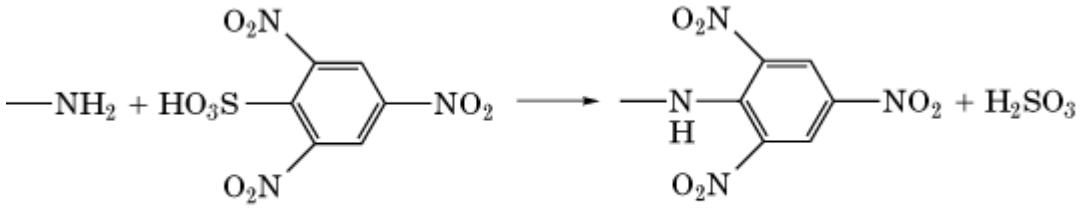
Trinitrobenzene Sulfonic Acid

2,4,6-Trinitrobenzene sulfonic acid (TNBS) [I], usually obtained as the sodium salt has a molecular weight of 315.15. TNBS reacts specifically with amino groups of amino acids, peptides, and proteins under mildly alkaline conditions (Scheme 1) and yields trinitrophenyl derivatives [II] with a yellow color (340 to 350 nm).This reaction is employed to detect or measure of amino groups (1, 2). TNBS also reacts with thiol groups.



[I] Trinitrobenzene sulfonic acid [II]

Trinucleotide Repeats

The application of molecular **genetic** approaches to identifying responsible **genes** has advanced our understanding of the molecular mechanisms of a number of hereditary neurological diseases. Among these diseases, a distinct group constitutes a new type of disease mechanism, caused by an unstable expansion of a trinucleotide repeat in the genome, such as a CAG trinucleotide repeat. The expansion of trinucleotide repeats in eleven human gene loci causes the development of at least eight hereditary diseases that affect the nervous system: (*1*) fragile X-chromosome syndrome; (*2*) myotonic dystrophy; (*3*) spinal and bulbar Kennedy's amyotrophy; (*4*) Huntington's chorea; (*5*) type 1 spinocerebellar ataxia; (*6*) Friedreich's ataxia; (*7*) dentatorubral-pallidoluysian atrophy; and (*8*) Machado–Joseph disease.

The triplet repeat may be located in the 5′ untranslated region of the gene (for example, an expanded CGG repeat in the case of the fragile-X syndrome) or in the 3′ untranslated region(for example, an expanded CTG repeat in the case of myotonic dystrophy). An expanded GAA repeat within the first intron of the gene has been identified in Friedreich's ataxia. Within protein coding regions, an expansion of CAG repeats (and therefore of a corresponding protein with long stretches of glutamine residues) has been identified in spinal and bulbar muscular atrophy, Huntington's disease, spinocerebellar ataxia type 1, dentatorubral-pallidoluysian atrophy, and Machado–Joseph disease. Similar unstable trinucleotide repeat expansions have been suggested, but not unequivocally proven, in many neurological diseases, including dominant ataxia, schizophrenia, and bipolar illness.

Triplet repeats are present in normal individuals. The number of repeat units ranges up to nearly 35. Expanded alleles with the number of trinucleotide repeats exceeding the normal range lead to the expression of disease phenotypes. All the repeats seem to be intrinsically unstable. Unaffected individuals have varying size repeats within the normal range, and most have different numbers of repeats in their maternal and paternal alleles. Importantly, none of the affected genes shows a continuous gradient of repeat sizes from normal to abnormal. Instead, normal genes keep their slightly unstable repeats within the normal range, whereas the repeats in a small subset of abnormal genes jump into the abnormal range. Once abnormal, the repeats become highly unstable and lead to disease. Indeed, all the disorders seem to show linkage disequilibrium. Inheritance of the affected gene is linked to the inheritance of other genetic markers. This indicates that the lineage of most patients with each disease can be traced back to one or a few shared ancestors who acquired the archetype expansion mutation. Thus, it is an excessively rare event for any of the normal frequency

repeats to jump into the pathological range.The increase in the number of repeats appears to account for the phenomenon called *anticipation* in which the clinical severity of the mutation increases from generation to generation.

1. Some Examples

In the case of the fragile-X syndrome, the length polymorphism involving the CGG repeat at the 5′ end of the FRX gene can give rise to an increased length variant (premutation) that has no clinical phenotype, but is genetically unstable and can generate longer CGG repeats associated with the fragile-X phenotype. The normal length of the repeat expansion $(CGG)_n$ varies from $n = 6$ to 52, whereas it increases to $n = 52$ to 200 in diseased individuals. **PCR** amplification with primers flanking the CGG repeat distinguish the normal length range of polymorphic variants from the longer premutation variants. Some of the unstable variants, however, are sufficiently long to make PCR amplification of the CGG repeat inefficient. Then **Southern blotting** may be required.

In myotonic dystrophy, the CTG repeat, whose length is normally between 5 and 30 repeats, can reach 50 to 2000 repeats in the disease. In Huntington's disease, the respective figures for $(CAG)_n$ are $16<n<36$ and $42<n<86$. In spinobulbar muscular atrophy, the respective figures for $(CAG)_n$ are $17<n<26$ and $40<n<52$. In Friedreich's ataxia, expansion of the GAA trinucleotide repeat ranges from 200 to 1200 repeat units with no overlap in the normal range.

Although genetic rather than epigenetic events occur at these loci to produce affected individuals, the characteristics of these diseases often fulfill the definition of genetic imprinting because the disease locus is affected differently upon passage through female versus male gametogenesis. For example, in congenital myotonic dystrophy and fragile-X syndrome, expansion of the triplet repeat leading to the disease phenotype occurs only through female transmission, whereas in Huntington's disease the most dramatic repeat expansion occurs in the father's germ line.

2. Biochemical Data Linked to the Triplet Repeat Expansion

2.1. Chromosomal Fragile Sites

Unusual DNA secondary structures have been implicated in the expansion of trinucleotide repeats. Evidence has been presented consistent with folding of the DNA structure of the repeats into hairpin loops at the center of a long **palindromic** segment *in vivo* (1). In two types of fragile-X chromosome syndrome, FRAXA and FRAXE, the trinucleotide repeat expansion may alter the long-range chromatin structure, which could influence transcription of nearby gene sequences. FRAXF, another X-chromosomal fragile site that has been cloned, harbors a polymorphic compound triplet array, $(GCCGTC)_n(GCC)_n$. Expansion and **methylation** of the GCC repeat and the neighboring CpG-rich region result in chromosomal fragility. It has been suggested that hairpin formation may occur, accompanied by **DNA polymerase** slippage.

High-resolution NMR spectroscopy and other biophysical methods have given a global picture of the solution behavior of the disease-related CXG (X = A, C, G or T), which show a propensity for folding at lengths as short as 12 residues (2). The fragile FRAXA sites stain poorly on the chromosome, which suggests an altered chromatin structure. Repeating CCG DNA from FraX patients were tested for their ability to assemble into nucleosomes, the basic units of chromatin, using *in vitro* nucleosome reconstitution, electron microscopy, and competitive assembly gel retardation assays. CCG blocks of 50 repeats displayed strong nucleosome exclusion, providing a possible explanation for the nature of the fragile sites (3), although this conclusion is contradicted by others (4).

The CGG/CCG repeats, which unlike the CAG repeats contain a methylatable CpG dinucleotide, acquire considerable methylation when the repeat length exceeds about 200 trinucleotides.

Expansion appears to precede methylation, but how the DNA methylation is acquired remains unclear.

2.1.1. CAG and CTG Repeats

The consequences of the CAG repeat expansion seem to be at the protein level, conferring a gain or an altered function rather than a loss of function. The gene responsible for spinal and bulbar Kennedy's amyotrophy has been localized to Xq12 and the androgen receptor gene. This gene contains a trinucleotide repeat within the first **exon** that encodes a polyglutamine tract. The effect on the protein of lengthening this tract is currently unknown. Because the androgen receptor is a transcription factor, one hypothesis is that polyglutamine expansion alters the **gene expression**, leading to neuron degeneration.

The gene responsible for type 1 spinocerebellar ataxia contains an open reading frame that predicts an 87-kDa polypeptide of unknown function (*ataxin1*) containing a polymorphic polyglutamine tract interrupted by two histidine residues. By immunohistochemical methods, both wild-type and mutant ataxin1 have been found in cultured cells, predominantly in the nuclei. Mice containing a human transgene with 82 repeats experience the disease, confirming the dominant nature of the expanded allele.

In the case of Huntington's chorea, the *huntingtin* protein that is enlarged by the expanded polyglutamine tract is predominantly cytoplasmic and of unknown function.

The gene responsible for dentatorubral–pallidoluysian atrophy normally encodes a 4.5-kb transcript that is expressed in all tissues. The predicted normal polypeptide chain is 1184 residues long and contains the usual polyglutamine tract corresponding to the CAG repeat that is enlarged in the mutant protein.

In myotonic dystrophy, the aberrantly expanded CTG repeat resides in the 3′ untranslated region of a **serine–threonine protein kinase**.

A large scale screening project for CAG and CTG repeats in human reference cDNA has been undertaken. Nine new cDNA containing polymorphic CAG/CTG repeats have been identified and assigned to chromosomes. Three of them are highly polymorphic and represent the most likely candidate genes for inherited neurodegenerative diseases and, perhaps, neuropsychiatric disorders of multifactorial origin (5).

Triple Helix, Nucleic Acids

The formation of a triple-stranded nucleic acid structure, specifically, a triplex helix, was demonstrated nearly 40 years ago. It was found that titration of poly(A) with poly(U) resulted in two distinct types of stable structures: that of the 1:1 duplex and the 1:2 triplex. In the latter structure, the third strand of poly(U) is bound to the poly(A) strand of the poly(A).poly(U) duplex using Hoogsteen base pairs. The recent resurgence of interest in the triple helix is due primarily to its possible role in gene transcription and its possible application in the design of antisense oligonucleotides. It has been shown that stretches of $(GA)_n$:$(TC)_n$ sequence in a **plasmid**, which were found to be hypersensitive to **nucleases** during active transcription, underwent a notable change in DNA structure when the plasmid was negatively **supercoiled** under low-pH conditions. The structural change has been interpreted to be the formation of a triple helix for part of the $(GA)_n$:$(TC)_n$ sequence (named H-DNA), rendering the extrusion of a single-stranded loop. The three-dimensional structures of a number of triple-stranded DNA molecules have been studied by NMR. One such example is shown in Figure 1. As noted above, the formation the T.A.T triple base pair requires a Hoogsteen base pair. A similar triple C.G.C base pair is not stable unless the second C is protonated (thus forming a $C.G.C^+$ triple base pair). This explains the need for a low pH for H-DNA. Thus far, it has been shown that the formation of a stable triplex helix of the (Py).(Pu).(Py) type is relatively straightforward. It remains a challenge, however, to design oligonucleotides that can bind to a specific DNA duplex using all four bases.

Triple Resonance

A nuclear magnetic resonance (NMR) experiment involves application of pulses of RF energy to the sample under examination. At least one of these pulses must have a frequency that is close to the Larmor frequency of the spins of the sample that are to be observed (see NMR). Thus, application of a pulse at 750 MHz is sufficient to produce proton NMR signals from a sample that resides in a magnetic field of 17.62 T. When all of the RF pulses used for an experiment are at the same frequency, the experiment is referred to as a single-resonance NMR experiment. More complex experiments may use RF pulses at two different radiofrequencies; these are double resonance experiments. NMR experiments used to provide information for the determination of the tertiary structures of proteins or nucleic acids, commonly use materials that have been isotopically enriched in ^{13}C and ^{15}N. In these experiments, RF pulses near the ^{13}C, ^{15}N, and proton Larmor frequencies are applied to the sample to effect various coherence transfers or to produce spin decoupling; such experiments are triple resonance experiments. Multiple resonance experiments of almost any type are technically feasible, although the expense of these increases substantially as the number of different RFs involved increases.

Multiple resonance NMR experiments are often indicated by means of the notation M{X, Y,¼}, where M is the chemical symbol for the nucleus whose NMR signals are detected in the experiment, and X, Y,¼ are the chemical symbols for other spins of the sample that are affected by RF pulses applied at other radiofrequencies. Thus, the triple resonance experiments used to determine biological structures are indicated by $^{1}H\{^{13}C, ^{15}N\}$. (See also NMR and **Isotope filtering**.)

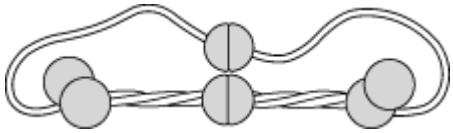
Triple-Helical Proteins

Reports of proteins with structures containing three interwound a-**helices** are becomingly increasingly common. One of the first to be characterized was collagen, a major component of connective tissue. Type I collagen contains two identical and one different chain, whereas other collagen types may contain either three unique chains or even three identical chains. Hence, both heterotrimers and homotrimers occur naturally *in vivo*.

Fibrinogen, a blood plasma glycoprotein with a molecular weight of about 340 kDa in humans, comprises a pair of heterotrimers, each containing an a, b, and g chain. The *N*-terminal **domains** of all six chains form a central, **disulfide-bonded** globular region, from which two identical three-stranded coiled-coil rod domains emanate. Each is about 16 nm in length and is stabilized at both ends by a cyclic pattern of interchain disulfide bonds. The rods terminate in globular regions, thus generating a trinodular structure for fibrinogen (Fig 1). These outer nodules consist of the *C*-terminal regions of both the b and g chains. The *C*-terminal region of the a chain, however, loops back and

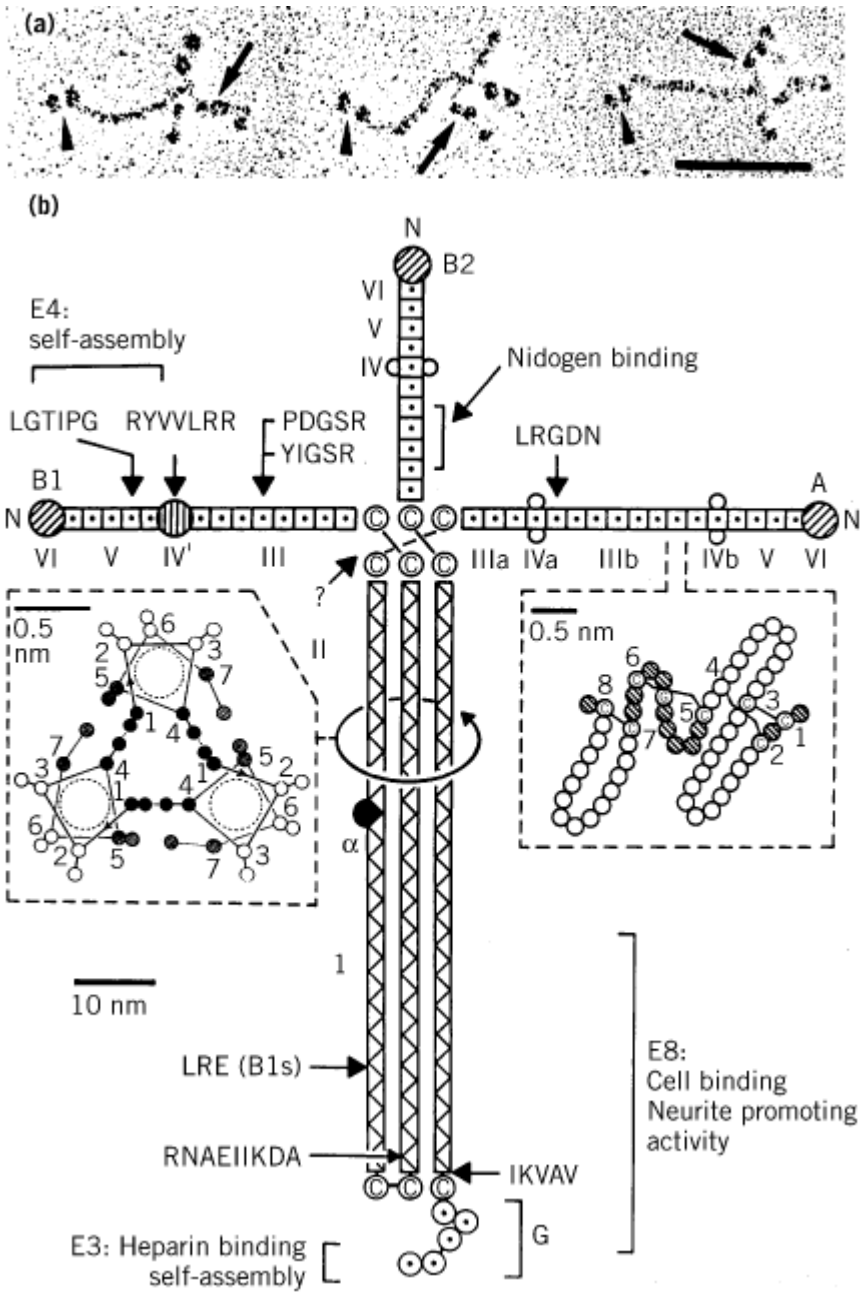
interacts with the central *N*-terminal disulfide-bonded knot. The D fragment from fibrinogen (86 kDa) has been crystallized (1), and its structure is currently being determined at atomic resolution.

Figure 1. The trinodular structure of fibrinogen, which consists of a pair of abg heterotrimers. The *N*-terminal regions of the a-, b-, and g-chains are cross-linked by disulfide bonds and together constitute the central nodule. Triple-helical coiled-coil rods extend from the central disulfide-bonded knot and terminate in the two outer nodules, which comprise the *C*-terminal ends of the b- and g-chains. The *C*-terminal end of the a-chain, however, folds back and interacts with the central nodule. (Courtesy of C. Cohen and D. A. D. Parry.)



Laminins have many functions in cellular processes and in the organization of the extracellular matrix. Some of the cellular functions include the promotion of growth, differentiation, neurite outgrowth, guidance, mobility, attachment, and mediation of cell communication (2). Laminins are a family of large multidomain **glycoproteins** with molecular weights about 800 to 900 kDa. While there are variations in the structures of different laminin molecules, each consists of three different chains that are disulfide-bonded to one another. They also form a characteristic, asymmetric cross-like structure (Fig 2). The chains aggregate via a long three-stranded coiled-coil domain of somewhat irregular heptad substructure that is located at or relatively close to the *C*-terminal ends of the chains. The three remaining ends of the cross are terminated by small globular domains. Each arm in turn comprises a series of tandem repeats or modules akin to epidermal growth factor motifs.

Figure 2. Structures of laminins. (**a**) Electron micrographs of rotary-shadowed sea urchin laminin showing an asymmetric cross shape. The long arm is 110 nm in length. The arrows indicate one of the short arms with three globular domains (A-chain), and the arrowheads show a short region of extended structure separating globular domains at the *N*-terminal end of the long arm. Bar = 100nm. (**b**) Model of mouse laminin molecules (A–B1–B2 heterotrimer). Different regions of the molecules are designated by Roman numerals. Synthetic peptides used in functional analyses are given in capital letters. Squares and circles with a central dot indicate the *eight-cysteine* and the *sex hormone-binding globulin* motifs, respectively. The three-stranded coiled-coil is stabilized at either end by disulfide bonds, indicated by the letter C in a circle. Ref. 11, with permission.)



There are many other triple-helical proteins.

1. These include macrophage scavenger receptor protein (3), a type II **transmembrane protein** in which the sequence contains motifs characteristic of both collagen (a triplet substructure based on glycine) and a-fibrous proteins (a heptad repeat with the nonpolar residues alternately three and four apart). The conformation of the extracellular domain in this homotrimeric molecule is believed to contain both a region of collagen-like triple helix and a three-stranded coiled-coil.

2. Mannose-binding protein, a member of the *collectin* family that consists of 18 chains arranged as a hexamer of homotrimers, facilitates the recognition of pathogens by **phagocytes** and plays a key role in first line host defense (4). Each chain has an *N*-terminal region rich in cysteine residues, 19 collagen repeats, a heptad-containing substructure, and a *C*-terminal region that is the carbohydrate-recognition domain. Mannose-binding protein, with its three- and seven-residue motifs, has a strong structural similarity with macrophage scavenger receptor protein and lung surfactant D.

3. Another three-stranded structure is found in the gp17 tail fiber of **bacteriophage** T7 (5). It contains a heptad repeat and forms a coiled-coil about 16 nm in length. The 150 residues *N*-terminal to the rod link the fiber to the tail tube of the bacteriophage. The region *C*-terminal to the rod forms four globular domains in a rigid linear array. These form the "foot" of the tail fiber.

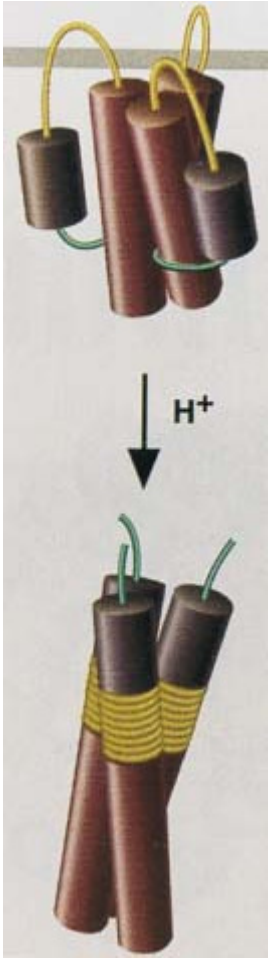
4. Evidence has also been presented to show that cartilage matrix protein (CMP) assembles through its *C*-terminal 36 residues into a three-stranded coiled-coil.

5. Tenascin, another major extracellular matrix glycoprotein, has some similarity with fibronectin. Each contains many **epidermal growth factor**-like repeats. Three tenascin chains aggregate via a short region of three to four heptad repeats to initiate the molecular structure.

6. The spectrin superfamily of proteins also form a triple helical structure, but in these cases a single chain folds to generate a three-a-helix motif.

7. The coiled-coil structure of the fibrous stem of the haemagglutinin in influenza virus displays a dynamic feature that is quite extraordinary. At neutral pH the stem forms a three-stranded coiled-coil about 8 nm in length. At pH 5, however, the coiled-coil is extended at its *N*-terminal end to generate a much longer coiled-coil (Fig 3). This is formed from a region that was a loop at neutral pH and from another (shorter) piece of coiled-coil that was oppositely orientated at the higher pH (6, 7).

Figure 3. The pH-dependent conformational change undergone by influenza virus hemagglutinin. At neutral pH (*top*) the fibrous stem of hemagglutinin consists (mainly) of a three-stranded coiled-coil of approximate length 8 nm, a loop, and a short stretch of a-helix oppositely oriented to the coiled-coil. At lower pH (*bottom*), however, the loop forms an extension to the coiled-coil at its *N*-terminal end. In turn, the a-helix becomes oriented in the same direction as the coiled-coil and the loop (now a coiled-coil) and adds even further length to it. The massive spatial change of the a-helical region promotes membrane fusion and cell entry *in vivo*. (From Ref. 12, with permission.) See color insert.



8. Finally, it should be noted that three=stranded protein structures are not restricted to collagen and a-fibrous proteins. A structure recognized only in recent times is one based on the b-**helix**, as in the crystal structure of the phage P22 tail spike (8). A similar conformation is proposed to occur in the long tail fibers of bacteriophage T4 (9) and in the adenovirus fiber (10).

Triploidy

In this type of **polyploidy**, somatic **nuclei** possess three copies of the basic haploid set of chromosomes. As a general rule, triploids undergo irregular **meiosis**, so the triploidy is not normally passed on to succeeding generations.

Tris Buffer

The primary amine known as Tris, $(HO–CH_2–)_3C–NH_2$, is frequently used in buffer solutions (see Buffers). It has a pK_a of 8.1 at 25 °C. The name *Tris* is derived from old forms of the name, such as tris(hydroxymethyl)methylamine; this is unambiguous, even if not quite in accord with modern systematic practice.

The hydroxy groups are electron-withdrawing, so that the lone pair on the nitrogen atom is much less

available than in a typical primary amine. This lowers the pK_a of Tris to 8.1, so that it is suitable for buffering near neutral pH. This, however, raises the first disadvantage of Tris, that the pK is not quite low enough for much biological work. If a Tris buffer has a pH of 7.5 or below, less than a fifth of the Tris will be in the R–NH_2 form with an amino group, and over 4/5 as R–NH_3^+ with an ammonio group (since 0.6 pH units below the pK_a implies a [R–NH_3^+]/[R–NH_2] ratio of 4). Hence, the buffering will be less for a fixed concentration of such a Tris buffer than for a buffer of the same concentration with a pK_a closer to the pH to be used.

An advantage of Tris is that both the free base and its hydrochloride are commercially available, so that a buffer can be made reproducibly without depending on pH measurements, by weighing out the required amounts of each form. This is valuable for any buffer, but especially so for Tris; it shares with all amines the property of a large positive DH for dissociation of the R–NH_3^+ form, so that the pK_a decreases with heating, by 0.028 per degree Celsius. Hence, accurate temperature control is necessary for pH measurements and adjustments.

The reactivity of Tris as a primary amine is not important for most uses, and its transparency in the UV can be helpful.

Trisomy

Trisomy is a special case of aneuploidy where one chromosome (or part of a chromosome) is represented in three copies instead of the normal two for a **diploid** cell. An extra or missing chromosome is the most frequent cause of mental retardation in humans, in whom partial or total trisomies of all chromosomes have been described. The five chromosomes most involved in this type of human aneuploidy are X, Y, 18, 13 and 21.

Trisomy 21, associated with Down's syndrome, is the most common aneuploidy among humans born alive. The karyotype of trisomy 21 has 47 chromosomes in all the cells of the organism, or only in certain cells (**mosaic**). A karyotype of 46 chromosomes has, however, been described, in which the supernumerary chromosome 21 is totally translocated onto chromosome 14. Partial trisomies are caused by chromosomal translocations. One example among many is a partial trisomy 21 of the short arm-centromere proximal long arm segment caused by maternal translocation to chromosome 12 (1). Partial trisomy 8 is accompanied by mild mental retardation, strabism, and anomalies of the skeleton. Trisomy 13 is characterized by altered skull and face morphology and often by polydactyly. Partial trisomy 22 is believed to be associated with **retinoblastoma**, etc.

1. Fine Localization of Trisomy 21

The preponderant role of the distal third of the long arm in Down's syndrome of trisomy 21 is well established. Trisomy of only band 21q22 results in a state identical to that caused by complete trisomy 21. If the trisomy involves only a part of the above band, the symptoms are diminished, but the appearance of the patient is still reminiscent of Down's syndrome. Monosomy in band 21q22 is lethal. Trisomy of the adjacent region 21q21 is not associated with malformations but leads to mental retardation (2).

2. Parental Origin and Cell Stage of Chromosomal Nondisjunction

In a study of 62 aneuploids with total trisomy 18, 56 were maternal in origin and only six paternal. Among the 56 maternally derived trisomics, a postzygotic error in **mitosis** could be excluded in 52 cases. Among those in which chromosomal nondisjunction was attributable to an error in **meiosis**, 11 were the result of meiosis I nondisjunction and 17 were caused by a meiosis II error. This result differs markedly from findings in **acrocentric** chromosomes, where nondisjunction at maternal meiosis I predominates. Among the six paternally derived cases, two originated from a meiotic error, showing that nondisjunction in paternal meiosis is not as rare as previously suggested (3).

Out of 100 cases of trisomy 21, the overwhelming majority of 94 were maternal in origin. This value, obtained with specific DNA markers, is significantly greater than the 75 to 80% nondisjunction rate observed in cytogenetic studies and illustrates the increased accuracy of the molecular approach (4). Among 36 cases of total trisomy 21 in which the supernumerary chromosome was of paternal origin, 15 were consistent with meiosis II errors, 8 with mitotic errors, and only 7 with meiosis I nondisjunction, this contrasts with maternally derived trisomy 21, in which meiosis I errors predominate. Study of the correlation with parental age indicates that the well-known increase in frequency of trisomy 21 with increasing age of the mother is caused by maternal nondisjunction (5).

2.1. Biochemical Studies

Patients with Down's syndrome due to trisomy 21 exhibit elevated activity of copper zinc superoxide dismutase, caused by the increased dosage of the **gene** for this enzyme, which is encoded at position 21q.22.1 of chromosome 21. Conflicting results have been reported, however, implicating this enzyme in Down's syndrome (6),(7).

Trithorax Group Genes

The trithorax group (trxG) consists of a genetically defined class of **genes** responsible for maintaining the active expression state of homeotic genes. Through the differential expression pattern of homeotic genes, cells become programmed to support specific structures and functions. Mutations in any member of the trxG result in reducted homeotic gene expression and in homeotic body pattern transformations. For the reciprocal process, the genes of the Polycomb group (PcG) are necessary for maintaining the repressed state of homeotic gene expression. In *Drosophila*, both groups are part of what is called a “cellular memory” mechanism. Their task is not to initiate the differential expression pattern of homeotic genes, which in *Drosophila* is performed by the early-acting patterning factors encoded by maternal and segmentation genes, but to maintain the genetic expression status stably and heritably over developmental time (for reviews, see Refs. 1, 2). Subsequently, it was found that many other developmentally important genes, whose expression patterns needs to be tightly and faithfully maintained, are also targets of this type of regulation in

addition to the homeotic genes.

Molecular analysis of several members of the two groups indicate involvement of their protein products at the level of chromatin structure. Each group acts in large multiprotein complexes to fulfill its functions. Although PcG proteins cooperate to generate **silenced** chromatin structures, to keep genes inactive, the proteins of the trxG cooperate to counteract the PcG-repressed chromatin by modifying chromatin structures for transcriptional activation.

1. The Trithorax protein and its targets

The gene *trithorax* (*trx*), the name-giving member of the group, was identified by its requirement for normal expression of multiple homeotic genes of the **bithorax** and Antennapedia complex. Different homeotic genes and their **promoters** are affected differently in *trx* mutants, suggesting a coordinated spatial and temporal requirement for *trx* to achieve normal expression patterns (3, 4). Several parts of homeotic gene expression are dispensable of *trx* function and probably require other factors of the trxG, like *ash1*, for maintenance (5, 6).

The *trx* gene expresses a complex pattern of messenger RNA transcripts which encode two large protein isoforms (4, 7, 8). The TRX proteins are characterized by containing several evolutionarily conserved protein motifs, a novel variant of the nuclear receptor-type **DNA-binding domain**, a 130- to 140-residue motif known as the SET domain, and a C_4HC_3 **zinc-finger** motif, known as the PHD finger. The SET domain is also found in ASH1 and in other chromatin-associated proteins, including Enhancer of Zeste, a member of the PcG (6, 9). The SET domain was functionally analyzed in yeast on a protein having this conserved part. It was demonstrated that the **domain** is necessary for transcriptional silencing and for other cellular processes dependent on defined chromatin structures (10). The PHD finger is found in a large class of nuclear proteins, most of which function as adapters between specific activator proteins and other components of the transcription machinery. A potential role in mediating protein–protein interactions has been proposed, but the precise molecular function of the domain remains unknown. Although no direct sequence-specific DNA-binding activity has been demonstrated for TRX *in vitro*, it was found by **immunostaining** that the protein binds to approximately 75 chromosomal sites on polytene chromosomes (7, 11). Interestingly, many TRX binding sites overlap with binding sites of PcG proteins at chromosomal elements known as PcG response elements (PRE), suggesting a functional cross talk between these counteracting factors (11, 12).

2. Brahma and the chromatin-remodeling machines

The trxG member *brahma* (*brm*) was isolated in a genetic screen searching for dominant **suppressors** of homeotic transformations produced in Polycomb mutants (13). The idea behind this screen was to identify additional genes involved in inactivating the expression of homeotic genes. Indeed, it was found that *brahma* mutants cause developmental defects similar to other mutants that fail to express homeotic genes adequately (14). Molecular analysis showed that the Brahma protein is homologous to the yeast SWI2 protein, a DNA-dependent ATPase (15) and also part of a multiprotein complex with similarities to the well-known SWI/SWF complex from yeast.

Identification of the function of Brahma and its relationship to yeast components involved in transcriptional activation was the key to isolating other components associated in what are now called chromatin-remodeling machines (16). ISWI is another SWI2 **homologue** of *Drosophila* and is found in several multiprotein complexes involved in opening chromatin structures in an energy-dependent fashion (17, 18). Thus far, four different machines involved in chromatin-remodeling processes have been isolated in *Drosophila*: (1) the BRM-SWI/SNF complex, whose ATPase activity is DNA-dependent; (2) the NURF complex, whose ATPase activity relies on chromatin; (3) CHRAC, where energy is used to increase DNA accessibility in chromatin; and (4) ACF which, like the previous two, is also an ISWI-containing and ATP-utilizing chromatin-assembly and remodeling

factor (for a review, see Ref. 19). The GAGA factor was originally identified biochemically as a DNA-binding transcriptional activator (20). GAGA factor cooperates with complexes like NURF to remodel chromatin. The recent isolation of mutations in the GAGA factor-encoding gene revealed a **phenotype** similar to *trx*. Hence, the gene was called Trithorax-like (TRL) and was classified as a trxG member (21).

3. Vertebrate homologues

Several members of the *Drosophila trxG* have counterparts in humans and mice. The mixed-lineage leukemia (MLL) gene (also known as ALL-1, HRX, Htrx), a TRX homologue, was found through its involvement in the majority of infantile acute lymphocytic and mixed lineage leukemias (for a review, see Ref. 22). Disrupting the murine *Mll* gene by gene targeting causes homeotic transformations of the vertebrae in heterozygotes and loss of homeotic gene expression, supporting the notion that *Mll* is a functional equivalent of *trx* (23). Moreover, conserved components of chromatin-remodeling complexes were found in mammalian systems. Two genes, *mbrm* and *brg1*, are homologues of *brm* and also part of a SWI/SNF-like complex (24-26). Another SWI/SNF component is encoded by the human *HSNF5 (Ini1)* gene, and the putative Drosophila homologue *snr1* interacts genetically with *trx* and *brm* (16, 27).

Initially, the genetic definition of the trxG been an entry point to identify genes involved in maintaining homeotic gene expression. It is becoming increasingly clear, however, that several members of the group fulfill much broader tasks and are parts of the general transcriptional activation complexes, thus allowing an assessment of the molecular interactions of these important regulatory factors that control transcriptional and eventually, other chromosomal processes at the level of chromatin structure.

Triton X-100 And X-114

Structural variations in **hydrophobic** side chains produce two different detergents in the Triton family, Triton X-100 and Triton X-114, that have markedly different physicochemical properties (see Detergents). Early studies showed that the polyoxyethylene glycol detergent Triton X-100 has a very low critical micelle concentration (cmc of 0.2 mM and is highly efficient in solubilizing membrane proteins without dissolving much membrane lipid (1). This strongly hydrophobic detergent and the structurally related Nonidet P-40 are widely used in lysing cells and solubilizing membrane proteins. Integral membrane proteins, whose functional activity does not critically depend on membrane lipids, are successfully solubilized by using Triton X-100. Examples include the receptors for **GABA** (2), prostacyclin (3), prolactin (4), transferrin (5), and insulin (6). Although Triton X-100 is highly efficient in solubilizing membrane proteins, it is relatively mild and non**denaturing** toward soluble, globular proteins, such as the g-globulins (see Immunoglobulin). This is underscored by the large number of current reports, in which cell lysis in a buffer containing 1% Triton X-100 or the closely related detergent Nonidet P-40, is successfully followed by **immunoprecipitation** of specific proteins (7-9).

Triton X-114 is prominent in recent literature for specific reasons. This detergent has a strikingly

greater solubility in water at lower temperatures (0°C), whereas at higher temperatures (30°C) it separates from water to form a separate detergent phase (10). Upon the formation of a discrete layer, the detergent retains specific, detergent-solubilized proteins, so the property of phase separation has been used in protein purification studies. When membrane proteins of adrenal medullary chromaffin granules are subjected to such fractionation in Triton X-114, cholesterol- and phospholipid-associated proteins like **ATPase I** and **glycoprotein** IV are obtained as detergent-insoluble proteins following solubilization at 0°C. Next, the detergent solution is warmed and layered over a cushion of 0.25 M sucrose in buffer containing 0.06% Triton X-114 and then centrifuged (see Density Gradient Centrifugation). The resulting aqueous phase (top layer, 0.04% Triton X-114) contains a mixture of soluble proteins, chromogranin A, soluble DBH, and membrane glycoproteins III, H, J, and K. Then the glycoproteins are isolated by removing the top layer, followed by exhaustive dialysis at 4°C in a buffer containing 1% Amberlite XAD-2 (11). Based on this phase separation method and the earlier observation that detergents with low cmc values (such as Triton X-100 and Triton X-114) are relatively inefficient in solubilizing the **GPI-anchored** proteins, Hooper and Bashir developed a technique of differential solubilization and temperature-induced phase separation in Triton X-114 to distinguish between the GPI-anchored proteins and those anchored by a simple membrane-spanning polypeptide (12, 13). When this method is applied to pig kidney microvillar membranes, abundant in both GPI-anchored and polypeptide-linked ectoenzymes, Triton X-114 at 0°C solubilizes only the ectoenzymes harboring a polypeptide anchor, whereas the GPI-linked ectoenzymes are sedimented by low-speed centrifugation. Then the detergent-solubilized supernatant is further fractionated by phase separation at 30°C into an aqueous phase and a detergent-rich phase, which contains the polypeptide-linked ectoenzymes.

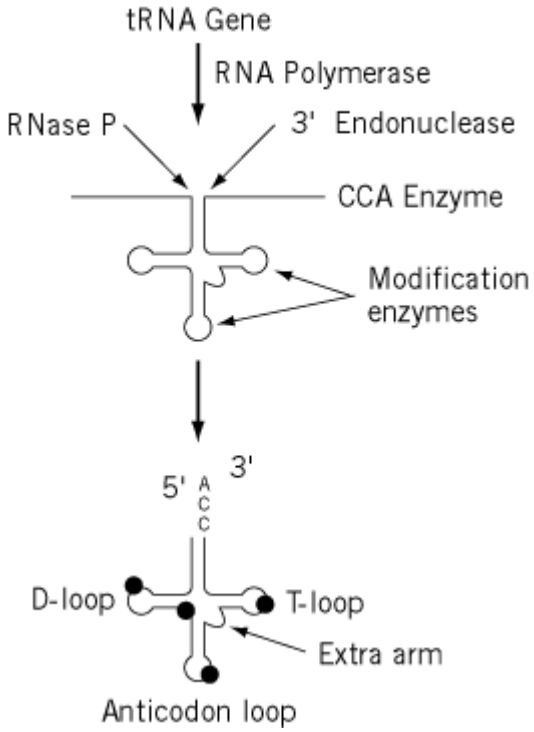
tRNA Biosynthesis

Depending on the organism and the organelle, any particular transfer RNA (tRNA) may be **transcribed** from the genome into an RNA molecule along with other tRNA, with messenger RNA

(mRNA), or with ribosomal RNA (rRNA). Therefore, the first step in tRNA biosynthesis in many cases is the initial release of a precursor tRNA from such a **polycistronic** transcript. tRNA precursors share the need for certain **posttranscriptional processing**, either as part of the releasing process or subsequent to it. These shared needs include removal of the 5′-leader and 3′-trailing sequences and modification of bases (Fig. 1). Addition of the trinucleotide CCA at the 3′ end is thought of as a universal requirement, and it is in **eukaryotes**, because the CCA end is not encoded in the gene. In contrast, many prokaryotic tRNA gene transcripts do not require CCA addition as an initial processing event, because it is provided in the primary transcript and becomes the 3′-terminal sequence after other 3′-processing **nucleases** remove downstream nucleotides. Some tRNA require additional posttranscriptional alterations for their maturation. These include 5′-base addition, removal of intervening sequences, and RNA **editing**. While there are critical sequence-specific requirements for some RNA processing enzymes, it is safe to state the general rule that the most critical substrate characteristic for tRNA processing enzymes is retention of the overall tRNA structure in the precursor. It has also been shown that tRNA processing can proceed via alternative routes such that end processing can either precede or follow splicing (1) and splicing can begin with cleavage at either the 5′ or 3′ end of the intron (2) (see discussion below).

Figure 1. Schematic diagram of tRNA biosynthesis. Transcription produces a pre-tRNA that is trimmed on the 5′ end by RNase P and on the 3′ end by an endonuclease (or exonuclease) in preparation for CCA addition. Base modification reactions occur throughout the processing pathway. Some tRNA genes have intervening sequences which are not shown here but are described in the text.



1. Removal of 5′ Leader

The 5′ leader is removed from tRNA precursors by ribonuclease P (RNaseP), an enzyme found in all organisms and organelles in which tRNA genes are found. The cleavage reaction is a hydrolysis, requires both monovalent and divalent cations, and leaves a 5′-phosphate on the mature tRNA and a 3′-hydroxyl on the 5′ leader. Prokaryotic, eukaryotic and organelle RNaseP enzymes, with some possible exceptions, are ribonucleoproteins and require both the RNA and protein subunits for

activity *in vivo*. Remarkably, the RNA subunit is responsible for catalysis in the bacterial enzymes (3) and is likely to serve the same function in eukaryotes. All RNaseP RNAs share short regions of sequence similarity and are predicted to take on similar elements of secondary structure. Although they can vary in size, most cluster in the 300–400-nucleotide range. The prokaryotic enzymes are about 10% protein, with a protein subunit of about 14 kDa (kilodaltons). Archaeal and eukaryotic enzymes are 50–70% protein, and the proteins identified so far are larger and share no sequence similarity to each other or to the prokaryotic proteins.

2. Removal of 3′ Leader

In some organisms, exoribonucleases perform 3′-end tRNA processing, while in others, endonucleases carry out that function. The best-studied exoribonucleases are from *Escherichia coli*. Six exoribonucleases that can trim tRNA precursors *in vitro* have been identified (4). Five can participate in 3′-end formation *in vivo*, but extensive functional overlap is demonstrated by the observation that cells retaining only one of these nucleases are viable. Complete 3′ processing *in vitro* required **ribonuclease** II and polynucleotide phosphorylase to shorten long 3′ trailers to intermediates extended by only two to four nucleotides. Final trimming by ribonulceases T and/or PH completes the process (5). The combined genetic and biochemical approaches of Deutscher and his colleagues have revealed that the relative importance of each exoribonuclease is different for different tRNA precursors, and that the combined action of the nucleases is most effective in maturing all tRNA. Whether exonuclease(s) or endonuclease(s) mature the 3′ end of nucleus coded tRNA in *S. cerevisiae* is still not established. However, examination of tRNA precursors and 3′ trailers from *Drosophila* (6), *Xenopus* (7), and silkworms (8) demonstrate that endonuclease cleavage prepares the 3′ end of nucleus-coded tRNA in these eukaryotes (9). Organelle tRNA precursor structure also establishes that 3′-end formation of mitochondrial and chloroplast tRNA is carried out by endoribonucleases. Indeed, these enzymatic activities have been measured in crude extracts and in some cases partially purified (10).

3. Addition of CCA 3′ End

ATP(CTP)-tRNA-specific nucleotidyltransferase adds the CCA end to tRNA, following 3′-end processing to provide the proper substrate. The enzyme also serves as a repair enzyme to restore the CCA end to tRNA victims of cellular nucleases and is required for this function regardless of whether the CCA end is gene-encoded. Since eukaryotic precursor tRNAs that contain intervening sequences have the CCA end, it is clear that the enzyme can bind partially processed tRNA. This is consistent with a model in which the enzyme interacts with tRNA at the corner of the tRNA where the T and D loops are juxtaposed and extends that interaction across the aminoacyl stem to the 3′ end (11).

4. Base Modification

Transfer RNA contains the highest concentration of modified bases of any type of RNA. There are 80 different nucleoside modifications known, and many display species and/or phylogenetic specificity (12). Modified bases are introduced after transcription and, depending on the enzyme, either precursor or fully processed tRNA can serve as the preferred substrates. In both prokaryotes and eukaryotes, characterization of precursors demonstrates that modifications do occur in a stepwise fashion (13, 14). Further enforcing an order of addition for nucleus-coded tRNAs, certain tRNA modification enzymes are confined to either the nucleus or the **cytosol**. Mutants deficient in a particular modification enzyme activity, so that a particular modification is not made, do complete subsequent modifications (10). Thus it is clear that an obligate order of modification per se is not required. Certain anticodon modifications are not found in unspliced precursors, suggesting that there is a requirement for splicing prior to the synthesis of the modified bases located in the anticodon region (15).

Histidyl tRNAs contain an extra 5′-G nucleotide relative to all other tRNAs. In *E. coli*, the G is derived transcriptionally, and RNaseP does not remove the extra G when it processes the 5′ end (16). In yeast, however, the 5′-most G in the histidyl tRNA is added by a histidyl tRNA guanylyltransferase in an ATP-dependent reaction (17). The 5′-G of spinach chloroplast histidyl tRNA is derived by transcription (18), whereas that of animal mitochondria is added posttranscriptionally (19).

5. Intron Removal

Since intervening sequences (introns) were discovered in yeast tRNA genes (20), the mechanisms involved in their removal have been sought. Splicing is initiated by an endonuclease that cleaves the pre-tRNA at the splice sites. Biochemical purification of the enzyme has been completed, and it is known to consist of three polypeptide subunits of 31, 42, and 51 kDa (21). Release of the intron leaves a 2′,3′-cyclic phosphate on the 3 end of the 5′ half of the tRNA (22), and a 5′-OH on the 5′ end of the 3′-half of the tRNA (23). The two half-molecules serve as the substrate for a tRNA *ligase*, which carries out the following steps: (i) creation of a 2′-phosphate by **phosphodiesterase** activity at the 2′,3′-cyclic phosphate; (ii) phosphorylation of the 5′-OH on the 3′ half by a **polynucleotide kinase** that uses GTP as the phosphate donor (24); (iii) transfer of AMP from the **adenylylated** form of the enzyme to the 5′-P on the 3′ half of the tRNA; and (iv) joining of the tRNA halves with the release of AMP (25). At this stage, the product contains a 3′,5′-phosphodiester linkage, as well as a 2′-phosphomonoester. The latter is removed by an **NAD**-dependent 2′-phosphotransferase in a reaction in which the 2′-phosphate displaces the nicotinamide part of NAD, to yield ADP-ribose 1′′–2′′ cyclic phosphate (26). The *RLG1* gene coding for the ligase has been characterized, and deletion analysis supports the idea that various activities can be attributed to separate domains in the protein (27). Similar enzyme activities are present in **HeLa** cell extracts, demonstrating that this is a conserved mechanism (28).

6. Editing

Like other RNA, tRNAs are substrates for **editing**, the remarkable process that alters the base sequence of an RNA after synthesis. So far, this type of tRNA processing has been identified only in mitochondria. Insertional editing in *Physarum* restores functional structure to mitochondrial tRNA (29). Substitutional editing also usually restores base pairing in stems. In *Acanthamoeba castellanni* A can be changed to G, U to G, and U to A, to correct mismatched base pairs (30). In the land snail, mitochondrial tRNAs sustain changes of C, U, and G to A that in all cases, except one, restore base pairing in the stem (31). This restoration of base pairing has been shown to be required for efficient removal of 5′ leaders and 3′ trailers in plant mitochondria (32, 33) consistent with the observation that tRNA-processing enzymes require at tRNA structure for optimal function. Finally, a C-to-U change in the second position of the anticodon of marsupial mitochondrial $tRNA^{Asp}$ is necessary for proper codon recognition (34). Although the mechanisms are not clear, there is no reason to expect that tRNA transcript editing is different from those editing processes operating on other RNAs.

tRNA Ligase

tRNA ligase is a form of RNA ligase that is thought to function in all eukaryotic cells. Its biological role is to catalyze the splicing of the precursor to transfer RNA. In contrast to the RNA splicing that occurs with messenger RNA, which proceeds via transesterification, without a protein to catalyze the

cleaving and ligating reactions, tRNA splicing requires both latter enzyme activities. The tRNA ligase of *Saccharomyces cerevisiae*, which is the most-studied (1), is a single polypeptide chain of 95.4 kDa comprised of **domains** that correspond to cyclic phosphodiesterase, kinase, and adenylylation activities. The overall reaction is quite similar to those of T4 **polynucleotide kinase** plus T4 RNA ligase, the only difference being that a 2′-phosphate group occurs with tRNA ligase, rather than a 2′-hydroxyl (see Fig. 2 of RNA Ligases). The mechanism of the reaction involves (i) opening of the 2′,3′-cyclic phosphate to a 2′-phosphomonoester (phosphodiesterase activity), (ii) addition of a phosphate group to the 5′-hydroxyl of the donor (kinase activity), (iii) transfer of an adenylyl group from an adenylylated enzyme, which is produced in advance by another kinase activity of the same enzyme, to the 5′-phosphate of the donor (adenylylation activity), and (iv) attack of the acceptor 3′-hydroxyl on the activated donor phosphoanhydride, to form a 3′,5′-phosphodiester bond (bond formation activity). The mature tRNA is then generated by the action of a distinct enzyme, 2′-phosphotransferase, which removes the 2′-phosphate from the product.

Yeast tRNA ligase has a rather strong substrate-specificity, while wheat germ tRNA ligase, another well-studied tRNA ligase, has less specificity and can also ligate oligo(A) and oligo(U_nG), in addition to tRNA precursors. The wheat germ and other plant (such as tobacco and *Chlamydomonas*) tRNA ligases are assumed to be exploited by viroids and virusoids for circularizing their **genomic** RNAs after **rolling-circle replication** and self-cleavage.

In addition to its catalytic function, tRNA ligase may play a role in transport within the nucleus of the precursor molecule that is to be spliced; this process seems to be performed by a group of PRP (precursor RNA processing) proteins in the case of mRNA splicing (2). Another novel function of yeast tRNA ligase is that it is involved in the splicing of the mRNA of Hac1 protein (a transcription factor required for the unfolded protein response) (3). This might unveil another important function of tRNA ligase, having a role in a crucial regulatory process.

Structural analysis of tRNA ligase is underway. In yeast tRNA ligase, Lys114 is responsible for accepting an adenylyl group by a phosphoamide bond. The region of the primary structure surrounding this lysine is well-conserved among tRNA ligases and T4 RNA ligase (see RNA Ligases) (Fig. 1). The region involved in nucleoside triphosphate-binding is also fairly well conserved among tRNA ligases, T4 polynucleotide kinase, and human 3′-cyclic nucleotide 3′-phosphodiesterase (4), implying that they have an evolutionary relationship.

TRP Operon

The **aromatic amino acid** tryptophan is synthesized by **plants** and by many **microorganisms**, but not by animals. The **genes** and proteins required for tryptophan biosynthesis were partially characterized very early in the history of modern molecular biology. Analysis and identification of all of the intermediates in the tryptophan pathway provided the background information and material that fostered numerous subsequent investigations. Studies were performed on the relationship between gene, enzyme, and biochemical reaction, enzyme structure and function, enzyme reaction mechanisms, and operon organization and regulation. Seven enzymatic functions are required to synthesize this amino acid from its common precursor, chorismate. Chorismate is also the source of the other amino acids, phenylalanine and tyrosine, as well as additional aromatic metabolites. Therefore, tryptophan formation must compete with other essential biosynthetic processes. The products of other pathways are also required for tryptophan formation. These include three co-substrates, L-glutamine, 5-phosphoribosyl-1-pyrophosphate, and L-serine, and the coenzyme, pyridoxal phosphate.

In this article we summarize our current understanding of the many features of the organization and functions of the *trp* operon of *Escherichia coli* and *Salmonella enterica*. We describe the operon's polypeptide products, the enzyme complexes they form, and how these enzymes catalyze the individual reactions of tryptophan formation. We also describe how operon expression is regulated and discuss the significance of the various regulatory mechanisms that these organisms use.

1. The *TRP* Operon of *E. coli* and *S. enterica*

The *trp* operon of *E. coli* and *S. enterica* is a single transcriptional unit that has five major structural genes (Fig. 1). The regulatory region has features that allow these organisms to sense and respond to changes in the availability of both tryptophan and tryptophan-charged $tRNA^{Trp}$, $Trp\text{-}tRNA^{Trp}$ (2, 3). Transcription initiation at the principal **promoter**, *trpP1*, is regulated by the tryptophan-activated trp repressor (2). Continuation of transcription beyond the regulatory region into the structural genes of the operon is regulated by transcription **attenuation**. This mechanism permits these bacteria also to regulate operon expression in response to changes in the intracellular level of $Trp\text{-}tRNA^{Trp}$ (3). An inefficient internal promoter, *trpP2*, is located at the distal end of *trpD* (Fig. 1) (1). *trpP2* directs the synthesis of a minor transcript containing *trpC*, *trpB*, and *trpA* genetic information (1). The operon's terminus is defined by two adjacent sites of transcription termination, designated *t* and *t′* (1)(Fig. 1). The first of these, *t*, is a relatively inefficient factor-independent termination site, whereas the second, *t′*, is a site of efficient **Rho-**dependent termination.

Figure 1. The *trp* operon, and the intermediates, reactions, and enzymes of tryptophan biosynthesis. The *trp* operon of *E* consists of five major structural genes (shaded rectangles) that encode the five polypeptides that catalyze tryptophan

formation. Two of the structural genes, *trpD* and *trpC*, have two genetic segments and encode bifunctional proteins. The structural genes are preceded by a transcribed leader region that contains *trpL*, a coding region for a 14-residue leader pe Transcription of the operon is initiated at the principal promoter, *trpP1*, and at an internal promoter, *trpP2*. (The transcri initiation sites are marked by horizontal arrows below the operon map) Transcription of the operon can be terminated at attenuator (*attn.*) in the regulatory region or can continue to the end of the operon and stop at either of the tandem termin sites, marked *t* and *t′*. Tryptophan biosynthesis from chorismate requires catalysis of seven reactions by enzyme domains designated TrpA through TrpG. The first two reactions are performed by a complex that contains the TrpE and TrpG domains. The next three reactions are catalyzed by the independent functional domains, TrpD, TrpF, and TrpC; however TrpG and TrpD are covalently joined, as are TrpC and TrpF. The last two reactions proceed at the separate active sites o TrpA and TrpB polypeptides of the tryptophan synthase complex, the product of the TrpA reaction, indole, being channe to the active site of TrpB. The features of the *trp* operon of *S. enterica* and its products are virtually identical to those of *coli.* PRPP = 5-phosphoribosyl-1-pyrophosphate. G3P = D-glyceraldehye-3-phosphate.

2. Reactions and Enzymes of Tryptophan Biosynthesis

Biosynthesis of tryptophan proceeds from chorismate, the precursor of most aromatic compounds in the cell, by the pathway shown in Fig. 1 (1, 2). The aromatic ring of tryptophan is derived from chorismate, the carbons and the nitrogen of the indolyl ring from 5-phosphoribosyl-1-pyrophosphate (PRPP) and L-glutamine, respectively, and the alanyl side chain from L-serine. In *E. coli* and *S. enterica* the seven reactions of the tryptophan pathway are catalyzed by three **multifunctional enzymes** made up of the five polypeptide products of the *trp* operon. Two of the polypeptides are bifunctional; each consists of two **domains**. Thus, the pathway relies on the sequential action of seven functional domains (Fig. 1).

The first three reactions of the pathway—production of NH_3 from glutamine, synthesis of anthranilate from chorismate, and phosphoribosylation of anthranilate with PRPP—are carried out by an enzyme complex consisting of the TrpE and TrpG-D polypeptides, which have anthranilate synthase and glutamine amidotransferase-anthranilate phosphoribosyl (APR) transferase activities, respectively. The fourth and fifth reactions, the conversion of phosphoribosyl anthranilate (PRA) to 1-(*o*-carboxyphenylamino)-1-deoxyribulose-5-phosphate (CdRP) and of CdRP to indoleglycerol phosphate (IGP), are catalyzed by the bifunctional IGP synthase-PRA isomerase polypeptide (TrpC-F). The sixth and seventh reactions, the formation of indole from IGP, and L-tryptophan from indole and serine, are performed by the IGP aldolase (TrpA) and L-serine hydro-lyase (adding indole) (TrpB) activities of the tryptophan synthase complex ($TrpA_2TrpB_2$, or TSase a_2b_2).

The enzymes of *E. coli* and *S. enterica* are very similar in structure and function. Active heterologous anthranilate synthase and tryptophan synthase complexes that contain one subunit from *E. coli* and one from *S. enterica* readily assemble and function *in vivo* and *in vitro*. Nevertheless, there is considerable variation among other microorganisms with respect to the molecular organization of the seven protein functional domains. In some bacteria, all seven domains exist independently, whereas in other bacteria and some fungi, a variety of domain fusions are found, including TrpE-TrpD, TrpG-TrpC, TrpG-TrpC-TrpF, and TrpA-TrpB.

3. Structure and Activity of the Tryptophan Biosynthetic Enzymes

3.1. Anthranilate Synthase and Anthranilate Phosphoribosyl Transferase

Anthranilate synthase, APR transferase of *E. coli* and *S. enterica* is a multifunctional, heterotetrameric, multienzyme complex (M_r = 228,200) composed of two TrpE and two TrpG-D polypeptides (Fig. 1) (4, 5). Assembly of the subunits into the complex occurs spontaneously *in vitro* and depends solely on interactions between the TrpE and the TrpG domains. The tetrameric complex is very stable and has no detectable dissociation or subunit exchange in solution. Anthranilate synthase activity, the synthesis of anthranilate (*o*-aminobenzoate) from chorismate and glutamine (Fig. 1), is catalyzed by the TrpE and TrpG domains of the complex. The APR transferase reaction, the formation of *N*-(5′-phosphoribosyl)-anthranilate from anthranilate and 5-phosphoribosyl-1-pyrophosphate (Fig. 1), is catalyzed by the TrpD domain of the complex.

In the anthranilate synthase reaction, the TrpG domain acts as a classic glutamine amidotransferase, hydrolyzing L-glutamine via a g-glutamyl-*S*-cysteinyl enzyme intermediate, and delivering its amide group to the TrpE subunit as nascent NH_3 (6). TrpG must be complexed with TrpE to elaborate its glutaminase activity, which is activated 20- to 30-fold by binding of chorismate at the active site of TrpE. The TrpE subunit uses the nascent NH_3 to aminate chorismate, forming an aminocyclohexadiene reaction intermediate that it then aromatizes to anthranilate with the release of

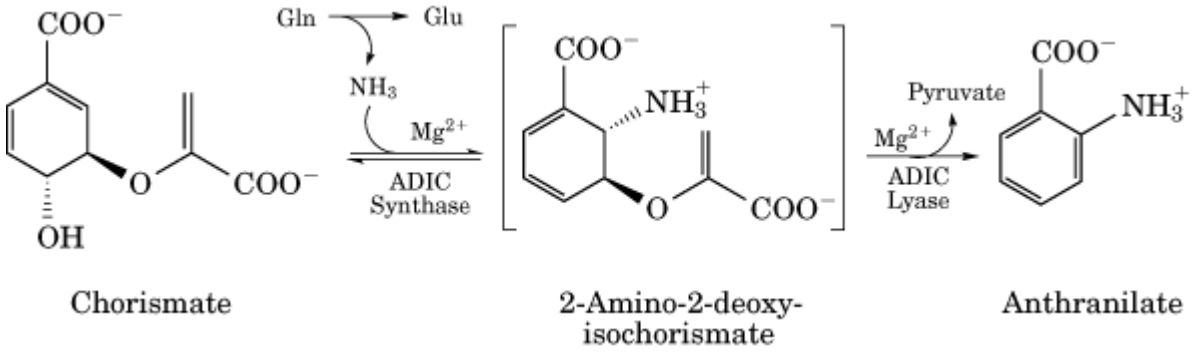
pyruvate (7). Complexed TrpE can use exogenous NH_3 in place of glutamine. The uncomplexed TrpE subunit, which lacks glutamine-dependent activity, can catalyze the NH_3-dependent anthranilate synthase reaction, albeit at a fivefold reduced rate. In contrast, the APR transferase activities of uncomplexed and complexed TrpG–TrpD are equivalent.

The anthranilate synthase and APR transferase reactions have an absolute requirement for a divalent metal cofactor, either Mg^{2+} or Mn^{2+}, whereas the glutaminase reaction is metal-independent. **Electron paramagnetic resonance**, NMR, and kinetic studies have demonstrated binding interactions between metal, chorismate, and the TrpE subunit, and between metal and the TrpD domain (8). It is believed that the role of the metal ion in the anthranilate synthase reaction is to serve as a general acid in catalyzing the elimination of the C4 hydroxyl group of chorismate. All of the activities of the complex are sensitive to **feedback inhibition** by L-tryptophan, mediated by its binding at a regulatory site on the TrpE subunit.

The TrpE subunit contains 520 residues (M_r = 57,100). Random mutational analysis and proteolytic probing has indicated that the polypeptide is composed of an amino-terminal regulatory domain of about 310 residues and a carboxy-terminal catalytic domain of about 200 residues (6, 9). Two separate clusters of residues have been identified by mutagenesis as essential for tryptophan binding and feedback inhibition: Glu39-Ser40-Ala41 and Asn288-Pro289-/-Met293-Phe294-/-Gly305. These residues are highly conserved in all known bacterial TrpE sequences. It is envisioned that these two polypeptide regions interact to form the tryptophan binding site in the folded polypeptide. Photoaffinity labeling of the TrpE subunit with 6-azidotryptophan, a false feedback inhibitor, has confirmed the role of the latter cluster as a structural component of the feedback site. Similar mutational analysis has identified five residues in the carboxy-terminal domain that are essential for catalytic activity: Thr329, His398, Thr425, Gly485, and Glu495. In addition, two arginine residues, Arg370 and Arg382, have been characterized as essential contact residues for assembling TrpE with TrpG in the formation of the intact complex.

The anthranilate synthase reaction proceeds as two sequential partial reactions (Fig. 2) (7). The first step, which is **rate-limiting**, is amination of chorismate, leading to the formation of the reaction intermediate, 2-amino-2-deoxyisochorismate (ADIC). ADIC remains enzyme-bound and is rapidly converted to anthranilate with the release of pyruvate. The two sequential reactions are referred to as the ADIC synthase and ADIC lyase reactions. Both the ADIC synthase and ADIC lyase activities of TrpE require Mg^{2+} and are feedback-inhibited by tryptophan. Mutant complexes that are substituted at His398 of the TrpE subunit have impaired ADIC lyase activity and therefore accumulate the intermediate. This made possible its isolation, identification, and use as a reagent in kinetic studies. It is likely that the role of His398 in the ADIC lyase reaction is either the abstraction of the proton from C-2 of ADIC or protonation of the leaving enol-pyruvyl group (Fig. 2).

Figure 2. The anthranilate synthase reaction. The reaction catalyzed by anthranilate synthase is a composite of two sequential subreactions, the conversion of chorismic acid to 2-amino-2-deoxy-isochorismate (ADIC) (ADIC synthase activity) and the conversion of ADIC to anthranilic acid (ADIC lyase activity). ADIC normally exists as an enzyme-bound reaction intermediate.



Chorismate | 2-Amino-2-deoxy-isochorismate | Anthranilate

The TrpG-D subunit contains 531 residues (M_r = 57,000). The TrpG domain is formed from the amino-terminal 193 residues of the polypeptide (M_r = 20,800) and the TrpD domain consists of the carboxy-terminal 331 residues (M_r = 35,500). The two domains are held together by a short peptide hinge. The bifunctional protein undoubtedly arose during evolution by the fusion of independent *trpG* and *trpD* genes (10). The TrpG and TrpD domains can be expressed as active, independent proteins, such as exist in other microorganisms, upon appropriate engineering of the *trpD* gene. The TrpD domain can also be removed from both the intact complex and the uncomplexed TrpG–TrpD subunit by *in vitro* trypsinolysis (5). Digestion by trypsin proceeds in three sequential steps from the carboxyl-terminal end of TrpD, suggesting the existence of three structural subdomains within TrpD. The limit cleavage event is at Lys193, the carboxy-terminal residue of TrpG. The resulting TrpE–TrpG "partial complex" is fully active in the anthranilate synthase reaction but lacks APR transferase activity. The independent glutamine amidotransferase domain assembles normally with TrpE, forming the tetrameric partial complex.

Anthranilate synthase is classified as a member of the family of Triad (formerly type G) glutamine amidotransferases (11). These are enzymes characterized by a glutamine amidotransferase domain that has active site Cys, His, and Glu residues arranged in a classic catalytic triad, similar to the arrangement of the Cys/His/Glu catalytic triad of cysteinyl proteases. The relevant catalytic residues in TrpG are Cys84, His170, and Glu172. Cys84 is the nucleophilic residue involved in forming the g-glutamyl-*S*-cysteinyl enzyme intermediate. His170 and Glu172 play essential roles as general acid–base catalysts, first in the formation of the glutamyl intermediate and then in the formation and release of products of the reaction, NH_3 and glutamate.

The three-dimensional structures of several Triad glutamine amidotransferases have been determined, including *E. coli* guanosine monophosphate synthetase and *E. coli* carbamoyl phosphate synthetase. Extrapolating from these structures, it has been postulated (11) that in the anthranilate synthase complex, activation of the glutaminase of the TrpG domain by the binding of chorismate to the active site of TrpE is the result of induced conformational changes that create both a "specificity pocket" for glutamine binding and a hydrophobic tunnel for the sequestered transfer of NH_3 between the active sites.

Recently, the three-dimensional structures of three different microbial anthranilate synthases have been solved by X-ray crystallography. These include the native TrpE–TrpG complexes from *Sulfolobus solfataricus* (12) and *Serratia marcescens* (13) and the genetically engineered TrpE–TrpG partial complex from *Salmonella typhimurium* (14). The respective TrpE and TrpG folds of the three enzymes are similar, and the subunit structures can be readily compared by superpositioning. Each of the heterotetrameric enzymes is organized as a dimer of TrpE–TrpG dimers related by the crystallographic twofold rotational axis. The heterodimer interface is the same in the three enzymes; however, the heterotetramer interface of the *Salmonella* and *Serratia* enzymes involves TrpE–TrpE interactions, whereas that of the *Sulfolobus* enzyme consists mainly of TrpG–TrpG contacts. It has

been postulated that this difference may be related to the lack of cooperativity in reaction kinetics in the latter complex.

The TrpE subunit has a novel fold that has a complicated a/b topology featuring two structural subdomains. The core of the subunit is made up of two orthogonal, antiparallel b-sheets arranged to form a b-sandwich. The sandwich interface, formed from the hydrophobic surfaces of the b-sheets of the two subdomains, contains two cavities located ~18Å apart. One cavity serves as the active site of the subunit that contains the binding sites for chorismate and metal cofactor. This site, which is made up of residues from each of the two subdomains of the sandwich, is appropriately oriented for communication with the GAT active site of the TrpG subunit of the heterodimer.

The coordination sphere of the chorismate molecule bound at the active site still remains to be determined directly. However, the crystal structure of the *Serratia* enzyme complexed with a benzoate derivative and pyruvate, products that presumably arose *in situ* either from some aberrant enzymatic conversion of chorismate or from the spontaneous or radiation-induced degradation of bound substrate or product, has been solved and can be used to infer the details of chorismate binding. Accordingly the carboxyl group of the planar ring of chorismate is coordinated with the main-chain nitrogens of Gly328 and Gly485, as well as with the bound metal cofactor. The carboxyl group of the substrate's enolpyruvyl side chain is hydrogen bonded with the hydroxyl of Tyr449, the main-chain nitrogen of Gly483 and the guanidinium nitrogen of Arg469. Besides its interaction with chorismate, the metal cofactor is coordinated by a charged pocket provided by Glu358 and Glu361, with which it directly interacts, and two water molecules held in position by Glu495 and Glu498. The putative catalytic residues, Thr329 and His398, are appropriately located close to the planar ring of chorismate.

The second cavity within the TrpE b-sandwich contains the binding site for the feedback inhibitor, L-tryptophan (13, 14). Tryptophan is positioned in the feedback site by multiple hydrophobic and hydrogen-bonding interactions with residues contributed by both subdomains of the b-sandwich. Its indolyl ring is anchored by hydrophobic interactions with the side chains of Leu38, Glu39, Tyr292, Gly454, and Cys465. The amino and carboxyl groups of tryptophan are hydrogen-bonded with the side chains of residues Ser40, Lys50, and Pro291, as well as with two fixed water molecules; in addition, the nitrogen of the indolyl ring of tryptophan is coordinated by the main-chain nitrogen of Met293. The large distance that separates the active site and the feedback site in the TrpE subunit requires that the competitive inhibition kinetics displayed by the enzyme are a manifestation of alternate conformations that accompany the binding of substrate and inhibitor.

The topology of the TrpG subunit of the anthranilate synthase complex is an a/b-structure that has the fold typical of the triad-type amidotransferase family (12-14). The core of the structure is an open, seven-stranded, mixed b-sheet. The residues of the catalytic triad, Cys84, His170, and Glu172, are appropriately poised for catalysis; Cys84 is strained in a characteristically unfavorable backbone conformation. Glutamate is bound in the active site via a covalent thioester linkage to Cys84 and additional hydrogen-bonding interactions with Ser135, Ser136, Gln89, Gly58, and Leu86 (13). The bound glutamyl moiety is positioned about 25Å from the chorismate-binding site on the opposing TrpE subunit of the complex. However, the anticipated hydrophobic tunnel for transporting nascent ammonia from the TrpG active site to the TrpE active site is not apparent in the crystal structure of the enzyme bound with the benzoate derivative and pyruvate (13). It has been suggested that, instead of a closed tunnel, ammonia may have a directed passage down the TrpE crevice to the chorismate-binding site. It is also possible that because of the lability of chorismate, the structure of the fully activated complex has yet to be characterized.

3.2. PRA Isomerase and IGP Synthase

In both *E. coli* and *S. enterica* the fourth and fifth reactions on the tryptophan biosynthetic pathway (Fig. 1) are catalyzed by a monomeric bifunctional protein encoded by the *trpC (trpC·trpF)* gene (15). Some microorganisms have a monofunctional PRA isomerase, and some have a monofunctional IGP synthase. In the enzyme pair from enteric bacteria, the IGP synthase reaction is

catalyzed by the N-terminal domain (M_r = 28,800) and the PRA isomerase reaction by the C-terminal domain (M_r = 21,200). The bifunctional protein probably arose during evolution by in-frame fusion of adjacent *trpC* and *trpF* genes that originally encoded two independently active proteins (see Gene Fusion). The advantage of gene fusion appears to be the mutual stabilization of the joined proteins against denaturation and degradation.

Both of the PRA isomerase and the IGP synthase domains possess the symmetrical barrel fold, known as the TIM barrel (Fig. 3) (16). It was observed first in triose phosphate isomerase and is currently the most frequently observed protein domain fold. Whereas PRA isomerase displays the canonical eightfold b/a-barrel (ie, no extensions at the termini and no major insertions in surface loops), IGP synthase has an extension of 49 amino acid residues at its N-terminus. The active sites in both cases are located at the C-terminal ends of the central b-barrels. The two functional domains are connected by a glycine residue between helix a8 of IGP synthase and strand b1 of PRA isomerase. Judged by the independent binding of the substrate/product analog *N*-5′-phosphoribityl anthranilate (rCdRP, CdRP where the keto group at C2′ is reduced to an alcohol group) to both PRA isomerase and IGP synthase, as well as by unchanged catalytic activities of the domains after their separation by protein engineering (17), the domains do not communicate reciprocally with each other as observed in the bienzyme complexes of anthranilate synthase (TrpE and TrpG–TrpD) and tryptophan synthase (TrpA and TrpB). Moreover, the product of the PRA isomerase reaction, CdRP, is not channeled to the active site of IGP synthase because the two active sites are both accessible to solvent and point away from one another (Fig. 3). The genetically separated domains of PRA isomerase (TrpF) and IGP synthase (TrpC), as well as of the a-subunit of tryptophan synthase (TrpA), unfold at equilibrium with increasing concentrations of **denaturants** (urea or **guanidinium chloride**), via a partially folded intermediate, I, (N↔I↔D), where N is the native and D the denatured state of the monomeric protein (18). In each of the three proteins, the intermediate contains the first 6 ba-modules [ba(1–6)] folded, and the last two ba modules [ba(7–8)] are disordered. Adherence to the same “6 + 2” folding transition argues for a common evolutionary origin of these three eightfold b/a-barrel enzymes of tryptophan biosynthesis. PRA isomerase catalyzes the practically irreversible conversion of a ribosylamine, PRA, to an a-amino ketone, CdRP (Fig. 1). This so-called *Amadori rearrangement* occurs spontaneously, albeit slowly in absence of the enzyme. In contrast, IGP synthase catalyzes a reaction that does not proceed in the absence of the enzyme, the irreversible ring closure of CdRP to IGP and concomitant loss of CO_2 and water.

Figure 3. Ribbon diagram of the bifunctional enzyme IGP synthase-PRA isomerase from *E. coli* (16). N- and C-termini are labeled. The filled circle marks the fusion site between helix a8 of IGP synthase and strand b1 of PRA isomerase at residue Gly255. Bound phosphate is shown as a ball-and-stick model, corresponding to the phosphate groups of the substrates (see Figs. 4**a** and 5**a**.

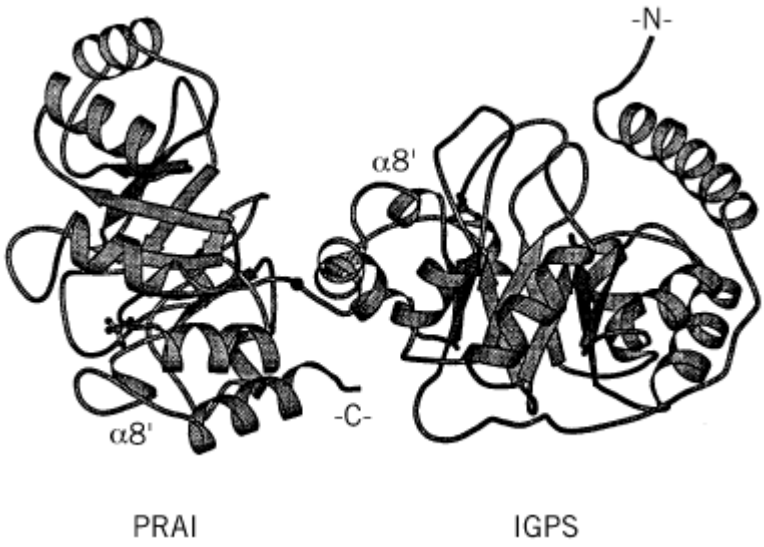


Figure 4a shows the product analog rCdRP fixed at the active site of PRA isomerase (Hennig and Kirschner, unpublished). The phosphate group is bound to the ba(7–8)-subdomain via salt bridges and hydrogen bonds and is stabilized further by the dipole of helix a8′. This binding mode is also observed in IGP synthase, the a subunit of tryptophan synthase, and in triosephosphate isomerase, further supporting the notion of a common evolutionary origin for these polypeptides (19). The anthranilate group is bound to a hydrophobic pocket at the opposite end of the active site; the catalytic residues are in between. Among the invariant, polar residues in this region, Cys260 and Asp397 have been identified as catalytically important. Figure 4b indicates how Asp397 as the general acid AH could protonate the furanose ring oxygen and lead to the aldimine. The anion of Cys260 (as B^-) could abstract a proton from C2′ of the aldimine, leading to the enolamine. The subsequent isomerization to the final product CdRP occurs spontaneously without enzymic catalysis (20).

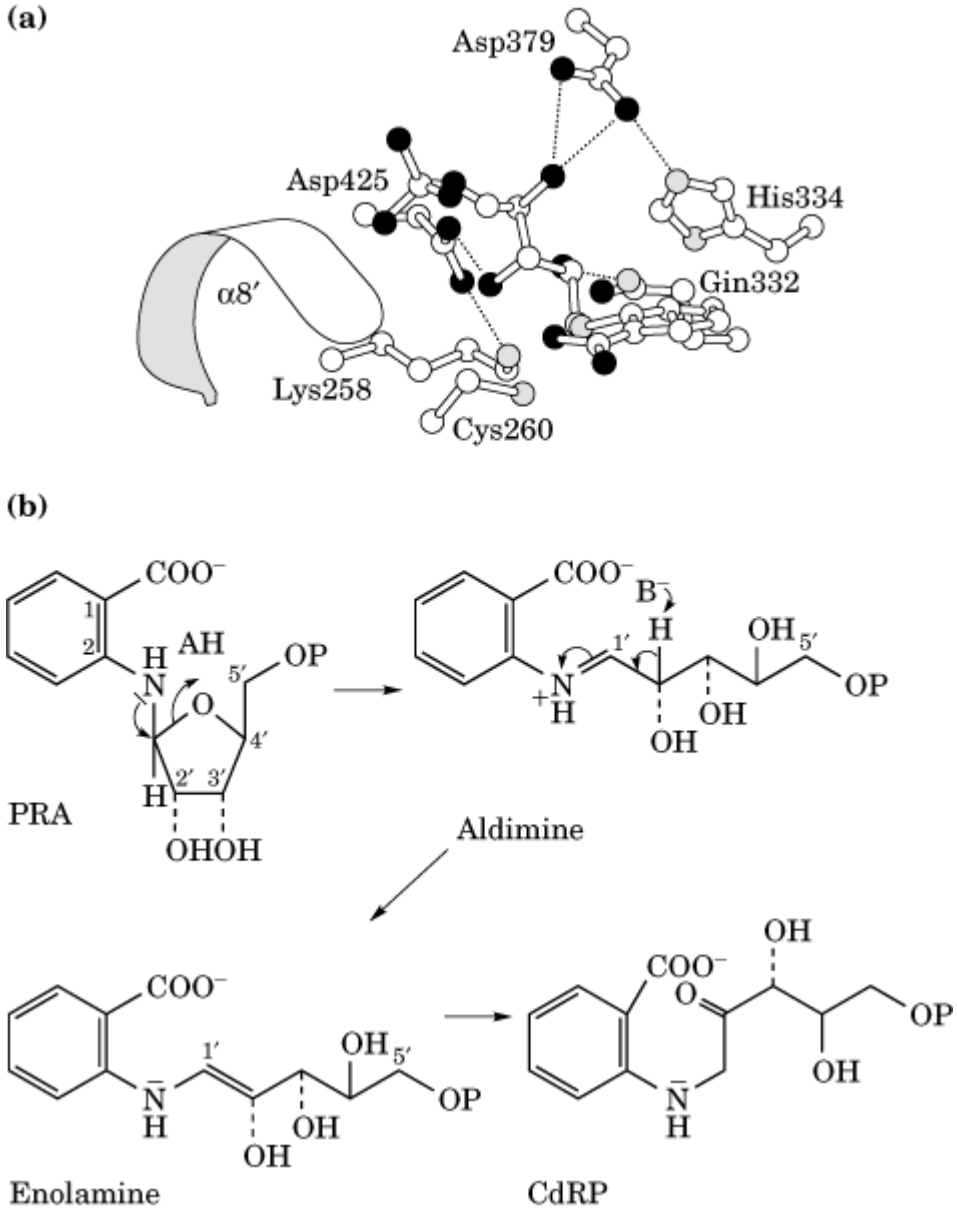
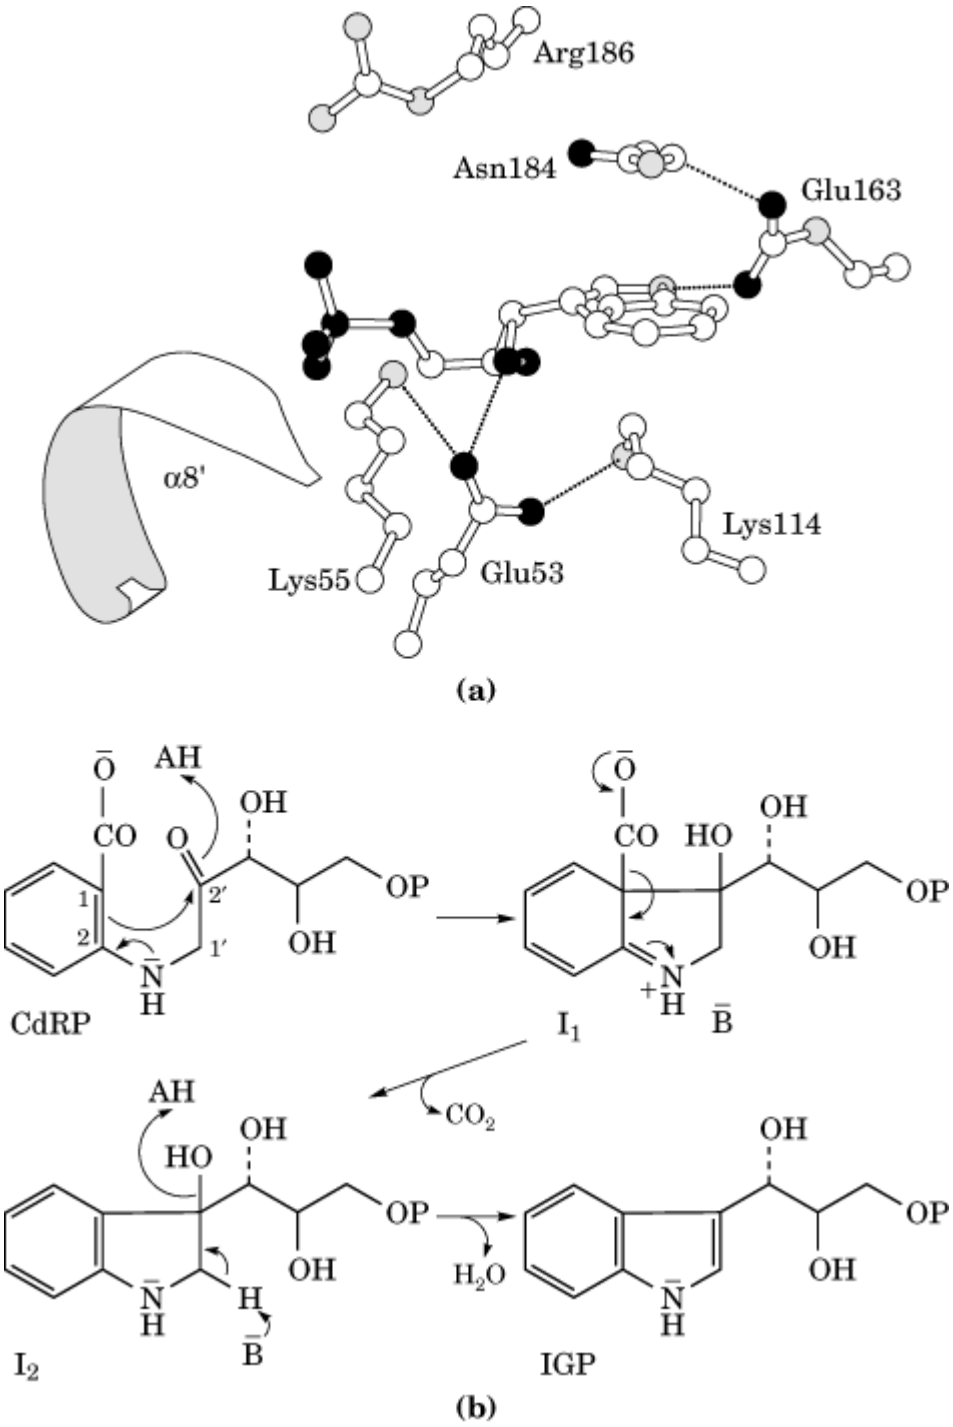
Figure 4. Catalysis by PRA isomerase. **(a)** The active site of PRA isomerase from *Thermotoga maritima* showing invariant residues and the bound product analog rCdRP. Numbering is as for PRA isomerase from *E. coli*. a8′ is the helix that stabilizes the phosphate group (Fig. 3). **(b)** Tentative intermediates (aldimine and enolamine) of the catalyzed reaction, where Asp397 is the general acid (AH), and Cys260 the general base (B^-).



3). Removal of helix a0 by deletion mutagenesis shows that it is important for binding the substrate (ground state) but not for stabilizing the transition state with respect to the bound substrate. Figure 5a presents the product IGP bound at the active site (Hennig and Kirschner, unpublished). The phosphate group is fixed to the ba(7–8)-subdomain, as in the complex of the product analog rCdRP with PRA isomerase (Figure 4a). The indole group is firmly anchored in a hydrophobic pocket at the other end of the active site. Several invariant, polar side chains are located in the region between the phosphate and indole group-binding sites. Among these, Lys114 and Glu163 are essential as catalysis (19), whereas the invariant residues Glu53 and Asn184 stabilize the active site and position the catalytic residues by a salt bridge and hydrogen bonding, respectively. Figure 5b indicates how bond formation between C1 of the anthranilate group and C2′ of the ribulose chain (step 1) could be catalyzed by Lys114 as a general acid (proton donor AH) and by Glu163 as a general base (proton acceptor B^-). Arg186 perhaps compensates for the negatively charged carboxylate group of anthranilate, thus stabilizing the sterically strained transition state. The spontaneous decarboxylation of I_1 to I_2 (step 2) is followed by removal of a proton and an hydroxyl ion from I_2 in step 3 and is probably catalyzed by the same general acid–base side chains as in step 1.

Figure 5. Catalysis by IGP synthase. **(a)** The active site of *IGP synthase* from *Sulfolobus solfataricus* showing invariant residues and bound product IGP. Numbering is as for IGP synthase from *E. coli*. a8′ is the helix that stabilizes the phosphate group (Fig. 3). **(b)** Tentative intermediates (I_1 and I_2) in the catalyzed reaction, where Lys114 is the general acid (AH), and Glu163 is the general base (B^-).



3.3. Tryptophan Synthase: IGP Aldolase, L-Serine Hydrolyase (Adding Indole)

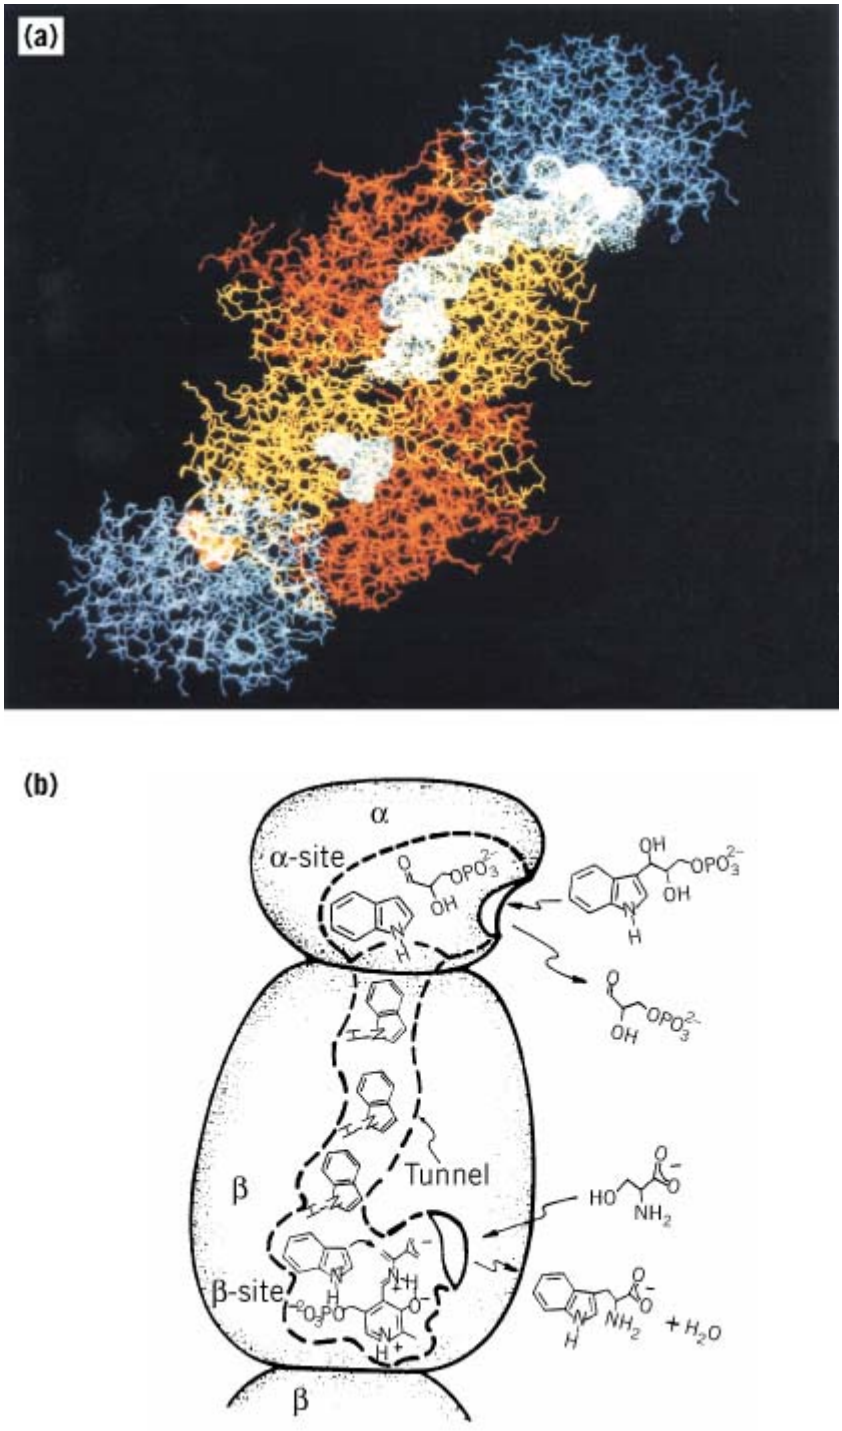
The last two steps in tryptophan biosynthesis (see Fig. 1) are catalyzed by tryptophan synthase. The enzyme from *S. enterica* and from *E. coli* is an a_2b_2 complex (M_r = 143,400) that can be dissociated reversibly into two monomeric a-subunits (M_r = 28,700) and one dimeric b_2-subunit

(M_r = 86,000), hereafter called the b-subunit. The a-subunit, which is encoded by *trpA*, is termed IGP aldolase; it catalyzes the reversible aldolytic cleavage of IGP to indole and D-glyceraldehyde 3-phosphate (G3P). The b-subunit, which is encoded by *trpB*, is termed L-serine hydro-lyase (adding indole); it catalyzes the pyridoxal phosphate-dependent b-elimination of water from L-serine followed by the b-addition of indole to form L-tryptophan. Although each reaction is catalyzed by the individual subunit, the rate is increased by one to two orders of magnitude when the a- and b-subunits associate to form an a_2b_2-complex. Thus, complex formation results in mutual activation of the a- and b-subunits. Because indole, the intermediate in the overall conversion of IGP to L-tryptophan, is not released free into solution, it must be a **channeled** intermediate that is transferred from one active site to the other within the enzyme complex.

3.3.1. Indole Channeling

The physical basis of indole channeling is evident in the X-ray crystallography structure of the tryptophan synthase a_2b_2-complex from *S. enterica* (21). The complex has an extended, nearly linear abba arrangement ~150 Å long (Fig. 6a). The active sites of neighboring ab-pairs are ~25 Å apart and are connected by a buried **hydrophobic** tunnel that has a diameter close to that of indole. This unique tunnel, it is believed, provides a passageway for diffusion of the indole generated at the active site of the a-subunit to the active site of the b subunit, as illustrated by the cartoon in Fig. 6b. Rapid kinetic studies have established that indole is a channeled intermediate [see (22, 23) for reviews].

Figure 6. Architecture of the tryptophan synthase a_2b_2-complex of *Salmonella enterica*. **(a)** The overall structure determined by X-ray crystallography (21). The a-subunits (blue) are on opposite ends of the b subunit dimer. The b-subunit residues 1–204 are in yellow; residues 205–397 are in red. Dot surfaces show the locations of indole-3-propanol phosphate at the active site of the a-subunit and of pyridoxal phosphate at the active site of the b-subunit in the lower ab pair. A tunnel, that connects the two active sites is shown in the upper ab pair. **(b)** Diagram based on the crystal structure showing the reaction of IGP at the active site of the a-subunit, passage of the intermediate indole through the tunnel, and the pyridoxal phosphate-dependent reaction of L-serine and indole at the active site of the b-subunit. See **(a).**



3.3.2. Structure and Function of the Tryptophan Synthase a-Subunit

Each a-subunit in the complex has a $(ba)_8$-barrel fold. The structure is similar to that of PRA isomerase and IGP synthase, described earlier. The three enzymes contain a common phosphate group binding site created by residues of the loop between strand-7, helix-7, and the N-terminus of helix 8′. The phosphate of the substrate analog, indole-3-propanol phosphate, binds at this position in the active center of the a-subunit. Most of the residue positions at which changes inactivate the a-subunit are located near the bound analog. Mutagenesis studies provide evidence that two of these residues, Asp60 and Glu49, catalyze the aldolytic cleavage of IGP (22) (see Protein Engineering and Site-Directed Mutagenesis). Thr183, another position at which there are inactivating changes, cannot be seen in the unliganded structure (21) because it is located in a

flexible loop, loop-6, between strand-6 and helix-6 that has weak electron density. Recent crystal structures provide direct evidence for ligand-induced closure of loop-6 (24). Loop-6 closes down over the bound inhibitor and interacts with residues in Loop-2, including the catalytic residue Asp60. The hydroxyl group of Thr183 interacts with Od of Asp60 and may play a role in positioning the carboxylate group for interaction with the substrate (Fig. 7a).

Figure 7. Residues at the active sites of the a-subunit **(a)** and the b-subunit **(b)** from X-ray crystallographic structures of the a_2b_2-complex that had an inactivating mutation in the b-subunit (24). **(a)** Hydrogen-bonding interactions (yellow dotted lines) between a-subunit residues Thr183 and Asp60 and indole-3-propanol phosphate (IPP). **(b)** Interactions between polar atoms of the external aldimine between pyridoxal phosphate and L-serine and protein residues in an X-ray structure are indicated by dashed lines. The numbers correspond to interatomic distances in angstroms.

(b)

3.3.3. Structure and Function of the Tryptophan Synthase b-Subunit

The larger b -subunit in the complex is composed of two domains of similar size (Fig. 6a). These domains are largely derived from N-terminal residues 1–204 (yellow residues) and C-terminal residues 205–397 (red residues). The pyridoxal phosphate coenzyme is buried in the interface between these two domains at one end of the indole tunnel. The substrate and product binding sites in the b-subunit have been identified in crystal structures of a_2b_2-complexes that contain an inactive, mutant form of the b-subunit in which the active site Lys87 is replaced by threonine (bLys87Thr) (24). The mutant b-subunits bind the substrate (L-serine) or the product (*L*-tryptophan) as stable external aldimine, Schiff Base intermediates, as illustrated in Fig. 7b for the external aldimine with L-serine. The structures identify residues of the b-subunit that interact with the coenzyme and substrate or product in these intermediates.

Monovalent cations activate the tryptophan synthase b-subunit and a_2b_2-complex.

Crystallographic studies have identified a binding site for Na^+ about 8 Å from the phosphate of the bound pyridoxal phosphate. Exchange of K^+ or Cs^+ for Na^+ induces local and long-range changes in the structure of the a_2b_2-complex [reviewed in (23)]. For example, the side chain of Lys167 forms a salt bridge with a-subunit Asp56 in the presence of K^+, but shifts ~7 Å to form a salt bridge with b-subunit Asp305 in the presence of Na^+. The interaction between bLys167 and aAsp56 may play a key role in allosteric communication between the a- and b-subunits (see below).

The reaction of L-serine at the active site of the b-subunit proceeds through a series of pyridoxal phosphate intermediates. Pyridoxal phosphate acts as an electron sink to facilitate electron withdrawal from the a-carbon of the L-serine aldimine shown in Fig. 7b. b-Subunit Lys87 serves a catalytic role as the acceptor of the a-proton of L-serine in converting of L-serine to aminoacrylate. Indole reacts as a nucleophile on the b-carbon of the aldimine of aminoacrylate as shown in Fig. 6b. Lys87 then protonates the resulting carbanion intermediate and facilitates the release of L-tryptophan.

3.3.4. Reciprocal Communication Between the a- and b-Subunits

Ligands or substrates that bind or react at the active site of either the a-subunit or the b-subunit alter the reaction kinetics of the partner subunit ~25 Å distant. For example, the reaction of L-serine to form aminoacrylate at the active site of the b-subunit (Fig. 6b) results in a 20-fold increase in the rate of turnover of IGP at the active site of the a-subunit. This **allosteric** activation coordinates the activities at the two active sites. The observed kinetic changes result from ligand-induced conformational changes in the protein that are communicated between the active sites of the two subunits. These conformational changes, it is proposed, switch the enzyme between an open, low-activity state, to which ligands bind, and a closed, high-activity state, which prevents the escape of indole (23). Mutagenesis studies provide evidence that a-subunit loops-2 and -6 play important roles in forming of the closed conformation.

Crystal structures of a mutant tryptophan synthase a_2b_2-complex that has ligands bound to the active sites of the a- and b-subunits provide direct evidence for ligand-induced conformational changes (24). Changes in the a-subunit include closure of loop-6 and the interaction of the closed loop-6 with loop-2 (see before and Fig. 7a). Because closure of loop-6 isolates the active site from solvent, the finding supports the proposal that closure of loop-6 prevents the escape of indole from the enzyme (23). Other conformational differences between the wild type and the two mutant structures include a rigid-body rotation of the a-subunit of ~5Å relative to the b-subunit and large movements of part of the b-subunit (residues 93–189) toward the rest of the b-subunit (24). The movement of part of the b-subunit creates new interactions between certain residues in the two parts of the b-subunit. The observed conformational changes may contribute to allosteric communication between the a- and b-subunits. Residues at the interface between the a- and b-subunits may also be important in intersubunit communication. Although the subunit interface residues and interactions are not greatly altered in the two mutant structures that have ligands bound at the active sites of the a- and b-subunits, the side chains of two b-subunit residues, Lys167 and Arg175, do exhibit large changes in their interactions with other residues in the two mutant structures. A role for b-subunit Lys167 in allosteric communication between the a- and b-subunits is supported by mutagenesis studies (23). Several residues in the closed a-subunit loop-6 also interact with residues in the b-subunit and may be important for intersubunit communication. Thus, the tryptophan synthase a_2b_2-complex appears to have evolved so that it can carry out efficient synthesis of L-tryptophan by channeling an indole intermediate between the active sites of the a- and b-subunits. The rates of the reactions are regulated by reciprocal communication between the two subunits.

Recent solution studies provide additional insights into the linkage between the conformation of tryptophan synthase and the regulation of catalysis. Temperature, allosteric ligands, monovalent cations, and mutations affect the equilibrium between a low-activity, "open" conformation and a high-activity, "closed conformation" (25, 26). Mutation of either bLys167 or aAsp56 produces deleterious effects on activity that can be repaired by increased temperatures in combination with CsCl or with NaCl plus an a-subunit ligand (26). The results provide evidence that interaction between aAsp56 and bLys167 is important in stabilizing of the active, closed form of the a_2b_2-complex (26). Spectroscopic and kinetic studies demonstrate that both binding of monovalent cations and formation of the bLys167–aAsp56 salt bridge are important in transmitting allosteric signals between the a- and b-sites (27).

4. Regulation of Gene Transcription

Transcription of the five major structural genes of the *trp* operon of *E. coli* and *S. enterica* is regulated by both repression and transcription attenuation. As previously mentioned, these regulatory mechanisms allow a response, respectively, to changes in the intracellular concentrations of tryptophan and tryptophan-charged $tRNA^{Trp}$, Trp-$tRNA^{Trp}$. The intracellular tryptophan concentration is determined by several events: tryptophan import from the cell's environment, tryptophan produced internally by biosynthesis, and the rate of use of tryptophan during **protein synthesis**. The concentration of charged $tRNA^{Trp}$ also depends on several factors: the intracellular concentrations of tryptophan, $tRNA^{Trp}$, and tryptophanyl-tRNA synthetase (see Aminoacyl tRNA Synthetases), and the overall rate of protein synthesis. It is apparent that the regulatory strategies that control transcription of the *trp* operon of *E. coli* and *S. enterica* were designed to adjust the rate of synthesis of this amino acid in response to all extracellular and intracellular events that alter the availability of tryptophan and Trp-$tRNA^{Trp}$ for protein synthesis. **Feedback inhibition** of anthranilate synthase provides an additional important level of regulation by tryptophan by controlling entry of chorismate into the biosynthetic pathway.

Repression of the *trp* operon is sensitive to slight to moderate decreases in intracellular tryptophan concentration. In contrast, attenuation is designed to allow transcription of the structural genes of the operon only when there is nearly complete depletion of the pool of charged $tRNA^{Trp}$. This occurs under two conditions; when the supply of intracellular tryptophan is grossly insufficient and/or when the demand for Trp–$tRNA^{Trp}$ greatly exceeds its availability. As we shall describe, the leader peptide coding region, *trpL*, of the *trp* operon of these two bacterial species has only two tryptophan codons, which are adjacent. This design allows relief of termination only when the intracellular concentration of Trp–$tRNA^{Trp}$ is so low that rapid translation of both of these tryptophan codons cannot occur.

When *E. coli* or *S. enterica* is grown in the presence of excess tryptophan, repression reduces the rate of transcription initiation at the *trp* promoter to about 1/80th the rate observed in the absence of repression (2). The extent of repression reflects several factors: the intracellular concentrations of tryptophan and repressor, the rate of repressor synthesis, and the fraction of repressor molecules that is available for *trp* operator binding. Repressor synthesis is autoregulated; thus the repressor level drops to one third when cells are grown with excess tryptophan. From the finding that increased production of repressor specified by a **multicopy plasmid** decreases operon expression appreciably, it may be inferred that the *trp* repressor concentration is normally limiting for repression.

Feedback inhibition of anthranilate synthase can have a significant impact on the extent of repression. Thus, when *E. coli* is synthesizing the tryptophan it needs for growth and thus,

repression is incomplete, feedback inhibition by the available tryptophan partially inhibits anthranilate synthase activity. This results in the production of slightly higher levels of the tryptophan biosynthetic enzymes, which is achieved by partial relief of repression. Feedback inhibition is a particularly effective regulatory mechanism because it reduces tryptophan synthesis instantaneously, whereas repression and attenuation have delayed effects. By employing complementary regulatory mechanisms, *E. coli* and *S. enterica* exploit the advantages that can be derived from different means of sensing and responding to tryptophan availability for protein synthesis.

Transcription termination at the *trp* attenuator is relieved completely only when cells are severely deficient in charged $tRNA^{Trp}$ (3). Under these conditions, there is about a six- to eight fold increase in the level of *trp* operon structural gene mRNA above the level observed when there is an adequate level of Trp–$tRNA^{Trp}$. Starvation for other amino acids contained in the leader peptide does not have a comparable regulatory effect, except for arginine. Severe arginine starvation also eliminates transcription termination at the *trp* attenuator. The arginine starvation effect is due to the presence of a single arginine codon immediately following the two tryptophan codons in the leader peptide coding segment of the *trp* transcript. Upon arginine starvation, the ribosome that translates the leader peptide coding region presumably also stalls on the critical segment of the *trp* transcript, that is, the segment that contains the tryptophan codons.

4.1. The Operator Region of the *trp* Operon and the Mechanism of Repression

The promoter region of the *trp* operon of *E. coli* and *S. enterica* contains multiple repressor binding sites, or **operators** (Fig. 8). The tryptophan-activated *trp* repressor can bind at these sites and inhibit transcription initiation at the major *trp* **promoter**. Three-dimensional structures have been determined by X-ray crystallography and by NMR of the tryptophan-free *trp* aporepressor, the tryptophan-activated *trp* repressor, and the repressor–operator complex. Both the aporepressor and repressor exist as dimers composed of interlocking identical polypeptide chains. Each *trp* aporepressor dimer has two tryptophan binding sites. Bound tryptophan displaces helix E of the two **helix-turn-helix** domains of the dimer and positions these domains so that the dimer can effectively bind the symmetrical operator. Binding of tryptophan at the two sites of the aporepressor is cooperative. The structure of the repressor–operator complex shows that the repressor makes multiple contacts with target operator sequences and that some important specific contacts are water-mediated. This mechanism of recognition has been termed *indirect readout* (28). Although crystallographic analyses suggest that the preferred operator binding sequence is 5′ACTAGT3′ (28), other studies indicate that the consensus operator sequence is 5′GNACT3′ and that there are three operators in the *trp* promoter/operator region (Fig. 8) (29). The presence of multiple bound repressor dimers in the operator region could facilitate inhibition of transcription initiation of the operon by reducing the liklihood that the promoter/operator will be repressor-free. Repressor dimers, it has been observed, associate in solution, but the significance of this association is not yet known. The *trp* repressor also regulates initiation of the transcription of several other operons concerned with tryptophan metabolism.

Figure 8. The *trp* operon promoter/operator region. The –35, –10, and +1 sequences of the promoter are marked. The sequences in the two DNA strands that are assumed to be recognized specifically by each *trp* repressor dimer are indicated in outline form. Note that the diagram implies that three repressor dimers can be bound per operator region. Based on the studies of Yang et al. (29).

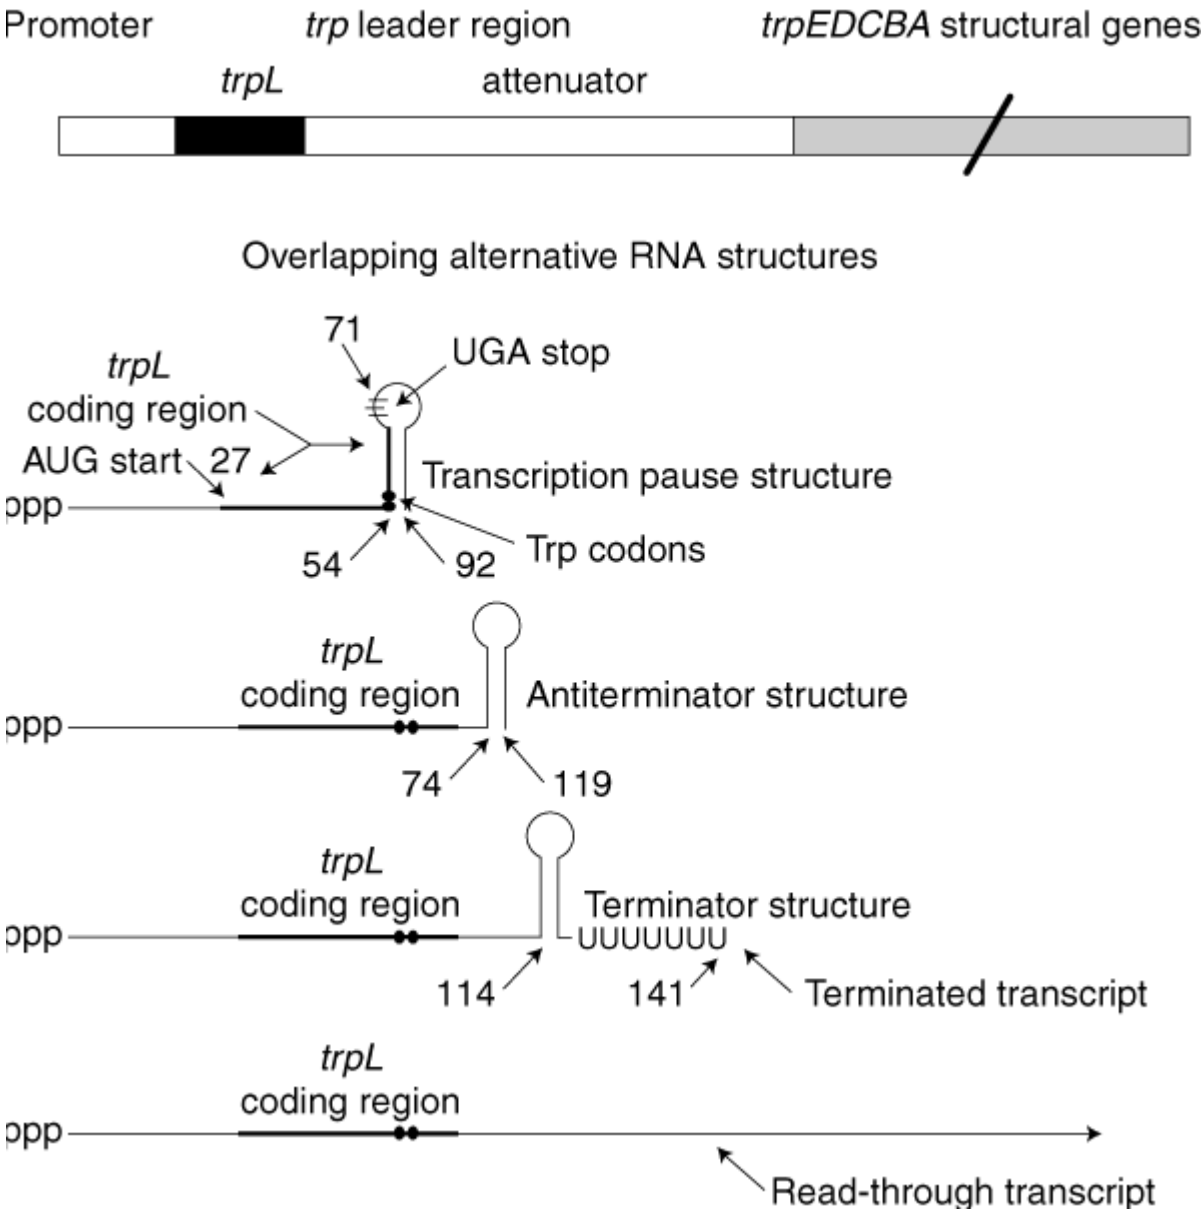
4.2. The Mechanism of Transcription Attenuation

The principal *trp* promoter, *trpP1*, is a relatively strong promoter; in tryptophan-deficient cells, **RNA polymerase** can initiate transcription at this promoter every 4–5 seconds (3). Inasmuch as a transcribing polymerase molecule could reach the attenuator region within a few seconds, it is essential that the decision be made quickly whether or not to terminate transcription at the attenuator. Because this decision is based on the transcript position of the ribosome that is attempting synthesis of the leader peptide, it is essential to synchronize translation of the leader peptide coding region with transcription of the leader region. Synchronization is achieved by features of the nucleotide sequence of the leader transcript; other features of the transcript determine the appropriate transcription termination response, which depends on the cellular level of charged $tRNA^{Trp}$ (3).

4.3. Transcription Pausing, the Initial Important Event in Transcription Attenuation

After initiation of transcription at the *trp* promoter, RNA polymerase synthesizes an RNA segment that forms a **hairpin** structure that causes the transcribing polymerase to pause in the leader region of the operon (Fig. 9). The paused polymerase probably remains at the pause site for less than 1 second (3). The sequence of the pause RNA hairpin, particularly its upper base-paired half, it is believed, is the predominant pause signal (3). However, the DNA region immediately downstream from the pause RNA-encoding region also contributes to pause stability, as does the RNA polymerase accessory factor, NusA. In the paused complex, the 5′ end of the nascent transcript is exposed and is available for ribosome loading and initiation of leader peptide synthesis. In fact it is the act of synthesis of the initial portion of the leader peptide that disrupts the transcription pause complex and reactivates transcript elongation. Thus, transcription pausing is the event that is essential to regulation by this form of transcription attenuation.

Figure 9. Organization and features of the *trp* leader region and the *trp* leader transcript. The operon map at the top expands the *trp* leader region and shows the locations of *trpL*, the leader peptide coding region, the attenuator, and the five structural genes. Below the operon map are transcripts that have the three alternative hairpin structures, the pause, antiterminator, and terminator. The terminated and the read-through transcripts are marked. Part of the leader peptide coding region, *trpL*, overlaps the pause structure, as indicated. The start and stop codons of *trpL* and the positions of its adjacent Trp codons are shown. Nucleotide positions that define the various transcript segments are indicated.



4.4. Transcription Beyond the Pause Site

When the paused RNA polymerase resumes transcription, the position assumed by the ribosome engaged in synthesizing the leader peptide dictates whether the RNA antiterminator or terminator structure will form (Fig. 9). If a cell has adequate levels of Trp–tRNA^{Trp} (and other required charged tRNAs), the translating ribosome will reach the leader peptide stop codon while transcription of the leader region of the operon is proceeding. A ribosome at this position would block formation of the antiterminator structure, thereby allowing what would be the 3′ strand of the RNA antiterminator to pair with the immediately following RNA segment to form the terminator (Fig. 9). Formation of the terminator within the transcription complex would signal the transcribing polymerase to terminate transcription. If the Trp–tRNA^{Trp} concentration was very low, the translating ribosome would stall during attempted translation of the adjacent tryptophan codons. Such stalling would promote formation of the RNA antiterminator structure. The antiterminator would prevent the subsequent formation of the terminator because the 3′ strand of the antiterminator must be free for it to serve as the 5′ strand of the terminator (Fig. 9). Thus the crucial location of the ribosome engaged in synthesizing the leader peptide dictates

which RNA hairpin structure forms, and this, in turn, determines whether termination or read-through will occur.

4.5. Basal Level Control

When cells have adequate levels of Trp–tRNA^{Trp} to satisfy their needs for protein synthesis and synthesis of the *trp* leader peptide can be completed, only about 90% of *trp* transcripts are terminated in the leader region, there is about 10% read-through transcription. These read-through transcripts provide a "basal level" of all five *trp* polypeptides. Read-through is principally due to ribosome dissociation from the leader peptide stop codon when the synthesis of the leader peptide is completed. Ribosome release allows the leader segment of the transcript to form an antiterminator structure occasionally, which results in read-through. This read-through depends on the ability of cells to initiate and complete synthesis of the leader peptide. When initiation of synthesis of the *trp* leader peptide is defective, transcription termination at the *trp* attenuator increases from about 90% to 98%. This increased termination is due to increased formation of the terminator and decreased formation of the antiterminator. The mechanism responsible for this change is termed basal level control. Although basal level control is a natural consequence of the sequence and arrangement of the *trp* transcript, it is conceivable that this regulatory feature was introduced to reduce *trp* operon transcription further when a severe amino acid deficiency interfered with general protein synthesis.

4.6. Cessation of Leader Peptide Synthesis

Whether transcription stops at the attenuator or continues into the structural genes of the operon, subsequent translation of the leader peptide coding region would no longer be necessary. In fact, after the attenuation decision has been made, leader peptide synthesis is shut down; both the terminated and read-through transcripts contain leader nucleotide sequences that can pair with the ribosome binding site of the leader peptide coding region, and block further peptide synthesis (3).

5. Feedback Inhibition

Regulation of carbon flow in the tryptophan pathway is mediated by classical negative **feedback inhibition** of the various activities of the anthranilate synthase–APR transferase complex by L-tryptophan. Feedback inhibition results from the binding of one molecule of tryptophan to the feedback site of the TrpE subunit of the complex. Complete inhibition of anthranilate synthase activity can be attained with the intact TrpE–TrpG-TrpD complex, the TrpE-TrpG partial complex, and the uncomplexed TrpE subunit. This is also true for the individual ADIC synthase, ADIC lyase, and glutaminase activities of the complexes (Fig. 2). In contrast, inhibition of APR transferase activity is partial and never exceeds a maximum of about 60%. Tryptophan inhibition of APR transferase occurs only when TrpG–TrpD is complexed with TrpE, consistent with the location of the tryptophan binding site on the TrpE subunit. In all cases, inhibition is competitive with respect to chorismate and noncompetitive with respect to the other substrates, indicating allosteric communication between the inhibitor site and the active sites of the TrpE and TrpG–TrpD subunits.

Significant conformational effects accompany tryptophan binding to the complex. These are manifest in the cooperative kinetics of tryptophan binding, in the tryptophan-induced cooperative kinetics for chorismate utilization, and in the tryptophan-induced alterations in the chromatographic behavior of the enzyme. The global nature of the conformational effects of tryptophan binding are perhaps best demonstrated in the properties of a doubly mutant hybrid complex, assembled *in vitro*, that contains one catalytically active, feedback-insensitive TrpE subunit, and one catalytically inactive, feedback-sensitive TrpE subunit (30). The feedback sensitivity of the anthranilate synthase activity of the hybrid complex demonstrates that the binding of a single tryptophan molecule to one TrpE subunit elicits conformational and kinetic

effects that are propagated to the active site of the unliganded companion TrpE subunit.

Comparison of the three-dimensional structures of the active and the inhibited enzyme forms suggests a likely molecular mechanism of feedback inhibition in the AS–APR complex (13). In the tryptophan-bound enzyme, a structural motif of the TrpE subunit, formed by residues 327–363 and 387–403, is shifted about 7Å away from the chorismate-binding pocket relative to its position in the chorismate-bound enzyme. Significantly, this movement displaces catalytic residues Thr329 and His398 as well as two metal-binding glutamate residues from the vicinity of the active site and results in the loss of catalytic activity. This rearrangement is the result of the ordering of a disordered loop made up of residues 42–49 in response to tryptophan binding (13, 14). In contrast, the binding of chorismate at the active site moves this same motif in the opposite direction toward the active site crevice and leads to activation of the enzyme. These reciprocal effects explain the competitive behavior of chorismate and tryptophan because binding of one of these molecules to TrpE necessarily precludes binding of the other. Also, the fact that the structural loops involved are situated at the heterotetramer interface explains how a single tryptophan molecule can inhibit both TrpE subunits; in view of the molecular twofold axis of the complex, a movement in one heterodimer must be accompanied by a corresponding movement in the other.

Binding of tryptophan by the TrpE subunit also induces relevant conformational changes in the TrpG subunit of the complex. Two b-strands of TrpG, made up of residues 103–109 and 130–140, become disordered in the tryptophan-bound enzyme (13) in response to the tryptophan-induced movement of an interacting TrpE a-helix at the heterodimer interface. These changes disrupt the glutamine binding site of the TrpG subunit. Thus, a unitary mechanism for both tryptophan inhibition and chorismate activation of the glutaminase activity of the complexed TrpG subunit is manifest. The mechanism of the partial tryptophan inhibition of the APR activity of the complexed TrpG–APR subunit remains unknown.

Clearly, the unique allosteric properties of the anthranilate synthase–APR transferase complex, coupled with its critical location at the beginning of the pathway, provide a rapid and efficient mechanism of metabolic regulation that modulates and complements the elegant regulatory circuitry at work at the transcriptional and translational levels.

6. Other Features That Influence *trp* Operon Expression

6.1. Internal Promoter *trpP2*

A secondary, internal promoter, *trpP2*, exists near the 3′ end of the *trpD* gene of *E. coli* and *S. enterica* (Fig. 1) (31). *trpP2* is a low-efficiency, **constitutive** promoter, that initiates transcription about 150 nucleotides upstream of the *trpD* stop codon (32). It is responsible for about 60% of the fully repressed expression of the *trpC*, *trpD*, and *trpA* genes. The *trpP2* sequence lacks a conserved nucleotide in both the –35 and –10 regions of the canonical promoter sequence, accounting for its poor efficiency. The *in vivo* role of *trpP2*, it is thought, is to aid the cell in responding to an environment that has extreme variations in the supply of exogenous tryptophan. The elevated basal level of the three-terminal pathway enzymes resulting from *trpP2* function might provide an advantage to the cell in adapting rapidly to conditions of tryptophan starvation. The conservation of this secondary transcriptional element in numerous enteric species indicates that it is physiologically significant, not merely a vestige of an earlier regulatory structure.

6.2. Translational Coupling

The multigene *trp* operon of *E. coli* and *S. enterica* is designed to permit regulated synthesis of a polycistronic mRNA that encodes the five polypeptides needed for tryptophan formation. The required concentration of each polypeptide would depend on its inherent catalytic activity, its affinity for its substrates, and its stability. Other potential variables that could influence the rate

of tryptophan synthesis are the efficiency of translation of each mRNA coding segment and the mRNA segments' functional half-lives. As mentioned, two pairs of *trp* polypeptides, TrpE and TrpD, and TrpB and TrpA, form enzyme complexes in which separate catalytic events are coordinated. To optimize catalysis, equimolar levels of each member of these complexes are achieved by translational coupling (2). Thus, the *trpD* and *trpA* ribosome binding sites are designed so they are inefficiently used unless translation of *trpE* and *trpB*, respectively, proceeds to the end of its coding region. Coupling ensures equimolar polypeptide synthesis.

6.3. Preferential Synthesis upon Tryptophan Starvation

TrpE and TrpA of *E. coli* and *S. enterica* lack tryptophan. A consequence of this deficiency is that upon severe tryptophan starvation—when synthesis of most tryptophan-containing proteins is reduced or prevented—synthesis of TrpE and TrpA continues, and the relative levels of these proteins increase (2). The disproportionate elevated level of TrpE would result in preferential sequestration of chorismate into the tryptophan pathway. This would occur despite the lack of a comparable increase in the formation of TrpG–D, which normally contributes the glutamine amidotransferase activity used for anthranilate formation, because anthranilate formation by anthranilate synthase does not absolutely depend on glutamine amidotransferase activity. The TrpE polypeptide acting alone can convert chorismate to anthranilate, using free ammonia as the amino source. Inasmuch as anthranilate synthesis proceeds by an irreversible reaction, the conversion of chorismate to anthranilate *in vivo* would lock chorismate into the tryptophan biosynthetic pathway.

6.4. *trp* mRNA Degradation

The half-life of *trp*mRNA is comparable to that of many *E. coli* mRNAs (see Messenger RNA). There is a modest gradient of decay along its length, *trpE*mRNA is about half as stable as *trpA*mRNA (2). As in other mRNAs, **hairpin** structures at the 5′ and 3′ ends of *trp*mRNA probably contribute to its stability.

6.5. *trp* Protein Turnover

During log phase growth in a minimal or rich medium, the five *trp* biosynthetic proteins of *E. coli* are relatively stable. Only upon prolonged starvation is there significant turnover of one of the *trp* proteins, the product of *trpC*. Apparently, *E. coli* adjusts the levels of the *trp* biosynthetic enzymes predominantly by regulating synthesis and by growth-dependent dilution.

7. Evolutionary Considerations

Although the same seven polypeptide domains appear to be responsible for tryptophan biosynthesis in all organisms that can synthesize this amino acid (33), in many organisms these domains are fused in different arrangements than in *E. coli* and *S. enterica* (15). In addition, chromosomal order and groupings of *trp* genes, as well as the mechanisms used to regulate *trp* gene/operon expression, vary in different species (15, 34). Providing explanations for these differences will require information that is difficult to obtain, such as understanding the functional demands that were imposed on each species during its evolution. There are species in which as many as five of the *trp* enzymatic functions reside in a single multifunctional polypeptide (35). In some species, novel metabolic reactions occur that use tryptophan pathway intermediates for other purposes; understanding these accessory reactions may provide explanations for the different gene arrangements and regulatory mechanisms that are observed (34).

The evolutionary origin of each of the *trp* polypeptide domains is also of considerable interest. The 3-D structures of six of the seven *trp* enzymatic domains are known now. As mentioned, three of these domains, TrpA, TrpF, and TrpC, form barrel structures that have similar characteristics; thus each could have evolved from one of the others or from other preexisting members of this family. In fact, the IGP synthase domain of *E. coli* has been mutationally altered

to yield a polypeptide that can catalyze the PRA isomerase reaction (36). In addition, the HisA barrel protein of *Thermotoga maritima*, an enzyme that catalyzes an Amadori rearrangement of a phosphoribosylamine similar to the PRA isomerase reaction (Fig. 4), has been mutationally converted into an enzyme that catalyzes the PRA isomerase reaction (37). These findings illustrate how simple it would be for a protein to evolve with a new catalytic activity, starting with a copy of a gene encoding an enzyme that could catalyze a similar reaction. Alternatively, both enzymes may have evolved from an ancestral enzyme that had broad substrate specificity (37). The TrpB structure is homologous to proteins in a family of pyridoxal phosphate-dependent enzymes, many of which, like TrpB, can catalyze an amino acid dehydratase reaction. The TrpG domain is highly homologous to members of the family of Triad glutamine amidotransferases. A close homolog of TrpE participates in synthesizing an analog of anthranilate, *p*-aminobenzoate (15). Identifying the true origins of the *trp* genes and tryptophan proteins probably will be difficult because there are numerous ancestral possibilities, and the true evolutionary intermediates may no longer exist.

8. Dedication

We dedicate this article to the fond memory of Irving P. Crawford, who also loved the genes and enzymes of tryptophan biosynthesis.

TRP Repressor

For many helix-turn-helix motifs the selectivity of the protein for a particular DNA sequence depends both on direct contacts between the protein and the bases and also on local conformational constraints on the DNA structure. However in the case of one hth protein, the tryptophan repressor, substantial selectivity is achieved in the absence of such direct contacts. In the presence of the ligand L-tryptophan, this repressor binds to an **operator** site within the promoter region of the *trp* operon and blocks transcription initiation. This operon encodes the enzymes required for the biosynthesis of tryptophan which on binding to the trp repressor completes a negative feedback loop.

The *trp* repressor has been crystallized as a complex with a symmetrized 18 bp operator, TGTACTAGTTAACTAGTAC. In this sequence, the base pairs whose function *in vivo* is most sensitive to mutation are the two ACTAG sequences centered 4–5 bp from the dyad. In the cocrystal there are no direct hydrogen bonded or nonpolar contacts between the helix-turn-helix motif and the DNA that can account for the selectivity of the interaction (The one direct contact between a base and an amino acid side-chain lies outside the mutationally sensitive region). Instead, direct hydrogen bonded contacts are made principally to the phosphate groups in the DNA backbone. These contacts serve to constrain the backbone in a defined configuration. However, three well-ordered and directed water molecules lying in the major groove between the helix-turn-helix motif and the CTAG sequence make hydrogen bonded contacts with the base pairs in this sequence. Notably recognition of the adenine residue immediately preceding the CTAG sequence by a water-mediated hydrogen bond is sequence specific. Mutations in the amino acids that bind to these water molecules result both in a reduced affinity, and in some examples an altered sequence selectivity, of the repressor for the operator. This structure thus suggests that a degree of sequence selectivity could be achieved by water molecules forming an essential component of the recognition surface of the protein and thus mediating direct readout of the operator sequence acting, as it were, by proxy for the protein.

True Breeding

A homozygote is a true breeding individual. A group of individuals with the same phenotype are said to breed true when their phenotype is maintained for any number of generations in the offspring of genetic **crosses** within the group. The group may consist of a single individual capable of self-fertilization. True breeding occurs when all members of the group are homozygous for the same **alleles**. A trait is said to breed true when the members of the group are homozygous for the same alleles of the genes responsible for the trait. A group of true-breeding individuals is called a *pure line*.

Trypsin Inhibitors

Moses Kunitz characterized, purified, and crystallized two very different trypsin inhibitors: bovine pancreatic trypsin inhibitor (Kunitz) and soybean trypsin inhibitor (Kunitz). He also showed that each of these inhibitors formed a strong but reversible stoichiometric complex with trypsin. The

complexes were totally devoid of trypsin activity. For several years after Kunitz's second achievement, only two well-characterized protein inhibitors were known. This gave rise to the incorrect surmise that most protein inhibitors are trypsin inhibitors. Many laboratories tested numerous biological materials for the inhibition of trypsin and frequently found it. This allowed for the isolation of many more trypsin inhibitors, largely reinforcing the mistaken belief about them. The standard mechanism of interaction between serine proteinases and their inhibitors was established by Laskowski by studying the interaction of trypsin with soybean trypsin inhibitor (Kunitz). It was shown that soybean trypsin inhibitor (Kunitz) is a single polypeptide chain of 181 amino acid residues, crosslinked by two (39–86,136–145) intramolecular disulfide bridges. Within the first disulfide loop lies the Arg^{63}-Ile peptide bond that serves the inhibitor as the reactive site for interaction with serine proteinases. In bovine pancreatic trypsin inhibitor (Kunitz), the reactive site peptide bond is Lys^{15} -Ala. Thus, there are two types of trypsin inhibitors—arginine and lysine. The latter but not the former lose their activity by acetylation. The replacement of the reactive site Arg or Lys by Trp by enzymatic semisynthesis converted soybean trypsin inhibitor (Kunitz) from a strong trypsin to a strong chymotrypsin inhibitor. Similar experiments are now done by site-specific mutagenesis, and many conversions of a trypsin inhibitor to a chymotrypsin inhibitor, elastase inhibitor, glutamic acid–specific proteinase inhibitor, or furin inhibitor have been reported. More importantly, workers who searched for natural inhibitors for the above enzymes generally found them. Often, they are homologous to known trypsin inhibitors. The differences are primarily in the enzyme inhibitor contact region.

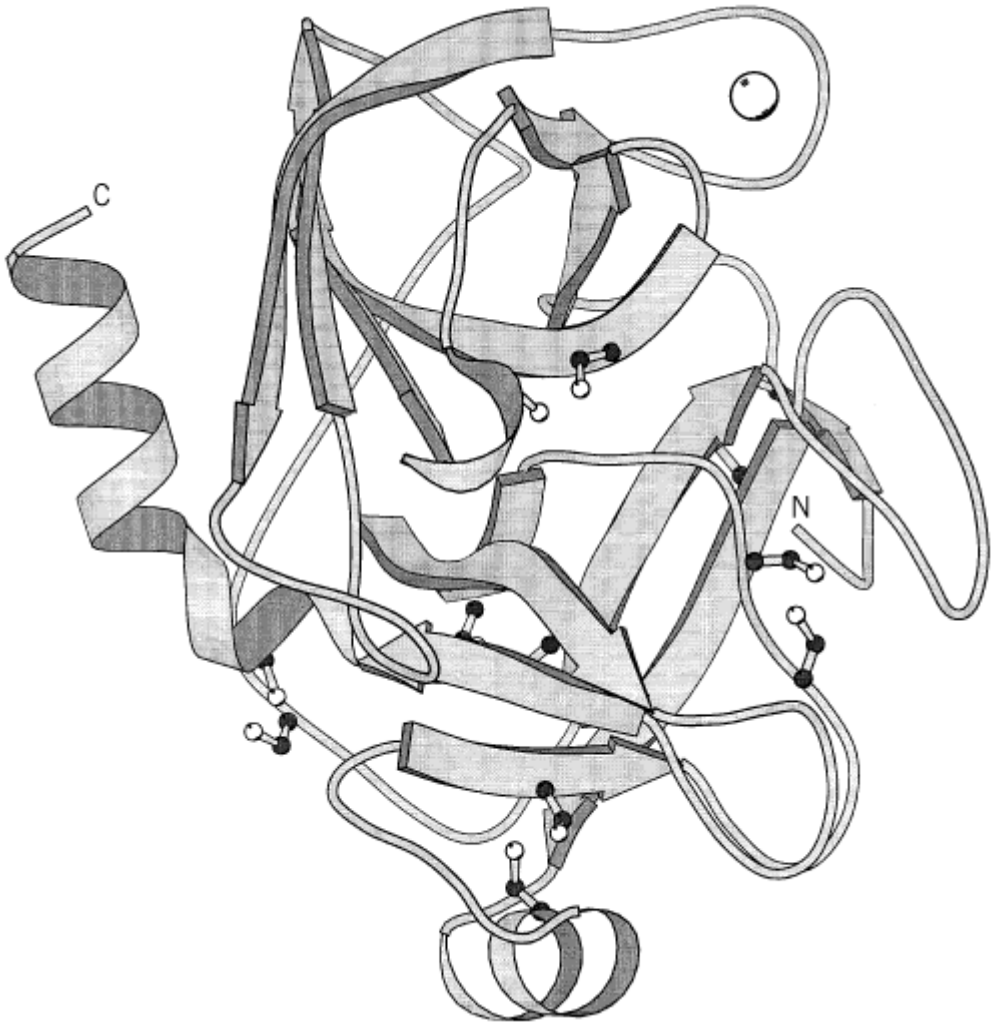
Trypsin, Trypsinogen

Trypsin is a serine proteinase of the **chymotrypsin** evolutionary family that is synthesized in the pancreas in the form of an inactive zymogen precursor, trypsinogen (1). When trypsinogen is secreted from the pancreas into the small intestine, it is activated by another serine proteinase, enterokinase, which is attached to the surface of the epithelial cells that line the intestine. Activation is accomplished by removal of a hexapeptide from the amino terminus of the precursor molecule, and this allows the remaining 223-residue polypeptide chain to change its conformation slightly (Fig. 1) and generate a catalytic triad at its active site; substrate hydrolysis can then occur. Trypsin is an important proteinase because, once it becomes active, it then activates all the other pancreatic zymogens—for example, chymotrypsinogen, pro-elastase, pro- carboxypeptidase, and so on. It is specific for cleaving peptide bonds in which the carbonyl group is contributed by arginine or lysine residues. It does not have much preference for the amino acid that contributes the NH-group to the peptide bond to be cleaved, except that it will be slower if that residue is acidic and will not work at all with proline. This specificity has made trypsin a favorite enzyme for sequence analysis of proteins (see Peptide Mapping). Arginine and lysine are not particularly abundant constituents of

most proteins. Hence, cleavage of a protein with trypsin usually generates a limited, (ie, experimentally manageable) number of peptides and in good yield. Trypsin preparations for use in sequencing usually have to be treated with TPCK, a potent inhibitor of chymotrypsin, which is the contaminant most frequently encountered in such preparations.

Figure 1. The three-dimensional structure of trypsin. The polypeptide backbone is depicted schematically as a ribbon, with arrows for b-strands and coils for a-helices. The sphere is a stabilizing calcium ion.



Trypsin is active at neutral to slightly alkaline pH, is stabilized by calcium ions, undergoes self-digestion fairly quickly, and is reversibly denatured in dilute acid. It is inhibited by, among others, **DIFP, TLCK, PMSF, leupeptin, soybean trypsin inhibitor**, a $_1$-***antitrypsin***, and a $_2$-macroglobulin. The last two normally circulate in blood plasma and thereby prevent inappropriate blood clotting.

Tryptase

Mast cells are white blood cells found in connective tissue that play a role in inflammation. They contain **secretory granules** —and thus are considered *granulocytes*—which contain substantial amounts of **proteolytic** enzymes known as *granzymes* (1). One of these is tryptase, a serine proteinase (E.C. 3.4.21.59) that is specific for the catalysis of the hydrolysis of peptide bonds in which the carbonyl group comes from arginine or lysine residues, like **trypsin**. It is secreted from the granules during the immediate reaction that occurs shortly after an individual is exposed to an allergen or an immunogen to which that person has been sensitized. In fact, it can be quantified in biological fluids by immunoassay and thereby has diagnostic significance (2). The exact functional role played by the granzymes is not well known, but tryptase can inactivate fibrinogen and prevent the coagulation that could otherwise occur when blood plasma diffuses into sites of inflammation. It also can lead to the activation of the matrix metalloproteinases that degrade interstitial tissue and regulate neuropeptide activity.

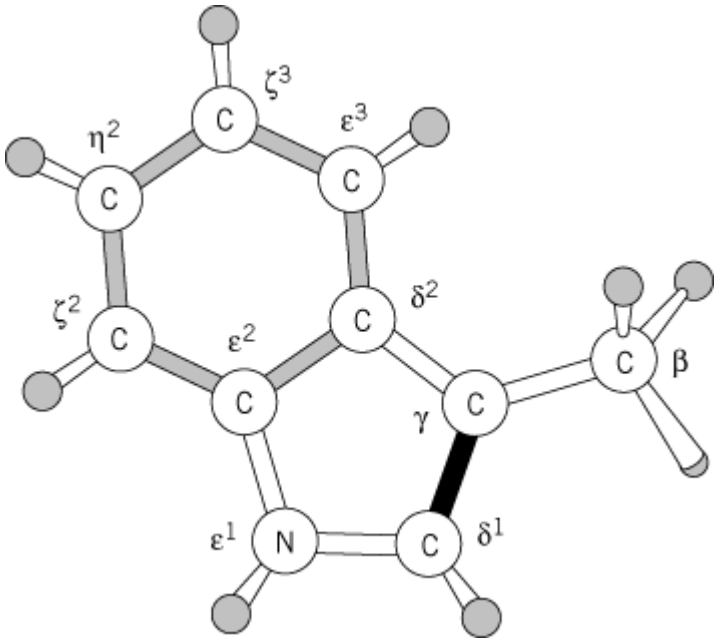
Tryptophan (TRP, W)

The amino acid tryptophan is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to only one **codon**—UGG. It is the least common amino acid residue and represents only 1.3% of the residues in the proteins that have been characterized. The tryptophanyl residue incorporated is the largest of the twenty normal residues, with a mass of 186.21 Da, a **van der Waals volume** of 163 $Å^3$, and an accessible surface area of 259 $Å^2$. Trp residues are those changed least frequently during divergent evolution, and are not replaced by any particular type of residue.

The indole-containing Trp side chain is the largest and most complex of all the normal amino acids:



(**1**)

The five-membered ring is susceptible to oxidation and various other chemical reactions. Ozone opens the indole ring to that of *N*-formylkynurenine. Peptide bonds following Trp residues can be cleaved with varying efficiencies by several chemical reagents, especially iodosobenzoic acid and BNPA-skatole. Most of these procedures have the disadvantages of side-reactions and of oxidizing **Cys** and **Met** residues.

The aromatic side chain is largely nonpolar (except for the tendency of the electrons of the peripheral H atoms to be drawn into the aromatic ring), and only the N atom is usually involved in **hydrogen bonding**, although only weakly. Consequently, Trp is considered the most **hydrophobic** of all the amino acid residues, but only about 27% of Trp residues in folded protein structures are completely buried. In contrast to **Tyr** and **Phe** residues, buried Trp side chains do not normally undergo flipping of the aromatic ring. This is due to the larger size of the indole ring and the absence of symmetry, so that full 360° flips would be required. Trp favors moderately the **alpha-helical** conformation in model peptides and occurs in this type of **secondary structure** in folded proteins, but more frequently in beta-sheets.

Trp residues occur so infrequently that many proteins have only one or a few Trp residues. This and the **absorbance** and **fluorescence** properties of Trp residues make them very useful in characterizing protein structure. Their fluorescence predominates in proteins and is especially sensitive to the environment of the side-chain, but in largely unpredictable ways. This is the only side chain capable of participating in charge-transfer complexes with pyridinium compounds and other electrophiles.

Tubulin

Tubulins are the protein building blocks of microtubules . They have been isolated and characterized

from many eukaryotic cells and organisms, including vertebrate brain, a favorite source because of the high abundance of microtubules in neurons, unicellular organisms such as the yeast *Saccharomyces cerevisiae*, invertebrate sources such as sea urchin eggs and sperm, plant cells, and cultured mammalian cells. Tubulin is a highly acidic protein, and early methods for its isolation by ion-exchange chromatography took advantage of its acidic nature. Most often, however, tubulin has been purified by cycles of polymerization at warm temperatures and depolymerization at cold temperatures, taking advantage of the assembly–disassembly properties of microtubules.

It has not yet proven possible to obtain tubulin crystals suitable for X-ray crystallography, but a molecular structure of b-tubulin and the ab-tubulin heterodimer at a resolution of ~3.7 Å have been constructed recently by electron crystallography of two-dimensional brain-tubulin sheet structures (1). This remarkable work has revealed that each tubulin monomer is a compact globular structure formed by a core of two b-sheets surrounded by 12 **a-helices** . The a- and b-tubulins are distinct but **homologous** proteins; as a rule, their amino acid sequences are quite similar and they have many structural features in common, even though there is significant **divergence** among tubulins across species. Indeed, the density maps for a and b tubulin from vertebrate brain are essentially superimposable. There are two guanine nucleotide-binding sites per tubulin dimer, one per subunit (see GTP-Binding Proteins). With brain tubulin, GTP binds nonexchangeably to a-tubulin, and the nucleotide remains in the GTP form at all times. GTP binds exchangeably to the b-subunit when the tubulin is in solution and becomes hydrolyzed to GDP plus orthophosphate (Pi) as, or shortly after, the tubulin adds to the growing end of a microtubule. Once incorporated into the microtubule, the b-tubulin-liganded nucleotide remains nonexchangeably bound as GDP until the subunit dissociates from the microtubule.

The a- and b-tubulins are members of gene families (2). The b tubulin gene family in vertebrates consists of seven or more genes that encode at least six distinct tubulin isotypes. The a-gene family has not been as extensively studied, but in the mouse at least seven genes encode six protein isotypes. There is extensive diversity in tubulin genes across species. A major variable region that distinguishes the b-tubulin isotypes is at the carboxyl terminus. This region, which is believed to be a major binding domain for MAPs, appears to be important in the regulation by MAPs of microtubule polymerization and dynamics.

The functional significance of tubulin diversity at both the tubulin gene and protein levels has remained unclear. Evidence primarily with b-tubulin isotypes has indicated that microtubules polymerized *in vitro* are copolymers of all available isotypes. These and related studies initially led to the idea that the multiple tubulin isotypes were not functionally important at the protein level. Recent evidence obtained in cells and *in vitro*, however, now indicates that the different tubulin isotypes—and, perhaps more interestingly, the specific isotype composition of a microtubule population—may indeed be important in specifying microtubule function.

The tubulins are also targets for multiple forms of post-translational modification (3). These include removal and replacement of the tyrosine residue at the *C*-terminus of a-tubulin in many species, polyglutamylation both of a- and b-tubulins near the *C*-termini, and **acetylation** of Lys40 of a-tubulin in many species, **phosphorylation**, and glycation. The functional significance of these diverse post-translational modifications remains poorly understood. Some modifications, such as the detyrosination and acetylation of a tubulin, are associated with formation of relatively stable microtubules. Others, such as polyglutamylation, which changes the charge properties in the MAP-binding *C*-terminal region, may regulate the binding of MAPs to the microtubule surface.

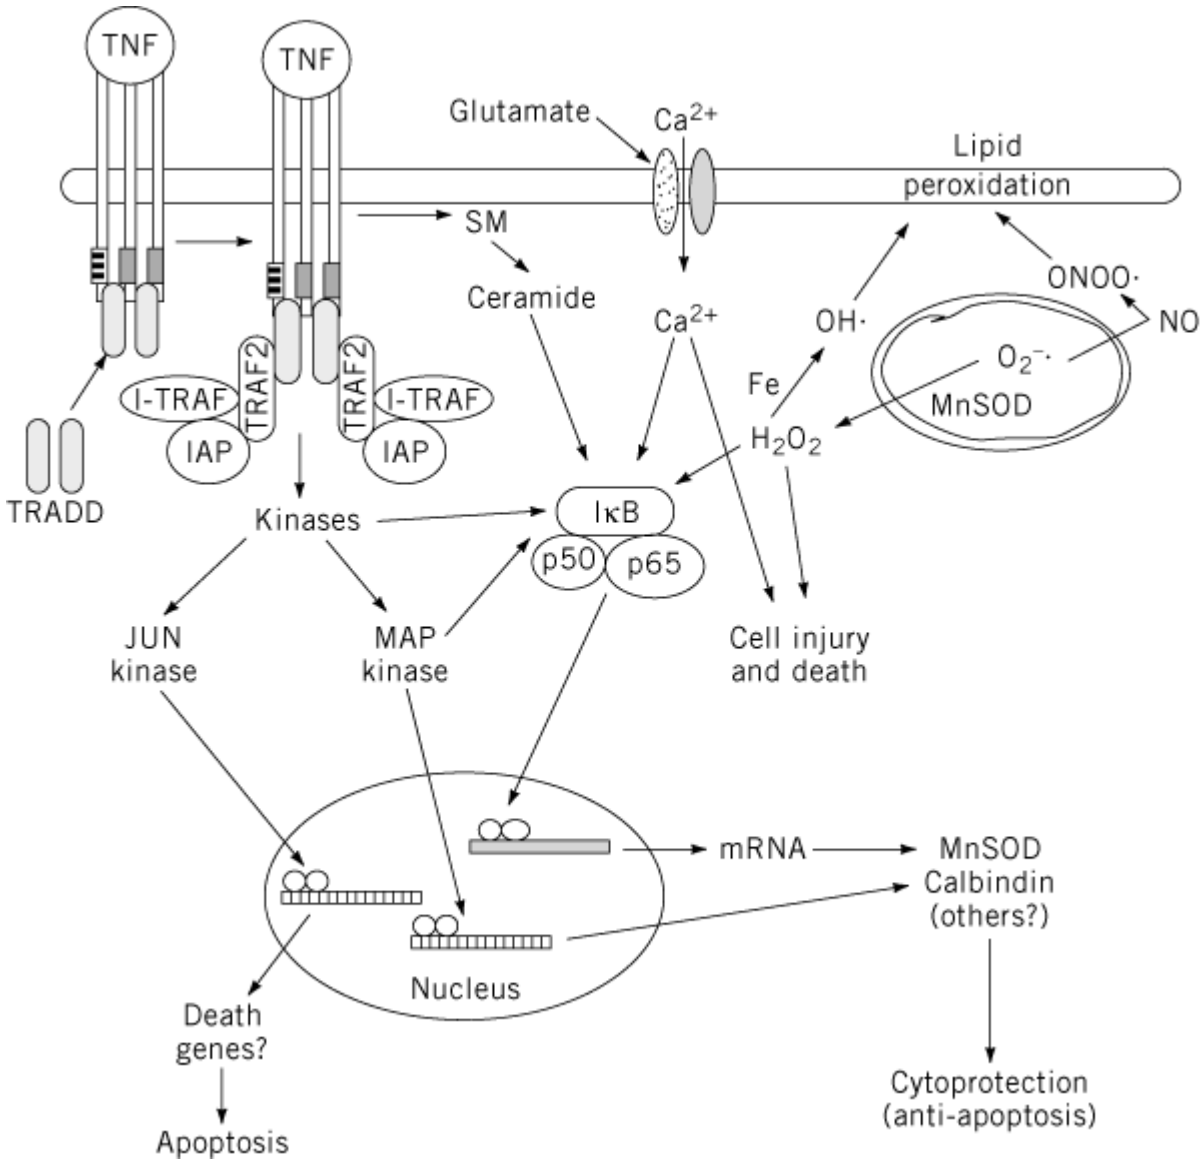
Tumor Necrosis Factor

Tumor necrosis factor-a (TNFa) is a 17-kDa protein that is a member of a **cytokine**/trophic factor family that includes TNFb (lymphotoxin-a), CD40, CD30, and ligands of CD27. TNFa is normally expressed at low levels in most tissues, but its expression is rapidly increased in many different organ systems following injury or infection. Many different cell types express receptors for, and respond to, TNFa. Two distinct TNFa receptors p55 and p75, have been identified; engagement of the receptors involves binding of TNFa multimers and receptor trimerization. TNFa binds both receptors with equal affinity, but the receptors appear to be linked to different signal transduction pathways. Binding of TNFa to the p55 receptor results in recruitment of a panel of cytosolic proteins to the cytoplasmic domains of the receptor, including proteins called TRADD, TRAF2, and IAPs (Fig. 1). This signaling pathway ultimately leads to activation of kinases, including a kinase that **phosphorylates** the I-kB subunit of the transcription factor NF-kB, and JUN (jun N-terminal) kinase and MAP (mitogen-activated protein) kinase. In addition, TNFa binding to p55 can activate a membrane-associated sphingomyelinase that liberates ceramide from sphingomyelin (Fig. 1). Ceramide may be another TNFa-induced second messenger that leads to activation of the transcription factor NF-kB. The signaling pathway of the p75 receptor is less well defined, but recent data suggest that this receptor may also be linked to NF-kB activation (1).

Figure 1. Signal transduction pathways activated by TNFa acting at the p55 receptor. Activation of the TNF p55 receptor occurs when TNF binds and induces receptor trimerization (upper left). The protein TRADD (TNF receptor-associated death domain) then associates with a “death domain” in the cytoplasmic portion of the TNF receptor which, in turn, causes association of TRAF2 (TNF receptor-associated protein 2) and IAP (inhibitor of apoptosis) with TRADD. Additional proteins, such as I-TRAF, may associate with TRAF2 and modulate signaling. This cascade of protein interactions results in activation of protein kinases and engagement of one or more downstream transcription-regulating pathways. The transcription factor NF-kB exists in an inactive form in the cytoplasm as a complex of three proteins, p50, p65, and IkB. Activation of a kinase by the TNF signaling cascade results in phosphorylation of IkB, liberating the p50/p65 dimer, which then translocates to the nucleus and binds to specific kB binding sites in the promoters of kB-responsive genes. An alternate TNF signaling pathway involving activation of sphingomyelinase (SM) and generation of ceramide may also result in NF-kB activation. NF-kB induces the expression of antiapoptotic genes, including those encoding the antioxidant enzyme manganese superoxide dismutase (Mn-SOD) and the calcium-binding protein calbindin. In many cell types, TNF also activates JUN kinase, which may induce the expression of proapoptotic death genes, and MAP kinase, which may regulate genes involved in cellular plasticity. Signaling pathways involving NF-kB, JUN kinase, and MAP kinases are sensitive to reactive oxygen species (eg, H_2O_2) and elevation of intracellular calcium levels.



In the inactive state, NF-kB consists of three proteins located in the cell cytosol: p50, p65, and I-kB. Signals that activate NF-kB do so by causing **ubiquitin**-mediated **protein degradation** of I-kB; the p50-p65 dimer then translocates to the nucleus and binds to DNA **enhancer elements** that contain specific kB-binding sequences. Genes responsive to NF-kB include those encoding various cytokines and cell-adhesion molecules (2). In addition, NF-kB induces the expression of cytoprotective gene products, including the antioxidant enzyme manganese superoxide dismutase and the calcium-binding protein calbindin D28k (3-6).

TNFa plays a variety of roles, prominent among them the propagation of cytokine cascades involved in cellular responses to injury and inflammatory responses. In tissues throughout the body, TNFa levels increase rapidly and dramatically following cell injury. For example, TNFa levels increase greatly in the brain following epileptic seizures and cerebral ischemia (7, 8). Studies have shown that TNFa can prevent apoptosis in cultured neurons by a mechanism involving activation of NF-kB (5, 9). The latter studies showed that activation of NF-kB with ceramide or I-kB **antisense** treatment suppressed apoptosis, whereas blockade of NF-kB activity using decoy DNA abolished the antiapoptotic action of TNFa. Although TNFa prevents death of postmitotic cells, such as neurons, it can directly kill many types of mitotic normal and transformed cells. In the latter cell types, TNFa apparently activates divergent pathways—a death pathway that may involve JUN/SAP kinases and an antideath pathway involving NF-kB (10). The ability of NF-kB to prevent apoptosis has important

implications for therapeutic approaches for a variety of major diseases, including cancer and neurodegenerative disorders. Thus, agents that block NF-kB activation may prove useful in treating certain types of cancer, whereas agents that activate NF-kB in neurons may prove beneficial in the many neurodegenerative conditions that involve apoptosis (eg, stroke, Alzheimer's disease, and Parkinson's disease). It should be noted that, whereas TNFa can act directly on some cell types (eg, neurons) to prevent or promote their death, it also activates macrophages and microglia, cells that produce cytotoxic substances, including nitric oxide and excitotoxins.

Targeted gene disruption methods have been used to generate mice lacking either p55 or p75, or both receptors. Remarkably, mice lacking one or both TNFa receptors exhibit no overt phenotypes and reproduce normally. However, challenges of the immune systems of these mice have revealed important roles for p55 in T-cell responses. Thus, mice lacking p55 are resistant to endotoxic shock but exhibit increased sensitivity to *L. monocytogenes* infection (13, 14). Responses of neurons and microglia to brain injury are also altered in mice lacking p55. Thus, the extent of neuronal degeneration following severe seizure activity and focal cerebral ischemia is increased in p55 knockout mice, whereas the microglial response to injury is suppressed (7, 15). Lack of TNFa-mediated upregulation of manganese superoxide dismutase may play a role in the altered cellular responses to brain injury in mice lacking p55 (7, 16).

Beyond its critical roles in cell injury responses, TNFa may serve important functions under normal physiological conditions. For example, recent studies have shown that TNFa can modulate neuronal excitability and plasticity in the brain. Thus, exposure of cultured rat hippocampal neurons to TNFa resulted in an increase in whole-cell voltage-dependent calcium currents and a decrease in currents through ionotropic glutamate receptors (11). Measurements of intracellular calcium levels in cultured neurons showed that glutamate-induced calcium influx was attenuated in neurons pretreated with TNFa (3). TNFa may also modify learning and memory processes, as suggested by recent studies showing that long-term depression of synaptic transmission in the hippocampus (a cellular correlate of learning and memory) is altered in mice lacking TNFa receptors. Interestingly, recent data suggest a role for TNFa in regulating sleep and circadian rythyms (12). These types of data suggest that TNFa may have important functions beyond its quite dramatic roles in tissue injury and repair.

Tumor Promoters

1. Definition

A tumor promoter is generally defined as a chemical, a complex of chemicals, or a biological agent that promotes a later stage of carcinogenesis, called *tumor promotion*, by altering expression of the genetic information, rather than altering the structure of DNA.

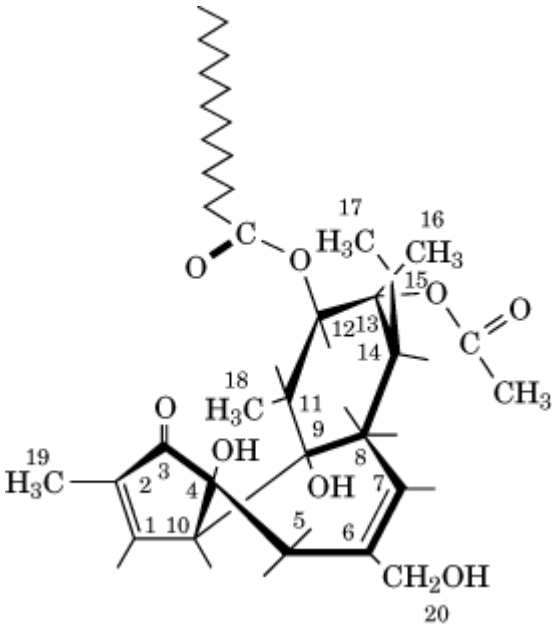
2. Tumor Promotion

Carcinogenesis in skin and other epithelia can be divided into three distinct stages: (i) initiation, (ii) tumor promotion, and (iii) tumor progression. Historically, Berenblum and Shubik (1) first demonstrated in 1947 the initiation and promotion stages in skin carcinogenesis of mice. Initiation resulted from the administration of a single dose of a known carcinogen, called the *initiator*, which initiates carcinogenesis but is not sufficient to develop tumors. The stage of promotion requires repeated applications of a second compound, called the *promoter*, which by itself is incapable of inducing carcinogenesis. Reversed order of application of these compounds—that is, first promoter, then initiator—does not produce tumors. Tumors developed by the initiation-promotion protocol (two-stage carcinogenesis protocol) are largely of benign nature, but they progress further to malignant tumors, either spontaneously or by treatment with carcinogens. This stage is called *progression*.

3. Tumor-Promoting Agents

The classical experiment of Berenblum and Shubik used croton oil, the seed oil of Euphorbiacea, *Croton tiglium*, as a tumor promoter. Hecker and coworkers (2) demonstrated that the 12,13 diesters of phorbol are the irritant and promoting principles of croton oil, of which the best known and most potent is 12-*O*-tetradecanoylphorbol 13-acetate (TPA), also known as phorbol myristate acetate (PMA) (Fig. 1). TPA is widely used not only as a tumor promoter but also as a modulator of biological responses in a wide variety of experiments.

Figure 1. Structure of 12-*O*-tetradecanoylphorbol 13-acetate (TPA), also known as phorbol myristate acetate (PMA).



Very many diverse chemicals, complexes of chemicals, or biological agents are listed as being tumor promoters with a significant degree of tissue specificity. For example, phenobarbital, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), mycotoxins, and hormones have all been shown to promote liver carcinogenesis in rats and mice. Saccharin acts as a promoter in bladder carcinogenesis of rats. Human carcinogenesis may be promoted by chemicals, environmental factors, and life styles. These include dietary fat in breast and colon cancer, sodium chloride in stomach cancer, cigarette smoke in lung cancer, asbestos in lung cancer and mesothelioma, synthetic estrogens in liver adenoma, and alcoholic beverages in liver and esophageal cancer.

4. Biological Responses

Phorbol ester tumor promoters evoke a wide variety of biological responses in cells, including stimulation or inhibition of terminal differentiation, stimulation of DNA replication and cellular proliferation, modulation of cellular responses to external stimuli (eg, **cytokines**), and disturbance of cell–cell communication. Topical application of TPA to dorsal skin of mice results in epidermal hyperplasia. In skin carcinogenesis models, tumor promoters induce clonal expansion of the initiated cells as a consequence of these biological responses.

5. Activation of Protein Kinase C

The pleiotropic cellular effects of phorbol esters were hardly understood before the revolutionary work of Nishizuka's laboratory in 1982 (3). They demonstrated that phorbol ester tumor promoters activated protein kinase C (PKC), a **serine-threonine kinase** normally activated by metabolic modification of polar head groups of membrane lipids. Physiologically, PKC is normally activated by **diacylglycerol** (DG) in the presence of phosphatidylserine (PS) and Ca^{2+} (for conventional PKC). DG is formed through phosphatidylinositol turnover by phospholipase C. Phorbol ester tumor promoters activate PKC in place of DG. While DG is formed and further metabolized within a short period of time, phorbol esters bind to and activate PKC strongly, resulting in sustained down-regulation.

PKC exists as a family containing at least 10 members classified into three groups: (i) Ca^{2+}, PS, and DG-dependent conventional PKC (a, bI, bII, and g **isoforms**); (ii) Ca^{2+}-independent novel PKC (d, e, q, and h isoforms); and (iii) Ca^{2+}- and DG-independent atypical PKC (z and l/ isoforms). It is not known which isoforms are involved in promotion, although the h isoform was found to regulate negatively the tumor promotion process by induction of terminal differentiation of keratinocytes (4).

6. Induction of Ornithine Decarboxylase

Ornithine decarboxylase (ODC) is a key enzyme regulating the polyamine biosynthetic pathway. Topical application of phorbol esters causes rapid and dramatic induction of ODC (5). In tumors produced by the two-stage skin carcinogenesis protocol, the levels of ODC and polyamines are elevated constitutively. Of particular interest is that tumor promoters are no longer required for two-stage carcinogenesis when ODC is overexpressed in hair follicle keratinocytes, implying a crucial role of ODC induction in carcinogenesis (6).

7. Gene Expression

In contrast to initiators that interact with cellular genes, most tumor promoters alter **gene expression** in an epigenetic manner. There is convincing evidence that phorbol ester tumor promoters exert their biological effects by induction of the transcription factor complex AP-1, which consists of members of the *fos* and *jun* nuclear **oncogene** families. The AP-1 complex activates transcription of the genes having the TPA-responsive element (TRE) in their **promoter** regions (7, 8) (see Response Element). Thus, the transcription regulated by AP-1/TRE plays a key role in the early events triggered by phorbol ester tumor promoters.

8. Genotoxicity

There is some evidence that phorbol ester tumor promoters lead to genotoxicity at the chromosome level, including aneuploidy, chromosomal aberrations, and gene amplification . However, these effects might be indirect, resulting from diverse cellular responses.

Tumor Suppressor Genes

Oncogenes are usually dominant, mutated forms of proto-oncogenes. In several instances, however, cell transformation is also induced by recessive mutations of certain **genes**, termed antioncogenes or

tumor suppressor genes. As the name indicates, the loss of the functional activity of these genes, by either point mutations or deletions, leads to oncogenesis, suggesting that the products of these genes suppress tumorigenesis (1). Such loss of tumor suppressor gene function causes retinoblastoma, Wilm's tumor, colorectal carcinoma, nerofibromatosis type 1, and familial adenomatosis polyposis. Although several tumor suppressor genes have been identified, many remain unknown. Two well-characterized tumor suppressor genes, the **retinoblastoma** gene and the p53 gene, are discussed here and in their individual articles.

The protein encoded by the retinoblastoma (Rb) gene is a 105-kDa polypeptide chain, also known as p105RB, that can be **phosphorylated** . The phosphorylation state of p105RB is tightly regulated during the cell cycle, is maximal during the S-phase, and minimal soon after mitosis. Stimulation of quiescent T cells leads to hyperphosphorylation of p105RB, whereas differentiation of myeloid cells is associated with very low levels of phosphorylated p105RB. Interestingly, only the hypophosphorylated form of RB is tumor suppressive. p105RB is phosphorylated in the late G1/S-phase and dephosphorylated in the late M-phase. In its dephosphorylated state, the Rb gene product binds to a group of transcription factors, termed the E2F class of proteins, which are required for DNA synthesis (1, 2). Growth factors stimulate phosphorylation of the Rb protein by activating a group of kinases known as CDC kinases, which phosphorylate Rb. The p34CDC2 kinase (2) is a candidate kinase involved in this process. In turn, this process reduces the affinity of p105RB for E2F, allowing these transcription factors to bind to DNA and to activate the transcription of genes required for DNA synthesis. Interestingly, growth inhibitors, such as transforming growth factor b (TGF-b) which inhibits cell proliferation, prevent phosphorylation of p105RB, even in the G_1/S-phase. These observations suggest that the phosphorylation of p105RB is a critical regulatory event in cell proliferation.

p105RB binds to the adenovirus E1A protein, and this association is essential for adenoviral transformation. Hence, transforming DNA viruses induce transformation by sequestering the hypophosphorylated form of RB105. The biochemical mechanism of tumor suppression by p105RB is at the level of expression of the proto-oncogenes c-*myc* and c-*fos* because RB expression suppresses the expression of both genes.

p53 is another well-characterized tumor suppressor gene, which encodes a polypeptide chain of 375 amino acids. As with RB, loss of p53 function results in the onset of oncogenesis. p53 plays a pivotal role during the execution of **apoptic** (programmed cell death) pathways that are induced as a result of **DNA damage** caused by agents, such as ultraviolet or ionizing radiation. Current models suggest that DNA damage results in up-regulating p53 gene transcription and accumulation of this protein in the cell (3). Accumulation of p53 results in enhanced transcription of a group of genes, such as the cell cycle-dependent kinase inhibitor p21/WAF-1/cip-1, that are responsible for stalling the cell cycle in either the G_1- or G_2/M-phases. This mechanism provides the cell with valuable time to make critical repairs in its genetic material. If the necessary repairs cannot be made, the p53 protein initiates a “suicidal” apoptotic program that results in cell death to prevent clonal expansion of a cell that has a mutated genome. Malignant cells have evolved novel strategies to destroy p53 function. One mechanism is through mutating the p53 gene and protein. Normal p53 protein binds to DNA and transactivates transcription of a distinct set of target genes. Mutated forms of p53, however, have lost the ability to bind DNA in this fashion and therefore behave abnormally. A second mechanism by which normal p53 function is subverted in a cancerous cell is through the MDM2 protein. The MDM2 protein binds to p53 and is amplified in many tumor cells. When these two proteins are bound, p53 cannot mediate growth arrest at the cell cycle checkpoints (as described previously), which leads to rapid clonal expansion of cells that have unstable, mutated genomes.

Turnover Number

The turnover number for an **enzyme**-catalyzed reaction is defined as the number of moles of substrate converted to product per mole of enzyme per second under conditions at which the concentration of all substrates is saturating. Turnover numbers are expressed in units of s^{-1}. The turnover number can also be expressed as moles of substrate converted to product per mole of catalytic subunit per second; this is the most useful definition for the enzymologist, but such a definition can apply only when the number of catalytically competent subunits is known. The relationship between the rate constants associated with a reaction and its turnover number can be illustrated by reference to an ordered Uni–Bi reaction (Fig. 1). Such a **kinetic mechanism** might be catalyzed by a **phosphatase**, with inorganic phosphate as the last product to be released. For the most general case in which catalysis and the release of both products limit the maximum velocity of the reaction V, the turnover number would be given by the expression

$$\frac{V}{E_t} = \frac{k_3 k_5 k_7}{k_3(k_5 + k_7) + k_7(k_4 + k_5)} \tag{1}$$

where E_t is the total amount of enzyme present. Equation (1) simplifies to

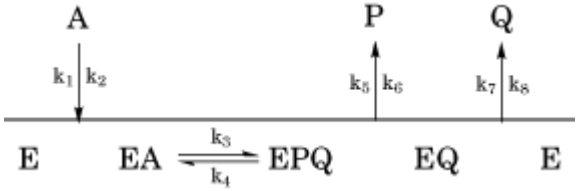
$$\frac{V}{E_t} = \frac{k_3 k_5}{(k_3 + k_4 + k_5)}$$

if the release of Q from the EQ complex is fast compared with catalysis and the release of P. The equation would simplify to

$$\frac{V}{E_t} = \frac{k_5 k_7}{(k_5 + k_7)}$$

if the maximum velocity was limited by the rate of release of the products, which is common for enzyme-catalyzed reactions (1). If the rate of release of the products was much faster than catalysis, V/E_t would simply be equal to k_3, which is the relationship that is derived from Michaelis-Menten kinetics. In connection with the aforementioned comments, it should be noted that values for k_3 and k_4 cannot be obtained directly by the use of steady-state kinetic techniques although they might well be determined through the application of transient-state kinetic analysis (2).

Figure 1. Ordered Uni–Bi reaction kinetic mechanism to illustrate the unimolecular steps that can limit the maximum velocity of the reaction.



The turnover numbers for enzymes vary considerably from 2 to 5 s^{-1} for **ribulose bisphosphate carboxylase** (3), which is a very sluggish enzyme, to 1 million s^{-1} for carbonic anhydrase (see Michaelis–Menten Kinetics).

Turns

Turn is a general term that describes several types of nonregular secondary structure in **protein structures** that cause a change in the direction of the polypeptide chain. Turns are also known as reverse turns (since they reverse the chain direction). They include b-turns, g-turns, **hairpins**, W-loops, and b-bulges (although for b-bulges, the change in direction is much less than that of other types of turn).

The b-turn defines a four-residue turn stabilized by a backbone hydrogen bond between the first and fourth residues. Similarly, a g-turn defines a three-residue turn stabilized by a backbone hydrogen bond between the first and third residues. Different types of b-turn and g-turn exist and are classified by their backbone conformation. Hairpin defines a b-strand-turn-b-strand motif, where the turn is often a b-turn or a g-turn. The W-loop defines a loop-shaped backbone conformation of six or more residues that resembles the Greek letter omega (W); b-bulge defines a disruption to the regular structure of a b-sheet caused by an additional residue in an edge b-strand.

Turns are distinguished from the regular types of secondary structure (b-helix and b-sheet) in that they do not have repetitive backbone conformations and hydrogen bonding patterns. Most residues in turns, however, adopt backbone conformations close to the a-helical or b-strand conformations. The difference is that the backbone conformations of successive residues in a turn vary, whereas in b-strands and a-helices the backbone conformations of consecutive residues are usually similar. Glycine or proline residues are often found in turns, especially where unusual backbone conformations are required. Turns are usually found at the surface of proteins, where the peptide bonds that do not interact with protein atoms can form hydrogen bonds with the solvent.

Twist, DNA

Twist is an aspect of DNA structure that concerns DNA topology.

1. Total Twist

1.1. General Considerations

The twist is a property of two curves that are connected by a one-to-one correspondence surface. Generally, the twist $Tw(C', C'')$ of one curve (C') about another (C'') is a measure of how often C' spins about C'' as one advances along C''. In contrast to the **linking number**, the twist depends on the ordering of the two curves; hence, except for certain special cases (1), $Tw(C',C'') \neq Tw(C'',C')$. In considering the twist of DNA, one possible choice of C' and C'' is to use the two backbone chains, C_1 and C_2, giving $Tw(C_1, C_2)$ or, alternatively, $Tw(C_2, C_1)$, as the DNA twist. Although this is useful in certain special cases (2), the choice is unnatural for closed duplex DNA (cdDNA). This is because the fundamental relationship (3) for cdDNA, $Lk = Tw + Wr$, would then involve the **writhe** of either of the backbone chains, which is seldom desirable.

1.2. The Strand-Axis Twist in DNA

As applied to DNA, the choice of C' and C'' is dictated by the natural duplex helical geometry: one of the curves is customarily chosen to be the duplex axis, A; and the other curve, C, is taken to be a line along either of the two strands. The symbol Tw alone is understood to mean $Tw(C, A)$. The question then arises as to whether $Tw(C_1,A) = Tw(C_2,A)$; that is, does it matter which strand is chosen? This is answered by writing the fundamental equation for both choices: $Lk(C_1,A) = Tw(C_1,A)+Wr(A)$ and $Lk(C_2,A) = Tw(C_2,A)+Wr(A)$. Now $Lk(C_1,A) = Lk(C_2,A)$, except for special cases in which the DNA contains asymmetric local substructures (as, eg, the extrusion of imperfect palindromes into cruciforms). Such special cases require use of the intersection number, a separate topological quantity (2), in the fundamental equation. For most cases of practical interest, in which the duplex axis is uninterrupted, $Tw(C_1,A) = Tw(C_2,A)$. If the DNA axis is a straight line, or if the axis is closed and lies entirely in a plane, the twist is simply the number of revolutions made by C as it winds around A. Here both C and A are taken to be oriented in the same direction. For example, a B-DNA containing 15 bp has a twist of $Tw_0 = N/h_0 = 15/10.5 = 1.429$, where N is the number of base pairs and h_0 is the number of base pairs per turn of the helical repeat. DNA is, however, rarely encountered with a truly linear axis. Any out-of-plane motion of axis A leads to values of $Tw \neq Tw_0$, with the extent of the deviation dependent on the amount of axial torsion. A more general way of calculating Tw is therefore needed.

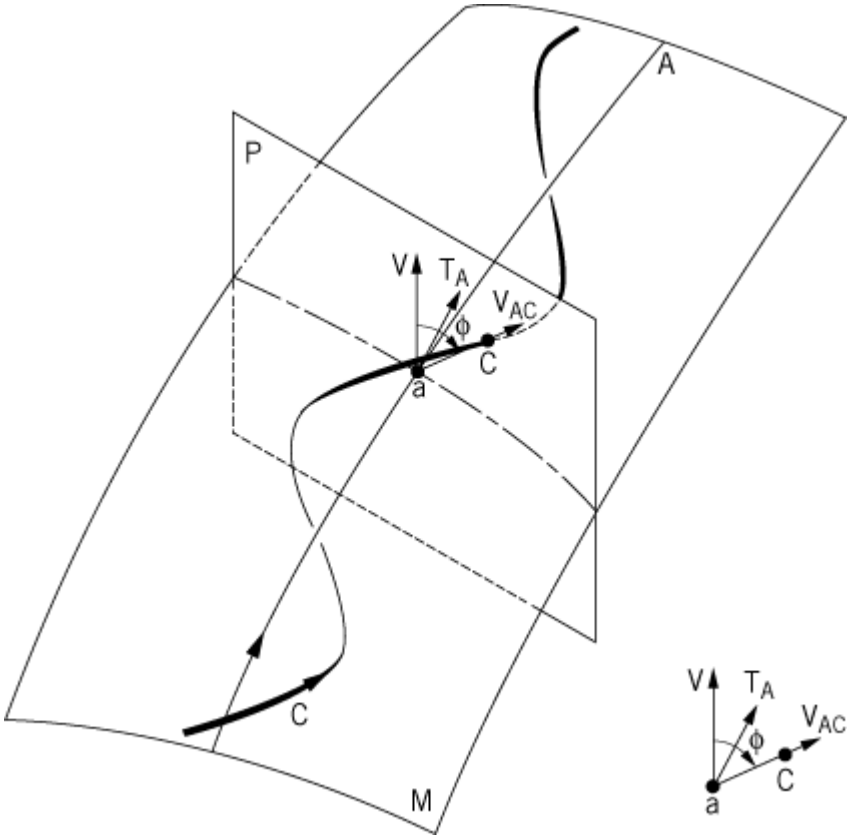
Since the twist depends on the joint trajectory of A and C, it is most straightforward to use vector notation, as described in Figure 1. Let the DNA axis, A, lie on a surface as shown. $\mathbf{T}_A$ is the unit tangent vector to A at a particular point a. One of the two DNA backbone curves, here C, winds

around A and cuts the surface twice per revolution. The vector $\mathbf{v}$ is the surface normal at any point on A. The unit vector $\mathbf{v}_{AC}$ is perpendicular to A and connects A to C. Then the twist of either of the two DNA strands about the duplex axis is

$$Tw \equiv Tw(C, A) = \frac{1}{2\pi} \int_A [\mathbf{T}_A \times \mathbf{v}_{AC}] \cdot d\mathbf{v}_{AC} \qquad (1)$$

This equation can be used to calculate the twist of duplex DNA having any particular axis and backbone geometry. In the case of DNA, the twist is a measure of the spinning of either backbone phosphodiester–sugar chain about the (imaginary) duplex axis. Conceptually, Tw is the total change in $\mathbf{v}_{AC}$ in the direction of the normal vector, $\mathbf{T}_A \times \mathbf{v}_{AC}$, as the entire DNA segment is traversed. Physically, Tw provides the torsional contribution to the elastic energy of the DNA segment modeled as an elastic rod.

Figure 1. Definition of the vectors used in calculation of the twist and the surface twist. The DNA axis, A, lies on a surface M as shown. One of the two backbone curves, C, winds around A and cuts the surface twice per revolution. The vector $\mathbf{v}$ is the surface normal to M at any point on A. An imaginary plane (P), is perpendicular to the axis curve and moves along A. The plane intersects backbone curve C at successive points c. The unit vector $\mathbf{v}_{AC}$ is perpendicular to A and connects A to C at point c. The backbone chain passes, in a right-hand sense, alternatively above and below the surface. $\mathbf{T}_A$ is the unit tangent vector to A at a particular point, a. The winding number, $\mathrm{F}(A)$, of C about A is given by the number of revolutions of $\mathbf{v}_{AC}$ about $\mathbf{v}$ as P advances along curve A. This is shown separately in the inset. For the calculation of the total twist, Equation (1), the surface M is not needed, nor is the vector $\mathbf{v}$.



2. Twist of DNA Wrapped on a Protein Surface

DNA is commonly associated with proteins; the best documented example is the nucleosome. In

most cases, this interaction brings about a nonlinearity in the DNA axis, meaning that the twist differs from that for a straight-line axis. In general, the twist for DNA that is wrapped on a protein surface may be divided into two parts (4):

$$Tw = \Phi + STw \tag{2}$$

where the two independent components of the twist are F(A), the winding number of the DNA axis, A, and STw, the surface twist.

2.1. Winding Number

The winding number, F(A), is a measure of the number of times that $\mathbf{v}_{AC}$ rotates about $\mathbf{v}$ as the axis curve A is traversed:

$$\Phi(A) = \left(\frac{1}{2\pi}\right)\int_A d\phi \tag{3}$$

where f is the angle between $\mathbf{v}$ and $\mathbf{v}_{AC}$ (Fig. 1, inset). The winding number has also been called (5) the "local reference frame twist," in which context Tw is called the "laboratory frame twist." The winding number can be measured directly by any technique that is differentially sensitive to either DNA chain when it is near or removed from the protein surface. Examples include **nuclease** digestion (6) and chemical reagents, such as hydroxyl radical footprinting (7, 8). In both cases, the DNA is preferentially cleaved when away from the surface, leading to a periodicity in the cleavage pattern that is a direct measure of F.

2.2. Surface Twist

The second term that appears on the right in Equation (2) is the surface twist, STw. This can be calculated for DNA lying on any smooth surface with the integral (1)

$$STw = \frac{1}{2\pi}\int_C \mathbf{T}_A \cdot \mathbf{v} \times d\mathbf{v} \tag{4}$$

Reference should again be made to Figure 1. As before, $\mathbf{T}_A$ is the unit tangent vector to A at a particular point a. The integral for STw differs from that for Tw by the use of $\mathbf{v}$ instead of $\mathbf{v}_{AC}$. The vector $\mathbf{v}$ is the surface normal at any point on the surface touched by the DNA axis and includes the required information about the local surface contour. The correspondence vector $\mathbf{v}_{AC}$, in contrast, contains only information about the correspondence between A and C, without regard to the surface chosen.

2.3. Example of the Nucleosome

Equation (4) can be used to calculate STw for any DNA wrapping surface of known geometry (9). For example, the nucleosome can be described as a cylindrical surface M of radius R on which the DNA axis A wraps n times as a left-handed helix of pitch 2pp (where R is the sum of the radius of the histone octamer core and the radius of the DNA). The central line of the cylinder is labeled L. The unit normal vector $\mathbf{v}$ to M points radially outward from the surface. The application of Equation (4) to this geometry gives the result (9)

$$STw = \frac{-np}{\sqrt{p^2 + r^2}} \tag{5}$$

The minus sign in this equation is a consequence of the left-handed chirality of the winding. In order to calculate the DNA twist from Equation (2), the winding number, F, must be determined independently. The experimental data are that n = 1.85, 2pp = 2.8 nm, and R (the radius of the cylinder plus the radius of the DNA) = 5.3 nm. The calculated value of STw is then –0.16. The value

of F for the 146 bp of DNA wrapped on the nucleosome is 14.6 turns, based on the experimentally determined helical repeat of 10.0 bp/turn (10). The twist of the DNA about the nucleosome core is the sum of *STw* and F, giving *Tw* = 14.44. Had the DNA duplex been linearly extended in solution, $F;_0 = Tw_0 = 146 / 10.54 = 13.85$. For the nucleosome, therefore, the **surface wrapping** and accompanying curvature of the DNA axis increases the twist by about 4%.

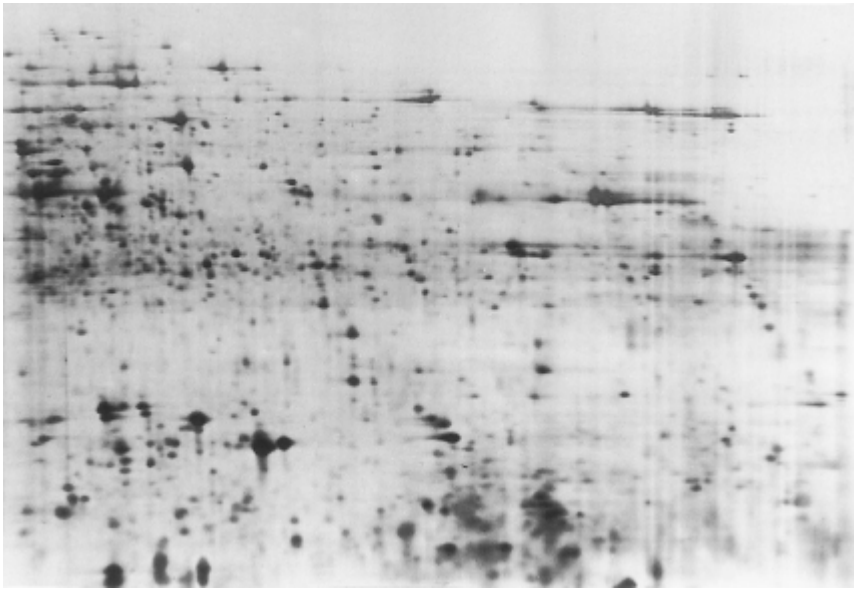
Two-Dimensional Gel Electrophoresis

A two-dimensional gel is uniquely suited for analysis by gel electrophoresis of samples containing many components. The reason is simply geometric: A 10-cm lane covered with evenly spaced idealized bands may be able to resolve 50 such bands; a square of the same dimensions correspondingly can resolve 50^2, or 2500, spots.

Size and net charge are the predominant properties by which proteins differ from one another, so that the first-dimensional gel commonly uses isoelectric focusing to provide a charge separation whereas the second-dimensional gel provides a size separation by means of SDS-PAGE (1). Such gels can resolve thousands of proteins, including those from an entire cell (Fig. 1). The position of each protein on the gel is defined by its isoelectric point (*pI*) and its molecular weight (M_r).

Figure 1. An example of a two-dimensional gel, separating alkaline yeast cell proteins. First dimension: isoelectric focusing in an Immobiline gel, pH 7–10, containing 0.5% carrier ampholytes, 8-M urea, and 0.5% (v/v) NP-40; electrophoresis was for 90,300 V-h. Second dimension: SDS-PAGE, pore gradient gel of 12% to 15% (w/v) acrylamide, 4% Bisacrylamide, in a Tris-chloride-glycinate discontinuous buffer separating at pH 9.5. The proteins were detected by **silver staining**. [Fig. 4 of A. Goerg et al. (1988), *Electrophoresis* **9**, 37.]



Other combinations of separation techniques may be more suitable for specific applications. For example, agarose gel electrophoresis of **viruses** employs an initial low-concentration gel for charge separation and a more concentrated second gel for size separation (2).

With hundreds to thousands of spots, the reproducibility of spot positions on two-dimensional gels is a problem in comparing different gels. It has been solved in part through use of immobilized pH gradients for the isoelectric focusing; these help to produce constant positions for each protein at its *pI* at the steady-state in the first dimension (3). Densitometry and pattern displacement techniques further assist analysts in comparing different gels. To some degree, immunologic detection of spots after blotting has made it unnecessary to identify each spot from its position alone. The identities of proteins in spots can also be confirmed by their molecular weights, which are determined very accurately by mass spectrometry. Nevertheless, even conventional two-dimensional electrophoresis using isoelectric focusing and SDS-PAGE, along with identification of the spots by their positions alone, has been successful in the construction of ever-growing protein databases (4).

Two-Hybrid Systems

(*In memoria*)

Maria Dimitrova

Michèle Granger-Schnarr

Protein–Protein Interactions play a major role in almost all relevant physiological processes occurring in living organisms, including DNA replication and **transcription, RNA splicing, protein biosynthesis, signal transduction**, and many other processes (1). Since the early 1990s, two-hybrid systems have emerged as a powerful new genetic tool for studying binary protein–protein interactions. These two-hybrid assays are generally conducted in the **yeast** *Saccharomyces cerevisiae* and use the activation of transcription of one or several reporter genes to detect the protein–protein interaction in question. In the past, these systems have been used to evaluate the interaction between defined proteins and as a method to identify novel partners for a known protein. As a result of the **sequencing** of several model organisms, however, and the predicted sequencing of the *Homo sapiens* genome in the near future, the two-hybrid approach will probably occupy an even larger place in the biologist's toolbox. The human genome is likely to encode about 50,000 to 100,000 **genes** (2), giving rise to an even greater number of hypothetical proteins due to alternative splicing. This number is an order of magnitude greater than the 6,000 or so genes in *S. cerevisiae*. Unfortunately, the sequence of a gene does not always reveal its biological function, and even in the laboratory workhorse *S. cerevisiae* fewer than half of the genes could be classified as "functionally characterized" in 1997 (3, 4). It is likely that the situation will be even worse for mouse and human gene products, which frequently lack significant homology with proteins from simple model organisms and for which gene **knockout** studies are costly and time-consuming or unfeasible for ethical reasons.

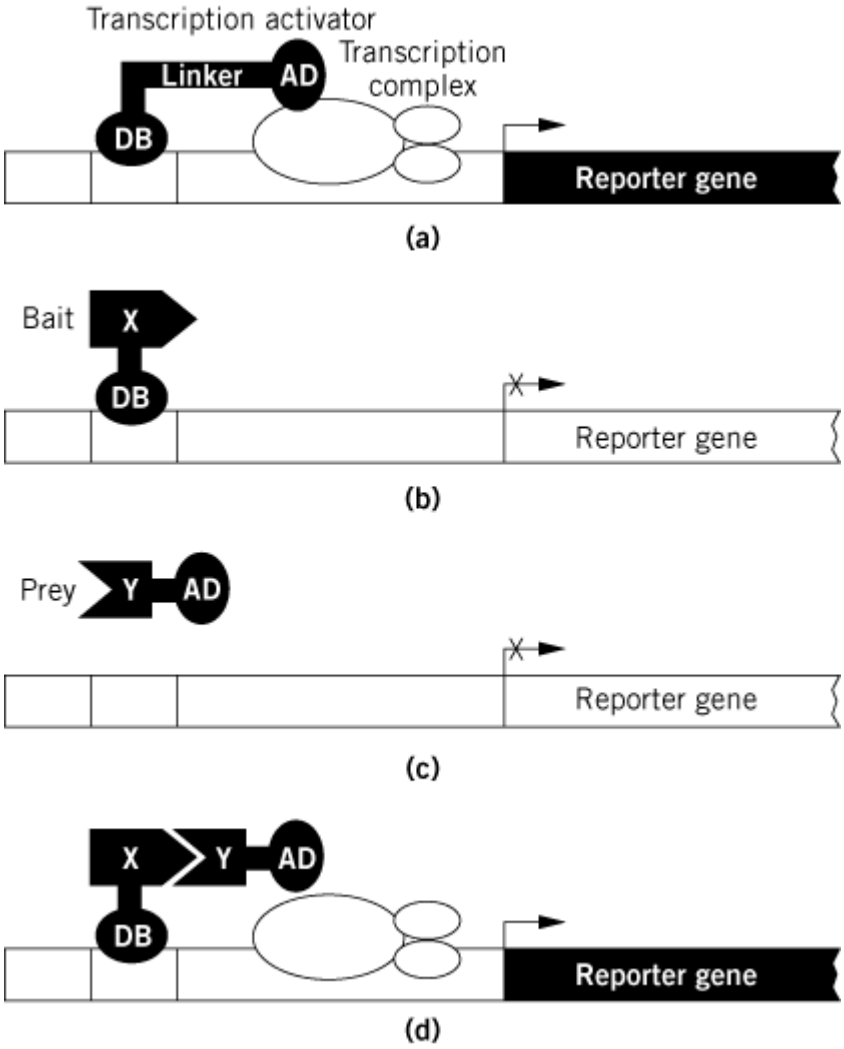
One potential way to classify a protein with unknown function will be to search systematically for its protein partners using two-hybrid methods. If one of these partners has already been functionally characterized, the protein with the yet unknown function is likely to belong to the corresponding regulatory or metabolic pathway.

0.1. History of the Yeast Two-Hybrid System Based on Transcriptional Activation

Most **eukaryotic** transcription activators are modular proteins that harbor at least a DNA-binding **domain** and an activation domain held together by a covalent linker (Fig. 1a). Those proteins, it is thought, trigger the assembly of the transcription preinitiation complex (5). The observation that transcription activators act at variable distances from the transcription start point suggested further that transcription activation in eukaryotes occurs via a mechanism with one or more flexible elements. Along these guidelines, Brent and Ptashne (6) showed that a eukaryotic activation domain fused to the DNA-binding domain of the bacterial LexA repressor functions as a transcriptional activator in yeast. Ma and Ptashne (7) went one step further in showing that transcription is activated even by binary protein complexes in which the DNA-binding and activation domains reside on separate polypeptide chains.

Figure 1. Principle of the yeast two-hybrid assay based on transcriptional activation. (a) A classical eukaryotic transcription activator binds upstream of the promoter via its DNA binding domain (DB) and activates transcription via its covalently linked activation domain (AD). (b) A bait protein X fused to DB generally does not activate transcription

because in most cases it lacks a functional activation domain. (c) A prey protein Y fused to AD also does not activate the reporter gene because this protein cannot bind to the promoter. (d) Interaction between X and Y fused respectively, to DB and AD reconstitutes a functional transcription activator and induces transcription of the reporter gene.



Independent work by Fields and Song (8) that gave rise to the first general two-hybrid assay to monitor protein–protein interactions in yeast. In this assay, a first protein of interest (X) is synthesized fused to a DNA-binding domain (DB). This first hybrid protein (DB-X) binds upstream of a reporter gene. If X is devoid of transcriptional activation capacity, binding of DB-X to the promoter does not activate transcription of the reporter gene (Fig. 1b). A second protein (Y) is synthesized fused to an activation domain (AD). Because this second hybrid protein (AD-Y) cannot generally bind to the promoter, it also fails to induce transcription of the reporter gene (Fig. 1c). However, if the two hybrid proteins (DB-X and AD-Y) are coexpressed and if X and Y interact physically, this interaction brings the activation domain close to the promoter and leads to activation of the reporter gene (Fig. 1d). Since 1989, this two-hybrid strategy has been used widely to study the interaction between known proteins and to isolate from activator domain-tagged cDNA libraries new proteins that interact with LexA or Gal4 fusion proteins used as DB-X "baits". The advantage of this interaction cloning strategy is that the DNA coding for the "prey" protein Y is immediately available. In 1991, Fields and colleagues (9) published the first example of this kind of two-hybrid interaction cloning, using *lacZ* as a screenable reporter gene.

0.2. The Yeast Two-Hybrid System: From Screen to Selection

A significant improvement in the initial two-hybrid system was including additional reporter genes

whose expression is required for yeast growth (10-13). Reporters derived from the yeast *Leu2, His3*, or *URA3* genes transformed the two-hybrid system from a screen to a selection (see Table 1) allowing relatively rare clones to be isolated. The *URA3* reporter (13) has the additional advantage of using either direct selection for growth on uracil for productive protein–protein interactions, and it also makes possible negative selection by using 5-fluoro-orotic acid, which is toxic for yeast growth if the *URA3* gene is expressed. In this case, the *URA3* reporter may be used to probe the lack of interaction between the proteins X and Y. This is particularly useful for identifying a mutation in one or the other hybrid protein that disrupts the interaction between the two proteins. This kind of counterselection may also be useful for identifying reagents that inhibit specific protein interactions. One example of this "reverse two-hybrid" approach has been described by Vidal et al. (14).

Table 1. Different Combinations of DNA Binding (DB) Moieties, Activation Domains (AD), and Reporter Genes Used in Classical Yeast Two-Hybrid Assays

DB	AD	Screen	Selection	Ref.
GAL4	GAL4	lacZ	–	(9)
GAL4	GAL4	lacZ	HIS3 (+3–*AT*)[a]	(10)
LexA	VP16	lacZ	HIS3	(11)
LexA	B42	lacZ	LEU2	(12)
ER	VP16	–	URA3	(13)

[a] 3-AT: 3-aminotriazole.

The various improved two-hybrid variant systems reported in 1993 differ further in the activation domains, using either the strong VP16 activation domain (11), the intermediate Gal4 domain (10), or the weak bacterial B42 domain (12). Weak activation domains potentially increase the spectrum of proteins recovered by avoiding the toxic effects that strong transcriptional activators may have in yeast (15). Most laboratories use either $Gal4_{1–147}$ or the full-length LexA repressor as a DNA-binding moiety. $Gal4_{1–147}$ corresponds to the amino-terminal domain of the yeast transcriptional activator Gal4. This part of the molecule contains specific DNA-binding and dimerization capacity (16). LexA is a bacterial repressor of 202 amino acid residues that harbors an amino-terminal, DNA-binding, and a carboxyl-terminal dimerization domain (17, 18). The most significant difference in the use of LexA or the Gal4 amino terminus in the yeast two-hybrid assay is that the Gal4 domain contains a nuclear localization signal (see Lambda Phage), whereas LexA does not (19). This leads to a lower nuclear concentration of LexA, which may be a problem if LexA fusion proteins are expressed from **vectors** that integrate into the genome, leading to a loss of sensitivity not found for integrating Gal4 vectors.

0.3. Correlation of Yeast Two-Hybrid Data with *in Vitro* Measurements

Despite the extensive use of the yeast two-hybrid technology by hundreds of different research groups for interaction cloning, little is known about (1) the equilibrium binding constant between proteins X and Y necessary to produce significant reporter gene expression and (2) the extent to which the degree of protein interaction determined by yeast two-hybrid methods correlates with the degree of interaction determined by biochemical techniques.

In regard to the first question, Estojak et al. (20) showed that the yeast two-hybrid assay may detect protein–protein interactions with a **dissociation constant** (K_d) as high as ~1 μM. These results were

obtained mainly with dimerization-defective versions of the lambda phage cI repressor and **Myc**, Max, and Mxi1 **helix-loop-helix** proteins. To extend the range of sensitivity and discrimination of the assay, the authors used different reporter **plasmids** that have one, two, and 8 LexA operators in front of the *lacZ* gene. With the one-operator *lacZ* reporter, the system was able to detect interactions with a predicted K_d ranging from 20 nM to nearly 1 μM, whereas interactions with lower affinities of K_d>1 μM were not detected. The results with two operators were comparable, but allowed more resolution of differences between weak interactions, plus detection of interactions in the K_d range of 1 μM. Finally, the eight-operator reporter allowed clear detection of interactions in the 1 μM K_d range but had high background levels of activity for many of the baits and showed compression of differences between strong and moderate interactions.

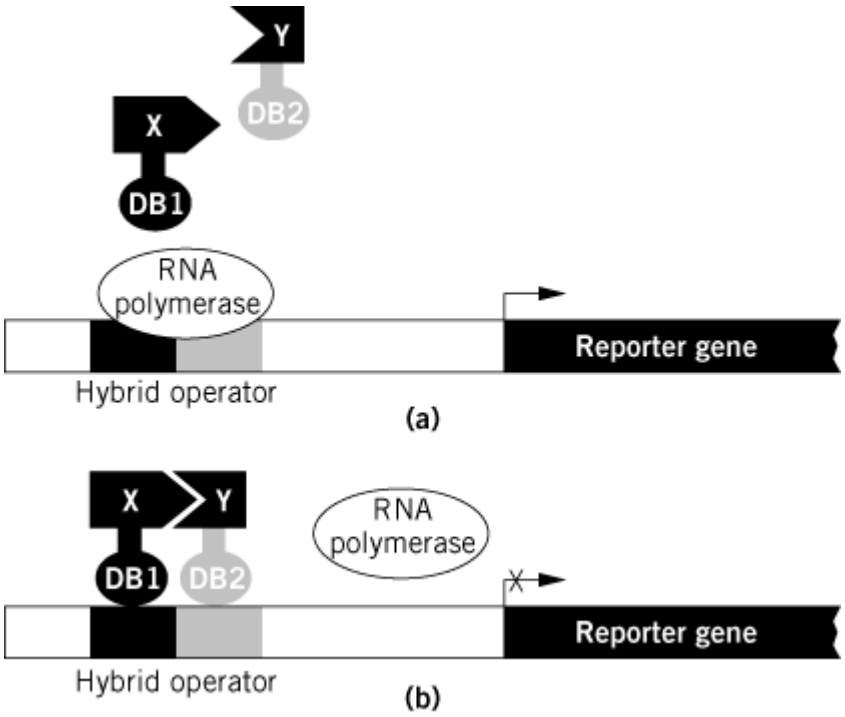
These observations lead immediately to the second question that involves attempts to correlate yeast two-hybrid data more quantitatively with relative binding affinities determined *in vitro*. At least in the case of the phage lambda cI variants, this kind of correlation is difficult to establish (20). A comparison of a lambda wild-type dimerization domain fusion (K_d = 20nM) with the partially dimerization-deficient Ala152Thr variant (K_d~1 μM) shows that the relative affinities deduced from *in vivo* data would depend strongly on the reporter plasmid. Depending on the reporter used for these studies, formation of a Ala152Thr homodimer would be 200-fold less, seven-fold less, or even two-fold greater than the formation of a cI wild-type repressor homodimer. In this case, the data from the least sensitive *lacZ* reporter (that harbors a single LexA operator) would most closely parallel the *in vitro* data. Surprisingly, the *LEU2* reporters did not detect interactions for this set of lambda cI repressors. This may be due to the fact that in these experiments the *lacZ* reporters were carried on multicopy plasmids, whereas the *LEU2* reporters were integrated into the chromosome .

Given these issues, the data of Estojak et al. (20) suggest that prudent use of a two-hybrid system to study protein interactions should involve assays with low- and high-sensitivity *lacZ* reporters and with at least one *LEU2* reporter. Further, putative interactions should be tested in both orientations, because the two-hybrid assay is subject to directionality for some protein pairs (20).

0.4. Bacterial Two-Hybrid Systems Based on Transcriptional Repression

Given the difficulties encountered with the yeast two-hybrid system, it seemed worthwhile to develop in parallel transcription-based two-hybrid reporter systems in model organisms even simpler than yeast. The eubacterial transcriptional apparatus is much simpler than that of yeast and other eukaryotic organisms, and transcription in eubacteria may be efficiently inhibited by repressor molecules that simply prevent the **RNA polymerase** holoenzyme from interacting with a given promoter. Dimitrova et al. (21) recently developed a LexA-based two-hybrid assay in *Escherichia coli*, whose principle is outlined in Fig. 2. In this assay, a protein Y is fused to the LexA wild-type DNA-binding domain (DBD2) and a protein X is fused to an altered-specificity DNA-binding domain (DBD1) that harbors three point mutations in the LexA helix-turn-helix motif. These two hybrid proteins regulate the expression of a reporter gene placed under the control of a hybrid LexA **operator** that has a wild-type half-site and a mutated half-site recognized by the altered-specificity LexA variant.

Figure 2. Principle of a bacterial two-hybrid assay based on transcriptional repression. (a) Protein X is fused to an altered-specificity LexA DNA binding domain and protein Y to a wild-type DNA-binding domain comprising in both cases the 87 first amino acids of LexA. Without a dimerization domain, $LexA_{1–87}$ cannot act as a repressor. Thus, if X and Y do not interact, the reporter gene is transcribed. (b) If the proteins X and Y interact, the two hybrid-proteins bind efficiently to the hybrid operator and transcription of the reporter gene is repressed.



In this system, significant DNA binding *in vitro* and transcriptional repression of the *lacZ* reporter *in vivo* are observed only upon coexpression of the two fusion proteins DBD1-X and DBD2-Y (21). This assay allows specific detection of a complex between X and Y even if both X and Y can form homodimers. This possibility was not included in a lambda cI repressor-based system, where X and Y were both fused to a wild-type cI DNA binding domain (22), so that both heterodimerization and homodimerization may give rise to transcriptional repression.

The opposite limitation is inherent in bacterial systems, which use a dominant-negative **phenotype** to monitor heterodimer formation with repressor fusion proteins in *E. coli* (23-26). In this case, a DBD-X homodimer, which confers transcriptional repression, is challenged with a protein expressed either alone (23) or fused to a DNA-binding-deficient domain (24-26). If Y can dissociate an appreciable amount of the DBD-X homodimers, transcriptional repression is relieved, leading to a dominant-negative phenotype. Obviously, this strategy can be applied only if either X or Y can form homodimers. This kind of assay has been used for interaction cloning of a **HMG**-box protein, which binds to the helix-loop-helix domain of the c-Myc **oncoprotein** (25). It remains to be seen if these bacterial two-hybrid systems becomes as popular as the yeast two-hybrid assay for studying known protein interactions and molecular cloning of unknown interaction partners for a known protein.

0.5. Identification of Unknown Interaction Partners with Yeast Two-Hybrid Systems

Using yeast two-hybrid systems, an increasing number of previously unrecognized protein–protein interactions have been detected. Many of these were compiled by Golemis et al. (27). This and other reviews (28-31) describe in much detail the vectors, reporter strains, procedures, and possible problems of two-hybrid interaction cloning experiments. Obviously the bait protein DB-X must have little or no intrinsic ability to activate transcription on its own, must be expressed at reasonably high levels, and must be able to enter the yeast nucleus and bind DNA. Conversely, it has to be verified that the prey protein AD-Y does not activate transcription of the reporter gene on its own. But even in those cases where X and Y definitely interact in the yeast nucleus, this interaction is not necessarily biologically relevant, and its functionality has to be extensively tested *in vivo* and *in vitro*. For example, two heterologous proteins may interact specifically in the yeast nucleus but may not be expressed in the same cell type at the same time. Additionally, several classes of proteins have been isolated by using very different baits, including **heat-shock** proteins, **ribosomal** proteins,

cytochrome oxidase, **mitochondrial** proteins, and proteasome subunits. Because these proteins generally have no obvious biological relationship to the bait protein, these interactions are generally classified as false positives. Another potential problem of the two-hybrid approach is that a detected interaction supposed to be binary may depend in fact on one or more yeast proteins, which may serve as either bridge or connecting proteins between X and Y, or simply stabilize an existing physical interaction between X and Y.

This potential ability of the two-hybrid assay to detect ternary protein complexes has been intentionally used by several groups. Van Aelst et al. (32) demonstrated, for example, that the signal transduction proteins Ras and MEK interact only in the two-hybrid assay if the Raf protein is overexpressed at the same time. Legrain and Chapon (33) showed that the yeast splicing factors PRP9 and PRP11 do not interact directly but that these two proteins can bind simultaneously to a third protein (SPP91, now called PRP21) to form a three-molecule complex.

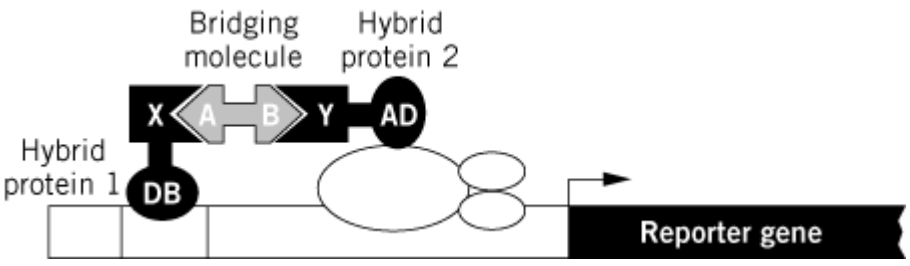
Protein–protein interactions sometimes depend on the **posttranslational modification** of one component of the complex. In particular, protein **phosphorylation** plays a major role in numerous signal transduction pathways. However, yeast cells generally do not employ, for example, tyrosine phosphorylation as a major regulatory modification. To overcome this problem, Osborne et al. (34, 35) coexpressed a **tyrosine kinase**, a cytosolic immunoreceptor domain (that contains phosphorylatable tyrosine residues), and an **SH2 domain**. As expected, the immunoreceptor domain and the SH2 domain interacted in the yeast two-hybrid assay only upon coexpression of a functional tyrosine kinase (34).

To develop a more general system for identifying of a third bridge or connecting protein, Xu et al. (36) developed a two-bait system in which transcription of selectable and counterselectable reporters is directed by different baits. The *URA3* reporter is placed under the control of a tetracycline repressor fusion protein, and the *lacZ* gene is controlled by a LexA repressor fusion. The prey protein (or a prey protein library) is fused as usual to the B42 activation domain.

0.6. Systems that Detect Interactions Dependent on a Third Nonprotein Molecule

Figure 3 shows the rationale of this kind of experiment. The two DB-X and AD-Y fusion proteins do not interact directly but are connected by a covalently linked bifunctional molecule for which the A-moiety interacts with X and the B-moiety with Y. Licitra and Liu (37) used this strategy for a small synthetic ligand, where A was dexamethasone, which readily interacts with the glucocorticoid receptor (which was fused to LexA), and B was the small molecule Development, which interacts with the FKBP12 protein (fused to the B42 activation domain). As outlined by the authors, the dexamethasone/FK506 hybrid molecule is **hydrophobic** and penetrates readily into yeast cells. This is generally not the case for hydrophilic or charged ligands. To generalize this approach, it is important to develop yeast strains that are more permeable and do not significantly affect yeast viability.

Figure 3. Principle of the yeast three-hybrid approach. The two hybrid proteins DB-X and AD-Y do not interact directly as in Fig. 1d, but this interaction is mediated by a third bifunctional bridging molecule. This bridging molecule may be a synthetic organic molecule or a hybrid RNA molecule that has an A moiety that interacts with protein X and a B moiety that is prey for the search of a RNA-binding protein Y.



A–protein interactions are pivotal in fundamental cellular processes, such as **translation, messenger RNA** processing, early development, and infection by RNA **viruses**. In spite of the central importance of these interactions, however, few approaches are available to analyze them rapidly *in vivo*. In the three-hybrid approach, the A-moiety in Fig. 3 corresponds to a RNA **stem-loop structure** that interacts with the well-characterized, sequence-specific, RNA-binding coat protein from **bacteriophage** MS2. For the covalently linked B-moiety, the authors used either iron response element RNA, which interacts with the iron regulatory protein 1, or HIV **transactivation response element** RNA, which interacts with the HIV transactivator protein Tat. Subsequently the same group used this approach to identify an RNA-binding protein that interacts with the 3′ untranslated region of a mRNA involved in the regulation of sexual fates in *Caenorhabditis elegans* hermaphrodite germ lines (39).

0.7. Interaction Mating and Functional Genomics

A major question for most biologists in the approaching post-genome-sequencing era is how to handle the protein sequence data generated by systematic DNA sequencing projects. There will be an enormous amount of protein primary structure information, which must be converted into biologically more relevant information, that is, we have to understand how a given protein is involved in one, or potentially several, regulatory or metabolic pathways. Extrapolating from the experience with the *S. cerevisiae* genome (3, 4), the function of fewer than half of the proteins will be inferred from their primary structure by sequence homology with functionally characterized proteins. For the remaining proteins, new concepts and techniques will have to be developed, especially for those higher eukaryotes without developed genetics. One way to proceed will be establishing genome-wide, two-hybrid information from systematic application of yeast interaction mating experiments (40-43). DNA Libraries yeast cells exist in two **mating types** that mate with one another and form diploids if they come into contact. By mating haploid strains of opposite mating types that contain potential interacting proteins, exhaustive and rapid screens of cDNA and genomic DNA libraries may be conducted.

Fromont-Racine et al. (43) used this strategy to establish a partial yeast protein interaction map, starting from ten protein baits that are involved in pre-mRNA splicing. Several identified prey proteins were used subsequently as new baits for further rounds of interaction cloning experiments. Conceivably, this strategy may be extended to establish protein linkage maps for whole genomes if most of the work is done by laboratory robots. Based on the nature of the interacting partners, such protein linkage maps will suggest functions for new proteins and lead to hypotheses as to the role of a protein in a special regulatory or metabolic pathway. Given that so many proteins function by interacting with other proteins (44), in principle two-hybrid approaches can provide useful information for a significant fraction of the **proteome** of any given organism.

Ty Elements

Ty elements are transposable elements that were originally found in *Saccharomyces cerevisae* (1). Tys are retrotransposons, resembling retroviruses in many ways, although Tys are not infectious nor do they have an extracellular phase. Such retrotransposons are widespread and fall into two major classes; both are similar to retroviruses, but differ most obviously in gene order. The two most extensively studied yeast Tys are Ty1 and Ty3, and these elements represent the two classes of retrotransposons. Ty1 and the similar *Drosophila* retrotransposable element copia are the prototypes of one class, while Ty3 and the *Drosophila* retrotransposable element gypsy are prototypes for the other.

As is true with retroviruses, retrotransposons insert into new target sites by making the actual mobile DNA segment by **reverse transcription** of an RNA copy of the element. This is in contrast to other elements that move strictly through DNA intermediates; that is, a DNA segment is excised from the donor chromosome and then inserted into a target site, in steps that involve only DNA breakage and joining events. However, it is important to realize that the chemistry of the DNA processing steps are the same for DNA-only elements and for those that use a reverse transcription-generated copy of the element (2). Indeed, the transposases that mediate these reactions two types of transposition reactions are structurally related (3, 4).

The Ty1 element was the first nonviral element shown to transpose through an RNA intermediate (5) and has been studied extensively (1). In cells, Ty1 is found in large complex particles that resemble intracellular forms of retroviruses. Isolation of these Ty1 virus-like particles has allowed *in vitro* analysis of transposition. The copy number of Ty1 elements varies from yeast strain to yeast strain. In plants, related elements are often present in very high copy number and are heterogeneous.

An interesting feature of yeast Ty1 is that this element prefers to insert into pol III **promoter** regions (6), which may be a useful strategy to protect the genome from insertions into genes themselves. Although Ty1 transposition can be done *in vitro* using purified virus-like particles, this preference for promoter regions is not observed (7). It is likely that Ty1 is attracted to promoter regions through interaction with some component of the transcription machinery and that this component is lacking from the *in vitro* system. Another yeast retrotransposon, Ty3, inserts highly specifically into Pol II promoters; in this case, it has been shown that this targeting is mediated in the presence of the transcription factors that interact with this region of the promoter (8).

Type II DNA-Binding Proteins

The bacterial type-II DNA-binding proteins include the abundant HU and integration host factor (IHF) proteins and the phage-encoded TF1 and are believed to condense their cognate genomes by binding at multiple sites and inducing coherent bends. HU and TF1 possess little, if any, binding sequence specificity, but IHF which is also required for site-specific recombination, DNA replication, and transcription, binds at specific sites characterized by a limited consensus sequence.

All proteins of this type bind to DNA as dimers and bend the DNA to a substantial extent. In particular IHF induces a bend angle of at least 160° and possibly in excess of 180° within the 2 1/2 double helical turns that comprises its binding site. IHF is normally a heterodimer; HU can exist either as a homo- or as a hetero-dimer. In both IHF and HU, the two ~10 kDa subunits intertwine to form a compact core, from which two long b ribbon arms extend. These arms track along the minor groove from the inside to the outside of the wrapped DNA, where they terminate at the two substantial kinks. In addition to these interactions via the b arms, IHF also clamps the hairpin by minor-groove contacts with a helices from both subunits in the core of the dimer. All the contacts to the DNA are either in the minor groove or part of an extensive network of electrostatic interactions with the phosphate backbone.

The two kinks are induced by the partial intercalation between adjacent basepairs of an absolutely conserved proline side chain located at the tips of the b arms. In the IHF–DNA complex, the DNA bend is maintained by two distinct mechanisms. On the outside of the bend the hydrophobic intercalation stabilizes the opening of the minor groove. On the inside charge neutralization counteracts the enhanced repulsion between the phosphates on opposite sides of the narrowed grooves.

The sequence dependency of IHF binding is determined by the conformation of DNA rather than by base-specific contacts. The “consensus” sequence consists of two short elements separated by approximately half a turn in only one of the two half-sites. The conserved sequence, CAA, at the kink site, can accommodate the severe distortion induced by the protein better than other short sequences, and so is favored.

Tyrocidine

Tyrocidine is cyclic decapeptide antibiotic and secondary metabolite that is synthesized on three nonribosomal peptide synthetases by the so-called thiotemplate mechanism. It was one of the first examples of nonribosomal peptide antibiotic biosynthesis and is best investigated regarding its genetic analysis and possible biological function for the producer *Bacillus brevis*. Tyrocidine possesses antibacterial properties, notably against many Gram-positive bacteria. However, it is considered today to be too toxic for systemic use.

1. Structure

Tyrocidine is a mixture of at least four known structural variants (Fig. 1, C). Tyrocidine A, the most prominent of these, is a cyclic decapeptide with the primary structure (-DPhe-Pro-Phe-DPhe-Asn-Gln-Tyr-Val-Orn-Leu-)$_{cyclic}$, where the indicated amino acids are the unusual D-isomer and Orn is the unusual amino acid ornithine. In tyrocidines B, C, and D, the aromatic residues at positions three, four, and seven are gradually replaced by tryptophan (Fig. 1, C). The biosynthesis of a mixture of products is a consequence of the low specificities of the protein templates of the nonribosomal thiotemplate system, compared with the ribosomal system of protein biosynthesis (1, 2). The relative concentrations of the aromatic amino acids in the growth medium affect the ratios of the four variants (3). Although one should refer to tyrocidine as a mixture, the singular will be used here for reasons of simplicity.

Figure 1. The genes **(a)** and proteins **(b)** for the biosynthesis of the tyrocidines **(c)** are shown. **(a):** The biosynthetic gene *tycB*, and *tycC* are transcribed in one operon. The modular organization typical of nonribosomal peptide synthetases is ap The modules can be subdivided into domains responsible for the single chemical reactions: adenylation **(black),** thiolatic **stripes),** condensation **(white),** epimerization **(grey),** and thioesterase domains **(coarse stripes),** which were defined by analysis of the genes and by biochemical studies of the encoded proteins. **(b):** Tyrocidine is synthesized on an enzyme co the tyrocidine synthetases TycA, TycB, and TycC. Each modules is represented by a sphere, and each incorporates one a into the growing peptide chain. The **zigzagged lines** represent the prosthetic group 4′-phosphopantetheine. **(c):** The prim structures of the four known cyclic decapeptide tyrocidines. Amino acid substitutions at positions three, four, and seven the relatively modest substrate specificities of the corresponding modules.

	D	-Trp-DTrp- -Trp-

(c)

Tyrocidine is produced by certain strains of the soil bacterium *B. brevis*, such as *B. brevis* ATCC 8185 and ATCC 10068. These strains produce infact a mixture of two antibiotics, which is called *tyrothricin*, consisting of tyrocidine and the linear pentadecapeptide gramicidin.

2. Activity and Mode of Action

The combination of basic groups and nonpolar side chains gives tyrocidine the properties of a cationic detergent and a strong hemolytic activity. Tyrocidine is bactericidal for many Gram-positive organisms, much less so for some Gram-negative bacteria. With its biosurfactant property, it disrupts the integrity of the bacterial cell surface, resulting in the loss of amino acids, pyrimidine and purine bases, and other vital small molecules from the susceptible organism (4). It uncouples oxidative phosphorylation and in eukaryotes it disturbs the function of certain intracellular organelles, such as the mitochondria. All four known variants of tyrocidine display similar activities. Tyrocidine is not absorbed orally and undergoes degradation in the gut, it is primarily utilized as topical agent. The side effects, however, make it today inappropriate for systemic use (5).

3. Possible Biological Function

Biosynthesis of the two peptide antibiotics tyrocidine and linear gramicidin is switched on at the onset of stationary growth and shortly preceding the sporulation process. This close correlation in time has always raised speculation about the possible functions of these compounds in the producer cell. The finding that tyrocidine accumulates in the forespore and can also be found in the spore suggested that they have roles in sporulation. Some *in vitro* and *in vivo* experiments indeed pointed to such function, but others were apparently contradictory. Tyrocidine was shown to bind to DNA *in vitro* (6) and to inhibit RNA polymerase isolated from exponentially growing cells. Interestingly, the addition of linear gramicidin had a counteracting effect, suggesting antagonistic regulatory roles of the two antibiotics (7). In contrast to these *in vitro* results, tyrocidine was demonstrated to stimulate RNA synthesis under certain conditions *in vivo*. When exponentially growing cells were shifted to a medium lacking a nitrogen source, the addition of tyrocidine was essential for effective sporulation (8). A mutant strain defective in tyrocidine synthesis was reported to form spores that were less heat-resistant than those formed by wild-type cells. To date, however, the possible roles of tyrocidine remain unclear. No direct target or binding site has been identified. The inaccessibility of the producer strains to genetic manipulation has hindered further investigations.

In general, the biological functions of peptide antibiotics synthesized by thethiotemplate mechanism are obscure (9). Genetic studies on the cascade leading to sporulation in related bacteria, such as *Bacillus subtilis*, do not suggest a necessity for such compounds for regulatory functions. The most obvious explanation for their production is still as a defense weapon in the competition for limited nutrients.

4. Biosynthesis

The biosynthesis of tyrocidine proceeds by the thiotemplate mechanism. As one of the best investigated systems of this kind, tyrocidine attracts most of the current interest. According to that mechanism, large multifunctional enzymes, the NRPSs, carry out all steps required to activate, modify and link the amino acids to give the product (1, 2, 10). In some cases other than tyrocidine, further enzymes can be involved in product modification to yield the biologically active molecule. The NRPSs resemble in architecture, an assembly line. They contain one so-called module for each amino acid to be incorporated. It first activates the residue as its aminoacyl adenylate, with the consumption of ATP, then transfers it to the thiol moiety of an individual 4′-phosphopantetheine prosthetic group, which serves as a swinging arm to facilitate transport of the amino acid (or the growing peptide chain) to the next module. The modules can be subdivided into domains that perform the individual chemical reactions (1), for example, the core domains adenylation for

recognition and activation of the substrate monomer thiolation (or peptidyl carrier protein) for binding it as thioester on the 4′-phosphopantetheine, and condensation for formation of the peptide-bond between acyl groups on adjacent modules (Fig. 1). Optional domains like epimerization modify the amino acids upon incorporation into the growing chain.

In the case of tyrocidine, the functional enzyme complex consists of three such NRPSs, namely, TycA, TycB, and TycC (11). TycA is a one-module enzyme (molecular weight 123 kDa) that activates and epimerizes L-Phe. It initiates tyrocidine biosynthesis by transferring the D-Phe onto TycB, where the first peptide bond is formed between D-Phe and L-Pro. TycB (405 kDa) comprises three modules and activates L-Pro, L-Phe, and a second L-Phe, which is also epimerized to the D-enantiomer. TycB catalyzes the stepwise growth of the peptide chain to the tetrapeptide. The tetrapeptide is then transferred to TycC (724 kDa), which incorporates in the same manner the residual six amino acids and then cyclizes head-to-tail the linear decapeptide intermediate, to generate the final product (12) (Fig. 1 B).

The obscure biological function of many antibiotic products of secondary metabolism is in striking contrast to the size of their biosynthetic clusters, which often make up several percent of the genome. The genes *tycA, tycB*, and *tycC* encoding the tyrocidine synthetases have been cloned and sequenced (13). They are transcribed in an operon that spans over 35 kbp (Fig. 1 A). The promoter of this operon was shown to be functional in *B. subtilis*, where it is negatively regulated by the DNA-binding protein AbrB during vegetative growth (14). At the end of vegetative growth, AbrB derepresses a number of genes associated with stationary growth and sporulation. Sequence analysis of the tyrocidine NRPSs genes has revealed their typical domain structures (Fig. 1 A). TycC, which activates six amino acids and has six modules, is one of the largest enzymes known. Expression as recombinant protein fragments has allowed many biochemical analyses. It was shown that the adenylation domains that correspond to the variable positions in tyrocidine (Fig. 1 A and C) have only modest substrate specificities. In contrast, the adenylation domains corresponding to the invariant positions have been found to be specific for single amino acids (13). These results explain the naturally occurring variants of tyrocidine. The construction of hybrid NRPSs by fusing gene fragments encoding modules of TycB and TycC in an artificial order allowed the production of the predicted new peptides by the purified enzymes (15). These results indicate the potential of generating new tailored peptide antibiotics by combinatorial biosynthesis. The thioesterase domain (28 kDa) of TycC was excised and shown by using decapeptide-thioesters as substrate substitutes to act as the macrolactamase in the cyclization of the linear decapeptidyl-S-enzyme precursor (16). Directly adjacent to the tyrocidine biosynthesis genes are two genes that encode ABC (ATP-binding cassette) transporters (13). These transporters may confer resistance of the cell against its own product.

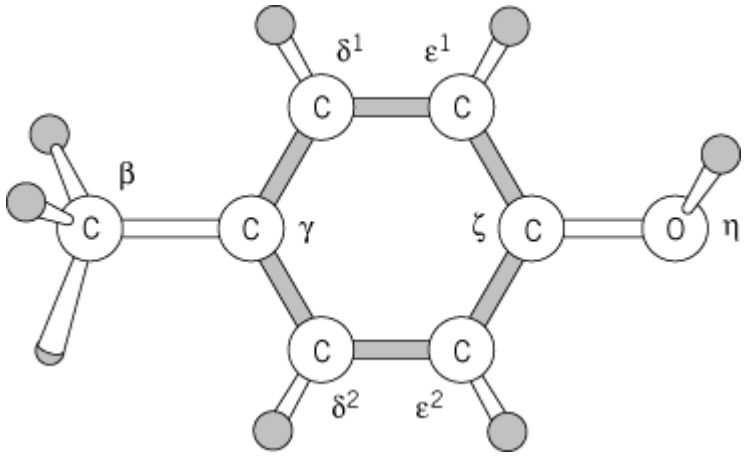
Tyrosine (Tyr, Y)

The amino acid tyrosine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to two **codons**—UAU and UAC—and represents approximately 3.2% of the residues in the proteins that have been characterized. The tyrosinyl residue incorporated has a mass of 163.18 Da, a **van der Waals volume** of 141 $Å^3$, and an accessible surface area of 229 $Å^2$. Tyr residues are changed only moderately frequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with phenylalanine residues.

The Tyr side chain is predominantly a phenolic group:



The hydroxyl group makes this aromatic ring, in comparison to that of **Phe residues**, relatively reactive in electrophilic substitution reactions. These usually occur at the symmetric positions designated here as ε1 and ε2, which elsewhere are often numbered as 3 and 5, respectively. Consequently, Tyr side chains can be readily **nitrated** and **iodinated**.

The Tyr hydroxyl group ionizes only at very alkaline pH values, with an intrinsic pK_a of about 11.1. In the nonionized form, it can function as either a donor or acceptor of hydrogen bonds. Consequently, Tyr residues are more hydrophilic and less **hydrophobic** than the closely similar Phe residues. Tyr residues are usually buried only if the hydroxyl group can participate in hydrogen bonding, and only about 15% of Tyr residues are fully buried in folded protein structures. Nevertheless, even fully buried residues are generally flipping rapidly by 180° rotations about the C_b—C_a single bond. Tyr residues stabilize the **alpha-helical** conformation only slightly in model peptides and in folded proteins are found twice as frequently in beta-sheets.

The spectral properties of Tyr residues are sensitive to their environment, and both **absorbance** and **fluorescence** are very useful in monitoring changes in the protein structure, for example, on unfolding. Tyr residues are the sites of **phosphorylation** and adenylylation in covalent **enzyme regulation**. They can also be subject to the post-translational modification of sulfation.

Tyrosine Kinase Receptors

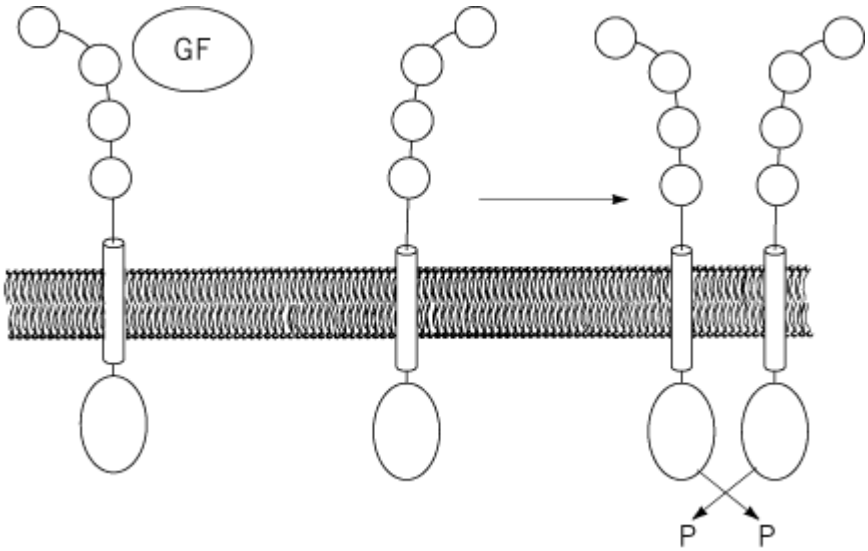
Growth Factors exert profound effects on the metabolism, survival, and differentiation of numerous cell types. Studies on the genetics and physiology of development have revealed that the synthesis of these factors is under tight control, and furthermore that their functions are highly specialized; yet the receptors for these molecules appear to be surprisingly similar in structure. Growth-factor receptors have three distinct **domains**: an extracellular ligand-binding region, a **hydrophobic** transmembrane region, and a cytoplasmic region that contains tyrosine kinase activity. These receptor tyrosine kinases (RTKs) comprise a gene superfamily of over 30 members that are similarly activated upon ligand binding, undergoing dimerization and autophosphorylation on **tyrosine** residues, which initiates a series of distinct, but often redundant, signal transduction pathways.

Growth factors induce a variety of changes in transport properties, acute metabolic activities, membrane trafficking, **cytoskeletal** interactions, and a program of gene induction governing cell growth, differentiation, and migration. Some of the factors induce a program of cell growth and viability in some cells, differentiation in others. Interestingly, growth factors with quite different cellular effects induce many of the same signaling pathways upon receptor binding, suggesting that subtle differences result from combinations of divergent and convergent signaling pathways, invoking complex mechanisms that allow cells to respond appropriately.

1. Molecular Interactions of Growth Factor Receptors

The gaps in our understanding of signal transduction for RTKs have been narrowed by recent insights into protein–protein interactions produced as a result of receptor activation. It is generally believed that most of these receptors undergo a similar program of dimerization and transactivation following ligand binding, resulting in tyrosine phosphorylation (Fig. 1) (1, 2). In turn, these tyrosine-phosphorylated proteins serve as binding sites for a number of functionally related signaling molecules. Such interactions are typified by those with proteins containing ***src*** homology 2 (**SH2**) domains (3). These are conserved noncatalytic regions of approximately 100 amino acid regions that function as recognition motifs for specific sequences containing phosphotyrosine residues. Some of these proteins, like the $pp60^{src}$ tyrosine kinase itself, as well as phospholipase C (PLC)g, ras GTPase activating protein (GAP), the protein tyrosine phosphatase (PTPase) SHP2, and the **oncoprotein** vav, have catalytic activities that are involved in signaling pathways. These proteins can be tyrosine-phosphorylated upon binding to RTKs in some cases, although the functional consequences are unclear. For other SH2 proteins, including the 85-kDa regulatory subunit of phosphatidylinositol-(PI)-3 kinase Grb-2 and the oncoproteins crk and nck, catalytic activities have not been detected; this suggests that these molecules serve as adapter proteins, linking receptors or their substrates to other pathways. In all cases, the binding of SH2 proteins is absolutely dependent upon tyrosine phosphorylation of the receptor and is mediated solely through the SH2 domain (4-6).

Figure 1. Dimerization of growth factor receptors. These receptors undergo a program of dimerization and autophosphorylation upon binding of growth factor. The tyrosine phosphorylation is thought to occur between receptors brought together by the dimerization.



The structural basis for differential association of RTKs with SH2 domains is now fairly well understood (7). Direct binding measurements have revealed quantitative kinetic differences in these interactions, perhaps accounting for differential activation of pathways that are dictated by receptor

concentration. Analysis of competition binding among SH2 domains to mutated receptors and studies using peptide inhibitors or peptide libraries have revealed certain preferential primary structure motifs in receptors for SH2 binding. In general, the amino acid residues contiguous to the carboxy-terminal side of the phosphotyrosine residue prescribe the binding specificity, in which the specific recognition can be dictated by residues 2 to 5 positions toward the *C*-terminus. Additionally, conserved sequences in SH2 domains appear to be critical for phosphotyrosine binding, as demonstrated with the conserved FLVRES (Phe—Leu—Val—Arg—Glu—Ser) sequence. Analysis of these binding data for the **abl** SH2 domain, considered in light of the solution structure, suggested that the two primary amino groups from the conserved Arg residue undergo bidentate interactions with two of the oxygen atoms of the phosphate, while surrounding Ser hydroxyl groups may hydrogen bond to the remaining phosphate oxygen.

There are likely to be other protein-interaction domains found in proteins that interact with RTKs. One such domain was identified in the tyrosine kinase substrates Shc and IRS-1, known as the PTB or PI domain (8). These domains are functionally similar to SH2 domains, in that they recognize sequences containing phosphotyrosine, but they appear to have a different sequence specificity, in which residues amino-terminal to the tyrosine are important for binding. Many of the proteins that interact with Shc through this domain have the sequence NPXY(Asn—Pro—X—Tyr), where the Tyr residue may be phosphorylated, although sequence variations on the *N*-terminal side are likely to influence the binding affinity further. Structural studies (9) suggest that these domains may resemble **pleckstrin homology** (PH) domains, another motif commonly found in signaling proteins.

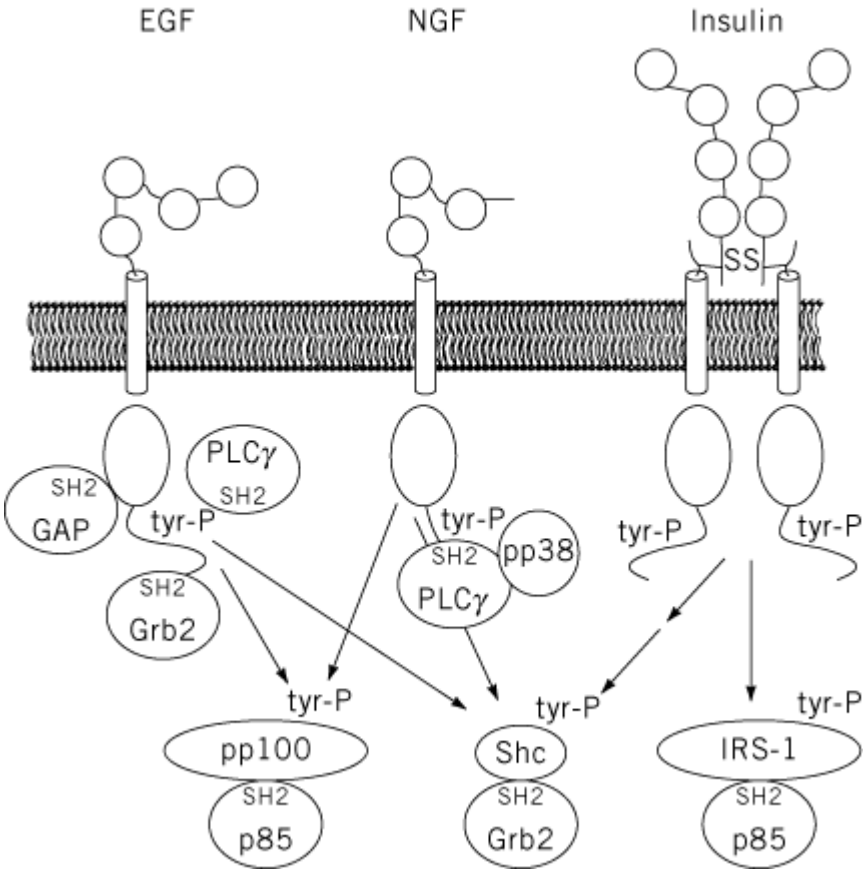
2. Signaling Pathways Activated by Receptor Tyrosine Kinases

Although the three-dimensional structures and molecular dynamics for many examples of RTK-SH2 or PTB binding are well understood, the precise functions of these interactions have been more difficult to resolve. In some cases, SH2 domain occupancy directly modulates the activity of the protein, as is the case for the tyrosine phosphatase SHP2, in which the catalytic activity is markedly elevated by the interaction of the phosphatase with tyrosine-phosphorylated receptors or their substrates (10). In other cases, SH2- and PTB-containing proteins are tyrosine-phosphorylated when bound to RTKs, presumably due to the induced proximity. In the case of phospholipase Cg, tyrosine phosphorylation may be a requirement for activation of the enzyme (11).

The emerging large numbers of RTKs and SH2 proteins begs one central question: where is the specificity? Indeed, most SH2 domains can interact with phosphotyrosine alone, but at significantly higher concentrations than are required for RTK interaction. However, **immunoprecipitation** experiments have indicated that these molecules discriminate in their binding to receptors or substrates, perhaps providing the biochemical basis for initiation of the divergent cellular effects of growth factors. In the case of some receptors, typified by that for insulin and IGF-1, and intracellular kinases, such as the JAK family that are activated by cytokine receptors (see JAK/STAT Signaling), the tyrosine kinase can phosphorylate endogenous substrates that serve as surrogates for SH2 binding. The phosphorylation of IRS-1 by insulin or IL-4 induces stable complexes between IRS-1 and SH2 proteins. These interactions can lead to the activation and/or localization of signaling cascades, including **phosphatidylinositol-3 kinase**, MAP kinase, and others. These examples of different pathways of RTK-SH2 protein coupling may reflect a combinatorial diversity that allows for subtle differences in signal discrimination (Fig. 2).

Figure 2. Combinatorial diversity in growth factor signaling. The specificity of signal initiation in growth-factor action depends on the molecular interaction of receptors. Interactions of the epidermal growth factor (EGF), **nerve growth factor** (NGF), and insulin receptors with proteins containing SH2 domains are depicted. These three growth factors produce different effects on cells, but they can activate some of the same pathways. The EGF receptor can form high-affinity complexes with signaling proteins such as PLCg1, ras GAP, and Grb2, through their respective SH2 domains. The pp140trk NGF receptor can interact with PLCg1 and an associated 38-kDa tyrosine-phosphorylated protein, the function of which is unknown at present. In contrast, the insulin receptor does not form stable complexes with these

SH2-domain proteins. All three of these growth factors stimulate the activity of phosphatidylinositol-3 kinase, probably by the tyrosine-phosphorylation of proteins that bind to the SH2 domain of the 85-kDa regulatory subunit of the enzyme. In the case of the insulin receptor, this surrogate phosphoprotein, called IRS-1, has 10 known phosphorylation sites within the YMXM (Tyr—Met—X—Met) sequence that is thought to be recognized specifically by p85. The mechanism of activation of phosphatidylinositol-3 kinase by EGF and NGF is less clear, but it may involve phosphorylation of a 100-kDa protein functionally analogous to IRS-1.



3. Serine/Threonine Phosphorylation Cascades

In cells treated with growth factors or **transfected** with tyrosine-kinase **oncogenes**, tyrosine phosphorylations are relatively scarce compared to those found on serine and threonine residues. These observations suggested that serine kinases were activated directly or indirectly after tyrosine phosphorylation by growth factor receptors, thus dramatically amplifying the initial signal in the cell. Numerous growth-factor-dependent protein kinases have been described. The best characterized of these is the family of enzymes known collectively as mitogen-activated protein kinases (MAP kinases).

Tyrosine Kinases and Phosphatases

Phosphorylation of tyrosine residues occurs at a much lower level than that of serine and threonine, but it is of critical functional importance in signal transduction. In eukaryotes, phosphorylation of tyrosine residues is the result of the action of either specialized enzymes, which phosphorylate only these residues, or of dual-specificity protein kinases that act on both tyrosine and threonine residues of specific protein substrates. Up to now, specialized tyrosine kinases (Tyr kinases) have been found only in multicellular animals, suggesting that these enzymes have evolved as part of the control of cell–cell interactions. In contrast, dual-specificity protein kinases are found in all eukaryotic species. In addition, phospho-tyrosine residues have been detected in a number of bacterial species belonging to eubacteria and cyanobacteria (1). However, the function of tyrosine phosphorylation in these organisms, as well as the nature of the protein kinases and phosphatases involved, is not known.

1. Tyr Kinases

1.1. Structure and Regulation

Specialized Tyr kinases display strong sequence homologies in their catalytic domains, which are also closely related to those of Ser/Thr kinases (2). Tyrosine kinases are more closely related to each other than to Ser/Thr kinases, and a number of signature residues are found in all of them, making it possible to predict the specificity of these enzymes on the basis of their amino acid sequences. The three-dimensional structure of the catalytic domain of tyrosine kinases, as determined by X-ray crystallography, is also very similar to that of Ser/Thr kinases (3-5). Tyrosine kinases can be grouped into two categories (Table 1): those that have a **transmembrane** segment, which are usually receptors for extracellular ligands (receptor tyrosine kinases, RTK), and those which are only intracellular (nonreceptor tyrosine kinases, NRTK) (see Receptors Linked To Tyrosine Kinases and Tyrosine Kinase Receptors).

1.2. Receptor Tyrosine Kinases

These proteins have a single transmembrane segment, an extracellular **domain** of varying length, and an intracellular catalytic domain (see Fig. 1a and Refs. 6-8). In the absence of ligand, they can be found as monomers or interacting with other proteins. In some cases, the polypeptide chain possesses the transmembrane and catalytic domains, which lacks the receptor domain. The latter is provided by an associated protein, which may itself not be a transmembrane protein but is attached to the transmembrane polypeptide by a disulfide bond (eg, insulin receptor) or to the membrane by a glycosyl-phosphatidyl-inositol GPI anchor, as in the case of the tyrosine kinase Ret, which associates with such a protein that is the receptor for GDNF glial derived neurotrophic factor (9, 10). In all cases that have been well-studied, activation of RTKs requires their dimerization (11, 12). In some cases, the dimer is preformed (eg, the insulin receptor) but inactive. In other cases, ligand binding promotes dimerization, which may result from a conformational change of the extracellular domain or from the divalent nature of the ligand itself (11). Upon ligand binding, a *trans*-phosphorylation of the intracellular catalytic domains occurs, leading to the phosphorylation of tyrosine residues located in the activation loop, a critical loop of the catalytic domain, and thereby enhancing its enzymatic activity. Recent work suggests that some receptors have a high rate of basal phosphorylation (ie, in the absence of ligand), compensated by a high rate of dephosphorylation, and that activation could result from a tilting of the balance in favor of the phosphorylation (13). Additional phosphorylated tyrosine residues provide docking sites for protein domains that interact specifically with tyrosine-phosphorylated peptides, the **SH2** (Src-homology 2) and PTB (phospho-tyrosine binding) domains (14). In some cases, cytoplasmic proteins that associate with the receptor are also highly phosphorylated on tyrosine residues and provide additional docking sites (eg, the insulin receptor is associated with IRS-1 and 2 proteins). SH2 and PTB domains are found in a variety of proteins that cluster around the activated receptor, forming membrane-associated “signal transfer particles” (11). Thus, a number of enzymes are translocated from the cytosol to the membrane area surrounding the receptor. Several of these enzymes have lipid substrates, such as **phospholipase C**g (PLCg) and **phosphatidylinositol 3 kinase** (PI3-kinase), and translocation to the membrane enhances their

activity by putting them in contact with their substrates (15). Another class of proteins with SH2 or PTB domains contains adapter proteins that are devoid of enzymatic activity but associate with active proteins (14). One example is Grb2, which possesses a SH2 domain, but interacts also with a guanine nucleotide exchange factor, SOS, via two SH3 domains. Thus, recruitment of Grb2 to a phosphorylated receptor brings SOS in close contact with the membrane to which its substrate, the small GTP-binding protein Ras, is attached. SOS promotes the GDP/GTP exchange on Ras, which in its GTP-bound form becomes capable of interacting with a Ser/Thr kinase, Raf, that activates the MAP-kinase cascade (16). Thus, activation of a RTK by its ligand triggers a number of Ser/Thr phosphorylation pathways, since the stimulation of PLCg increases the activity of protein kinase C, and the action of PI3-kinases activates additional serine/threonine kinases (17, 18). These various serine/threonine protein kinases mediate many of the effects of growth factors by altering transcription and translation. It should be pointed out, however, that each SH2 or PTB domain has its own specificity, in addition to its requirement for a phosphorylated tyrosine residue (14). Therefore, phosphorylation of particular tyrosine residues on a tyrosine kinase receptor or its associated proteins will only lead to the recruitment of specific proteins. Consequently, different receptors may recruit different signaling proteins. Another factor that is important for the specificity of the signaling of each RTK is the rate of its deoleactivation (19). Some receptors may be rapidly inactivated by dephosphorylation or by endocytosis, whereas others will stay activated for a long time.

(b)

1.3. Nonreceptor Tyrosine Kinase

NRTKs form a heterogeneous group of tyrosine kinases in which the catalytic domain is associated with various other domains (Fig. 1b). Some of these NRTKs are functionally equivalent to the catalytic domain of RTKs. For example, the tyrosine kinases of the JAK (Janus kinase) family associate by their amino-terminal domain to the intracellular segment of **cytokine** receptors (20). Activation of the JAKs occurs in response to cytokine binding to its receptor and dimerization of the receptor, and it leads (i) to the phosphorylation of the receptor on tyrosine residues and (ii) the recruitment and tyrosine phosphorylation of a group of transcription factors containing a SH2 domain, the STATs (signal transducers and activators of transcription) (see JAK/STAT Signaling). Following tyrosine phosphorylation, STAT dimerizes and translocates to the nucleus, where it activates the transcription of specific genes. Focal adhesion kinase (FAK), which is important in signal transduction in response to the extracellular matrix, also associates with transmembrane proteins. Following engagement of receptors for the extracellular matrix, the integrins, FAK is recruited to focal adhesions and becomes autophosphorylated (21). This allows the binding of Src-family kinase SH2 domains, their activation, and the phosphorylation of a number of associated proteins, leading to the formation of transducing complexes reminiscent of, but distinct from, those

created by RTKs. Src-family kinases possess a SH2 and a SH3 domain, in addition to their tyrosine kinase catalytic domain (22). They can be associated to the membrane by an amino-terminal **myristoyl group**. In the inactive state, they are phosphorylated on a carboxy-terminal tyrosine residue that undergoes an intramolecular interaction with the SH2 domain, blocking access of substrates to the active site . This inactivation is strengthened by the binding of the SH3 domain to a specific peptide sequence located between the SH2 and the catalytic domains (4, 5). Thus, activation of Src-family kinase may result from the dephosphorylation of the carboxy-terminal tyrosine residue and/or from displacement by other ligands of the intramolecular binding by the SH2 or SH3 domains. In many cells, these kinases appear to be involved secondarily, following activation of other tyrosine kinases, including RTKs or FAK (22). They also play a critical role in the activation of lymphocytes, a process in which Src-family kinases and other NRTKs, such as Syk/Zap70 and Btk, interact closely with the antigen receptors. Another NRTK, Csk (carboxy-terminal Src kinase), exerts a potent negative control on the activity of Src-family kinases by phosphorylating their carboxy-terminal tyrosine residue, thereby promoting its inhibitory intramolecular interaction with the SH2 domain, as indicated above. Finally, it should be mentioned that although the majority of tyrosine kinases are localized and activated at the plasma membrane, some tyrosine kinases (eg, Abl, Fer) are located in the nucleus, where they participate in the regulation of transcription and the cell cycle (23).

2. Tyr Phosphatases

Several groups of enzymes, belonging to different gene families, have the capacity to dephosphorylate tyrosine residues (Table 2). They have in common a signature sequence Cys–X_5–Arg and a similar configuration of the catalytic site, which also contains a conserved **aspartate** residue (24-26). The catalytic mechanism involves the formation of a covalent phosphate thioester intermediate. Because of the presence of a cysteine residue in the active site, tyrosine phosphatases are highly sensitive to thiol-group reagents and oxidizing agents. Tyrosine phosphatases are also inhibited nonspecifically by chemicals that mimic phosphate (eg, sodium orthovanadate, pervanadate) or phosphotyrosine (phenylarsine oxide). The four groups of tyrosine phosphatases include two groups that dephosphorylate exclusively tyrosine residues, the “classical” phosphotyrosine phosphatases (PTP) and the low-molecular-weight PTPs, and two groups of dual-specificity protein phosphatases (25).

Table 2. Protein Tyrosine Phosylatases and Dual Specificity Phosphatases

Protein Tyrosine Phosphatases

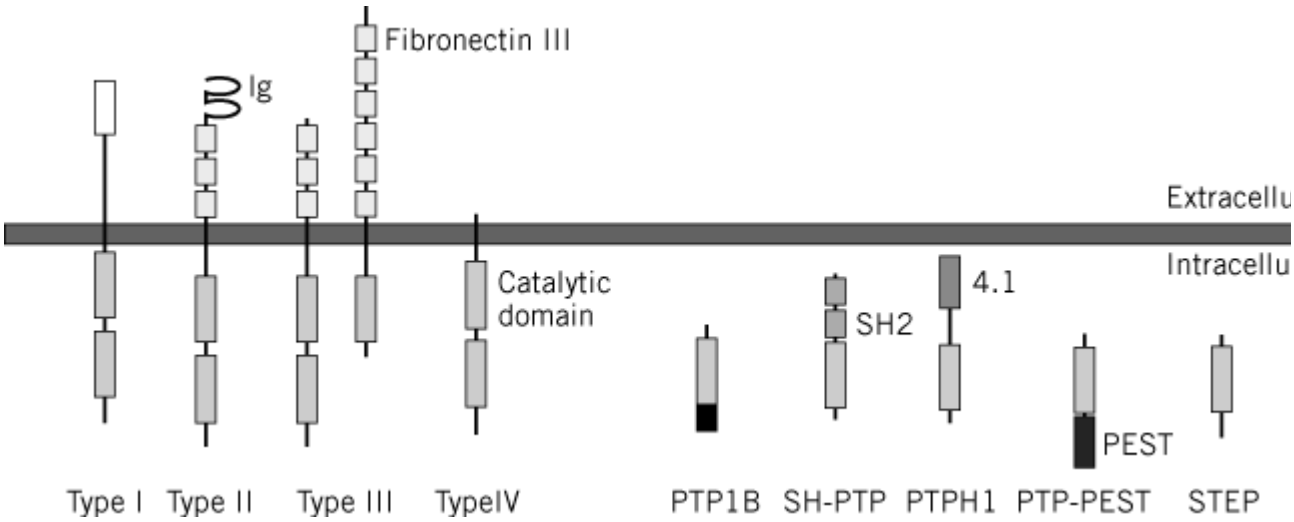
cdc 25 group
Dephosphorylate cyclin dependent kinases (eg, cdc25)

2.1. Classical PTPs

Like tyrosine kinases, PTPs may have a transmembrane segment and an extracellular domain, or they can be entirely intracellular (Fig. 2). PTPs from the first group have the organization characteristic of transmembrane receptors and are therefore termed RPTPs (receptor PTPs). Ligands for the extracellular domains of some of these RPTPs have been identified, but no clear regulation of the phosphatase activity by these ligands has yet been demonstrated. The extracellular domains of RPTPs contain modules often found in cell adhesion molecules, and some of them appear to be involved directly in cell–cell interactions (27). Such RPTPs play an important role during development in axon pathfinding (28). The crystal structure of the intracellular catalytic domain of RPTP-a suggests that it may be inactivated by dimerization (29). An intriguing feature of many RPTPs is the possession of tandem intracellular catalytic domains. However, most or all the phosphatase activity appears associated with only one domain, and the function of the other is not known. PTPs lacking a transmembrane domain nevertheless possess various targeting domains, including SH2 domains and band 4.1 domains (which may target them to membrane-associated proteins) (30). When studied *in vitro*, PTPs have a very high catalytic activity, suggesting that they are tightly regulated in cells. Although these regulations are still poorly understood, they are likely to involve a variety of mechanisms, including phosphorylation, targeting, and ligand binding. PTPs appear to have multiple functions (27, 28, 31-34). On the one hand, they oppose the action of tyrosine kinases, and this role is clearly illustrated in many cells by the sharp increase in tyrosine phosphorylation of many proteins following inhibition of tyrosine phosphatases with nonspecific agents. On the other hand, some PTPs may activate tyrosine phosphorylation pathways—for example, by dephosphorylating specifically the carboxy-terminal inhibitory tyrosine of Src-family kinases (33). Interestingly, PTPs are used by pathogenic microorganisms to deceive cell defenses, as demonstrated in the case of bacteria from the *Yersinia* genus (35). Low-molecular-weight PTPs, which form a separate group of enzymes, are expressed in many cell types, and their regulation and function is not well-characterized (36).

Figure 2. Domain structures of classical protein tyrosine phosphatases. Ig, immunoglobulin-like domain; SH2, Src-homology domain 2; 4.1, band 4.1-like domain, PEST, proline, glutamate, serine, threonine-rich domain.



2.2. Dual-Specificity Phosphatases

Two groups of protein phosphatases are able to dephosphorylate serine and threonine residues, as well as tyrosines (25). Such phosphatases play a critical role in the control of cell division, because they dephosphorylate tyrosine and threonine residues of cyclin-dependent kinase, cdk2, a step necessary for its activation (37). Another group of enzymes is comprised of relatives of the vaccinia virus gene VH1. Some of these dual-specificity phosphatases dephosphorylate the two residues necessary for the activity of MAP kinases. Interestingly, several of them are immediate-early genes, whose transcription is stimulated by MAP kinase, providing a strong feedback mechanism (38).

Ubiquitin

Ubiquitin (Ub) is a 76 amino acid–residue, heat-stable **protein** that occurs in virtually all cells and is highly conserved in its amino acid sequence. Largely through the work of Hershko and Ciechanover, ubiquitin was first shown in the late 1970s to be an essential cofactor in ATP-dependent **protein degradation** in reticulocyte extracts. Their experiments showed that ubiquitin must first be activated at its C-terminal glycine residue to be conjugated to a substrate. The activated ubiquitin molecule is then covalently linked through an isopeptide bond to an e-NH_2 group of a lysine residue in the substrate protein. In most Ub-conjugated proteins, the C-terminal glycine residue of one ubiquitin is linked to Lys48 of the next ubiquitin, forming long multiubiquitin chains. These long chains that usually consist of at least five ubiquitin moieties, rather than free ubiquitin, are preferentially bound and degraded by the 26S proteasome.

1. Biosynthesis

Ubiquitin itself is generated by a novel mechanism. It is found as part of two larger **polypeptide chains** that are cleaved **proteolytically** in a post-translational modification to release ubiquitin and proteins of ribosomes. However, most of the ubiquitin in stressed cells is generated from a polyprotein containing multiple, tandemly repeated ubiquitin units. After translation, the ubiquitin multimers are rapidly cleaved to monomers by a ubiquitin terminal hydrolase. Unlike ubiquitin-conjugated proteins destined for degradation, in which the ubiquitin is attached by isopeptide linkages to internal lysine residues, the ubiquitin multimers are simple end-to-end chains. A large number of ubiquitin C-terminal hydrolases are found in cells, but their specific functions are still unclear. They are probably important in the regulation of ubiquitin conjugate formation and disassembly. Some of these isopeptidases can be found in association with the 26S proteasome and may be important in the release of free ubiquitin monomers after the ubiquitin chain has been

removed from the protein substrate. In this way, ubiquitin monomers can be reused in degradation of new substrates.

2. Linkage of Ubiquitin to Proteins for Degradation

At least three enzymes (Table 1) act in succession to link ubiquitin to protein substrates (Figure 1):

Figure 1. Pathway of ubiquitin proteins conjugation. Key: E1, ubiquitin-activating protein; E2, ubiquitin carrier protein; E3, ubiquitin-protein ligase; PP_i, pyrophospate.

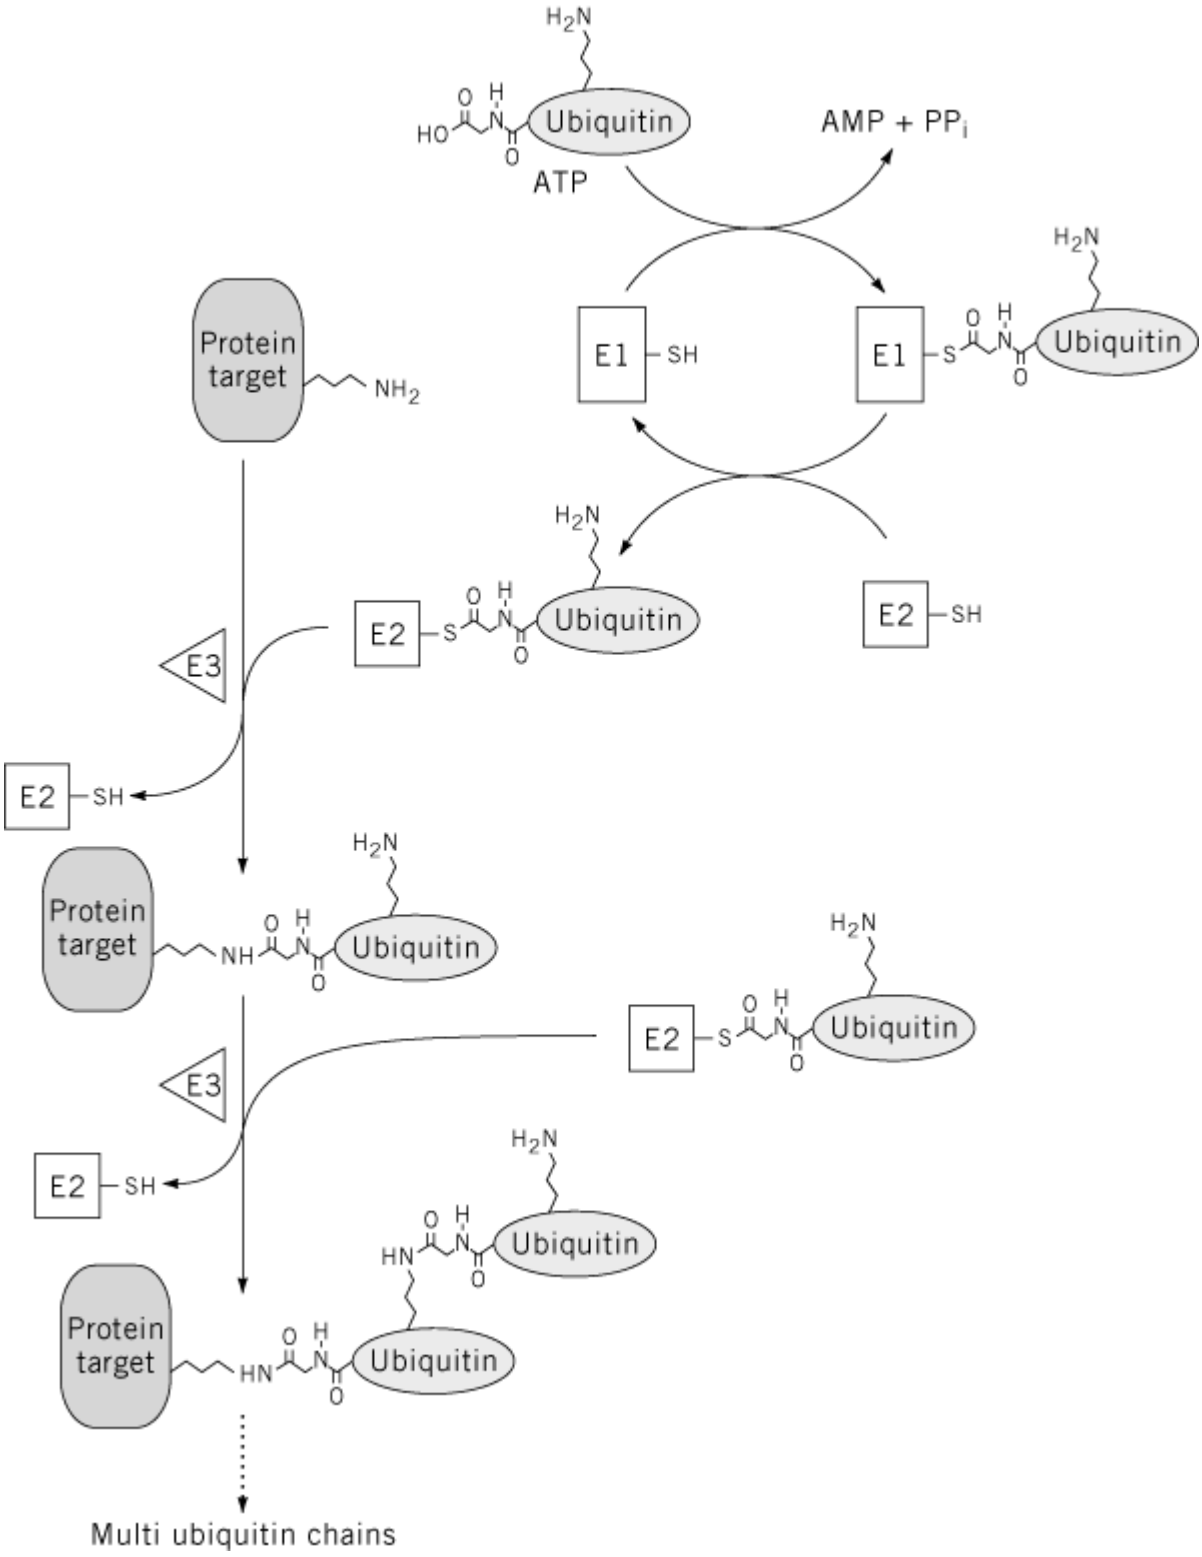

Table 1. Ubiquitin-Conjugating Enzymes

Enzyme	Name	Abbreviation	Family Members

E1	Ubiquitin activating protein	Uba	1
E2	Ubiquitin carrier protein	Ubc	~15
E3	Ubiquitin protein ligase	Ubr	Numerous

2.1. E1 (Ubiquitin-Activating Protein)
The cycle begins with a reaction that generates activated ubiquitin. Hydrolysis of ATP between its a and b phosphoryl groups drives the formation of a covalently bound C-terminal ubiquitin adenylate; this step is the only one in ubiquitin conjugation that requires energy input. The activated ubiquitin is transferred to a thiol group of an active-site cysteine residue of E1, liberating AMP, in a reaction similar to the charging of transfer RNA by amino acyl-tRNA synthetase . The E1-ubiquitin thiolester undergoes another round of AMP-Ub formation, ultimately yielding a ternary complex in which E1 bears two molecules of activated ubiquitin:

$$\mathrm{E1 + 2\ ATP + 2\ Ub \rightarrow E1 - Ub \bullet AMP\text{-}Ub + AMP + 2\ PP_i}$$

This high-energy thiolester form of ubiquitin, generated by E1, is essential for the eventual linkage to substrate in a series of reactions requiring two other ubiquitin-conjugating enzymes, E2 and E3.

E1 is an abundant 110-kDa protein, and it may occur in **phosphorylated** forms that seem to differ in their subcellular localization. In plants, a family of related E1 proteins exists, but in mammalian organisms only a single functional E1 protein has been found to date. E1 is essential for cell viability. **Temperature-sensitive mutants** of E1 have been isolated, originally from a mouse tissue culture cell line, as mutants that block the cell cycle, and they have been very useful in implicating the ubiquitin-proteasome pathway in the degradation of specific protein substrates.

2.2. E2s (Ubiquitin Carrier Proteins)
In the second step of the conjugation process, the activated ubiquitin bound to E1 is transferred to a thiol group of a ubiquitin carrier protein, or E2. At least a dozen such carrier proteins exist in cells. They have a limited ability in vitro to transfer the activated ubiquitin directly to protein substrates, but in vivo they generally serve as intermediary “carriers” in a process catalyzed by E3s. The E2s are small and share a conserved 16-kDa core containing the cysteine residue that forms a thiolester linkage with the activated ubiquitin. In fact, E2s can be isolated with ubiquitin covalently attached to this residue. A large family of E2 enzymes have been characterized in mammalian cells, plants, and yeast. These genes have been found on the basis of their conserved 16-kDa domain, and the proteins have been isolated biochemically due to their propensity to bind to a ubiquitin affinity chromatography matrix in the presence of E1 and ATP. The large number of E2s helps to generate the specificity of the ubiquitination system, as selected E2s function in the degradation of different types of substrates.

2.3. E3s (Ubiquitin-Protein Ligases)
In the final step of the conjugation process, the activated ubiquitin is transferred from E2 to the protein substrate by E3, the Ub-protein ligase. Most E3s catalyze formation of long ubiquitin chains, which means that the E3 active site is able to transfer ubiquitin directly either to a lysine residue of the substrate or, processively, to the preceding ubiquitin moieties to form a chain. The E3 proteins must contain binding sites for the protein substrate, E2, and at least one, possibly two, ubiquitin molecules. It is believed that E3 alone, or in a complex with an E2, generates the specificity of the ubiquitination process. A variety of structural determinants in the ubiquitinated substrate can be recognized by E3s. These include certain amino-terminal residues, certain **domains** within the substrate (ie, the “destruction box” found within many proteins degraded during mitosis), phosphorylated domains, and, perhaps, having unfolded domains. Only a small fraction of the large number of E3s have been described to date. These fall into several disparate families, with much less structural similarity than among E2s. Several appear to be high molecular-weight multimers or

complexes.

2.4. HECT Family
Proteins with HECT (*h*omologous to *E6*-AP *c*arboxyl *t*erminus) domains form another class of proteins with E3 activity. The prototype of this family, E6-AP, is involved in the degradation of p53 protein in certain cells infected with human papilloma **viruses**. Unlike other E3s, HECT-family E3s actually form a short-lived thiolester with ubiquitin transferred from E2, and then pass the activated Ub on to the substrate. These E3s appear to be important in the turnover of **RNA polymerase**, certain cell cycle regulators, and some membrane-bound **sodium channels**.

2.5. Anaphase-Promoting Complex (APC)/Cyclosome
This ligase is a large multisubunit complex (~1500 kDa) known as the cyclosome or APC and is involved in the conjugation of ubiquitin to mitotic cyclins and other proteins involved in movement through mitosis. This large E3 complex utilizes a unique E2 enzyme (E2C/E2x/UbcH10) and recognizes a nine-residue motif in the substrate protein, known as the "destruction box." The destruction box restricts degradation by the E2C/cyclosome pathway to only those proteins that contain that tag.

2.6. SCF
Regulated protein destruction during the cell cycle can also be catalyzed by another set of ubiquitination enzymes. This pathway has been best elucidated in yeast at the transition between the G1 and S phases of the cell cycle. Here, a heterotrimeric E3 complex termed SCF (Skp1/cullin/F-box protein) acts with a specific E2 (Cdc34) to ubiquitinate a cell cycle inhibitor (sic1), allowing progression to S phase. The existence of large families of both cullins and F-box proteins suggests numerous functions in the degradation of other substrates by combining different subunit modules. Members of the SCF family have also been shown to degrade other phosphorylated proteins, such as IkB.

Other E3s undoubtedly exist to ubiquitinate specific cellular substrates. In yeast, for example, a number of E2s serve particular functions (eg, degradation of abnormal proteins by UBC4/5), yet their cognate E3s are unknown.

3. Ubiquitin Homologues

A number of proteins with homology to ubiquitin have been discovered recently. Although they have low overall amino acid sequence identities, (perhaps 20%), they share a characteristic ubiquitin-like tertiary structure . Most interestingly, some members (SUMO1 and its yeast homologue Smt3) that contain the same -Gly-Gly C-terminus as ubiquitin have been found conjugated to cellular proteins in a way similar to ubiquitin. This SUMO1 conjugation appears to be involved in targeting RanGAP1 to the nuclear pore complex, where it is required for nuclear import/export. Unlike most cases of ubiquitin conjugation, the conjugation of SUMO1 to cellular protein substrates is not associated with protein degradation. It seems likely that the attachment of ubiquitin and ubiquitin-like proteins to other cellular substrates will prove to be a general mechanism for targetting substrates, to highly regulated cellular processes.

4. Degradation

The ubiquitin-conjugated protein is then proteolyzed by the proteasome.

Ultrabithorax Genes

Ultrabithorax (Ubx) is a gene required for the development of the specific morphology of the abdominal and the last thoracic segments of insects. It was discovered in the fruit fly *Drosophila melanogaster*, where it is located in the Bithorax complex, but in other insects it is located in the single cluster that comprises both the genes of the Antenapedia and Bithorax complexes. *Ubx* is a prototypical homeotic gene as mutations of loss or gain of function result in the morphological transformation of one segment into another. *Ubx* encodes a transcription factor with a homeodomain DNA binding motif of the Antennapedia class. The homeodomain of *Ubx* is most closely related to that of *Anntenapedia (Antp)* and *abdominal-A (abd-A)*, which evolved from a single ancestral gene that also gave rise to the HOX6-HOX8 orthologs in the vertebrate lineage. Because of its function during development, its homeodomain sequence and its location in a complex with other homeotic genes, *Ubx* is catalogued as a *Hox* gene.

Drosophila Ubx is expressed and required in the ectoderm and mesoderm derivatives of the abdominal and the posterior thoracic segments (1, 2). Its expression is very dynamic, not coinciding with segmental landmarks but with parasegments (units shifted by half segment). *Ubx* is the only Hox gene required for the morphological differentiation of parasegments 5 and 6 (that coincide roughly with the third thoracic and first abdominal segment) and contributes to the differentiation of parasegments 7 to 13 in combination with *abd-A* and *Abd-B*. The different morphology of parasegment 5 from parasegment 6 is mainly due to the different temporal and spatial regulation of *Ubx* during the development of these parasegments (3). In the gut, *Ubx* is expressed in the visceral mesoderm in parasegment 7 but is not expressed in the endoderm. Despite this, mutations in *Ubx* also affect the development of the endoderm. This occurs because *Ubx* in the gut mesoderm activates the expression of *decapentaplegic*, a TGFb homolog that induces gene expression in the underlying endoderm (4).

Mutations that abolish the function of *Ubx* are lethal. In *Ubx* homozygous larvae, the third thoracic and first abdominal segments are transformed into the second thoracic segment (parasegments 5 and 6 into parasegment 4). These larvae also have some incomplete homeotic transformations in the abdominal segments 2 to 7 (5). *Ubx* function is also required for the adult imaginal structures as shown by mutations in cis-regulatory sequences that remove the expression of *Ubx* in the adult primordia of specific segments. The most spectacular mutants show a complete transformation of one segment into another. For example, the combination of three viable alleles of *Ubx* (*abx, bx, pbx*, see below) gives rise to flies with two pairs of wings. This is due to the transformation of the metathorax and the halteres typical of dipterans into a mesothorax with a second pair of wings. Flies

mutant for other alleles (*bxd*) develop four pairs of legs due to the formation of an extra pair in the first abdominal segment. Complementary to the loss-of-function mutations, alleles causing expression of *Ubx* in the wing where it is normally absent produce flies in which the wings disappear and are replaced by a pair of halteres.

UBX proteins control the development of segment morphology by transcriptional regulation of downstream target genes in specific regions. It is this battery of genes that is ultimately responsible for the correct morphogenesis of the segment. Several target genes of *Ubx* have been found, and some have been proved to be transcriptionally activated or repressed by UBX. Direct UBX targets include transcription factors (like the homeobox gene *Distalless*); signalling molecules (TGFb homolog *decapentaplegic*) and membrane-associated proteins involved in cell adhesion *(connectin)*. The number of direct target genes has been estimated to be around 100 to 200 (6, 7).

The spatial regulation of *Ubx* transcription is controlled at several levels (8). Early expression is regulated by a combination of transcriptional activators required for the segmentation of the embryo (homeodomain protein like *fushi-tarazu* and *even-skipped*) and repressors (like the *hunchback* zinc finger protein). These early regulators are only transiently expressed, and other proteins replace them to keep the restricted spatial expression. The *Polycomb* genes maintain the repression of *Ubx*, and the *trithorax* genes maintain its expression. There is a less well characterized group of regulators required for the fine modulation of *Ubx* expression. The homeodomain protein encoded by the *engrailed* gene belongs to this group, but many other transcription factors, like the zinc-finger protein encoded by the *spalt* gene, are likely to be involved in the dynamic pattern of *Ubx* regulation (9).

Mutations in the *Ubx* gene map to a 100 kb region. There is a 40 kb upstream regulatory region, the *bxd* region, that gives rise to several untranslated transcripts, the *bxd*-unit (10). The UBX proteins are encoded in a large transcription unit of 77 kb that generates mRNAs of 3.2 kb and 4.3 kb, the *Ubx* unit. The differential use of two splicing acceptors and the inclusion or not of two microexons results in the translation of six protein isoforms (11, 12). The expression of the different isoforms is tissue-specific but not segment-specific. The longest isoforms are expressed mainly in the ectoderm and mesoderm, while the shortest isoforms lacking both microexons are mainly expressed in the central nervous system (13). The spatial distribution of UBX isoforms has been conserved in *Drosophila* species that diverged 60 million years ago, suggesting a functional requirement for the tissue-specific expression (14). Functional differences between UBX isoforms have been found (15). However, experimentally induced ectopic expression of different protein isoforms shows that they also have equivalent functions (16). These results suggest that isoform diversity may serve to optimise UBX protein function in different contexts, rather than to confer different regulatory properties (15).

The UBX protein has two conserved regions: the homeodomain required for the DNA binding and the YPWM peptide, a stretch of aminoacids N terminal to the homeobox that is required for protein-protein interactions. In vitro, the UBX homeodomain binds to DNA with an ATTA core sequence that is also bound by other homeobox proteins (17). *In vivo*, the binding specificity of UBX is acquired by interaction with cofactor proteins that increase the sequence specificity. A *Ubx* cofactor protein has been well characterized, *extradenticle* (18). Extradenticle is a homeobox protein, and it could function either by increasing the affinity of UBX for its target DNA sequences or by allowing DNA-bound UBX proteins to act as transcriptional activators (19).

The *cis* regulatory elements of *Ubx* are located in a wide region that includes both the introns and the upstream region. The viable loss-of-function alleles in cis regulatory elements do not affect the coding potential but alter the spatial distribution of *Ubx*. According to their phenotypes, mutations in cis regulatory regions have been classified in four groups: *anterobithorax (abx), bithorax (bx), bithoraxoid (bxd), and postbithorax (pbx)* (20). *abx* and *bx* alleles are homozygous viable and transform, to a variable extent, the anterior third thoracic segment into anterior second segment. The *abx* alleles are deletions while *bx* alleles are caused by insertions of transposable elements in the third intron of the *Ubx* transcription unit (21). The *pbx* and *bxd* alleles map in the upstream region.

The *bxd* alleles are caused by insertions of transposable elements; insertions closer to the promoter have a stronger phenotype consisting in the disappearance of the abdominal structures and the formation of an extra pair of legs. The *bxd* alleles also have a mild transformation of the posterior metathorax into posterior mesothorax that affects mainly proximal structures. The pbx alleles are caused by deletions in a more distal area of the upstream regulatory region. They result in the transformation of the posterior metathorax into posterior mesothorax. All the above viable alleles have mild phenotypes in larvae. Analysis of reporter gene constructs carrying DNA from the *abx, bx, pbx*, and *bxd cis* regulatory regions show that these elements are capable of driving expression in the adult as well as in the larva. Analysis of the effect of different breakpoints in the upstream region as well as the work with reporter genes suggest the existence of a degree of redundancy in the cis regulatory elements. These elements are required for activation or repression as well as maintenance of the expression (4, 8) and could be acting either as enhancer/silencers or as chromatin isolators that regulate the accessibility to DNA of transcription factors.

The *Contrabithorax (Cbx)* alleles are dominant gain-of-function mutations that result in the ectopic expression of UBX proteins in the wing. This ectopic expression results in the transformation of wing to haltere and, in some cases, mesonotum to metanotum. The *Cbx* alleles are mainly caused by breakpoints in the upstream or downstream regulatory regions or in the case of the Cbx^1 allele by the transposition of the *pbx cis* regulatory element into the second intron of *Ubx*. Similar phenotypes to the *Cbx* alleles can be obtained in constructs expressing *Ubx* regulated by some *abx, pbx*, and *bxd* regulatory elements. This minigene is capable of partially rescuing the *Ubx* mutant phenotype, but its lack of restricted expression results in *Cbx* phenotypes (22). *Cbx* phenotypes can also be obtained by mutation of the *Ubx* repressors encoded by the *Polycomb* genes.

The regulatory elements of *Ubx* act mainly in cis. However, in certain experimental conditions, it has been shown that they can activate the promoter of the homologous *Ubx* gene. This trans complementation is sensitive to the disruption of pairing between homologous chromosomes and has been termed “transvection” (23). Transvection occurs in other loci of *Drosophila* and happens due to the pairing of the homologous chromosomes during interphase. The chromatin binding protein encoded by the *zeste* gene is required for transvection, and mutations in *Polycomb* affect the degree to which transvection occurs (24, 25).

The Hox genes of *Drosophila* have cross-regulatory interactions. Genes expressed in more posterior segments repress the transcription of more anterior genes. Thus, UBX protein represses the transcription of genes of the Antennapedia Complex, while the ABD-A and ABD-B proteins repress *Ubx* transcription (26). Generalized expression of UBX protein in the embryo results in the transformation of head and thoracic segments into A1, the segment where homogeneous and high UBX protein levels are expressed. In contrast, this ectopic expression has only mild defects in regions posterior to A1. This difference in the effects of ectopic UBX expression is due to the expression of ABD-A and ABD-B proteins in the posterior segments. A similar effect occurs when ANTP and UBX are expressed simultaneously. In this case, expression of both proteins does not give the expected intermediate phenotype but the phenotype of UBX expression alone (27). This epistatic phenomenon at the level of protein expression in which the simultaneous expression of two HOX proteins results in the same phenotypic outcome as expressing the most posterior one has been called in *Drosophila* phenotypic suppression and, in vertebrates, posterior prevalence (28).

From the evolutionary point of view, the *Ultrabithorax* gene predates the evolution of insects and their derived body plan (29). Real *Ubx* homologs (orthologs) have been cloned from several species of arthropods including many insects, crustaceans, and onycophorans (30, 31). In many instances, changes in the spatial expression of *Ubx* orthologs in different, species correlate with the morphological differences observed between species (32, 33). In the flour beetle *Tribolium castaneum*, there is strong evidence supporting that mutations in the *Ultrathorax* gene that transform the morphology of abdominal segments towards that of thoracic segments are mutations in the *Ubx* ortholog (34). Experiments expressing the *Ubx* ortholog of *Onychophora* in *Drosophila* suggest that

although many of the functions of the protein have been conserved some have diverged. This divergence is partly due to interaction of the *Ubx* orthologs with different co-factor proteins (35).

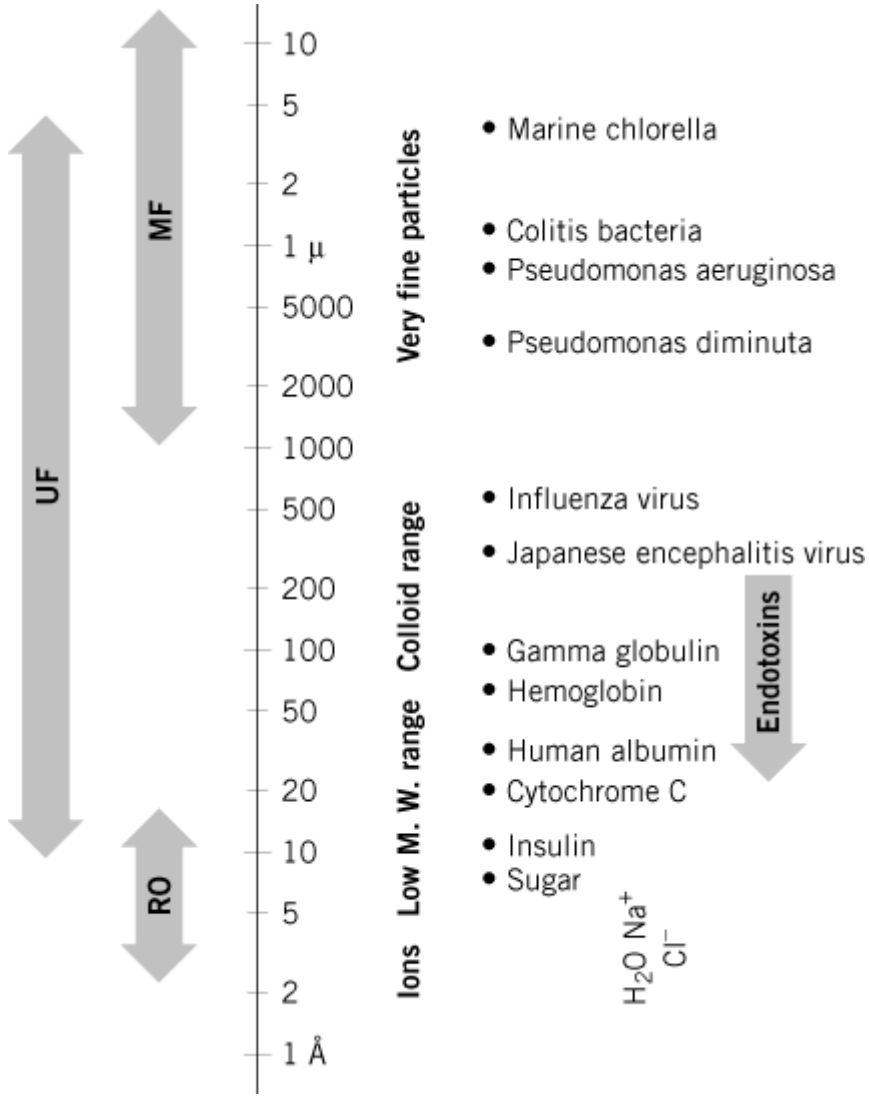
Ultrafiltration, Microfiltration

Ultrafiltration and *microfiltration* are pressure-driven processes that use a semipermeable membrane to separate dissolved and suspended materials on the basis of size; only molecules smaller than the pore size of the membrane may pass through it. The technique of ultrafiltration can deal with molecules with molecular weights in the range of 500 to 1,000,00 da, or approximately 10 to 100 Å (1 to 10 nm) in size. In contrast, microfiltration uses membranes in which the pore sizes range from 0.01 to 10 µm (Fig. 1). Ultrafiltration is suitable for concentrating or washing macromolecules such as proteins, peptides, polysaccharides, lipids, synthetic polymers, **viruses**, and colloids, or the concentration of dilute samples of **nucleic acids**. The range of molecular sizes for which it is used distinguishes the process from *reverse osmosis*, in which even salts or other low molecular solutes are retained.

Figure 1. Application range for ultrafiltration, microfiltration, and reverse osmosis.



Ultrafiltration cannot discriminate between macromolecules that have sizes similar to one another, and for this reason the process is unsuited for the separation of soluble molecules whose molecular weights or effective sizes in solution (Stokes radii) differ by less than a factor of 6. For the separation of such molecules, alternate techniques such as chromatography, electrophoresis, or adsorption should be considered.

1. Dead-Ended and Cross-Flow Apparatus

The ultrafiltration process may be either *cross-flow* or *dead-ended*, where the feed stream is forced through the membrane and collected. An example of dead-end filtration is the disposable syringe end filters that use membranes bonded to a sealed plastic support plate. This unit has Luer-type connectors that permit its attachment to a syringe. The fluid to be filtered is placed in the syringe, manually driven through the filter, and collected. A technique particularly suited for the micro-purification of proteins, **antibodies**, and nucleic acids is shown in Figure 2. Samples of up to 500 µl may be placed in the microconcentrator module, which is placed into a centrifuge and spun. The centrifugal force generated forces the filtrate through the membrane and concentrates the molecules too large to pass through it. For larger sample volumes, stirred cells may be used, such as those developed by Amicon (Fig. 3). In this technique, a flat sheet of membrane is placed on an appropriate support structure and spacer that forms part of the cell assembly. The fluid is added and agitated with a magnetic stirrer. The cell is pressurized, either by air or nitrogen, and the filtrate is forced through the membrane. The use of air pressure avoids the damage of highly labile products that can occur during pumping.

Figure 2. Centrifugal concentrator (MicroconR). After centrifugation, the module is inverted and recentrifuged for more complete recovery of the concentrate in the vial. (Courtesy of Millipore Corporation, Bedford, MA.)

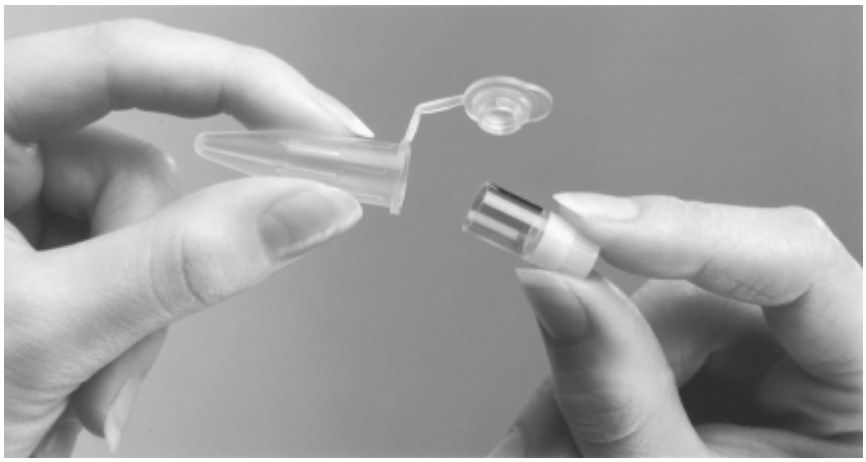


Figure 3. Stirred cell for ultrafiltration. Pressurized vessel with magnetic stirring bar. The membrane in the form of a disk is situated under the stirring bar. (Courtesy of Millipore Corporation, Bedford, MA.)

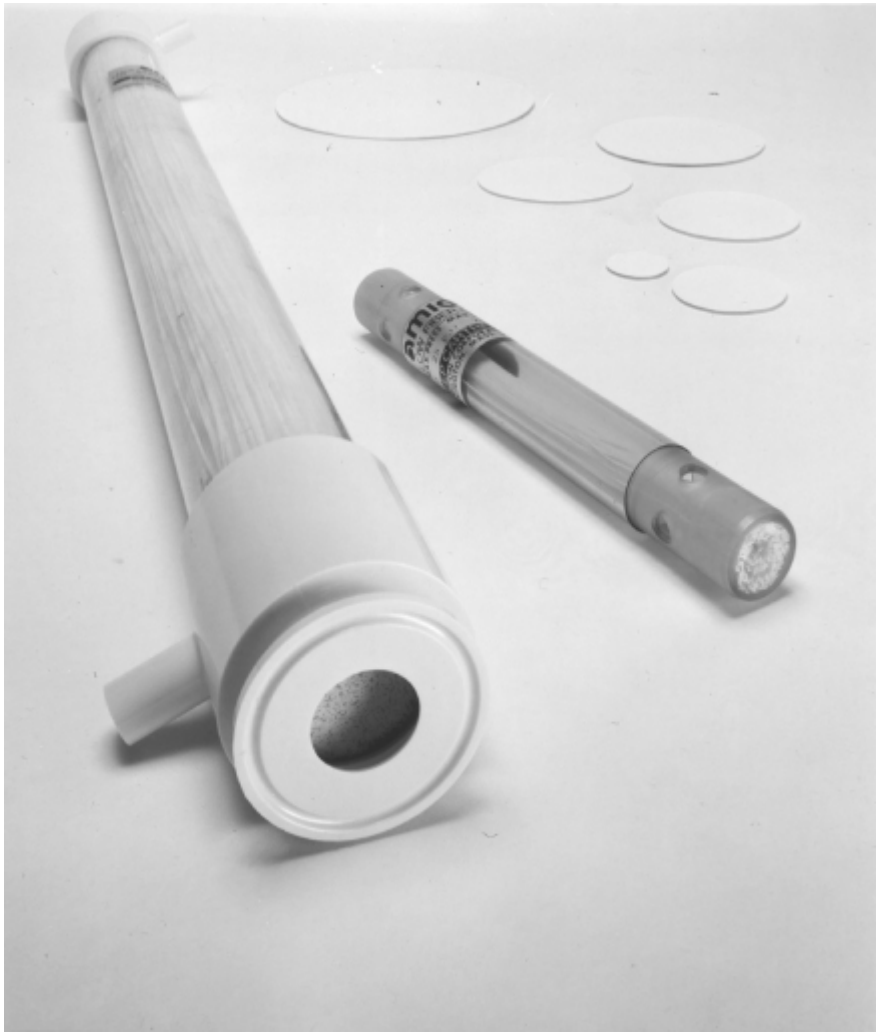
The main disadvantage of such techniques is membrane fouling. As the filtrate is forced through the membrane, the retained particles accumulate on the membrane surface. This layer is the *concentration polarization layer*; its development will depend on several factors, such as temperature, solubility, and pH. As the thickness of this layer increases, the efficiency of filtration diminishes. Control of such membrane fouling may be achieved by the use of a thin channel device, in which the feed is forced through a narrow channel that spirals outward over the surface of the membrane. The flow in this narrow channel generates high shear rates, leading to improved solute transfer across the membrane.

For the filtration or concentration of solutions at process scale, hollow fiber or flat sheet cross-flow devices are used (Fig. 4). In cross-flow filtration modules, the feed flow is parallel to the membrane and perpendicular to the filtrate flow. The solvent and solutes smaller than the pore size of the membrane pass through the membrane to form the ultrafiltrate, or permeate. In such devices, the retentate or concentrated solution flows across the membrane when in the form of a flat sheet, or along the fibers. The permeate or filtrate passes across the membrane and flows out of the module for collection. Cross-flow systems are inherently more complex, but they have high rates of mass transfer, due to high shear rate or tangential velocity, as well as turbulence adjacent to the membrane.

Figure 4. Hollow fiber ultrafiltration modules for process scale applications. (Courtesy of Millipore Corporation, Bedford, MA.)



2. Ultrafiltration Membranes

The membranes that are used in ultrafiltration or related processes may be **hydrophobic** or hydrophilic, uniform in their cross section or asymmetric, with a dense thin (0.1 to 1.5 μm) top layer supported by a porous sublayer containing macrovoids. The dense surface layer determines the membrane's convective transport properties, since it contains the pores, with the substructure providing mechanical strength. The membranes are made from either cellulose (cellulose ester or nitrocellulose) or synthetic materials, such as polysulfone and polyacrylonitrile, which exhibit relatively low protein binding.

The basic characteristics of membranes are represented by (*1*) the flux, (*2*) rejection of solutes, and molecular-weight cutoff. The flux J is defined as

$$J = \frac{Q}{A\Delta t} \tag{1}$$

where Q is the permeated amount, A the membrane area, and Dt the sampling time. The rejection R is calculated from the difference in the concentration of the solute in the feed solution C_F and the concentration in the permeate C_P, such that

$$R = 1 - \frac{C_P}{C_F} \tag{2}$$

The cutoff of a membrane is the maximum molecular-weight molecule that the membrane will allow through. For molecules or nucleotides, this parameter is generally defined as the maximum molecular weight, or the number of nucleotides in the DNA fragment, for which 90% of the molecules are retained by the membrane.

3. Solute and Solvent Transport Mechanisms During Filtration Processes

The membranes used in ultrafiltration and related processes may be considered a polymeric matrix in which pores are present. Although the actual morphology of the membranes is complex, considerable insights into the behavior of the membrane may be made by the application of a model to describe the transport phenomena. As the mean pore diameters of the membranes suitable for ultrafiltration and microfiltration differ, so do the expressions that are used to determine the flux. For microfiltration membranes, the equations used are based on capillary flow:

$$J = K_P \frac{\Delta P}{L} = K \frac{\Delta P}{\eta L} \tag{3}$$

$$J = \frac{\pi r^4 \Delta P}{8 \eta L} \tag{4}$$

The first of these equations is the D'Arcy flow equation, whereas the second is the Hagen Poiseuille equation. In these equations, J represents the volume flux, DP the pressure difference across the two sides of the membrane, K the permeability or the D'Arcy permeability K_p, h the fluid viscosity, and p the universal constant. L is the length of the pore capillary, which can be taken to be equal to the thickness of the membrane, since at this level the membrane may be considered a series of parallel cylindrical pores, with a radius of r, perpendicular to the membrane surface. The equation may also be written to include a tortuosity factor T in the denominator, which provides a measure of the actual fluid path length through the membrane, relative to the thickness of the membrane.

For ultrafiltration membranes, the equations for the transport of solvent and solute may be expressed as

$$J_V = L_V(\Delta P - \Delta \Pi) \tag{5}$$

$$J_S = L_S(C_M - C_P) + (1 - \sigma) J_V C_S \tag{6}$$

where J_V and J_S are the fluxes of the solute and solvent, respectively, L_V and L_S their respective hydraulic permeabilities, C_M, C_P, and C_S the solute concentrations in the membrane, permeate, and solution, respectively, DP the pressure difference across the membrane, DP the osmotic pressure, and s the Staverman reflection coefficient.

Cross-flow filtration techniques are commonly used in which the mixture requiring separation is recirculated over the membrane surface. In this case, the flux rate will depend on the applied or transmembrane pressure DP, the mass transfer coefficient k of the device, the solute concentration in the formed gel C_G, and the bulk solute concentration C_B such that

$$J = k \log_e \left(\frac{C_G}{C_B}\right) \tag{7}$$

In the filtration of macromolecular solutions of low concentration by ultrafiltration, their osmotic pressures are low compared to the applied pressure and can be neglected. In high concentration solutions, the osmotic pressure effects may be significant, and the volume flux equation (5) requires modification to account for the osmotic pressure of the macromolecular solution. The osmotic pressure exerted by such solution is generally in the form

$$\Delta\Pi = AC + A_1C^2 + A_2C^3 \tag{8}$$

where A, A_1, and A_2 are osmotic virial constants and C is the concentration of the bulk macromolecular solution. The coefficient A describes Van't Hoff's limiting law for the osmotic pressure, which is applicable at very dilute concentrations, whereas A_1 can be expressed in terms of the solute molecular weight.

In order to achieve high rates of mass transfer, it is necessary to have a high tangential velocity or shear rate and/or turbulence in the vicinity of the membrane. Theoretical expressions are available for the derivation of the mass transfer coefficients for differing membrane module and flow geometry configurations. Such expressions implicitly assume that the density, viscosity, and solute diffusivity are constant across the boundary layer.

Ultrafiltration and microfiltration are able to prepare reasonably concentrated samples of macromolecules, but they permit only a limited separation of the retained solutes from the smaller or more permeable components present in the solution needing to be filtered. In order to remove such smaller components more effectively from the retained species, the feed solution can be washed in a process known as diafiltration.

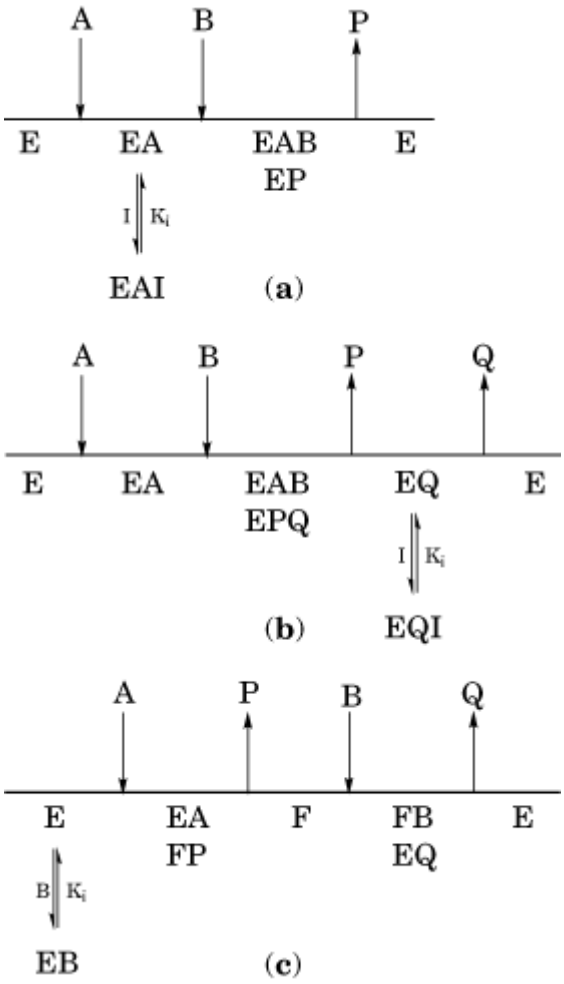
Uncompetitive Inhibition

Linear uncompetitive inhibition of an enzyme occurs when the variable substrate and the inhibitor combine with different enzyme forms and no reversible connection exists between the two points of addition (see Product Inhibition and Dead-End Inhibition). This type of inhibition is observed with a two-substrate reaction with an ordered **kinetic mechanism** when an inhibitory analogue of substrate B (I) combines with EA and A is the variable substrate (Fig. 1**a**). The inhibition by I would be linear **competitive** with respect to B because B and I combine separately with EA. But it would be linear uncompetitive with respect to A, because I and A combine with different enzyme forms and there is no *reversible* connection between the reaction of A with E and of I with EA. Increasing concentrations of A can only increase the concentration of the EA complex with which I reacts. The same type of inhibition would be observed if an inhibitory analogue of substrate B combined only with the EQ complex on the release side of an ordered Bi—Bi mechanism (Fig. 1**b**). This inhibition

would be linear uncompetitive with respect to both substrates.

Figure 1. Enzyme **kinetic mechanisms** that give rise to linear uncompetitive inhibition.



Linear uncompetitive inhibition is commonly observed with Ping-Pong mechanisms with structural analogues of either of the two substrates (Fig. 1**c**). When I is an analogue of A, it would compete with A for binding to E and thus cause linear competitive inhibition. The inhibition with respect to B would be linear uncompetitive because B and I combine with different enzyme forms and no reversible connection exists between the combination of I with E and of B with F. The release of P or Q, at what can be considered to be zero product concentration when initial velocities are being measured, breaks the connection between the points of addition of I and B. Similar results would be obtained with an inhibitory analogue of substrate B.

The general form of the equation to describe linear uncompetitive inhibition is shown in equation (1):

$$v = \frac{VA}{K_a + A\left(1 + \frac{I}{K_{ii}}\right)} \qquad (1)$$

The reciprocal form of the equation is illustrated in equation (2):

$$\frac{1}{v} = \frac{K_a}{V}\frac{1}{A} + \frac{1}{V}\left(1 + \frac{I}{K_{ii}}\right) \qquad (2)$$

In equations (1) and (2), V represents the maximum velocity of the reaction, K_a and A are the K_m (Michaelis constant) and concentrations of substrate A, respectively, I is the concentration of the inhibitor, and K_{ii} denotes the inhibition constant associated with the intercepts of double-reciprocal Lineweaver-Burk plots. Because the slope of the curves is independent of the concentration of I (eq. (2)), a plot of $1/v$ against $1/A$ would consist of a family of parallel straight lines (Fig. 2). A replot of the vertical intercepts against I would yield a straight line according to

$$\text{Intercept} = \frac{1}{VK_{ii}}I + \frac{1}{V}$$

and the horizontal intercept gives the value of K_{ii}. For the mechanism illustrated in Figure 1**a**, the K_{ii} value would not be a true dissociation constant (K_i) but rather an apparent value equal to K_i $(1 + B/K_b)$. The true value could be calculated using the values of the Michaelis constant and the fixed concentration of B. The best estimate of K_{ii} would be obtained by least-squares fitting of the inhibition data to the general equation for linear uncompetitive inhibition (1).

Unfolded Protein Response

When cells accumulate substantial amounts of unfolded protein in their endoplasmic reticulum (ER), as when expressing a mutant form of a secreted protein that cannot fold efficiently or under stress conditions (see **Stress Response**), the ER grows in volume. It also changes from a network surrounding the nuclear envelope to one that fills the peripheral cytoplasm. In yeast, the genes for many ER proteins share a 22-bp transcriptional element that mediates this coordinate unfolded protein response (UPR) (1). A special transcription factor, Hac1p, binds to this element and is required for mounting the UPR. Hac1p is regulated in a novel and complex fashion. Its normal product is synthesized constitutively, but does not induce UPR, either because it is rapidly targeted for **protein degradation** or because its messenger RNA is sequestered in the nucleus (2). A more stable form of the factor, $Hac1^{i}$, is produced as a result of nonconventional RNA splicing of the Hac1 mRNA precursor, in a reaction that does not require the normal RNA processing machinery, but instead requires the tRNA ligase encoded by the gene RGL1 (3, 4). The endonuclease activity involved in this splicing reaction resides, surprisingly, in the cytosolic domain of the ER transmembrane protein Ire1 (5). This protein is a **serine/threonine kinase**, whose activity is required to induce the UPR in yeast (6, 7). The luminal, *N*-terminal **domain** of Ire1 can sense, by an unknown mechanism, the folding status in the lumen of the ER and mediate dimerization of the protein in the plane of the ER membrane. Dimerization activates *trans*-**phosphorylation**, in which each monomer phosphorylates the other; this in turn is thought to activate the endonucleolytic activity and initiate the alternative splicing. Significantly, yeast mutants in the various components of the UPR are also inositol auxotrophs, thus providing a genetic link between the induction of ER **protein biosynthesis** and membrane lipid synthesis (8). Because ER biogenesis is induced in higher eukaryotes and yeast by similar physiological demands, it is expected that the signal transduction cascade to the genome would be similar, yet the mammalian homologues of the yeast machinery are yet to be characterized.

Unfolded Proteins

Disrupting the native protein structure upon **denaturation** implies disappearance of the specific contacts between the groups of the protein and a decreased compactness of the polypeptide chain conformation, that is, its unfolding. The completeness of unfolding of the polypeptide chain of proteins upon denaturation is one of the most debated subjects in protein science. It is an important problem because in all theoretical considerations of the mechanism of formation and stabilization of the native protein structure, the completely unfolded polypeptide chain in a random-coil conformation is a standard reference state. The ideal unfolded state, however, can probably not be achieved in practice. Extreme conditions can change the balance of forces that maintain the native protein structure and can destroy specific interactions between clusters of protein groups, but they certainly cannot eliminate completely all the interactions between the great variety of groups.

It has been believed that proteins are most unfolded in concentrated solutions of urea or **guanidinium** chloride (GdmCl) (see Denaturation, Protein), because these solutes significantly increase the intrinsic **viscosity** of proteins at room temperature (an indicator of the hydrodynamic **volume** of the polypeptide chain) and decrease almost to zero the **circular dichroic** (CD) ellipticity at 220 nm (an optical indicator of the content of helical structure). According to these criteria, the least unfolded are thermally denatured proteins, proteins at high temperatures. The intrinsic viscosity of unfolded proteins at high temperatures is significantly smaller than in concentrated solutions of denaturants at room temperature, and thermally unfolded proteins show some residual CD ellipticity (1). From the observed temperature-dependence of the apparent equilibrium constant for unfolding, it has also been assumed that denaturation by denaturants leads to a much greater **heat capacity** increment than denaturation by temperature. Because the denaturation heat capacity increment is regarded as an index of nonpolar group exposure to water, this fact was considered evidence for more complete unfolding of proteins by denaturants than by temperature (1). However, it was found later that the intrinsic viscosity of unfolded polypeptide chains depends markedly on temperature and decreases significantly with increasing temperature (2, 3). This is the main reason that the intrinsic viscosity of heat-denatured proteins measured at high temperatures is significantly lower than that in concentrated solutions of GdmCl or urea measured at room temperature. The same was found for the CD ellipticity of proteins in concentrated solutions of denaturants. It also depends on temperature (4), and at high temperatures it has the same magnitude as that of the heat-denatured protein in water (3). Furthermore, direct **calorimetric** measurements showed that the heat capacity increase observed upon protein denaturation by urea or GdmCl is greater than that by thermal denaturation only because denaturants interact strongly with proteins and this interaction is enthalpic (5, 6). With increasing temperature, denaturant molecules bound to proteins dissociate gradually, absorbing heat, which increases the value of the apparent heat capacity increment (see Denaturation, Protein). If the heat effect of gradual dissociation of denaturants on temperature rise is taken into account, the real heat capacity increment of protein denaturation by denaturants and by temperature are similar. With increasing temperature, polypeptide chains in solutions of denaturants come closer to the random-coil conformation because bound denaturant molecules dissociate and because the dissipative forces of thermal motion increase. At sufficiently high temperatures, denaturants do not much affect the state of a polypeptide chain, and it becomes close to that of a heat-denatured protein without denaturants. There may still be some nonspecific, chaotic interactions between the groups of the polypeptide chain, particularly the attractive **hydrophobic** interactions between nonpolar groups, which increase with increasing temperature and squeeze the hydrodynamic volume of the polypeptide chain. But they do not form stable, ordered clusters of groups. Thus, concentrated solutions of urea and GdmCl cannot be regarded as q-solvents, in which the interactions of one group with other groups of a polymer are the same as with the solvent, and the polypeptide chains in these solutions cannot be considered ideal random coils (7, 8). Nevertheless, calorimetric

measurements of the **enthalpies** of unfolding of small globular proteins by various means (GdmCl, acid, and temperature) showed that if the heats of protonation of groups upon unfolding and of solvation by denaturants are properly taken into account, the enthalpy of unfolding is a universal function of temperature (5, 9). This shows that, for small proteins that do not aggregate, the total energy of residual interactions between the groups of denatured proteins is small. Therefore, because there is no way to determine experimentally the energy of these residual interactions in the denatured protein, the denatured state of a protein is usually regarded as the reference unfolded state close to the truly random-coil state.

With increase of molecular weight and length of a polypeptide chain, the local effective molarities of groups in the unfolded protein increase, as do their attractive interactions, which significantly complicates the situation. This is especially so when a large protein consists of several domains that unfold under different denaturing conditions. Then, the denatured state of the protein, the state that lacks specific functional activity, does not always correspond to the unfolded state. It might be a partly unfolded state in which some **domains** are unfolded, whereas others preserve their native structure (see Denaturation, Protein). This partly unfolded state of multidomain proteins is sometimes called a "molten globule" state because it is rather compact. However, this designation is hardly justified because the term "molten globule" implies a global change (disruption) of the protein molecular structure, not just of some of its parts (10-12).

Unidentified Reading Frame

The term *unidentified reading frame* (URF) was previously used by scientists working on the DNA

from mitochondria and chloroplasts, but it has now been abandoned for the term open reading frame (ORF), which applies to all classes of DNA. By definition, an ORF is unidentified. When it is identified, this means that its product is known and it is now a *bona fide* **gene**.

Unit Cell

A crystal is characterized by the regular and periodic arrangement of its parts, which are ions, atoms, or molecules (see Crystallography). In this regular packing, three repeating vectors **a**, **b**, and **c** can be recognized with angles a, b, and g between them. The three vectors define a unit cell in the crystal (Fig. 1). The unit cell can be selected in many different ways, but it is conventional to choose it according to certain rules, given in Ref. 1 (see Space Group). In protein crystals, the unit cells have dimensions from 30 Å up to several hundred Å. It should be stressed that vectors **a**, **b**, and **c** are imaginary vectors in the crystal and indicate only the periodicity of the crystal lattice. The unit cell in many crystal lattices, is composed of two or more identical structures, related by the symmetry of the lattice and known as the asymmetric unit. The great advantage of the unit cell concept is that only the content of one unit cell or asymmetric unit needs to be described in a report on the crystal structure (see X-Ray Crystallography).

Up-And-Down b-Barrel

Up-and-down b-barrel describes the topology of a type of b-barrel motif found in some protein structures, in which the protein polypeptide chain folds into two b-sheets that pack against each other to form a cylindrical or barrel shape (Fig. 1, see top of next page). The characteristic feature of up-and-down b-barrels is that all connections between the 8 or 10 b-strands are **hairpins**, so that b-strands adjacent in sequence are also adjacent in the structure. This topology is equivalent to a b-meander . The barrel is closed by interactions between the first and last b-strands, and a **hydrophobic** cavity is formed in the interior. Proteins having this type of structure often function as **transporters** or solubilizers of hydrophobic ligands (such as retinoids, fatty acids, and bile salts) that bind in the interior of the barrel.

Figure 1. Structure of up-and-down b-barrels. (**Top**) Topology of the b-strands in the up-and-down b-barrel, with hairpin connections for all the b-strands. (**Bottom**) Backbone representation of the three-dimensional structure of a typical up-and-down b-barrel protein, retinol binding protein (1). This was generated using Molscript (2).

Upstream

Nucleotide sequence elements are designated as being *upstream* or downstream, with respect to the direction of transcription of a given gene. Initiation of transcription of the **gene** and initiation of translation of messenger RNA depend on numerous sequence signals located upstream of the initiation codon, usually within the nearest 200–500 bp of the 5′ region, but sometimes as far as several kilobase pairs away. Sequence features relevant to translation are located between the transcription and translation starting points, whereas transcription signals reside further upstream. **Promoters** are usually located immediately upstream of the transcription starting points and comprise a separate category of upstream elements.

In prokaryotes, the first upstream element is the Shine-Dalgarno sequence, also called the **ribosome**-binding site (see Translation). It is located within a few bases from the translation starting point and has the **consensus sequence** GGAGG. This sequence is important for initiation of translation. It base-pairs with a complementary sequence at the 3′ end of the small-subunit ribosomal RNA. Upstream of the prokaryotic promoters are **operator** sequences—binding sites for repressors of transcription. In many instances, the operator sequences are located rather far away—200–300 bp—so that the interaction of the corresponding repressors with the transcription complex requires bending of the DNA, with formation of a loop (1, 2).

In eukaryotes, the sequences upstream of the translation starting points are not necessarily the same as in the **genomic** DNA. The 5′ regions of the RNA transcripts before the initiation codon often contain intervening sequences (**introns**), which will be excised during processing of the RNA transcripts, together with any introns that interrupt the protein-coding sequences (see RNA Splicing).

Nucleotide sequences in eukaryotes immediately upstream of translation starting points are not related to the prokaryotic Shine-Dalgarno sequence. A different type of interaction of the mRNA starting region with the eukaryotic 18 S rRNA is suggested, in which certain trinucleotides that are the most frequent in the starting region of the mRNA make complementary contacts with the rRNA (3).

The 5′ untranslated regions of eukaryotic genes harbor binding sites for an immense variety of species-, tissue-, gene family-, and gene-specific transcription factors (4). Many different factors bind to DNA sites with similar **consensus sequences**, thus clustering in groups, or families. The CCAAT group of constitutive transcription factors is one example. Another frequent consensus sequence is GGGCGG, the binding site for Sp1 factor. Both such sequences are usually located in

the region 50–100 bp upstream of the transcription starting point.

Important families of sequences involved in the regulation of transcription in eukaryotes are the enhancers (5) and **silencers** (6). One general feature of these functional sites is the independence of their effect on their location, which can be either upstream or downstream of the protein-coding sequences, at distances from about 100 to several thousand bases away. Changes in their polarity in the sequence also are of no importance for the enhancement or silencing of transcription. The sequences themselves are 100–200 bp. The enhancer sequences harbor a variety of often crowded binding sites for various transcription factors, and they sometimes occur as several copies in tandem.

Urea

Urea is one of the most common protein **denaturants**. Classically, it is used at 8 *M* concentration, which unfolds most globular proteins. Its limit of solubility at room temperature is ~10 M . As a denaturant, urea has the same efficacy as **guanidinium** acetate and is, thus, a much weaker denaturant than **guanidinium chloride**. It has the advantage of being a neutral molecule, which precludes the various effects of ionization. Urea acts principally by the formation of hydrogen bonds with protein peptide groups, although it also has some **hydrophobic** character. At lower concentrations, 0.5 to 1.0 *M*, it is used as a breaker of protein aggregates and solubilizer of proteins synthesized by recombination techniques, following the dissolution of inclusion bodies. See also Stabilization And Destabilization By Co-Solvents, **Denaturants, stabilizers**; Guanidinium Salts.

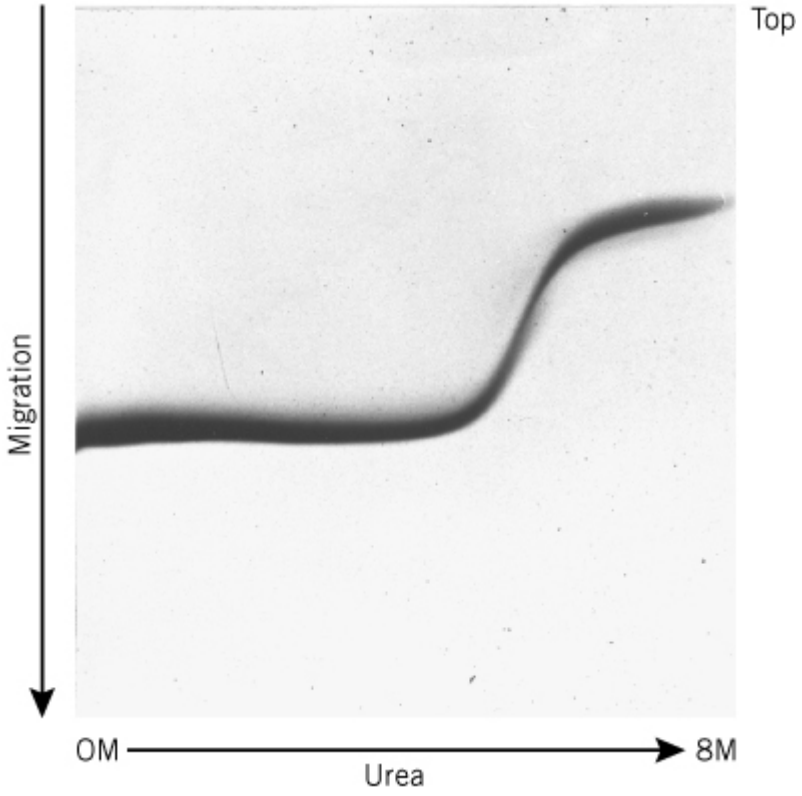
Urea Gradient Gel Electrophoresis

The denaturant urea is commonly used in studies of **protein unfolding** and in the denaturation of **nucleic acids**. Because it is nonionic, urea may be incorporated into polyacrylamide gels for electrophoresis (**PAGE**). When incorporated as a concentration gradient perpendicular to the direction of electrophoretic migration, it is the most commonly used form of transverse gradient gel

electrophoresis (TGGE). The electrophoretic mobilities of proteins and nucleic acids depend on their conformations, so urea gradient gel electrophoresis is very useful in studying protein and nucleic acid structure and stability.

A concentration gradient of urea is incorporated horizontally into a slab polyacrylamide gel on which a sample of protein or nucleic acid is layered and then subjected to electrophoresis vertically. Each molecule in the sample migrates at a constant denaturant concentration, but the concentration varies continuously across the gel and the sample. The final pattern reveals the electrophoretic mobility of the sample at continuously varying urea concentrations. As with other types of TGGE, the result is a single continuous band across the gel, that has a sigmoidal change in mobility when the structure changes, if the change in structure is reversible and rapid on the timescale of the separation. Slow or irreversible transitions produce discontinuities in the band across the gel. An example of a rapid and reversible unfolding transition of a protein is illustrated in Figure 1. The unfolding transition is apparently two-state, $N \leftrightarrow U$, as shown by the single inflection point of the band through the unfolding transition region. The electrophoretic profile graphically displays the relative proportions of the N and U states present at equilibrium as a function of the urea concentration. The results obtained in this way are generally consistent with other studies of the urea-induced unfolding monitored in other ways.

Figure 1. Transverse urea gradient gel electrophoresis of cytochrome *c*. A sample of the folded protein was layered on the top of the polyacrylamide slab gel, which contained a linear gradient of urea from left to right. Electrophoresis at pH 4 was from top to bottom. The gel was stained with Coomassie Brilliant Blue. At low urea concentrations, the protein remains folded and migrates relatively rapidly. At high urea concentrations, it unfolds and migrates more slowly. At about 6 *M* urea, the protein unfolds in a rapid and reversible unfolding transition. The same pattern is obtained starting with unfolded protein. This and the continuous band of protein throughout the unfolding transition region indicate that unfolding and refolding are rapid relative to the electrophoretic time at all urea concentrations. Therefore, the fraction of unfolding at equilibrium determines the migration rate at each urea concentration. The smooth shape of the band through the unfolding transition region and a single inflection point indicate that only two conformational states with different electrophoretic mobilities are present to significant extents. That cytochrome *c* undergoes a rapid, two-state unfolding transition is known from other studies. Taken from Ref. 1.



Urea increases the rate of unfolding (N↔U), and decreases that of refolding. In both cases, the urea concentration is proportional to the logarithm of each rate constant (see Protein Folding In Vitro). Consequently, the logarithm of the equilibrium constant for the reaction N↔′U is proportional to the urea concentration. In this case, the **free energy** difference DG_f between N and U varies linearly with the urea concentration and is zero at the midpoint of the transition. Its value at other urea concentrations for a two-state unfolding transition are estimated by extrapolating from the transition region (see Protein Stability). In the case of equilibrium urea gradient gel patterns, like that of Figure 1, the values of DG_f are extrapolated through the midpoint of the transition defined by the slope of the electrophoretic band at its inflection point. The scale of the free energy difference is defined by the mobilities of the N and U states, which occur at $DG_f = -2RT$ and $+2RT$, respectively.

In a multidomain protein, unfolding of the individual domains are observed as separate transitions if they occur at different urea concentrations. In proteins comprised of multiple identical subunits, the mobility initially increases upon dissociation to folded monomers, and then decreases as they unfold. With different subunits, the dissociation is generally irreversible as the different subunits separate in the gel, unless they just happen to have the same electrophoretic mobility. Similarly, dissociation of a small ligand is generally irreversible. If electrophoresis is carried out rapidly at low temperatures, information about the kinetics of unfolding and dissociation and of refolding are obtained. Multiple unfolded forms that are only slowly interconverted are detected, and the tendency of very slow folding forms to fold is obtained.

Double-stranded nucleic acids lose their structure at high concentrations of urea, which is often augmented with the denaturant **formamide**. The electrophoretic mobility of a double-stranded oligonucleotide usually decreases slightly with increasing urea concentrations, probably because of fraying of the double helix at the ends. Then the mobility decreases dramatically and very abruptly, as the relatively stiff double helix dissociates into two random polynucleotide chains. The decrease in mobility can be very dramatic. Consequently, migration into an increasing urea concentration gradient parallel to the direction of electrophoresis is used to determine at which concentration the mobility change occurs.

Temperature gradient gel electrophoresis, is a related technique, which uses high temperature rather than urea to unfold macromolecules.

Urokinase

Mammalian species have two plasminogen activators, urokinase- or urinary-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA), that are the products of separate genes and members of the chymotrypsin family of serine proteinases. Both are mosaic proteins with a modular structure similar to that of the blood coagulation proteinases to which they are closely related [see Blood Clotting]. The two plasminogen activators provide an excellent example of the regulatory potential made available by the modular construction of these proteinases. Although catalyzing the same reaction, *i.e.* specific hydrolysis of Arg560-Val561 of plasminogen, gross differences in the organization of the N-terminal modules of the plasminogen activators, together with subtle differences in the serine proteinase domain, lead to remarkably different functional properties. These are reflected in their biological roles with tPA being predominantly responsible for plasmin-catalyzed fibrin dissolution, whereas uPA is thought to be responsible for generating plasmin activity in the context of extracellular matrix degradation and thus to be involved in tissue remodeling and invasive cell migration (*e.g.* tumor invasion and metastasis; vascular remodeling).

Urokinase, or uPA, is composed of three independent domains; an N-terminal epidermal growth factor-like EGF domain, a kringle module and the serine proteinase domain. It is secreted by a wide variety of cell types as a single-chain glycoprotein of 411 residues (M_r 54,000). This zymogenic form (pro-uPA) is activated by a single cleavage at Lys158-Ile159 giving rise to two disulfide-bridged polypeptides. This cleavage is catalyzed *in vitro* by a variety of trypsin-like proteinases including plasmin, which is the most likely activator *in vivo*. There has been considerable controversy concerning the intrinsic proteolytic activity of pro-uPA, with some investigators reporting an activity similar to that of the two-chain enzyme. However, the absolute level of the activity appears to be less than 0.1% that of the activated enzyme, although there is no consensus yet.

The structure of the catalytic domain of uPA, in complex with the peptide inhibitor Glu-Gly-Arg-CH_2Cl, has been determined by X-ray crystallography at a resolution of 2.5 Å (1). The solution structure of the N-terminal domains has been solved by heteronuclear NMR (2). No constraints between the domains of uPA have been detected by NMR, demonstrating an exceptionally high degree of interdomain flexibility (3).

In recent years much of the interest surrounding uPA has been focused on the high-affinity interaction between its N-terminal EGF-like module and a specific cell-surface receptor termed uPAR. This is a 55 kD glycosylphosphatidylinositol-anchored (GPI-anchored) membrane protein composed of three domains structurally homologous to snake venom a-neurotoxins (4). This binding regulates the function of uPA by focusing the enzyme to the pericellular region and providing a mechanism to enhance plasmin generation. The interaction of uPA with uPAR does not alter its activity *per se*, consistent with the observed independence of the EGF-like and serine proteinase domains, but requires the coincident cellular binding of plasminogen (5). This is thought to lead to the formation of ternary or higher order complexes which promote plasminogen activation by appropriate juxtaposition of the reactants and give a large reduction in the apparent K_m (Michaelis constant) for the reaction (6). The activation of uPAR-bound pro-uPA by cell-associated plasmin is also enhanced, leading to an efficient system of reciprocal zymogen activation and consequently a large amplification of plasmin generation. The precise molecular interactions underlying these kinetic effects have only been partially elucidated.

V Genes

The genetic information that encodes the **variable regions** of immunoglobulins, as defined at the protein level, is split into several gene segments; these are not classical exons (see Introns, Exons), because they have RNA splicing signals on only one end, whereas the other end contains specific *recombination signal sequences* (RSSs) that allow them to recombine before becoming functional. This organization provides a major combinatorial basis for generating a large number of different immunoglobulin chains from a limited number of genes. Heavy chains are encoded as the result of the gene rearrangement of three such genes or gene segments, called V (for variable), D (for diversity), and J (for junction); light chains are comprised of only two, V and J. As a consequence, complementarity determining regions CDR 1 and CDR2 are V-gene encoded, whereas CDR3 results from a VDJ or VJ combination (see Immunoglobulin Structure). This makes the CDR3, especially that of the heavy chain, the most diversified. All these genes are clustered together with the corresponding constant region genes in three loci, IGH, IGK and IGL, located (in humans) at chromosome positions 14q2, 2p12, and 22q11, with sizes of 1350 kbp, 1800 kbp, and 1000 kbp, respectively.

The V gene accounts for most of the variable region, because it encodes for more than 90 amino acid residues, the remaining being contributed by D–J for the heavy chain and J for the light chain. The organization of each V gene has the same pattern, whatever the locus [ie, one leader sequence (L)], encoding a signal peptide that is cleaved off in the rough endoplasmic reticulum and is separated from the V gene by a short **intron**. Each L-intron-V unit has its own 5′-**promoter** region that includes several classical sequences, including a TATA box. This organization is quite remarkable, because the V gene that will rearrange will carry over its own promoter region. As a result of this organization, V genes may have individual, very low levels of transcription before they rearrange, presumably because a transient accessibility of the DNA gives rise to germline V transcription. By contrast, the enhancer regions are not present at the 5′ position of each V gene, but are split into one intronic and one 3′ localization. In heavy chains, the enhancer regions are organized so as to be conserved after class switching.

In humans, all three loci have been completely sequenced, so the actual number of V genes is known. There are, however, minor differences between individuals, due to polymorphism. The IGH

locus contains between 46 and 50 VH genes, 27 D, and 6 J gene segments. A significant fraction of the VH genes are pseudogenes (~40%). The same phenomenon is observed in the mouse. In birds, there is only one potentially functional gene, whereas all others are pseudogenes. In that case, diversity is mostly generated by **gene conversion**, indicating that pseudogenes behave as a reservoir of diversity; this might explain not only why they have been maintained, but also why they have conserved the same general structure, including CDR1 and CDR2. VH genes may be classified in seven families on a homology basis. These families are interspersed, a situation different from that of mice, where VH genes of the same family are clustered. The number of genes that defines a family greatly varies, from a single member to 30, depending on the family.

The IGK locus contains 76 Vk genes (only 34 of which are functional), and 5 Jk genes. The Vk genes may also be grouped in five homology families. The IGVK locus contains a large internal duplication, within which Vk genes have an inverted orientation. As a consequence, rearrangement of these genes is made by inversion instead of the classical deletion of the intervening sequences.

The IGL locus contains 52 Vl genes grouped into 10 families. A little more than 50% are functional. The Jl–Cl are tandemly organized in seven basic units, three of which are pseudogenes. One region is found duplicated in certain individuals, creating an allelic **polymorphism** in the population.

Chain diversity that results solely from the combinatorial association of the various V–D–J and V–J genes would be sufficient to generate about 10^7 distinct antibody molecules if their combination were completely random, but this is apparently not entirely true. For example, careful analysis of the expressed repertoire indicated that some V genes are frequently expressed, whether some others are rarely used. This probably results from a selective event that takes place early in **B-cell** differentiation. It has been shown that the surrogate light chain, encoded by the l-like (14.1) and the VpreB genes, which associates with the m heavy chain in preB cells, does not combine equally with every heavy chain, so negative selection operates already at the preB stage of differentiation. This may be amplified upon selection of immature B cells before they leave the bone marrow.

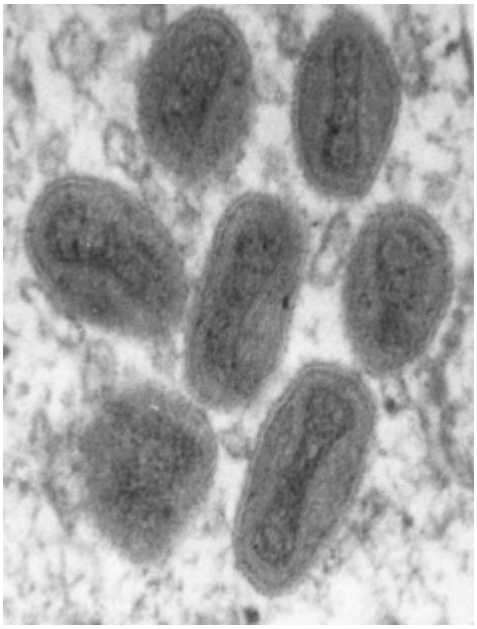
Vaccinia Virus

Vaccinia virus (VV) is a member of the genus *Orthopoxvirus* in the subfamily *Chordopoxvirinae* of the large family *Poxviridae*, comprising a group of complexed animal DNA **viruses**. VV is a "brick-shaped" particle 200 to 400 nm long, the external surface of which is ridged in parallel rows. The detailed structure of the particle is not known. Two kinds of particles are known: extracellular forms containing two membranes (EEVs—extracellular enveloped virions) and intracellular particles having only an inner membrane (IMVs—intracellular mature virions). The former is believed to be responsible for dissemination. Thin sections in electron microscopy reveal that the outer membrane surrounds the core, which is biconcave (dumbbell-shaped), with two lateral bodies (Fig. 1). The core is composed of a tightly compressed nucleoprotein that contains more than 10 enzymes, mostly concerned with transcription and genome replication.

Figure 1. Electron micrographs of thin-sectioned vaccinia virus particles. Magnification is ×96,000.



The genome is a linear, double-stranded DNA molecule of approximately 190 kbp. The ends of the genome consist of a terminal hairpin loop with several tandem repeat sequences. The ends of the genome form terminal inverted repeats (ITRs), identical but oppositely oriented sequences. The majority of the essential **genes** map in the central part of the genome, while the genes nonessential for replication in tissue culture are located at the ends. There are ~200 genes in the genome. Virus replication occurs in the cytoplasm, because the virus encodes almost all the functions necessary for genome replication.

The host nucleus contributes to the maturation step in forming virus particles. Receptors for the virus are not known. During penetration, uncoating occurs in two stages: (i) removal of the outer membrane and (ii) further uncoating to produce the naked core that passes into the cytoplasm.

Gene expression is temporarily regulated and divided into three phases: the early genes, intermediate genes, and late genes, each of which have their own characteristic **promoters**. The early genes comprise about half of the genome, are expressed before genome replication, and mainly encode enzymes involved in viral DNA replication and transcription factors for the intermediate genes.

Expression of the intermediate genes begins immediately after genome replication and produces late-gene transcription factors. The late genes encode major constituents of the virus particles, including early transcription factors, and are expressed after genome replication. Thus, the transcription factors synthesized in each phase govern the gene expression of the next phase.

Replication of the genome involves a self-priming mechanism, leading to the formation of large **concatemeric** branched structures, which are then resolved into unit genomes. Assembly of the progeny virions occurs in inclusions that are formed in the cytoplasm. During the maturation process, various modifications of the virion proteins occur, including **proteolytic** cleavage, acylation, and glycosylation.

IMV is transported on cables of actin and wrapped with the membranes comprising the **Golgi** cisternae. The virions move further through the cytoplasm to the cell surface and bud into environmental fluid to form EEV. VV produces many secretory proteins that resemble **cytokines** and their receptors, including interferon, **interleukin**-1, tumor necrosis factors, and a component of **complement**. These viral proteins probably compromise the host **immune system**, because mutant viruses lacking these genes have attenuated virulency, although they replicate in tissue culture as well as the wild-type virus.

VV is now used frequently as a live recombinant vector to express heterologous genes, which provides very useful tools for study of immunology and cell biology, as well as for development of novel vaccines.

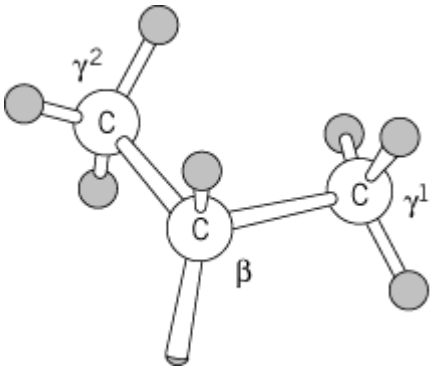
Valine (Val, V)

The amino acid valine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to four **codons**—GUU, GUC, GUA, and GUG—and represents approximately 6.6% of the residues in the proteins that have been characterized. The valyl residue incorporated has a mass of 99.14 Da, a **van der Waals volume** of 105 $Å^3$, and an accessible surface area of 160 $Å^2$. Val residues are changed moderately frequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with isoleucine, leucine, alanine, and threonine residues.

The Val side chain is nonpolar with no functional or reactive groups:



Consequently, Val is one of the most **hydrophobic** residues, and 54% of its residues are completely buried in native protein structures. Val is one of the residues least likely to adopt the **alpha-helical** conformation in model peptides, probably because its branched side chain is constrained to adopt only a limited number of conformations. In folded proteins, it occurs most frequently in beta-sheet type of **secondary structure**.

van der Waals Interactions

All gaseous atoms and molecules condense to liquid when cooled and then, on further cooling, to the solid state; the single exception is liquid helium. From this observation, we learn that even neutral atoms and molecules attract and repel each other at long and short distances, respectively. Repulsion at short distances gives finite volumes to solid materials. Not surprisingly, polar molecules attract each other, as they participate in attractive interactions, such as **hydrogen bonding** or dipole interactions, but so do perfectly spherical and nonpolar molecules, for which neither of the above could be expected. Such interactions became apparent from careful studies of the behavior of real gases. The molecules of an ideal gas occupy no volume and have no interactions, so n moles of an ideal gas obey the equation of state known as the Boyle–Gay-Lussac' law: $PV = nRT$, where P equals the pressure, V the volume, R the gas constant, and T the absolute temperature. The behavior of real gases, however, is better described by the equation of state given by J. D. van der Waals:

$$(P + n^2a/V^2)(V - nb) = nRT \qquad (1)$$

where the pressure and volume terms are modified. The parameters a and b account, respectively, for the attractive and repulsive intermolecular interactions of the molecules (1). The values of a and b determined experimentally for selected gases are given in Table 1. It should be noted that a and b have finite values for both polar and nonpolar atoms and molecules.

Table 1. Values of the Parameters *a* and *b* of the van der Waals Equation for Various Substances

Substance	*a*	*b*
H_2	0.248	0.0266
He	0.034	0.024
H_2O	5.52	0.0304
CO	1.47	0.0304
HCl	3.72	0.0408
CO_2	3.66	0.0428
Ar	1.36	0.0322
C_6H_6	18.9	0.120
Xe	4.17	0.0513
O_2	1.38	0.0317
N_2	1.37	0.0387

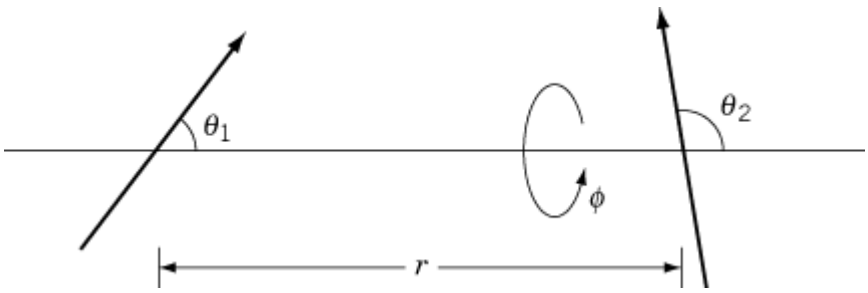
[a] The unit of *a* is (bar^{2}molar^{-2}) and of *b* (molar^{-1}). Taken from 1 with permission.

The attractive interaction between neutral atoms and molecules that is experimentally observed and quantified in the van der Waals equation of state is usually called the *van der Waals interaction* or *van der Waals force*. It is easy to understand that the value of *a* is large for polar molecules such as CO_2, H_2O, or HCl, where the gas molecules are characterized by finite permanent dipole moments. Two dipole moments m_A and m_B with a fixed orientation attract or repel each other when their orientation is antiparallel or parallel, respectively. In both cases, the interaction potential has an inverse 3rd power dependence on the distance between the two dipoles (Fig. 1). When this interaction potential is averaged, with respect to the Boltzmann distribution, over all possible orientations of the two dipoles, and if we assume that the potential is small compared to the thermal energy of *kT*, the average potential energy, as obtained by Keesom is (2)

$$U = -2\mu_A^2\mu_B^2/3(4\pi\varepsilon_0)^2kTr^6 \qquad (2)$$

where ε_0, *k*, and *T* are the dielectric constant of vacuum, the Boltzmann constant, and temperature, respectively.

Figure 1. Interaction between two molecules with permanent dipoles.



When one of the two does not have a permanent dipole, but has polarizability a, it will have an induced dipole in the neighborhood of another molecule with permanent dipole m. The interaction energy in this case is also dependent on the inverse 3rd power of the distance between the two molecules, and the thermally averaged potential between two molecules A and B was given by Debye (2) as

$$U = -(\alpha_B \mu_A^2 + \alpha_A \mu_B^2)/(4\pi\epsilon_0)^2 r^6 \quad (3)$$

It was difficult initially to explain the nonzero value of *a* for nonpolar atoms and molecules, such as Ar, Xe, N_2, or CH_4, until 1930, when the newly emerging quantum mechanics were successfully used to explain the interaction between two nonpolar particles. The results may be interpreted in classical terms as follows. The average centers of gravity for the positive and negative charges in a nonpolar atom coincide precisely, so it lacks a permanent dipole moment, but the instantaneous positions of the two centers do not match exactly. Consequently, nonpolar atom and molecules have an instantaneous dipole moment, whose magnitude and direction are constantly changing. When two such particles come into close proximity, the fluctuating dipoles influence each other, and their electron distributions fluctuate so as to produce an attractive interaction between them.

Such an attractive interaction between nonpolar atoms and molecules in the gaseous state is known as the dispersion force of London (3). A similar attractive interaction between such molecules occurs in the liquid state, where molecules are also in constant agitation and rotation, although the influence of the dense medium cannot be neglected. For example, the dispersion force between two nonpolar molecules dissolved in water is expected to be reduced by at least an order of magnitude compared to their interaction in a vacuum (4). The London dispersion interaction potential as described above has the following dependence on various electronic parameters of the interacting particles:

$$U_L = -\frac{3h\nu_0\alpha^2}{4(4\pi\epsilon_0)^2 r^6} = \frac{3I_A I_B}{2(I_A + I_B)} \frac{\alpha_A \alpha_B}{(4\pi\epsilon_0)^2 r^6} \quad (4)$$

where *h* is Planck's constant; n_0, is the transition frequency, I_A and I_B are the ionization potentials and a_A and a_B the polarizabilities of molecules *A* and *B*. In some textbooks, the term van der Waals interaction is reserved for the London dispersion interactions alone. In conclusion, thermally averaged potentials for all types of interactions, ie, dipole–dipole (Keesom), dipole-induced dipole (Debye), and dispersion interactions between two fluctuating dipoles (London), have inverse 6th power dependence on the distance between them.

The origin of repulsive interactions between closed-shell atoms and molecules is due to Pauli's exclusion principle, which states that two electrons are allowed to occupy the same orbital only if their spins occur in opposite directions. Since each of the electronic orbitals in closed-shell atoms and molecules is already occupied by such paired electrons, they repel other electronic systems that come close enough for their outermost electron clouds to overlap each other.

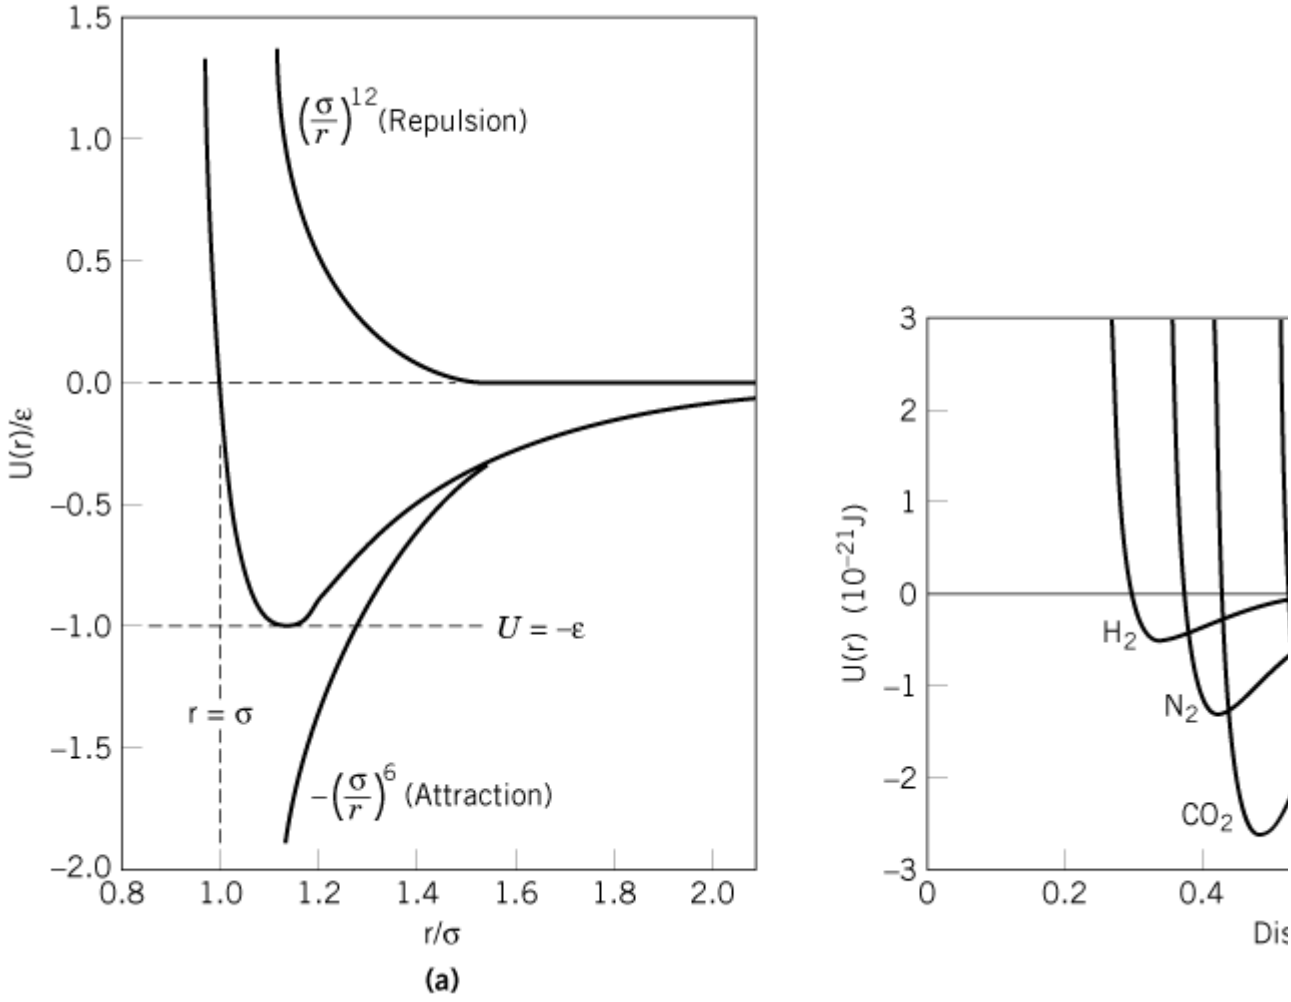
Lennard-Jones presented a concise form of the overall potential between two neutral molecules by expressing it with an equation having two adjustable parameters, ϵ and s:

$$\phi(r) = 4\epsilon \left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6} \right] \quad (5)$$

The parameters ϵ and s are, respectively, the dissociation energy and inter particle distance where the potential becomes zero, as depicted in Figure 2. The inverse 6th power dependence of attractive interaction becomes inverse 7th power at a large distance, approximately 100 nm, due to the so-

called “retardation effect” resulting from the two molecules exchanging electro-magnetic interactions at a finite speed, that of the speed of light. When the distance is large, this causes a more rapid decrease in the potential with distance. Further refinements of the potential taking into account the interactions involving quadrupole moments will give –8th and –10th power dependences on the distance.

Figure 2. The Lennard-Jones potential in terms of two parameters e and s as a function of intermolecular distance *r*. The the two terms e and s and breaks down the potential into the attractive and repulsive forces. The graph on the right gives gases. Taken from (1) with permission.



Although its origin from Pauli's exclusion principle is clear, the inverse 12th power dependence of the repulsive potential is not of exact physical derivation. It is sometimes represented by the exponential term $r \exp(-D_{12})$, which has a similar steepness against *r*. The potential function, when differentiated with respect to *r*, gives the force, and therefore the repulsive force has inverse 13th power dependence on distance, and the attractive force has the inverse 7th power. Where the potential is at a minimum, the force is zero.

The inverse 6th power dependence of van der Waals interaction potential on the distance between two point atoms or molecules decreases when applied to spheres of finite sizes and surfaces of infinite extension (Fig. 3).

1. van der Waals Interactions in Biochemistry and Molecular Biology

An example of the usefulness of the van der Waals potential in biochemistry and molecular biology may be found in computer-aided calculations to explain the behavior of biopolymers, including proteins and nucleic acids (see Molecular Dynamics). The majority of biologically important molecules are either ionic or polar molecules, and thus their interaction potentials are dominated by electrostatic interactions, but the van der Waals potential is involved in all kinds of interactions. The importance of van der Waals potential becomes more obvious in molecular model calculations and model building when the participating molecules are not explicitly charged.

2. van der Waals Radii

The meaning of the van der Waals radius is closely related to our intuitive notion of the size of atoms and molecules. In the van der Waals equation of state for real gases, the volume of gaseous particles was parameterized in the excluded volume *b*, which is expected to be equal to $4\times(4/3)\ \mathrm{pr}^3$, where *r* is the radius of the gas particle when it is approximated by a hard sphere. Experimentally, the value of *b* can be obtained from the measurement of the second virial coefficient. It can be determined more precisely from the radii of atoms and molecules in their closely packed crystals. If one defines such a radius for a single kind of atom in different kinds of molecules, a remarkably constant value can be obtained. The radius is then defined from the balance between the repulsive force due to Pauli's exclusion principle and the van der Waals force. It may thus be related to the parameter s in the Lennard-Jones potential, for when the distance between two particles is equal to this parameter, the potential is zero. When $r = 2^{1/6}$ s, the potential energy is at its minimum, and the distance

corresponds to the sum of the two van der Waals radii. The meaning is that when two particles come closer than their van der Waals radii, they repel each other. Table 2 summarizes the currently accepted values of the van der Waals radii for representative atoms and molecules, together with their covalent radii. The van der Waals radius is not a constant parameter for each element but depends on the neighboring atoms with which it is in contact.

Table 2. Table of Values of the van der Waals Radius (r_{vdw}) and Covalent Radius (r_{cov}) of Common Elements in Biochemistry

Elements	r_{vdw} (nm)	r_{cov} (nm)
H	0.120–0.145	0.037
He	0.180 (0.150)	0.030
Li	0.180	0.134
C	0.165–0.170	0.077
N	0.155	0.075
O	0.150	0.073
F	0.150–0.160 (0.135)	0.071
Na	0.230	0.154
Mg	0.170	0.145
P	0.185 (0.190)	0.110
S	0.180	0.120
Cl	0.170–0.190	0.099
K	0.280	0.196
I	0.195–0.212 (0.215)	
Organic groups		
CH_3	0.200	
C_6H_6	0.170 (perpendicular to the ring)[a]

van der Waals Surface, Volume

Every atom of a molecule can be regarded as a sphere of the appropriate van der Waals radius, which defines the normal limit of closest approach of other atoms in its environment. The spheres of atoms that are covalently bonded are normally truncated. The surface that results from all these spheres corresponding to all the atoms in a macromolecule is called the van der Waals surface.

The van der Waals volume of a molecule is defined as the space enclosed by the van der Waals spheres of the constituent atoms. The van der Waals volume and surface area of entire small molecules that are not structurally strained may be estimated by simply adding the values for the constituent atoms or chemical groups. In the case of folded, globular proteins, however, the van der Waals surface and volume are not very indicative of the actual surface and volume of the molecule (see Protein Structure). The interior of a protein molecule is densely packed, with adjacent atoms frequently in van der Waals contact. The average volumes occupied by residues in folded proteins are virtually the same as those they occupy in crystals of the amino acids (Table 1). These volumes are, of course, larger than the van der Waals volume of each amino acid residue.

The van der Waals surface of a folded protein is very complex; much of the surface is in the interior, surrounded by other atoms of the protein and inaccessible to the solvent. Although it has a strictly defined surface area and encloses a defined volume, no chemical procedure can measure this area and volume directly. For that reason, the surface that is generally considered most relevant is the accessible surface, which is defined as that surface that is normally in contact with the solvent.

The packing density of the interior of a macromolecule is defined as the ratio of the van der Waals volume to the volume actually occupied in a solvent. Thus, about 75% on average of the interior volume of a protein is filled with atoms. This is close to the maximum value of 74% possible with close packing of identical spheres and within the range of 70 to 78% found for crystals of small organic molecules (Table 1). This means that the interior of a protein is not an oil drop but resembles instead a molecular crystal. The packing is not necessarily uniform throughout the interior, however, because the atoms are covalently bonded, which exaggerates the close packing. Generally, the atoms in topologically regular parts, such as alpha-helix and beta-sheet, pack closely, whereas the active sites of enzymes are usually packed more loosely. There are small cavities in the packing defects, some of them being large enough to accommodate other molecules. Cavities form only a small percentage of the total volume, but they play an important role in structural flexibility (thermal fluctuation), which is believed to be necessary for most protein functions.

Table 1. Volumes of Amino Acid Residues

Residue	Van der Waals volume[a] (Å^3)	Residue crystal volume[a] (Å^3)	Average volume of buried residues[a] (Å^3)
Ala	67	96.6	91.5
Arg	148		202
Asn	96		135.2
Asp	91	122.0	124.5
Cys	86	108.7	105.6
Gln	114	148.0	161.1
Glu	109	143.9	155.1
Gly	48	66.5	66.4
His	118	166.3	167.3
Ile	124	169.7	168.8
Leu	124		167.9
Lys	135		171.3
Met	124	176.1	170.8
Phe	135		203.4
Pro	90	124.4	129.3
Ser	90	102.2	99.1
Thr	93	124.3	122.1
Trp	163		237.6
Tyr	141	201.7	203.6
Val	105	143.4	141.7

[a] Volume enclosed by van der Waals radii of atoms.

[b] Estimated by assuming 11.1Å^3 for the volume lost by an amino acid on becoming a residue.

[c] A residue is defined as buried if 5% or less of its potential accessible surface area is available to solvent contact (1).

Vapor Phase Crystallization

Crystallization of a **protein** for determination of its three-dimensional structures by X-ray crystallography requires the gradual development of a state of supersaturation of the protein in the medium that contains the crystallizing agent. One way of approaching that state is by vapor phase

equilibrium. This technique is based on the principle that when two solutions of different concentrations of the same nonvolatile solute are placed in a single sealed chamber, water molecules will be transported in the vapor phase from the solution of lower concentration (higher vapor pressure) to that of lower concentration until the vapor pressures (solute concentrations) of the two become identical.

This principle is used successfully in the crystallization of proteins. The crystallizing agent used most frequently is *polyethylene glycol* (PEG) of a molecular weight between 1,000 and 20,000. In this procedure, a droplet of the protein solution (10 to 20 μℓ) is deposited on a well-siliconized glass plate. This plate is inverted over a well containing 0.5 to 1.0 ml of the solvent at a considerably higher concentration (about twice) of the PEG, and the system is left to equilibrate at constant temperature. When the concentration of the crystallizing agent on the platelet has increased to that in the well by vapor phase transfer of water molecules, the droplet is examined under a microscope for crystal formation. A great advantage of this technique is the ability to examine simultaneously a large number of crystallizing agent concentrations. For example, a 24-well tissue culture tray may be used for the wells, each of which contains a different concentration or size of PEG and above each of which is suspended a droplet from a coverslip.

Variable Domain, Region

The variable (V) regions of immunoglobulins (Igs) are organized as two complementary **domains**, one VH and one VL (see Immunoglobulin Structure), each encoded by gene rearrangement of VH–D–JH and VL–JL genes, respectively (see Immunoglobulin Biosynthesis). VH and VL are associated noncovalently in the so-called Fv fragment that can be released by **proteolytic** digestion of the native immunoglobulin. Because of the symmetrical organization of the molecule, one antibody contains two identical Fv fragments, and each possesses one **antigen**-binding site. Physicochemical measurements have shown that the **dissociation constant** of the isolated Fv is very close, if not identical, to that of the corresponding antibody, indicating that the three-dimensional protein structure is well-conserved in the isolated fragment. This is in agreement with the domain hypothesis and is a consequence of the rigid structure of the globular organization of Ig domains, which defines the Ig superfamily.

The V domain architecture consists of nine antiparallel **b-strands**, labeled a, b, c, c′, c″, d, e, f, and g, that are organized in two **b-pleated sheets** anchored to each other by an intrachain disulfide bond. The structure of a V domain closely resembles that of a C domain, with the notable exception of the additional c′ and c″ b strands, which contribute an interacting H–L region in the antibody combining site. X-ray crystallography structures have demonstrated the complete correspondence between the sequence organization of V regions and the architecture of the combining site. Amino acid sequences of VH and VL regions allowed Kabat to identify within V regions three hypervariable segments, around positions 30, 60, and 90, separated by framework regions that ensure the structure of the domain. Hypervariable regions are designated CDR1, CDR2, and CDR3 (for complementarity determining regions) (see Immunoglobulin Structure). CDR1 and CDR2 are encoded entirely by V genes, whereas CDR3 have an increased diversity, especially in the heavy chains, because they are

located in the area encoded by the V–D–J joint (and V–J for the L chains). X-ray crystallography structures have clearly demonstrated that all six CDRs from both interacting chains contribute directly the residues involved in binding an antigen.

Fv fragments have retained the complete antibody binding sites, so they may be considered as "mini-antibodies" that might be convenient for therapeutic or laboratory use. This has stimulated their production by several approaches of protein engineering. Phage combinatorial libraries may be prepared with vectors containing complementary DNA encoding VH and VL regions; their combinatorial random association will result potentially in an enormous repertoire of Fv fragments. Alternatively, Fv with preformed specificity may also be constructed and expressed in a filamentous phage as a single chain, called scFv, by introduction of an artificial linker between the VH and the VL cDNAs. Such vectors may be amplified and produced by the classical technologies in phage, bacteria, or Baculovirus. One interesting potential usage is medical imaging to tag a given organ or tumor with a specific scFv bearing a radioactive reporter that may be detected by its radioactivity. Also, "humanized" scFv may be engineered by inserting the CDRs derived from hyperimmunized mice into the framework regions of human origin. Finally, random mutagenesis directed at the CDR sites may amplify the diversity of these new tools almost indefinitely, and all these approaches are being widely explored.

Vertical Gene Transfer

Vertical gene transfer is the mechanism by which a **gene** is transmitted from parents to offspring; this is the normal way to inherit a gene. This term was coined to make a clear distinction in evolution with horizontal gene transfer, which is a phenomenon where genes are transferred between different species, probably by the mediation of **viruses** or bacteria.

Vesicular Stomatitis Virus (VSV)

Vesicular stomatitis virus (VSV) is the prototype rhabdovirus and has been used for viral and

biochemical studies because it can be highly purified from infected cells in high yields. This animal pathogen is also frequently used in the laboratory as an efficient inducer of interferon. Like other rhabdovirus, such as rabies virus, the virion has a typical rod-shaped bullet-like morphology, and the VSV genome is a linear single-stranded RNA (11 kb) of negative polarity that serves as the template for both transcription and replication.

For all negative-strand RNA viruses, including rhabdoviruses, infection begins with the synthesis in the infected cells of the viral messenger RNA. VSV virions contain all the enzymes (the P and L proteins, see text below) required for the synthesis and processing of five mRNAs, and these virion-associated enzymes are inserted into the cell upon infection, together with the RNA genome; each transcript has a cap and is **polyadenylated** at its 3′ end. Like all other rhabdoviruses, the genomic organization of VSV starts with a small leader sequence at the extreme 3′ terminus of the linear single strand RNA and is followed by the template for mRNAs encoding the proteins N (nucleocapsid; 49 kDa), P (phosphoprotein; 29 kDa), M (matrix; 25 kDa), G (glycoprotein; 69 kDa), and then L (large; 241 kDa). Several lines of evidence, such as ultraviolet transcriptional mapping, indicated that the five genes are transcribed sequentially in the same order as they appear in the genome. All of these mRNA synthesis and post-transcriptional modifications can be studied *in vitro* using **detergent**-disrupted purified virions or purified ribonucleoprotein particles (RNPs). Even after many years of study both *in vivo* and *in vitro*, it is not yet fully understood how these five mRNAs can be generated discontinuously from a linear template, in spite of the fact that transcription is apparently sequential. It could be explained by **nuclease** processing of a single precursor RNA molecule or by sequential reinitiation by transcriptase at the 5′ end of each mRNA. At the intergenic junctions, polyadenylation and capping should be tightly coupled to VSV RNA synthesis.

The primary transcription causes the accumulation of viral proteins in the infected cells and leads to the onset of genome replication. The **RNA polymerase** switches mode to produce the positive-strand genome-length RNA, which also involves the newly synthesized N-protein, to form the positive-strand RNP. These positive-strand RNPs function as the template for the production of the negative-strand RNPs, which accumulate in the cell and contribute to the synthesis of positive-strand RNPs (secondary transcription). This in turn induces high-level expression of viral proteins in the later stages of infection.

The accumulated negative-strand RNP also serves as the genome of progeny virion, which are assembled at the plasma membrane of the infected cell. When the virions are released from the cells by budding, they have acquired lipid envelops. Spike-like projections, composed of trimers of G protein, emanate from the envelop, while the M protein lines the inner surface of the envelope or associates with the RNP. So all five viral proteins are found associated with the purified virion. Upon infection, VSV-G protein binds to a cellular receptor, which is known to include such widely present anionic phospholipids as phosphatidylserine, while some protein components might also be necessary for full efficiency. These properties of the G protein partly explain why VSV has a very broad host range; this rhabdovirus not only replicates in several vertebrates, but also can infect insects. The G protein can be also used for the envelope proteins of other distantly related viruses, such as retrovirus and lentivirus, a phenomenon known as phenotypic mixing. For these reasons, several retroviruses having VSV-G instead of their own envelope protein have been developed for use as stable and high-titer retrovirus vectors with a broad host range.

VSV-G has been also well-studied from the standpoint of **protein targeting** in the cell. When expressed in polarized epithelial cells, VSV-G locates exclusively at the basolateral plasma membrane domain, rather than the apical surface of the same cell. In such a polarized cell, morphogenesis and budding of VSV-G particles occurs specifically in the basolateral plasma membrane.

Vibrational Spectroscopy

1. Infrared, Raman, and Resonance Raman Spectroscopies

The vibrations of molecules provide an avenue to their identification and to the characterization of their structure and environment (see Spectroscopy). The stretching and bending of bonds occur with characteristic frequencies (energies), depending on force constants and the masses of the connected atoms (1). These frequencies occur in the *infrared* (IR) region of the electromagnetic spectrum, and the vibrations can be detected via absorption of infrared light. The infrared spectrum contains a series of peaks, or bands, whose frequencies are characteristic of the molecule under study. The spectrum is a fingerprint and can be used for identification and quantification. In addition, variations in the band positions and intensities provide information about changes in bonding and conformation that may result from intermolecular interactions.

The same vibrations can be accessed with Raman spectroscopy, a laser light scattering technique. Most of the laser photons scattering from a sample emerge with unshifted energy (Rayleigh scattering), but a few photons excite vibrations in the molecules and emerge with diminished energy (*Raman scattering*). The shifts in frequency (from the loss of energy) are the same as the infrared frequencies, and the Raman spectrum contains vibrational bands, as does the infrared spectrum. However, the intensities differ in the two spectroscopies: infrared intensity depends on the change in *dipole moment* produced by a vibration, whereas Raman intensity depends on the change in the *polarizability* . Thus, the two techniques provide complementary information.

Raman spectroscopy is advantageous for studies in aqueous solution, because water is a poor Raman scatterer but a strong IR absorber. Also, Raman spectroscopy requires less sample, because the scattering volume of the laser is only microliters, whereas IR spectroscopy requires ~1cm diameter disk of material. However, the use of condensing optics in an IR microscope can overcome this limitation (2, 3). The main obstacle to Raman spectroscopy is interference from **fluorescence**. Because a very small fraction of the laser photons appear at the Raman frequencies, not a great deal of laser-induced fluorescence (whether intrinsic to the molecule under study or from impurities) is necessary to swamp the Raman spectrum. One way to overcome this difficulty is to shift the laser wavelength either into the ultraviolet region (4), as most fluorescence occurs in the visible region, or into the far red region, where excitation of fluorescent species is avoided (5).

Both IR and Raman spectroscopy suffer from low sensitivity and selectivity. Molecular concentrations must be quite high (>0.1M), and spectral crowding is severe for complex molecules because there are 3N-6 modes of vibration (*N* being the number of atoms). This problem can be overcome by difference spectroscopy, in which subtle changes can be detected by careful subtraction of most of the vibrational spectrum. The advent of Fourier transform (FT) techniques (FTIR and FT-Raman) has made highly accurate subtractions possible, and sensitivity at the single residue level in proteins has been demonstrated (6).

Resonance Raman (RR) spectroscopy provides a powerful way to increase sensitivity and selectivity (7-9). When the laser frequency approaches that of an electronic transition of the molecule, a large increase in scattering power is observed, but this occurs only for those vibrations that carry the molecule into its excited state geometry. Thus, RR scattering is selective for the chromophoric region of the molecule and can be detected at quite low concentrations. It provides a structure probe for active sites of biomolecules, if their electronic transitions can be accessed by available lasers. Information about nonresonant parts of the molecule, however, are lost. The technique has been

particularly useful in the study of colored cofactors. The advent of reliable ultraviolet lasers has also made it possible to probe nucleic acid bases (10-13), protein aromatic side-chains (14-17), and even the peptide bond (18-20), using RR spectroscopy.

2. Proteins

2.1. Backbone Vibrations; Amide Bond

The protein backbone has several characteristic vibrations, labeled amide I, II, III, IV, V, VI, VII, A, and B and found at about 1650, 1540, 1300, 650, 725, 300, and 3280, 3090 cm^{-1}, respectively (21-23). Because all peptide bonds (OC-NH) are chemically the same, their vibrations overlap in the spectrum. However, the elements of their **secondary structure** (eg, a-**helix**, b- **sheet**, turns) have sufficiently different geometries and interpeptide interactions that their frequencies can be resolved in favorable cases, especially for the amide I and III bands (Table 1). These can be used to evaluate the secondary structure from IR or Raman spectra (21-26).

Table 1. The Infrared and Raman Frequencies (in cm^{-1}) of the Amide I and III Bands for Various Peptide Secondary Structures

	Amide I		Amide III
Conformation	**Infrared (cm^{-1})**	**Raman (cm^{-1})**	**Raman (cm^{-1})**
a-helix	1650	1645–1660	1265–1300
b-sheet	1632	1665–1680	1230–1240
b-turn	—	1660–1680	1260–1300
Unordered	1658	1660–1670	1240–1260

The amide II and III bands are strongly enhanced in RR spectra when the laser wavelength approaches the strong amide p-p* transition at ~190nm (18-20). An additional band, at ~1390cm^{-1}, is also enhanced, the intensity of which is sensitive to secondary structure. This mode involves bending of the C_a-H bond and is suppressed in a-helices because of kinematic effects (20).

The X-Pro peptide bond preceding a proline residue differs from other peptide bonds because it lacks the N-H bond, an important contributor to the amide II and III modes (21-23, 27, 28). Its amide II frequency is much lower than others (~1470cm^{-1}). In addition, its p-p* transition is red-shifted, giving it stronger resonance enhancement at wavelengths greater than 200 nm (28). Consequently, the X-Pro bond can be detected in ultraviolet resonance Raman (UVRR) spectra, even for a single proline residue. Its frequency is insensitive to ***cis/trans*** **isomerization**, but it does reflect the hydrogen bond status of the X-Pro carbonyl (29, 30).

2.2. Amino Acid Side-Chains

The diversity of amino acids makes it difficult to disentangle side-chain vibrations. However, the aromatic residues—phenylalanine (Phe), tyrosine (Tyr), and tryptophan (Trp), including histidine (His)—have characteristic ring vibrations that sometimes can be distinguished in IR and Raman spectra. In addition, the p-p* transitions provide enhancement in UVRR spectra (17), although the transition for histidine is weak (16, 31-33). Except for Phe, the aromatic side-chains have hydrogen bond sites, and the vibrational frequencies and intensity patterns are sensitive to environment. Some

mode frequencies are listed in Table 2.

Table 2. Selected Vibrational Frequencies of Aromatic Amino Acids[a]

Observed Frequency (cm^{-1})	Assignment
	Phenylalanine
1606	F8a: ring C-C stretch
1586	F8b: asymmetric ring C-C stretch

2.2.1. Tyrosine

Several ring modes show sensitivity to hydrogen bonding. These include n_{7a}, $n_{7a'}$;, n_{8a}, n_{8b}, and n_{9a} (34, 35) and also the 830 / 850 cm^{-1} doublet band, which arises from a Fermi resonance between the ring-breathing vibration, n_1, and an overtone of an out-of-plane ring bending vibration, n_{16a} (36). This doublet has been much studied because it is well separated from other bands and is easily distinguishable, even in off-resonance Raman spectra. The intensity ratio of the two components (I_{850}:I_{830}) is an environmental indicator, being low for a buried Tyr side-chain and high for a solvent-exposed one (26, 37). In UVRR spectra, the strongly enhanced n_{8b} is particularly useful because its frequency has been calibrated as a measure of hydrogen bond strength (38, 39).

2.2.2. Tryptophan

Like Tyr, Trp has an environmentally sensitive doublet band, at 1360 / 1340 cm^{-1}; the intensity ratio is high for buried Trp side-chains and low for solvent-exposed ones (33, 40). The frequencies of the W17, W6, W4, and W2 modes are also environmentally sensitive and have been found in model compounds to correlate well with hydrogen bonding (41-43). W17 should be particularly useful because it is enhanced in UVRR spectra, but some doubt exists about the applicability of the model data to proteins. W17's frequency has been found not to change when cytochrome c is denatured, even though the single Trp residue is strongly hydrogen-bonded to a heme propionate substituent in the native state (44). W17's frequency is sensitive to deuterium/hydrogen exchange because it is partially composed of N-H bending. W17 can therefore be used as a monitor of exchange rate (45).

Another useful marker is W3, whose frequency depends on the dihedral angle of the bond connecting the indole ring to the C_b; atom (41). This dependence was very useful in distinguishing the W3 modes of the three Trp residues (per dimer unit) in the UVRR spectrum of hemoglobin and thereby in discriminating between **tertiary** and **quaternary** interactions (35).

2.2.3. Histidine

Like Trp, His has a band, n(C_4 = C_5), whose frequency (1575–1600cm^{-1}) is sensitive to the dihedral angle of the bond connecting the ring to the C_b; atom (46). In addition, a marker of its ionization state (1408cm^{-1}) has been reported in D_2O (47).

2.2.4. Cysteine (Cys)

The S-H stretching vibration (~2575cm^{-1}) is a useful marker for cysteine hydrogen bonding, because, although its intrinsic IR or Raman intensity is low, it is in an isolated region of the vibrational spectrum that has a low background (48).

2.2.5. Cystine

The disulfide bond S-S stretch is readily detected in off-resonance Raman spectra, and its frequency is diagnostic for the disulfide conformation: ~505cm^{-1} for the *gauche-gauche-gauche* conformation, ~525cm^{-1} for *gauche-gauche-trans*, and ~550cm^{-1} for *trans-gauche-trans* (49, 50).

2.3. Protein-Bound Chromophores

2.3.1. Polyenes

Carotenoids give rise to strong RR scattering (51, 52). The retinal chromophore has been studied extensively in rhodopsin and bacteriorhodopsin by RR spectroscopy (52, 53), which has provided structural details of their photocycles.

2.3.2. Tetrapyrrole Cofactors

Heme proteins provide rich RR spectra of the heme group that are sensitive to protein-induced distortions (54), and to the oxidation, ligation, and spin states of the central Fe ion (55). The status of heme-bound CO, NO, and O_2 (56) can be assessed through detection of their vibrations, as can the strength of the bond from Fe^{2+} to the proximal histidine ligand (57). RR spectroscopy has also been applied to reduced tetrapyrrole chromophores, including chlorins, chlorophylls, bacteriochlorophylls (58), isobacteriochlorins (59), corrins (60), and biliverdin (61).

2.3.3. Other Aromatic Chromophores

RR studies have been reported for **flavin** (62), folate (63), molybdopterin (64), pyrroloquinolinequinone (65), **pyridoxal** (66), nicotinamide (67), and **nucleotide** chromophores (68), as well as for tyrosyl radicals (69).

2.3.4. Metal Ions

Vibrations of metal-bound ligands can be enhanced in RR spectra excited in ligand-metal charge-transfer absorptions. Studies have been reported for iron-sulfur (70), iron-tyrosinate (71), copper-cysteinate (72), and molybdenum-dithiolene (64) proteins.

2.4. Protein Complexes

Protein complexes have been studied by various sensitive difference techniques and artificial labeling. Specific examples include antibody /antigen, hapten/antibody, **coenzyme**/enzyme, **ligand**/hemeprotein, drug/enzyme, enzyme/ substrate, protein/ membrane, and protein/nucleic acid interactions (52, 73-75).

3. Nucleic Acids

3.1. Backbone Vibrations

The vibrations of the sugar-phosphate backbone are sensitive to conformation. Bands that are diagnostic (Table 3) for secondary structure (A-form, B-form, etc) include the symmetric stretching of the P-O bonds connecting to the sugar rings (~800cm^{-1}) and the symmetric and antisymmetric stretching modes of the terminal P-O bonds (~1090 and ~1225cm^{-1}) (76, 77).

Table 3. Conformationally Sensitive Nucleic Acid Vibrations (in cm^{-1})[a]

[a] Adapted from W. L. Peticolas and E. Evertsz (76).

3.2. Base Vibrations

The purine and pyrimidine bases give rise to many ring vibrations (Table 4), leading to complicated IR and Raman spectra. RR enhancement in the UV absorption bands can be used to discriminate between the different bases, as the excitation profiles differ (13, 78). Base stacking in duplex and triplex structures diminishes RR intensities as it does the absorptivity; RR hypochromism (79-81) can be monitored in a base-selective manner. Frequencies of the purine and pyrimidine ring bending modes at ~670cm^{-1} and ~770cm^{-1} are sensitive to the conformation of the sugar ring (76, 82, 83). The carbonyl stretching vibrations (~1650cm^{-1}) are sensitive to hydrogen bonding and dipole coupling effects in the base pairs (83, 84). Secondary structure-sensitive base vibrations are also given in Table 3.

Table 4. The Vibrations of the Nucleotides[a]

Observed Frequency (cm^{-1})	Assignment
	Adenine (dAMP)
1649	C5C6 (48), dNH2 (20)

3.3. Nucleic Acid Complexes

Nucleic acid complexes have also been studied by various difference techniques and artificial labeling. Specific examples include complexes with anticancer drugs, antibiotics, histones, and capsid proteins, DNA/gene regulatory proteins, DNA/RNA hybrids, and 3- and 4-stranded nucleic acids (85-87).

4. Lipids

These molecules do not absorb at accessible laser wavelengths and provide no opportunity for RR enhancement, but because the local molecular concentration is high in membranes, IR and Raman spectra can be obtained for liposomes, planar bilayers, and membranes using surface-sensitive techniques ((88-91). Lipid vibrational frequencies are given in Table 5. Particularly useful are the C-C vibrations of the hydrocarbon tails, which give rise to bands at ~1065 and ~1130cm^{-1} for the all *trans* conformation and at ~1100cm^{-1} for the *gauche* conformation. The relative intensities of these bands provide a measure of lipid ordering (93-95).

Table 5. Vibrational Modes of Lipids and Phospholipids[a]

Observed Frequency (cm^{-1})	Assignment
218 / 224	Longitudinal acoustical mode
710-720	C-N sym. stretch
725	O-P-O sym. stretch
860-890	C-C stretch involving acyl carbon
870-875	C-N stretching
960-1130	C-C stretching
967	CH deformation
1065	C-C stretch (all *trans*)
1070-1075	C-O stretching
1095-1105	O-P-O stretching
1100	C-C stretch (*gauche*)
1130	C-C stretch (all *trans*)
1230	PO^{-}_{2} stretching
1200-1470	CH / CH_2 / CH_3 deformations
1650-1666	CC (*cis*)
1670-1680	C=C (*trans*)
1730	C-O stretching (ester)
1732	CO stretching
2800-3000	C-H stretching

[a] Adapted from A. T. Tu (92).

The degree of unsaturation can be determined from the ratio of the intensities of the ~1303cm^{-1} methylene and ~1265cm^{-1} methine bending vibrations, whereas the position of the C=C stretch is diagnostic for the geometric isomer: 1675cm^{-1} for *trans* and 1660cm^{-1} for *cis* (96). The C-H stretches (between 2800 and 3000cm^{-1}) are sensitive to the lateral packing density of the chains. The ratio of the intensities of the two methylene vibrations at ~2880 and ~2850cm^{-1} is 1 in the crystalline state and decreases as the density decreases (97). Finally, the C-N vibration at ~715cm^{-1} is sensitive to the O–C–C–N^{+} conformation of the head group (98).

5. Carbohydrates

As is the case with lipids, these molecules are unsuitable for RR spectroscopy; however, at high concentrations they provide rich IR and Raman spectra (99) (Table 6). Of particular use in probing structural details of these molecules are the ring vibrations at about 920 and 770cm^{-1} and a C-H bending vibration at about 865cm^{-1}. These modes are sensitive to the a and b conformers of the sugar ring (73, 100, 101). The most sensitive of the three is the C-H bending vibration found at ~840cm^{-1} in the a conformer and at ~890cm^{-1} for the b conformer.

Table 6. Vibrational Frequencies of a-D-Glucose[a]

Frequency (cm^{-1})	Assignment
3200-3400	O-H stretching
2800-3000	C-H stretching
1462	CH_2 bend
1442-1360	CH bend +OH bend
1345-1350	COH bend
1335-1340	CH_2
1328	CH_3
1298	
1270-1280	C(6)OH +C (1)OH
1250	C(1)H bend
1220-1225	CH_2
1205	
1150	CO, CC stretch +CH, COH bend
1130	
1115	
1070-1076	C(1)H, COH bend
1040-1055	C(1)H bend
1020-1026	COH bend
1000-1010	CH_3

913	C(1)H +COH bend
890-900	CH
860	C(2)OH
720	CC, CO stretch
380-600	Skeletal vibrations
100-365	Torsional vibrations

6. In vivo Studies

Raman and IR microspectroscopy can provide spatial resolution on the order of 1 μm^3 and have been applied to the study of biological cells and organelles. Examples include bacteria, algae, and cells from plants, blood, sperm, tumors, and photoreceptors (102).

7. Time Resolution: Dynamics

Vibrational spectroscopy can be applied in a time-resolved mode to monitor the evolution of molecular structure following rapid mixing, temperature-jump, or photoexcitation. Examples include enzyme-substrate interactions (103); protein folding (104); the photocycles of bacteriorhodopsin (105) and of bacterial reaction centers (106) ligand photodissociation and re-binding in myoglobin (107) and cytochrome oxidase (108); and the **allosteric** transition in hemoglobin (109).

8. Other Vibrational Techniques

8.1. Chiroptical Techniques

Vibrational circular dichroism (VCD) (110) and Raman optical activity (ROA) (111) spectroscopies afford exquisite sensitivity to stereochemistry. The measurements, which involve the small intensity differences for left- and right-circularly polarized light, are technically demanding, but recent improvements in instrumentation offer considerable promise.

8.2. Surface Enhanced Raman Spectroscopy (SERS)

Very large enhancements are observed for Raman signals of molecules adsorbed on small metal particles, (especially silver and gold) through electromagnetic coupling of the vibrations to collective oscillations of the metallic electrons (*surface plasmons*) (112). Extremely high sensitivities can be achieved, but the preparation of reproducible surfaces has been problematic, although promising new techniques have been developed (113-115).

8.3. Non-linear Optical Techniques

Vibrational spectra can be produced by monitoring the intensities of multiple overlapping laser beams, which can interact through higher-order polarizabilities of the molecule. A variety of configurations are possible, including coherent anti-Stokes Raman spectroscopy (CARS) (116), Raman gain spectroscopy (117), and sum-frequency generation spectroscopy (118). They offer a number of advantages, including fluorescence rejection and sensitivity to molecular environment, but they are technically demanding.

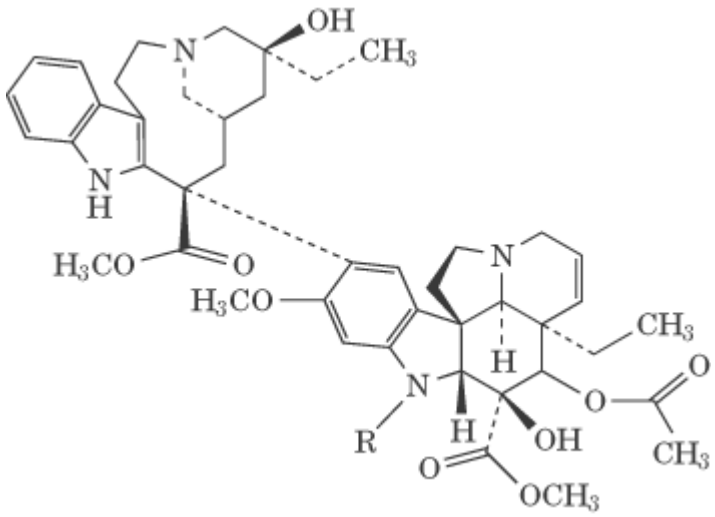
Vinblastine

Vinblastine and its analogue vincristine (Fig. 1), known as "vinca alkaloids," are natural products obtained from the ornamental flowering plant *Catharanthus roseus*. They were discovered to be potent antimitotic agents in 1959–1960 and since then have become effective chemotherapeutic drugs for treating a number of leukemias and lymphomas, both singly and in combination with other anticancer drugs. Several new vinca alkaloids, including vindesine and vinorelbine, have been introduced into the clinic recently and have shown broad antitumor activity. The vinca alkaloids, and especially vinblastine, have also become important tools in molecular and cell biology for studying the roles of microtubules and their dynamics in cellular processes. The value of vinblastine as a molecular tool derives from its ability to inhibit microtubule polymerization and, at very low concentrations, to kinetically stabilize microtubule dynamics.

Figure 1. Structures of vinblastine (R = CH_3) and vincristine (R = CHO).



1. Vinblastine Binding to Tubulin and Microtubules

Vinblastine binds to tubulin rapidly, reversibly, and independently of temperature between 0°C and 37°C. Vinblastine binding to tubulin induces an unusual conformational change in tubulin that is associated with tubulin self-association (1); this phenomenon appears to be responsible for the vinblastine-tubulin paracrystal formation in cells and *in vitro* that occurs at high vinblastine concentrations (≥10 μM) (see Ref. 2). The vinblastine-induced increase in the affinity of tubulin for itself also appears to play a critical role in the ability of vinblastine to bind strongly to microtubule ends and to stabilize microtubule dynamics (see text below).

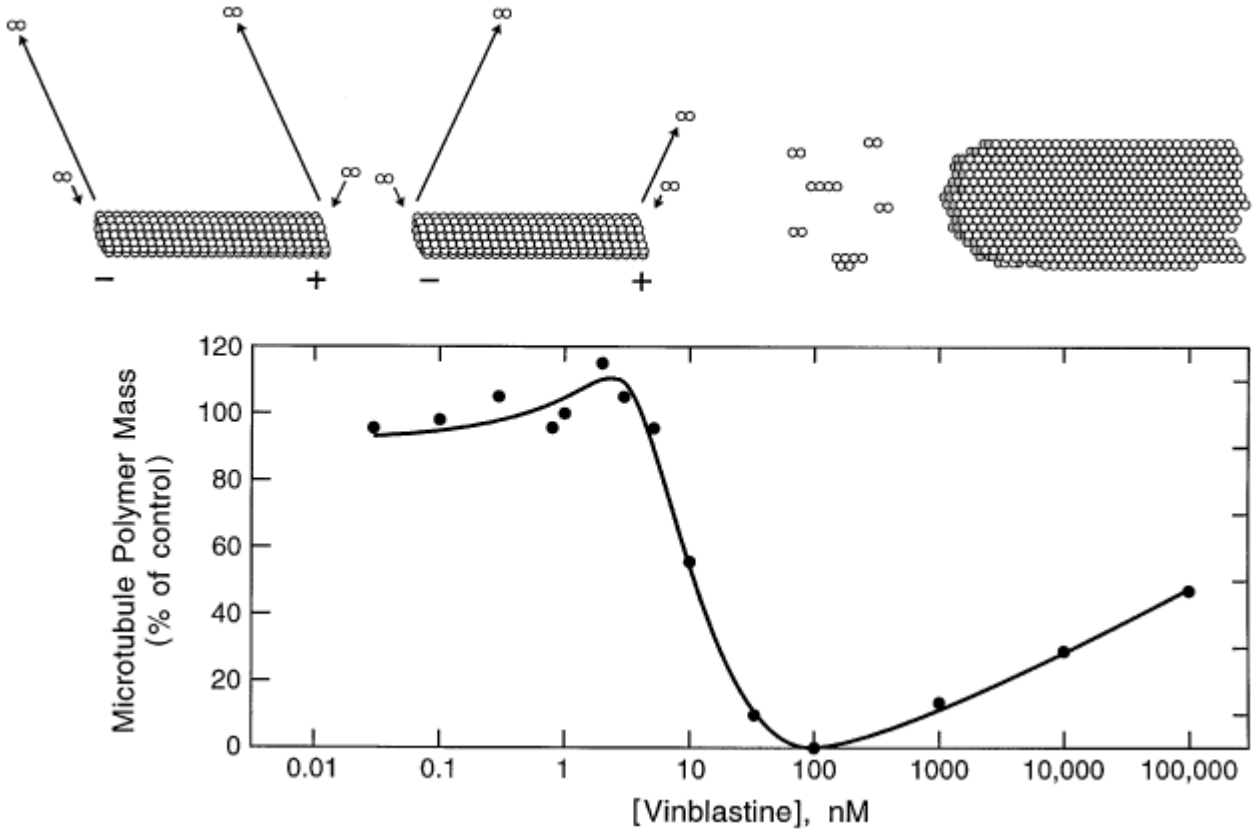
In contrast to the antimitotic drug colchicine, vinblastine can bind directly to microtubules without first forming a complex with soluble tubulin (3). Vinblastine binds to microtubule ends with relatively high affinity (K_d of 1 to 2 μM), and it binds with low affinity (K_d of 0.25 to 0.3 mM) to multiple tubulin sites located along the sides of the microtubule cylinder. There are only 16 to 17

high-affinity binding sites per microtubule end, and the binding of vinblastine to these few sites is responsible for the powerful suppression of tubulin exchange at the ends (described below). The binding of the vinca alkaloids to the low-affinity tubulin binding sites along the microtubule surface is responsible for the ability of relatively high vinca alkaloid concentrations to depolymerize microtubules and to induce tubulin paracrystal formation in cells.

2. Effects of Different Vinblastine Concentrations on the Mass, Dynamics, and Organization of Microtubules in Cells

The effects of vinblastine on tubulin and microtubule organization *in vitro* and in cells are strongly concentration-dependent. The cartoon diagrams in Figure 2 (top) show the effects of vinblastine (10 pM to 100 µM) on dynamic instability and organization of the tubulin polymers in cells (see Refs. (4-6)). Figure 2 (bottom) shows the effects of vinblastine on the mass of tubulin polymer in HeLa Cells. In the absence of vinblastine, microtubules undergo dynamic instability, episodes of rapid shortening and slow growing at both microtubule ends (top, left-hand microtubule; the rates are arbitrarily represented by the lengths of the arrows; see Microtubules). Low nanomolar concentrations of vinblastine suppress dynamic instability preferentially at plus ends, without changing the microtubule polymer mass (top, right-hand microtubule). The growing and shortening rates at the plus ends are depicted as being reduced by 50% (shortened arrows), whereas the minus-end rates are unchanged.

Figure 2. Effects of vinblastine (10 pM to 100 mM) on microtubules and tubulin. The cartoon drawings (top) show the effects of vinblastine on the organization and dynamics of microtubules and tubulin. The graph (below) shows the effects of vinblastine on the mass of polymerized tubulin. See text for explanation.



Intermediate (low micromolar) vinblastine concentrations depolymerize the microtubules. Vinblastine induces self-association of tubulin; thus both tubulin dimers and small oligomers are

represented at intermediate concentrations [free dimers and small oligomers; Fig. 2 (top); 10 nM to 1000 nM]. High concentrations of vinblastine (≥10,000nM) induce aggregation of tubulin into large paracrystalline arrays (top, far right). Figure 2, (bottom) depicts the polymer mass as a function of vinblastine concentration as occurs in HeLa cells. Low vinblastine concentrations (<1to5nM) do not affect microtubule polymer mass. Intermediate vinblastine concentrations reduce polymer mass in association with increased soluble tubulin and small oligomers, and very high vinblastine concentrations increase polymer mass in association with formation of large tubulin aggregates (paracrystalline arrays).

3. Kinetic Suppression of Microtubule Dynamics

Microtubules exhibit two kinds of nonequilibrium dynamics that are important for their functions in cells, treadmilling and dynamic instability (see Microtubules). Recent studies have revealed that vinblastine and many other compounds that depolymerize microtubules (see Colchicine) strongly suppress these dynamics at relatively low concentrations in the absence of appreciable microtubule depolymerization. Vinblastine was found some years ago to inhibit treadmilling *in vitro* and the rate of microtubule disassembly upon dilution of the microtubules (called *kinetic capping*; see Ref. 7). However, its stabilizing effects on dynamics were only fully appreciated with the introduction of differential-interference contrast video microscopy, which enabled one to visualize in real time the stabilizing action of the drug on the growing and shortening dynamics of individual microtubules. Small numbers of vinblastine molecules bound to bovine brain microtubules *in vitro* strongly stabilized microtubule plus ends by suppressing the rate and extent of growing and shortening, decreasing the catastrophe frequency, increasing the rescue frequency, and increasing the percentage of time that the microtubule spent in a state of pause or attenuated (undetectable) dynamic instability (Table 1) (5). In contrast, vinblastine destabilized microtubule minus ends. Vinblastine suppresses plus-end microtubule dynamics in living cells in a similar manner. For example, in BS-C-1 monkey kidney cells, 32 nM vinblastine suppressed the rate of microtubule shortening by 67%, the rate of growing by 20%, and the catastrophe frequency by 67%, and it increased the percentage of time in pause or attenuation by 64% (6) (Table 1). Mitosis was strongly reduced at this vinblastine concentration, and no net microtubule depolymerization accompanied suppression of dynamics. Suppression of mitotic spindle microtubule dynamics appears to be one of the key actions of the vinca alkaloids that result in mitotic block at the metaphase–anaphase transition.

Table 1. Comparison of Effects of Vinblastine on the Dynamic Instability Parameters of Microtubules in BS-C-1 Cells and Microtubules Assembled from Purified Bovine Brain Tubulin *in Vitro*[a]

Parameter	Control Microtubules in Cells	Microtubules in Cells, 32 nM Vinblastine (%)	Control Microtubules *in Vitro*	Microtubules *in Vitro*, 0.2 μM Vinblastine (%)
Rate of growing	6.9±3.9 μm/min	–20	1.0±0.1 μm/min	–52
Rate of shortening	15.5±10.6 μm/min	–67	14.4±1.2 μm/min	–56
Growing length[a]	1.8±1.6 μm	–50	2.3±0.2 μm	–61
Shortening length[a]	2.4±2.4 μm	–71	5.8±0.7 μm	–75

Time in pause, %	36	+64	7.7	+40
Catastrophe frequency	0.03±0.01/sec	–67	0.005±0.001/sec	–45
Rescue frequency	0.07±0.01/sec	No change	0.013±0.005/sec	+107
Dynamicity[a]	7.2±1.2 µm/min	–75	2.28 µm/min	–82

[a] Data in columns 2 and 3 are from R. Dhamodharan, M. A. Jordan, D. Thrower, L. Wilson, and P. Wadsworth, *Mol. Biol. Cell* **6**, 1215–1229, 1995; data from columns 4 and 5 are from D. Panda, M. A. Jordan, K. C. Chin, and L. Wilson, *J. Biol. Chem.* **271**, 29807–29812, 1996; table is from M. A. Jordan and L. Wilson. The use of drugs to study the role of microtubule assembly dynamics in living cells, *Methods in Enzymology*, **298**, 252–276, 1998.

[b] *Growing length* is the mean microtubule length added during a growing event, *shortening length* is the mean microtubule length lost during a shortening event; *dynamicity* is the total microscopically measurable gain and loss of tubulin subunits at microtubule ends over time; it is a measure of overall dynamic instability.

4. Inhibition of Mitosis by Vinblastine

One of the many microtubule-dependent processes affected by vinblastine is mitosis. Vinblastine totally blocks or slows mitosis in many eukaryotic cells. At high vinblastine concentrations (eg, >10nM in HeLa cells, >300nM in BS-C1 cells), mitotic block is accompanied by, and most likely results from, microtubule depolymerization. Mitotic spindles do not form. Chromosomescondense normally, but in the absence of microtubules they cannot move. The chromosomes ultimately separate along their lengths but remain attached at the centromeres (8). Mitotic block in some cells can last for more than 50 h and may result in return to interphase in the absence of anaphase or cytokinesis, accompanied by chromatin decondensation and reformation of multiple nuclei or multilobed nuclei (see Ref. 8).

At low vinblastine concentrations (<10nM in HeLa cells, <300nM in BSC-1 kidney cells), mitotic block occurs specifically at the transition from prometaphase/metaphase to anaphase. The block occurs in the presence of a full complement of spindle microtubules, and strong evidence indicates that blockage of mitotic progression at low vinblastine concentrations is due to perturbation of spindle microtubule dynamics ((4); see also Suggestions for Additional Reading). Low concentrations of vinblastine also inhibit the normal tension-associated fluctuations in separation between sister kinetochores (9), suggesting that microtubule dynamics are required to produce spindle tension.

Low concentrations of vinblastine induce several structural alterations in mitotic spindles in association with mitotic block. Although bipolar spindles form and most chromosomes become attached at both kinetochores and are moved to the metaphase plate, a few to many chromosomes (depending upon the vinblastine concentration), remain near the spindle poles. This most likely occurs because these chromosomes become attached to the spindle at only one kinetochore because of the reduced dynamics. Long-term (20 h) incubation also induces formation of abnormal centrioles, accumulation of membranous vesicles in the centrosome, separation of mother and daughter centrioles by large distances, and a decrease in the number of microtubules attached to kinetochores of congressed chromosomes (10). The significance of these effects on centrosome organization is unknown.

Viroids

Viroids were discovered in the early 1970s as a result of studies aimed at identifying and characterizing the agents of some **plant** diseases that were originally thought to be **viruses**. Viroids are the only well-defined class of subviral pathogens capable of autonomous **replication** (1). The 28 known viroid species (Table 1) indicate that they are single-stranded, circular **RNA** molecules of between 246 and 401 bases. Such a genome is only about one-tenth the size of that of the smallest known RNA virus. Their other most striking feature is that they are naked RNA molecules; all the available evidence indicates that, in contrast to viruses, viroids do not code for any protein. Consequently, viroids are the lowest known step of the biological scale.

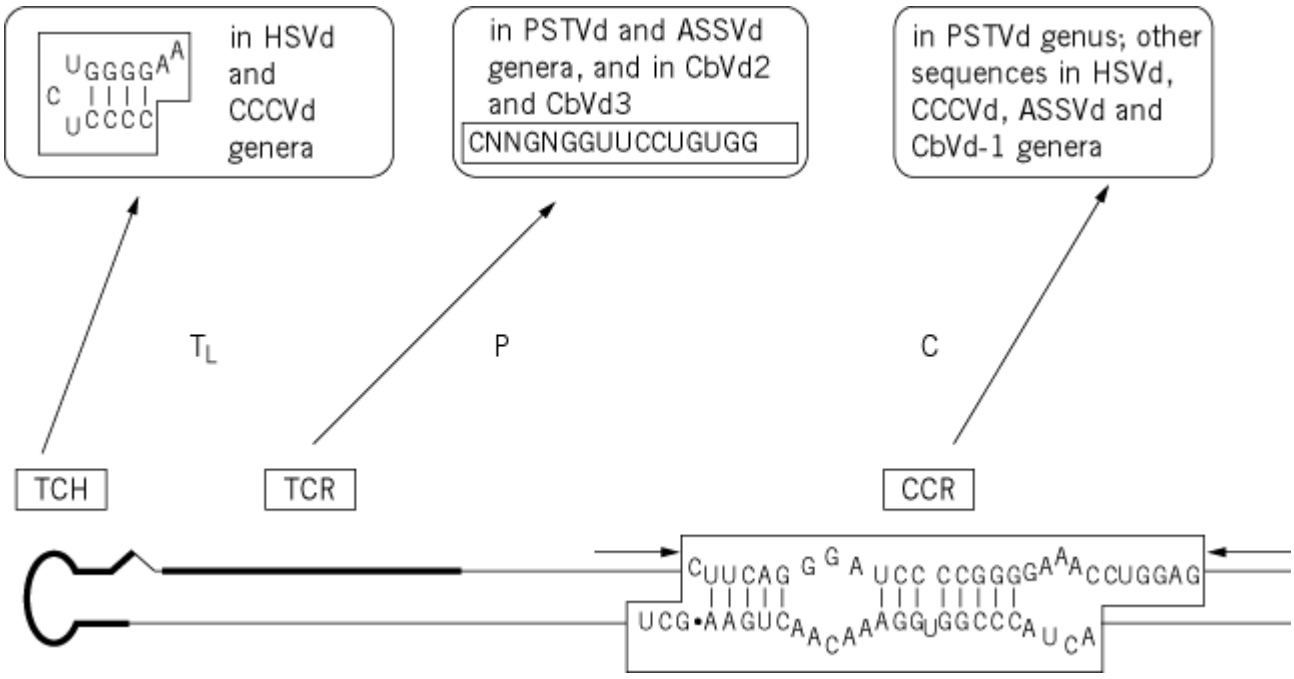
Viroids must be replicated by pre-existing host **RNA polymerases**, which are activated, but not coded, by the viroid genome. The viroid RNA itself, or one of its replicative intermediates, must also trigger the pathogenic effects on the host by direct interaction with one or more cellular targets. From the viroid names (Table 1), it is clear that they cause a series of maladies affecting crops of economic importance. Some viroids can also replicate without eliciting any symptom in their hosts. Thus far, no viroid has been found to infect bacterial, fungal or animal cells, although the RNA of human hepatitis delta virus shares some properties with viroid and viroid-like **satellite RNA** (see Virusoids).

1. Conserved Structural Domains and Classification

Viroid RNAs display a high degree of **secondary structure** as a result of extensive intramolecular self-complementarity (2). In most, but not all, cases, they adopt *in vitro* rod-like or quasi-rod-like conformations containing five structural domains that house the various functional determinants (3, 4). Viroids can also adopt other metastable conformations during their replication (5). The structure of viroids *in vivo* is not known, although there are indications of at least a partial rod-like structure in some cases. Within the rod-like structure, several conserved motifs can be distinguished: 1) the central conserved region (CCR) located in the central domain and comprised of two segments of nucleotides flanked by an imperfect inverted repeat in the upper strand, 2) the terminal conserved region (TCR) found in the upper strand of the left terminal domain, and 3) the terminal conserved hairpin (TCH) also located at the end of the left terminal domain and conserved in secondary structure as well as sequence (Fig. 1). The type of CCR as well as the presence or absence of the TRC and TCH motifs are useful criteria for classifying most viroids in different genera within family *Pospiviroidae* (Table 1) (6). Within a second family, *Avsunviroidae*, comprising ASBVd, PLMVd, and CChMVd (6), the situation is very different; they do not have these conserved motifs, but their strands of both polarities are able to adopt hammerhead structures (7) (see Ribozyme/Catalytic RNA). Moreover, PLMVd and CChMVd adopt *in vitro*, and probably *in vivo*, branched rather than rod-like conformations (7).

Figure 1. Schematic rod-like structure model for viroids of the family **Pospiviroidae**. The approximate location of the fi (pathogenic), V (variable) and TL (terminal left) and T_R (terminal right) are indicated on top of the figure. The core nucl region (CCR), terminal conserved region (TCR) and terminal conserved hairpin (TCH) are shown, as well as the presenc different members of the family. **Arrows** indicate flanking sequences that form, together with the core nucleotides of the inverted repeats.



2. Functional and Evolutionary Aspects

Differences between the two viroid families are not restricted to structure. The subcellular replication and accumulation sites of PSTVd and ASBVd, the type members of the two families, are the nucleus and the chloroplast, respectively. The available evidence indicates that other members of both families behave in this respect as their type species. Viroid replication has been proposed to occur through RNA intermediates (8) and by means of a **rolling circle replication mechanism** (9). In both families, the circular monomeric plus-strand RNA is transcribed into linear multimeric minus strands as a first step. PSTVd and members of the first family subsequently follow an asymmetric pathway in which the multimeric minus strands generate linear multimeric plus strands in a second round of RNA-RNA transcription, which are then processed to unit-length and ligated. ASBVd and other members of the second family follow a symmetric pathway, in which the linear multimeric minus strands of the first step are cleaved and ligated to the monomeric, circular minus RNA strand, which then acts as the initial template for the second half of the cycle. On the basis of sensitivity to a-**amanitin**, nuclear RNA polymerase II is probably involved in the polymerization of the RNA strands of PSTVd and related viroids of family *Pospiviroidae* (10). Additional studies using a monoclonal antibody against a conserved domain in the largest subunit of RNA polymerase II support this view (11). In contrast, an a-amanitin-resistant chloroplastic RNA polymerase appears to catalyze RNA elongation in ASBVd starting from definite sites in both polarity strands (12). One remarkable aspect of the last three viroids is that they self-cleave *in vitro* and almost certainly *in vivo* also, through hammerhead ribozymes to produce unit-length strands. Conversely, members of the PSTVd family may depend on host **ribonucleases** for cleavage, although self-cleavage through a different class of ribozyme structures cannot be excluded. The final circularization step in both families is probably mediated by host RNA ligases although, at least in the case of PLMVd, this step has been proposed to occur autocatalytically.

An evolutionary origin totally independent from that of RNA viruses has been proposed for viroid and viroid-like satellite RNAs (see Virusoids). Their circular structure and small size, and especially the frequent occurrence of ribozyme activities in these RNAs, all suggest that they may be molecular fossils of the RNA world that possibly preceded on Earth the appearance of cellular life based on DNA and proteins. Mutation and recombination events between viroids coinfecting the same host plant would seem to have contributed to their divergent evolution.

There are still fundamental properties of the viroids to be identified: 1) the molecular determinants targeting some viroids to the nucleus and others to the chloroplast; 2) the initiation sites of RNA synthesis in other viroids apart from ASBVd and the nature of promoters directing this synthesis; 3) whether additional RNA polymerases and transcription factors are involved in viroid replication; 4) the exact *in vivo* processing site of members of the PSTVd family; 5) the primary interaction between the viroid RNA, or a replicative intermediate thereof, and a cellular target leading through a signal transduction pathway to the onset of symptoms; and 6) the molecular basis of the interference observed between related viroids co-infecting the same plant.

Virus Infection, Animal

1. Definitions

1.1. Viruses

Supramolecular structures made of nucleic acid (the viral genome), proteins, glycosylated or not, and, eventually (in the case of enveloped viruses), lipids. Viruses are obligatory parasites of cells. They use the cell machinery of protein biosynthesis to make enzymes and regulatory and structural

proteins. In some cases, they also use cellular polymerases to synthesize their nucleic acids. The lipid-bilayer, the coat of enveloped viruses, is of cellular origin.

1.2. Infection

Invasion of a cell or an organism by an agent that, most of the time, will propagate, kill the host cell, and eventually cause disease.

2. Classification of Viruses

The International Committee on Taxonomy of Viruses (1) (ICTV) has proposed adopting a universal system of virus taxonomy. The system uses hierarchical levels such as order (suffix -virales), family (suffix -viridae), subfamily (suffix -virinae), genus (suffix -virus) and species ("a virus species is defined as a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche"). It should be recognized that great difficulties are being encountered in deciding whether a particular virus should be designated as a species or as a subspecies or strain or variant. The properties of viruses used in taxonomy are properties of the virion (morphology, physicochemical, and physical properties) and of the viral proteins, carbohydrates, lipids, and antigenic and biologic properties. The ICTV was recognizing more than 3,600 virus species and hypothesizing that more than 30,000 viruses, virus strains, and subtypes were being tracked in reference centers and culture collections (1). The ultimate goal is to catalogue "data down to subspecies, strain, variant, and isolate levels, that is, levels important in medicine, agriculture, and other scholarly fields." Obviously, the task is gigantic. Its achievement will require major investments in biochemical and biophysical techniques, as well as in bioinformatics. The 1995 state of the art has been updated and amplified (2).

This classification takes no account of the diseases caused by viruses. Indeed, it is more and more often observed that many viruses cause no, or only occasional, disease. They have reached a state of harmony with their host; an example is the case of the African green monkey (AGM) strain of simian immunodeficiency virus (SIV), which is very frequently found in the wild with no induction of disease.

Families of viruses infecting invertebrates or vertebrates are illustrated on Figure 1 as virus diagrams. Taxa containing double-stranded (ds) or single-stranded (ss) DNA or RNA (either the + or – strands) are separated by frames. Nonenveloped viruses are depicted as icosahedra. A dotted or hairy outer layer identifies enveloped viruses. A simple classification of viruses, based on how viral messenger RNA is produced, was proposed by D. Baltimore (3) (Fig. 2).

Figure 1. Families of viruses infecting invertebrates and vertebrates. Frames separate taxa containing double-stranded (ds) and single-stranded (ss) genomes. Horizontal blocks separate taxa containing DNA and RNA viruses. Taxa containing reverse transcribing (RT) viruses and the negative (–) and positive (+) ss RNA genomes are also indicated. A **dotted or hairy outer layer** indicates an enveloped virus. Icosahedral structures designate nonenveloped viruses. All diagrams were drawn approximately to the same scale (From Ref. 2, with permission).

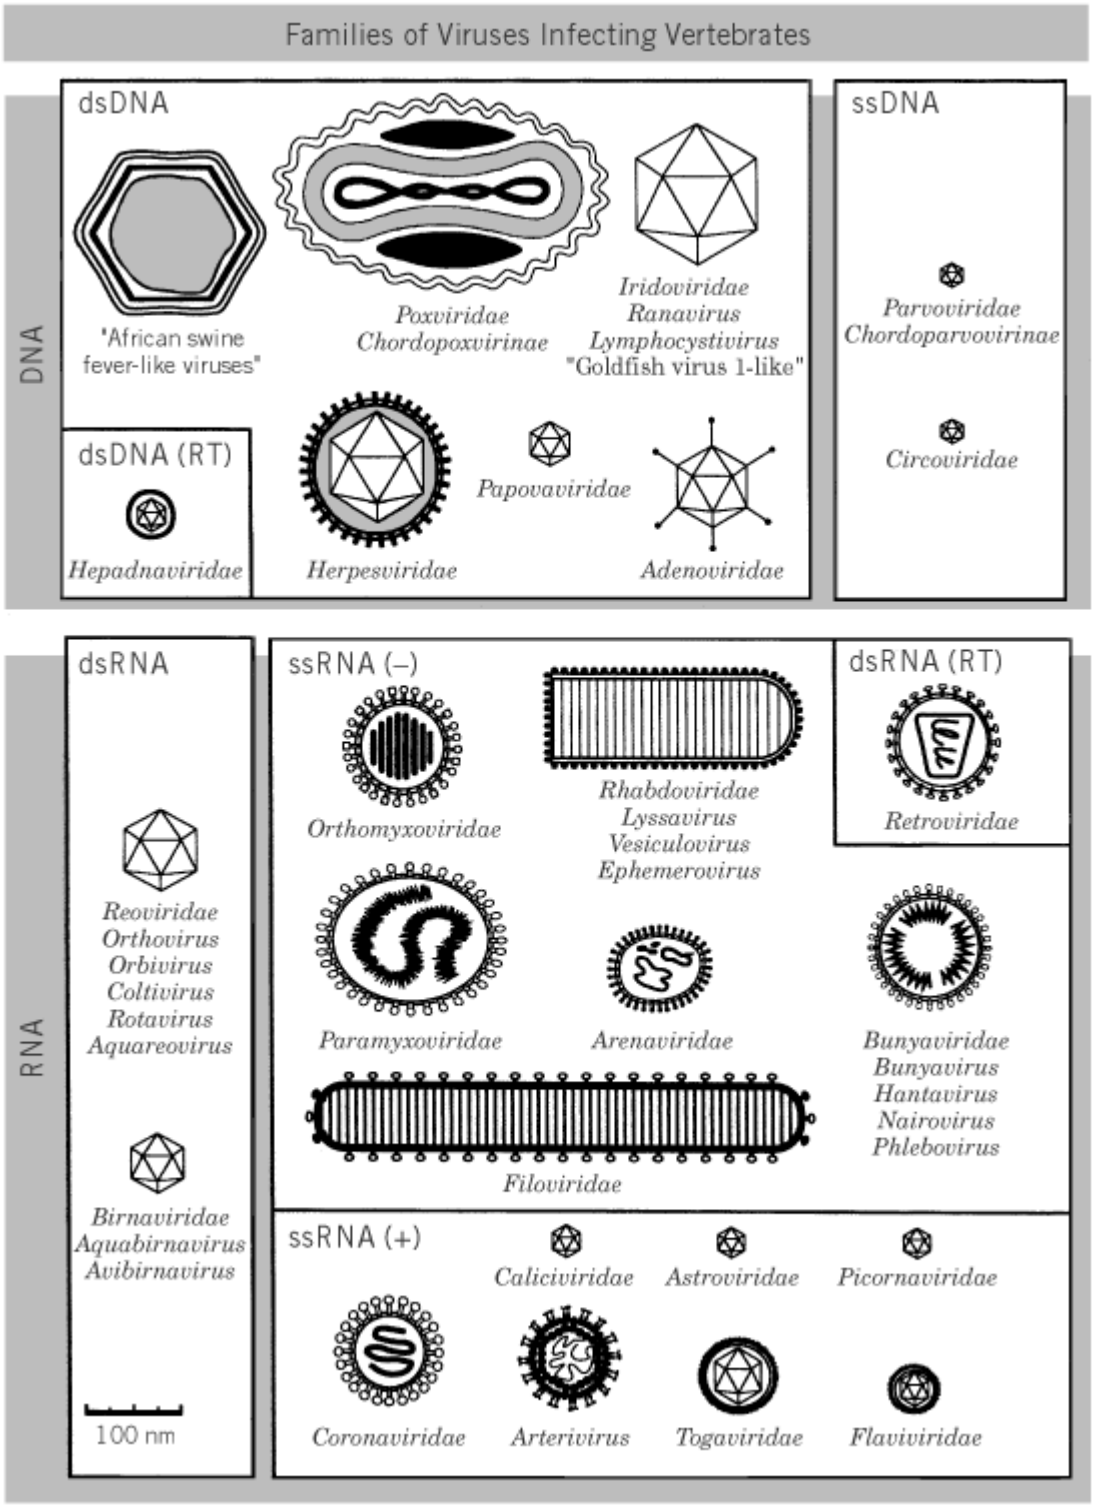

Figure 2. Baltimore's simplified classification of viruses. This classification is based on the type of nucleic acid in the genome and the mode of production of mRNA (3). Class I: Viruses with a ds DNA genome; mRNA is transcribed by the classical mechanism of transcription of a ds DNA template. Class II: Viruses with a ss DNA genome; the DNA strand has the same, positive sense as the mRNA, or else the sense of the genomic strand is negative, opposite to the mRNA. Synthesis of viral mRNA does not proceed before the ss DNA genomes of class II viruses are converted to a ds molecule. Class III: Viruses with ds RNA genome; such genomes are segmented. Transcription of mRNA is catalyzed by an RNA-dependent RNA polymerase packaged in the virion. Class IV: Viruses with an ss RNA genome of the same polarity as mRNA; an ss RNA (–) template is made before mRNA synthesis. Class V: Viruses with an ss RNA (–) genome complementary to the mRNA. Virion RNA is transcribed into mRNA by virion-associated enzymes. Class VI: Retroviruses have a diploid RNA genome made of two molecules of RNA (+). The + sense RNA is used as

template by reverse transcriptase for the synthesis of a ds provirus to be integrated in the host DNA; transcription is catalyzed by a cellular DNA-dependent RNA polymerase (From Ref. 3, with permission).

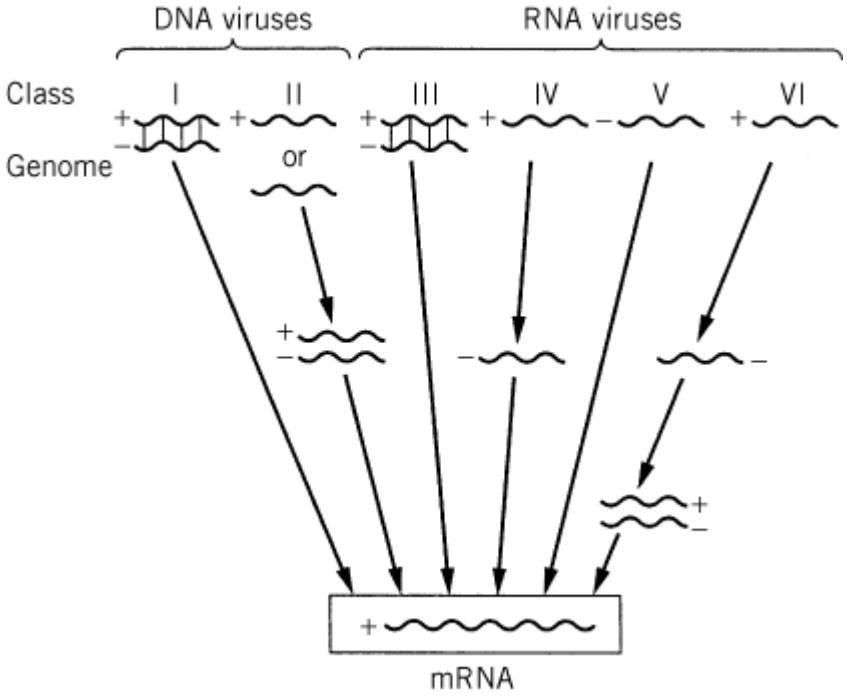

Figure 3. Structure of viruses. **(a)** A helical virus. The **wavy red line** represents RNA protected within successive arrays of proteins. **(b, c)** Spherical viruses. Icosahedral capsids have vertices made of symmetrically organized pentons. Hexons make the faces and are arranged along the edges. (From Ref. 19, with permission). **(d)** The fivefold, threefold and twofold symmetry axes of a regular icosahedron (From Ref. 20, with permission).

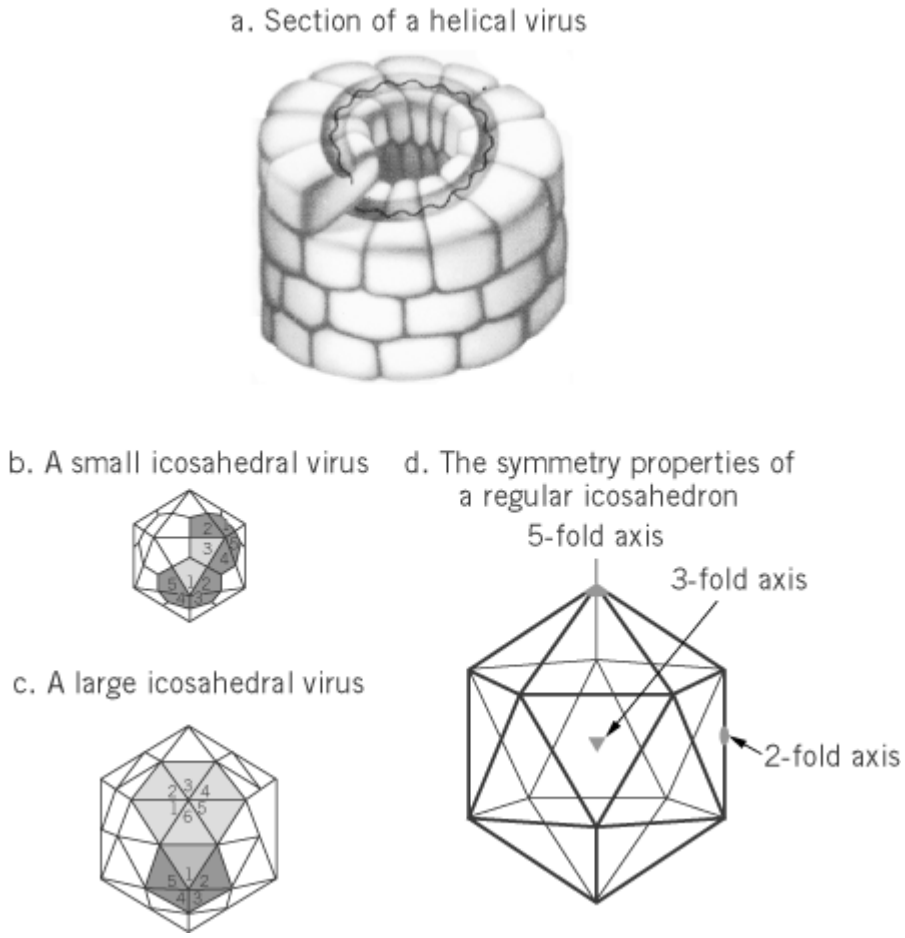


3. Structure of Virions

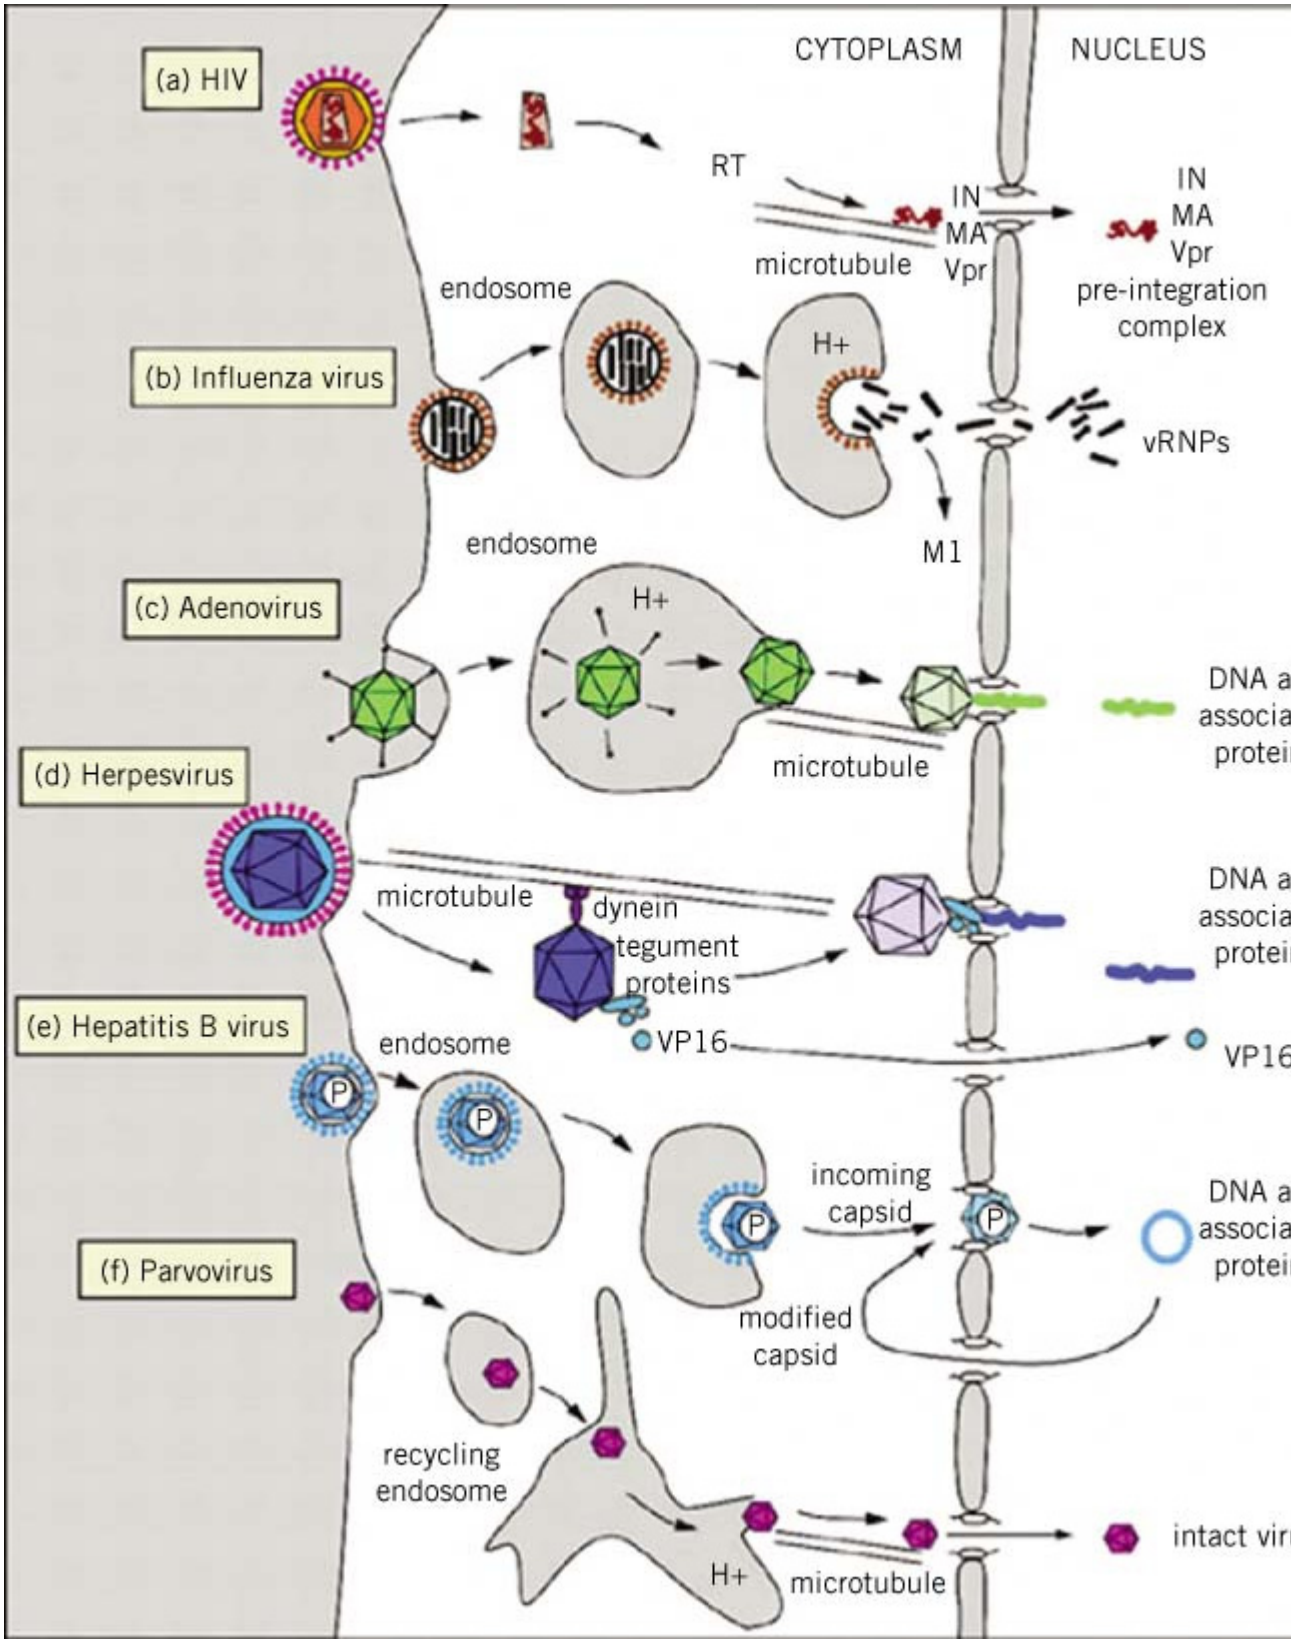
Figure 1 presents simple diagrams of the structure of virions. Two capsid structures exist; they are either multimers of protein subunits arranged as icosahedra symmetry (quasi-spherical volumes with an external molecular sheet built of 20 identical faces, each of which is an equilateral triangle) or multiple copies of protein subunits arranged as helices. Icosahedral structures can form independently of the presence of nucleic acid, whereas the helical arrangements generally require the presence of nucleic acid to assemble.

The detailed structure of picornaviridae capsids has been determined by X-ray crystallography. Models of other virus capsids at 28 to 35 Å resolution were provided using cryo-electron microscopy and computer single-particle reconstruction methods (rotaviridae, orbiviridae).

Models of helical and icosahedral viruses are illustrated in Fig. 3. Helical viruses largely expose protein subunits, and nucleic acid is protected within (Fig. 3**a**). Figure 3**b**, 3**c**, and 3**d** illustrate icosahedral structures with 20 triangular faces (each being made of three identical or equivalent capsid subunits), 12 vertices (where five subunits make contact symmetrically) and 30 edges (along which the protein subunits exhibit 6-fold symmetry, as well as the subunits making up the surfaces in between). Although the shape of the 20 faces is not a flat triangle as illustrated in Figure 3 (**b** and **c**), the overall appearance of these solids is that of nearly spherical volumes with triangular faces. At each vertex, edge, or face, symmetry is n = 5, 2, and 3, respectively (Fig. 3**d**).

Figure 4. Virus import into the nucleus. The pathway form the plasma membrane (PM) to the nuclear membrane is illust

for four families of viruses. Nucleic acid-protein complexes enter the nucleus through nuclear pore complexes. The HIV capsid is released in the cytoplasm and moves to the nucleus. On the way, the capsid protein is disorganized, reverse transcription occurs, and a complex containing the matrix protein, integrase, Vpr, and the nucleocapsid protein (probably cleaved in the nucleus) enters the nucleus via the nuclear pore complex. Influenza virus (an enveloped virus) and adenov (a nonenveloped virus) follow similar pathways. They are internalized via the endosomal pathway, and they rupture the endosomal membrane via protein conformational changes induced by the low pH of the late endosome. Ribonucleoprote (for influenza) and deoxyribonucleoproteins (for adenovirus) enter the nucleus via the nuclear pore. The envelope of her viruses fuses with the plasma membrane. The capsid travels along microtubules, moved by dynein. At the nuclear pore, I and its associated proteins are released into the nucleus, whereas the empty capsid remains in the cytosol. Hepatitis B vir may possibly disassemble within the nuclear pore while parvoviruses can enter the nucleus essentially intact (From Ref. with permission). IN = integrase; INM = inner nuclear membrane; MA = matrix; ONM = outer nuclear membrane; RT = reverse transcriptase; Vpr = viral protein R.



The capsid structure of retroviruses corresponds to the above description. It contains an external matrix protein (a key factor in nuclear targeting) underlying the lipid bilayer and an internal capsid protein, limiting the internal cavity, which contains two identical (+) viral RNA molecules associated with the nucleocapsid protein, the reverse transcriptase, and other enzymes of cellular origin. Originally, retroviruses were classified according to their morphological appearance and budding

phenotype as observed by electron microscopy (4) (see virus assembly below).

4. Virus Attachment, Entry, Uncoating, and Transport

Viruses enter cells by interaction with their receptor; human immunodeficiency virus (HIV) and simian immunodeficiency virus (SIV) use two receptors (it is often spoken of as one receptor, CD4, and one coreceptor, which belongs to the family of receptors for chemokines).

Adenoviridae also use two receptors. The presence of the receptor to a given virus does not *ipso facto* mean that the cell will be permissive to that virus. Nonreceptor genetic controls of early events in infection have been amply documented in mice, chickens, hamsters, and so on. Receptors can be proteins, sugars, polysaccharides, ceramides, and so on, present at the cell surface. Virus-receptor attachment rates have been measured on a variety of systems. Some happen to be very fast, with a second-order rate constants of about 10–7 cm 3 min–1, others are much slower, 10^{-12} $cm^3 min^{-1}$ (from Ref. 7, p. 629).

Two major mechanisms of virus entry have been recognized: virus-cell fusion at the plasma membrane, which is pH-independent, and virus endocytosis, which is pH-dependent. Passage of viral structures through a lipid bilayer probably implies extrusion of hydrophobic peptide sequences, as suggested for poliovirus (5). In the case of fusogenic enveloped viruses, the fusogenic peptide at the amino-terminus of the F protein inserts obliquely in the lipid bilayer of the target cell and destabilizes it (6). Virus-cell fusion occurs at the plasma membrane for pH-independent viruses (eg, retroviruses) or in endosomes for pH-dependent viruses (eg, influenza virus) (7).

Enveloped viruses recognize their target cell via interaction of their external envelope protein with a cell membrane protein acting as receptor. The cases of HIV and SIV are more complex because the virus requires both a receptor and a coreceptor for entry. The most commonly used receptor is CD4; the coreceptor is a chemokine receptor. Induction of a conformational change by interaction of HIV-1 external glycoprotein (gp120) with the CD4 receptor was demonstrated by the crystal structure at 2.5 Å resolution of an HIV-1 gp120 core complexed with a two-domain fragment of human CD4 and an antigen-binding fragment of a neutralizing antibody that blocks chemokine-receptor binding (8). The structure revealed a cavity-laden CD4-gp120 interface and a conserved binding site for the chemokine receptor.

Virus-cell fusion implies a major contribution by the viral transmembrane moiety of the envelope glycoprotein. In pH-dependent viruses (ie, influenza virus), each subunit of the trimeric envelope gets rearranged and reorganized largely as an a helix, the fusion peptide (located at the NH2 end of the transmembrane protein, HA2 in this case) being cast some 100 Å outwards towards the target membrane (9). X-ray diffraction studies applied to HIV-1 transmembrane protein gp41 and to Moloney murine leukemia virus illustrate the great similarity between pH-dependent and pH-independent envelope transmembrane protein architectures, suggesting a common mechanism for initiating fusion (9-11).

Virion interaction with the virus receptor(s) leads to release in the cytoplasm of the viral capsid or of the viral nucleic acid. Many aspects of uncoating are still undefined, even in thoroughly studied systems such as poliovirus or HIV. In poliovirus, preinfection maturation of the particle involves loss of protein VP4 and swelling of the particle, and, at very low frequency of a few percent, the stage of an infectosome is supposed to deliver the RNA genome through the membrane and into the cytosol. There is a receptor-mediated extrusion of a hydrophobic structure into the host cell membrane. In this system, the uncoating steps occur outside the cell, with the particle being attached to the receptor (a member of the immunoglobulin family) and in close contact with the cell membrane (Ref. 7, p. 633).

Virus nuclear import (12, 13) is illustrated in Figure 4 and summarized in Table 1. Engulfed in an

endosome, adenovirus capsid external protein causes disruption of the endosomal membrane. Freed in the cytosol, the capsid interacts with the nuclear pore complex through a penton structure at one vertex. Viral DNA and associated proteins penetrate the nucleus, leaving behind the empty capsid. Similar mechanisms mediate the transport of herpesvirus capsids to the nucleus. This enveloped virus fuses at the plasma membrane; the capsid moves to the nucleus along microtubules. The capsid-nuclear pore interaction involves one vertex. DNA and associated proteins penetrate the nucleus.

Figure 5. Export of viral material from the nucleus to the cytoplasm and the extracellular compartment. The HIV Rev protein is required for export from the nucleus of full-size and singly spliced viral RNA. An immature capsid gets progressively organized underneath the lipid bilayer of the plasma membrane where viral envelope glycoproteins are concentrated. An analogous process leads to budding of influenza virus particles. Fully assembled herpes virus capsids bud from the inner nuclear membrane and fuse with the outer nuclear membrane, being released naked into the cytoplasm. Naked particles become enwrapped by membranes of the Golgi apparatus and accumulate within a vesicle. Alternatively, the capsid buds through the double membrane of the nucleus, and the outer membrane fuses with a membrane of the Golgi apparatus. The final outcome of this pathway is again an enveloped virus within a cytoplasmic vesicle. Enveloped particles will be released from the cell through fusion of the vesicular membrane with the plasma membrane of the infected cell (From Ref. 14, with permission).

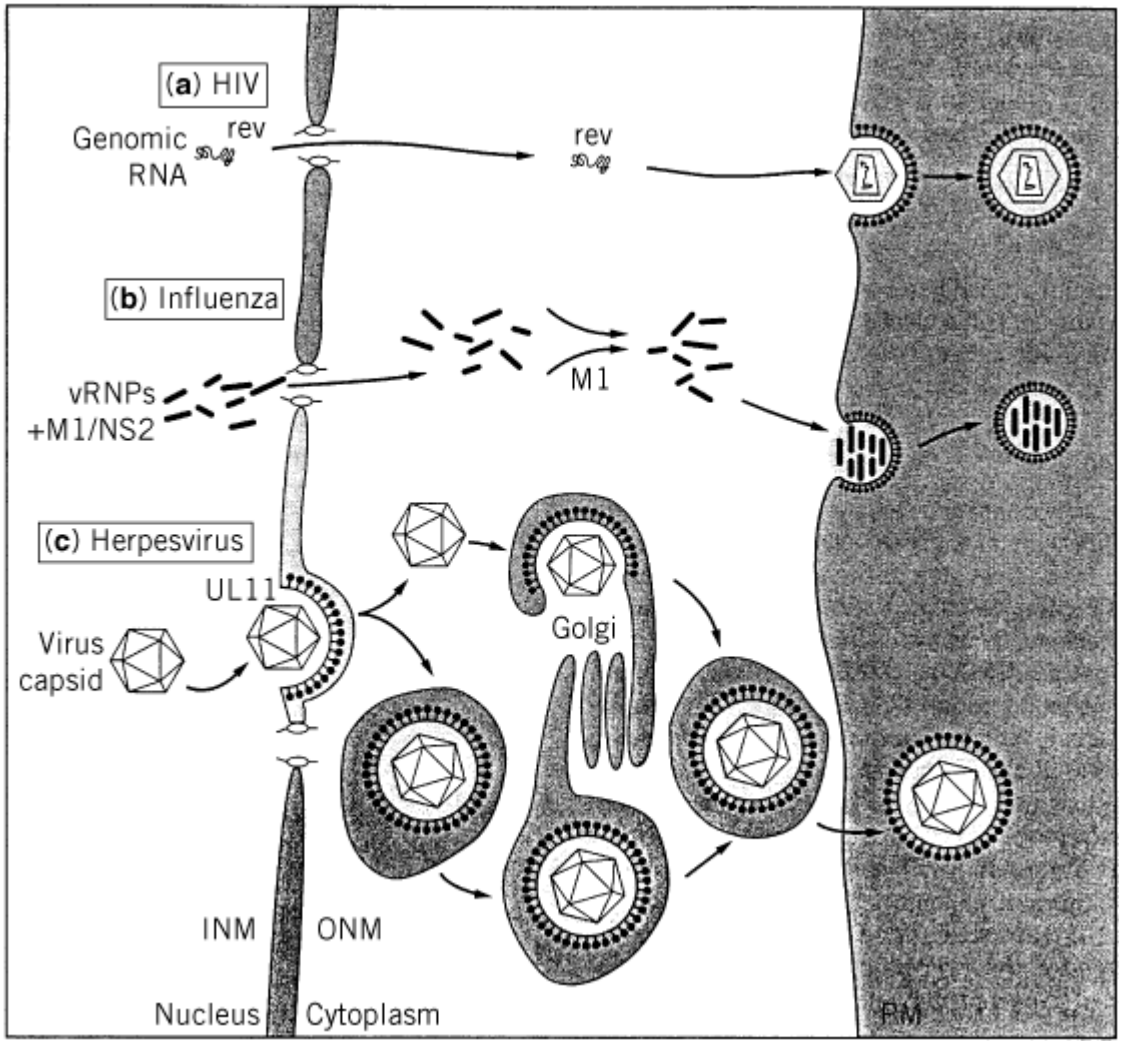


Table 1. Summary of Viruses That Enter the Nucleus

Method of Nuclear import	Virus Family	Selected Example(s)	
Entry during mitosis	Retroviridae: Oncovirus	Simian retrovirus type 1	RNA (RT)
Uncoating in the cytoplasm + NPC translocation	Retroviridae: Lentivirus	Human immunodeficiency virus type 1 (HIV-1)	RNA (RT)
	Orthomyxoviridae	Influenza virus	ss RNA(–)
Uncoating in the cytoplasm	Bornaviridae	Borna disease virus	ss RNA(–)
Docking of virus to the NPC/transit of intact virus?	Hepadnaviridae	Hepatitis B virus (HBV)	ds DNA (RT)
Transit of intact virus	Parvoviridae	Minute virus of mice Parvovirus B19	ss DNA
	Papovaviridae	Papovavirus Simian virus 40	ds DNA
Docking of intact virus to the NPC	Adenoviridae	Adenovirus 2	ds DNA
	Herpesviridae	Herpes simplex virus (HSV) Cytomegalovirus (CMV)	ds DNA
	Baculoviridae	Autographa californica multiple nuclear polyposis virus	ds DNA

RT, reverse transcriptase; NPC, nuclear pore complex.

Influenza viruses enter cells by receptor-mediated endocytosis. Uncoating of the virus in endosomes depends on the acidic pH of this compartment. It is supposed that the low pH-activated ion-channel activity of the virion-associated M2 protein permits the flow of ions (essentially protons) inside the virus particle, disrupting of protein-protein interactions and, thus, freeing the ribonucleoproteins (NPs). The low pH also induces a major change in the three-dimensional structure of the transmembrane protein HA2 (see above). The viral envelope fuses with the membrane of the endosome, releasing NPs in the cytosol from where they will move to the nucleus.

Uncoating and transport of retroviral capsids delivered in the cytosol after virus-cell membrane fusion are poorly understood. Reverse transcription, initiated in the producing cell, proceeds during the transport to the nucleus, where integration of the proviral DNA will take place, catalyzed by the viral integrase. Onco-retroviruses depend on the breakdown of the nuclear envelope during mitosis to achieve DNA integration and completion of their life cycle. On the contrary, lentiviruses use the nuclear localization signal of the matrix protein to establish infection in macrophages and quiescent T-lymphocytes (15). In addition to the matrix protein, reverse transcriptase and integrase, the nucleocapsid protein also plays a role by potentiating provirus integration in the presence of Mg^{2+}.

5. Virus Replication

The strategies of viral nucleic acid replication depend on the nature and strandedness of the viral genetic material.

5.1. Double-Stranded DNA Viruses

These viruses, Picornaviridae, replicate in the nucleus. DNA duplication can be carried out by either cellular or viral DNA polymerases. Poxviridae are exceptions. Their multiplication is cytoplasmic. The pox genome encodes the viral DNA polymerase. In single-stranded DNA viruses (Parvoridiae), DNA synthesis takes place in the nucleus, uses cellular DNA polymerases, and derives from a self-priming mechanism. The replicative intermediate is a linear duplex molecule. Virions carry either a (+) or a (–) DNA strand. Hepadnaviridae have a peculiar genomic structure. One strand of DNA (negative sense, complementary to the viral messenger RNAs) is full-length; the other is of variable size. Before transcription by the host RNA polymerase II, the DNA is converted into a covalenty closed circle. The closed-circular DNA species can serve as template for the synthesis of a full size mRNA that will serve as a template for synthesis of the minus-strand DNA by reverse transcription using a protein primer.

5.2. Double-Stranded RNA Viruses

These viruses, Reoviridae, carry a genetic material made of ds RNA segments (10 to 16 segments, according to the genus) and a virion-associated RNA-dependent RNA polymerase (or transcriptase). Transcription products of the double-stranded genome are RNA (+) molecules that are either used as mRNA or encapsulated in nascent virions, where they are used as templates to generate a double-stranded genome.

5.3. Single-Stranded RNA (–) Viruses

These viruses, Rhabdoviridae, harbor a negative-sense RNA molecule (11 kb to 15 kb in size) and a virion-associated transcriptase. Replication takes place in the cytoplasm. Host protein factors are required for replication. Replicative intermediates are made of RNA (+) molecules linked to a so-called N protein. In turn, RNA (+) molecules are used as templates for new genomic (–) strands. Segmented negative-strand RNA viruses (ie, orthomyxoviridae [influenza viruses]) have a genome size of 10 kb to 13.6 kb, made of six or seven segments, depending on the genus. At infection, viral nucleocapsids are transported to the cell nucleus, where the virion trancriptase synthesizes mRNA species, which act as templates for new viral RNA synthesis. The latter RNA (–) molecules exist as nucleocapsids in the nucleus of infected cells.

5.4. Single-Stranded RNA (+) Viruses

Virions of single-stranded (+) RNA virus (7 kb to 8.5 kb in size for picornaviruses) contain one molecule of infectious, positive-sense ss RNA. Translation of the genomic RNA generates a polyprotein, which is processed by a viral protease, giving rise to structural virus proteins and nonstructural ones, among which are one subunit of replicase (RNA-dependent RNA polymerase). The replicase probably associates with cellular proteins to make up a functional RNA polymerase. This situation is analogous to that of the Qb phage, in which the virus-encoded replicase subunit associates with elongation factors Tu and Ts and ribosomal protein S1, to build up a highly active replicase to which the virus contributed minimally. Replication first produces a negative-sense RNA, complementary to the RNA (+) genomic RNA. Due to the higher affinity of replicase for the 3′ end sequence of minus strands, many more RNA (+) molecules than RNA (–) molecules are produced, which are either translated or encapsidated in progeny virus.

Retroviridae have a diploid, single-stranded RNA (+) genome and a virion-associated reverse trancriptase (RNA-dependent DNA polymerase). Reverse transcription starts in the virus particle and produces a linear ds DNA copy of the genomic RNA. The linear DNA is integrated into the host cell DNA via the activity of a virus-coded integrase and is transcribed as regular cellular genes. Viruses of that family are oncogenic through their site of integration (activation of proto-oncogenes); other

members of the family have incorporated and mutated proto-oncogenes and, consequently, become acute transforming viruses; others (such as human T-cell leukemia virus) are transforming entities through dysregulation of the cell transcription machinery. The lentivirinae are primarily inducers of immunodeficiency.

6. Synthesis of Viral Messenger RNA and Viral Proteins

6.1. Double-stranded DNA viruses (ie, Papovaviridae)
The life cycle of many viruses can be divided into an early and a late period. In ds DNA viruses, proteins made in the first period are called early; they play regulatory functions. Proteins made later in the life cycle of the virus are structural molecules. Precursor mRNAs undergo classical post-transcriptional processing, including 5′-capping, polyadenylation, and RNA splicing. Efficient use of the available information involves alternative splicing and use of overlapping open reading frames. A peculiarity seen in Poxviridae, adenoviridae, and some families of parvoviridae is the transcription of early proteins from both strands of the ds genome; this is another strategy to use maximally the available genomic sequences.

6.2. Double-Stranded RNA Viruses
Viruses of this family carry a virion-associated transcriptase. Transcription of each segment of the ds segmented genome generates an mRNA coding for a single polypeptide chain, a polyprotein.

6.3. Single-Stranded RNA (–) Viruses
The genes of these viruses are transcribed processively, from the 3′ to the 5′ end of the template virus RNA and in decreasing molar abundance. The mRNAs are 5′-capped, 3′-polyadenylated, and generally monocistronic. In the case of viruses with a segmented genome, the largest genome segments encode one protein each, whereas some of the smaller segments code for additional proteins from spliced or bicistronic mRNAs. Influenza virus mRNA synthesis occurs in the nucleus. It requires initiation by host-cell primers and specifically capped RNA fragments derived from host-cell RNA polymerase II transcripts. In this system, viral mRNAs start with cellular sequences (10 to 13 nucleotides).

6.4. Single-Stranded RNA (+) Viruses
A frequent strategy found in this group of viruses is the translation of the + sense genomic RNA into a polyprotein, maturated later on by a virus encoded proteinase (ie, picornaviridae, poliovirus). In alphaviridae (Semliki Forest Virus), the full-length genomic RNA codes for nonstructural proteins. The message for structural proteins is subgenomic and corresponds to the 3′ region of the genomic RNA.

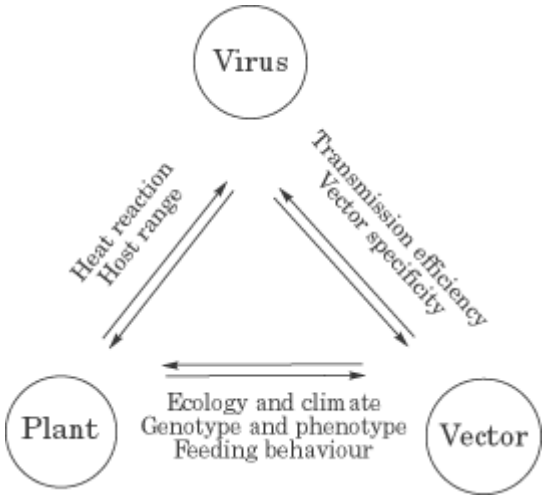
Transcription of retroviral messages occurs from the integrated proviral DNA. It combines all the known mechanisms of eukaryotic transcription. Expression of retroviral information includes expression of regulatory functions from spliced mRNAs, expression of internal structural proteins from genomic, full-length RNA, and expression of envelope proteins from a singly spliced mRNA. Nuclear export of the full-length and singly spliced viral RNA requires interaction with a viral regulatory protein called Rex in Human T-lymphotropic Virus (HTLV) and bovine leukemia virus (BLV). A lentiviral protein with analogous function is called Rev in HIV and SIV.

Virus Infection, Plant

The natural infection of a plant by a virus involves complex interactions between three genomes: that

of the virus, that of the host, and that of the vector (Fig. 1). Superimposed on these interactions are abiotic factors that affect the behavior of the host and vector. The application of molecular techniques is leading to a more detailed understanding of these interactions. However, only a small number of virus–host, virus–vector, and host–vector combinations have so far been studied, and it would be risky to extrapolate from these data to a wide range of viruses. Details of the structures and genome organizations of these viruses are given in Viruses, plant.

Figure 1. Genomes that interact in the natural infection of a plant by a virus. Reproduced from (21) by kind permission of W. B. Saunders Co.



1. Host Range and Symptoms

Viruses differ in the number of plant species that they can infect systemically. Some viruses have wide host ranges; eg, *cucumber mosaic virus* has been reported to infect more than 800 species in 85 families (1). Other viruses (eg, *apple stem grooving virus*) have narrow host ranges, naturally infecting very few species. Some viruses are restricted to one plant organ, eg, *necroviruses* are usually restricted to the roots, *luteoviruses* are usually restricted to the phloem cells in the vascular bundle. Experimental infections show that some viruses can infect protoplasts of species that they do not infect systemically; this is termed *subliminal infection* and occurs because of the restriction of the cell-to-cell spread of the virus (see below).

Plants react to viruses with a wide range of symptoms, but the symptom type is usually specific to the virus and frequently used in the name of the virus (see Table 1 in Viruses, Plant). In some virus–host combinations, local symptoms, which are usually *chlorotic* (yellow) or *necrotic* spots, develop on inoculated leaves around the site of virus entry. If the spots become necrotic, the virus often does not spread systemically to the rest of the plant. The number of necrotic spots produced on a leaf after mechanical inoculation can be related to the virus concentration, and a local lesion assay is frequently used for the quantification of an infectious virus. The most common systemic symptom is mottle or mosaic patterns of light and dark green, and sometimes yellow, areas on the leaves. The distribution of light and dark green is usually delimited by the veins on the leaves, giving an irregular mosaic in dicotyledons and striping in monocotyledons. The mosaic expression in flowers is termed *color breaking*, the best-known example being tulip flower color breaking seen in many Dutch old master paintings. Other color symptoms on leaves include yellowing, often associated with phloem-limited viruses, and ringspots formed by concentric rings or irregular linepatterns of yellowed tissue, which may become necrotic. Viruses can also cause growth abnormalities, which include stunting of the plant, reduction of the leaf lamina, enations that are outgrowths from the leaf veins, and

tumorlike growths.

2. Plant-to-plant Spread

To infect a plant, a virus has to pass the cuticle and cellulose cell wall, a process that requires mechanical damage. In experimental conditions, many viruses that are not restricted to the phloem can be transmitted by rubbing sap from an infected plant, together with an abrasive, on a leaf of a host species. In nature, some viruses, eg, **tobacco mosaic tobamovirus** (TMV) and potato virus X potexvirus, spread from plant to plant via broken leaf hairs that result from leaves rubbing together. However, for the majority of viruses, natural transmission involves a biological *vector*. These include insects that feed by piercing and sucking (eg, aphids, leafhoppers), nematodes, **fungi** (various lower fungi), and pollen. The interactions between a virus and its vector are very specific, and viruses that are transmitted by one type of insect, say, aphids, are not transmitted by other insect types or by fungi or nematodes. The specificity goes even further, and some viruses are transmitted by only one insect species.

There are two basic forms of virus–vector interactions: one in which the virus is externally borne and does not enter inside the vector and the other, internally borne, in which the virus enters the vector's body. The externally borne interaction is characterized by rapid transmission and short persistence of the virus associated with the vector. Internally borne viruses persist in the vector for much longer periods and, if the virus replicates in the vector, the vector can usually transmit for all its life. In each case, there is a specific interaction. Most is known about details of interactions between viruses and insect vectors.

Externally borne, insect-transmitted viruses interact with specific region(s) of the vectors' anterior food canal. This interaction can be either directly between the virus coat protein and the specific site, as exemplified by aphid transmission of cucumber mosaic cucumovirus (CMV), or involve a virus-encoded nonstructural protein, such as the helper component of potyviruses and the aphid transmission factor (P18 or gene II product) of **cauliflower mosaic caulimovirus** (CaMV). The potyviral helper component is a protein of 53 to 58 kDa (depending on the virus) that is processed proteolytically from the N-terminal part of the viral polyprotein (see Fig. 1 in Viruses, Plant) and is thought to be a heterodimer in its active form. There are several theories as to how these transmission proteins function (2), the most widely accepted being that they act as a bridge between the viral coat protein and mouthparts of the vector. The predicted **secondary structure** of CaMV P18 indicates that it has an N-terminal **domain**, which is primarily **b-sheet**, separated from the predominantly **a-helical** C-terminal domain by a random structure region. The C-terminal domain of CaMV P18 binds to the viral coat protein, and mutations of the N-terminal domain abolish insect transmissibility (3). The helper component of potyviruses is thought to function in a similar manner, and recently that of tobacco vein mottle potyvirus was shown to bind to the viral coat protein (4). An amino acid residue triplet, Asp-Ala-Gly (DAG), is conserved near the N-terminus of the coat protein of all aphid-transmissible potyviruses and, as this is exposed on the surface, it is thought that this domain interacts with the helper component.

Internally borne viruses have to cross one or more barriers to enter the vector, and further barrier(s) to pass from the vector to the plant. In arthropod vectors, the virus has to cross the gut wall to enter the hemocoel and the basal lamina of the salivary glands to be able to be introduced into the new host together with saliva. The details of the routes by which luteoviruses pass these barriers in their aphid vectors by endocytosis and movement though various vesicles have been detailed by Gildow (5). However, little is known at present about details of the interactions between the virus and vector involved in receptor binding at these barriers; it is these interactions that presumably control vector specificity. Stability within the hemocoel appears to be controlled by *symbionin*, the product of symbiotic bacteria in the vector, which has chaperonin like properties (6).

Internally-borne viruses that replicate in their vector often have to cross further barriers to enter the insect cells in which they replicate (7). Many of these viruses, which can be regarded as viruses of

insects that are adapting to plants, have more complex structures (such as Reo virus). There are surface proteins on the virus particles that are presumed to interact with cell surface receptors.

3. Replication cycle

The details of events leading to the production of new virus particles from incoming virus into an uninfected cell differ according to the type of viral genome, although there are some commonalities in the general strategy. The initial event is the uncoating of the virus particles followed by expression of the gene product(s) involved in genome replication; for DNA viruses and (–)-strand RNA viruses, this will require transcription of the incoming viral genome. The viral genome is then replicated, and later gene products such as viral coat protein and vector transmission proteins are expressed. The newly synthesised viral genome passes to adjacent uninfected cells (see below) or is encapsidated and accumulates in this initially infected cell. For many viruses with (+)-strand RNA genomes, virus particle uncoating occurs by the process of cotranslational disassembly (8). In this process, the particle structure is relaxed (often by the chelation of divalent cations and/or a pH of about 7), and host cell ribosomes locate the 5′ end of the viral genome, which is an mRNA. The ribosome translocates along the RNA, translating the viral genetic information and, at the same time, displacing the viral coat protein subunits. For TMV, it is thought that cotranslational disassembly slows down or stops at the origin of assembly (see Tobacco Mosaic Virus); for some isometric viruses, it is thought that the whole genome is disassembled by this process. It is not proven that all (+)-strand RNA viruses employ cotranslational disassembly. Obviously, viruses with DNA genomes and (–)-strand or double-stranded RNA genomes cannot be uncoated by this process, as their genomic nucleic acid is not translated, and the mechanism of their uncoating is unknown. Viruses with (–)-strand and double-stranded RNA genomes have an **RNA-dependent RNA polymerase** incorporated within the virus particle, and thus the genome can be transcribed into a (+)-strand on entry into the cell. In viruses with DNA genomes, the genome is transported to the nucleus, where it is transcribed by the host DNA-dependent RNA polymerase II.

All RNA viruses encode an RNA-dependent RNA polymerase, and most of the viruses with (+)-strand genomes do so at their 5′ end (see Fig. 1 in Viruses, Plant, Tobacco Mosaic Virus, and Tomato Bushy Stunt Virus) (also see RNA Polymerases, RNA-Dependent); thus, these protein(s) will be expressed early during the cotranslational disassembly process. For (+)-strand RNA viruses, production of the (–)-strand RNA starts at the 3′ end of the input (+)-strand, proceeding toward the 5′ end and, at least in the case of TMV, completes the disassembly of the virus particles (see Tobacco Mosaic Virus). The promoters for (–)-strand synthesis are thus located in the 3′ region of the viral genome. The sequences at the 3′ ends of genomic RNA of several genera of plant viruses can be folded into **transfer RNA**-like structures that can be aminoacylated with histidine (most tobamoviruses), tyrosine (bromoviruses, cucumoviruses), or valine (tymoviruses, one tobamovirus) (see Fig. 1 in Viruses, Plant). Mutagenesis indicates that these tRNA-like structures are required for RNA replication and especially for the determination of template specificity. Some viruses (see Fig. 1 in Viruses, Plant) have a **poly(A)** tract at their 3′ end and thus resemble the animal-infecting picornaviruses. It is thought that, as with, say, Polio virus, this tract is important in initiating replication. Most other (+)-strand RNA viruses do not have obvious sequence features at their 3′ ends, but this region must be involved in initiating replication. The (–)-strand is then the template for the formation of both the full-length and any subgenomic RNA. Similar considerations must be involved in sequences initiating (+)-strand synthesis, but little is known about these. In some cases, however, the sequences required for initiating subgenomic RNA synthesis have been identified [see 9 for a review].

The replication of viruses with (–)-strand or double-stranded RNA genomes is similar to that of (+)-strand RNA viruses except, as described above, the initial event is transcription of the incoming genome by encapsidated RNA-dependent RNA polymerase.

Single-stranded DNA viruses (the geminiviruses) replicate by a **rolling circle** mechanism [see 10, 11

for reviews]. It is thought that the virus gene products interact with the host cell cycle and host DNA-dependent **DNA polymerase** to overcome the limitation of one round of DNA replication per cell division.

The viruses with double-stranded DNA genomes (badnaviruses and caulimoviruses) are pararetroviruses and replicate by **reverse transcription**. Details of the replication cycle are given in Cauliflower mosaic virus .

4. Virus Movement through the Plant

To spread from the cell initially infected to an adjacent one, a virus has to pass through the cellulose cell wall. Plant cells communicate with each other by cytoplasmic connections through the cell wall termed *plasmodesmata* [for details of plasmodesmata structure, see (12)] and it is generally accepted that viruses move from cell to cell via them. The effective diameter of plasmodesmata is too small to allow the direct movement of virus particles, and many viruses encode gene product(s) that help with this movement. A further problem is that any permanent increase in plasmodesmatal diameter would affect the control of cell-to-cell communication and thus be detrimental to the plant. Two mechanisms of cell-to-cell movement of viruses are currently recognized, although it is likely that others will be found in the future. In the first, exemplified by TMV, a *movement protein*, termed P30 (see Tobacco Mosaic Virus for details of genome organization), temporarily increases the exclusion limit of plasmodesmata from 850 Da to more than 10 kDa. P30 binds to the RNA genome of TMV, melting out its secondary and tertiary structure and thus making long narrow nucleoprotein molecules that are thought to pass through the enlarged plasmodesmata. Observations on the intracellular location of P30 indicate that it interacts with microtubules and to a lesser extent with actin filaments (13, 14). It is suggested that these interactions might target the movement protein, and hence the movement protein-RNA complex, to the plasmodesmata. After it has functioned, P30 is phosphorylated and "stored" adjacent to plasmodesmata. Cowpea mosaic comovirus (CPMV) and CaMV (see Cauliflower Mosaic Virus for details of genome organization) are examples of the second mechanism. One or more gene products of these viruses (P58 / 48 of CPMV; gene 1 product of CaMV) is involved in forming permanent tubular structures that pass from cell to cell across the cell wall, most probably through plasmodesmata. Virus particles are observed in these tubules, and it is thought that they are moving from cell to cell. The functional movement proteins have been attributed to gene products of many groups of viruses (see Fig. 1 in Viruses, Plant). In a few cases, such as those cited above, there is direct evidence for the involvement of these proteins in cell-to-cell movement. In other cases, the evidence is indirect, such as mutagenesis leading to subliminal infections.

The mechanisms for cell-to-cell movement allow the passage of the virus through the mesophyll tissues to the vascular bundle cell. The mechanisms of movement of viruses across the bundle sheath (cells that surround the vascular bundle) and from cell to cell within the vascular bundle are not clearly understood.

Long-distance movement of viruses causing systemic infection usually occurs in the phloem sieve elements following the source-sink movement of photoassimilates. However, it is not known how viruses enter or exit the sieve element system. For many viruses, the viral coat protein is required for long-distance movement and, most probably, for cell-to-cell movement within the vascular bundle. Long-distance movement in the xylem elements has been suggested for southern bean mosaic sobemovirus.

5. Symptom Production

The ability to manipulate and mutate viral genomes has led to the identification of sequences that influence symptom production, and there are numerous publications on the effects of such changes. For example, a single nucleotide has been identified as being responsible for differences in symptoms of different isolates of the RNA virus TMV (15) and of the single-stranded DNA virus,

maize streak geminivirus (16); also both gene II and VI products are involved in the symptom and host range determination of CaMV (17, 18). However, little is known about the details of the interactions that these mutations have with the host.

There are many fewer studies on details of how the host reacts to virus infection. A progressive series of metabolic changes occur with a local lesion caused by the infection of *Cucurbita pepo* by CMV (19). At least some Potyviruses transiently inhibit host gene expression in the cells in which they replicate, thus resembling some animal viruses (20).

Virus Structure

Viruses spend part of their time inside the living cells they have infected, either in a latent form or, more familiarly, replicating to produce progeny viruses. The rest of the time they are outside the cell in the form of **virions**, the discrete particles that usually come to mind when we think of viruses. Virions are quite varied in shape and size among different known viruses, but detailed examination of their structures reveals that they all share a set of common features (described below) that can be seen to derive from the biological functions that are carried out by the virion. Virions are small, ranging from roughly 30 nm to 300 nm in diameter or longest dimension. The upper end of this range overlaps slightly the lower end of the range of known sizes for cells, but any specific virus is always substantially smaller than the cells it infects.

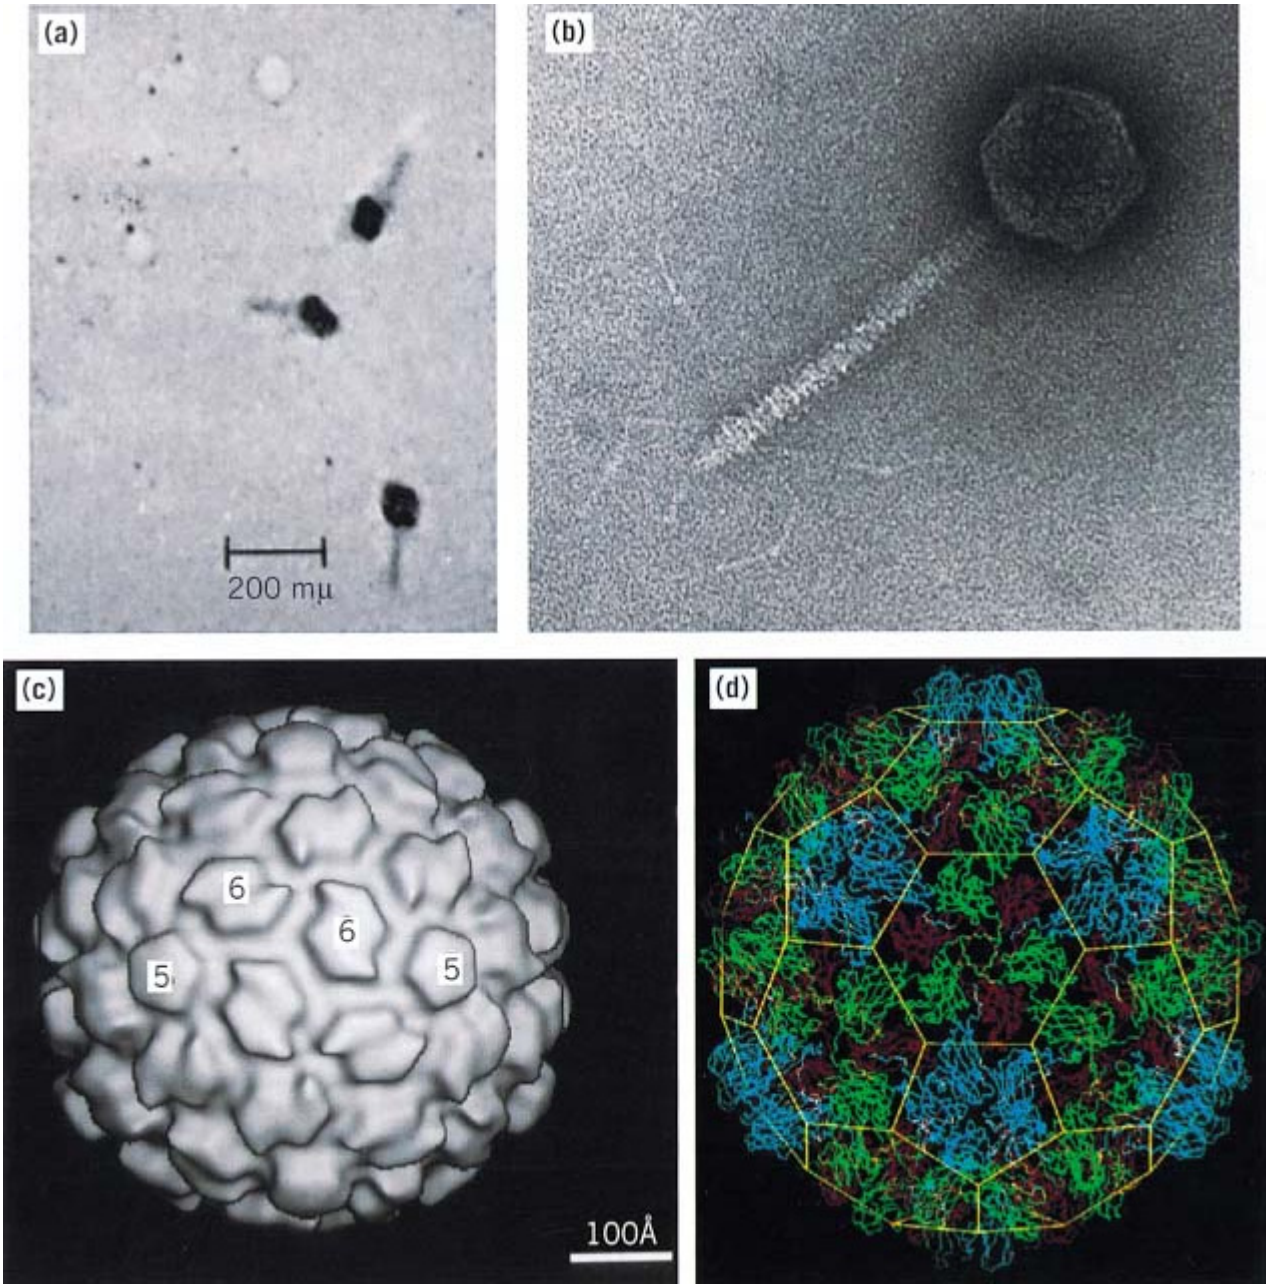
1. Methods Used to Determine Virus Structure

Their small size puts virions below the practical resolution limit of the light **microscope**. Because we are therefore denied a direct "look" at the virions, the way we conceptualize them depends on a series of more indirect techniques, which will be reviewed here briefly before describing more specifically what is known about virus structure. When viruses were first discovered a century ago, they were initially defined simply as disease-causing agents that could pass through a filter that retains bacteria. This provides a rough upper limit on the size of virions, and this estimate was refined in subsequent years by using sets of filters with graded series of pore sizes and by biophysical techniques such as **sedimentation velocity** and **sedimentation equilibrium**, which gave estimates of both size and shape for the virus particles under study. However, it was not until the invention of the **electron microscope** that a detailed idea of the shapes of virions was possible. The first experiments with viruses and electron microscopy showed that tobacco mosaic virus (TMV) is rod-shaped (and of dimensions consistent with the earlier biophysical measurements) and that bacteriophage T2 looks somewhat like a tadpole or a spermatozoan. The quality of the images obtained by electron microscopy improved substantially in the mid-1950s with the advent of the technique of **negative staining**, which provides improved contrast and also stabilizes virions against the distortion produced when they are dried before being inserted into the vacuum of the microscope. Much of what we currently know about virus structure comes from experiments with negative stain electron microscopy (in conjunction with an extensive catalog of genetic, biochemical, and biophysical methods that make it possible to enumerate the component molecules in the virion, dissect the virion, and localize different components in the structure). In recent years, three additional techniques have substantially increased the resolution with which we know the structures of the virions to which they can be applied. These are, first, cryoelectron microscopy, which allows virions to be viewed in the frozen hydrated state, with their structure essentially perfectly preserved. The resulting images have very low contrast and are of limited use by themselves, but the second technique, computerized image processing and filtering, allows a large number of individual images to be combined to produce three-dimensional **reconstructions** of the virions of very good quality. The third technique, X-ray crystallography, has now been applied to a number of viruses and yields three-dimensional structures at near atomic resolution. A particularly interesting recent development is that in favorable cases, the above three techniques can be combined to produce structural results that neither technique alone would be able to produce.

While it is impractical to reproduce here examples of all the structural types that have been determined for different viruses, Figure 1 shows a few representative examples of the different sorts of images that are produced. There are now extensive collections of such images widely available on

the World Wide Web.

Figure 1. Different methods of visualizing virion structures. (**a**) One of the first electron micrographs of a virus. This picture of bacteriophage T2 is from Luria and Anderson (5). (**b**) Bacteriophage l, negatively stained with uranyl formate (courtesy of Robert L. Duda). (**c**) Image of the "Prohead II" capsid precursor of bacteriophage HK97, viewed down a twofold symmetry axis at a resolution of 24 Å. This image is reconstructed from images of approximately 100 individual particles, produced by cryoelectron microscopy. The numbers superimposed on the capsid indicate the positions of some of the pentamers and hexamers of the identical protein subunits (courtesy of James F. Conway). (**d**) Image of Cowpea Chlorotic Mottle Virus at near-atomic resolution, produced by X-ray crystallography and viewed down a three-fold symmetry axis. The red, green, and blue lines are traces of the a-carbon backbones of the 180 protein subunits. (The positions of the amino acid side chains are known but omitted from this representation for clarity.) Like colors identify protein subunits related to each other by the icosahedral symmetry axes. The yellow lines show the positions of the hexamers and pentamers of the protein subunits (courtesy of John E. Johnson). Approximate magnifications for the four images are: (**a**), 53,000×; (**b**) 320,000×; (**c**) 1,100,000×; (**d**) 2,000,000×. See color insert.



2. Composition and Structure of Virions

Virions are the structures by way of which the viral genome travels from one cell to another—from the cell where the virion was produced to the cell it will infect. As such, the virion has two apparent functions. First, it must protect the genome from environmental damage; and second, it must successfully deliver the genome to the next cell. Viruses with different hosts typically face rather different "problems" in both regards, and these differences, particularly differences in mechanisms of infection, appear to account for many of the observed differences in the structures of virions. Beyond the various structural elaborations that address differences in extracellular environment and differences in the properties of cells to be infected, we will see that the viral coats are constructed according to a rather small number of structural principles.

All virions must of course contain a copy of the nucleic acid that constitutes the viral genome. However, for different viruses the genome can be DNA or RNA, it can be single- or double-stranded, or it can exist as one molecule or several. Whatever its form, virions typically contain only one copy of the genome—that is, they are haploid—but the retroviruses have two copies per virion of their single-stranded RNA genome. Viral genomes vary in size, from having enough sequence to encode only 3 to 4 proteins (eg, the single-stranded RNA bacteriophages with ~3000 bases/genome) up to genomes of several hundred kilobase pairs. The largest genome of a well-characterized virus is the 330,740-bp dsDNA genome of the algal virus PBCV1. Bacteriophage G has a double-stranded DNA genome measured at ~650,000 bp—bigger than the smallest bacterial genomes—but it is not yet known whether that is all unique sequence DNA. As a rule, RNA genomes cluster at the small end of the genome size scale. DNA genomes span nearly the whole range, and all the biggest of the known viral genomes—over about 20 kbp—are double-stranded DNA. Some genomes are modified by the covalent addition of a protein; examples include Poliovirus, which has a protein called **VpG** attached to the 5′-end of its single-stranded RNA genome with a role in facilitating translation from the genome when it acts as messenger RNA, and Adenovirusand some bacteriophages (f29 and PRD1), which have proteins covalently bound to the 5′-ends of their double-stranded DNA genomes to carry out a crucial role in initiation of DNA replication (1). The genome in many viruses is associated noncovalently with protein, either virus-encoded protein(s) or host histone proteins, while in other viruses the nucleic acid is packed devoid of protein and accompanied only by water and counterions.

The only other structural feature of virions that is invariant over all known viruses is that a major component of the virion is protein. At a minimum, there is one protein, present in multiple copies (typically several hundred). More often, there are several different proteins present, one or a few in large numbers ("major proteins") and the rest ("minor proteins") in smaller numbers (1 to 50 copies/virion). The major protein or proteins make a container for the genome known as a **capsid**. (There is some variability in usage for different virus groups. Here we will take capsid to refer to just the helical or icosahedral proteinaceous container, and not any other nongenome components that might be part of the virion.) As discussed in more detail in the entry **Capsids**, the major protein(s) of the capsid are arranged either with helical symmetry, resulting in a rodlike structure, or with icosahedral symmetry, which produces a roughly spherical protein shell.

For some viruses, there is no more to the structure of the virion than the genome and a simple protein capsid. For many plant viruses, no additional structural elaboration is needed for successful infection because they are delivered directly to their host cells by insects feeding on the plants. Other structurally simple viruses incorporate into their capsid proteins the receptor-binding function they need to attach to cells as the first step of infection. It is also very common, however, for viruses to have additional, more or less elaborate protein structures in addition to the basic capsid, and these usually have a role in getting the virus or its genome into the cell it is infecting. Perhaps the best known of these are the tails and associated tail fibers of the double-stranded DNA bacteriophages (as well as of the morphologically similar examples of archaeal viruses). These six-fold symmetric helical structures attach to one of the five-fold symmetric "corners" of the phage head. Tails can be short structures or extended tubes, in some cases with contractile sheaths. They function to recognize

and attach to the surface of the host cell and to mediate passage of the phage DNA across the complex bacterial cell envelope. Many viruses have fibers or spikes extending out from the capsid shell. A well-studied example is the trimeric fibers of Adenovirus that are found at each of the 12 pentameric "corners" of the virion and which are responsible for the initial attachment of the virus to its host cell. Reovirus and its relatives, including some bacteriophages, have two concentric icosahedral protein shells surrounding the genome—in this case segmented dsRNA. The outer shell is important for attachment and entry of the virus, but it is removed once the virion is in the cell. The inner shell, in contrast, remains intact with the genome inside and serves as a factory for transcribing the genome. The resulting RNA leaves the inner shell and serves as mRNA and eventually as virion RNA in progeny virions. The transcription into ssRNA and the conversion of ssRNA to genomic dsRNA are both accomplished by a virus-encoded **RNA polymerase** found inside the virion.

Many animal viruses and, much less commonly, other viruses have a lipid envelope surrounding the protein capsid and genome. The envelope typically has a central role in virus entry through the cellular membrane; this is most often (but not invariably) accomplished by fusion between the viral and cellular membranes, which results in a joining of the contents of the viral envelope with the cytoplasm of the cell. The lipids in the viral envelope are derived from the membrane of the infected cell, and they are arranged in a standard bilayer. The membrane is usually heavily studded with virus-encoded glycoproteins, which have roles in cell entry and in dealing with the host immune system and other aspects of their extracellular environment. In many cases, these viral glycoproteins are responsible for inducing fusion between the viral and cellular membranes. The best-studied such "fusion protein" is the **Influenzavirus hemagglutinin**, which undergoes a dramatic rearrangement of its polypeptide fold as a part of the process of promoting fusion (2). A few viruses have internal membranes that surround the genome but are inside the protein capsid shell [eg, algal virus PBCV1 and bacteriophage PRD1 (1)]. The biological function of these internal membranes is not well understood.

Although virion structures as a class are quite well characterized, there are features of the structures of some virions that are rather poorly understood. Among these we give three examples: (i) Retroviruses have a protein shell inside the envelope and surrounding the genome, and this has been assumed to have icosahedral symmetry, like all the well-characterized "spherical" capsids. However, a recent study with this structure from the HIV virion shows that it is not icosahedral but rather has a less well-defined subunit arrangement (3). (ii) Although some of the viruses of the Archaea have the morphology of tailed bacteriophages, others have virions with the shapes of lemons or corn dogs, which have no parallels in the viruses of other hosts (4). The molecular architecture of these virions is very poorly known. (iii) Some viruses with otherwise well-characterized virions have substructures in their virions that are less well understood. For example, Herpesvirus has an apparently amorphous, thick layer of protein, called the tegument, which surrounds the icosahedrally symmetric capsid, but lies inside the membrane envelope.

Viruses, Animal

Viruses have long been invisible partners, because of small size of their particles, of life on this planet, including animals, and the discipline of virology was born only 100 years ago. Compared to cells, virus particles have much simpler structures, with splendid regularity (see Fig. 1 of Virus Infection, Animal). Therefore, **X-ray crystallographic** studies have been performed successfully for some kinds of viruses and have generated precise structures of the whole virion particles. These structural studies give an insight into molecular basis of interaction of proteins in assembled proteins of virion particles.

Viruses carry their own genomes that encode the genetic information for their replication in infected cells. Because of being obligatory parasites of host cells, viruses largely depend on host components and metabolism for their replication. In general, viruses use macromolecular biosynthesis pathways common to those in host cells. They often have, however, special mechanisms of DNA replication and gene expression that give advantage to viruses in the competition for cellular resources, resulting in death or immortalization of the host cells. Thus studies of virus replication have frequently led to discoveries of novel mechanisms in infected cells.

A number of molecular interactions between viral and host factors occur in infected hosts. Development of virus diseases must reflect the sum total of the interactions between virus and cells involved in the virus-specific response to replication, dissemination in an entire body, and host immune responses. Virus replications are actually limited to specific species, tissues, and cell types within hosts. These virus responses must be due to the distribution of host factors that support the virus replication. As such host factors, new molecules with unknown natural functions may be discovered, and new research projects with such molecules may open in other fields of the life sciences, such as cell biology. New functions of known molecules may also be found. Thus, identification of host factors affecting the virus replication and dissemination is very important for understanding the development of virus diseases, as well as of host mechanisms at molecular level. Complete understanding of the molecular basis of virus pathogenicity and replication in a whole body would help in the use of viruses as virus-related expression vectors in future gene therapy.

Animal virology has always been one of the leading edges in the field of molecular biology. This volume contains current molecular biological information available from studies on representative animal viruses, and individual entries describe the most recent molecular biological information of a particular virus: adenovirus, cytomegalovirus, Epstein–Barr virus, helper virus, hepatitis B virus, herpesvirus, HIV, influenza virus, papovavirus, poliovirus, polyomavirus, reovirus, rhinovirus, Rous sarcoma virus, Semliki Forest virus, Sendai virus, SV40, vaccinia virus, and vesicular stomatitis virus. The information contained is unlikely to be altered in the future, although new and important concepts of the field of animal virology will continue to contribute to all of the life sciences.

Viruses, Plant

More than 780 viruses that infect **plants**, some of which are of major agricultural importance, have now been recognized. These have been grouped into 48 genera and 10 families by the International Committee on Taxonomy of Viruses (1) (Table 1). This classification is based on various characters, such as composition and organization of their genomes, particle morphology, and biological properties (see Virus Infection, Plant). Most of these virus families are unique to plants but some, eg, Reoviridae, Rhabdoviridae, and Bunyaviridae, also have members that infect animals, including invertebrates; it is thought that members of these groups might be viruses of their insect vectors that are becoming adapted to plants. Because plant viruses often occur in relatively high concentrations in plants, many of them can be easily purified and have therefore attracted attention as models for studies on structure, protein:nucleic acid interactions, and molecular biology. Details on the pathology of these viruses are given in Virus infection, plant.

Table 1. Classification of Plant Viruses

Genome[a]	Family	Genus	Type member	Particle shape	No. genome segments	No. spp.	No. tentative spp.
ds DNA (RT)		Badnavirus	Commelina yellow mottle virus	b[a]	1	10	4
		Caulimovirus	Cauliflower mosaic virus	i	1	11	6
ss DNA	Geminiviridae	Subgroup I	Maize streak virus	g	1	11	2
		Subgroup II	Beet curly top virus	g	1	1	2
		Subgroup III	Bean golden mosaic virus	g	1 or 2	49	9
ds RNA	Reoviridae	Fijivirus	Fiji disease virus	ic	12	5	0
		Oryzavirus	Rice ragged stunt virus	ic	10	2	0
		Phytoreovirus	Wound tumor virus	ic	12	3	0
	Partitiviridae	Alphacryptovirus	White clover cryptic virus 1	i	2	16	10
		Betacryptovirus	White clover cryptic virus 2	1	2	4	1

ss RNA (–)	Rhabdoviridae	Cytorhabdovirus	Lettuce necrotic yellows virus	bc	1	8	0
		Nucleorhabdovirus	Potato yellow dwarf virus	bc	1	6	0
		Unassigned		bc	1	61	0
	Bunyaviridae	Tospovirus	Tomato spotted wilt virus	ic	3	2	0
		Tenuivirus	Rice stripe virus	f	4	4	3
ss RNA (+)	Bromoviridae	Alfamovirus	Alfalfa mosaic virus	b	3	1	0
		Bromovirus	Brome mosaic virus	i	3	6	0
		Cucumovirus	Cucumber mosaic virus	i	3	3	0
		Ilarvirus	Tobacco streak virus	(i)	3	16	0
	Comoviridae	Comovirus	Cowpea mosaic virus	i	2	15	0
		Fabavirus	Broadbean wilt virus	i	2	3	0
		Nepovirus	Tobacco ringspot virus	i	2	28	8
	Potyviridae	Bymovirus	Barley yellow mosaic virus	f	1	5	0
		Potyvirus	Potato virus Y	f	1	75	93
		Rymovirus	Ryegrass mosaic virus	f	1	5	2
	Tombusviridae	Carmovirus	Carnation mottle virus	i	1	12	7
		Tombusvirus	Tomato bushy stunt virus	i	1	13	0
	Sequiviridae	Sequivirus	Parsnip yellow fleck virus	i	1	3	0

Waikavirus	Rice tungro spherical virus	i	1	3	0
Carlavirus	Carnation latent virus	f	1	29	31
Capillovirus	Apple stem grooving virus	f	1	3	1
Closterovirus	Beet yellow virus	f	1	6	19
Dianthovirus	Carnation ringspot virus	i	1	3	1
Enamovirus	Pea enation mosaic virus	i	2	1	0
Furovirus	Soil-borne wheat mosaic virus	r	2	5	5
Hordeivirus	Barley stripe mosaic virus	r	3	4	0
Idaeovirus	Raspberry bushy dwarf virus	i	2	1	0
Luteovirus	Barley yellow dwarf virus	i	1	16	14
Machlomovirus	Maize chlorotic mottle virus	i	1	1	0
Marafivirus	Maize rayado fino virus	i	1	3	0
Necrovirus	Tobacco necrosis virus	i	1	2	2
Potexvirus	Potato virus X	f	1	20	21
Sobemovirus	Southern bean mosaic virus	i	1	10	5
Tobamovirus	Tobacco mosaic virus	r	1	13	2

Tobravirus	Tobacco rattle virus	r	2	3	0
Trichovirus	Apple chlorotic leafspot virus	f	1	2	3
Tymovirus	Turnip yellow mosaic virus	i	1	17	1
Umbravirus	Carrot mottle virus	—	1	5	4

[a] Genome type: ds DNA(RT) = double–stranded DNA (replicating by reverse transcription); ss DNA = +single–stranded DNA; ds RNA = double–stranded RNA; ss RNA(–) = (–)–sense RNA; ss RNA(+) = (+)–sense RNA(mRNA).

[b] b = bacilliform; bc = complex bacilliform; f = filamentous rod; g = geminate; i = isometric; (i) = possibly isometric; i = complex isometric; r = rigid rod.

1. Structure

The particles of most plant viruses have a relatively simple structure, being composed of the viral genome surrounded by a **capsid** composed of one or more coat protein species. As well as protecting the genome from degradation by, say, **nucleases**, the capsid presents the external features of the virus to the environment. Thus, it is involved in interactions essential to stages of the virus infection cycle external to the cell. Viruses require such interactions in movement from plant to plant, but not from cell to cell within the plant (see Virus Infection, Plant). There are two basic forms of structure: *rod-shaped* and *isometric* particles (Table 1).

The rod-shaped particles of viruses range from short rigid rods (eg, tobacco mosaic virus, TMV) to long flexuous rods (eg, beet yellows closterovirus). In these particles, the coat protein subunit is arranged in a helix, with the RNA genome embedded in it (see Tobacco Mosaic Virus for more detail) and the particles are stabilized by both protein:protein and protein:RNA interactions.

The structure of isometric particles follows the constraints imposed by **icosahedral symmetry** (2), with the **quasi-equivalent** arrangement of coat protein subunits according to strict surface lattice criteria. Most plant isometric particles have a triangulation number $T = 3$ (180 coat protein subunits), but there are examples of $T = 1$ (60 subunits; eg, *satellite tobacco necrosis virus*) and $T = 7$ (420 subunits; eg, cauliflower mosaic virus). A range of interactions are involved in the stabilization of the isometric particles. For instance, the particles of *alfalfa mosaic alfamovirus* (AMV) and *cucumber mosaic cucumovirus* (CMV) are stabilized primarily by electrostatic interactions between protein and RNA and dissociated by high salt concentrations. Those of *brome mosaic bromovirus* (BMV) are stabilized by protein:RNA interactions and a protein:protein interaction that involves an unusual carboxylate group which protonates above pH 7. The particles of *southern bean mosaic sobemovirus* (SBMV) have the two interactions found in BMV and also a protein:protein interaction mediated by Ca^{2+}. Adjustment of the pH to more than 7 and chelation of Ca^{2+} leaves the particles of viruses such as BMV and SBMV stabilized by just protein:RNA interactions; in this situation, the particles appear to swell hydrodynamically. These swollen particles and those of AMV and CMV have been shown to be uncoated by the cotranslational disassembly mechanism (see Virus Infection, Plant). Other viruses, such as *cowpea mosaic comovirus*, have icosahedral particles stabilized by

strong protein:protein interactions with relatively little involvement of protein:RNA interactions. Preparations of such viruses have a proportion of "empty" particles that do not contain nucleic acid.

Variations on icosahedral symmetry are found among plant viruses. The particles of *geminiviruses* appear to be two $T = 1$ icosahedra joined together at a five-fold axis (3). Other viruses (eg, alfalfa mosaic virus, *badnaviruses*) have bacilliform particles that can be considered isometric particles cut in two, followed by the insertion of a tubular portion made up of hexamer subunits (4).

There are some groups of plant viruses that have more complex structures. These are viruses such as rhabdoviruses, tospoviruses, and reoviruses that have counterparts among animal viruses and are considered to be insect viruses adapting to plants. Details of these structures can be found in (1).

2. Genomes

The majority of plant viruses (71%) have (+)-strand (messenger-sense) RNA as their genome; genomes are also found that consist of double-stranded DNA (4%), single-stranded DNA (9.5%), double-stranded RNA (5%), and (–)-strand RNA (10.5%). The double-stranded DNA genome plant viruses replicate by **reverse transcription**, and there are no plant viruses known with double-stranded DNA genomes that replicate the DNA directly.

2.1. Genome, Structure, Organization, and Expression

Plant viruses encode products that facilitate their replication, encapsidation, and in most cases, their movement within and between plants (see Virus Infection, Plant). Expression of these products is constrained by the limitations of eukaryotic ribosomes being able to **translate** only the 5′ **open reading frame** of a messenger RNA (mRNA). Both plant and animal viruses, have developed various strategies for overcoming this limitation. The genome organizations of typical members of the 48 genera (where sequence data are available) are illustrated in Figure 1.

Figure 1. Genome organizations of groups of plant viruses. The illustration is of the type member of the group (Table 1) except subgroup III geminiviruses, African cassava mosaic virus; nucleorhabdovirus, sonchus yellow net virus; nepovirus, tomato blackring virus; carlavirus, potato virus M; dianthovirus, red clover necrotic mottle virus; umbravirus, groundnut rosette virus. The genome is represented by two concentric circles for double-stranded circular genomes; one circle for single-stranded circular genomes; a straight line for linear genomes; subgenomic mRNA are shown as thin lines. The size of the genome is given in nucleotides (nt or base pairs, bp). The terminal features of the genomes, when they are known, are listed on the figure. The gene products are indicated by boxes, with the directions of those of ambisense genomes given by an arrow. The molecular size of the gene product is $\times 10^{-3}$. The symbols for functions of gene products and expression by read through of a weak stop codon are indicated on the figure.

2.2. Double-stranded DNA Viruses

The genomes of the two genera of double-stranded DNA viruses are similar in that they are circular molecules of about 7.2 to 8.0 kbp, with one or more discontinuity in each strand; these discontinuities are described in more detail in Cauliflower mosaic virus. The viral DNA of both these genera is transcribed asymmetrically to give a more-than-genome length RNA. The genomes of the badnaviruses encode three or four proteins. The largest badnavirus open reading frame is expressed as a **polyprotein** (Fig. 1), which is processed to yield the viral coat protein (CP), a carboxyl proteinase (Pro), and reverse transcriptase plus ribonuclease H (RT + RH) (the enzymes involved in reverse transcription). The three open reading frames of most badnaviruses are expressed from the genome-length RNA transcript by unusual mechanisms involving '*ribosomal shunting*' and leaky translation initiation (see (5) for a review).

2.3. Single-stranded DNA Viruses

Geminiviruses have circular single-stranded DNA molecules of about 2.7 to 3.0 kb. The three genera of the Geminiviridae have similarities in their genome organizations and expression, but there are differences. Subgroups I and II have monopartite genomes, with members of subgroup 1 infecting monocotyledenous plants and those of subgroup II dicotyledons. The genome of most subgroup III members (which infect dicotyledenous plants) is divided between two DNA molecules. Members of subgroups I and II are transmitted by leafhoppers, those of subgroup III by whiteflies. In all cases, the genomes are transcribed bilaterally from a characteristic region near the mapping zero point (termed the *common region* for subgroup III members), the transcripts terminating on the opposite side of the genome. Thus, one transcript is from the virus-sense DNA and the other from the complementary-sense DNA. Each of these transcripts expresses one or more proteins (Fig. 1) through mechanisms that involve both different transcript origins and splicing. Molecular aspects of geminiviruses are reviewed in (6, 7).

2.4. Double-stranded RNA Viruses

The genome organizations of plant viruses with double-stranded RNA genomes in many cases resemble those of animal-infecting reoviruses. Members of the plant Reoviridae are insect-transmitted, and the virus multiplies in the vector. The genomes of these viruses are divided between 10 or 12 segments of about 2.5 to 0.8 kb that, in most cases, are monocistronic (8). These encode the various proteins that make up the virion structure, together with various nonstructural proteins, including the viral polymerase.

The *cryptic* viruses (Partitiviridae) have no known vectors and are spread by the vegetative propagation of their hosts. Their genomes have only two monocistronic genome segments, one encoding the viral polymerase and the other the coat protein (9).

Each genomic RNA of these double-stranded RNA viruses has a conserved terminal oligonucleotide sequence that is thought to be genus-specific (8).

2.5. Single-stranded (–)-Sense RNA Genomes

Two of the three families of plant viruses with (–)-sense RNA genomes resemble viruses that infect animals, and they have many common genome organizational features. They also replicate in their insect vectors. The best characterized rhabdovirus, Sonchus yellow net virus, belongs to the Nucleorhabdovirus genus and has a genome organization identical to animal rhabdoviruses, except that it has an extra gene product (sc4) (Fig. 1) (10). The genome length (–)-sense RNA is transcribed into monocistronic subgenomic mRNA, molecules.

The Tospoviruses resemble the animal Phlebovirus genus of the Bunyavirus family in having three genome segments, the largest (L RNA, Fig. 1) of which is (–) sense and the other two having an *ambisense* expression strategy. In this, the medium and smallest RNA segments of Tospoviruses (M and S RNA) each encode one protein from the 5′ end of the viral-sense RNA and another protein from the 5′ end of the complementary RNA strand (ie, the open reading frame is at the 3′ end of the viral-sense RNA). The ambisense strategy is taken even further in the Tenuiviruses, which have their

largest genome segment (RNA1, Fig. 1) as (–)-sense RNA and the other three (RNAs 2, 3, and 4) with the ambisense arrangement. In both the Tospoviruses and Tenuiviruses, the largest RNA encodes the RNA-dependent **RNA polymerase**. Molecular aspects of tospoviruses are reviewed in (11) and those of tenuiviruses in (12).

2.6. Single-stranded (+)-Sense RNA Genomes

This genome, the most common type found in plant viruses, acts as an mRNA. A range of structures are found at the ends of these RNA (indicated in Fig. 1). Many viruses have a methylated blocked 5′ teminal group

$$m7G^{5'}ppp^{5'}X^{(m)}Y^{(m)}p\cdots$$

where $X^{(m)}$ and $Y^{(m)}$ are methylated bases. Others have a virus-encoded protein covalently linked to the 5′ end of the genomic RNA. The linkage of this protein, the *Vpg*, has been identified in some cases and, for cowpea mosaic, has been shown to be a phosphodiester bond between the b-hydroxyl group of a serine residue at the N-terminus of the Vpg and the 5′-terminal uridine residue of the two genomic RNA. At the 3′ end, some viruses have a **polyadenylate** sequence resembling that of many eukaryotic mRNAs. Other viruses have 3′ sequences that fold to resemble transfer RNA (tRNA). These structures will accept amino acids; eg, that of TMV accepts histidine, BMV and CMV accept tyrosine, and turnip yellow mosaic tymovirus accepts valine. Barley stripe mosaic hordeivirus has a 3′-terminal tRNA-like structure (accepting tyrosine) and an internal poly(A) tract (Fig. 1). The functions of these 3′ structures are unknown but thought to be involved with replication.

The 5′ noncoding regions of several plant viruses have been shown to have translational enhancing activity. That of TMV, the W sequence, is discussed in Tobacco mosaic virus. The 3′ noncoding regions of some viruses fold as **pseudoknots** with unknown function.

An apparently wide range of genome organizations and expression is found in viruses with (+)-sense RNA genomes (Fig. 1), but, if we take into consideration the limitations of eukaryotic ribosome translation, certain basic features emerge. There are two predominant methods by which the four or more gene products are expressed from these viral genomes. In the first, exemplified by carmoviruses, luteoviruses, potexviruses (see Fig. 1), and TMV, the 5′ cistron is expressed from the virion RNA, and most of the downstream cistrons are expressed from subgenomic RNAs that are transcribed from the (–)-strand replication intermediate. There are some subtleties in the expression of the 5′ genetic information in that, in eg, carmoviruses and TMV, the first two or three open reading frames are separated by weak stop codons that are read through. A variant of this strategy is to **frameshift** between the first and second open reading frame of, eg, luteoviruses, when ribosomes change reading frame from one **cistron** to that of an overlapping cistron. In both read through and frame shift, the larger product is formed to a much lesser extent than the 5′ product. The division of the genome into monocistronic units is taken even further in many genera of plant viruses that have multipartite or divided genomes. The genome is divided into two or three segments that are encapsidated separately. For example, members of the Bromoviridae (Alfamovirus, Bromovirus, and Cucumovirus) have their genomes divided into three segments. The larger two segments are monocistronic, whereas the smallest segment is bicistronic but expresses the 3′ cistron from a subgenomic RNA.

The second predominant method by which viral gene products are expressed is by having a single open reading frame on the genomic RNA that is translated to give a polyprotein. This is processed to the functional proteins by one or more proteinases encoded within the polyprotein. Potyviruses, Sequiviruses, and Waikaviruses are examples of viruses with a single genome segment that follow this strategy. Comoviruses, Nepoviruses, and Bymoviruses have their genomes divided into two segments, each of which encodes a polyprotein. The processing pathways can be complex, as shown by Comoviruses (Fig. 1).

2.7. Genome Replication
The replication of the various type of genome is discussed in Virus infection, plant.

Virusoids

Virusoids are a particular class of plant **satellite RNA** (Fig. 1). Satellite RNAs are always functionally dependent on specific helper viruses and are encapsidated by the coat protein of these helper viruses. They can be regarded as molecular parasites and in most cases reduce the titer and attenuate the symptom expression of their supporting viruses. Satellite RNAs do not have extensive sequence similarity with the RNA of the helper virus.

Figure 1. Classification of satellite RNAs from plants.

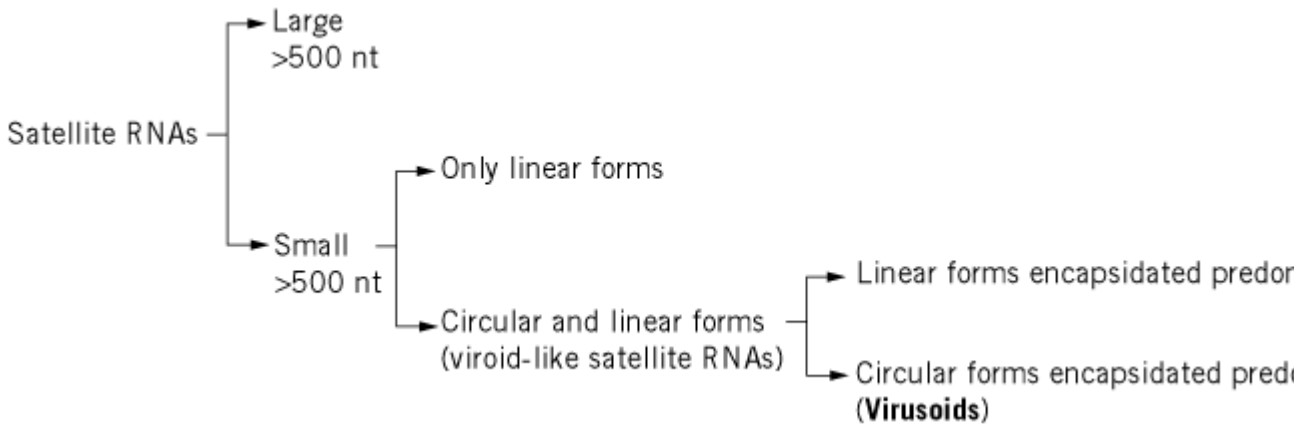

Figure 1 shows the groups into which plant satellite RNAs can be subdivided. Large satellite RNAs can encode proteins, whereas small satellite RNAs do not. Viroid-like satellite RNAs (Table 1) are single-stranded molecules present in infected tissue in both circular and linear forms, are structurally similar to viroids, and most likely replicate by the same type of **rolling circle** mechanism. A property that is unique to the viroid-like satellite RNAs of sobemoviruses is that the circular form is the predominant RNA encapsidated by the coat protein of the helper virus, and on this basis the term virusoid has been proposed for them; in contrast, the linear form is predominantly encapsidated in viroid-like satellite RNAs of nepo- and luteoviruses (1). It is also worth noting that at least one plant viroid-like RNA has been found in association with an **homologous** DNA counterpart forming what has been called a retroviroid-like element (2).

Table 1. Virusoids and Other Viroid-like Satellite RNAs with Their Abbreviations, Genomic Accession Numbers of Typical Sequence Variants, Sizes, and Group to Which They Belong

Viroid-like Satellite RNA	Abbreviation	Accession	Size (nt)	Group
Lucerne transient streak virusoid	vLTSV	X01984	322–324	Sobemovirus
Solanum nodiflorum mottle virusoid	vSNMoV	J02386	377	Sobemovirus
Subterranean clover mottle virusoid	vSCMoV	M33000	322, 388	Sobemovirus
Velvet tobacco mottle virusoid	vVTMoV	J02439	365–366	Sobemovirus
Rice yellow mottle virusoid	vRYMV	AF039909	220	Sobemovirus
Cereal yellow dwarf virus RPV satellite RNA	SCYDV-RPV RNA	M63666	322	Luteovirus
Tobacco ringspot virus satellite RNA	sTRSV RNA	M14879	359–360	Nepovirus
Arabis mosaic virus satellite RNA	sArMV RNA	M21212	300	Nepovirus
Chicory yellow mottle virus satellite RNA	SCYMoV RNA	D00721	457	Nepovirus

All known viroid-like satellite RNAs contain ribozyme (catalytic RNAs) domains in one or in both polarity strands. The ribozymes of virusoids and sCYDV-RPV RNA are of the hammerhead type and can be adopted by either both polarity strands (vLTSV and sCYDV-RPV RNA) or only their plus polarity strands (vSNMoV, vSCMoV, vVTMoV, and vRYMV). Viroid-like satellite RNAs from nepoviruses can form hammerhead and hairpin (or paperclip) ribozymes in their plus and minus polarity strands, respectively. These ribozymes most probably play a role in replication: hairpin structures mediate both RNA self-cleavage and self-ligation (3), whereas hammerhead structures mediate self-cleavage only (4-6).

It has been proposed that viroid-like satellite RNAs have a common **phylogenetic** origin with viroids and that they could be molecular fossils of the RNA world (7). The RNA of human hepatitis delta virus shares some properties with viroid-like satellite RNAs, including circular structure, functional dependence on a helper virus, and presence of ribozymes in both polarity strands. One key question to be addressed is the characterization of the determinants responsible for the specificity of the interaction between each viroid-like satellite RNA and its helper virus.

Water

Water is common yet indispensable to life. It is the most abundant constituent of most living organisms, comprising more than 60% of the weight of an adult man. A living creature constructs its own structure, having a definite boundary with its environment but not isolated from it. In physical terms, it is a stationary, open system that maintains its structure and functions by using materials and energy incorporated from the environment. For metabolism to function, a liquid medium is required. Many of the biomolecules involved in metabolism must have polar groups, and the liquid medium needs to dissolve these substances. Only water satisfies this requirement and exists in large amounts on the earth. Various biological effects of water arise from the characteristics of its interactions with biomolecules, i.e., their hydration. According to their physical nature, hydration phenomena are grouped into two categories: (*i*) hydrophilic hydration of ionic and nonionic polar groups, and (*ii*) **hydrophobic** hydration of nonpolar groups (1, 2). The structural and physical properties of pure water are described here to help in understanding the role of water in biological phenomena.

Water exhibits three phases—gas, liquid and solid—around its triple point at a pressure of 610.6 pascal (Pa) and a temperature of 273.16 K. Under other conditions, two phases coexist at the phase boundary between them. The gas-liquid coexistence curve ends at the critical point pressure of 22.12 MPa, temperature of 647.3 K, and density of 0.322 g cm^{-3}, no liquid phase appears at higher temperatures. Unlike most other liquids, water has a solid-liquid coexistence curve with a negative slope near the normal pressure of 1 atm (0.101325 MPa), at which point an increase in pressure leads to a decrease in the melting (fusion) temperature. At normal pressure, water can be supercooled to –39.5°C, but this is only a metastable state, not an equilibrium, and the solution will eventually freeze. Various physical properties of water are listed in Table 1.

1. The Water Molecule

The water molecule is small, composed of one oxygen and two hydrogen atoms, and has an average molecular weight of 18.01529. There are three isotopes for both oxygen and hydrogen atoms: ^{16}O, ^{17}O, and ^{18}O for oxygen, and ^{1}H (H, or protium), ^{2}H (D, or deuterium), and ^{3}H (T, or tritium) for hydrogen. Tritium is a radioisotope with a half-life of 12.33 years, so there are nine stable isotopic species of water. The natural abundances of the major species are 99.728% $^{1}H_2{}^{16}O$, 0.200% $^{1}H_2{}^{18}O$, 0.040% $^{1}H_2{}^{17}O$, and 0.032% $^{1}H^{2}H\ ^{16}O$. The molecular weight listed in Table 1is the average weight, with respect to these proportions.

Various unique properties of water originate from the specific structure of the water molecule. It has a bent structure (Fig. 1(**a**)), and the HOH bond angle is 104.52°. The O-H bond length is 95.72 pm

(or 0.9572 Å) for the lowest-energy structure but fluctuates thermally about 10% at room temperature. Two of the six outer-shell electrons of the O atom are involved in the formation of two O-H bonds, and the remaining four electrons make two lone pairs. As the electronegativity of the O atom is significantly greater than that of the H atom, the electron cloud of the O-H bonds is pulled closer to the O atom. As a result, a deficit and an excess of electron density are produced near the H and O atoms, respectively. This is the reason the water molecule has a fairly large electric dipole moment, 1.834 debye (D, or 6.117×10^{-30} Coulomb m), for its small size. In molecular models for computer simulations, the polarized distribution of electrons in the water molecule is approximately taken into account by assuming that the H and O atoms have positive and negative partial point-charges, respectively (Fig. 1(**b**)) (3).

Figure 1. The water molecule: (**a**) the lowest energy structure; (**b**) a molecular model, TIP3P, where r and ε are the position and the depth, respectively, at the minimum of the Lennard-Jones 6-12 potential, and q is the partial charge in the unit of elementary electric charge (3); (**c**) the most stable linear conformation of the water dimer, where q_d and q_a are the donor and acceptor angles, respectively; (**d**) the normal modes of vibration: n_1, symmetric stretching; n_2, deformation; and n_3, asymmetric stretching.

In the gas state, two water molecules form various types of dimers making one or two hydrogen bonds; the most stable dimer is depicted in Figure 1(**c**) (4). The hydrogen bond involves primarily Coulombic interactions between partial charges on the donor and acceptor molecules. The binding energy of such a hydrogen bond is much greater than thermal energy (*RT*). It is estimated to be 22.6 kJ mol^{-1} (5) for the linear conformation in which the three atoms O_a–H_a ¼O_b are in a straight line, as in Figure 1(**c**). The angles between the bond axis O_a O_b and the bisectors of the angles H'_a O_a H_a and H_b O_b H_b are called the donor angle q_d and the acceptor angle q_a, respectively. Although the hydrogen bond has a directional propensity, allowances for the deviation of q_d and q_a from their optimum values are fairly large: about 25° for q_d and as much as 100° for q_a (6). Both the directional propensity and the flexibility of the hydrogen bond significantly affect the structural and thermodynamic properties of liquid water and the hydration of biomolecules.

A water molecule has nine degrees of freedom: three translational, three rotational, and three intramolecular vibrational. The three vibrational modes are those of symmetric stretching (n_1 = 3656.65 cm^{-1}), deformation (n_2 = 1594.59 cm^{-1}), and asymmetric stretching (n_3 = 3755.79 cm^{-1}) (Fig. 1(**d**)). These three frequencies depend strongly on the interactions of the water molecule with neighboring molecules, especially on hydrogen bonding.

2. Ice

At normal pressure, water freezes at 0°C (273.15 K) to form a crystal called ice-I_h (Fig. 2). On being frozen at a temperature lower than –80°C in the gas phase, water forms a crystal named ice-I_c, where *c* indicates cubic. The crystal lattice of ice-I_h is hexagonal and has a tridymite-like structure: Each O atom of the water molecules is surrounded tetrahedrally by four O atoms of the nearest neighbor molecules, located at a distance of 275 pm (2.75 Å) from it. There are twelve second-nearest neighbor molecules, at a distance of 45 pm (4.50 Å). The number of nearest neighbors in ice-I_h—four—is much smaller than the 12 present in a hexagonal closest-packed structure. The resulting crystal has a large cavity parallel to its *c* axis, producing a loosely packed structure. In fact, the density (r) of ice-I_h at 0°C, (0.91671 g cm^{-3}) is only 91.7% of that of liquid water at the same temperature (0.99984 g cm^{-3}) and is also smaller than the density at the boiling point temperature of 99.974°C (0.95837 g cm^{-3}). As the water molecule can be approximated by a sphere with a diameter of 275 pm (2.75 Å), the packing density of ice at 0°C can be estimated to be 33.37%, which is only 45% of that for the closest-packed structure (74.05%). Every water molecule in ice-I_h provides two donor sites and two acceptor sites for hydrogen bonds, and the neighboring molecules are hydrogen-bonded to each other. Thus, the hydrogen bond plays an essential role in the tetrahedral structure of ice.

Figure 2. Crystal structure of ice-I_h. The filled circles are oxygen atoms and the lines connecting them are hydrogen bonds between water molecules; the hydrogen atoms are not indicated. Thick lines are drawn to indicate hexagonal rings typical of the ice-I_h structure.

Under pressures greater than about 200 MPa, ice exhibits various phases, named II–IX (7). Ice-II to ice-VI and ice-IX have the same number of first-nearest neighbors as ice-I_h, but the distances are slightly longer. Furthermore, the angles between the two axes of neighboring hydrogen bonds deviate greatly from the tetrahedral angle of 109.47°, and the distances to the second-nearest neighbors are shorter than in ice-I_h. Ice-VII and ice-VIII, which are made under the high pressure limit, both have a much greater density of ≈1.65g cm^{-3}. They have structures in which two identical lattices are overlapped, filling in each other's cavities. Each molecule in the two ices has an equal distance of 286 pm to the first- and second-nearest neighbors.

In crystals of both ice-I_h and ice-I_c, all of the O atoms are located regularly, but the position of each H atom is not specified definitely, even at 0°K, which produces a residual **entropy**. There are two potential minima for a proton between two O atoms of water molecules hydrogen-bonded to each other. If a proton moves to another minimum, a pair of ions, HO^- and H_3O^+, are created. Successive transfer of a proton from an H_3O^+ ion to an HO^- ion or to neighboring molecules brings about electric conduction. On the other hand, if a proton moves to one of the two hydrogen-bond acceptor sites of the same molecule, it results in an effective rotation of the molecule. Proton jumps of this type in an external electric field contribute to the dielectric permittivity of ice, and its large value of 94 at –2°C in the low frequency region is caused by this mechanism.

3. Liquid Water

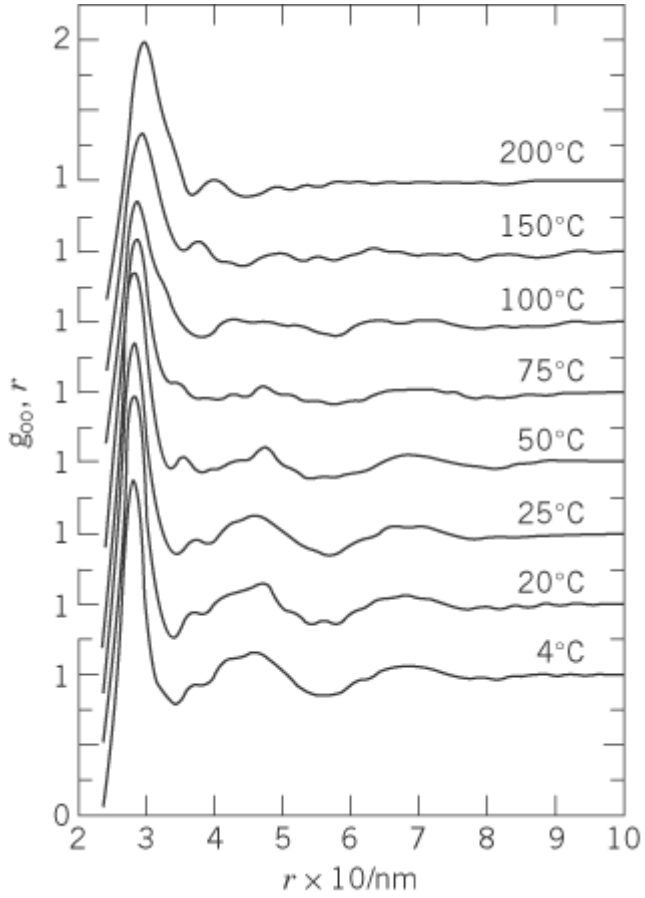
Liquid water has various structural and physical properties that differ from those of other liquids. They have significant effects on the structure and function of proteins and nucleic acids.

3.1. Structure

Using the same approximation made previously for ice, the packing density of water at 25°C is estimated to be only 36.29 %, which is significantly lower than that of nonpolar organic liquids. This suggests that liquid water has a loosely packed structure similar to that of ice. As the liquid molecules continually change their positions, the characteristics of their spatial distribution can be described only statistically. If the ordinary definition of the word “structure” for solid substances is extended to describe the spatial correlation among the molecules or atomic groups in the system

considered, the word can also be applied to liquids. The simplest function to characterize liquid structure in the above sense is the radial distribution function, $g_{ij}(r)$. It is defined as the normalized density of atom *j* at a distance *r* from the center of an atom *i*. Experimentally, the radial distribution function of the O atoms of water, $g_{OO}(r)$, can be determined from measurement of X-ray scattering by water (Fig. 3) (8). Furthermore, measurement of the **neutron scattering** profile for mixtures of light and heavy water can determine all of the three radial distribution functions, $g_{OO}(r)$, $g_{OH}(r)$, and $g_{HH}(r)$ (9). The first maximum of $g_{OO}(r)$ at $r \approx 280$ pm in Figure 3 is due to the nearest-neighbor molecules. At temperatures lower than about 50°C, a small but obvious maximum exists at $r = 450$ pm, corresponding to the distance of the second-nearest neighbors in ice-I_h. Integration of $g_{OO}(r)$ from $r = 0$ to the distance of its first minimum yields an estimate of 4.4 for the number of the nearest neighbors, *n* (the coordination number), at 25°C. This is only 10% greater than that for ice and much smaller than the mean value—about 10—for nonpolar liquids. The first peak broadens with increasing temperature, as seen in Figure 3, but *n* increases only slightly, to 4.9 at 83°C. On the other hand, both the minimum and the second peak nearly disappear at 100°C. These results indicate that a short-range structure like that of ice is nearly preserved in liquid water, but the long-range spatial correlation almost disappears at distances further than those of the second-nearest neighbors.

Figure 3. The radial distribution function, $g_{OO}(r)$, of liquid water and its temperature dependence (8).



To explain these experimental facts, various models of liquid water have been proposed. The continuum model assumes that the water structure is generated by distorting the tetrahedral structure of ice in various ways (10). The mixture model regards water as an ensemble of water clusters with

different sizes, one example of which is the flickering cluster model (11). In the interstitial model, water is supposed to have a structure in which some of the water molecules enter the ice-like cavities, and the fraction of these molecules increases with increasing temperature (12). Analyses based on these models have shown that every model can reproduce the experiment observations fairly well, which means that it is difficult to define the correct structure of water only by experiments. With advances in the performance of computers, **Monte Carlo** and molecular dynamics simulations on systems composed of hundreds to thousands of water molecules have provided detailed information about the microscopic structure of water. Molecular models of water, such as ST2, SPC, TIP3P, TIP4P, and so on, are used in these calculations (3). The force field of the water molecule is assumed to be given by the sum of the repulsive forces due to outer-shell electrons, the attractive dispersion forces (see van der Waals Interactions), and the electrostatic Coulomb forces due to partial point-charges (see Electrostatic Interactions).

These theoretical studies revealed that in addition to the basic unit of the hydrogen-bond network in ice of a hexagonal ring of water molecules (Fig. 2), a similar number of pentagonal rings also exists in water. Hydrogen-bonded to each other, these rings form water clusters in which formation and rupture of hydrogen bonds continually occur. In most cases, these processes do not occur independently but are strongly correlated in nearby molecules; they occur through rearrangement of hydrogen bonds on a time-scale of picoseconds, and about 10–40 molecules participate in the collective motion (13).

3.2. Static and Dynamic Properties

Liquid water has a maximum density of 0.9997 g cm^{-3} at a temperature of 3.98°C. The observed decrease in density with increasing temperature near the freezing point is one of the unique characteristics of water. It is believed to arise from the decrease in volume due to partial collapse of the tetrahedral ice-like structure exceeding the increase in volume due to the general effect of thermal expansion caused by the increase in thermal energy. Compared to other liquids of molecules of a similar size, water has higher temperatures for melting and boiling and larger values for the dielectric permittivity, heat of fusion, heat of vaporization, specific **heat capacity**, and surface tension. All of these come about from water being an associative liquid, where constituent molecules interact with each other through hydrogen bonds. The hydrogen bond is much stronger than the van der Waals interaction which is the major cohesive force of nonpolar liquids. The large dielectric permittivity results from the combined effects of (*i*) a single water molecule having a large electric dipole for its size, (*ii*) nearby water molecules combining their dipoles by forming a locally regular structure, and in addition (*iii*) polarizing each other cooperatively to increase the magnitude of their dipole (14). The average dipole moment estimated for the water molecule in liquid at 0°C—2.45 D—is significantly greater than that in the gas state—1.834 D. This polar nature of water serves to increase the solubility of polar molecules essential to biological functions. The heat of fusion at the melting point, 6.008 kJ mol^{-1}, is only 13.3 % of the heat of vaporization at the melting point, 45.05 kJ mol^{-1}, and 14.8 % of that at the boiling point, 40.66 kJ mol^{-1}. This clearly shows that the cohesive energy of ice is mostly conserved in liquid water. The large specific heat capacity of water has an important biological significance of minimizing changes in the temperature of living organisms on changes in the ambient temperature. The large interfacial energy between water and a nonpolar medium is closely related to the **hydrophobic interaction** that occurs between nonpolar groups or molecules in water.

The intramolecular and intermolecular vibrational motions of water molecules in the liquid yields several broad bands in the spectra of infrared absorption and Raman scattering (see Vibrational Spectroscopy) (15). The peak frequency of the band for the stretching mode in the liquid, n_s, is lower than both n_1 and n_3 for the vapor. In contrast, the peak frequency for the deformation mode in liquid is shifted to a higher frequency. The values of n_s and n_2 for liquid water are intermediate between their corresponding values for vapor and ice. These changes in frequency can be explained by the effect of hydrogen-bond formation in liquid water. Besides these intramolecular modes,

intermolecular vibrational modes are observed in the frequency range lower than 1000 cm^{-1}: the constrained rotational vibration, or the libration, whose frequency spreads over the range of 300–800 cm^{-1}, and the constrained translational vibrations with frequencies of 60 and 170 cm^{-1}, which originate from the stretching and deformation vibrations of intermolecular hydrogen bonds, respectively. Rotational correlation times of the vector and tensor quantities are obtained from measurements of dielectric dispersion and nuclear magnetic resonance (NMR), respectively. The rotational correlation time for the dipole moment of water molecules in the liquid is estimated to be 8.25 ps at 25°C. This agrees fairly well with the theoretical estimate of 7.06 ps obtained by assuming that the water molecule is approximated by a sphere with a diameter of 275 pm and applying the Stokes-Einstein formula (see Hydrodynamic Volume). This indicates that water molecules in the liquid are making random rotational motions on the picosecond time-scale.

Wilson Plot

In X-ray crystallography the Wilson plot is used to determine the absolute scale of the diffracted intensities and to find the temperature factor. This is based on the equation

$$\ln \frac{\overline{I(hk\ell)}}{\sum (f_i^0)^2} = \ln C - 2B \left(\frac{\sin\theta}{\lambda}\right)^2 \qquad (1)$$

The average values of the X-ray intensities, $\overline{I(hk\ell)}$, in narrow ranges of $\frac{\sin\theta}{\lambda}$ are divided by , $\sum(f_i^0)^2$ where the summation is over all atoms in the unit cell and f_i^0 is the scattering factor of atom *i* at rest. The natural logarithm is plotted against $(\frac{\sin\theta}{\lambda})^2$, where q is the reflection angle and l the X-ray wavelength. From the straight line obtained, the thermal parameter *B* of the isotropic temperature factor and the constant *C* can be derived. This constant *C* is a factor that relates the measured intensities to their absolute value:

$$I_{\text{meas}}(hk\ell) = C \times I_{\text{abs}}(hk\ell) \qquad (2)$$

Intensities are on the absolute scale when the amplitudes of the structure factor $|F(\text{h k}\ell)| = \sqrt{I(hk\ell)}$ are expressed in electrons.

Wingless Signaling

The Wnt gene family encodes secreted **glycoproteins** that act as extracellular signals in a variety of biological processes. These proteins are approximately 400 amino acid residues long and are highly conserved at the sequence level within a pattern of 24 cysteine residues (1). Because of the conservation of Wnt genes and their importance, the elucidation of Wnt gene function has been of paramount interest for diverse disciplines. Wnt genes are important for embryonic development and cell fate specification in many organisms (2-4). In addition, *Wnt-1*, the first Wnt gene identified, is a common site of insertion for the mouse mammary tumor virus (MMTV) that results in ectopic Wnt expression in the mammary gland (1). Ectopic Wnt also transforms mammary epithelial cells in a paracrine fashion (5). Because the Wnt genes encode ligand signals, the identification of signal transduction components required for their function has been the focus of much research.

0.1. *Drosophila Wingless* as a Genetic Model for Wnt Genes

The *wingless* (*wg*) gene in *Drosophila* is a member of the Wnt gene family, as demonstrated by its ability to mimic *Wnt-1* in transforming mammary epithelial cells (6). *Drosophila* is an excellent model for studying developmental signals because it is possible to combine genetics, developmental biology, and biochemistry. Much of our understanding of Wnt gene function during development has in fact come from studies in *Drosophila*. *wg* acts as a signal to perform a variety of regulatory roles during the development of *Drosophila*. Specifically, *wg* is required for maintaining segment polarity during embryogenesis and in imaginal disc morphogenesis and visceral mesoderm patterning (reviewed in Ref. 4). However, most of the information about the mechanism of *wg* signaling comes from studies on segment polarity, which will be the focus here.

wg is expressed in stripes that are a single cell wide in every segment of the developing *Drosophila* embryo. If *wg* function is absent during embryogenesis, the polarity of segments in the larva is lost and a “lawn” of denticles is all that remains in the ventral region (7, 8). During embryogenesis, *wg* is also required to maintain transcription of several other segment polarity genes (such as ***engrailed***) in adjacent cells (9). These studies have demonstrated that *wg* acts as a signal to instruct adjacent cell

fates. These genetic studies have also been complemented with cell biological analysis that has shown that secreted *wg* protein (WG) travels several cell diameters away from the cells expressing it (10, 11). In addition, the *wg* mutation acts non cell autonomously in genetic mosaic experiments (12). Because Wg functions as a signal, much of the focus on the study of Wg signaling has been the elucidation of the Wg signaling pathway. Two main approaches have led to rapid progress in our understanding. Most of the information has come from (1) genetic analysis, although (2) biochemical approaches in *Drosophila* and in other systems have also led to the identification and analysis of novel Wg signaling components.

0.2. Genetic Analysis of the *wg* Signaling Pathway

Because the *wg* phenotype is stereotypical, it has been possible to identify *wg* signaling pathway genes by analyzing mutants whose phenotypes resemble the "lawn" pattern of denticles in *wg* mutant embryos. Historically, this approach was successful in identifying several new components of *wg* signaling in *Drosophila*. Three genes have mutant phenotypes identical to that of *wg*: *dishevelled* (*DSH*), *porcupine* (*PORC*), and *armadillo* (*ARM*) (13, 14). Just as in the case of *wg* mutants, these genes are also required to maintain *en* expression in the embryo and for other *wg*-dependent processes during development (4). The differences in these mutants became apparent in the study of their behavior in genetic mosaics. The *porc* mutation (like *wg*) behaves noncell-autonomously, whereas *dsh* and *arm* behave cell-autonomously (15-17). Simple interpretation of these tests suggested that, as in the case of *wg*,, *porc* is required outside the cell receiving the *wg* signal, whereas *dsh* and *arm* are required inside the cell. The molecular characterizations of these genes are consistent with this interpretation. The *porc* gene encodes a protein (Porc) that has eight transmembrane domains and is localized perinuclearly, consistent with its association with the Golgi apparatus (15). The *dsh* gene encodes a pioneer cytoplasmic protein that has been well conserved in evolution (16). *dsh* protein (DSH) also has some homology to other proteins within three distinct domains. Dsh has a pleckstrin homology (PH) domain that is homologous to Axin (discussed later) and a PDZ (*P*SD-95/*D*lg/*Z*O-1) domain found in a variety of proteins that are targeted to intracellular signaling complexes (17). Finally, the *arm* gene encodes the *Drosophila* homologue of b-catenin, a protein that functions in nuclear signaling pathways (18). Other distinctions in the behavior of the *porc*, *dsh* and *arm* mutants have also contributed to the elucidation of *wg* signaling. Cell biological analysis has shown that *porc* mutants may be defective in the secretion of Wg. In the absence of *porc*, Wg is intracellular and is not detected outside the cells that transcribe *wg* (19). Even though *arm* is expressed ubiquitously in the embryo, *arm* protein (ARM) also accumulates at higher levels in cells that receive Wg during development (20). This accumulation is also relevant at the subcellular level because it is mostly cytoplasmic. This cytoplasmic accumulation is abolished in each of *wg*, *dsh*, and *arm* mutant embryos (20). Therefore, based on these observations, *porc* functions upstream of *wg*, and *arm* functions downstream of all three genes. Because *dsh* acts cell-autonomously and encodes a cytoplasmic protein, it is also logical to assume that dsh functions downstream of *wg*. These hypotheses have since been proven more formally.

Because *wg* is expressed in a restricted stripe pattern that is a single cell wide, it was possible to express *wg* ubiquitously to generate a phenotype that can be interpreted as the opposite of *wg* mutants. This was initially done by inducing the expression of *wg* from a heat-inducible transgene (HSWG). *en* expression expands in embryos that express HsWg, and the resulting larva are devoid of denticles in the cuticle's ventral region (21). Instead, these larva have "naked" cuticle that is part of the reiterating pattern of segmentation in wild-type larvae. Simplifying these phenotypes, we can say that the "naked" regions in *wg* mutants are deleted and leave only denticles, and in HsWg embryos, the denticles are deleted and leave only the naked regions. Furthermore, Arm accumulates in the cytoplasm of all cells in the embryo, reflecting the ectopic Wg induction in these embryos (21). Because HsWg creates the phenotype opposite to that of *wg*, it was possible to perform genetic epistasis tests to determine the *wg* genetic pathway. In the absence of *porc*, HsWg still specifies "naked" cuticle and maintains *en* expression (22). This suggests that *porc* functions upstream of *wg*, as was predicted previously. HsWg is, however, completely ineffective in the absence of either *dsh* or *arm*, suggesting that these genes function downstream of *wg* (22). Another opportunity for epistasis with wg pathway genes came with the discovery of the *zeste-white 3* mutant (*ZW3*).

Because *zw3* has a phenotype similar to that of HsWg, it was postulated that the *wg* signaling pathway in *zw3* mutants is constitutively active (23). Therefore, it was possible to make double mutants with *zw3* and each of the *wg* pathway genes. Double-mutant epistatic analysis placed *zw3* function downstream of *wg*, *porc*, and *dsh* but upstream of *arm* (23). The **cloned** *zw3* gene encodes the functional homologue of the **serine/threonine kinase**, glycogen synthase kinase 3b (GSK3B) (24). In *zw3* mutant embryos, Arm accumulates in the cytoplasm of all cells in the embryo, mimicking the effects of HsWg (24, 25). Therefore, it is quite likely that Arm functions downstream of *zw3* protein (ZW3). Other studies have also shown that Arm phosphorylation in the embryo depends on Zw3, suggesting a direct interaction between Zw3 and Arm (26). Therefore, epistatic experiments have ordered the *wg* pathway genes in a purely genetic pathway. Because all identified *wg* signaling components are conserved in other organisms, it was possible to use other systems to confirm and to extend the results of genetic analysis in *Drosophila* by using other approaches (17).

0.3. Biochemical Analysis of the Wg/Wnt Signaling Pathway

Biochemical studies in *Drosophila* and in other systems, have also identified *wg*/Wnt signaling components. The transfection of *Drosophila frizzled 2* (*DFZ2*) into cells that are unresponsive to Wg enables these cells to stabilize cytoplasmic Arm in response to Wg (27). Because *Dfz2* encodes a seven-transmembrane receptor-like molecule, it has been postulated that *Dfz2* encodes a receptor for *wg* (27). Although Wg binds Dfz2-expressing cells, this binding is general among all *Dfz2* gene family members (17). The identification of a *Dfz2* mutant in *Drosophila* should make it possible to test whether Dfz2 is a crucial Wg receptor.

Another novel component identified is the product of the *fused* locus in mouse, called Axin. The Axin protein is cytoplasmic and acts as a negative regulator of Wnt signaling (28). Recent studies have provided provocative evidence suggesting that the role of Axin may be as an adaptor protein that allows binding GSK3 to the mammalian Arm homologue, b-catenin (29). This allows the simplest interpretation for the repression of Arm by Zw3, whereby Zw3/GSK3 phosphorylates Arm/b-catenin at the four conserved **phosphorylation** sites of this kinase. The *Drosophila Axin* homologue has not been identified, and genetic tests for this interaction are lacking. Recent studies have shown that the GSK3 phosphorylation targets b-catenin for conjugation with ubiquitin and its rapid **protein degradation** via the 26S proteasome (30). Genetic evidence for these observations has come from the recent identification of mutations in an enzyme involved in ubiquitin regulation. The E3 class of ubiquitin-conjugating enzymes is responsible for targeting specific proteins for ubiquitination. This gene, named *slimb*, encodes an E3 enzyme, and its mutation results in the accumulation of Arm (31).

In addition to cytoplasmic stabilization, Arm and b-catenin also accumulate in the nucleus and associate physically with **HMG** box transcription factors of the Tcf/LEF-1 family (32-34). Although the actual mechanism of Arm/b-catenin nuclear translocation is not known, it is very clear that this translocation is important for Wg/Wnt signaling (32, 35). The identification of a *Drosophila* mutant for Tcf/LEF-1, called *pangolin* (*pan*), has established the validity of these hypotheses. The *pan* gene has a mutant phenotype identical to that of *wg* and also functions downstream of *arm* (36, 37). Physical interaction between Arm and *pan* protein (Pan) also has been demonstrated (36).

It has been known for some time that heparin treatment of Wnt-expressing cells leads to release of Wnt from the extracellular matrix (5). It has also been shown that heparin binds Wg (38). Recent genetic studies have confirmed the biochemical evidence for interaction between heparin-like glycosaminoglycans (GAGs) and Wg /Wnts. *Drosophila* mutants in UDP-glucose dehydrogenase (UDP-GLCDH), which is critical for biosynthesizing GAGs, result in a phenotype that is *wg*-like and block, yet do not completely abolish, the effects of ectopic Wg (39-41). Therefore, GAGs are important for Wg function. The long list of potential GAGs was limited to one because heparanase injections mimic the *wg*-like phenotype, and the injection of only heparan sulfate alleviates the UDP-GlcDH mutant phenotype (39). More biochemical experiments will be required to determine the exact role of heparan sulfate and proteoglycans in *wg* signaling.

Other potential components of *wg* signaling have been suggested through biochemical analysis. Many of these studies, however, lack other corroborating evidence and await further investigation. Of particular interest is the hypothesis that the ***Notch*** (*N*) gene may encode a receptor for Wg. Although it was shown that *N* and *wg* share several phenotypic and genetic features during *Drosophila* development (42), the inability of N mutants to block the effects of HsWg were used to discount the *N-wg* signaling hypothesis (43). However, the lack of biochemical experiments addressing this issue make it difficult to accept or dismiss the idea that *N* protein acts as a receptor for Wg.

0.4. The Mechanism of Wg Signaling

The combined genetic and biochemical approaches discussed before have led to the following scenario for Wg signaling (Fig. 1). Porc is involved in secreting Wg that in turn binds to Dfz2. Heparan sulfate proteoglycans might be involved in all steps leading to this interaction (Dfz2-Wg). Once Wg binds Dfz2, Dsh functions to repress Zw3 function via an unknown mechanism. If Zw3 is not repressed by Dsh, Zw3 enters into a complex with Axin and Arm, leading to the phosphorylation and degradation of Arm (via ubiquitination). When Dsh does repress Zw3, however, Arm is not phosphorylated, cannot be degraded, and is free to accumulate in the cytoplasm. Once Arm accumulates in the cytoplasm, it can enter into a nuclear complex with Pan, resulting in the regulation of genes, such as *en*. The exact mechanism of Arm nuclear translocation is not known.

Figure 1. Diagram of the current view of the mechanism of *wg* signaling. Signaling components confirmed via both genetic and biochemical approaches are depicted in gray, and components missing genetic confirmation are depicted in black (eg, Dfz2 and Axin). See text for details.

Wobble Pairing

In translation of the genetic information present in the messenger RNA using transfer RNA during **protein biosynthesis**, Crick suggested, in 1966, that base pairing of the first (5′) base of the anticodon of transfer RNA with that at the third (3′) position of the **codon** (see Genetic Code) does not necessarily conform to normal Watson–Crick base pairing (1). He introduced the term *wobble pairing* for this noncanonical base pairing. Crick pointed out, as a typical example of wobble pairing, that the inosine (I) (a derivative of G) located at the first position of the yeast $tRNA^{Ala}$ anticodon can base-pair at the third position of the codon with not only C but also with U and A. Since then, as nucleotide sequences of numerous tRNAs from various sources have been determined (2), knowledge of the extent of wobble pairing has expanded, as shown in Table 1. (See top of next page) The wobble pairings have been verified experimentally both *in vitro* (3) and *in vivo* (4).

Table 1. Anticodon-Codon Paring Rules So Far Elucidated[a]

Anticodon 5′	Codon 3′			Occurrence
1. U or modified U at the wobble positionof the anticodon				
a. Unmodified U				
UNN	UNN	UNN	UNN	Family boxes in mitochondria, *Mycoplasma* spp., and chloroplasts
AN′N′	UN′N′	CN′N′	GN′N′	
b. U modified to U* (mo^5U or cmo^5U)				
U*NN	U*NN	U*NN		Family boxes in eubacteria
AN′N′	UN′N′	GN′N′		
c. U modified to U^+ (Um, $cmnm^5U$, or mcm^5U)				
U^+NN	$U^{\pm}NN$			2-codon sets in mitochondria, bacteria and eukaryotes
AN′N′	GN′N′			
d. U modified to $U^\#$ (mnm^5s^2U, $mcnm^5s^2U$ or $cmnm^5s^2U$)				
$U^\#NN$	$U^\#NN$			2-codon sets in eubacteria and eukaryotes
AN′N′	GN′N′			
2. G or modified G at the wobble positionof the anticodon				
a. Case 1 for unmodified G				

GNN	GNN			2-codon sets of all organisms, and family boxesin bacteria
CN′N′	UN′N′			
b. Case 2 for unmodified G				
GNN	GNN	GNN		IleAUN (except AUG) and AsnAAN (except AAG) instarfish mitochondria. SerAGN (except AGG) in *Drosophila* mitochondria
CN′N′	UN′N′	AN′N′		
c. G modified to Q				
QNN	QNN			2-codon sets in eubacteria and eukaryotes
CN′N′	UN′N′			
d. G modified to I				
INN	INN	INN		ArgCGN in eubacteria, and all family boxes ineukaryotes except GlyGGN
CN′N′	UN′N′	AN′N′		
e. G modified to G* (m^7G)				
G*NN	G*NN	G*NN	G*NN	SerAGN in starfish and squid mitochondria
CN′N′	UN′N′	AN′N′	GN′N′	
3. A at the wobble position of the anticodon(rare)				
ANN	ANN	ANN	ANN	ThrACU and ArgCGN in mycoplasma spp. and yeastmitochondria. ArgCGN in nematode mitochondria
UN′N′	CN′N′	GN′N′	AN′N′	
4. C or modified C at the wobble positionof the anticodon				
a. Unmodified C				
CNN				Only $^{5'}$N′N′G$^{3'}$ codons in all organisms
GN′N′				
b. C modified to C*(f^5C)				
C*AU	C*AU			MetAUR in animal mitochondria
GUA	AUA			
c. C modified to L				
LAU				IleAUA in eubacteria and plant mitochondria
AUA				

[a] The anticodon-codon pairing is shown by $^{5'}$ANTICODON (NNN)$^{3'}$ $^{3'}$CODON(N′N′N′)$^{5'}$ where N in the anticodon and its corresponding N′ in the codon (beneath the N) form Watson-Crick base pairing. The underlined letters are involved in wobble pairing. Family box means that 4 synonymous codons are included in a box in the genetic code table (for example, GUU, GUC, GUA and GUG for Val codons). 2-codon set means that only 2 codons are used for one amino acid (for example, AAA and AAG for Lys codons).

Abbreviations used are: mo^{5}U, 5-methoxy U; cmo^{5}U, 5-carboxymethoxy U; cmnm ^{5}U, 5-carboxymethyl-aminomethyl U; mcm^{5}U, 5-methylcarboxymethyl U; Um, 2′-O-methyl U; mnm ^{5}s^{2}U, 5-methylaminomethyl-2-thio U, cmnm^{5}s^{2}U, 5-carboxymethyl-aminomethyl-2-thio U; mcm^{5}s^{2}U, 5-methylcarboxymethyl-2-thio U; Q, queosine (in eubacteria) or its derivatives, manQ or galQ (in eukaryotes); f ^{5}C, 5-formyl C; L, lysidine. From Osawa (5) with modifications (6, 7). See also Bjork (8).

The importance of wobble is that there is no need for a unique transfer RNA specific for each codon of the genetic code. Consequently, one transfer RNA can respond to several codons, inserting the same amino acid for each.

Writhe, DNA

Writhe is an aspect of DNA structure that concerns DNA topology.

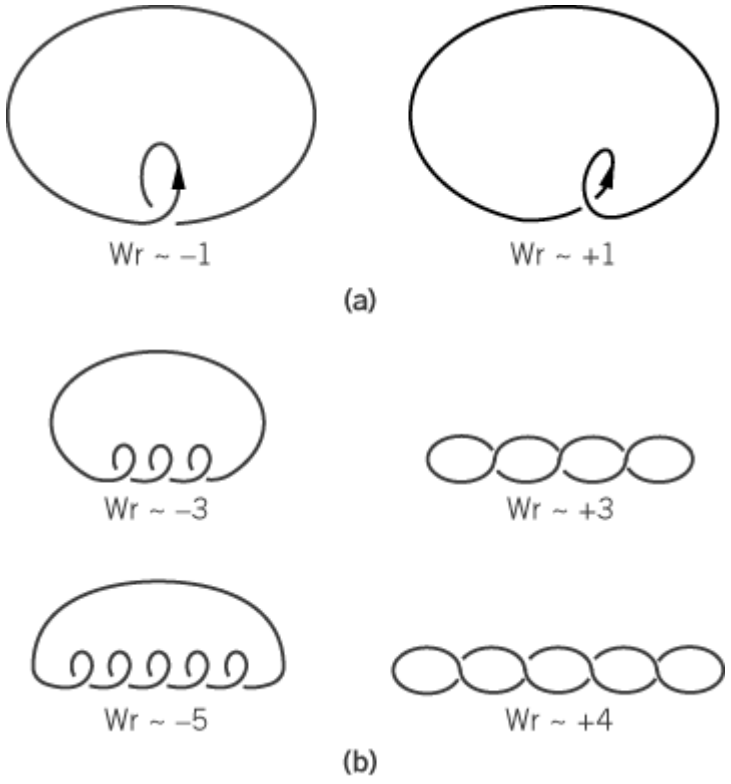
1. Writhing Number

The writhe or writhing number (*Wr*) is a property of a single closed space curve; in application to DNA, the appropriate space curve is taken to be the duplex axis *A*. For considerations of DNA structure, the writhe is important insofar as it enters into the fundamental relationship between the **linking number** (*Lk*), the **twist** (*Tw*), and *Wr* for a closed circular duplex DNA, $Lk = Tw + Wr$. Since *Wr* is calculated only for a closed curve, the quantity is not applicable to nicked circular or linear DNAs. The magnitude of the writhe is directly proportional to *n*, where *n* is the number of superhelical turns (see Supercoiling of DNA). For a nicked circular duplex DNA, whose axis on the average lies in a plane, $Wr = 0$. In all other cases, some of the winding is always converted into changes in *Tw*, and $|Wr| < n$.

1.1. The Index Approach

As with the linking number, conceptually the easiest way to calculate the writhe is with the index approach (see Linking Number Of DNA). The axis is assigned an orientation and projected onto a plane. Although a specific orientation must be chosen for the axis in order to calculate the directed writhing number, the actual choice of orientation is immaterial, since a reversal of orientation changes the orientations of both curve segments simultaneously. Some examples are shown in Figure 1. For any given projection, an index number of +1 or –1 is assigned to each crossing of one strand by the other. The index number is negative if the tangent vector to the upper portion of the curve must be rotated clockwise to coincide with the tangent vector of the lower part of the curve. The index number is positive in the opposite case. Since the writhe is not a topological quantity, however, its calculation is *not* independent of the projection chosen. This serves to distinguish *Wr* clearly from *Lk*. The sum of all the index numbers gives the projected writhing number, Wr_p, for the DNA axis in the projection chosen.

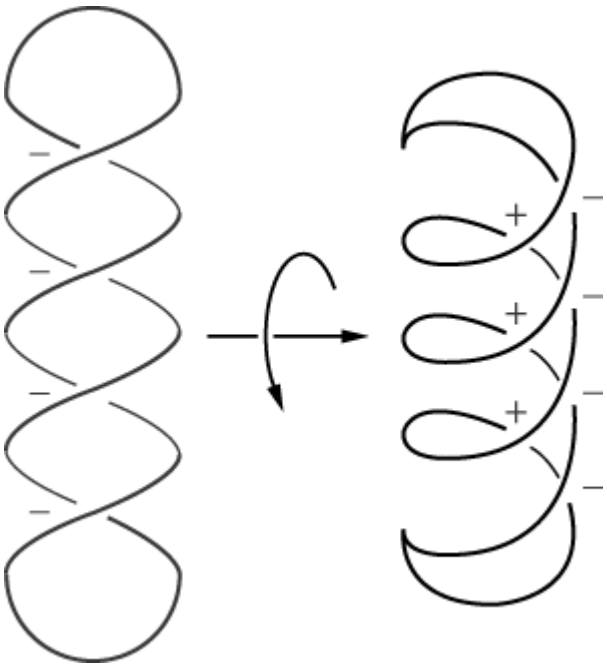
Figure 1. Examples of calculation of the writhe for some simple curves using the index approach. (**a**) The writhing number of curves with one coil. In the projections shown, the projected writhe, Wr_p, is ±1. However, if the curves are rotated so that other projections are viewed, there are some side views where no crossings are observed. Since *Wr* requires that all values of the projected writhe be averaged, the actual values of *Wr* will be slightly greater than –1 in one case and slightly less than +1 in the other case. (**b**) The extension to curves having multiple coils is straightforward. In the views shown here, the projected writhes are the numbers shown under each curve. As with the loops of one coil, however, some projections will have no crossings, giving rise to values of *Wr* that are slightly more positive than the negative integers indicated and slightly more negative than the positive integers indicated.



The writhing number, *Wr*, is obtained by averaging the projected writhing number over all possible projected views. The values of the directed writhing numbers, and hence of *Wr*, are changed by deformation of the axis. As an example, DNA supercoiled into a regular plectonemic superhelix is shown schematically in Figure 2. In most views, the crossings are all negative and equal in number to the number of supercoils. These have a projected writhe of $-n$. In some projections, however, positive crossings are also observed. These have a projected writhe more positive than $-n$. The

writhe is the sum of all projected writhes, so it is clear that $|Wr| < n$. Finally, Wr changes by 2 if the axis is passed through itself once, as happens by treatment with a type II DNA **topoisomerase**. This is because such a passage converts a +1 crossing to a –1 crossing, a change of –2, or a –1 crossing to a +1 crossing, a change of +2.

Figure 2. Analysis of the projected writhe for an interwound DNA superhelix. The solid curve represents the axis of a cdDNA wound into an unbranched, interwound superhelix. Two views of the same structure are depicted. The view on the left shows only the nodes with negative index numbers, and $Wr_p = -4$. These result from the crossing of distant DNA segments. The view on the right results from rotation about the horizontal axis so that the top of the molecule is tipped toward the observer. This view contains the same negative contributions but contains additional nodes that have positive index contributions, resulting from the crossing of nearby DNA segments. The value of Wr_p for this view is thus –1. The Wr is the average of the Wr_p values of all views; hence $|Wr|$ is less than the number of supercoils.



1.2. Application of the Gauss Integral

If the trajectory of the DNA axis is known, the writhe may alternatively be calculated from the Gauss integral in a manner analogous to the calculation of Lk (1) (see Linking Number Of DNA):

$$Wr = \frac{1}{4\pi}\int_{C\times C}\int \frac{\mathbf{e}\cdot\mathbf{T}_2\times\mathbf{T}_1}{r^2}ds_1 ds_2 \qquad (1)$$

where $\mathbf{T}_1$ and $\mathbf{T}_2$ are the unit tangent vectors to the axis curve at any two locations, x_1 and x_2; r is the distance between the points $r = \|\mathbf{x}_2 - \mathbf{x}_1\|$; and ê; is the unit vector $(\mathbf{x}_2 - \mathbf{x}_1)/r$.

1.3. Use of the Surface Linking Number

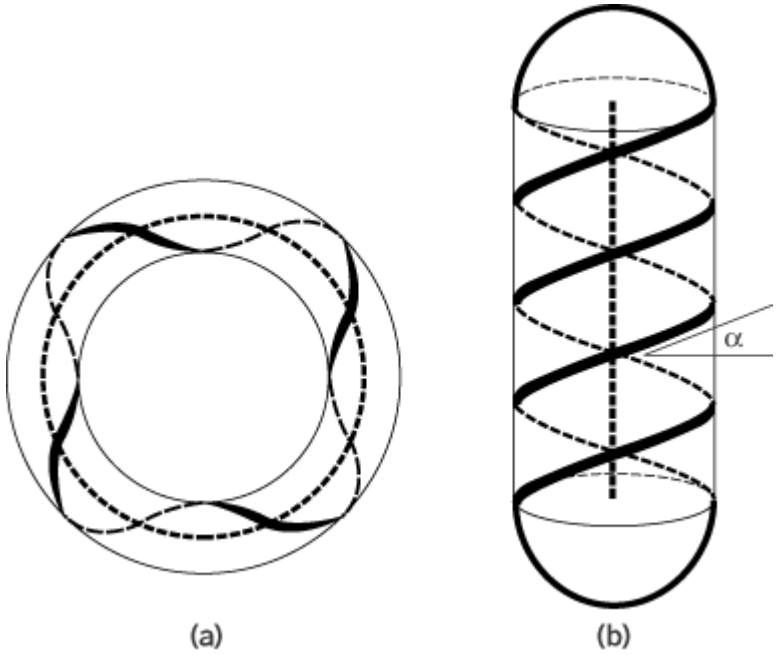
The third and easiest way to calculate the writhe takes advantage of the fundamental relationship for a closed circular DNA (2), in the form $Wr = Lk - Tw$. Although this method is indirect, it is considerably easier than the direct methods because both Lk and Tw are much more readily obtained than Wr itself. Even more straightforward is the combination of the fundamental relationship with considerations of surface linking (see Surface Wrapping Of DNA). The fundamental relationship then becomes

$$Wr = SLk - STw \tag{2}$$

The surface linking number, *SLk*, is simply related to the geometry of the real or virtual surface about which the DNA winds. For the two most commonly encountered cases, *SLk* = 0 for superhelical DNA having the form of any plectonemic superhelix, no matter how distorted; *SLk* = ±*n* for any toroidal superhelix, where the sign is positive for right-handed winding and negative for left-handed winding. Equation (2) then becomes *Wr* = –*STw* for a plectonemic superhelix and *Wr* = ±*n*–*STw* for a toroidal superhelix.

The calculation of the writhe therefore reduces to a problem in the calculation of the surface twist. The calculation of *STw* requires knowledge of the shape of the surface and of the associated path of the DNA axis. If the surface is a protein or other real object, the required information can be obtained, at least in principle, by X-ray diffraction. In the case of a free cdDNA, the axis can sometimes be considered to wrap on a virtual surface. The two most commonly encountered surfaces of this type are the capped cylinder (for plectonemic supercoiling) and the circular torus (for toroidal supercoiling). These are illustrated in Figure 3. For the plectonemic superhelix, *STw* = *n* sin(a) for DNA whose axis winds as a regular right-handed superhelix of *n* turns and superhelix pitch angle a. It follows immediately that *Wr* = –*n* sin(a) for a right-handed plectonemic superhelix (D*Lk* < 0), and *Wr* = +*n* sin(a) for a left-handed plectonemic superhelix (D*Lk* > 0).

Figure 3. Two types of geometry used in the calculation of the writhe by means of the surface linking number (see Surface Wrapping Of DNA) and surface twist (see Twist, DNA). (**a**) Toroidal superhelical DNA wrapped on the surface of a virtual torus. The DNA axis wraps +4 times in a right-handed sense on the surface of a torus. *SLk* = +4. (**b**) Plectonemic interwound DNA, wrapped on the surface of a virtual capped cylinder. The DNA wraps +2 times up and +2 times down a virtual cylinder, with circular closure at the caps. *SLk* = 0. The superhelix pitch angle is a.



If the DNA is wound in a regular right-handed toroidal superhelix, *SLk* = +*n*. The calculation of *STw* in this case is more involved than for the plectonemic superhelix and requires knowledge of the dimensions of the virtual toroidal surface on which the DNA is wrapped. If the DNA axis wraps *n* times around a circular torus of major radius *R* (distance from the center of symmetry to the central axis of the torus) and minor radius *r* (radius of the torus), then *STw* is given by an elliptical integral that must be solved numerically (3). If the torus is highly extended relative to its width, so that $r/R \ll 1$, the result is approximately $STw \approx nR/\sqrt{R^2 + n^2 r^2}$ In the limiting case

where $r/R \to 0$, *STw* is the same as for the plectonemic superhelix. In the other limiting case that $r/R \to 1$, numerical solutions to the elliptical integral must be obtained.

2. Absolute Writhe

The absolute writhe, *AWr*, is formally similar to the writhe except that the absolute value of the writhe integrand, instead of the usual signed one, is used in the Gauss integral (3). Although it not part of the basic relationship for a topological domain, $Lk = Tw + Wr$, *AWr* has the advantage that it is zero if and only if the curve is planar. Indeed, the closer the absolute writhe is to zero the more nearly planar is the curve. This contrasts with *Wr*, which may be zero even though the curve lies out of plane. For example, any curve that lies on the surface of a sphere has $Wr = 0$. Such a curve certainly does not have to be planar.

The difference between *Wr* and *AWr* may also be understood using the process of projections. If a closed space curve is viewed from a distant point, apparent crossings may be seen by the observer. To each of these crossings is assigned a value of +1 or –1, depending on the orientation of the tangents to the crossing segments. The projected writhe is the algebraic sum of these crossing numbers, and the writhe is the average of all projected writhing numbers over all possible projections. The absolute writhe is defined similarly, but with one major difference: instead of attaching a sign to any crossing, the absolute value of the number of crossings is counted. This number is called the *projected absolute writhe*. The absolute writhe is the average of all absolute projected writhing numbers over all possible projections. Thus, for a very tightly wound, almost planar figure eight, the writhe may be +1 or –1 depending on the overlay of the crossing segments; but the absolute writhe is always +1. In terms of the Gauss integral, *AWr* is calculated similarly to *Wr*:

$$AWr = \frac{1}{4\pi} \int_{C \times C} \int \left| \frac{(\mathbf{y} - \mathbf{x}) \cdot \mathbf{T}_2 \times \mathbf{T}_1}{r^3} \right| ds_1 ds_2 \qquad (3)$$

X-chromosome

In **eukaryotes** that utilize sexual **reproduction**, usually two distinct chromosomes exist, called sex chromosomes. In the majority of **plants** and animals, the male has one copy of each of these two chromosomes and is called the **heterogametic sex**. The two sex chromosomes (X and Y in humans) have partial homology. They pair during **prophase** of **meiosis** in the male, so that two kinds of **gametes** are produced, each containing just one of the two types of sex chromosomes. In the female, the **homogametic sex**, are two identical sex chromosomes (X in humans), so only one type of gamete results. The presence of different numbers of X-chromosomes in different cells, depending on the sex, relative to the constant number of autosomes requires that molecular mechanisms exist to compensate for the presence of two X-chromosomes in each cell of a female mammal. The process of **dosage compensation** leads to the inactivation of one of the X-chromosomes in humans (see X-Chromosome Inactivation). This process is generally random, in that either maternally or paternally derived X-chromosomes are inactivated (see Random X-Inactivation), and results in the appearance of a Barr body, consisting largely of facultative heterochromatin.

In *Drosophila* the male has a single copy of the X-chromosome, whereas the female is XX with two copies of the X-chromosome. However, the single X-chromosome in males produces the same amount of gene product as the combination of two X-chromosomes in females (1). The male X-chromosome is twice as transcriptionally active as the average female X-chromosome. This is accomplished by the targeting of an enzyme complex that hyperacetylates the histone proteins in the nucleosomes and chromatin of the male X-chromosome. Histone hyperacetylation promotes the processivity of **RNA polymerase** through nucleosomal arrays and along the chromatin fiber. Thus one gene in the single male X-chromosome in *Drosophila* is as active as the two copies of the gene in the female. An important aspect of the *Drosophila* dosage compensation pathway is the capacity to count the number of sex chromosomes relative to sets of autosomes. If a *Drosophila* egg has equal numbers of X-chromosomes and autosomes, it develops into a female. If there is an extra copy of autosomes relative to the number of X-chromosomes, it does not follow the female differentiation pathway (2).

In the nematode *Caenorhabditis elegans*, dosage compensation occurs in XX individuals that are hermaphrodites to normalize gene activity on the X-chromosome with males that are XO. This requires a reduction in transcription from the two X-chromosomes in hermaphrodites. A chromosomal modification is involved again, but unlike the case in *Drosophila* where gene activation was involved, in *C. elegans* hermaphrodites a specialized (stability and maintenance of chromosome SMC) chromosomal condensation protein is targeted to the X-chromosome to repress its gene activity twofold (3).

X-Chromosome Inactivation

Inactivation of an X-chromosome in female cells is part of the **dosage compensation** mechanism necessary to allow equivalent expression of X-linked genes in female and male cells, which have two and one X-chromosomes, respectively. The suggestion that X-inactivation might occur was first presented as an hypothesis by Mary Lyon (see Lyon Hypothesis). The result of the inactivation process is the appearance of the Barr body. In eutherian (placental) mammals, the initial choice between inactivation of maternal or paternal X-chromosomes is random (see Random X-Inactivation), but once established in a repressed state, the same X-chromosome is inactivated after every cell division. This is an excellent example of establishing and maintaining a chromosomally based state of determination.

Abnormalities in the process of X-chromosome inactivation have allowed the genetic definition of the X-inactivation center required for inactivation to occur (1). The X-inactivation center is actually on the inactive X-chromosome and contains the gene encoding Xist RNA. This site actually remains actively transcribed, whereas the rest of the X-chromosome is silenced. The Xist RNA is the key regulator of inactivation (2, 3). Remarkably the gene does not encode messenger RNA, but it produces instead a long, untranslated RNA that remains associated with the inactive X-chromosome (4, 5). Through some unknown mechanism, the Xist RNA has a causal role in directing the **heterochromatinization** of the inactive X-chromosome. The process of heterochromatinization leads to numerous differences between active and inactive X-chromosomes including DNA **methylation**, histone **acetylation** status, and replication timing (see Facultative Heterochromatin, Euchromatin).

DNA methylation is characteristic of many inactive **promoters** and genes. Consistent with this observation, many genes in the inactive X-chromosome are heavily methylated in contrast to the active X-chromosome (6). However, the kinetics with which particular sites within the X-linked genes become methylated during the differentiation of embryonic female **somatic cells** do not always correlate with the timing of transcriptional inactivation (7). Although it remains to be determined if a subset of key sites around regulatory elements is always methylated before transcription is repressed, it seems probable that other mechanisms must supplement any influence of DNA methylation on transcription.

Heterochromatin normally replicates late during **S-phase**. Replication timing has been proposed as a determinant of transcriptional activity. Genes that replicate late during S-phase might do so under conditions of limiting transcription factors, or they might be assembled into a repressive chromatin structure using components translated only late in S-phase. The active X-chromosome normally replicates early in S-phase, whereas the inactive X-chromosome replicates late (8). However, female lymphoma cell lines have been isolated in which the opposite occurs (9). Thus the inactive X-chromosome does not have to replicate late in S-phase to be transcriptionally quiescent.

The formation of local repressive chromatin structures in which key genetic regulatory elements are rendered inaccessible to transcription factors by inclusion within positioned nucleosomes is an important mechanism for transcriptional repression. Promoters in the inactive X-chromosome are incorporated into positioned nucleosomes, whereas promoters in the active X-chromosome are free of such structures and have transcription factors bound to them (10). Thus specific local chromatin structures clearly have a role in regulating differential gene activity between the two X-chromosomes. Nevertheless, a causal relationship between chromatin structure and transcription has yet to be established. Nucleosomes on the active X-chromosome contain predominantly acetylated histones, whereas those on the inactive X-chromosome are not acetylated (11). Thus establishing and maintaining specific chromatin structures containing modified histones is an excellent candidate mechanism for establishing and maintaining differential expression of genes between the two X-chromosomes. Differential methylation and replication timing may stabilize these different states of gene activity.

X-Ray Crystallography

X-ray crystallography is still the experimental technique that determines the most detailed structures of macromolecules. In 1912 Knipping and Friedrich in Laue's laboratory performed the first X-ray diffraction experiment with a crystal (1). Their result showed at the same time that X rays behave as waves and that crystals display a high degree of order in arranging their atoms, ions, or molecules. The crystal acts as a three-dimensional grating and diffracts X rays just as visible light is diffracted by an optical grating. Since 1912, X-ray crystallography has had an enormous impact on chemistry and biology. At first, great triumphs were obtained in the field of inorganic chemistry. The structures of simple ionic compounds and of complex structures, like the silicates, became understood, and ionic radii could be measured with high accuracy. Unlike inorganic compounds that are mainly ionic, organic compounds consist of molecules. The intensity of the beams diffracted by organic compounds is relatively low and, in the beginning, progress was slow in determining their structures. However, the introduction of improved hardware and Fourier analysis solved the problem, and now the X-ray structure determination of a small or medium-sized organic molecule is an easy job, at least when good quality crystals are grown.

Protein crystallography is the youngest branch of X-ray crystallography. It started in 1934 when Bernal took the first X-ray diffraction picture of a protein crystal (2), first a crystal of pepsin, soon followed by a crystal of insulin. These observations showed that even these large molecules are nicely ordered in their crystals and that their structures might be solved. This was not an easy problem, however, and it took twenty years to find a solution (3). Surprisingly, it could be done by a technique already successfully applied for small organic compounds: the method of isomorphous replacement in which a heavy atom is attached to the protein structure. It was Perutz' achievement to show that the method could also be used for proteins and that the heavy atoms cause a much larger change in intensity than initially expected. Because of the rather primitive instrumentation, progress was slow at first. With the introduction of more sophisticated instrumentation and computers with suitable software, X-ray crystallography of proteins has grown to a relatively common technique, and structures are being published with ever increasing speed. They are collected in the Protein Data Bank, Brookhaven National Laboratory, Upton, NY 11973-5000, USA (see Databases).

1. X-ray sources

In the home laboratory, X rays are produced in vacuum tubes by bombarding a metal anode with

accelerated electrons. They are either sealed tubes that have a static anode or they have a rotating anode and are continuously pumped. An X-ray tube emits a spectrum of wavelengths whose characteristics depend on the metal. For most diffraction experiments, a single wavelength is selected by a monochromator, 0.71 Å from a molybdenum anode or 1.5418 Å from a copper anode. Diffraction is stronger for the longer wavelength, and this is preferred for proteins. The maximum power of an X-ray tube is limited by heating of the anode caused by the accelerated electrons. Rotating anode tubes have better heat dissipation, produce a higher intensity beam, and therefore, are preferable for protein work.

Much stronger X-ray beams are produced in synchrotrons (4). These devices have electrically charged particles (electrons or positrons) circulating in a vacuum. A continuous spectrum of electromagnetic radiation down to a certain minimum wavelength is emitted when the particles change direction. The minimum depends on the power of the synchrotron. The higher the power, the shorter the minimum wavelength. A wavelength near 1 Å is often chosen for protein crystallography with synchrotron radiation. This has the advantage over the copper wavelength of 1.5418 Å that the absorption of the beam is much lower.

2. X-ray detectors

The beams diffracted by crystals of small compounds are usually detected and measured with a diffractometer. Using this instrument, the crystal can be rotated around three or four axes and can reach nearly every orientation. The diffracted beams are measured with a photon counter. Because the beams are measured one after the other, this process is slow and not very suitable for protein crystals where thousands of beams must be measured. Protein crystallographers prefer an instrument that has one or more axes to orient the crystal and is equipped with an area detector on which hundreds or thousands of diffracted beams are registered nearly simultaneously. A popular type is the imaging plate covered with phosphorescent material. After registration, the information collected on the imaging plate is released by a laser and read with a photomultiplier.

3. Diffraction theory

The most convenient way to understand the diffraction of X-rays by a crystal was introduced by Bragg (5). It is based on the idea of the reflection of X rays from lattice planes in the crystal (see Bragg Angle). They are the planes constructed through the lattice points, which are the corners of the unit cells. Within a set, the planes are parallel and equidistant, and have a perpendicular distance d. Such a set is characterized by three indices: h, k, and ℓ. The beams reflected at an angle q from the lattice planes reinforce each other only if the path difference for beams from successive planes is equal to a whole number of wavelengths. This occurs when Bragg's law is fulfilled:

$$2d \sin\theta = \lambda \qquad (1)$$

The reflected beams have the same indices h, k, and ℓ as the set of planes from which they are reflected. Bragg's law gives the direction of the diffracted beams, but not their intensity. The latter is determined by the distribution of atoms and molecules in the unit cell of the crystal. It can be shown that Bragg's reflection idea is equivalent to positive interference of the scattering by the individual unit cells in the crystal. The scattering by the unit cells is reinforced in the Bragg directions and extinguished in other directions.

In powder diffraction, the specimen is not a single crystal but consists of a large number of crystal grains. It is exposed to a parallel beam of X rays, and there are always some grains for which the Bragg condition is satisfied. The result is a series of circles centered around the direct beam. The powder method is suitable only for very simple structures, where only a limited number of data are sufficient for the structural determination and for detecting phase transitions. It is completely useless for proteins.

When X rays interact with a crystal, they are scattered by the electrons in the crystal. A unit cell contains a huge number of electrons, and every electron scatters the X-ray beam. These beams interfere with each other, and the net amplitude of the scattering by a unit cell corresponds to a number of electrons F, which is smaller than the total number of electrons in the unit cell and depends on the electron distribution in the unit cell. Because the crystal scatters only if the beams originating from the individual unit cells positively interfere, the amplitude of the scattered beam $hk\ell$ is proportional to F ($hk\ell$), the scattering by one unit cell. This is the amplitude of the vector **F** ($hk\ell$). It can be derived that

$$\mathbf{F}(hk\ell) = V \int_{x=0}^{1} \int_{y=0}^{1} \int_{z=0}^{1} \rho(xyz) \times \exp[2\pi i(hx + ky + \ell z)]dxdydz \tag{2}$$

where **F** ($hk\ell$) is called the structure factor for reflection ($hk\ell$). It can be regarded as a vector with amplitude F and phase angle a: $\mathbf{F} = |F|\exp[i\,\mathrm{a}]$; x, y and z are fractional coordinates along the unit cell axes **a**, **b**, and **c**; V is the volume of the unit cell and r the electron density distribution in the cell. Using Eq. (2), the scattering by the crystal can be calculated from the electron distribution in the unit cell. In the reverse direction, r(xyz) is derived from the **F**(hkl) 's of all scattered beams. This is accomplished by applying a mathematical procedure called Fourier transformation. If Eq. (2) is true, then it is also true that

$$\rho(xyz) = \frac{1}{V} \sum_{h} \sum_{k} \sum_{\ell} |F(hk\ell)| \times \exp[-2\pi i(hx + ky + \ell z) + i\alpha(hk\ell)] \tag{3}$$

using Eq. (3), the electron distribution in the unit cell can be calculated provided that the values of F ($hk\ell$) and a($hk\ell$) are known for all reflections. The F($hk\ell$) 's are easily found because, apart from correction factors, they are proportional to the square root of the scattered intensities I ($hk\ell$). The phase angles a($hk\ell$) cannot be measured, however (see Phase Problem), but must be derived indirectly by one of these four methods:

1. direct methods
2. isomorphous replacement
3. molecular replacement
4. **MAD**, multiple wavelength anomalous dispersion

Direct methods are the method of choice for small compounds, but they are not yet sufficiently developed for macromolecules. The other three methods are applicable to large molecules.

The degree of detail in the electron density map calculated with Eq. (3) depends on the number of reflections included in the summation. The greater the number, the greater the accuracy. The greater the volume of reciprocal space included, corresponding to reflections from smaller spacings in the crystal, the greater the atomic detail in the electron density map. This is the "resolution" that is always quoted with every structure determination by X-ray crystallography.

X-Ray Scattering

X-ray scattering is an important structural tool for studying biological macromolecules. When X-rays are scattered elastically and coherently by atoms, the scattered waves interfere in a manner related to the spatial distribution of the atoms. The most widespread application of X-ray scattering in structural biology is crystallography, in which the scattering from molecules in three-dimensional crystals is used to determine their structures at high resolution. For biological molecules in unordered or partially ordered systems, lower-resolution structural information is obtained that can also provide critical insights into function.

1. Interactions of X-Rays with Matter and the Information Content of Scattering Data

X-rays are photons and can be produced with wavelengths in the range 0.1 to 100 Å (1 Å = 10^{-10}m). They are ionizing radiation and therefore can be quite damaging to biomolecules. Like other electromagnetic radiation (such as light), they propagate as waves and are scattered via interactions with the electrons in a sample. The interference of coherent, elastically scattered X-rays interacting with biological samples gives structural information at different levels of resolution, depending on the degree of order in the system. Analysis of the scattering intensity distribution at small angles of unordered biological macromolecules in solution gives information on their overall shapes and the associations they form. Small-angle scattering data yield structural parameters such as the radius of gyration, R_g, molecular weight, M, and the vector length distribution function, $P(r)$, for the scattering particle. These experiments can provide critical information on the conformational changes and associations formed during biological function. For example, small-angle X-ray scattering data from the calcium-binding protein calmodulin (1) revealed that the a-helix connecting its two globular domains seen in the crystal form was flexible in solution. This flexibility has proven the key to calmodulin binding and subsequent activation of its regulatory targets (2). X-ray scattering from molecules that are ordered in one, two, or three dimensions is convoluted with the repeating lattice structure, giving rise to diffraction maxima in the scattering pattern. For example, oriented DNA molecules give rise to X-ray diffraction patterns that in 1953 yielded the double helical DNA structure (3). X-ray diffraction data from natural membranes were used to establish the lipid bilayer as the predominant structural component of membranes (4). The bilayer structure of membranes give rise to diffraction maxima relating to repeat distances both perpendicular and parallel to the plane of the bilayer (5) that can be important in understanding, for example, the influence of lipid type (6), protein content (7), toxins (8), drugs (9, 10), or molecules like cholesterol (10, 11) on the membrane structure and fluidity. Membranes can also give rise to two-dimensional diffraction patterns from ordered molecules, such as proteins within the planes of the bilayers [eg, **bacteriorhodpsin** (7, 12)]. These data can give information on the protein's structure and and/or position within the bilayer. Crystallography is the interpretation of X-ray diffraction data from three-dimensional crystals of molecules in terms of high-resolution molecular models. In the case of biological macromolecules,

the resolution obtained can be true atomic resolution, although more often it is at the level of individual chemical groups. Three-dimensional crystallographic data on biological macromolecules provide the level of detail that can ultimately reveal the chemistry of biomolecular mechanisms.

2. X-Ray Sources

Conventional laboratory X-ray generators work by exciting the characteristic emission lines of metallic elements. An electron beam of a few tens of kilovolts is directed onto a metal target and knocks electrons out of low-lying orbitals, creating "holes." Because these holes are refilled by electrons from higher orbitals, sharp emission lines are produced. Typically about half the X-ray energy will be converted into these lines. The other half contributes to a white background. The most common metal target used for X-ray production in a laboratory for biological studies is copper, and its K_a emission line ($\lambda = 1.54$ Å) is usually used. The nearby copper K_b can be removed using a nickel filter. Synchrotrons provide alternative sources of X-rays in the form of very high-intensity, well-collimated X-ray beams. Synchrotron radiation is emitted in short pulses (a few tenths of nanoseconds) at high frequencies (megahertz) when electrons are accelerated at very high speeds in a circular trajectory using electromagnets. This "white" radiation can be monochromatized for scattering experiments. Synchrotron technology requires large facilities, and there are an increasing number of synchrotron user facilities well-equipped with instrumentation for protein **crystallography, small-angle scattering**, as well as diffraction from partially ordered systems. The increased intensities of the synchrotron sources allow for faster studies on smaller samples, or samples that are inherently weak scatterers. In particular, synchrotron intensities make time-resolved studies possible. For example, they facilitate using small-angle scattering to follow protein conformational changes with time on time scales of milliseconds to seconds (13). The time scales and intensities of synchrotron radiation also facilitate Laue Diffraction (14) studies that utilize the white spectrum of the source to collect crystal diffraction patterns rapidly. X-ray damage to biological samples can be quite severe with synchrotron intensities. For solution scattering experiments, radiation-induced aggregation can also be a problem. These effects can be minimized by keeping samples at low temperatures, minimizing measurement times, using reducing agents to minimize free-radical concentrations, and/or lowering X-ray intensities by the use of attenuators.

Xenogeneic

Acceptance of an organ graft from one donor to a recipient is strictly conditioned by their respective genetic constitutions. Identity defines *syngeneic* conditions, which occur with monozygous twins or animals from the same inbred strain. Because there is no genetic difference between donor and recipient, the graft is accepted. Whenever the donor and the recipient belong to the same animal species, but differ in their genetic constitution, the *allogeneic* graft is rejected after 10 to 12 days. Allogeneic graft rejection is an immunological reaction, because it is specific, mediated essentially by cytotoxic T lymphocytes, and controlled by molecules of the major histocompatibility complex (MHC): HLA in humans and H2 in mice. Secondary responses are apparent by an accelerated rejection after a second graft from the same genetic origin as the first one. A *xenogeneic* donor and recipient belong to different animal species. In this case, the rejection is immediate and particularly violent. The mechanisms of xenogeneic graft rejection are numerous and complex. Hyperacute rejection is due to the presence of natural **antibodies** that bind to the endothelium, thereby inducing **complement** fixation, activation of the endothelium, and initiation of blood clotting. Many efforts have been made in the recent past to understand the mechanism of xenogeneic rejection and to define strategies to overcome it, because it might provide a valuable source of organs for human transplantation. So far, significant results have been gained at least for the hyperacute phase, but enormous difficulties are still to be solved. A second immunological barrier is that of the delayed xenograft/acute vascular rejection, which is still not fully understood. Third, rejection mechanisms similar to those encountered in allograft rejection are also operating, with an increased efficiency. All these barriers have to be solved before xenograft really become a reality. To date, no classical immunosuppressive drug can prevent such rejection. The present efforts aim to induce specific unresponsiveness to the most antigenic foreign constituents, but this remains a very difficult task.

Xenopus

More than a thousand different species of frogs have been characterized. The genus *Xenopus* (“strange foot” in Greek) arose more than 120 million years ago and includes 17 species. These aquatic frogs live in ponds in southern (sub-Saharan) Africa. One of these species, *Xenopus laevis*, has become, together with the mouse and chick, an attractive vertebrate model system for embryologists and developmental biologists. In fact, most of what is known of vertebrate

development comes from the study of the amphibian embryo. Already popular in Europe, *X. laevis* was first introduced in the United States in the early 1950s as a way to test for pregnancy in humans. When injected subcutaneously into female *Xenopus*, the gonadotropin hormone present in pregnant women's urine would induce her to lay eggs the next day. Unlike most other frogs, egg laying in *Xenopus* is not seasonal; these tests could thus be performed all year round.

For embryologists, a major advantage of this frog is the number and size of its eggs. A single female can lay up to several thousand eggs a day. This is particularly important for modern molecular techniques: the source of biological material such as complementary DNA (cDNA), **RNA**, or protein is virtually unlimited. In addition, a *X. laevis* egg is approximately 1 mm in diameter, which makes it one of the largest cells in the world, visible to the naked eye, and amenable to microsurgery and microinjection of molecular factors. Moreover, fertilization of the egg is external, so the amphibian embryo can be studied from the beginning, when the embryo is a single cell. Finally, perhaps one of the most important attributes of this system is the amount of knowledge accumulated over more than a century on the development of the amphibian embryo. There is an amazingly rich body of literature, from descriptive to experimental approaches, on the development of many different types of amphibian embryos, including *Xenopus*. Associated with this literature is a remarkable cast of characters, including Mangold, Spemann, Roux, His, Holtfreter, Hamburger, and Nieuwkoop. Their work and their vision established the foundations of vertebrate experimental embryology, on which modern molecular embryological approaches are built. Although powerful genetic approaches in *Caenorhabditis elegans* and **Drosophila**, and more recently zebrafish and mouse, have contributed substantially to our knowledge of early embryonic development, experimental embryology in the amphibian had already established many key features of embryonic development. For example, the concept of embryonic **induction**, so widely accepted today as a means to establish embryonic cell fate, was first defined in amphibians (1). This article presents (*1*) a descriptive overview of *Xenopus laevis* development, including the concepts of fate maps and gene maps; (*2*) a review of molecular approaches currently used in the *Xenopus* system in **oocytes** and in embryos; (*3*) the use of explants and experimentally perturbed embryos in molecular studies of early development; and (*4*) genomics, nuclear transplantation, transgenesis, and maternal knockout strategies.

1. The *Xenopus* Embryo

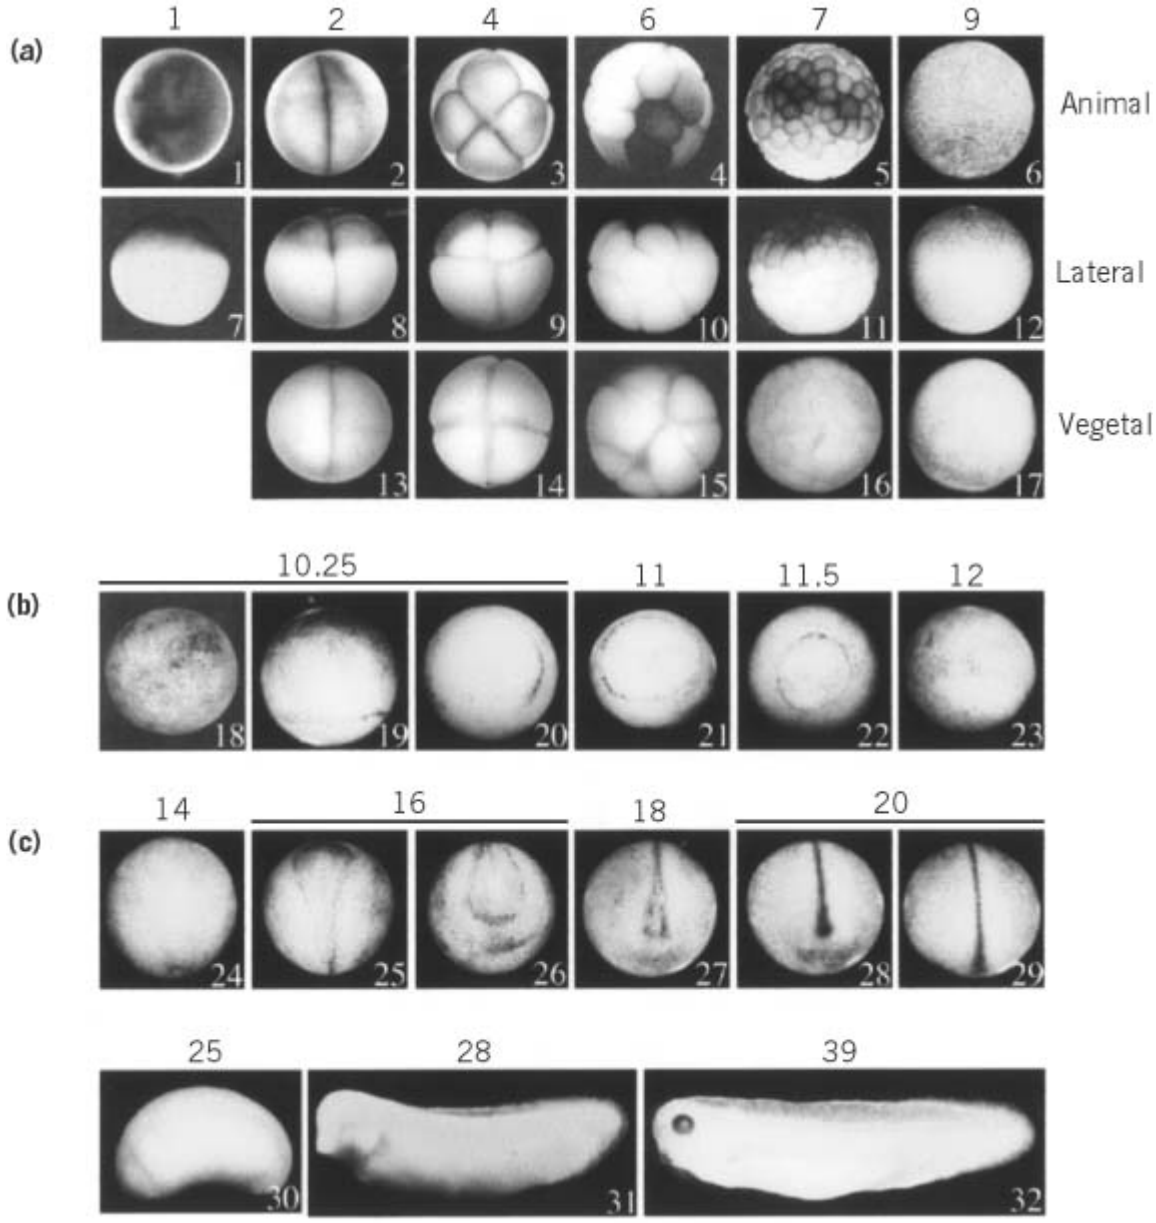
1.1. Early Embryonic Development

Large numbers of *Xenopus* embryos can be obtained year-round, either by natural mating or by *in vitro* fertilization. For “natural” mating, both the male and female are injected with human chorionic gonadotropin and left in a quiet dark tank overnight to copulate. A large number of embryos at different stages of development can be harvested the following day. For *in vitro* fertilization, females are injected subcutaneously with the chorionic gonadotropin and left overnight. The next day, a male frog is sacrificed, and fragments of surgically removed testis are used to fertilize eggs gently squeezed from the female. Each squeeze provides a few hundred eggs. Females can be squeezed every hour for several hours. The advantage of *in vitro* fertilization is that all the eggs for a given squeeze develop synchronously; thus, a large number of embryos of a given stage are available. When laid, the eggs have a single axis of cylindrical symmetry running from the pigmented pole at the top, also called the **animal pole**, to the yolky bottom or vegetal pole. This axis of symmetry is imposed maternally during the development of the oocyte (2).

The sperm can enter at any point around the circumference. The first cell cycle is unusually long, about 90 minutes at room temperature. About 30 min after sperm entry, a drastic cytoplasmic movement, referred to as *cortical rotation*, takes place: the inside of the egg rotates about 30° relative to the outside. The consequence of cortical rotation is that the original axis of cylindrical symmetry is broken, and one side of the egg is different from the other (2). With 85% accuracy, the side opposite the sperm entry point will become the dorsal side. A series of quick cell divisions follow, without change in the volume of the embryo; thus, the cells become smaller in size following each division (Fig. 1a). During the first 4 hs of development, all cells of the embryo divide synchronously. The length of each cell cycle, after the first, is about 20–30 min at room temperature;

the early blastomeres of the *Xenopus* embryos have barely enough time to replicate their genome before **cytokinesis** occurs and the next cleavage furrow becomes apparent. The development of the *Xenopus* embryo for the first few hours is entirely under the control of maternal determinants deposited in the egg.

Figure 1. Early embryonic stages of Xenopus laevis development. (**a**) The first 6 h of *Xenopus laevis* development. The numbers on top of each panel, or set of panels, represents the developmental stage (45). Each panel is indicated by a number for reference in the text. The first row shows animal pole views; the middle row, lateral views; and the third row, vegetal pole views. The embryo undergoes 13 synchronous cell divisions without an increase in size. (**b**) Gastrulation. Panel 18 is an animal pole view; 19, a lateral view; and panels 20–23, vegetal posterior views. (**c**) Neurulation and the formation of a tadpole. Panels 24 and 25 are dorsal views of neural plate and neural groove stage embryos, respectively; panels 26–28 are anterior, head-on views showing the progressive closure of the anterior neural tube; panel 29 is a dorsal view of the neurula with the entire neural tube closed; and panels 30, 31, and 32 are lateral views of late neurula, tailbud, and tadpole, respectively.

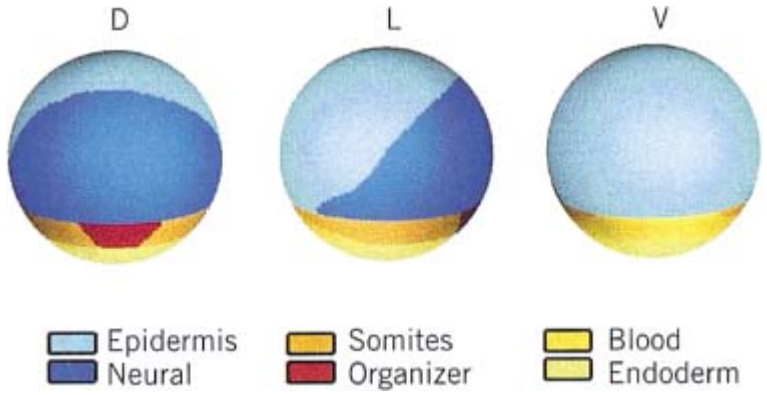


Dramatic changes occur after 13 synchronous cell divisions, when the embryo reaches about 4000 cells (Fig. 1b): (*1*) the synchronicity of cell division is lost, and embryonic cells divide at different

rhythms in different regions of the embryo; (*2*) zygotic transcription begins (3); and (*3*) finally, cell and tissue movements begin. Among the first of these movements is the spreading of the animal pole region toward the marginal zone, called *epiboly*. Also, the cells of the marginal zone begin to move toward the dorsal side by a process called *convergence and extension*, a process that will continue during **gastrulation** (4). At this stage of development, the three embryonic germ layers—**ectoderm**, **mesoderm**, and **endoderm**—have been specified. These early cell movements set the stage for gastrulation, which begins about 9 h after fertilization.

It is during gastrulation that both the antero-posterior and right-left axes are determined and that cells of the prospective mesoderm and endoderm move to the interior of the embryo. Cells in a subequatorial region on the dorsal side involute first (Fig. 1, panels 19 and 20). This invagination is recognizable morphologically by the formation of a small arc of pigment in the dorsal side, called the *blastopore lip*. The emergence of the blastopore lip defines the dorsal midline. A group of cells located within a 30° angle at each side of the dorsal midline have the capacity to direct development of the entire dorsal axis, including axial mesodermal derivatives, such as somite and notochord, and the entire central nervous system (5). These group of cells are called the " organizer" (Fig. 2) because classic experiments demonstrated that removing this group of cells from a donor early gastrula embryo and implanting it in the ventral axes (6). One axis is generated by the host organizer; the other one forms under the influence of the ectopic organizer implant.

Figure 2. Gastrula fate map. Three views of the superficial gastrula, with the fate map adapted from Keller (1975) (D—is a dorsal view, L—a lateral view, V—a ventral view). The ectoderm is derived from the top of the embryo (animal pole, shades of blue). Mesoderm is derived from the equatorial region (marginal zone, shades of red), and endoderm from the bottom (vegetal pole, yellow). See color insert.



Involution gradually spreads from the dorsal side to the mediolateral and ventral region of the embryo; this is manifested by the expansion of the blastopore lip arc (Fig. 1, panels 20–23). The lip finally becomes a closed circle when cells located in the entire circumference of the embryo have invaginated. The first cells that involute on the dorsal side are the prechordal plate (or head) mesoderm; these cells will contribute to mesodermal components of the craniofacial structures and are therefore anterior in nature. Cells that involute later, on the dorsal side, give rise to somites and notochord (4). As gastrulation proceeds, the blastopore ring becomes smaller and smaller until it closes to engulf the entire vegetal pole (endoderm). The closure of the blastopore demarcates the end of gastrulation and the beginning of neurulation. The blastopore will ultimately become the anus of the tadpole. Thus, at the end of gastrulation the embryo has successfully brought the entire endoderm inside, covered its surface with ectoderm, and placed mesoderm in between.

At the end of gastrulation, the cells of the dorsal ectoderm thicken to form the neural plate (which is two cell layers thick). This is the first morphological sign of the nervous system (Fig. 1c). The neural

plate is flanked laterally by the neural crest and anteriorly by the sensory placodes and an amphibian-specific organ, the cement gland. Within the neural plate itself, mature neurons emerge in three stripes on each side of the dorsal midline (7). The ones closest to the midline will become motor neurons, those in the intermediate strip will contribute to the interneurons and the most lateral stripe will give rise to sensory neurons. During neurulation, morphogenetic movements elevate the lateral edges of the neural plate to give rise to a neural groove (8). The neural groove will ultimately close to generate the neural tube, with a brain at the anterior and the spinal chord at the posterior end. In *Xenopus laevis*, neural crest migration begins at the neural groove stages and continues following neural tube closure. The eye buds and optic vesicles, as well as the cement gland, become morphologically distinct. Neurulation ends with the closure of the neural tube and the appearance of a tailbud at the posterior end of the embryo. The cells of the heart primordia that flank the organizer on both sides meet in the ventral midline and fuse to form a tube that will later fold to form a functional heart. The progenitors of other organs have begun their differentiation as well. These include the embryonic kidney (pronephros) from lateral mesoderm, as well as the blood islands in the ventral mesoderm that will give rise to cells of the entire hematopoeitic pathway.

By the tailbud and tadpole stages, the embryo has a functional nervous system (Fig. 1, panels 31 and 32). Most neuronal axons have reached their targets, and the embryo is motile. A few hours later in the tadpole, the folded heart pumps blood derived from the blood islands into the newly formed arteries and veins. The development of internal organs, such as pancreas, gut, and intestine, is complete. The maternal yolk, which sustained embryonic life up to this point, is exhausted, and the tadpole begins feeding. Concomitant with this is the emergence of specific behavior.

The tadpole continue to grow in size until metamorphosis occurs. During this dramatic stage of the frog's life, major remodeling of almost the entire body changes the morphology and the physiology of the tadpole, to generate a frog. There has been tremendous progress in the understanding of the molecular basis of metamorphosis in amphibians, and excellent reviews are available on this topic (9).

1.2. Fate Maps and Developmental Commitment

Fate maps, a fundamental concept in embryology, tell us what regions of the early embryo will contribute to later structures. Of course, the fate map does not tell us about how those structures are formed or their state of commitment, only about their spatial origin. In *Xenopus laevis*, several detailed fate maps of different stages of embryogenesis, as early as the 16- and 32-cell stage, are available (10). The pioneering work of Keller has provided a very high resolution fate map of gastrula and neurula embryos (11). In addition to fate maps of the whole embryo, there are fate maps of the neural plate and sensory placodes (12). At the gastrula stage, the fate maps described in *Xenopus laevis* are very similar to those described in other amphibians, including *X. tropicalis*, *X. borealis*, *Rana pipiens*, and *Triturus* (newt). Fate maps in the amphibian are usually constructed by marking cells with vital dye or by injecting them with other lineage tracers, followed by a statistical assessment of where the labeled cells end up later in the tadpole. Knowledge of the amphibian fate maps has been key in the understanding the molecular processes involved in early development (see text below).

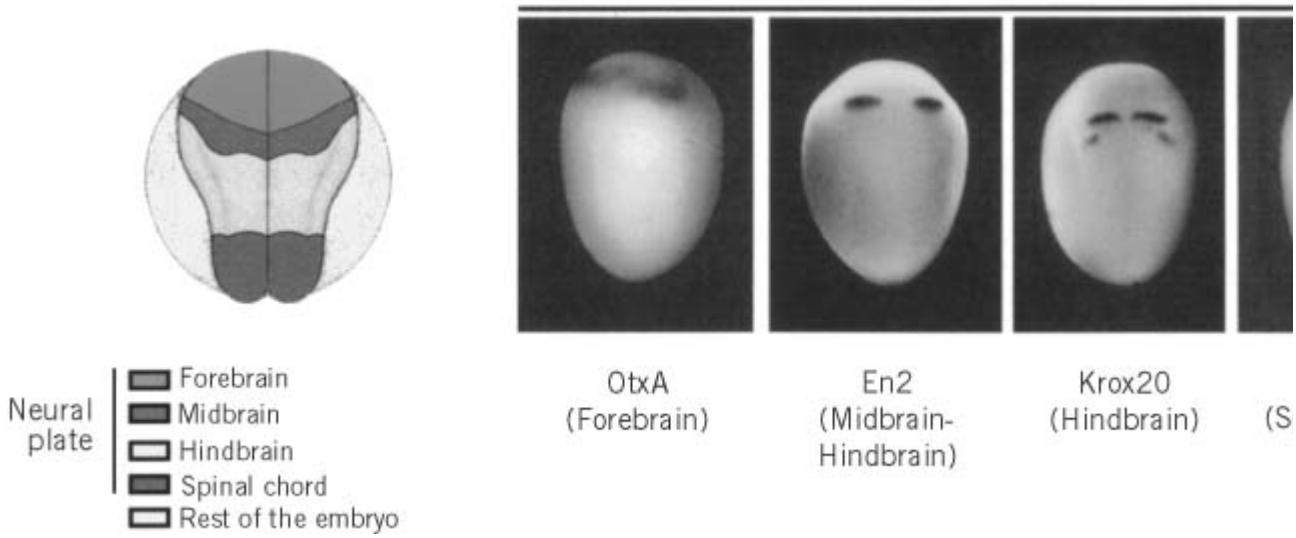
To determine the state of **commitment** of a region of the embryo, approaches such as specification and determination assays can be used (13). In a specification assay, different regions of the early embryo are removed by microsurgery and cultured in a simple saline solution. Because a source of food is contained within each cell, these cultures do not need extrinsic factors to develop. By comparing the behavior of the explants cultured in isolation and the behavior of this region in the context of the embryo, it is possible to assess the state of commitment of that tissue. If the explant in culture gives rise to the same structure as in the embryo, then the explant is **specified**. Additionally, if the explants are derived at different times, it is possible to assess the state of commitment of a tissue at a given time toward a given fate. In determination assays, a cell or group of cells are transferred from a donor embryo into a different environment of a host embryo of the same or different developmental stage, and their development is compared to when they are cultured alone

(as in specification assays). A region of an embryo is **determined** if it can give rise to the same structures regardless of its environment (in culture alone or placed in different region of the embryo). Slack (1984) suggested that analysis of the state of commitment can be expanded to include not only tissue and single cells, but nuclei also. Molecular analyses of these commitment states are used in molecular embryology to assess the molecular pathways involved in cell commitment and cell fate determination (see section on use of *Xenopus* embryos and embryonic explants in molecular biology, below).

1.3. Gene Maps

While early embryonic cells can appear morphologically identical, they do not necessarily express the same repertoire of **genes** (Fig. 3). This observation has allowed the unveiling of what Kirschner and Gerhart call the "second anatomy" of the embryo, based on the region-specific distribution of gene products (14). Sometimes the gene map correlates very well with fate maps, and sometimes it does not. When a given gene demarcates the same territory as the fate map for a given time in development, the gene can be considered to be a molecular marker for those cell types (Fig. 3). In molecular embryology, the expression of these genes is used as a testimony for the formation of the cell type in which they are expressed. It is very important to remember that, because some genes have an extremely dynamic pattern of expression, a molecular marker for a given cell type will only attest to the presence or absence of that cell at the appropriate time of expression. For example, the gene brachyury (*Xbra* in Ref. 15) demarcates the entire marginal zone of the early gastrula in *Xenopus*; fate mapping studies have established that the entire mesoderm will derive from this region. A few hours later, at the end of gastrulation and the beginning of neurulation, *Xbra* is expressed in the notochord and as a ring around the blastopore. Thus, *Xbra* is a panmesodermal marker when its expression is measured at gastrula stages; however, at neurula stages *Xbra* is a marker of notochord and blastoporal ring. Other markers are less dynamic in their expression; for example, the neural cell adhesion molecule (NCAM) (16) is expressed in the neural plate from the onset of its formation and remains entirely neural-specific until at least very late tadpole stages.

Figure 3. Neurula fate map and molecular anatomy. The fate map shown in the left panel defines four domains along the axis of the neural plate: forebrain, midbrain, hindbrain, and spinal chord (adapted from Eagelson and Harris (12)). The g right shows the expression of region-specific molecular markers within the neural plate. From left to right: the homeobo marker of presumptive forebrain; Engrailed-2 (En2) is a homeobox gene that demarcates the midbrain-hindbrain junctio factor Krox20 is a marker of rhombomers 3 and 5 of the hindbrain; the homeobox HoxB9 demarcates the presumptive sp



2. Molecular Tools for the Study of Early *Xenopus* Development

The combination of experimental embryological approaches and molecular techniques has armed modern embryologists with powerful tools to dissect the molecular basis of early vertebrate development. Traditional lambda phage–based gene libraries are available from almost every stage of embryonic development, as well as from different regions of the embryo at a given stage. More recently, stage- and region-specific expression libraries have been developed that introduce a very powerful means to **clone** the factors responsible for a given activity. Expression cloning is discussed below (see section on *Xenopus* embryos for molecular studies). As with other animal model systems, screens for gain of function, loss of function, and modifier using expression libraries are available in *Xenopus*. For these approaches, nucleic acids or proteins (wild-type or mutated forms) are **microinjected**, either alone or simultaneously with pools of clones from cDNA libraries, into the oocytes, eggs, or blastulae (17). Injected oocytes and embryos are allowed to develop to the desired stage, after which they are submitted to **phenotypic**, histological, and molecular analysis. While gain-of-function experiments use ectopic expression of wild-type or constitutively active forms of the proteins encoded by the injected DNA or RNA, loss-of-function experiments utilize dominant-negative proteins or injections of **antisense** RNA, antisense DNA oligonucleotides, **ribozymes** or neutralizing **antibodies**. An in-depth review of the use of dominant-negative mutant approaches in embryology has been presented elsewhere (18). It is important to remember that the specificity of effects derived from antisense RNA, ribozymes, or antibody injections need to be interpreted with extreme caution. It is also important to control for the *in vivo* stability of micro-injected reagents.

2.1. Microinjection of DNA

Up to 100 pg of supercoiled, nicked, or linear DNA can be microinjected into oocytes or early embryos (17). The DNA topology has no effect on expression. In oocytes, the size of the nucleus (germinal vesicle) allows direct injection of the DNA into the nucleus. This type of microinjection has been used for transcriptional studies, as well as examination of RNA **splicing** and **DNA** recombination. In embryos, transcription begins when the blastula reaches about 4000 cells (see text above); consequently, injected DNA is not transcribed for the first few hours of development. Because of this property, injection of DNA, rather than RNA, is sometimes used to study later developmental events. The injected DNA is stable until gastrula–early neurula stages, after which it gradually decays. For reasons that are not well understood, only a fraction of the embryonic blastomeres that inherit the DNA will ultimately express it; thus, expression driven from injected DNA is always **mosaic**. As is the case with genetic studies, mosaic expression has its own advantages when contrasted with uniform expression.

The requirement for **promoters** is not very stringent in *Xenopus laevis*: most vertebrate and **virus** promoters work well in oocytes or embryos. However, with a few exceptions, tissue-specific expression cannot be achieved in this type of transient expression experiment. Another type of DNA injection involves the injection of single-stranded antisense oligonucleotides. In these experiments, regular or chemically modified antisense oligonucleotides are microinjected in the oocyte or embryos with the aim of binding to and eliminating the function of endogenous, sense mRNA.

2.2. Microinjection of RNA

The microinjected RNA can be of a biological origin, for example, **poly** *b***A***b*$^{+}$ RNA isolated from different tissue samples. More frequently, however, single RNA or a population of RNAs are generated synthetically by *in vitro* transcription. In this case, specific **vectors** that contain prokaryotic transcriptional promoters, such as those of SP6, T3, or T7 are used. In addition, these vectors usually contain short stabilizing 5′ and 3′ untranslated regions flanking the cloning sites. Some vectors also add a polyA-polyC tail to the 3′ end of transcripts to increase their stability (17). Synthetic RNAs obtained by *in vitro* transcription of a single clone or pools of clones from expression libraries can be injected into oocytes and embryos. In oocytes, up to 50 ng of RNA can be injected, while embryos can tolerate up to 5 ng of RNA. Injected RNA or DNA may encode either wild-type or mutant versions of proteins. These mutant proteins can include constitutively active forms of known proteins, for example, constitutively active **receptors**, **signal transducers**, or

transcription factors, which will activate signaling pathways or target genes in a ligand-independent fashion. Alternatively, they can encode dominant-negative versions of embryologically active proteins to generate loss of function phenotypes.

2.3. Microinjection of Proteins

Finally, injection of proteins, such as immunoglobulins, have also been reported in *Xenopus* embryos (19, 20). In these experiments, neutralizing antibodies against specific proteins are microinjected with the aim of eliminating the function of the endogenous protein. Again, as in the case with antisense techniques, interpretation of **phenotypes** should done with great care. Rescue experiments, in which the antigen and antibody are coinjected, provide the most stringent control for specificity.

3. The *Xenopus* Oocyte

Because of its size, the ease with which it can be obtained, and the relative ease with which it can be cultured, the *Xenopus* oocyte has become popular with researchers with a wide variety of interests. The fully mature *Xenopus laevis* oocyte is a large cell of about 1 mm in diameter. The oocyte is surrounded by a vitelline membrane and several layers of follicular cells. For most experimental conditions, the latter are removed, either mechanically or by enzymatic treatment, for example with collagenase. These defolliculated oocytes still have the vitelline membrane attached, which provides mechanical stability.

Oocytes can be used for a variety of functional studies, a few of which are described below. Up to 50 ng in a total of 50 nL of RNA can be microinjected into the **cytoplasm** of the oocyte. Unlike early embryos, the *Xenopus* oocyte is transcriptionally active. For DNA injections, most, if not all, mammalian promoters work well for expression in the context of the oocyte. Similarly, the polyadenylation signals from **SV40 virus** or mammals function well in the frog. Up to 10 ng of DNA can be injected directly into the germinal vesicle (nucleus) of the oocyte.

The *Xenopus* oocyte expression system has been used successfully for expression cloning, the study of individual proteins, and large-scale production of secreted proteins. The success of expression cloning depends on both the quality of the library and the specificity of the assay. For example, membrane proteins such as **ion channels** have been cloned by injecting oocytes with populations of RNA or DNA, followed by electrophysiological analysis to determine whether the desired channel is present in the pool. Further sib-selection of active fractions leads to the isolation of the clone encoding the channel. For isolation of receptors for hormones or growth factors, similar approaches can be used: binding of a labeled ligand is used to identify positive fractions.

Alternatively, individual cell-surface proteins can also be studied by injection of single RNA or cDNA. This has traditionally been used to study mutant forms of channels and receptors. Finally, although most oocyte experiments involve the analysis of membrane proteins, the *Xenopus* oocyte has been used more recently for the production of large amounts of secreted factors. In fact, one of the most efficient ways to obtain large quantities of highly-purified secreted growth factors, from any source, is to harvest the conditioned medium of oocytes injected with synthetic RNA encoding these factors.

Because of its size, the oocyte is also one of the favorite systems used by cell biologists interested in subcellular trafficking. Thus, trafficking between the endoplasmic reticulum and the Golgi apparatus in the secretory pathway, nuclear translocation, and subcellular localization of RNA have all been explored using *Xenopus* oocytes (for a detailed review, see *Methods in Cell Biology*,1992).

4. Use of Xenopus embryos and Embryonic Explants in Molecular Biology

Examples of a few assays that are commonly used in *Xenopus* to identify molecular players involved in embryological functions are presented here. It is important to emphasize that, while these techniques are widely used, new approaches emerge continuously that are custom fitted to address

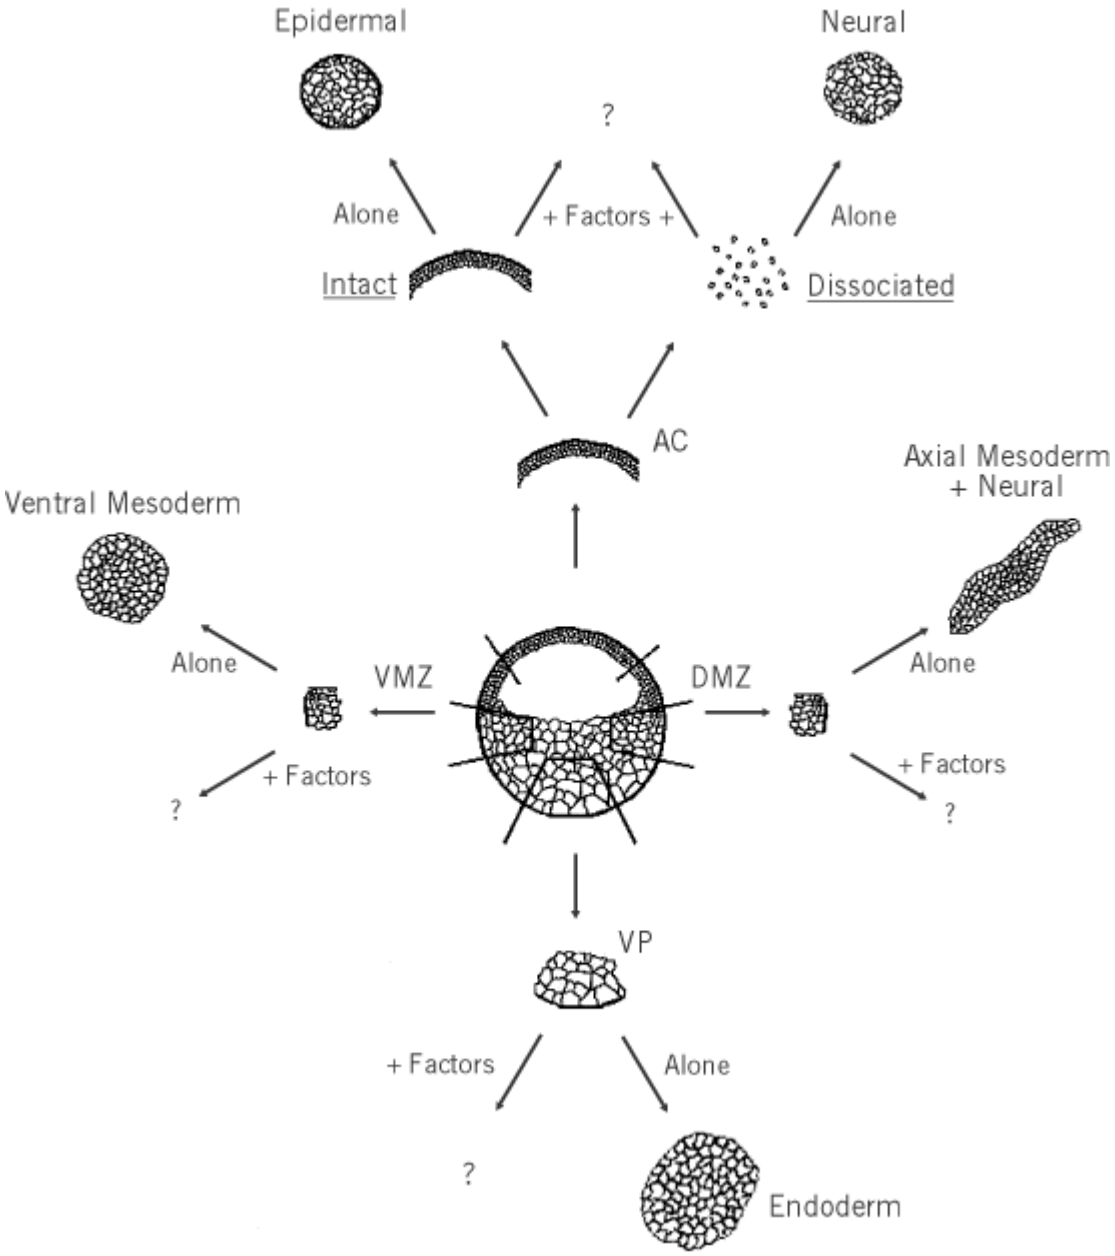
specific questions.

4.1. Embryonic Explants

Specification studies combined with the analysis of cell-type-specific markers have provided a simple but powerful means of identifying factors involved in embryonic development. Explants can be cultured alone or in the presence of factors; alternatively, explants from different regions of the embryo of the same stage or different stages can be recombined to assess their influence on each other, as illustrated by the following examples for each case.

Although many type of explants can be derived from different regions of the amphibian embryo at various times of development, the most frequently used explants are derived from the early blastula or gastrula (Fig. 4). There are three types of explants traditionally used: from the ectoderm (or animal caps), mesoderm (ventral marginal zone, lateral marginal zone, and dorsal marginal zone), and endoderm (or vegetal poles).

Figure 4. Embryonic explants. A schematic cross section of a late blastula stage embryo (~4000 cells) is shown in the center. When the animal cap (AC) is removed and kept intact, it will differentiate as epidermis; if dissociated, it will give rise to neural tissue. The explanted dorsal marginal zone (DMZ) cultured in isolation will form axial mesoderm, such as notochord and somites, as well as neural tissue. The vegetal pole (VP) differentiates as endoderm (gut) in culture. The ventral marginal zone (VMZ) will form ventral mesoderm derivatives, such as blood cells, in culture. The behavior of these explants can be challenged in culture by the addition of molecular factors. These factors can be added to the explant culture after its isolation, or they can be presented as injected RNA or DNA at early stages of development by microinjection in the appropriate region of the embryo.



The most popular explant assay is the animal cap assay. When explanted at blastula or early gastrula stages and cultured alone, animal cap ectoderm differentiates as epidermis (Fig. 4). However, these early animal cap cells are pluripotent and are able to change their fate in response to exogenous factors. These factors can be provided as soluble protein directly incubated with the explants (21) or as synthetic RNA injected in the animal hemisphere during the first three embryonic cleavages (22). The injected RNA remains confined to the site of injection, so one can target the RNA to different regions of the embryo. It was the use of *Xenopus laevis* animal caps that first allowed the characterization of molecular candidates involved in embryonic induction. A variant of the same assay involves the dissociation of the animal cap explants in Ca^{2+}- and Mg^{2+}-free medium. When the cells of the animal cap are dissociated and maintained for several hours in culture, they all adopt a neural fate (Fig. 4 (23). The type of neural tissue obtained by dissociation of animal cap explants is always anterior in character, including the cement gland (24). Animal caps assays have been used to answer a variety of questions concerning the study of inducers, morphogens (which are substances that elicit different fates at different concentration), and modifiers (factors that cannot induce specific cell fates on their own but have the ability to modify the character of cell types induced by other

factors) (25). For example, when varying concentrations of the growth factor *activin* (which belongs to the transforming growth factor (TGF) b ligand superfamily) are applied to dissociated cells, it can induce mesoderm and endoderm in intact animal caps and can display morphogen-like properties. At low concentrations, activin will induce ventral mesoderm; at higher thresholds, axial mesoderm and ultimately endoderm. Growth factors belonging to the Wnt superfamily act instead as modifiers; they cannot induce mesodermal cell fates on their own, but they can change the type of mesoderm induced by activin. Inherent to an understanding of inducers and modifiers is the concept of competence, which relates to the window of time during which a given population of cells can respond to an inductive signal. The animal cap has also provided a means to address competence. Even though our knowledge of competence at the molecular level remains sparse, factors such as fibroblast growth factor (FGF) have been suggested to regulate the capacity of embryonic cells to respond to mesoderm inducers such as activin (25). It is important to note that animal cap explants have dorsal–ventral polarity (imposed upon them during the first cell cycle by cortical rotation), which may influence the response of these cells to inducers or modifiers. This polarity can be eliminated by using animal caps derived from hyperventralized or hyperdorsalized embryos.

Intact ventral marginal zone explants develop as ventral mesodermal cell types, including those of blood; once dissected, these explants adopt a rough spherical shape in culture. Dorsal marginal zone explants, however, elongate in culture and produce axial mesoderm, such as notochord and somites, as well as neural tissue. Ventral and dorsal marginal zone explants are useful for the assessment of the modifier activity of molecular vis-à-vis mesodermal patterning. Substances that can change the fate of these explants are good candidate modifiers.

Finally, vegetal pole explants of blastula or early gastrula embryo give rise exclusively to endoderm. These explants have been used to assess induction, patterning, and competence in the context of endoderm formation and have been gaining in popularity of late.

4.2. Recombinant Explants

Explants can also be recombined in different ways to evaluate a wide variety of embryological activities, such as induction, patterning, and cell autonomy. One of the most informative recombinant explants was originally performed by Nieuwkoop in 1969 (26). It was known that animal cap explants cultured alone give rise to only ectoderm (epidermis) and that vegetal pole explants give rise solely to endoderm (gut). Nieuwkoop showed that these explants cultured together also form mesoderm. This was the first demonstration of mesoderm induction in the vertebrate. Later experiments using lineage tracers (see text below) established that the vegetal pole was the source of the mesoderm-inducing signal; animal pole cells respond to these signals by changing their fate from ectoderm to mesoderm. Once it was established that the animal pole cells could respond to mesoderm-inducing signals, simple modifications of this assay allowed the molecular characterization of the molecular factors involved. The vegetal pole was replaced by conditioned medium from different cell lines or purified factors; the animal pole cells incubated in the presence of these factors were assayed for the formation of mesoderm.

In general, recombinant explants that generate more tissue types when recombined together than when cultured independently provide the basis for bioassays aimed at isolating the molecules involved. Similar approaches have also been used in the nervous system to recombine anterior and posterior neural plate tissue. Anterior neural plate explants, cultured alone, develop as forebrain, while posterior explants develop as spinal chord; when recombined, intermediate neural tissue also develops, including midbrain and hindbrain (27). Another famous explant system was introduced by Keller and co-workers. Known as “Keller” explants, they include both dorsal mesoderm and ectoderm, contacting each other only at a narrow boundary (28). These explants have been used to study the way planar inductive and patterning signals operate to generate the nervous system (29). It is also possible to recombine tissues of different age. For example, notochord from a neurula or tailbud can be sandwiched together with the animal cap of a blastula stage embryo (like a hotdog, where the bread is the animal cap and the meat is the notochord) to study vertical signals from the axial mesoderm that influence neural patterning in the ectoderm (30).

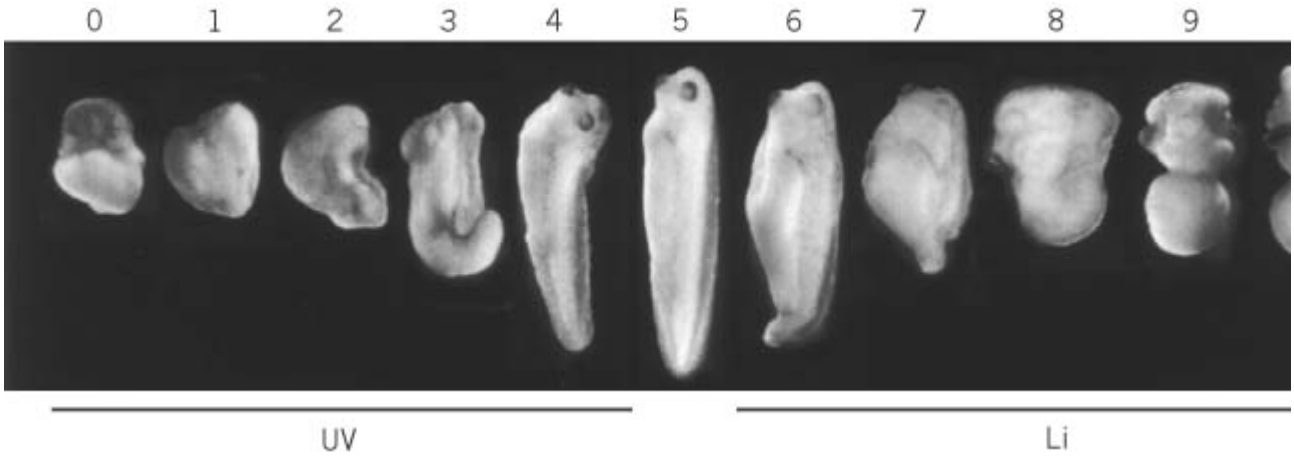
Heterospecific recombinant explants between *Xenopus* and chick and between *Xenopus* and mouse embryonic tissues have also been described (31, 32). In these cases, particular care should be taken to accommodate the physical requirements for the proper survival of the recombinants, such as temperature of incubation (different between the cold-blooded amphibian and the warm-blooded amniotes) and the ionic strength of the solution (50 m*M* salt for the amphibian tissue versus 150 m*M* for amniotes). The use of these heterospecies explants has led to the suggestion, for example, that the molecular natures of neural-inducing signals are conserved from amphibians to birds. Theoretically, therefore, an enormous variety of recombinant explants can be generated from amphibian tissue. The rationale behind their design depends solely on the questions asked and the creativity of the investigator.

4.3. Xenopus Embryos for Molecular Studies

In addition to the use of embryonic explants to isolate and characterize embryonic factors, expression cloning strategies have been successfully used in intact *Xenopus* embryos. In these approaches, fractionated cDNA libraries are subjected to *in vitro* transcription to generate synthetic RNA that is microinjected in different regions of either wild-type or perturbed embryos (see text below). Active fractions that generate a specific phenotype can be fractionated further by sib-selection until a single clone is obtained. These approaches have been extremely successful in isolating neural and mesodermal inducers and modifiers (33, 34). Injection in the animal pole, marginal zone, or vegetal pole of a one- or two-cell stage embryo will affect the differentiation of ectoderm, mesoderm and endoderm, respectively.

Expression libraries can also be used to rescue experimentally perturbed *Xenopus* embryos. Three types of perturbed *Xenopus* embryos are traditionally used: ventralized embryos, dorsalized embryos, and exogastrulae. In *Xenopus*, there is a link between the dorsal axis and anterior structures, as well as a link between the ventral and posterior structures (35). Ventralized embryos are obtained by UV irradiation of the vegetal pole during the first cell cycle (Fig. 5). This treatment blocks cortical rotation; thus, the dorsal side is never specified, and the embryo develops without a dorsal axis or head. Screening expression libraries based on their ability to rescue the ventralized phenotype of UV embryos has allowed the characterization of a large number of genes involved in the differentiation of dorsal structures. At the other end of the spectrum, incubation of the early blastula embryo (8- to 16-cell stage) in 300 m*M* LiCl will hyperdorsalize the embryo so that all ventral and posterior structures are eliminated (Fig. 5). In extreme cases, the embryo develops as a radially symmetrical head with retinal pigmented cells all around the circumference. Rescue of these embryos has been reported by injection of a single RNA, which suggests that these embryos could also be used for expression cloning strategies (33). Finally, exogastrulae represent another form of perturbed embryo in which, instead of invaginating, the cells of the gastrulae move out of the embryo (16, 36). Although these embryos have been used to study ectodermal and mesodermal interactions, they could also theoretically be used in expression cloning experiments, especially for screening genes involved in morphogenetic movements.

Figure 5. Experimentally perturbed *Xenopus* embryos. Varying amounts of exposure to UV irradiation during the first c generates embryos that are gradually ventroposteriorized (left panels), while treatment with LiCl for varying times produ that are dorsoanteriorized. This range of phenotypes represents the dorsoanterior index (DAI) (46) indicated by the numb each embryo. In this scale, the normal embryo has a DAI of 5 (in the middle), numbers below 5 represent ventralized ph numbers above 5 dorsalized embryos. At the extremes, an embryo with a DAI of 0 entirely lacks head and dorsal axial st while an embryo with a DAI of 10 contains only radially symmetrical head structures.



5. Genetics

5.1. *Xenopus* Genomics

The size of the *Xenopus laevis* genome has been estimated to be approximately 3×10^9 bp (37), which is comparable to that of the human genome. The somatic genome has 36 chromosomes (18 pairs). *Xenopus laevis* is a pseudo- **tetraploid** organism: evidence for tetraploidy is based on both comparison of DNA content between *X. laevis* and other Pipidae and the fact that most, but not all, genes examined are duplicated (37). About 20–30% of the entire *X. laevis* genome consists of repetitive DNA, and more than 2500 genes have been cloned from *X. laevis* to date and are available in the databases . In addition, the entire 17,553-bp mitochondrial DNA genome of *X. laevis* has been sequenced and shown to encode 13 proteins, 22 transfer RNA, and two **ribosomal** RNA (38). There is even a very rough provisional **linkage map** for *X. laevis* (37). Finally, the egg contains 4 ng of total maternal RNA, of which approximately 1% (40 pg/egg) is mRNA.

5.2. Genetic Approaches in *Xenopus*

Despite the fact that there are 40 recessive mutants known in *X. laevis* (39), its polyploidy (see text above) and large number of pseudogenes cause the system to be not accessible presently to classic genetic analysis. Nevertheless, a large number of approaches have recently made progress toward a genetic analysis of *Xenopus* embryonic development. Three such approaches will be described: nuclear transplantation, transgenesis, and maternal knock-outs. Recent work targeting *Xenopus tropicalis* as a bona fide genetic system have been initiated by several groups, however, and classic mutagenesis approaches in progress with this frog should yield their first fruit soon.

5.2.1. Nuclear Transplantation

While nuclear transplantation in mammals, and the generation of the clone Dolly, the lamb have recently received a lot of attention, it is important to remember that the first successful nuclear transplantation was performed in frogs. In 1952, Briggs and King, using the frog *Rana pipiens*, reported the first successful transfer of nuclei from a blastula to an egg and obtained embryos that survived until neurula stages. Shortly after, two groups using genetic markers demonstrated that cloning could work in *X. laevis*. It was, however, John Gurdon and colleagues who first obtained a genetically marked, sexually mature cloned frog (40). Nuclear transplantation requires the isolation of nuclei from donor cells and their subsequent placement into an egg in which the natural haploid nucleus has been eliminated. The donor cells can be derived from various tissues at various times in development. In *Xenopus*, the younger the nuclei, the better the survival rate. Nuclei isolated from blastula or gastrula stages sustain development beyond metamorphosis with higher efficiency than nuclei derived from the skin or intestine of a tadpole. Unlike what has been reported recently in mammals, however, no nuclei from adult frog tissue have been able to carry development beyond metamorphosis. The recipient cell is always an egg in which the haploid genome has been eliminated

by UV irradiation. The use of genetic markers in the donor and recipient cells, for example nuclei derived from albino embryos transferred into a wild-type pigmented egg, are used to assay for the successful elimination of the maternal nucleus. After nuclear transfer in this case, an albino frog derived from a pigmented egg represents a successful clone.

A modification of the nuclear transplant approach, in which nuclei from a *Xenopus* cell line are used for transplantation, has also been reported. This approach provides the advantage of manipulating the genome of the cultured cell prior to implantation. The number of embryos that develop normally after this procedure is low, and they usually do not survive beyond late neurula stages (41).

5.2.2. Transgenesis

Unlike transient expression of RNA or DNA by microinjection, transgenic technology allows stable and regulated **gene expression**. In *Xenopus*, unlike mouse, DNA injected into the egg or early blastomeres does not integrate into the genome, for reasons that are not clear. Using a technique originally developed in hydra, Kroll and Amaya reported recently the first successful transgenic frogs (42). This technique, called for *restriction-enzyme-mediated integration* (REMI), takes advantage of the nuclear transplantation technique in which nuclei are isolated from mature sperm, rather than somatic cells. The tightly packed sperm chromatin is decondensed *in vitro* and incubated with DNA that has been digested with restriction enzymes. This DNA is incubated with the decondensed sperm nuclei in the presence of a small amount of the same restriction enzyme and DNA Ligase. During this incubation, it is presumed that the restriction enzyme partially digests the sperm DNA; exogenous DNA that is mixed with the genome then integrates at the digested site(s) with the help of the ligase. Although several such transgenic frogs have been made, and this technique is becoming more widely used, no transgenic F1′ progeny have been reported yet; specifically, there have been no reports of germline transmission of transgenic DNA. Most of the transgenic *Xenopus* generated to date do not successfully complete metamorphosis. This is, however, not necessarily a major problem; it is possible to perpetuate a line with nuclear transfer, so there is no requirement for sexual reproduction. Therefore, transgenic lines can, theoretically, be perpetuated indefinitely.

Progress in this field is very rapid, and there are many other attempts in progress. These include the use of transposable elements and retroviruses in various species of *Xenopus*. It can be safely predicted that generation of transgenic frogs will become routine before the end of this millennium.

5.2.3. Maternal Knockout Strategies

Although conventional **knockout** or knockin strategies, which are commonly used in the mouse, are not presently available in amphibians, it is possible to eliminate maternal transcripts from the egg selectively to assess their role during early embryogenesis. In this approach, antisense oligonucleotides against specific RNA sequences are microinjected into oocytes (43), which are then reimplanted into a female (44). These eggs are marked so that they can be distinguished from controls, either by using the albino/pigmented technique described above or by incubation with lipophilic vital dyes. Later, these eggs are isolated from the surrogate mother and fertilized *in vitro*. Their development is compared to controls that are treated in the exact same way but injected with control sense oligonucleotide. A stringent control for the specificity of the phenotype is provided by rescuing the egg after fertilization by injection of sense RNA.

6. Conclusions and Perspectives

In addition to the use of *Xenopus* laevis embryos and oocytes in molecular studies, there are many other features of *Xenopus* that make it amenable to molecular studies, in fields as diverse as metamorphosis, tissue regeneration, behavioral studies, physiology, pharmacology, and neurobiology. Excellent books and reviews are available describing these topics in length and listed under “Suggestions for further reading” (see also Refs. 45 and 46). Finally, many other amazing species of frogs, some now near extinction, have been virtually ignored.

Although there is appreciation of the conservation of molecular factors in the vertical evolutionary scheme, it is important not to undermine horizontal differences in strategies of development among different frog species. Frogs certainly provide a fertile terrain to explore these differences at the molecular level, and it would be no surprise if the differences in molecular strategies turn out to be more impressive than the mechanisms that are conserved.

7. Acknowledgments

I would like to thank Curtis Altmann for help in generating Figures 1 and 2, and Chenbei Chang for help with Figure 5. I am indebted to the members of my laboratory for constructive criticism of the manuscript, especially Paul Wilson, Chenbei Chang, Daniel Weinstein, and Bart Eggen. I would also like to thank Shauna Seliy for excellent administrative assistance and Jennifer Marden for technical help. Finally, I thank Margaret Bolce Brivanlou for her love and patience.

FX174 Phage

Prior to the development of the **electron microscope**, the size of an object, such as a **virus**, was estimated by filtration through membranes of various pore sizes. By this criterion, the bacterial virus (bacteriophage) fX174, first described in 1935 (1), and its close relative S13 (2) were classified as much smaller than the **T phages** that were under investigation in the early days of molecular biology. Moreover, the fact that their genetic material is **DNA** made these two viruses attractive candidates as front runners in the race to unravel the molecular basis of heredity. The contributions began with the initial characterization of the fX174 DNA as being single stranded, as reported in the first issue of the *Journal of Molecular Biology* (3). The culmination came when fX174 was the first organism to have its genome subjected completely to DNA sequencing (4), which offered the first direct documentation of the existence of overlapping **genes** in nature.

1. Virus structure

The fX174 virion appeared polyhedral with “knobs” or “spikes” in early electron micrographs of metal-shadowed and stained preparations (4). These images led to the proposal that the virion has

icosahedral symmetry, a structural feature that was later confirmed at a higher resolution by cryoelectron microscopy (5) and at atomic resolution by X-ray crystallography (6). The major contribution of these structural studies was, however, the establishment of the three-dimensional protein structures of the three major proteins in the crystalline form of the fX174 virion and their quaternary structure in both the crystalline and aqueous states of the virion. In the virion, the fX174 circular, single-stranded, DNA genome is enclosed within a $T = 1$ icosahedral protein shell, the simplest of the possible deltahedrons (7). Consequently, the protein shell of the virion contains 60 copies of the proteins encoded in genes F, G, and J, and 12 copies of the gene H protein product (Table 1). Five copies of F capsid protein are clustered around each of the 12 vertices of the icosahedron, forming a shell that has no openings at the center of the 20 triangular faces, as seen in the reconstructed image of the virion exterior in Figure 1. Five copies of G protein form the spikes, or projections, that extend outward from the capsid surface at each vertex of the icosahedron (Fig. 1). The spikes are attached to the capsid outer surface by each G protein interacting with its F protein partner via eight direct hydrogen bonds and five indirect, water-mediated hydrogen bonds (8).

Figure 1. Three-dimensional reconstructed image of fX174 virion from electron micrographs of unstained frozen-hydrated preparations (courtesy of Norman H. Olson and Timothy S. Baker, Purdue University). The diameter of the virion is 33.5 nm between the exterior edges of the spikes at the fivefold axes (28).

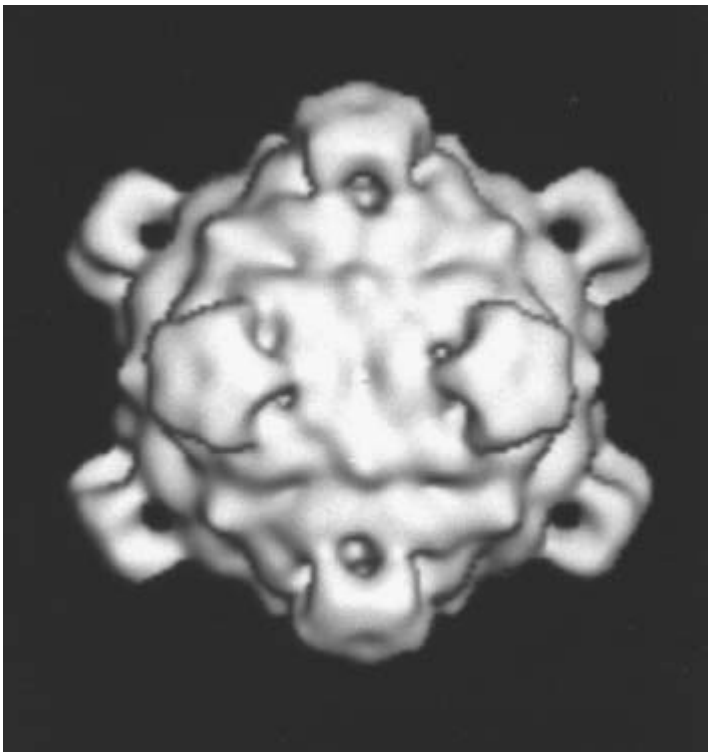

Table 1. fX174 Structural Proteins

Protein	Mol. Wt.	No. of Residues	No. in Virion	No. in Procapsid
B protein	13.8×10^3	120[a]	0	60
D protein	16.9×10^3	152	0	240
F protein	48.4×10^3	426	60	60

G protein	19.0×10^3	175	60	60
H protein	34.4×10^3	328[a]	12	12
J protein	4.2×10^3	36	60	0

[a] Based on DNA sequence (4).

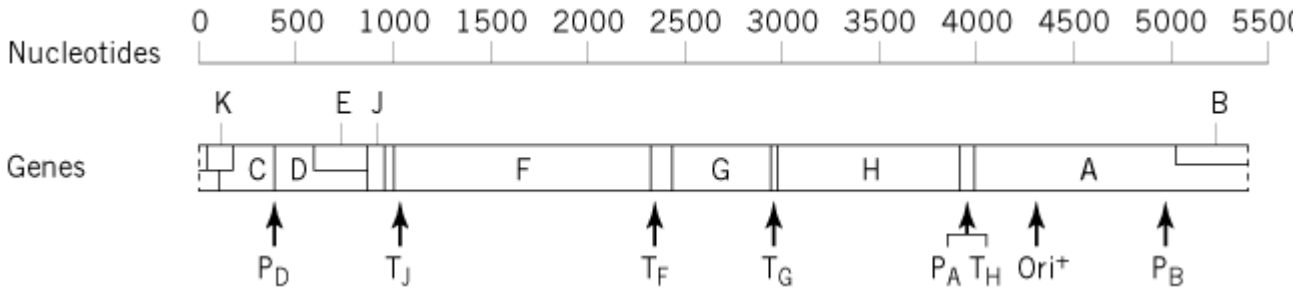
The single-particle reconstruction (5) and crystallographic data (6) also revealed structural details about the interiors of the capsid layer and the spikes, as well as additional structural components that are interacting with the interior surface of the capsid. For example, both F and G polypeptides contain an eight-stranded antiparallel beta-sheet motif (b-barrel) like that found in most viral capsid proteins. In addition, each F pentameric cluster contains a small, central channel that leads into a central channel within each G pentameric cluster. This continuous channel has mainly **hydrophobic** walls and varies between 0.6 and 2.6 nm in diameter (6). The unassigned electron density within the G channel near the junction with the F channel is thought to be the location of a short segment of the H protein that presumably lies within the channel. The remainder of the H polypeptide chain is believed to be located beneath the interior opening of the channel, in contact with both the DNA and the interior surface of the F capsid proteins. The main evidence for this location for each of the 12 H proteins (9) is the fact that urea treatment of virions removes both the G spikes and the H proteins, leaving a spherical DNA-containing particle (10). Although the H polypeptide chains could not be unambiguously located in the X-ray crystallography electron density map, all 36 residues of the basic J protein could be assigned to an S-shaped path on the inner surface of the capsid, linking two neighboring F proteins across each two-fold axis of symmetry. In addition, a four-nucleotide segment of single-stranded DNA was located in the difference Fourier map calculated from the differences in the diffraction data on 114 S virions and on 70 S particles that contain less DNA (1). These nucleotides are interacting with four amino-acid side chains of the *C*-terminal segment of the J protein and with the side chains of seven amino acid residues in the F protein.

2. Genome structure

Mutational analysis has identified 11 genes in the circular genome of fX174 (Fig. 2). The A segment of the DNA sequence codes for two gene products, endonuclease A and a truncated version of A that suppresses host DNA synthesis, A^* (not shown in Fig. 2). The A^* protein is **translated** in the same reading frame as A, but its translation start site is 173 **codons** downstream of the A translation start site. Furthermore, a portion of the DNA sequence in the A segment is read in a different reading frame as gene B, one of the scaffolding proteins required for the assembly of empty procapsids (Table 1). In fact, all three reading frames are used in the DNA sequence that encodes gene K, an unidentified protein that has an effect on progeny virion yield. The protein encoded by gene C is involved in switching DNA synthesis from replication of the double-stranded fX174 replicative form (RF) DNA to the simultaneous synthesis and packaging of fX174 single-stranded progeny DNA into empty procapsids. These packaged DNA strands have the same sequence as fX174 messenger RNAs that are **transcribed** from the fX RF DNA. Therefore, the packaged strands are labeled positive (+), while the complementary, unpackaged strands are labeled negative (–). The next region of the genome codes for a second set of overlapping genes read in two different reading frames. D is a second scaffolding protein found in procapsids, but not in virions (Table 1), and E induces cell lysis at the bacterial site for elongation and division. Genes J, F, G, and H code for structural proteins found in both virions and procapsids (Table 1).

Figure 2. Linear version of the fX174 circular genetic map. The locations of promoters (P), transcription terminations

sites (T), and the origin of replication (*ori*$^{+}$)) are shown.



The fX174 genome contains three types of DNA sequences, in addition to those that code for proteins and those that are involved in transcription and translation (**promoters**, terminators, and ribosome binding sites; Fig. 2). The first is an **origin of replication** (*ori*$^{+}$) located within gene A, where endonuclease A cleaves between nucleotides 4305 and 4306 (11). The second is an "incompatibility" or "reduction" sequence (12) that interferes with fX174 replication if the sequence is present on a **plasmid** in the uninfected cell. The 85-nucleotide sequence includes parts of genes H and A and the intergenic sequence between them. One suggestion for the function of this sequence is the binding of the incoming single-stranded fX DNA to a site on the bacterial membrane that is essential for fX DNA replication. Presumably, these sites are present in limiting amounts in the uninfected cell. Finally, the third type of DNA sequence includes the intergenic sequences. The H/A untranslated sequence found within the incompatibility sequence shares one feature with two of the three remaining intergenic sequences (J/F, F/G, and G/H): namely, the potential for forming complementary, double-stranded hairpin structures in the single-stranded states of either the DNA or mRNA. However, these potential nucleic acid secondary structures appear to play only subtle roles in fX174 infection, since disruption of the J/F potential hairpin increased the decay rate of only two species of fX mRNA (13).

3. Infection cycle

As with most viruses, the fX174 infection cycle begins with the attachment of the virion to receptor molecules on the outer surface of the bacterial host. The core oligosaccharide region of the lipopolysaccharide (LPS) in the outer membrane of *Escherichia coli* C constitutes the initial sites where the fX174 virion binds via several of its spikes (14). Since O antigenic side chains attached to the core monosaccharide units block fX attachment, most **gram-negative bacterial** species are resistant to fX174. Binding is mediated by Ca^{+2} cations (15), and there are three separate sites for the cation in the crystal structure of the virion, two in F protein near the threefold axes and one near the outer opening of the channel through the G pentamers in each spike (16). Of interest is the presence of a glucose molecule just below one of the Ca^{+2} sites in F. Moreover, another host gene, which lies between *gal* and *aroG* at 17 min in the *E. coli* map, is required for fX binding (17).

Due to the single-strandedness of its DNA genome, fX174 has an additional functional requirement that determines which bacterial species it can infect. The virion must penetrate the outer wall and cytoplasmic membrane to deliver the fX genome to the bacterial DNA replicative complex for synthesis of the complementary (–) strand. This transfer of the viral genome marks the beginning of the eclipse phase, the time period when infectious virions are not present in the infected cell. After binding to the LPS receptor, Ca^{+2}-induced structural changes in the fX virion proteins begin the ejection of the single-stranded, circular DNA from within the virion, presumably through an opening in its protein shell (18-20). Most evidence supports a model for ejection through the channel down the center of one "spike" (18, 21). However, a conformational change that would produce an opening where six F proteins meet at the threefold axis cannot be ruled out. Furthermore, it is not clear how

the fX virion encounters the bacterial components involved in DNA replication. Some experiments suggest that these host factors are located where the outer wall adheres to the cytoplasmic membrane (22, 23).

As the ejected fX174 genome enters the cell, the single-stranded DNA is converted to double-stranded RF (Stage I). The host **single-stranded binding protein** (SSB) coats the incoming DNA, and a protein complex (the preprimosome) is assembled on the coated DNA. The preprimosome contains the sequence recognition protein (PriA), PriB, PriC, dnaT, and gyrase (dnaB) (24), and synthesis of several RNA primers begins when primase (dnaG) joins the complex. Then **DNA polymerase** III adds deoxyribonucleotides to the primers; DNA polymerase I replaces the RNA primers with DNA; and DNA Ligase joins the two ends of the – strand to produce a **supercoiled** RF molecule.

The bacterial transcription system begins to transcribe the fX174 genome, using the RF molecule as the template. Since only two fX genes (A and A*;) code for enzymes, and the remaining fX genes code for proteins that function as structural components, the virus does not require a sophisticated mechanism for regulating transcription. Except for genes E and K, the fX genes are transcribed and translated at all times during the viral replication cycle. Moreover, the relative amounts of the fX proteins are determined by the relative amounts of the mRNAs that contain the message for each protein (25), Table 2. Thus, the message for endonuclease A (and A *;) is present only in the unstable mRNA and the two least abundant transcripts (8 and 9 in Table 2), while the message for the most abundant fX protein, D scaffold (see Table 1), is found in all transcripts (Table 2). Also, the ***rho***-independent termination is inefficient, producing two groups of transcripts that begin at the same promoter but end at different termination sites (1, 3, 7 and 2, 4, 5, 6 in Table 2).

Table 2. fX174 mRNA Transcripts(25)

Genes Transcribed	Promoter	Termination	Order of Abundance
D, J	P_D	T_J	1
B, C, D, J	P_B	T_J	2
D, J, F	P_D	T_F	3

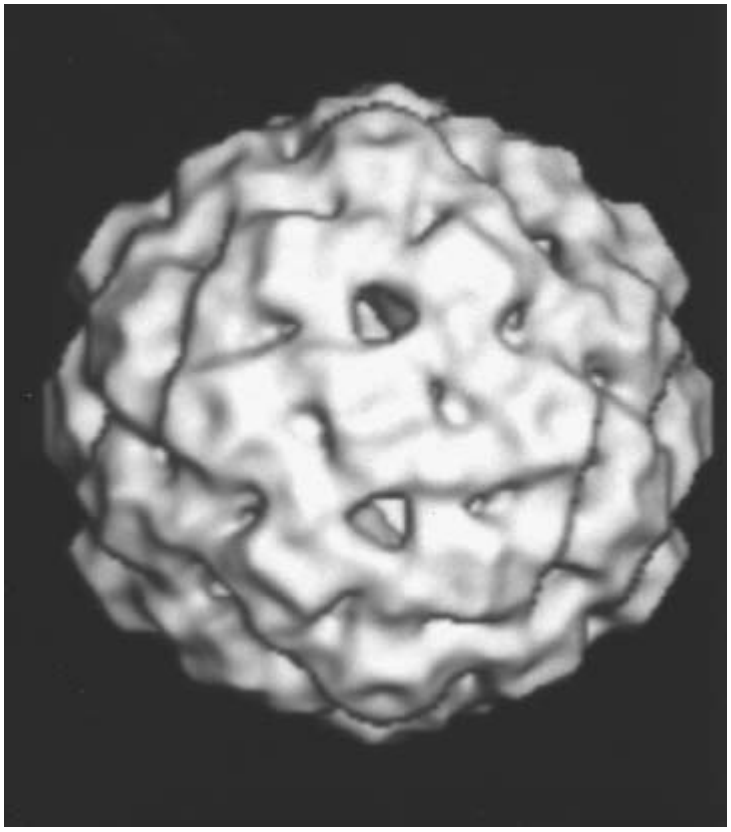
[a] Rare promoter

[b] Single copy

Endonuclease A is the first fX protein synthesized, to create a pool of RF molecules as templates for both transcription and fX genomic DNA replication. This Stage II RF DNA replication begins with endonuclease A cleaving the + strand within the A gene sequence and forming a covalent bond with the 5′ phosphate of the cleaved strand. The bacterial DNA helicase (Rep) unwinds the double-stranded RF, and DNA polymerase III adds deoxyribonucleotides to the 3′ OH of the cleaved + strand, until the new + strand is completed. At the same time, SSB coats the newly synthesized single-stranded fX DNA (26). As soon as the primosome assembly site in the F/G intergenic region (Fig. 2) of the new + strand becomes available, the preprimosome assembles on the new + strand and begins synthesis of a new – strand (see discussion of Stage I). To ensure continuous synthesis of RF, endonuclease A cleaves the + strand at the junction between the old and new strands and joins the ends of the old strand as soon as the A gene sequence on the new + strand becomes available. At the same time, A protein forms a covalent bond with the free 5′ phosphate group of the new + strand, to begin synthesis of the next RF molecule. Each new RF molecule is released from the replication complex when DNA ligase joins the ends of the completed – strand.

As the pool of RF molecules increases, the level of fX transcripts reaches a point where sufficient amounts of fX capsid (F), spike (G, H), and scaffold (B, D) proteins are available to begin the assembly of 108 S empty procapsids (27). First, 9S complexes are formed of F and 6S complexes of G (both containing five copies of the corresponding fX proteins). These two complexes are joined with H and assembled into a procapsid, with B crosslinking F pentamers on their interior surface across the twofold axes and D forming an exterior scaffold on the surface of the capsid (28, 29). In Figure 3, the pentameric G spikes at each fivefold axis are not as prominent as in the virion (Fig. 1) due to interactions with D on the capsid outer surface. These G/D interactions keep each G b-barrel attached to the capsid surface, but inclined at a 20° angle to the fivefold axis. In the virion, the G b-barrels are roughly parallel to the fivefold axis and held to the capsid surface with the aid of bound water molecules. In the procapsid, the mainly **alpha-helical** D scaffold protein is present in four radically different environments. However, protein–protein interactions between D molecules form a scaffold that holds each F and G pentameric complex in a shell that has almost three times the internal volume as the protein shell of the mature fX virion. Furthermore, the enlarged procapsid shell has holes with a diameter of 3.0 nm at the threefold axes (see Fig. 3).

Figure 3. Three-dimensional reconstructed image of fX174 procapsid from electron micrographs of unstained frozen-hydrated preparations (courtesy of Norman H. Olson and Timothy S. Baker, Purdue University). The diameter of the procapsid is 35.5 nm between the exterior edges of the spikes at the fivefold axes (28).



As procapsids are being assembled, fX C protein begins to compete with SSB for binding to RF at the fX A/helicase complex on the replicating fX DNA. Once bound, C stops Stage II RF replication and provides a binding site for procapsid, presumably at one of the 3.0-nm holes. fX + strand is then simultaneously synthesized and packaged, as 60 molecules of the basic J polypeptide are bound to the single-stranded DNA (30, 31). Each J protein displaces a B polypeptide on the interior surface of two neighboring F proteins as the single-stranded DNA is packaged. The 60 B chains presumably exit from the procapsid through the 19 other holes, forming the 132S provirion.

Meanwhile, small amounts of fX lysis (E) protein are slowly being translated from mRNA containing both D and E messages. The low level of E translation is probably due to a weak ribosome binding site, to rare codons in the E reading frame, and to competition from ribosomes translating D messages. fX E polypeptides begin forming a tunnel through the cell wall at the site of cell elongation and division (32). Once the cytoplasmic membrane extrudes through the tunnel, lysis occurs, and the fX provirions are exposed to the ionic environment of the medium. The D scaffold proteins dissociate from the provirions, allowing conformational changes in F capsid proteins and minor changes in inclination of G proteins in the spikes, as the protein shell collapses around the fX DNA. The newly formed progeny fX virions then begin the infection cycle when they encounter uninfected cells.

4. Related bacteriophage

Although most of the experimental data have been obtained with fX174, the Seventh Report by the International Committee on the Taxonomy of Viruses includes 38 other phages in the *Microviridae* family. The majority of the members belong to the same genus (*Microvirus*) as fX. The natural hosts for the members of the *Microvirus* genus are various species of *Enterobacteriaceae*. There is, however, at least one member in three additional genuses of the *Microviridae* family that infect other eubacterial species. These include members of gram-negative genuses *Bdellovibria* and *Chlamydia* and the wall-less genus *Spiroplasma*, which causes several plant diseases.

Y-Chromosome

The Y-chromosome is the sex chromosome that determines male sexual identity in humans. The Y-chromosome in humans is small, yet contains a pseudoautosomal region in which there are significant homologies to the X-chromosome. This region facilitates chromosome pairing at **meiosis**. Active genes in this region include those for steroid sulfatase and the Xg blood group. The Y-chromosome also contains the sex-determining region Y-gene (SRY gene). The SRY gene is expressed only in the male genital ridge during differentiation of the gonad. The SRY gene product encodes a DNA-binding protein that is a transcriptional regulator.

It has been proposed that X and Y-chromosomes evolved by **translocating** transcribed regions from the Y-chromosome to the X-chromosome. Then the Y-chromosome would be reduced in size, whereas the X-chromosome would progressively acquire the capacity to inactivate the domains of the chromosome that could not pair in meiosis. The fact that males have only one of each X- and Y-chromosome, whereas females have two X-chromosomes, means that males are more susceptible to genetic mutations on these chromosomes that lead to disease. These include, among very many, Duchenne muscular dystrophy, hemophilia, and fragile X-linked mental retardation.

Z-DNA

The left-handed, double-helix DNA structure known as Z-DNA, due to the zigzag path of the phosphate groups along the DNA backbone, was unexpected. It was discovered through X-ray crystallography analysis of d(CGCGCG$_2$ at 0.9 Å atomic resolution (1). The Z-DNA double helix is tall and thin, relative to B-DNA and A-DNA, with a diameter of ~18 and a helical pitch of ~45 (see Fig. 2 of DNA Structure). Z-DNA is favored by alternating Py-Pu sequences, especially (dC-dG)$_n$.

The repeat unit is a CpG dinucleotide; the glycosyl conformation of cytosine is *anti* and that of guanine is *syn*. The sugar pucker for cytosine is C2′-*endo*, while that for guanine is predominantly C3′-*endo*. The base pairs are slightly inclined by –9°, and there are 12 base pairs per helical turn. The rise per dinucleotide repeat is ~7.4, and the helical twist angle per dinucleotide repeat is –60°. The average helical twist angles are about –8° for the CpG and –52° for the GpC with a sum of –60° for the dinucleotide repeat unit (see Fig. 3 of Base Pairs). Several other oligonucleotides have been crystallized in the Z-DNA conformation, including fragments containing AT base pairs, nonalternating Pu-Py sequences, and guanine-thymine wobble pairs, etc.

The single groove of Z-DNA is narrow and deep. When the **van der Waals** radii of the phosphate group are included, the opening available for access to the groove is 6–7 Å. The major groove becomes very shallow, in fact almost nonexistent, and lies exposed to the solvent. Spermine and hydrated metal ions interact with the phosphate and the N7 of guanine. The interaction of spermine and metal ions with the phosphate groups of the DNA plays a role in charge neutralization. Some spermine molecules that are found located in the deep groove bridge the minor groove by interacting with phosphate groups on both sides, and thus may play a role in stabilizing the Z-DNA helix.

DNA, especially that associated with alternating dC-dG sequences such as poly(dC-dG), can readily undergo the reversible conformational change between B-DNA and Z-DNA. The conformational equilibrium is influenced by negative **supercoiling**, changes in the ionic environment (eg, high salt), and the presence of proteins that bind to Z-DNA. Z-DNA has been demonstrated to exist in polytene chromosomes of *Drosophila* using fluorescent **antibodies**. The left-handedness of Z-DNA is particularly powerful in relieving the strain of negatively supercoiled DNA (eg, during gene transcription). More recently, binding proteins specific for Z-DNA have been discovered. It has been established that Z-DNA occurs in metabolically active nuclei and that the level is dependent on DNA torsional strain and increases with transcription. Understanding the definitive biological role of Z-DNA is being actively pursued.

Zebrafish

Zebrafish, *Danio* (*Brachydanio*) *rerio* (Hamilton-Buchanan), is a member of the family *Cyprinidae*, order *Cypriniformes*. A native of rivers in Southeastern Asia, this small, tropical freshwater fish is now a popular inhabitant of home aquaria throughout the world. A number of features facilitating **embryological** and **genetic** manipulations has made zebrafish the most recent model system in which to study mechanisms of vertebrate embryonic development (1, 2). Zebrafish are also frequently used in toxicologic studies (3).

Zebrafish are elongated and flattened laterally, with dark blue and silver-gold stripes running along the longitudinal axis of their body. In their two- to three-year life span, zebrafish grow up to 5 cm in length. Zebrafish achieve sexual maturity at three months of age. They are omnivorous and thus easy to raise using a variety of live and dry foods. Furthermore, they tolerate a relatively wide range of water quality. In captive breeding, zebrafish can produce hundreds of eggs on a weekly basis without seasonal variation. Therefore, large numbers (10^5) of zebrafish can be raised and maintained at low cost and labor, facilitating large-scale genetic screens. The mating behavior is photoperiodic; spawning takes place at dawn or, in laboratory conditions, at the beginning of the light cycle. In the

course of mating, the male closely follows the fast-swimming female, culminating in the release of eggs and sperm into the water. Eggs and sperm can be harvested easily from anesthetized fishes and fertilized in vitro. Importantly, the sperm can be preserved by deep freezing, allowing for cost and space-effective maintenance of genotypes (4).

Embryos from a single clutch develop synchronously outside the mother in a range of temperatures, (between 23°C and 33°C, with the optimal temperature being 28.5°C). The embryo and surrounding chorion are translucent, allowing for a detailed microscopic inspection of development. Furthermore, the embryos can survive several days with major developmental defects (eg, without a functional cardiovascular system). The large size of the embryo (0.7 mm in diameter) facilitates microinjection, dissection, transplantation, and other embryological manipulations. All of the above features are critical for effective identification and subsequent analysis of mutant phenotypes.

1. Genomics

The haploid genome of zebrafish contains about 1.7×10^9bp (5), organized into 25 approximately metacentric chromosomes of similar size (6). A genetic linkage map of the zebrafish genome has been developed using **PCR** (polymerase chain reaction)-based polymorphisms: random amplified polymorphic markers (RAPID) (7) as well as CA dinucleotide repeats and simple sequence length polymorphisms (SSLP) (8). Furthermore, about 500 DNA sequences have been reported for zebrafish, and positions on the genetic map have been determined for 120 of these cloned genes. The current estimate of the size of the map is 3,000 centiMorgan (cM) with an average 600 kb cM^{-1}. Taking into account about 1,200 markers for which map positions are known, the average interval between the available zebrafish markers is approximately 1,500 kb. The mapping efforts also revealed a surprising conservation of many large chromosome segments in the genomes of humans and zebrafish (9).

2. Embryonic Development

Embryonic development is initiated by the segregation of nonyolky cytoplasm in the form of a blastodisc situated atop a large sphere of translucent yolk. A series of synchronous and rapid cleavages of the blastodisc leads to the formation of a **blastula** with a mound of blastomeres on a syncytial yolk cell. The establishment of dorso-ventral asymmetry of the embryo is not strictly correlated with the planes of the first cleavages (10, 11). This process, however, requires the transport of substances from the vegetal hemisphere into marginal blastomeres via cortical microtubules of the yolk cell (12). An important step in the establishment of the dorsal axis is a transient accumulation of b-catenin in the nuclei on the dorsal side of the zebrafish blastula (13, 14).

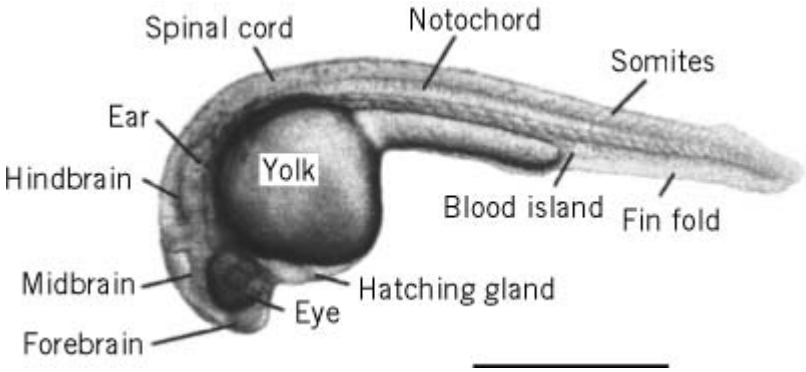
The embryonic body is shaped by three main morphogenetic movements of **gastrulation** (15). During epiboly, the blastoderm becomes thinner as its surface expands to cover the yolk cell completely 10 hours after fertilization. Tissue-restricted lineages can be identified in late blastula, when the blastoderm reaches the equator of the yolk cell. The three classically defined germ layers exhibit an overall organization reminiscent of the early gastrula fate maps of other vertebrates, with progenitors of **ectoderm** arising from near the **animal pole**, and the **mesoderm** and **endoderm** occupying the most marginal positions of the blastoderm (16). The germ layers form by involution/ingression movements at the blastoderm margin that bring prospective mesodermal and endodermal cells underneath the future ectoderm. Concurrent convergent extension movements bring the precursors of various tissues closer to the dorsal midline and are responsible for narrowing of the embryonic axis in the mediolateral direction and for its anterior-posterior elongation. These gastrulation movements create the embryonic shield, a thickening at the dorsal blastoderm margin. The embryonic shield is equivalent to the Spemann gastrula organizer of frog and other vertebrate embryos (17, 18). The dorso-ventral pattern specification involves highly conserved antagonistic interactions between dorsalizing signals emanating from the Spemann gastrula organizer and secreted factors like bone morphogenetic protein-4 (BMP-4) released by the ventral signaling center

(19, 20). Gastrulation movements bring precursors of various organs into their proper positions in the embryo.

During the subsequent segmentation period, organ rudiments form; notochord becomes visible as a prominent dorsal structure and blocks of somites appear on both sides of the notochord sequentially in the trunk and later in the tail. The primordium of the central nervous system becomes visible above the notochord as a thickened neural plate. By the process of epithelial infolding, the neural plate first transforms into a solid neural keel that subsequently hollows into the neural tube (21, 22). The regional morphogenetic processes lead to the formation of distinctive swellings (neuromeres) in the anterior region of the neural plate, corresponding to brain rudiments characteristic of all vertebrates. The most anterior forebrain rudiment consists of telencephalon and ventral diencephalon, from which the eyes develop. The medially located mesencephalon gives rise to the optic tectum dorsally and tegementum ventrally. The most posterior hindbrain is subdivided into seven rhombomeres. The neural tube posterior to hindbrain gives rise to spinal cord, which develops characteristic dorso-ventral organization, dependent on secreted proteins of the Hedgehog family (23).

During the segmentation period, while the embryo continues to narrow in the mediolateral direction and elongates, the rudiments of kidney, heart, and gut, as well as sensory placodes, also become distinct. The tail, originally closely apposed to the round yolk cell, becomes a prominent structure when it everts from the yolk. At 24 hours, the embryo reaches the pharyngula stage of development. At this phylotypic stage, the zebrafish embryo is most similar to other vertebrate embryos, exhibiting a prominent notochord in the trunk and tail, surrounded by chevron-shaped somites (Fig. 1). The nervous system positioned dorsal to the notochord is hollow and expanded anteriorly, with eyes and brain subdivisions visible in the head. The embryo exhibits circulation and is motile, and rudiments of most organs can be easily identified. The heart tube is located against the ventral body wall below the head and consists of an inner endocardial tube and an outer, myocardial tube. The adult fish heart will consist of a single atrium and a single ventricle, an arrangement characteristic of the early embryonic stages of other vertebrates. Blood cells develop in the intermediate cell mass located in the trunk between the notochord and endoderm, accumulating in a blood island at the trunk/tail border (24). Further development involves the formation of gill arches, including jaws and an outgrowth of pectoral fins. Hatching from the chorion occurs at 2–3 days of development, the swim bladder becomes inflated, and larvae start feeding on day 4 of development.

Figure 1. Zebrafish embryo at day 1 of development (pharyngula stage). Scale bar, 0.5 mm.



3. Genetics of Zebrafish Development

Efficient methods of induction, recovery and screening for mutations are available in zebrafish. *N*-

ethyl- *N*-nitrosourea is a potent mutagen of fish spermatogonia and sperm (25-28). g-ray-irradiation is used to induce mutations in embryos or in sperm of adult males (29, 30). Furthermore, insertional mutagenesis can be achieved by injecting a pseudotyped retroviral **vector** containing a genome based on the Moloney murine leukemia virus and the envelope **glycoprotein** of the vesicular stomatitis virus into zebrafish embryos (31, 32). Mutations induced by various mutagens in the G0 generation are transmitted to the F1 generation and are revealed by screening haploid progeny of F1 females (obtained by fertilization with genetically compromised sperm) or gynogenetic diploid progeny of F1 females (obtained by fertilization with genetically compromised sperm followed by inhibition of the second meiotic division). Alternatively, mutations are bred to homozygosity in a classic three-generation screen to be manifest in F3 embryos (33).

Large-scale genetic screens for mutations that alter embryonic morphology, behavior, or gene expression patterns resulted in the identification of mutations in over 400 genes (34-36). These screens identified genes involved in practically every aspect of early embryonic and larval development in the zebrafish: early pattern formation, notochord, brain, spinal cord, somites, muscles, heart, circulation, blood, skin, fin, eye, otic vesicle, jaw, and branchial arches (37). It is estimated that fewer than 50% of genes that could be detected by the screening methods employed have been identified so far. Comparison of the frequency of mutations in known loci with that of embryonic and early larval lethal mutations led to an estimate that 1,500–5,000 genes are essential for early development in zebrafish.

Genes identified by virtue of retroviral insertions are rapidly cloned using the retroviral tag (38). Genes identified by other types of mutagens are cloned by two main strategies. In the candidate gene approach, genes are identified that have been cloned in other systems and exhibit properties predicted for the mutant locus (39, 40). The positional cloning approach starts with the identification via genetic mapping of a DNA marker closely linked to a gene to be cloned. Next, this DNA marker is used to isolate chromosomal walking clones encompassing the gene, which is subsequently identified by **gene expression** patterns and sequence analysis, as well as by functional assays (41).

During the 1990s, zebrafish researchers recovered thousands of mutations that identify hundreds of genes essential for embryonic development. Furthermore, a genetic map of the zebrafish genome has been constructed, and its density is increasing rapidly. Considering the powerful tools available for the analysis of normal and mutant embryos, zebrafish will significantly contribute to our understanding of molecular mechanisms governing early vertebrate development.

Zimm–Bragg Model

The Zimm–Bragg model is a statistical mechanical model that describes the a-helix to random coil transition in peptides that do not adopt any other folded conformation (1) (see Alpha-Helix Formation). This and the other popular model for the helix–coil transition, the Lifson–Roig model (2), are compared and contrasted in Helix–coil theory. In the Zimm–Bragg description of helix formation in a peptide, there are three key parameters: n, the number of peptide units in the chain; s, the helix propagation parameter; and s the helix nucleation parameter. The Zimm–Bragg model defines n as the number of peptide units (—CONH—) in the chain, which causes some problems in ascribing s values to particular side chains, because a peptide unit encompasses parts of two amino acid residues. The alternative model, the Lifson–Roig model, does not use this definition and is therefore sometimes more convenient.

There are several implementations of basic Zimm–Bragg theory that can be used to describe helix formation in peptides. In the full treatment, a 4 × 4-correlation matrix is needed to assign statistical weights to helical or coil residues (see Helix–Coil Theory for a diagram) in order to calculate the partition function for the peptide system. With this full treatment, residue-specific s and s values can be used. A somewhat simplified version of the Zimm–Bragg model employs a 2 × 2-correlation matrix, where nearest-neighbor interactions can be included. Finally, a useful version of the Zimm–Bragg model for short homopolymers is called the *Zipper Model*. In this approximation, the peptide is treated as a homopolymer, and the single-sequence approximation is used, in which it is assumed that only one stretch of helical conformation exists at one time for a given peptide chain. In other words, because helix nucleation is an unfavorable event, it can be treated as occurring only one time for a given peptide, and the propagation of the helix "zips" up the chain.

This model does not employ matrix methods to calculate the partition function, and the fraction of helical residues can be expressed as

$$f_H = \frac{\sigma s}{(s-1)^3}\left(\frac{ns^{n+2} - (n+2)s^{n+1} + (n+2)s - n}{n\{1 + [\sigma s/(s-1)^2][s^{n+1} + n - (n+1)s]\}}\right) \quad (1)$$

This version of the model is especially useful for investigating the cooperative length-dependence of helix formation by simple repeating homopolymers (3).

Zinc-Binding Proteins

The 1985 report by Klug and co-workers (1) of a model for the *Xenopus laevis* transcription factor TFIIIA, which contains a zinc atom coordinated by two cysteine and two histidine residues, formally launched the study of metalloregulatory proteins (see Metalloproteins). A subsequent Zn-**EXAFS** study confirmed the presence of two N and two S atoms in the inner coordination sphere (2). And complete structures were subsequently determined by NMR. The function of the Zn^{2+} ion is to organize the protein structure into one that contains an alpha-helix suitable for recognizing the major groove of **DNA**. This protein displays the hallmark of a large family of proteins that display the zinc-finger motif and can be identified from the amino acid sequence -Cys-$X_{(2–4)}$-Cys-X_{12}-His-$X_{(3–5)}$-His-, where X represents any amino acid. This pattern of cysteine and histidine residues has been used repeatedly to infer the presence of a zinc-finger protein or **domain** from just the amino acid sequence. This protein motif is especially common in eukaryotes, including humans. Some zinc fingers also bind **RNA**, however, complicating the elucidation of a zinc-finger "recognition code."

Other zinc-binding motifs have been discovered, as shown in Table 1. Zinc-activated transcription factors also include the nuclear hormone receptors, which bind cooperatively to DNA as homodimers (see **Steroid receptors**). The Zn^{2+} sites in these proteins possess tetrahedral environments of four cysteine residues. Fungal transcription factors include members of the GAL4 family, which also bind as homodimers to DNA. However, these contain a $(Cys)_3$-Zn-(Cys_2)-Zn-$(Cys)_3$ dimer that has two cysteine residues bridging the two zinc centers. Structures of the human estrogen receptor and of GAL4 both show that DNA recognition is also via an a-helix. Nucleocapsids of retroviruses (e.g., **HIV**-1) contain large amounts of Zn^{2+}, probably ligated by three cysteine residues and one histidine (3). The functions of the zinc-binding domains probably involve the recognizing RNA packaging signals. Many other classes of zinc-binding proteins, including those that possess RING and LIM domains, may also function in nucleic acid regulatory capacities.

Table 1. Major Families of Zinc Metalloregulatory Proteins

Family	Consensus Sequence[a]	Recognition Site
Zinc finger	$CX_{(2–4)}CX_{12}HX_{(3–5)}H$	DNA, RNA
Nuclear hormone receptor	$CX_2CX_{13}CX_2CX_{15}CX_5CX_{12}CX_4C$	DNA
GAL4	$CX_2CX_{9–27}CX_2CX_6C$	DNA
Retroviral nucleocapsid	$CX_2CX_4HX_4C$	RNA[x]

[a] C, cysteine residue; H, histidine; X, any residue

Why zinc? After iron, zinc is the most plentiful of the trace-metal ions in humans. More importantly, zinc is soluble, exchanges ligands rapidly, does not undergo biological redox reactions, and tolerates a variety of coordination geometries. Sulfur-containing ligands display a marked preference for "soft" metal ions, including Zn^{2+}. Hence, it is not surprising that cysteine residues play such a prominent biological role in binding zinc.

Zinc-Containing DNA-Binding Motifs

A number of different DNA-binding motifs contain one or more zinc atoms whose function is to stabilize the modular structure of the domain by coordinating with amino acids, usually cysteine or histidine, in the appropriate spatial orientation. The only common feature of these domains, of which six have been identified to date, is the presence of zinc. Otherwise they are structurally diverse.

The most ubiquitous of these structures is the "zinc finger" found in many eukaryotic transcription factors. The structure of a typical zinc finger consists of a well-defined a-helix packed against two b-strands arranged in a hairpin structure. The finger structure is stabilized by the tetrahedral

coordination of zinc to two closely spaced cysteine residues in the b-strands and two closely spaced histidine residues at the C-terminus of the helical region. In addition the structure is further stabilized by a hydrophobic pocket in the interior of the structure.

When bound to DNA, the finger is directed into the major groove such that base-specific contacts are made by the proximal end of the a-helical region with contacting successive amino acids being separated by approximately one helical turn. The sugar-phosphate backbone is contacted by one of the zinc-coordinated histidine residues. A single zinc finger generally contacts three successive base-pairs in DNA, usually in a single-strand of the duplex. However many zinc-finger proteins contain multiple contiguous fingers separated by a short linker. In such examples synergy can occur between adjacent zinc fingers so that each specify four bp subsites overlapping by one base-pair. In proteins with multiple DNA-binding zinc fingers, the structure of the first finger often differs from the canonical structure. For example, the first finger of the SWI5 protein is preceded by a short a-helix and contains an additional b-strand preceding the normal b hairpin loop. In proteins with multiple zinc fingers, some of the fingers may not be involved in DNA binding but instead can act to mediate protein–protein contacts.

Another DNA-binding motif which contains zinc is exemplified by DNA-binding domain of the steroid receptors. In this fold zinc is coordinated by four cysteine residues. In this case, the path of the polypeptide backbone between the proximal and distal pairs of coordinating cysteines is distinct from that of the TFIIIA type of finger. In the receptor motif, the proximal cysteine residues, as in zinc fingers, reside in the b-sheet structures. By contrast, although the histidine residues involved in zinc coordination are often contained within an a-helix, the corresponding distal cysteine are not. This difference is directly related to DNA binding. The DNA binding domains of the glucocorticoid and oestrogen receptors contain two C-C···C-C coordination domains, the first of which is of similar extent to the TFIIIA fingers whereas the second is significantly shorter. Unlike the TFIIIA fingers both pairs of distal cysteines are immediately followed by an a-helical region. The second a-helix forms direct hydrophobic contacts with the first so that the two fingers and the two a-helices together form a single structural domain, the ‘double-loop-zinc-helix’. This domain also includes a region that specifies the dimerization contacts. The determinants for sequence specific recognition lie within the a-helix immediately distal to the first cysteine tetrad. For each receptor the DNA recognition domains bind as dimers to a palindromic sequence containing three conserved bases on each side. But the separation between the conserved trimers differs for different receptors. This means that the rotational orientation of the individual components of the dimer must also be different and be determined by the position of the dimerization contacts relative to the a-helix responsible for sequence recognition.

In a third type of zinc-containing DNA binding domain, typified by the GAL4 protein, the zinc-stabilized structure is connected by a flexible region of polypeptide chain to a short amphipathic a-helix which forms hydrophobic contacts with another monomer in dimer formation. In GAL4, as with other zinc-containing motifs, direct contact with the bases is mediated in the major groove by amino acids contained within a short a-helical region. However, most of the contacts to the sugar-phosphate backbone are effected by amino acids in the more extended chain. The GAL4 protein, like the steroid hormone receptors, binds to its DNA recognition site as a dimer with the two monomeric units being held together by a short coiled-coil of two parallel a-helices.

Zoo Blot

A zoo blot (Fig. 1) is the result of an experiment in which a short DNA fragment from the genomic region of interest is first **cloned** and then used as a radioactive probe to test for related DNA from a

variety of species by Southern blot analysis. If hybridized fragments related to the probe are found in several species, there is a strong possibility that the probe is an exon of a gene, because of its sequence conservation (1). Such candidates can be further characterized by DNA sequencing to determine whether they contain open reading frames (ORFs). If so, the identification of the new protein-coding gene is possible by further experiments, such as isolation of complementary DNA or messenger RNA. Thus, a zoo blot is a powerful tool, not only to see how the probe of interest is conserved among a variety of species, but also to identify a new protein-coding gene.

Figure 1. Schematic representation of a zoo blot. Southern blot analysis of genomic DNAs from various species was performed using a particular probe, such as a segment of human DNA.

Zwitterion (Dipolar Ion)

A zwitterion is a molecule that simultaneously has one positively charged group and one negatively charged group. The best examples are the individual amino acids that have a cationic amine group and an anionic carboxylate. Proteins usually have both cationic and anionic side chains.

Zygote

The **diploid** zygote is formed by the fusion of two haploid **gametes** at fertilization. After fertilization, the zygote undergoes cleavage divisions to form a mass of cells called the **blastula**.

Zymogen

A zymogen is an enzymatically inactive precursor of an enzyme, often but not always a **proteolytic** enzyme (or proteinase). Some zymogens are named by adding the suffix *-ogen* to the name of the enzyme itself, as in **trypsinogen** or **pepsinogen**, whereas others are indicated by the prefix *pro-*, as in pro-collagenase or pro-**carboxypeptidase**. No strict rules of nomenclature pertain. Hence, pro-renin rather than reninogen, pre-kallikrein rather than pro-kallikrein, **Factor X** rather than proFactor Xa, etc. Also, some proteins are given the suffix -ogen even if they are not a proteinase (or even an enzyme) precursor—for example, fibrinogen or *angiotensinogen*.

Zymogens are one of Nature's ways of ensuring that proteinase (or other) activity will be generated only at the most appropriate time and in the most appropriate place. Most of the digestive proteinases produced in the pancreas are synthesized as zymogens and stored as such in zymogen granules in the acinar cells. The contents of these granules are only released into the small intestine when food is eaten, and the zymogens are only activated once they enter the small intestine. This latter process is initiated by an intestinal proteinase, enterokinase. Inappropriate activation of these zymogens within the pancreas can cause pancreatitis and have devastating consequences.

Zymogen activation typically involves cleavage of a single peptide bond in the precursor protein. Sometimes, as in the case of pepsinogen, the proteinase responsible for cleaving that peptide bond is the zymogen itself. Briefly, in the acidic environment of the stomach the pepsinogen molecule unfolds enough to expose the active site, which then catalyzes a process of autoactivation by clipping off a peptide segment from the *N*-terminus of other pepsinogen molecules, thereby activating them and setting off a chain reaction. The pancreatic zymogens are activated by **trypsin**, which is itself generated from trypsinogen by enterokinase. Activation of trypsinogen involves removal of a six-residue peptide from its amino terminus, whereas activation of **chymotrypsinogen** involves cleavage of the peptide bond joining Arg15 and Ile16. The first 15 amino acids are linked to the rest of chymotrypsin by a disulfide bond, so there is no actual removal of a peptide. After activation, chymotrypsin undergoes some proteolytic fine-tuning and loses two internal dipeptides, but this is more for stabilization than for activation.

Many other strategies have evolved for zymogen activation, but basically they all come down to inducing a change in the conformation of the precursor by cleaving a peptide bond and thereby altering the primary structure (amino acid sequence) of the protein; or by interaction with another molecule, a cell surface, or some other type of structure.

Once a zymogen has been activated, Nature must resort to other means to control its activity, and in the case of proteinases there is no shortage of inhibitors (see Proteinase Inhibitors and Proteinase Inhibitors, Proteins). Moreover, proteinases being what they are, they can serve as their own substrates and their activities can be abolished by autolysis (self-digestion).
