RNA Helicases

RNA helicases form a class of proteins that **catalyze** the unwinding of double-stranded **RNA** driven by the hydrolysis of a nucleoside triphosphate (NTP). Therefore, RNA helicases are associated with **nucleic acid**-stimulated nucleoside triphosphatase (NTPase) activity. In most cases, the NTPase activity displays a specificity for ATP or dATP, but some of the helicases use any one of the four NTPs or dNTPs equally well (1).

RNA helicases are distinct from *RNA unwindases*, a class of enzymes that unwind RNA by converting adenine into inosine residues. This modification creates local I-U mismatches and thereby lowers the melting temperature of RNA duplexes in a reaction that does not require Mg^{2+} and a nucleoside triphosphate (2).

Most of the RNA helicases known thus far belong to class II of the helicase superfamily (3). All class II helicases possess a core domain that contains seven conserved amino acid motifs. A bipartite NTP-binding site, consisting of the residues Gly-Cys-Gly-Lys-Thr (or GCGKT; site A) and Phe-Ile-Leu-Asp-Asp (or FILDD; site B), is found in motif I. a DEXD/H signature (Asp-Glu-X-Asp/His) shows up in motif II, and a putative RNA-binding site XRXGRXXR (or X-Arg-X-Gly-Arg-X-X-Arg) has been assigned to motif IV of some RNA helicases, such as the eukaryotic translation initiation factor (eIF-) 4A (4) and the plum pox potyvirus CI helicase (5). The DEXD/H signature is found in many RNA helicases, with eIF-4A being the prototype of the so-called **DEAD box** family, whereas the motif DEXH is found only within a distinct subfamily of RNA helicases (6). Numerous open reading frames from both prokaryotes and eukaryotes contain DEXD/H motifs and on this basis have been assigned helicase functions. The existence of these motifs in a protein sequence is suggestive of a helicase function, but as long as NTP-dependent unwinding has not been demonstrated experimentally, such an assignment should be regarded as preliminary and tentative.

RNA helicases unwind two complementary RNA strands to yield single-stranded products. The time-course of unwinding can be followed by subjecting the reaction products to gel electrophoresis, where the double-stranded RNA substrate migrates more slowly than the single-stranded products. In principle, there are two ways to unwind RNA: the helicase might move 3′–5′ with respect to the single-stranded RNA to which it has bound, or it might move in the opposite direction (ie, 5′–3′). Correspondingly, the directionality of unwinding can be determined by offering single-stranded RNA substrates with duplexes at either end. Only eIF-4A in conjunction with eIF-4B does not display a preferred directionality on unwinding of the secondary structure at the 5′-end of mRNA (7).

Some of the canonical RNA helicases also unwind double-stranded **DNA** (see DNA Helicase) once they have bound to a single-stranded RNA entry site. For example, the *Escherichia coli* **Rho** transcription termination factor induces the release of an RNA transcript from its template DNA, when the factor has migrated to the RNA-intrinsic rho-dependent terminator sequence (8). Some DEXD/H-containing RNA helicases even unwind DNA/DNA duplexes, yielding a class of enzymes that unwind both RNA and DNA. Members of this type of helicase are the nonstructural protein 3 of hepatitis C virus (9), the nucleic acid-dependent phosphohydrolase II of vaccinia virus (10), and the "maleless" (MLE) protein of Drosophila (11). Also, the **SV40 virus** large T Antigen, which is not a member of the DEXD/H-family of helicases, unwinds both RNA and DNA (12).

It is thought that RNA helicases first bind to a single-stranded template and then undergo a conformational change that is induced by NTP binding and hydrolysis. The NTP-driven conformational change is an example of an **energy transduction** process that transduces chemical energy into mechanical work that is used for translocation of the helicase and disruption of the RNA duplex. The protein structure of the NS3 RNA helicase of hepatitis C virus might give an example of the coupling between NTP hydrolysis and RNA unwinding (13). In addition to the **RNA-binding** site of the catalytic core, many RNA helicases of the DEXD/H type contain auxiliary binding sites for nucleic acids that contribute to the specificity and/or affinity of substrate binding but may not be subjected to conformational changes driven by NTP hydrolysis (14). The presence of auxiliary

binding sites complicates currently discussed unwinding models, where nucleotide binding and hydrolysis coordinate alternating DNA binding affinities during translocation and unwinding (15). In the case of the Rho helicase, the auxiliary RNA binding sites are thought to contribute to a "tethered tracking" mechanism, in which Rho forms tight primary binding interactions with the recognition region of the RNA and remains bound there, while transient secondary RNA binding interactions coupled to ATP hydrolysis serve to scan along the RNA to contact the DNA/RNA duplex (16).

Functional aspects of RNA helicases have been addressed mainly by studying **conditional mutants** of the respective **genes**, both in yeast and in bacteria. In that way, it has been shown that RNA helicases are involved in numerous aspects of RNA metabolism, such as RNA splicing, assembly of ribosomes, and initiation of translation (17). A manifold of RNA helicases exist in yeast, with more or less defined functions. A group of RNA helicases, known as the pre-mRNA processing (PRP) factors prp2, prp5, prp16, prp28, and prp43, participate in consecutive steps of pre-mRNA splicing. PRP proteins are either tightly associated or transiently interacting with the spliceosome (18). Among these, prp2, prp16, prp22, and prp43 contain a DEAH signature in motif II, whereas prp5 and prp28 display a DEAD signature in the same motif. The PRP proteins facilitate interactions between small nuclear RNPs and pre-mRNA, and they are involved in splice site recognition, spliceosome activation, mRNA release, and spliceosome disassembly. The well-known ATP dependence of spliceosome-catalyzed mRNA processing is thought to involve RNA helicase functions that may also contribute to the accuracy of the splicing reaction. Ribosome biogenesis is another process that requires RNA helicases, with possible functions in tRNA transcription (19), rRNA maturation (20), and ribosome assembly (21). RNA helicases may assist endo- and exonucleolytic pre-rRNA processing steps, they may regulate interactions between small nucleolar RNA (snoRNA) and pre-rRNA, and they may rearrange rRNA-protein interactions during ribosome assembly.

Some RNA helicases of the DEXD box family promote the **nuclear export** of RNA. The RNA helicase Dbp5 from yeast (22) has been shown to be a **nuclear pore**-associated protein that is essential for mRNA export (23). Moreover, **homologues** of Dbp5 helicase seem to be present in most eukaryotic organisms (23). Also, the human homologue of the Drosophila MLE helicase is thought to be involved in the nuclear export of unspliced type D RNA of retroviruses (24).

The apparent homology between many yeast and mammalian RNA helicases can be exploited for rescuing functional yeast mutants by complementation with the mammalian counterpart. This might determine the suspected physiologic role of the mammalian homologue, once the function of the yeast enzyme has been defined. Due to the lack of suitable genetic approaches, however, the physiologic function of many mammalian RNA helicases is still unknown. Nevertheless, RNA helicases of metazoan origin are thought to be involved in embryogenesis, differentiation, and spermatogenesis, as well as in cellular growth and division (17). The MLE helicase from Drosophila is a well-characterized RNA helicase that is involved in the hypertranscription of the single X chromosome of the male gender. MLE-promoted hypertranscription equalizes the amount of transcripts obtained from the single X chromosome of males with that obtained from both X chromosomes of females (25). MLE is highly conserved between nematodes, dipterans, and mammals, but it is missing from yeast. A less complex form of MLE has been found in the plant Arabidopsis by comparisons with protein sequence databases, although this enzyme has different N- and C-termini compared to the conserved nematode to mammalian counterparts (26). Therefore, computer-assisted comparisons of the sequences of various RNA helicases may give further hints to the structures and functions of distinct members of this important class of enzymes.

RNA Ligases

RNA ligase is an enzyme that can catalyze the ligation of RNA molecules via phosphodiester bonds. Several species of RNA ligases are currently known from all three kingdoms of organisms: bacteria, archaebacteria, and eukaryotes. The majority of them are involved in RNA splicing, splicing transfer RNA. Another important function of RNA ligation is in RNA Editing. The basic reaction steps related to RNA ligation are shown schematically in Figure 1, which indicates that every RNA ligation follows one or more cleavages of the precursor RNA. Therefore, we can categorize ligation reactions into three types, depending upon whether they are directed by an intron, exon (see Introns, Exons), or guide RNA (gRNA) and also depending upon what connects the two RNA segments that are to be ligated together (Table 1). Intron-directed means that most of the information necessary for determining the cleavage sites and the two RNA molecules to be ligated is conveyed by an intron moiety, the portion between the two segments to be ligated, which will be removed. This is very reasonable in splicing of messenger RNA, because each RNA molecule to be ligated is an exon, which should retain its own information other than that for specifying the cleavage sites. This ligation reaction is usually carried out by protein catalysts. Conversely, exon-directed indicates that the exon parts, which are to be joined, are responsible for those requirements. In this case, an elaborate construct must have been exploited in order to reconcile the exon-specific information with the information specifying the cleavage sites (see tRNA Ligase). On the other hand, gRNA-directed means that the ligation reaction requires an additional RNA element, the guide RNA. Currently, the origin of gRNA is far more mysterious than that of introns. The functions of some RNA ligases are not known (Table 1).

Figure 1. The basic steps involved in RNA ligation. All of the phenomena, splicing (mRNA and tRNA) and editing (insertion and deletion), can be reduced to the forward and reverse steps shown in this figure, so long as the details are not considered; only insertional editing involves the reverse steps. An RNA molecule is divided into three parts that are designated (from left to right) as 5′-E (exon), I (intron), and 3′-E. The overall reaction considered here consists of two cleavages and one ligation (or one cleavage and two ligations, in the case of a single event of insertional editing). It involves the recognizing of the sites for cleavage and the joining of segments 5′-E and 3′-E.

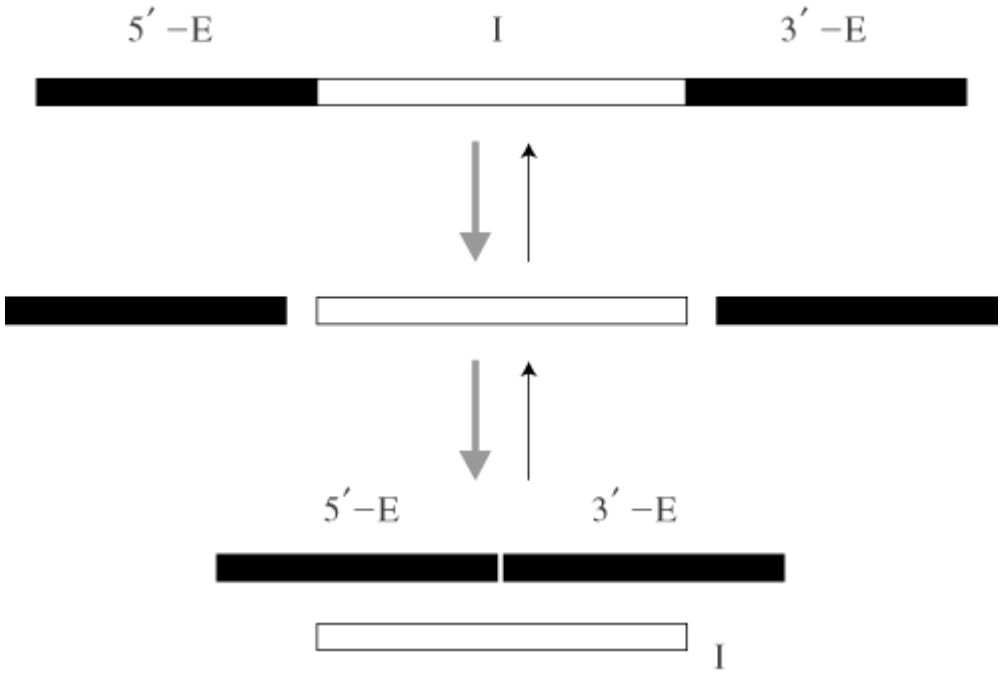

Table 1. Categories of RNA Ligation

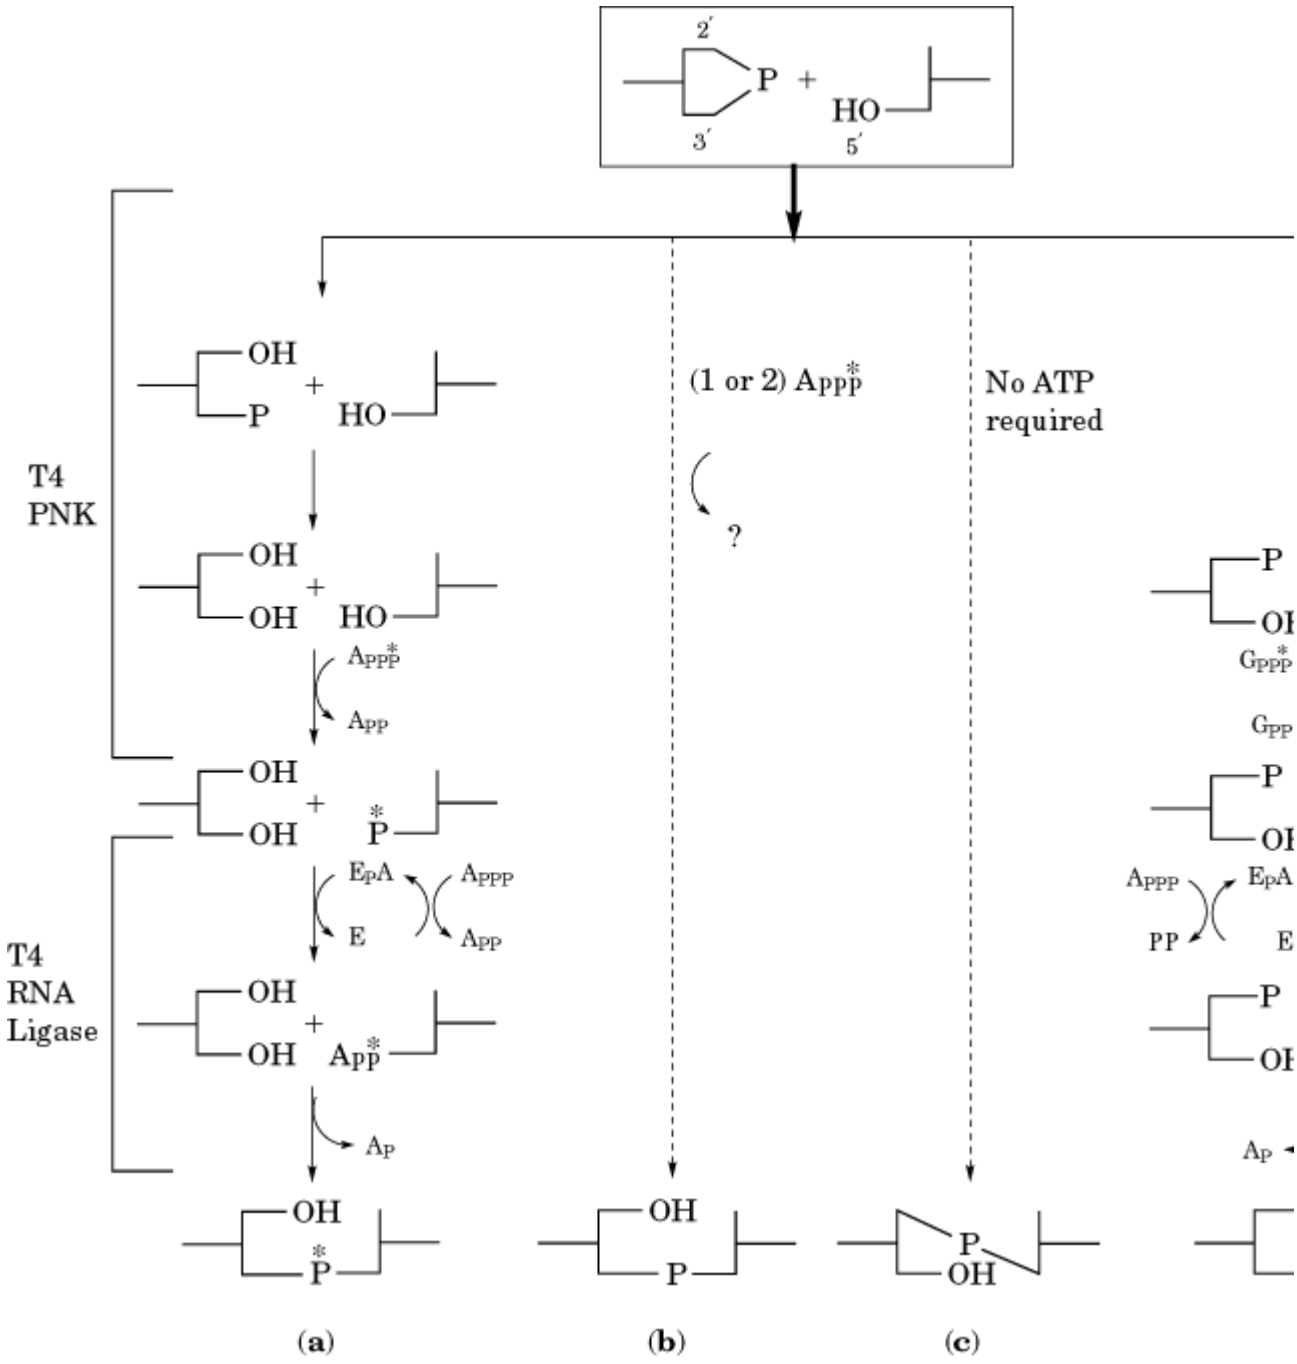
Name of phenomena or key enzymes	Function	Pairing information[a]	Reactions
Self-splicing		Intron-directed	Transesterification (Non-protein catalysis)
Spliceosome	Splicing		
tRNA Splicing		Exon-directed	Cleavage and ligation
Insertional/Deletional editing	Editing	gRNA-directed	Cleavage, insertion/deletion, and ligation
T4 RNA ligase	Unknown	Unknown	(Unknown)+ligation
E. coli 2′-5′RNA ligase			

[a] Information necessary for determining the two fragments to be ligated and bringing them neighbored.

The reaction mechanisms of RNA ligases are summarized in Figure 2. In general, the RNA-joining reaction begins with two kinds of RNA molecules, a 2′,3′-cyclic phosphate acceptor and a 5′-hydroxyl donor. Eukaryotic tRNA ligase has a whole set of activities for this mechanism: (i) opening of the 2′,3′-cyclic phosphate to a 2′-phosphomonoester (phosphodiesterase activity), (ii) addition of a phosphate group to the 5′-hydroxyl of the donor (kinase activity), (iii) transfer of an adenylyl group from an adenylylated enzyme, which is produced in advance by another kinase activity of the same enzyme, to the 5′-phosphate of the donor (adenylylation activity), and (iv) attack of the acceptor 3′-hydroxyl on the activated donor phosphoanhydride, to form a 3′,5′-phosphodiester bond (bond formation activity). The mature tRNA is then generated by the action of a distinct enzyme, 2′-phosphotransferase, which removes the 2′-phosphate from the product. T4 RNA ligase accomplishes the same reaction with steps iii and iv, although the donor for T4 RNA ligase must have a 2′-hydroxyl structure (not 2′-phosphate). Therefore, tRNA ligase has the combined functions of T4 **polynucleotide kinase** and T4 RNA ligase, as indicated in Figure 2.

Figure 2. Reaction mechanisms of RNA ligases. (**a**) T4 RNA ligase; (**b**) animal pathway RNA ligase (ligases that resem exclusively in the cells of vertebrates); (**c**) 2′,5′ RNA ligase; (**d**) tRNA ligase. The 3′ end of the left-hand RNA segment ribose indicated; the 5′ end of the right-hand RNA segment has the 5′ ribose position indicated. A_{PPP}:ATP; G_{PPP}:GTP; P bridging phosphate in the product (bottom) is not the starting phosphate incorporated in the 2′,3′-cyclic phosphodiester b phosphate is shown capped with an asterisk. The source of the ATP is indicated similarly.



RNA editing enzymes in kinetoplastids of *Trypanosoma brucei* and *Leishmania tarantolae* are also assumed to have a reaction mechanism similar to that of T4 RNA ligase, although a transesterification mechanism that does not require a ligase for joining of the RNAs cannot be completely ruled out (1). *Escherichia coli* 2′,5′ RNA ligase and animal pathway ligase have been reported, but their functions and detailed reaction mechanisms are not well understood (Fig. 2). Recent genome sequencing analyses made it clear that the archaeon *Methanococcus jannaschii* and the **gram-positive bacterium** *Bacillus stearothermophilus* each have a homologue of the *E. coli* 2′,5′ RNA ligase, but the bacterium *Haemophilus influenzae* does not. Interestingly, the archaeon does not contain homologues of T4 RNA ligase or tRNA ligase, although it does retain the homologue of eukaryotic tRNA splicing endonuclease, supporting the suggestion that 2′,5′ RNA ligase may be a relevant ligase for tRNA splicing in those organisms. The eukaryotic and archaeal endonucleases are very similar in substrate recognition and protein structures (2, 3).

The common reaction steps of enzyme adenylylation (or guanylylation) and nucleotidyl transfer are shared among RNA ligases (T4 RNA ligase and tRNA ligases), DNA ligases (those of **T4 phage**, *Saccharomyces cerevisiae*, and *Homo sapiens*), and mRNA capping enzymes. In all three, a lysine residue at the active site of the enzymes, which is highly conserved, is transiently adenylylated (or guanylylated in the case of mRNA capping) using ATP (or GTP), and then the nucleotide is transferred to the 5′-phosphate group (5′-pyrophosphate in the case of mRNA capping) of a donor molecule. The activated diphosphoanhydride form facilitates ligation of both DNA and RNA. In the case of mRNA capping, the same reaction occurs without a further reaction, generating G(5′) $pppN_1N_2$ ¼. Being similar in function, structure, and reaction mechanism, these enzymes are believed to have had a common progenitor.

Ligation might be performed by the reverse of the reactions of endonucleases like **ribonuclease A, RNase T_1**, and RNase PH. These ribonucleases usually cleave RNA to produce a transient 2′,3′-cyclic phosphate and a 5′-hydroxyl at the newly exposed ends, so the substrate structures are the same as those used in authentic RNA ligation (although it would not require that the reaction mechanism be the same in detail). There is, however, no evidence that such a reverse ribonuclease reaction occurs under physiological conditions.

Ribozymes (RNA enzymes) capable of RNA ligation have been produced using the technique of *in vitro* selection (4, 5). Currently, two types of ligation reactions are used, mimicking the reactions of (i) RNA polymerase [attack of the 3′-hydroxyl on the 5′-triphosphate (4)] or (ii) RNA ligase [attack of the 3′-hydroxyl on the 5′-5′- diphosphate (5)]. These studies may lead to elucidation of the mechanism of **self-splicing** and development of highly useful ligation techniques.

1. T4 RNA Ligase

T4 RNA ligase is encoded by gene 63 of T4 phage, has a molecular weight of 43.5 kDa, and is composed of 375 amino acid residues of known primary structure (6). Originally, T4 RNA ligase was discovered as an enzyme that intramolecularly ligates the terminal 3′-hydroxyl of a polyriboadenylate with its own 5′-phosphate, generating a circular RNA. Then, this enzyme was found to have a more general function, to ligate the 3′-hydroxyl of a single-stranded RNA/DNA with the 5′-phosphate of the same or another single-stranded RNA/DNA, although the ligation of RNA molecules is 200-fold more efficient than is that of DNA. The biological role of T4 RNA ligase is not known, though it has a distinct function, carried out by a different part of the enzyme, in **T4 phage** tail-fiber attachment as part of phage morphogenesis. An intriguing hypothesis is based on the observation that one strain of *E. coli* (CTr5x) that contains an anticodon nuclease (ie, a nuclease targeted at the anticodon site of the host $tRNA^{Lys}$) is resistant to T4 mutants that carry a defect in either RNA ligase or **polynucleotide kinase** (PNK) activity. The interpretation of this is that these T4 mutants cannot proliferate in *E. coli* cells that have an anticodon nuclease activity induced by T4 stp protein (part of the host **restriction/modification** system) due to their inability to repair the resulting breakage of the $tRNA^{Lys}$ which is now essential for the T4 growth. To restore the tRNA, the following serial reactions are required: 2′,3′-cyclic phosphodiesterase, 3′-phosphatase, and the 5′-kinase activities of T4 PNK and the ligation activity of T4 RNA ligase (see Fig. 2). This hypothesis, which considers T4 RNA ligase to be a kind of tRNA ligase, also implies that T4 RNA ligase may have arisen from an ancestral tRNA splicing enzyme.

The enzymatic properties of T4 RNA ligase have been investigated thoroughly, and the reaction mechanism is shown in Figure 2. For ligation, first, the **ε-amino group** of Lys99 of T4 RNA ligase is adenylylated, using one ATP molecule. Second, a donor RNA/DNA properly located on the enzyme accepts the adenylyl group on its 5′-terminal phosphate, generating a 5′,5′-phosphoanhydride bond. Finally, the 3′-hydroxyl of an acceptor attacks nucleophilically the activated phosphoanhydride of the adenylylated donor, forming a 3′,5′-phosphodiester and releasing

AMP. Asp101 of this enzyme is known to be important in the second and the final steps of ligation. Short-circuiting of the first and the second steps by use of a previously 5′-adenylylated donor is possible and enhances the overall reactions, indicating those steps to be rate-limiting.

Because T4 RNA ligase is very permissive in its substrate recognition, various techniques that use this enzyme have been developed: (i) enzymic ligation of oligoribo/oligodeoxyribonucleotides (7), (ii) 3′- or 5′-end labeling of RNA/DNA with **biotin, fluorescent** dyes, or radioisotopes (8), (iii) introduction of nicotinamide nucleotides into RNA (9), (iv) end-closing of DNA/RNA (10), and so forth.

RNA Polymerases, DNA-Dependent

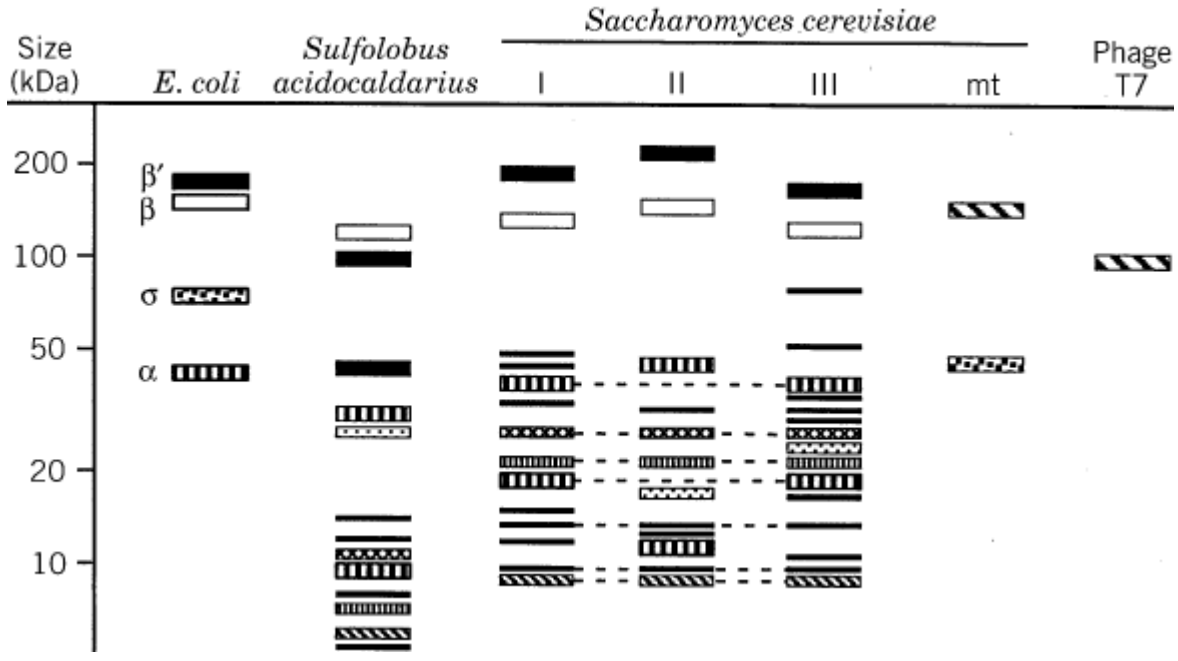
DNA-dependent RNA polymerases (RNAPs) are essential components of **gene** expression in organisms that use DNA to encode their genetic information. These enzymes catalyze the formation of phosphodiester bonds between ribonucleotides to form a single-strand RNA polymer using DNA as a template (see Transcription). DNA-dependent RNAPs thus produce an RNA copy of a gene that may, after further modification, function directly, in the case of transfer RNA, **ribosomal** RNA, or **small nuclear RNA** (snRNA), or undergo further decoding by the protein translation machinery, in the case of messenger RNA. DNA-dependent RNAPs can be divided into two distinct homology classes, multi- and single-subunit RNAPs. The multisubunit RNAPs are found throughout the living world; they function as the main cellular RNAPs in eubacteria, archaea, and eukaryotes. Some virally-encoded RNAPs are also members of the multisubunit RNAP group. The single-subunit RNAPs (ssRNAPs) were first discovered in **bacteriophages T7** and T3, but related members of this group are also found in eukaryotic mitochondria and chloroplasts.

The evolutionary relationship between the two classes of DNA-dependent RNAPs is not clear, because there is no obvious sequence similarity between the single-subunit RNAP and the subunits of the multicomponent cellular RNAP. As described below, however, the two classes of RNAPs have several mechanistic similarities. Both classes also undergo a similar transcription cycle involving (a) DNA **promoter** recognition, (b) opening of the promoter DNA, (c) initiation of transcription, (d) a conformational change releasing the RNAP-promoter interaction and triggering a processive mode of transcript elongation, and (e) termination and transcript release.

1. Multisubunit RNAPs

The multisubunit RNAPs are of ancient origin. As shown in Figure 1, the cellular RNAPs from the three domains of life are clearly related, suggesting that the last common ancestor of the three lineages contained a multisubunit RNAP (1, 2). Additional multisubunit RNAPs function within chloroplasts (3) and in certain cytoplasmic DNA **viruses** (4, 5). The multisubunit chloroplast RNAP is very similar to the eubacterial enzyme, consistent with the endosymbiotic origin of the organelle, whereas the viral RNAPs are most closely related to eukaryotic nuclear RNAPs.

Figure 1. Relationships between the subunits of multisubunit and of selected bacterial, archaeal, eukaryotic nuclear and mitochondrial, and bacteriophage DNA-dependent RNA polymerases. This figure represents a schematic SDS-PAGEseparating the subunits of the indicated RNAPs according to their masses. Amino acid sequence homologies are indicated by similar shading of the thicker bars used to denote some of the subunits. Dotted lines connect subunits of the eukaryotic nuclear RNAPs encoded by the same genes. In the following list, the parenthesis include the mass in kDa and in some cases the name of the encoding gene. *Escherichia coli* RNAP is composed of b′ (160, *rpoC*), b (155, *rpoB*), a (40, *rpoA*), and one of several s factors; the major vegetative factor (70, *rpoD*) is shown here. The archaeal RNAP from *S. acidocaldarius* is composed of B (122), A′ (101), A″ (44), D (30), E (27), G (13.8), F (12), H (11.8), L (10), I (9.7), K (9.7), N (7.5), and M (5.5) subunits. The *S. cerevisiae* nuclear RNAP I is composed of (190, *RPA190*), (135, *RPA135*), (49, *RPA49*), (43, *RPA43*), (40, *RPC40*), (34, *RPA34*), (27, *RPB5*), (23, *RPB6*), (19, *RPC19*), (14, *RPA14*), (14, *RPB8*), (12, *RPA12*), (10, *RPC10*), and (10, *RPB10*) subunits. RNAP II is composed of (220, *RPB1*), (150, *RPB2*), (45, *RPB3*), (32, *RPB4*), (27, *RPB5*), (23, *RPB6*), (17, *RPB7*), (14, *RPB8*), (13, *RPB9*), (13, *RPB11*), (10, *RPC10*), and (10, *RPB10*) subunits. RNAP III is composed of (160, *RPC160*), (128, *RPC128*), (82, *RPC82*), (53, *RPC53*), (40, *RPC40*), (37), (34, *RPC34*), (31, *RPC31*), (27, *RPB5*), (25, *RPC25*), (23, *RPB6*), (19, *RPC19*), (17), (14, *RPB8*), (11), (10, *RPC10*), and (10, *RPB10*) subunits. The *S. cerevisiae* mitochondrial RNAP (mt) is composed of (145, *RPO41*) and (43, *MTF1*) subunits. The T7 RNAP is a single polypeptide chain of 100 kDa. The data used to create this figure came from Refs. 2, 11, 24, 38, and 63.



The multisubunit RNAPs include a core enzyme that is fully capable of RNA chain elongation and termination. Most of these core enzymes can initiate transcription *in vitro* from single-stranded DNA or, in some cases, from model copolymer templates like poly dAT. However, the core RNAPs are incapable of initiating transcription selectively at a specific promoter sequence on a natural DNA template. The multisubunit RNAPs therefore rely on associated factors for promoter recognition and, in some cases, for the initial steps of transcription. The required initiation factors in eubacteria and eukaryotes differ greatly. In eubacteria, specific sigma factors associate with the core RNAP and confer promoter-specific transcription initiation properties to the otherwise nonspecific enzyme. While not similar at the level of primary structure or three-dimensional protein structure to sigma factors, TATA box binding protein (TBP) plays an analogous role in both archaea and eukaryotes. TBP binds the TATA box sequence in promoter DNA and, with the aid of several other transcription factors, recruits the RNAP to promoter regions of the DNA.

As shown in Figure 1, the multisubunit RNAPs of all three kingdoms are clearly related, but the eukaryotic and archaeal RNAPs are more closely related to each other, in terms of both subunit composition and similarity of the individual subunits, than they are to the eubacterial RNAP. The eubacterial core RNAP is composed of only three subunits, b′, b, and a. The eukaryotic and archaeal RNAPs include homologues of the eubacterial core polypeptides, but they also have many additional subunits. The eubacterial RNAP therefore represents a minimal multisubunit core RNAP that functions similarly to the larger RNAPs in the basic mechanisms of initiation, elongation, and termination of transcription. Indeed, much of what we know about the multisubunit RNAPs is derived from studies of *Escherichia coli* RNAP.

1.1. Eubacterial RNAP

Early studies of the bacterial RNAP revealed that it is a multisubunit enzyme found in two forms. The core RNAP consists of three subunits a, b′, and b, with a stoichiometry of 2:1:1 ($a_2b'b$), while the holoenzyme also includes a s sigma factor (see Fig. 1). Core RNAP functions in elongation and termination, while the holoenzyme is responsible for initiating transcription. Although differences occur between the promoters and initiation factors of multisubunit RNAPs, the basic steps of transcription are similar for all RNAPs (6, 7) (see also Transcription and Sigma Factors). They include, but are not limited to, the following six steps.

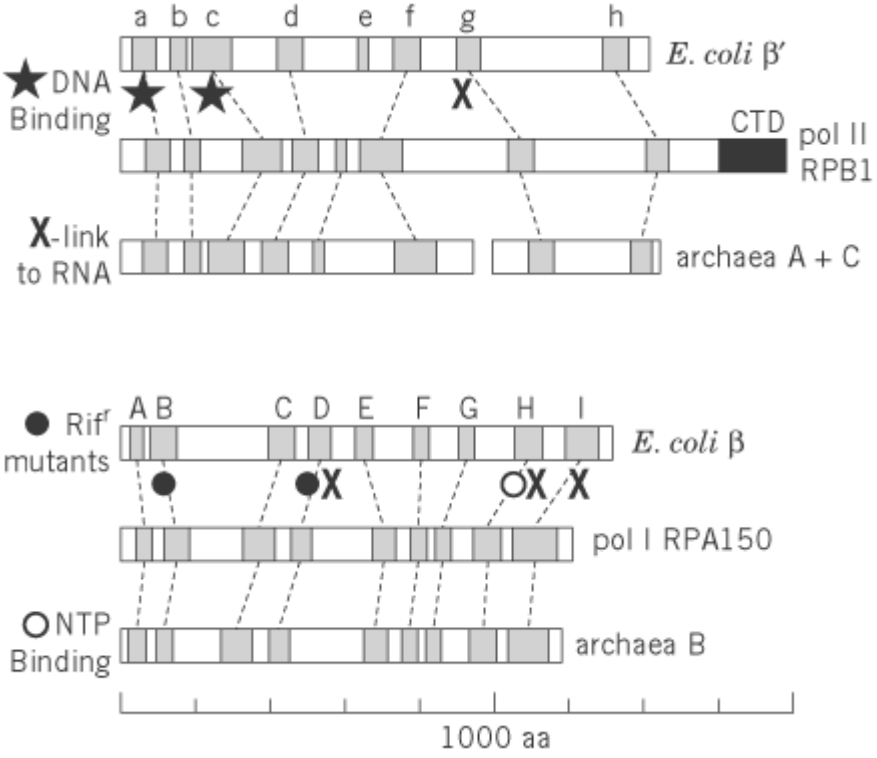
1. The holoenzyme binds to the promoter DNA.
2. The promoter is isomerized into an open complex in which the DNA strands are separated.
3. Transcription is initiated in a poorly processive process where many abortive short transcripts are released while the RNAP maintains contact with the promoter.
4. The RNAP undergoes a significant change called *promoter escape*, which occurs after the transcript reaches a length of about 8 to 12 nucleotides. Escape is marked by the release of the s factor and by a transition to a processive form of transcription.
5. The transcript is elongated.
6. The transcript is released in a process called termination.

Footprintingof *E. coli* RNAP/promoter DNA complexes revealed that the RNAP initially protects a large region of DNA spanning from –55 to +20 relative to the start site of transcription (7, 8). During the isomerization and early initiation steps, the upstream border of the footprint remains fixed, while the DNA is opened to form a 18-bp “bubble” within the protected region. The downstream border of the footprint also remains fixed until the RNAP escapes from the promoter. At that point, the downstream border of the footprint jumps forward, and the footprint decreases in size coincident with the release of the sigma factor. The open DNA bubble is maintained though contacts with the RNAP and through the formation of an RNA/DNA hybrid 8 to 12 bp long. Destabilization of the RNA/DNA hybrid is associated with termination of transcription.

The structures of the *E. coli* core and holoenzyme have been analyzed by X-ray crystallography methods (9, 10). Although the reported resolution is currently low, these initial studies reveal a fundamental difference in the structures of the two forms of the RNAP. Both structures contain a channel of a size that could accommodate binding of the template DNA. The channel of the core RNAP appears to be closed, while the channel of the holoenzyme is open and potentially accessible to DNA, consistent with its role in initiation. Furthermore, the closed form of the channel in the core RNAP leads to a plausible mechanism for the processivity of the core enzyme. Closing of the open channel when s dissociates may "clamp" the RNAP into a more stable elongating form.

The two largest subunits of the *E. coli* RNAP (b′ and b) form the catalytic core of the enzyme. These subunits have been shown to function in DNA binding and transcription elongation and termination (8). b′ and b are homologous to the largest subunits of all multisubunit RNAPs (see Fig. 1). As shown in Figure 2, b′, b, and their homologues contain eight (labeled **a–h**) and nine (labeled **A–I**) collinear segments, respectively, that have strong amino acid sequence similarities (11). Mutational analyses support the idea that these conserved segments are critical for the function of RNAP; many mutations affecting elongation and termination map to these universally conserved regions (8).

Figure 2. Primary structure relationships of the largest subunits of the bacterial, eukaryotic, and archaeal RNA polymerases. Similarities between the *E. coli* b′ subunit and its eukaryotic and archaeal orthologues are shaded and labeled **a–h** . Similarities between the *E. coli* b subunit and its orthologues are labeled **A–I**. pol I and pol II are the yeast RNAP I and RNAP II, respectively Regions of known function for the *E. coli* subunits are indicated by symbols below the shaded regions. The data used to create this figure came from Refs. 11, 13, and (14).



b′ contains a Cys_4- **zinc finger**-like motif near the *N*-terminus within conserved region **a** (Fig. 2) that is thought to function in **DNA-binding** . This motif is conserved in the corresponding subunits of all multisubunit RNAPs. Additionally, within conserved region **c** there is a small region of similarity between b′ (and its homologues) and a DNA-binding region of **DNA polymerase** I. In confirmation

of the role of this region in DNA binding, mutations there destabilize the binding of the RNAP to promoter DNA during initiation (12). Finally, the 3′ end of the nascent RNA transcript is capable of crosslinking to conserved region **g**, strongly suggesting that this region of b′ may form part of the active site of the RNAP (8).

The b subunit is responsible for binding the substrate nucleoside triphosphates (Fig. 2) (13). The b subunit also contains three regions (**D, H, I**) that are in close proximity to the 5′ end of the nascent transcript, with mutational studies placing **H** near the active site (8). Additionally, analysis of **rifampicin**-resistant RNAP variants has identified mutations in several regions of the b subunit that result in a lower affinity for the drug (Fig. 2) (14). Rifampicin blocks the path of nascent RNA emerging from the catalytic center, so that only short transcripts are made; therefore, the rifampicin binding site is thought to be near the catalytic center. This is supported by crosslinking studies showing that the rifampicin binding site is within 15 Å of the initiating nucleotide and within 2 Å of the –2 and –3 positions of the template DNA (14). Recent work using photocrosslinking agents is resulting in more detailed information about the location of the catalytic center and the path of RNA and DNA in the elongating complex (7).

In both eubacteria and archaea, the genes coding for the b and b′-like subunits are organized in an operon, with the b-like subunit gene always preceding that for the b′-like subunit. The operon organization, in addition to providing coordinate regulation, may allow the subunits to assemble cotranslationally, which might predict that the b *C*-terminus is in close proximity to the b′ *N*-terminus in the RNAP. This idea is supported by the finding that the two genes are naturally fused in the bacterium *Helicobacter pylori* (15), and experimental fusion of the two *E. coli* genes results in a catalytically active protein that is functional *in vivo* (16). In addition, crosslinking studies have confirmed that these domains are close in space in the folded protein (17).

The a subunit functions in three main processes (8). First, it plays a vital role in the assembly of the core RNAP. The core assembles in an ordered fashion $2a > a_2 > a_2b > a_2bb'$. Truncated proteins lacking the *C*-terminal third of a are competent for core assembly, showing that the *N*-terminal domain (a-NTD) mediates assembly. Additional studies show that discrete regions of a are required for each step of RNAP assembly. These regions of a are conserved in subunits of the other multisubunit RNAPs, suggesting that there may be similarities in the assembly of all of these enzymes. Second, using a DNA-binding function in the *C*-terminal domain (a-CTD), a binds to DNA sequences that are found upstream of some strong promoters and augments the activity of RNAP at those sites. Finally, a is required for transcriptional activation by a number of activators; holoenzyme containing only the a-NTD is functional for basal transcription, but cannot be activated at certain promoters. The importance of the a-CTD in activation was confirmed by experiments showing that the CRP activator makes direct contacts with the a-CTD (18).

The s subunit (see Sigma Factors) is responsible for promoter-specific DNA binding and specific initiation (19, 20). Prokaryotic organisms contain multiple sigma factors that function at various stages of growth or under different environmental conditions. Normally, the primary s factor (s^{70} in *E. coli*) is used to transcribe the **housekeeping genes** of the cell. Alternative s factors coordinate expression of specific sets of genes that are required for more specialized functions. Each s factor recognizes and binds to different subsets of promoters to direct transcription of specific genes. In addition to its role in initiation of basal transcription, s is also required for transcriptional activation at certain promoters.

There are many ancillary factors that associate with the core RNAP during transcription to alter its properties. They include factors such as NusA, which increases the efficiency of pausing and termination, Gre factors, which stimulate elongation by rescuing paused RNAP complexes, and Rho protein, which functions in termination of transcription at specific sites.

1.2. Eukaryotic RNAPs

Eukaryotes contain three nuclear RNAPs. The three enzymes differ in their subnuclear location, sensitivity to a-amanitin, and subunit composition (see Fig. 1), as well as in the types of RNA that they transcribe. RNAP I is located in the nucleolus, where its sole function is the synthesis of precursor ribosomal RNA from the multiple rRNA genes. Although only a single type of promoter is utilized by RNAP I, its products may represent up to four-fifths of the RNA being synthesized in a rapidly growing cell (21). The nucleoplasmic RNAP II synthesizes mRNA and some snRNA genes and is therefore responsible for transcribing many different genes with widely divergent promoters. RNAP III, also nucleoplasmic, is responsible for the synthesis of 5 S rRNA, tRNAs, and the remaining snRNAs.

Much of the study of eukaryotic RNAPs has focused on the mechanisms of transcription initiation. The subunit structures are shown in Figure 1. Although they are more complex than the eubacterial enzyme, all represent core RNAPs that are unable to recognize promoter DNA in the absence of additional factors. Although, as described below, each RNAP has its own complement of initiation factors, they have one factor in common: Each eukaryotic nuclear RNAP requires the TATA-binding protein (TBP) for transcription initiation (22). Indeed, all eukaryotic promoters can be divided into two classes, depending on whether or not they contain a TATA box. In TATA-containing promoters, found in some but not all RNAP II- and RNAP III-dependent genes, TBP and its associated factors play an important role in binding the promoter and nucleating the association of additional factors required for recruitment of the RNAP. In TATA-less promoters, including RNAP I promoters and some RNAP II and III promoters, additional factors are required to bind first to the promoter and then to recruit TBP.

1.2.1. Subunit Composition of Eukaryotic RNAPs

The eukaryotic nuclear RNAPs are built on the same basic plan as the eubacterial enzyme (Fig. 1). Each enzyme contains two large subunits that are homologous to b and b′ of the eubacterial RNAP and two polypeptides with amino acid sequences similar to the a subunit. The largest subunits contain several regions of amino acid sequence and functional similarity to b and b′ (Fig. 2). These subunits, like their bacterial counterparts, bind DNA and contact the nascent RNA (23). The second-largest subunit has also been implicated in substrate binding. As indicated in Fig. 1 by dotted lines, five of the smaller RNAP subunits are encoded by single genes and are common to all three enzymes, forming a shared core, while two subunits are shared by RNAP I and RNAP III. Additionally, each enzyme contains unique subunits. Despite the large number of components, most of the subunits are essential in *Saccharomyces cerevisiae* (24). The overall shape and structure of RNAP I and RNAP II from *S. cerevisiae* have been investigated by electron microscopy of two-dimensional crystals (25, 26), demonstrating similar overall shapes and containing the thumb-like projection and channel as described above for the core RNAP from *E. coli*.

1.2.2. Features of RNAP I

To initiate transcription from rRNA promoters, RNAP I requires two DNA-binding transcription factors, UBF (upstream binding factor) and SL1 (TIF-IB) (21, 27). UBF is an **HMG box** protein that binds DNA as a dimer (see DNA-Binding Proteins). SL1 contains TBP and three additional factors unique to rRNA synthesis. SL1 and UBF form a complex on the core rRNA promoter that is remarkably stable and can catalyze multiple rounds of transcription initiation. Both proteins can also bind an upstream control element (UCE) that functions to enhance the function of the core promoter. RNAP I is recruited to the initiation complex through interactions with SL1. The activity of RNAP I is very sensitive to the growth state of the cell, and additional factors are involved in modulating the level of rRNA synthesis.

1.2.3. Features of RNAP II

Because of its pivotal role in the regulation and expression of eukaryotic proteins, the mechanism of initiation by the eukaryotic RNAP II has been the focus of intense research. Early studies identified several factors required for selective initiation by RNAP II including TFIIB, TFIID, TFIIE, TFIIF and TFIIH (28-30). TFIID is the RNAP II-specific, multisubunit form of TBP (22, 31). TFIIH is a multisubunit factor that also plays a critical role in nucleotide excision repair (32). Although TFIIB

is a single polypeptide chain, TFIIE and TFIIF are also multisubunit factors, and the minimal initiation-competent form of RNAP II contains more than 30 proteins!

Several protein factors are known to associate with, and modify the activity of, the elongating form of RNAP II. TFIIF, also a component of the initiation complex, increases the rate of RNA chain elongation (33). Like the *E. coli* Gre factors, TFIIS stimulates paused RNAP complexes that are arrested by transcriptional blocks. Both the Gre factors and TFIIS function by stimulating the inherent ability of RNAPs to reverse the polymerization reaction and to remove incorrectly incorporated bases (7). Two recently described RNAP II elongation factors, elongin (34) and P-TEFb (35), appear to play important roles in the regulated expression of subsets of mammalian genes. In particular, P-TEFb is critically important for high level of expression of genes of the **HIV virus** (35, 36).

The largest subunit of RNAP II contains a unique *C* -terminal domain (CTD, see Fig. 2) consisting of repeats of a heptad sequence, Tyr–Ser–Pro–Thr–Ser–Pro–Ser, not found in any other RNAP (37-39). The number of repeats varies among organisms, with yeast RNAP II containing 26 repeats, while mouse RNAP II has 52. Deletion analysis of the CTD reveals that a minimum number of repeats is required for viability in *S. cerevisiae*. This domain is the site of complex protein associations that have broad implications in the regulation of RNAP II and mRNA synthesis and processing. Extensive **phosphorylation** of the CTD tail has been observed shortly after the transition between initiation and elongation, implicating the CTD in the conversion of RNAP II into an elongation-competent form. Although several kinases have been identified that can phosphorylate the CTD, it is of particular interest that the initiation factor TFIIH and the elongation factor P-TEFb possess CTD kinase activity (32, 35). These factors appear to play a role in the transition between initiation and elongation.

The unphosphorylated form of the CTD apparently nucleates the formation of a large complex of proteins referred to as the *mediator*. A high-molecular-weight form of RNAP II, including the mediator and several of the TFII initiation factors, has been dubbed the “holoenzyme” (40). Mediator proteins are required for transcriptional activation through contact with transcriptional activator proteins. The CTD also binds a number of additional proteins involved in the subsequent processing of pre-mRNA transcripts. These proteins include cleavage and polyadenylation factors, as well as proteins that could associate the spliceosome with the transcription machinery (41).

1.2.4. Features of RNAP III

Although RNAP III is the most complex of the eukaryotic nuclear RNAPs, with 17 subunits (Fig. 1), it still requires three additional basal transcription factors, TFIIIA, TFIIIB, and TFIIIC, to initiate transcription selectively (27, 42). TFIIIC from yeast contains six subunits, while TFIIIB, the RNAP III TBP-containing factor, is composed of at least three subunits. TFIIIB also contains a homologue of the RNAP II transcription factor TFIIB, known as BRF (for TFIIB related factor). TFIIIB is the central transcription factor for RNAP III and is required to recruit the polymerase to the promoter. TFIIIC serves as an assembly factor for TFIIIB. It binds to elements that are internal to the gene and directs positioning of TFIIIB at RNAP III promoters. TFIIIA, a single polypeptide chain containing nine zinc-finger domains that bind DNA or RNA, is a gene-specific transcription factor for the 5 S rRNA genes. TFIIIA binds to sequences within the 5 S rRNA gene and functions as an adaptor for TFIIIC. Most genes transcribed by RNAP III, including 5 S rRNA and tRNA genes, utilize promoter sequences internal to the gene coding region. However, some RNAP III transcripts depend on upstream promoters, in some cases including a TATA box (22).

1.3. Archaeal RNAP

The single RNAP from *Sulfolobus acidocaldarius* is composed of 13 subunits, with an overall structure more like the eukaryotic nuclear enzymes than the eubacterial RNAP ([Fig. 1 (2)]. The b′ homologue of the archaeal RNAP is split into two subunits, A′ and A″: A′ corresponds to the first two-thirds of b′, while A″ is homologous to the *C*-terminal one-third. The b′ homologue is split in all known archaea, as well as in cyanobacteria and some chloroplasts (43, 44). The b homologue is also

divided in halophilic and methanobacteria (45-47). Like the eukaryotic nuclear RNAPs, two of the subunits of the archaeal RNAP have some similarity to the a subunit of bacterial RNAP (Fig. 1). The *S. acidocaldarius* RNAP includes five homologues of the eukaryotic nuclear RNAP subunits, in addition to the a, b, and b′ homologues. Three of these homologues are similar to the shared core subunits of the nuclear RNAPs, whereas four additional subunits do not resemble proteins from either eubacteria or eukaryotes.

Most archaeal gene promoters have an A-box motif (TTTA[T/A]A) centered around position –27 that plays an important role in selection of the start site. The location and composition of the A-box closely resembles the TATA box found in many RNAP II promoters. In addition, the archaeal RNAP requires homologues of TBP and TFIIB for initiation (48), and it utilizes a homologue of the eukaryotic transcription elongation factor TFIIS (2). Overall, the archaeal transcription apparatus is much more similar to that found in the eukaryotic nucleus than to that in eubacteria.

2. Single-Subunit RNAPs

While the multisubunit RNAPs show a clear evolutionary history, the origin of single-subunit RNAPs is uncertain (49). **Phylogenetic** analyses group the ssRNAPs into three nonoverlapping and well-defined clusters (phage, nuclear-encoded, and mitochondrial plasmid encoded). The phage ssRNAPs include four enzymes encoded by bacteriophage T7 and T3, *Salmonella* phage SP6, and *Klebsiella* phage K11. The nuclear-encoded class was limited for a number of years to a single example, the yeast mitochondrial RNAP. Recently, genes for several putative mitochondrial RNAPs have been cloned and sequenced, including those from other fungi (50), plants (51, 52), and mammals (53). The ssRNAPs of the third group are found within the mitochondria of certain plants and fungi, where they are encoded by linear plasmids. It is possible that the plasmid-borne genes represent an early step in the acquisition of the ssRNAP from a phage, prior to transfer to the nucleus (reviewed in (49).

One additional RNAP has recently been discovered that may represent a fourth group of ssRNAPs. In *Arabidopsis thaliana*, a second chloroplast RNAP has been identified, in addition to the chloroplast-encoded eubacterial-like enzyme (3). This nuclear-encoded ssRNAP appears to transcribe a subset of chloroplast genes. Phylogenetic comparisons show that the chloroplast ssRNAP is closely related to the mitochondrial ssRNAPs, and it seems to have arisen from a duplication of the nuclear-encoded mitochondrial ssRNAP gene (51).

2.1. Phage RNAPs

The phage RNAPs are the best characterized group of the ssRNAPs, with the phage T7 RNAP serving as a model for the entire class (54). The T7 RNAP is a 99-kDa enzyme. Like the multisubunit RNAPs, T7 RNAP is capable of *de novo* RNA synthesis, RNA chain elongation, and transcription termination at appropriate signals. Despite its small size, however, the phage RNAP is itself a holoenzyme with the ability to recognize and to bind promoter DNA without the addition of s- or TBP-like factors. Promoters for the four phage RNAPs are similar and consist of two functional domains as defined by the analysis of point mutations (55). The region from –17 to –6 of the promoter (relative to the start site of transcription) constitutes the binding domain, while the initiation domain covers the region from –5 to +6.

Its structure indicates that T7 RNAP is related to DNA polymerases, showing the most similarity to the Klenow fragment of DNA polymerase I (pol I) (56, 57). Although not strikingly similar at the amino acid sequence level, both T7 RNAP and pol I resemble a cupped right hand containing three subdomains: the “fingers,” “palm,” and “thumb.” There is conservation of sequence within four functional motifs that are found in many DNA-directed RNAPs (54, 58). Two of the motifs, designated “A” and “C,” contain **aspartate** residues that chelate metal ions within the catalytic pocket of the polymerases. The “B” motif is located within the fingers domain and contributes to substrate binding. These motifs are required for catalytic function and cluster within a small part of the folded structure of the RNAP. The fourth motif, designated T/DxxGR, is found in all DNA-

directed polymerases, including the largest subunits of the multimeric RNAPs, and is involved in template strand contacts. Mutations within the 'B' motif allow T7 RNAP to use deoxynucleotide triphosphate substrates, converting the RNAP to an enzyme more like a DNA polymerase (59, 60).

Footprinting studies at various points of transcription have revealed several features about the T7 RNAP (61). Before initiation, the T7 RNAP footprint protects ~20 bases. During the initial stages of transcription, the downstream border of the footprint extends, while the upstream border remains fixed, with the result that the footprint increases in length, reaching a maximum length of ~30 bases. The static nature of the upstream border suggests that the RNAP maintains contact with the promoter during this early abortive stage of transcription. After the transition to processive transcription, the upstream border of the footprint moves downstream, until the footprint returns to the preinitiation length. The transition from abortive to processive transcription is thought to depend on an RNA/RNAP interaction and a conformational change in the structure of the RNAP (62). On the basis of the structural data, it is easy to envision a conformational change in which the thumb or finger domain closes around the DNA, thus preventing its premature release from the RNAP. Similarly, hairpin structures that terminate transcription may disrupt the RNA/RNAP interaction, reversing the conformational change and leading to a release of the RNAP, as is also envisioned for the multisubunit RNAPs (7).

2.2. Mitochondrial RNAP

The yeast mitochondrial core RNAP is encoded by a nuclear gene (*RPO41*) with sequence similarity to T3 and T7 phage RNAPs (Fig. 1). The similarity extends along the entire length of phage RNAPs and includes the amino acid residues that make up the A, B, C, and T/DxxGR motifs mentioned above (63). The similarity to phage RNAPs is surprising, because it was thought that the mitochondrial transcription machinery would reflect the eubacterial origin of the mitochondria (3). Until recently, the possibility existed that the yeast mitochondrial RNAP was an evolutionary anomaly, not representative of mitochondrial RNAPs of other eukaryotes. However, the recent identification of related ssRNAPs in other fungi, plants, and mammals has confirmed the yeast enzyme as a useful model for the class. Homologues have also been identified in algae and protozoa, including some of closest relatives of amitochondriate eukaryotes (64), demonstrating that the T7-like RNAP was recruited at an early stage in the evolution of the mitochondria.

Despite homology to T7 RNAP, yeast mitochondrial RNAP requires a second factor for promoter recognition and initiation of transcription (Fig. 1) (63). In yeast, the factor is also encoded by a nuclear gene (*MTF1*). This promoter recognition factor functions like sigma factors during the initial stages of transcription, interacting with the core RNAP in solution to provide specific promoter recognition. The core RNAP/factor complex recognizes a short nonanucleotide promoter sequence (ATATAAGTA) that resembles the –10 TATAAT region of the eubacterial sigma 70 promoter. Like sigma, the mitochondrial factor is required only for initiation, and it is released shortly after. Whether or not a separate s-like initiation factor is required for all mitochondrial RNAPs is still unclear, although the reported composition of the Xenopus mitochondrial RNAP includes a 40-kDa dissociable initiation factor (65). The mitochondrial RNAPs, therefore may represent a hybrid between the initiation factor-requiring multisubunit enzymes and the self-sufficient ssRNAPs.

3. Concluding Remarks

This brief description of DNA-dependent RNA polymerases omits many important details about mechanism and regulation of these critical enzymes. In addition, many interesting enzymes, including several of bacteriophage and viral origin, have not been described. The factors regulating the activity of the RNA polymerases represent a very large and rapidly growing family of proteins, and the reader is encouraged to explore the references below and additional sources to learn more about these complex enzymes and their role in transcribing the genetic information in DNA into RNA.

RNA Polymerases, RNA-Dependent

In all organisms the major flow of genetic information is from **DNA** to **RNA** using DNA-dependent **RNA polymerases**, with the DNA itself being replicated by DNA-dependent **DNA polymerases**. Some of the DNA synthesis, primarily of specific viruses (retroviruses) and retroelements, is from RNA by reverse transcriptase. However, there are many **viruses** of both prokaryotes and eukaryotes that have RNA **genomes** and that replicate by the synthesis of RNA from the genome. This replication is performed by RNA-dependent RNA polymerases (EC 2.7.7.48) (RdRp) (also termed *"RNA replicases"*) and usually involves other additional enzyme activities such as RNA Helicases and capping and **methylating** enzymes; these are frequently on the same protein molecule as the polymerase itself. There is also some evidence for RdRp activity in uninfected cells, and there was initially considerable controversy as to whether RNA viruses were replicated by host or viral enzyme (s) (1)

RdRp can be considered to be an ancient enzymatic activity. It is widely suggested that, at an early stage in the evolution of life, there was the "RNA World" (2) with the initial synthetic and processing activities being performed by catalytic RNAs, or **ribozymes**. In this scene, the early proteins would have been better enzymes than their RNA counterparts and thus would eventually dominate (2). It is likely that RdRp activity was among these early proteins.

1. Uninfected Cells

RdRp activity has been found in uninfected cells from both animals and plants. Mouse erythroleukemia cells contain a cytoplasmic RNA synthesis activity which is resistant to actinomycin D, leads to the formation of (–) strand globin messenger RNA and can use poly(A)-oligo(U) as a template-primer combination (3, 4). This activity required Mg^{2+} but was inhibited by Mn^{2+}. The best-characterized plant RdRp is that from tomato leaves (5, 6). This 128-kDa polypeptide chain sedimented at 6.6 S in its native form, which indicated that it was probably a monomer. Its optimum activity was at pH 7.8. It required a divalent cation, Mg^{2+}, which is much more effective than Mn^{2+}. The enzyme activity could transcribe RNA from both RNA and DNA templates, most of the transcripts being very short. Transcription could take place either with or without a primer; in the latter case priming was at, or close, to the 3′ end of the template.

As noted above, there was controversy about the role of host RdRp in viral RNA replication, which was exacerbated by the fact that the host RdRp activity increases upon virus infection. However, it is now generally assumed that the host RdRp is not involved, at least significantly, in viral replication. Its function is unknown, but the short lengths of RNA that it transcribes might be involved in some control mechanism, such as post-transcriptional suppression of **gene expression** (7).

2. Viral RdRps

Viral RdRps have three remarkable features: (i) they amplify their RNA template many-fold during a very short infection period; (ii) they specifically replicate the viral genomic RNA in the presence of a great excess of host RNAs; (iii) they copy the entire template RNA, and also express subgenomic RNAs, in most cases without using endogenous primers. In all viral enzyme complexes, the catalytic polymerase activity is virus-encoded. The detailed mechanisms by which viral RNA replicases operate are unknown, but there would appear to be differences between them, as is exemplified by the current understanding of different viruses.

2.1. Bacteriophage Qb

The RdRp holoenzyme of coliphage Qb is capable of *in vitro* synthesis of (–)-strand RNA from a (+)-strand template; it consists of four subunits, three of which are host-derived proteins [**ribosomal** protein S1 (subunit a) and translation elongation factors EF-Tu(g) and EF-TS(d)], and the fourth(b) is virus-encoded and is the catalytic subunit. Details of the function and structure of the basic holoenzyme are reviewed by Blumenthal and Carmichael (8) and by Ishihama and Barbier (9) and a working model has been proposed (10). Recent evidence indicates that a host factor is also required for efficient *in vivo* RNA replication (11). As with other RdRps, that of Qb is template-specific, and the template recognition involves complex interactions between the holoenzyme and the RNA. The tertiary structure of the RNA is recognized as being important in bringing together the sites with which the proteins of the holoenzyme interact (12). Recent studies suggest that template recognition and specificity involve both the carboxyl-terminal region of the virus-encoded subunit and the host-derived S1 protein (12, 13) (see also b Replicase).

2.2. Poliovirus

The core enzyme of poliovirus RdRp (the 3D gene product) is processed by the adjacent gene product (3C) from the **polyprotein** translated from the viral genome, and it forms a membrane-associated complex with the primer **VPg protein** (which covalently attaches to the 5′ end of the viral RNA) and protein 3C. Although there is not a clear picture of the detailed mechanism by which poliovirus, and other picornaviruses, replicate their RNA, there are various observations that have to be incorporated in any model (14). These include: (i) the need for the replication complexes to be membrane-associated for initiation and elongation of minus- and plus-strand synthesis; (ii) the VPg is covalently linked to all newly synthesized RNA; (iii) the primer for the processive RdRp is unknown although there are various hypotheses; (iv) the precursor 3CD protein binds to the 5′-terminal cloverleaf structure of the plus strand in the presence of cellular and/or viral factors; (v) various cellular proteins have been implicated in RNA synthesis, including a report that human protein Sam68 interacts with poliovirus 3D protein (15).

2.3. Plant (+)-Strand RNA Viruses

Understanding of the functioning of the RdRps of plant (+)-strand RNA viruses is limited because of the difficulties in isolating actively replicating systems from the membrane-bound replication complexes in infected cells. The replication complexes of several viruses have been shown to contain host-encoded proteins, as well as the predicted virus-encoded products. The replication complex of tobacco mosaic virus (TMV) associates with a protein related to GCD10 protein, which is the RNA-binding subunit of yeast eIF-3 (16) and that of brome mosaic virus associates with the 41-kDa subunit of wheat eIF-3 (17); the replication complex of cucumber mosaic virus is associated with a 50-kDa host protein (18). As the TMV and brome mosaic virus replicase complexes are associated with different eIF-3 subunits, it is thought likely that these host proteins play different roles in their respective virus replications (16).

The replication of RNA by RdRp is considered to have several stages covering initiation to elongation (19). There is recent evidence pointing towards the involvement of the **transfer RNA**-like structures at the 3′ end of virion RNAs of several plant viruses in the initiation and priming of at least (–)-strand synthesis (19, 20).

2.4. Double-Stranded RNA-Viruses and (–)-Strand RNA Viruses

As the genomes of double-stranded or (–)-strand RNA viruses cannot be translated directly, the virus particles carry the RdRp to initiate synthesis of mRNA on entry into the infected cell.

The RdRp of influenza virus, which has a (–)-strand segmented genome, has essentially two functions, the synthesis of mRNA from the genome segments and the replication of the virion RNA via the complementary RNA. Influenza mRNA synthesis is primed at the 3′ end of the virion RNA by 10- to 13-nucleotide capped RNA fragments that are “cap-snatched” from the 5′ ends of host heterogeneous nuclear RNA (**hnRNA**). The exact details of priming of the complementary RNA are not yet fully understood.

3. Groups of RdRps

Kamer and Argos (21) recognized various sequence motifs characteristic of RdRps. The most conserved of these is the central Gly-Asp-Asp (GDD) triplet flanked by 5-residue segments that are mainly **hydrophobic** amino acids. This is taken as being suggestive of a b-hairpin structure comprising two **hydrogen-bonded** antiparallel **beta-strands** connected by a short exposed loop containing the GDD amino acids. Mutation of the GDD box can abolish the replicase function (reviewed in ref. 22).

Alignment of the RdRp sequences has been extended with the recognition of eight motifs (23, 24). This led to the classification of the RdRps into three supergroups (Table 1), with a number of lineages within each supergroups. The supergroups extend across viruses that infect animals, plants and bacteria and bring together viruses whose genome structures and expression have properties in common. However, these groupings have not been fully supported by other analyses (25-27) and care has to be taken in deriving evolutionary relationships from these analyses.

Table 1. Grouping of RdRps[a]

Supergroup 1	Supergroup 2	Supergroup 3
Picornaviruses (a)[a]	Leviviruses (b)	Togaviruses (a)
Arteriviruses (a)	Flaviviruses (a)	Caliciviruses (a)
Astroviruses (a)	Pestiviruses (a)	Bromoviruses (p)
Caliciviruses (a)	Dianthoviruses (p)	Capilloviruses (p)
Coronaviruses (a)	Enamovirus RNA2 (p)	Carlaviruses (p)
Nodaviruses (i)	Luteoviruses subgroup I (p)	Closteroviruses (p)
Comoviruses (p)	Machlomoviruses (p)	Furoviruses (p)
Enamovirus RNA1 (p)	Necroviruses (p)	Hordeiviruses (p)
Luteoviruses subgroup II (p)	Tombusviruses (p)	Idaeoviruses (p)
Potyviruses (p)	Umbraviruses (p)	Potexviruses (p)
Sequiviruses (p)		Tobamoviruses (p)
Sobemoviruses (p)		Tobraviruses (p)
Barnaviruses (f)		Trichoviruses (p)
		Tymoviruses (p)
Properties in common for most of subgroup		

1 genome segment	1 to several genome segments	1 to several genome segments
Polyprotein expression	Individual gene translation	Individual gene translation
VPg	Capped RNA	Capped RNA

[a] Ref. 24.

[b] Hosts of viruses: (a) = higher animal; (i) = insect; (p) = plant; (f) = fungus; (b) = bacteria.

4. Structure

The three-dimensional structure of the RdRp of poliovirus has been determined by X-ray crystallography to 0.26 nm (2.6 Å) resolution (28). The overall shape of this polymerase resembles those of other polymerases, being likened to a right hand. The palm domain that contains the catalytic core structure is very similar to that of other polymerases, but the structures of the "fingers" and the "thumb" subdomains differ from those of other polymerases. Extensive regions of interactions between neighboring molecules were observed in the crystals, which suggests that an unusual higher order structure might be important in polymerase function.

5. Mechanism Action

As noted above, it has been suggested that the functioning of RdRps has several stages (19). By analogy with the functioning of DNA-dependent DNA polymerases, these were proposed as being: (i) template binding, (ii) promoter localization, (iii) melting the template to give a transcriptionally open complex, (iv) nucleotide substrate binding, (v) formation of the first phosphodiester bond, (vi) promoter clearance, and (vii) progressive elongation. Relatively little is known about any of these functional stages for RdRps, and it is likely that there will be differences between the various virus systems for at least some of the stages. For example, there is evidence for priming of some of the plant (+)-strand viruses at the tRNA-like 3′ terminal structures, whereas other plant viral RNAs do not have these structures. Also, there appear to be two different priming systems for influenza mRNA and complementary RNA synthesis. There also has to be priming for the formation of the (–) strand, most likely at the 3′ end of the (+)-strand, and then for the synthesis of the (+) strand, again most likely at the 3′ end of the (–)-strand. The latter is the complement of the 5′ end of the (+)-strand and, for most viruses, the 5′ and 3′ genome sequences bear little resemblance.

This lack of detailed information is mainly due to the difficulties of studying these enzymes systems, especially those of eukaryotes that are associated with membranes. Furthermore, as well as the RdRp itself, the replication complex also contains several other virus-encoded and host-encoded activities. Some of the other virus-encoded activities, such as helicases (probably involved in the melting of the template stage), capping, and methylation enzymes are reviewed by Buck (22).

RdRps lack proofreading activity, and thus, there is a high rate of error in the synthesis of the new RNA strand. It is estimated that 1 in 10^3 to 10^4 nucleotides is misincorporated, which gives a high rate of genome mutation (29). This, coupled with the high rate of replication, can lead to rapid evolution of RNA viruses.

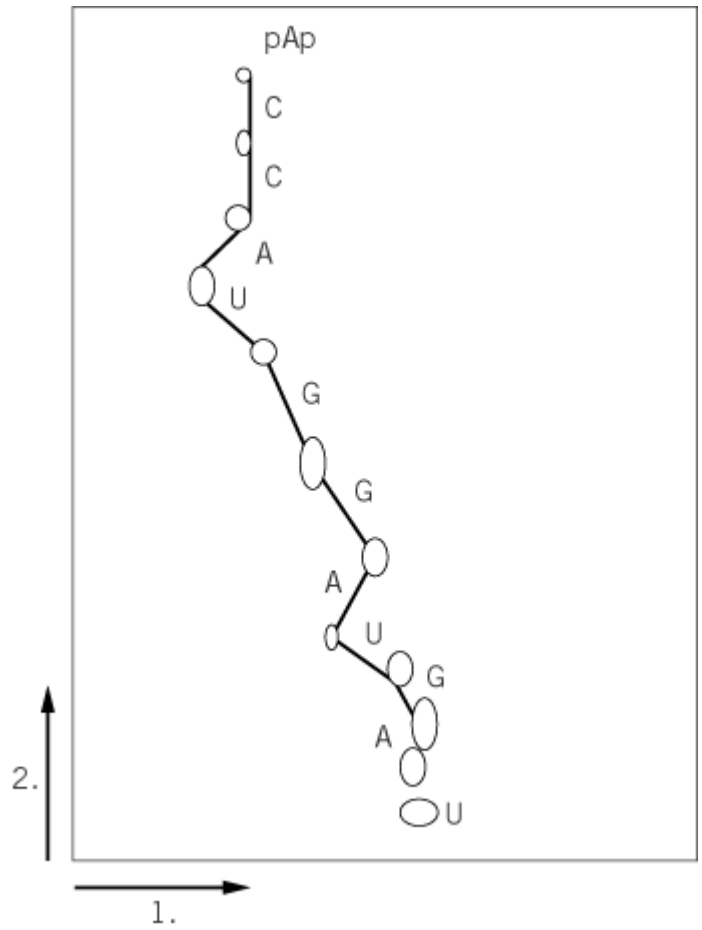
RNA Sequencing

The majority of **RNA** sequences have been obtained by sequencing of either **cloned** DNA for RNA **genes** or complementary DNA prepared by transcription of RNA with **reverse transcriptase**. Such sequences of RNA genes do not, however, provide information about post-transcriptional modification of RNA. In addition to RNA splicing, cleavage, addition of cap, polyadenylation, and RNA Editing, the primary transcripts of eukaryotic and prokaryotic RNAs are often processed by specific modification of the nucleotide residues. Almost 100 base and ribose modifications of the standard four ribonucleotides are known (1), and they are located primarily in the functionally important regions of RNAs. Consequently, rapid methods for RNA sequencing, similar to those for DNA sequencing, have been developed, in addition to special chemical, enzymatic, and spectrophotometric techniques to identify modified nucleotides in RNA.

1. Sequencing Oligoribonucleotides

Methods to sequence RNA were developed almost two decades before rapid DNA sequencing technology became available. The early sequencing of transfer RNA used column chromatography to separate oligoribonucleotides. Guanine-specific **ribonuclease T1** (RNase T1) from *Aspergillus oryzae* and pyrimidine-specific **ribonuclease A** (RNase A) from bovine pancreas were used to achieve alternative cleavages of RNA to oligoribonucleotides. Spectroscopic characterization, determination of nucleoside composition, and stepwise degradation provided partial sequences from which the sequence of the original RNA was derived. Two-dimensional separation by high-voltage electrophoresis and chromatography of oligoribonucleotides obtained by ribonuclease cleavage, so-called fingerprinting (2)—considerably increased the resolution and speed of RNA sequencing. Two oligoribonucleotides that differ by one nucleotide in length have a characteristic mobility shift in the two-dimensional fingerprint depending on the nucleotide by which they differ. These shifts depend mainly on the pK_a values of the particular nucleotide residue. After partial cleavage of end-labeled oligoribonucleotides, followed by two-dimensional separation and chromatography, a sequence of 8–15 nucleotides could be read in one experiment (Fig. 1) (3).

Figure 1. Two-dimensional separation of radioactively end-labeled oligoribonucleotides obtained by limited cleavage by an endonuclease. First dimension: electrophoresis; second dimension: chromatography. The shift in mobility on removal of each 3′-terminal nucleotide provides its identity (3).



2. Rapid Sequencing by Electrophoresis of End-labeled RNA on Polyacrylamide Gels

The methods developed for rapid sequencing of DNA have been modified for RNA sequencing. 5′-End-labeling is usually achieved by dephosphorylation of RNA with alkaline phosphatase, followed by phosphorylation with phage T4 **polynucleotide kinase** and [g-^{32}P]ATP (4). Alternatively, the 3′-end of an oligoribonucleotide can be phosphorylated by cytidine-3′,5′ [^{32}P] diphosphate ([^{32}P]pCp) and T4 RNA ligase in the presence of ATP (5). Limited base-specific cleavage of end-labeled RNA can be achieved either enzymatically (6, 7) or chemically (8) (Table 1). The oligoribonucleotides generated are separated by electrophoresis, and the bands with the label are detected by autoradiography. For comparison, a nonspecifically cleaved sample is usually prepared by hydrolysis of an end-labeled RNA.

Table 1. Cleavage Reactions for RNA Sequencing

(a) Enzymatic cleavage (6, 7)

Ribonuclease (RNase)	Specificity	Product
RNase T_1 from *Aspergillus oryzae*	¼GpN¼	¼*Gp* + *N*¼
RNase U_2 from *Ustilago sphaerogena*	¼ApN¼	¼*Ap* + *N*¼

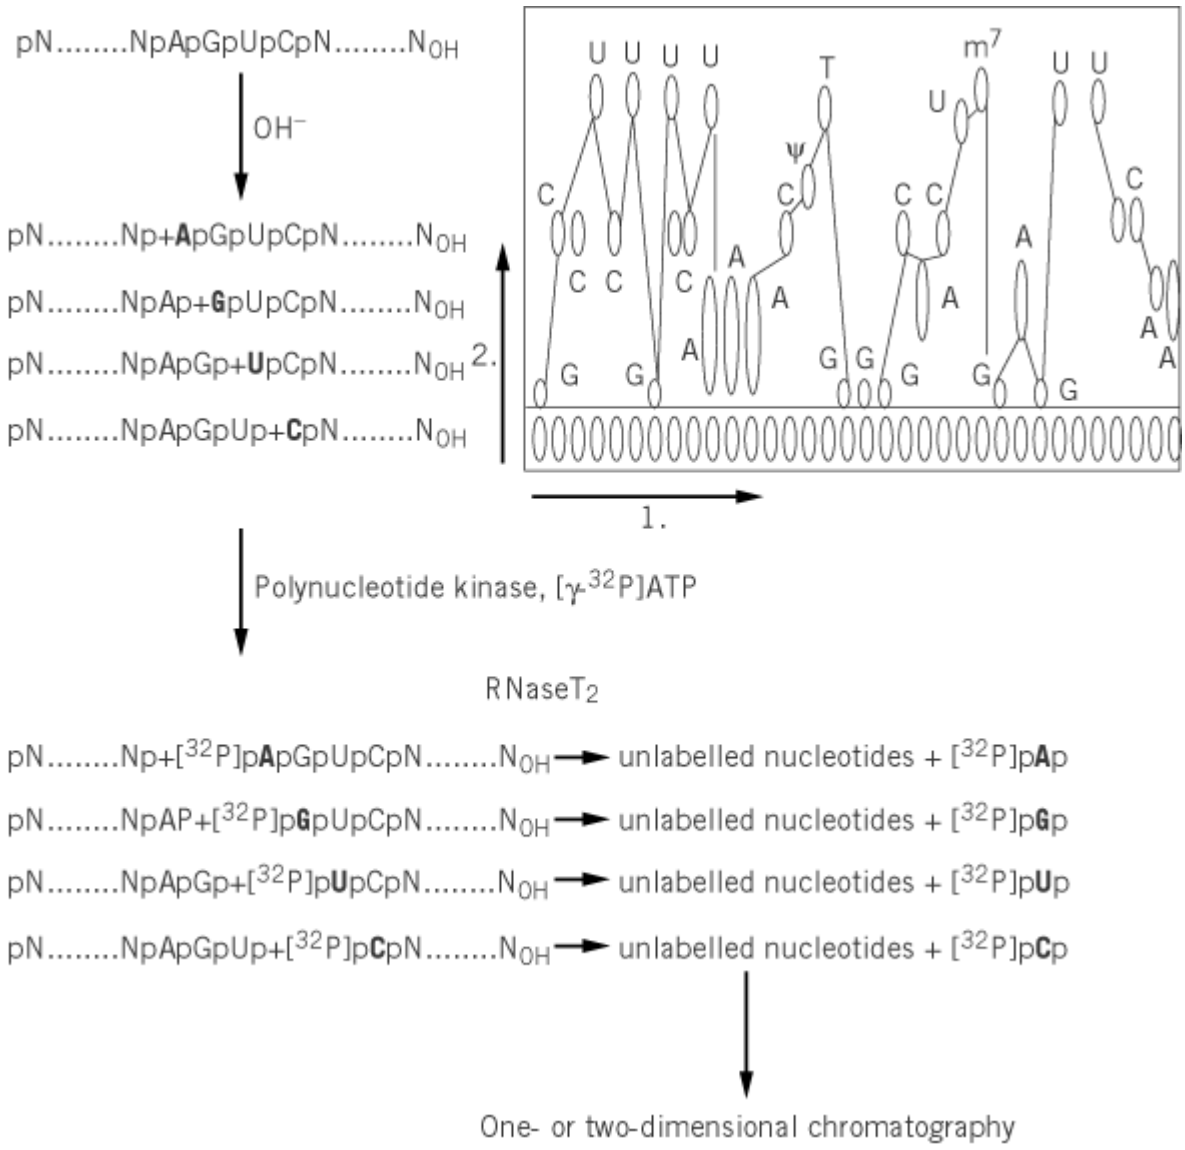
(b) Chemical cleavage (8)

Reagent	Cleavage	Specificity
Dimethylsulfate, $NaBH_4$	Aniline (pH 4.5)	G
Diethylpyrocarbonate	Aniline (pH 4.5)	*A* > *G*
Hydrazine	Aniline (pH 4.5)	*U* > *C*
Hydrazine in 3M NaCl	Aniline (pH 4.5)	*C* > *U*

A serious disadvantage of the rapid sequencing methods is their inability to detect modified nucleotides in RNA. Methods to detect them were developed that combine polyacrylamide gel electrophoresis (PAGE) separation of oligoribonucleotides according to their length, with chromatographic identification of the radioactively labeled nucleotide present at the cleavage site (9, 10). These methods were especially successful in determining the sequences of tRNAs. A mixture of oligoribonucleotides is prepared by nonspecific cleavage in aqueous solution in the presence of **formamide** at elevated temperature. The 5′-hydroxyl groups of the oligoribonucleotides formed by this cleavage are then labeled by T4 RNA kinase and [g-^{32}P]ATP. After separation by gel electrophoresis, bands of the different oligoribonucleotides are blotted onto chromatographic plates and digested *in situ* to mononucleotides by RNase T2. For each band, the terminal ^{32}P-labeled nucleotide is identified separately by one- or two-dimensional chromatography (Fig. 2).

Figure 2. Sequencing of RNA by the post-labeling method. Limited alkaline hydrolysis leads to mixture of oligoribonucleotides, which are end-labeled and then separated by polyacrylamide gel electrophoresis (PAGE; first dimension) and by chromatography (second dimension). After hydrolysis of each fragment by ribonuclease T2, the identity of the labeled nucleotide at the terminus is identified by chromatography (9).



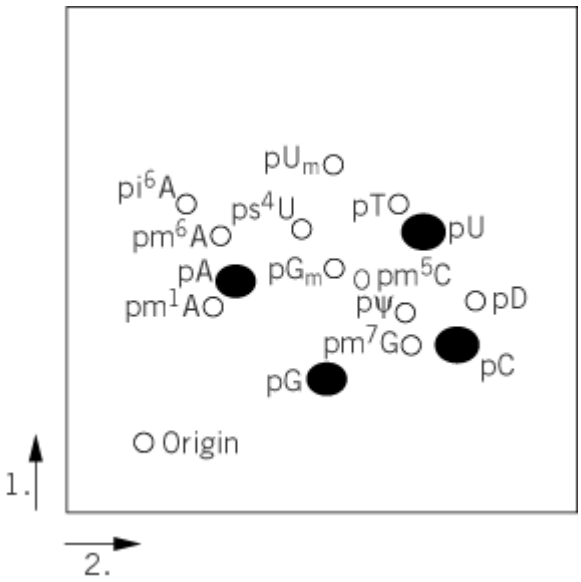
Sequencing of RNA by primer extension using AMV reverse transcriptase (11) is very similar to the common enzymatic **Sanger method** of DNA sequencing with chain-terminating inhibitors. A synthetic oligodeoxyribonucleotide complementary to part of the RNA to be sequenced is used as a primer for DNA synthesis in the presence of radioactively labeled nucleoside-5′-triphosphates and one of the four nucleoside-5′-triphosphate **dideoxynucleotide** analogues. The sequence is then read from the ladder produced by PAGE. More common, however, is transcription of the RNA to DNA, cloning, and determination of the sequence by standard DNA-sequencing technology. Reverse transcription is now used primarily for identification of positions occupied by bulky modified nucleotides, where the reverse transcriptase frequently terminates DNA synthesis. The corresponding positions are then detected as enhanced bands on the PAGE sequencing ladder. The primer extension method was successfully used to identify regions of RNA susceptible to chemical reagents (12) or to identify modified nucleotides in **ribosomal** RNA (13).

3. Identification of Modified Nucleotides in RNA

Rapid sequencing of RNA may provide hints to the presence of modified nucleotides in RNA, because the bands of oligonucleotides terminating there may be irregular, missing, or enhanced on the sequencing gels. This is due to the different reactivities of modified nucleotides to chemical reagents and ribonucleases. However, analysis by **thin-layer chromatography** (4) or **HPLC** (14)

and comparison with synthetic standards still is the most common way of detecting modified nucleotides in RNA (Fig. 3).

Figure 3. Identification of modified nucleoside-5′-phosphates by two-dimensional chromatography (10). RNA is digested by nuclease P_1 and the nucleotides separated by first dimension: electrophoresis; second dimension: chromatography. i^6 A denotes N^6-isopentenyladenosine; U_m, 2′-*O*-methyluridine; m^6A, N^6-methyladenosine; s^4U, 4-thiouridine; m^1 A, 1-methyladenosine; G_m, 2′-O-methylguanosine; m^5C, 5-methylcytidine, Y, pseudouridine; D, 5,6-dihydrouridine; m^7G, 7-methylguanosine; T, 5-methyluridine.



Considerable progress has been achieved in analysis of modified nucleotides by coupling liquid chromatography and electrospray ionization mass spectrometry. This method was used successfully to analyze modified nucleosides in tRNA and ribosomal RNA (15, 16). In view of the rapid progress in instrumentation, the limits of this method have not yet been defined.

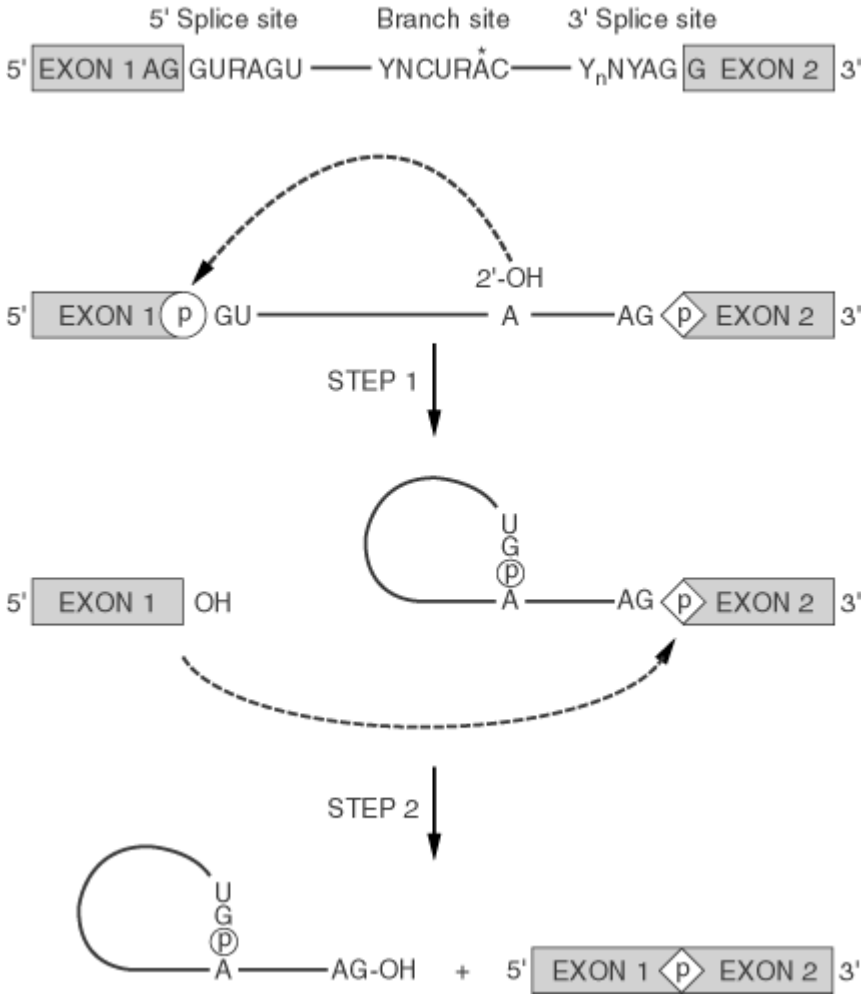
RNA Splicing

Splicing of messenger RNA precursors is a critical step in the long chain of events required for the expression of most eukaryotic **genes**. The majority of these genes are transcribed as a large precursor mRNA (pre-mRNA) in which the coding regions are interrupted by intervening sequences (**introns**). In higher eukaryotes, nuclear pre-mRNAs typically contain multiple introns (in some cases greater than 50) with variable lengths extending up to 200,000 nucleotides. The conversion of pre-mRNA to functional mRNA requires the precise excision of these introns and the subsequent ligation of the coding sequences (exons), a process called *splicing*. Even the smallest of errors in the splicing reaction can have deleterious effects (for example, shifting the reading frame of the mRNA) that result in the production of altered, nonfunctional protein. The splicing of some pre-mRNAs is regulated during development or in a tissue-specific manner, such that **alternatively spliced** mRNAs, which are either nonfunctional or code for different protein isoforms, are generated from the same pre-mRNA. Alternative splicing thus represents an additional level of genetic regulation that enhances the genetic capacity of eukaryotes.

Much has been learned about the mechanism of nuclear pre-mRNA splicing through biochemical studies in both mammalian and yeast systems, as well as via genetic approaches in yeast. In particular, the development of an *in vitro* splicing assay has played a key role in identifying components involved in the splicing reaction and elucidating the splicing pathway. These studies have demonstrated that the basic chemical mechanism of splicing is conserved between higher and lower eukaryotes. The removal of an intron and subsequent ligation of the flanking exons is a two-step process that involves two temporally distinct transesterification (ie, phosphate transfer) reactions (see Fig. 1). The phosphodiester bonds of the pre-mRNA that are to be cleaved and then ligated are precisely defined by **consensus sequences** located around the 5′ and 3′ splice sites. The first step of splicing is initiated by a nucleophilic attack on the phosphate at the 5′ splice site by the 2′-OH group of an adenosine (designated the branch point), which is normally located 18 to 40 nucleotides upstream of the 3′ splice site. This results in cleavage of the 3′,5′ phosphodiester bond at the 5′ splice site and the concomittant formation of an unusual 2′,5′ phosphodiester bond between the first nucleotide of the intron and the branch site adenosine. This reaction produces two splicing intermediates, the 5′ exon and a circular tailed molecule (ie, a so-called lariat) containing the intron and 3′ exon. In the second step, the 3′ OH of the 5′ exon, which is released by the first transesterification reaction, carries out a nucleophilic attack on the phosphate at the 3′ splice site. This results in excision of the intron in the form of a lariat and the simultaneous ligation of both

exons via a 3′,5′ phosphodiester bond. Despite the fact that pre-mRNA splicing requires the hydrolysis of ATP, the phosphates present in the products of the splicing reaction (ie, the spliced mRNA and excised intron) are derived from the pre-mRNA substrate and not from ATP (1-3). Splicing thus essentially involves the exchange of one pre-mRNA substituent for another on the phosphodiester bond at the 3′ splice site.

Figure 1. Schematic representation of the two-step splicing pathway of nuclear pre-mRNA introns. Boxes and solid lines represent exon and intron sequences, respectively. The consensus sequences found at the mammalian 5′ and 3′ splice sites and branch site of U2-dependent introns are indicated, where N = any base, Y = pyrimidine, and R = purine. The branch site adenosine is marked with an asterisk, and the polypyrimidine tract is indicated by Yn. The nucleophilic attacks on the splice sites by the 2′ OH of the branch site adenosine (step 1) and of the 3′ OH of the cleaved 5′ exon (step 2) are depicted by dashed arrows. The phosphate groups at the 5′ and 3′ splice sites, which are conserved in the splicing products, are also indicated.



Similar reaction intermediates and products are also observed during the splicing of group II introns, which are found in pre-mRNA molecules synthesized in plant and fungal organelles (4) (see Self-Splicing Introns). This has led to the hypothesis that group II and nuclear pre-mRNA introns may be evolutionarily related and that both types of splicing may involve similar catalytic mechanisms. Group II introns, in contrast to nuclear pre-mRNA introns, can be spliced autocatalytically *in vitro* in the absence of proteins or other factors. The self-splicing nature of these introns lies in their ability to fold into an elaborate, highly conserved intramolecular structure that favorably aligns the 5′ and 3′ splice sites and the branch site for the two cleavage/ligation reactions of splicing. Nuclear pre-

mRNA introns, on the other hand, possess only short conserved cis-acting sequence elements that are confined to the 5′ and 3′ splice sites, the polypyrimidine tract (present only in higher eukaryotes), and the branch site (see Splice Sites). The folding of nuclear pre-mRNA introns into a catalytically favorable conformation thus requires the presence of a large number of *trans*-acting factors. These include the small nuclear RNP-(snRNPs), evolutionarily highly conserved ribonucleoprotein (RNA-protein) complexes, and non-snRNP proteins. These factors interact stepwise with the pre-mRNA to form the spliceosome, a large ribonucleoprotein complex that catalyzes both steps of splicing. Two distinct spliceosomes have to date been identified. The major or U2-dependent spliceosome is found in all eukaryotes and is responsible for the excision of so-called U2-dependent introns, which comprise the vast majority of nuclear pre-mRNA introns. The recently identified minor or U12-dependent spliceosome catalyzes the removal of the less abundant U12-dependent introns, which at present have been identified in only a subset of eukaryotes (5-7).

Despite recent advances in the splicing field, our understanding of the complex process of nuclear pre-mRNA splicing is far from complete. Currently little is known about the three-dimensional structure of the spliceosome and the nature of the spliceosomal active sites (i.e., whether the **catalyst** is RNA and/or protein) remains a matter of intense debate and investigation. One of two structurally distinct active sites appears to be responsible for each catalytic step of splicing (8, 9). During spliceosome assembly, the RNA components of the spliceosomal snRNPs (ie, the UsnRNAs) base-pair in a dynamic fashion with the short conserved regions of the pre-mRNA around the 5′ and 3′ splice sites, as well as with one another. This leads to the formation of a dynamic network of RNA–RNA interactions (see Spliceosome) that apparently provides the structural framework necessary for the catalysis of pre-mRNA splicing (reviewed in Refs. 10 and 11). In fact, structural elements that closely resemble highly structured functional domains characteristic of self-splicing group II introns have been identified in the spliceosomal RNA network, supporting the long-standing hypothesis that nuclear pre-mRNA splicing is largely, if not exclusively, catalyzed by RNA (12). In addition to the snRNAs, however, proteins also play important roles in pre-mRNA splicing, particularly during the assembly of the spliceosome. Over 70 spliceosomal proteins have been identified thus far, and much effort is still currently invested in their structural and functional characterization. Proteins are involved in a number of protein–protein interactions and protein–RNA interactions that are required for the formation of a catalytically active spliceosome (see Spliceosome). In addition, several spliceosomal proteins possessing enzymatic activity (eg, RNA unwindase or protein isomerase activity), which are thought to catalyze conformational changes in the spliceosome during the splicing process, have also been identified (reviewed in Refs. 13 and 14). More recently, proteins have even been proposed to contribute directly to the spliceosome's active sites. At present, a clearer understanding of how the splicing machinery functions awaits more detailed information about the nature and dynamics of the myriad of protein–protein and protein–RNA interactions formed within the spliceosome.

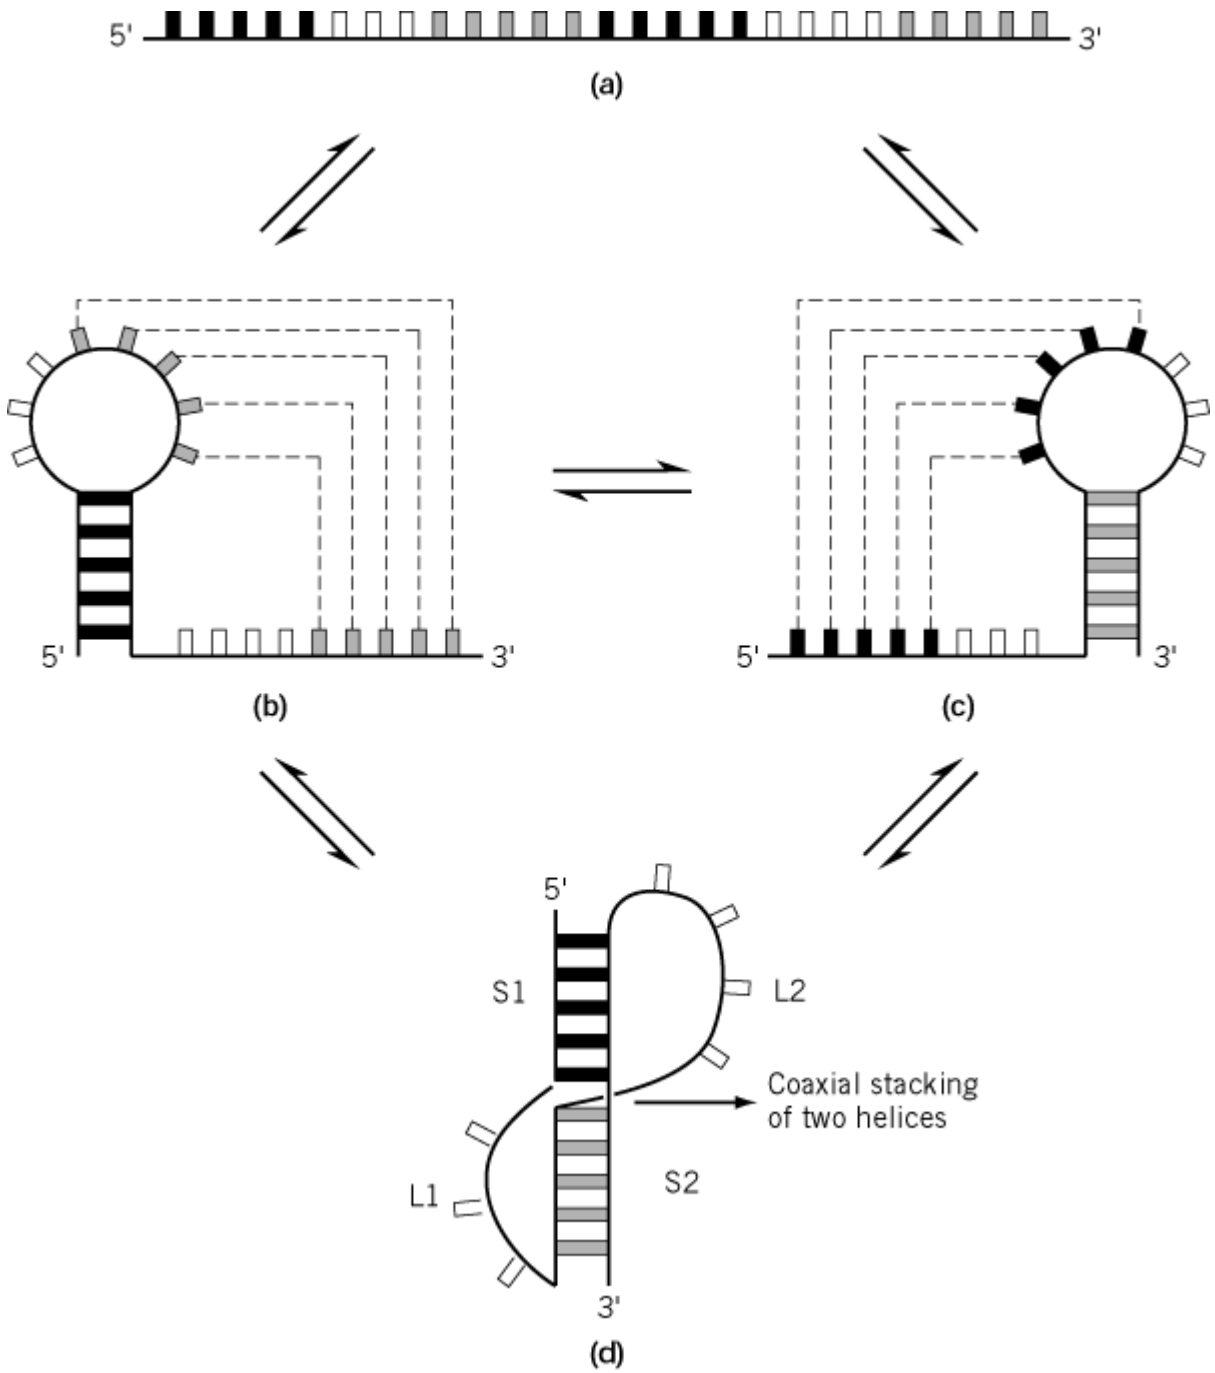
RNA Structure

The diversity of function of RNA molecules in living organisms ranges from the **enzyme**-like activity of **ribozymes** to storage of genetic information in RNA **viruses**. RNA molecules adopt diverse structures in response to these functional requirements. RNA has a covalent structure very similar to that of **DNA**, the only differences being the change from a 2′-deoxyribose sugar in DNA to a ribose sugar in RNA and from a methyl group in thymidine to a hydrogen atom in uracil. However, their functional differences lead to correspondingly different structures. The requirement for storage of genetic information imposes the double-helical structure on most DNA molecules, whereas RNA molecules adopt an array of structures to rival protein structures in their complexity. This is not the result of an intrinsic limitation of DNA stereochemistry, but rather the result of different functional requirements.

It is convenient to describe RNA structure in hierarchical terms (Fig. 1), comparable to those used in describing protein structure: **primary**, **secondary**, **tertiary**, and **quaternary** structures. The primary structure refers to the sequence of an RNA molecule. Unlike proteins, which in most cases function only when properly folded, many RNAs function as unstructured, single-stranded species. For example, messenger RNA must be unfolded for the genetic message to be **translated**, and stable RNA secondary structures inhibit **protein biosynthesis**.

Figure 1. Hierarchy of RNA folding. **(a)** The primary structure corresponds to the RNA sequence. (**b**, and **c**) The secondary structure (in this case, two stem-loops or hairpins) form by Watson–Crick base pairing between complementary nucleotides. **(d)** Tertiary interactions (coaxial stacking of double helices) lead to the final three-dimensional structure (in this case, a pseudoknot).

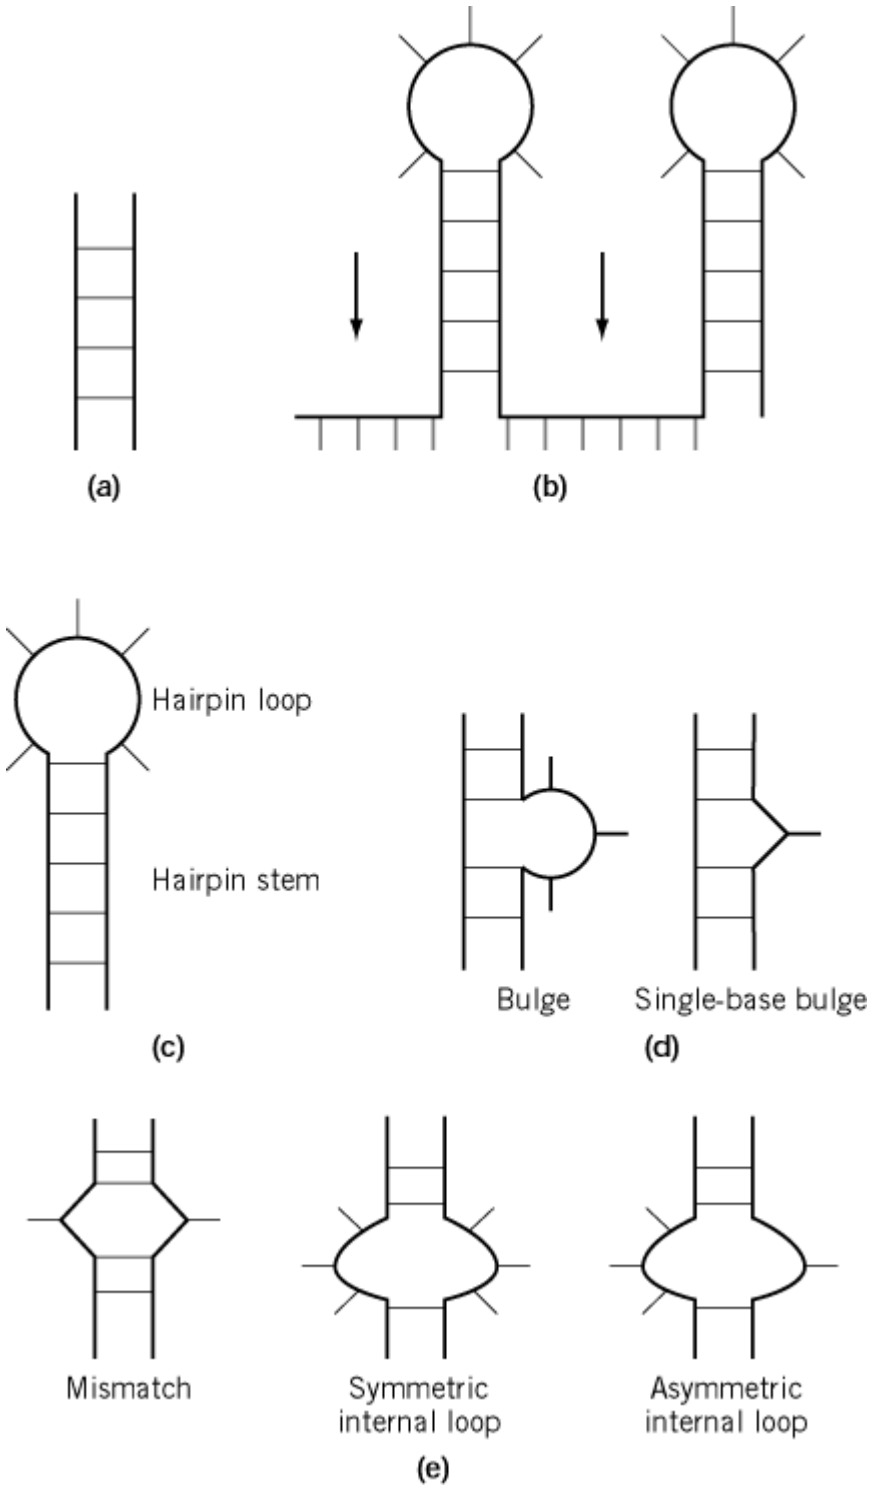


1. Secondary Structure of RNA

Secondary structure in DNA and RNA is dominated by Watson–Crick base pairing, leading to the formation of double-helical structures of varying length. Isolated base pairs are not thermodynamically stable, but formation of several consecutive base pairs readily occurs, resulting in a variety of possible arrangements (Fig. 2). These so-called secondary structure motifs represent the building blocks through which the most complex RNA three-dimensional structures are constructed. There is a fundamental difference between RNA and protein structures. Protein secondary structure is generally only marginally stable in the absence of stabilizing tertiary structure interactions, whereas RNA secondary structure is often stable on its own. Thus, formation of the secondary structure dominates the process of RNA folding, and RNA tertiary structure forms through relatively weak interactions between pre-formed secondary structure motives. Because of this property, RNA secondary structure can often be predicted successfully from **thermodynamics**

(1) or phylogeny (2).

Figure 2. RNA secondary structure motifs. **(a)** Duplexes; **(b)** Single-stranded regions; **(c)** hairpins; **(d)** bulges; **(e)** internal loops.



RNA secondary structure is dominated by the formation of double helices stabilized by Watson–Crick base pairs between complementary stretches. Unlike DNA, these helices are relatively short, seldom more than 8 to 10 base pairs in length, and are interrupted by single-stranded nucleotides

forming loop elements: hairpins, bulges, and internal loops (Fig. 2). These, together with the helical junction that is formed when more than two double helices come together, are the secondary structure motives and the building blocks upon which the most complex RNA structures are built.

In many RNAs, more than half of all nucleotides are incorporated into double-stranded helices. Duplex regions can form through very long-range interactions, and these interactions are crucial to determine and stabilize the overall fold of an RNA molecule. For example, opposite strands in double helices within ribosomal RNA can be separated by as many as 2000 nucleotides. In RNA, G·U pairs are almost as common as the canonical G·C or A·U base pairs, and they introduce slight distortions in double-helical structure that are recognized by proteins and other RNAs (3, 4). RNA (and DNA) double helices have an antiparallel right-handed helical conformation. RNA double helices adopt the A-form structure, which differs significantly from the canonical B-form adopted by DNA double helices (see DNA Structure). RNA duplex structures are not uniform, although their variability is less than that in DNA. These variations depend on the sequence and structural context of the helix relative to the global three-dimensional structure. A-form double helices differ from B-DNA in the conformation of the sugar and the displacement of the bases from the helical axis. These local differences lead to very diverse shapes, with profound consequences for recognition by proteins and other ligands (5).

The most common element of RNA secondary structure is the hairpin (or stem-loop) (Fig. 2). For example, bacterial 16S ribosomal RNAs contains approximately 30 phylogenetically conserved hairpins (2). A hairpin forms when the phosphodiester backbone folds back on itself to form a double-helical tract (called the *stem*), leaving unpaired nucleotides to form a single-stranded region, called the *loop*. Hairpin loops represent the most extensively studied RNA structure motif (apart from double helices). Small hairpin loops contain a high degree of structure, whereas longer loops (containing more than 7 to 8 unpaired nucleotides, such as those present in transfer RNA) are generally more poorly structured and thermodynamically less stable. Most loops in ribosomal RNA are small, 4 to 9 nucleotides in length, perhaps reflecting these thermodynamic preferences.

1.1. Tetraloops

Hairpins containing four nucleotides (tetraloops) are unusually common in cellular RNAs, and their sequences cluster within three exceptionally common families: UNCG, GNRA, and CUUG (where N is any of four nucleotides and R is a purine). For example, 70% of all tetraloops in 16S-like ribosomal RNAs from all organisms belong to the UNCG and GNRA families. The exceptionally common tetraloop structures have high thermodynamic stabilities, UNCG being the most stable. Capping a double-helical tract with a UNCG tetraloop is thermodynamically equivalent to extending the double-helical stem by two base pairs. Despite the differences in sequence, there are extensive structural similarities between these three families. In each of them, the first and last unpaired nucleotides form non-Watson–Crick base pairs to close the loop, reducing the number of unpaired nucleotides to only two. Longer loops, such as those found in tRNA, preserve extensive base stacking interactions that presumably stabilize the loop structure, but are generally characterized by significant conformational flexibility.

1.2. Bulges and Internal Loops

Bulges and internal loops form when two double-helical tracts are separated on either one (bulge) or both strands (internal loops) by one or more unpaired nucleotides. Internal loops containing equal numbers of bases on each strand are symmetric, whereas they are asymmetric when the number of bases are different. For example, single base mismatches are symmetric internal loops of two nucleotides. The presence of an internal loop or bulge reduces the thermodynamic stability, when compared to a perfect double helix, but unpaired nucleotides are more readily accessible to protein or nucleic acid ligands, which often recognize such sites. Non-Watson–Crick base pairs readily form within internal loops, while unpaired nucleotides within a bulge may stack within the helix or be bulged outside. The presence of an internal loop or bulge can induce bending in an RNA molecule; the extent of bending depends on the RNA sequence within the loop and can change upon ligand binding (6, 7). Thus, these motifs are ideal sites for conformational switches, where ligand binding

can result in long-range conformational changes.

2. Tertiary Structure of RNA

Interactions between two or more secondary structure elements give rise to RNA tertiary structure and define the overall folding of RNA molecules. In essentially all cases investigated thus far, RNA secondary structure elements maintain their three-dimensional structure even when extracted from very complex tertiary structures. Noncanonical base pairs, unpaired bases, and the backbone functional groups (the negatively charged phosphate groups and the unique 2′-hydroxyl group of RNA) are very important for tertiary interactions. Unpaired bases can twist or flip out of an helical patch to define unique surfaces for recognition by other RNAs during formation of the tertiary structure. The RNA secondary structure helps in orienting key residues into appropriate positions for tertiary interactions to occur. For example, the geometry of the four-way junction in tRNA, combined with a conserved length of the double-helical regions, help in positioning T-loop and D-loop nucleotides in close proximity to facilitate the tertiary loop–loop base pairs that define the L shape of all tRNAs (8).

Tertiary interactions often consist of base stacking and hydrogen bond interactions. Helical stacking between the terminal base pairs of two helices enables the building of the molecule into an extended helix (coaxial stacking) (Fig. 1). A common example of a structural module built upon base-stacking interactions is provided by the adenosine platform motif . Consecutive adenine bases within an internal loop can form a pseudo-A·A non-Watson–Crick base pair, to create a platform capable of mediating long-range tertiary interactions (9). Base triplets form when a preformed base pair becomes involved in another set of hydrogen bonds with a third base (8); this can occur on either the minor groove or major groove side of an RNA double helix. Hydrogen bonds between bases and backbones are observed when double helices are packed together in compact structures (10). Finally, divalent metal ions, especially hydrated magnesium ions, are often used to screen the negatively charged phosphate groups along the helical backbone, in order to build a compactly folded structure with close packing of negatively charged phosphates (11).

Unpaired nucleotides embedded within a secondary structure motif often form tertiary structures by interacting with unpaired nucleotides from another secondary structure module. These interactions can involve any secondary structure motif: hairpin loops, internal loops, and bulge loops. The nature of the tertiary contacts can be intercalation, base triplet formation, and Watson–Crick base pairing between complementary loop sequences. The loop–loop interaction module is best illustrated by the tertiary interaction of tRNA (8). The folding of tRNA is initiated by the formation of four hairpin loops via Watson–Crick base pairing, resulting in the organization of a four-way helical junction. Tertiary interactions, by helical stacking, further organize the tRNA into two extended helical domains. This arrangement positions all unpaired residues in the loop regions close in space and facilitates the formation of the tertiary base pairing and base triplets that lock the tRNA into the L-shaped three-dimensional structure.

2.1. Pseudoknots

Pseudoknots form when complementary primary sequences of a hairpin or internal loop and a single-stranded region interact with each other by Watson–Crick base pairing (12). When a pseudoknot forms between a hairpin loop and a complementary single-stranded region, then formation of two alternative hairpin structures can occur (Fig. 1). The formation of a pseudoknot creates an extended helical region through helical stacking of the hairpin double-helical stem and the newly formed loop–loop interaction helix. Although the pseudoknot is only marginally more stable than the two hairpins, tertiary interactions (such as base triplets) between unpaired nucleotides in the bridging loops and between base pairs within the extended helix can increase the stability of this structure.

2.2. Magnesium Ions

Double-helical regions must be packed together to build compact RNA structures, as found for example in the catalytic core of catalytic RNA ribozymes. This process is opposed by the strong

electrostatic repulsion between the negatively charged phosphate groups. RNA molecules overcome this repulsion through the direct or indirect coordination of divalent metal ions. In group I self-splicing introns, a magnesium-organized ion core containing five magnesium ions constructs an exterior surface that facilitates the close packing of noncanonical loops into the minor groove of a double helix. Within the interior of this ion core, base-stacking and hydrogen-bonding interactions between nucleotides form specific metal ion binding sites (10, 11).

3. Quaternary Structure of RNA

There are relatively few well-characterized examples of the association of RNA molecules to form supramolecular quaternary structures, but these are relatively important. For example, during pre-mRNA splicing, messenger RNAs associate with five major ribonucleoprotein (RNP) particles called small nuclear RNPs; such snRNPs interact with each other and with mRNAs. These interactions and their dynamic disruption and formation by means of RNA–RNA quaternary interactions are essential for RNA splicing to occur (13).

In most examples characterized thus far, the quaternary association of RNA molecules occurs by conventional Watson–Crick base pairing. For example, small regulatory RNAs with longer complementary sequences within RNA molecules (**antisense** RNAs) form intermolecular duplexes during the control of gene expression in both prokaryotes and eukaryotes (14). Similarly, guide RNA recognizes complementary sequences to identify sites where mRNAs are edited post-transcriptionally (15) (see RNA Editing). Although more complex RNA quaternary structures do not rely exclusively on Watson–Crick pairing, base pairs are still very important. So-called "kissing-hairpins" form between self-complementary loop nucleotides in two stem-loop structures (16, 17). These structures provide protein-recognition sites during the regulation of prokaryotic plasmid copy number, and possibly during the dimerization of the HIV genome. The best-characterized example of supramolecular association of RNA molecules by means of non-Watson–Crick interactions is provided by so-called "G-quartet structures" (18). These structures form readily *in vitro* for RNA and DNA sequences containing stretches of guanidines or uracils (18), but it is not clear whether these structures occur at all *in vivo*.

4. Summary

In conclusion, formation of Watson–Crick base pairs provide a simple structural code of RNA secondary structure formation, and helical pairing can be predicted very successfully by phylogeny and thermodynamics. As demonstrated for the first time by tRNA, tertiary interactions between the secondary structural elements fold RNA molecules into their three-dimensional structures. Helical regions generally define the RNA secondary structure. Tertiary contacts between secondary structure regions of the RNA, often involving nucleotides in single-stranded regions, fold the RNA into its three-dimensional structure. RNA quaternary structures are less well understood, yet relatively important in gene expression and its regulation.

RNA Structure Prediction

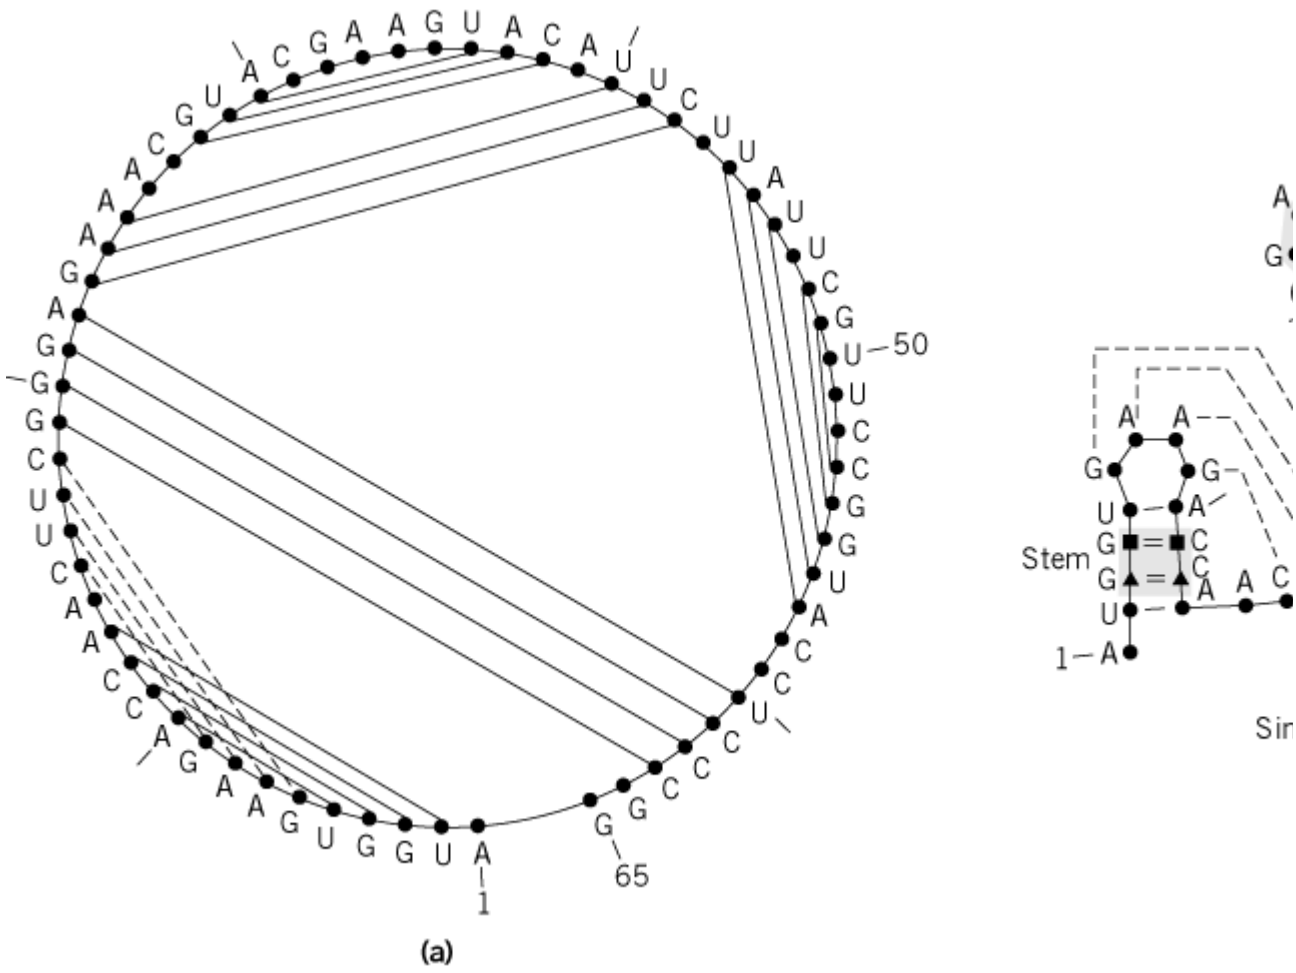
RNA molecules play many roles in the cell, and their biological functions are definitely not restricted to the relatively simple reading and decoding of the sequence of bases along the polynucleotide backbone that is exemplified by a simple view of messenger RNA. On the contrary, many RNA molecules exert their biological activities through the chemical architectures they form, as **polypeptide chains** do (see Protein Structure). In aqueous solutions containing simple cations like sodium or magnesium ions, single-stranded RNA molecules, depending on their base sequence, either remain mostly unstructured (or **randomly coiled**) or they fold back on themselves to form complex three-dimensional (3-D) structures. The driving force for the folding is the stacking between the bases, which minimizes their exposure to water, with the specific molecular recognition between RNA segments occurring overwhelmingly by Watson–Crick base-pairing mediated by hydrogen bonds. Some RNA molecules are able to self-assemble into complex objects because they also contain additional tertiary contacts between segments of the polynucleotide chain (eg, the self-splicing group I **introns**). RNA molecules can also be observed in states containing only the **secondary-structure** double helices, without tertiary interactions, and they often need protein cofactors for folding into their biologically active conformations *in vivo*.

1. Partitioning Between Secondary and Tertiary Structures

The term “secondary structure” includes all segments that can build double-stranded helices by any combination of the isosteric Watson–Crick pairings, but this has some ambiguity. A secondary structure can be broken down into recurrent separable elementary motifs, such as the helical regions (stem structures, pseudoknots) and linking nonhelical elements (hairpins and internal loops, bulges and multiple junctions) (Fig. 1). In secondary structure, a pseudoknot is a specific RNA motif that

results from standard Watson–Crick pairing between a single-stranded stretch that is located between two paired strands and a second, distal single-stranded region. The single-stranded regions may belong to a hairpin loop, an internal loop, or a 3′ (or 5′) dangling end, but at least one of them must occur between strands that form a double helix. When both single-stranded regions belong to a hairpin loop, they are said to form a *loop-loop* motif, which is formally equivalent to a pseudoknot. On the other hand, the two-dimensional (2-D) structure reduces the secondary structure to the set of Watson–Crick base pairs that form a planar graph (ie, without crossing edges) when the sequence of bases is arranged along a circle and the base pairs are connected by edges. Consequently, pseudoknots should be considered as belonging to the secondary structure, perhaps even the tertiary structure. This distinction is important, since the most efficient and most frequently used algorithms for predicting the two-dimensional structure do not take into account pseudoknots. At the next level of organization, that of the active tertiary structure, a three-dimensional architectural motif is a simple but recurrent arrangement containing a few secondary-structure elements that interact with a specific geometry and topology. The combination of such substructures leads to compact domains, which often fold autonomously and independently of the rest of the RNA architecture. A variety of observations support a view of RNA folding in which the three-dimensional architecture results from the cooperative compaction of separate, preformed, and stable substructures, which might undergo only minor and local rearrangement during the process. In summary, the secondary structure implies a local folding, whereas the tertiary structure refers to the global three-dimensional architecture of the RNA. The introduction of modular units, hierarchically organized and folded, circumvents most of the numerical nightmares inherent in the purely mathematical prediction of RNA structure.

Figure 1. (**a**) Secondary structure with the sequence arranged within a circle graph. A pseudoknot element (represented a the graph nonplanar. (**b**) The more conventional representation shows basic structural elements. The free energy of the s the contributions of all the elements. According to Nussinov's first proposition (8), each structural element is a base pair. which is complex but very powerful, each structural element is a *k*-loop ended by a closing base pair (black triangles in t interior base pairs of the loop (black squares in the figure). In Figure 1**b**, five different *k*-loops are represented and labele a 0-loop (no interior pair); two stacked base pairs, an internal loop, and a bulge form 1-loops (one interior pair); and junc pairs is shown in the example). The black circles have no particular meaning.



Energetically, the secondary structure is the main component of RNA architecture, while tertiary structure contributes only slightly to the Gibbs **free energy** stability of the native state. Therefore, determination of the secondary structure is an essential step in the study of the structure-function relationships of an RNA molecule. The state in which an RNA molecule exists can be monitored by UV absorption spectroscopy as a function of temperature, RNA concentration, and the concentrations of ions. A molecule with definite secondary and tertiary structures will normally display two melting peaks: a first sharp low-temperature transition corresponding to the melting of the tertiary structure, and a second broad high-temperature transition to the melting of the secondary structure (1). In a complex and compact three-dimensional structure, the sugar-phosphate chain folds several times on itself and, by necessity, negatively charged phosphate groups come into close contact. In order to relieve the resulting electrostatic repulsions, positively charged cations are necessary. Biologically, the most prevalent and efficient cations are magnesium ions and polyamines. Magnesium cations are “hard” ions that interact favorably with the “hard” negatively charged oxygen atoms of the phosphate groups. Polyamines always carry positively charged amino groups, and their flexibility and small size allow them to snuggle in helical grooves and in-between helical sugar-phosphate backbones. By monitoring the UV absorbance at low and high magnesium concentrations, one can distinguish the tertiary melting peak (it moves to still lower temperatures with decreasing concentrations of magnesium ions) from the secondary peak (it remains rather invariant). Native gel electrophoresis at various temperatures also distinguishes between folded and unfolded RNA molecules. Most important, electrophoretic methods are useful to ascertain the presence (and to evaluate the yields) of dimeric or higher oligomeric RNA species. The measurement of UV absorbance at various RNA concentrations allows one to calculate the concentrations of dimers and monomers and to measure the **melting temperature** of both dimers and monomers. Oligomerization may also depend on the concentrations of cations or polyamines.

2. Prediction of Secondary Structure

Computer programs exist that automatically produce a set of possible two-dimensional structures for a given RNA sequence. All are based on thermodynamic considerations, and the subsequent optimization of a set of criteria approximating the total free energy. In most cases, however, the selection of one secondary structure from the several that are usually produced by these programs and are indistinguishable in energy within the approximations used requires additional chemical or biological information stemming from experimental probing (biological approach) or comparisons of related sequences (**phylogenetic** or comparative approach). When a set of **homologous** sequences is available, which have common ancestry and function, one can search for a consensus core of secondary-structure elements, common to all the sequences, which should include a consensus three-dimensional architecture with the given function. In practice, one aims to organize the sequences so that the Watson–Crick paired regions align vertically, by searching for base covariations, ie, regions demonstrating compensatory base changes (eg, an A-U pair changing into a C-G pair) horizontally in all sequences. The more compensatory base change events there are in the sequences, the more firmly the secondary structure will be established. The efficiency of the comparative approach stems from the fact that molecular three-dimensional architectures evolve much more slowly than sequences. However, both the thermodynamic and phylogenetic methods are fraught with problems related to statistical relevance. With only four bases to choose among, purely coincidental compensatory base changes (or covariations between positions) are bound to occur. In the thermodynamic approach, they are mathematically resolved on the basis of the given set of thermodynamic parameters. Phylogenetically, the level of ambiguity can be reduced with additional sequences presenting additional covariations. For the establishment of a two-dimensional structure, and especially of a secondary structure, one should ideally employ all three of the approaches described above, with the caveat that the experimental data be gathered under conditions that favor a stable and functional structure. In practice, a comparison of foldings based solely on thermodynamics with the structures of 16S and 16S-like **ribosomal** RNA derived by the comparative approach shows that the quality of the thermodynamic predictions is variable, with percentages of correctly predicted base pairs ranging between 10 and 90% (2, 3).

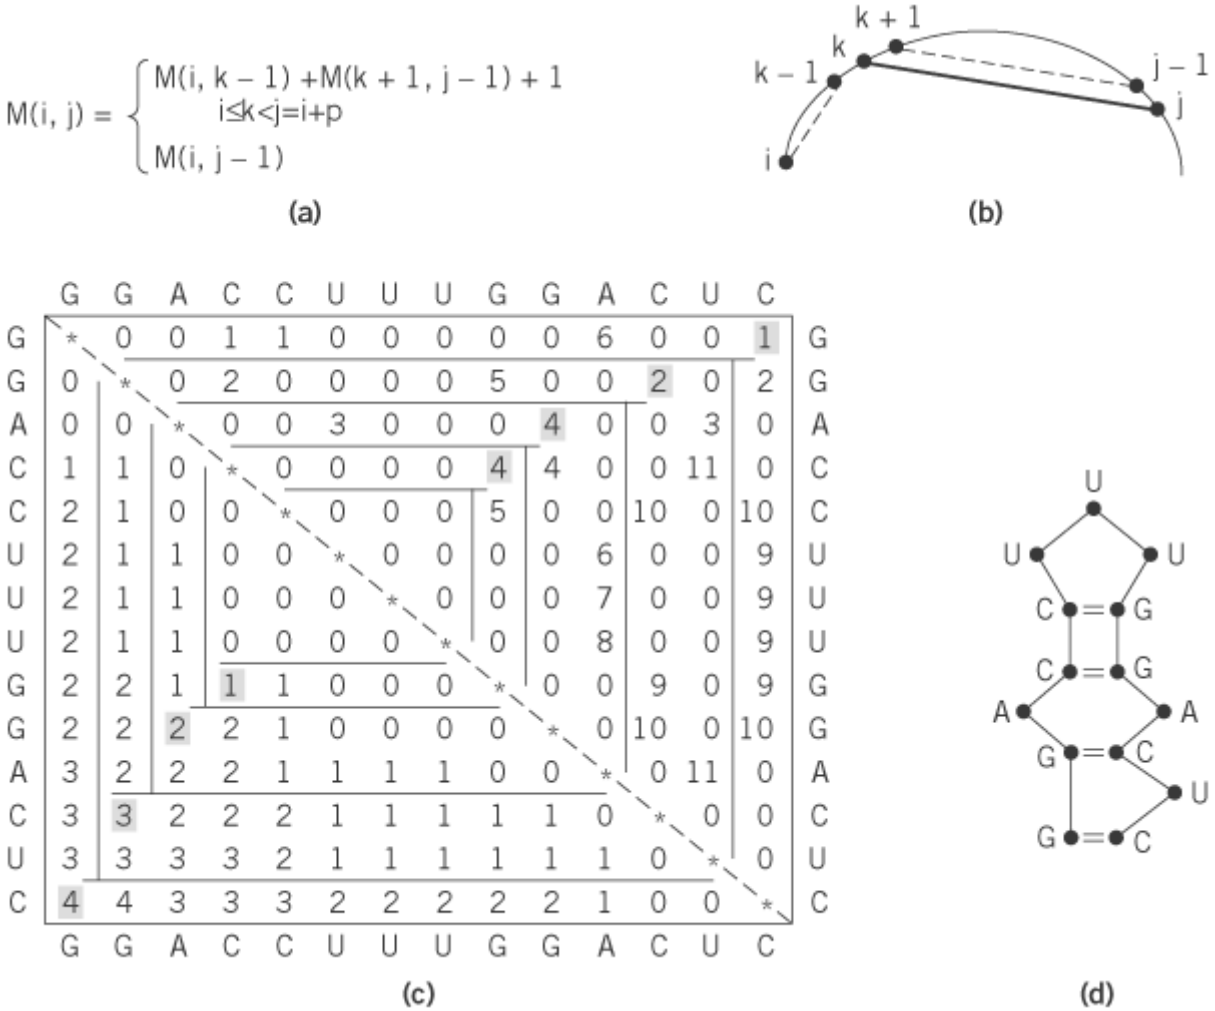
2.1. The Thermodynamic Approach

The thermodynamic approach is based on the empirical observation that the two-dimensional structure of an RNA molecule can be decomposed into elementary motifs that are identifiable and recurrent. It originates in the work of Tinoco and co-workers (4), who first generated from UV absorbance melting studies a set of thermodynamic parameters for the stability of structures formed by short oligonucleotides. Structural stability is measured by the decrease in free energy accompanying the transition from the unfolded or **denatured** state to the native state. The total decrease in free energy is equal to the sum of the independent contributions from each elementary motif present in the structure (the Tinoco–Uhlenbeck approximation), if we assume that tertiary interactions are weaker than secondary interactions and the sum of free energies of secondary elements is a reasonable approximation of the total free energy. The stability of a given base pair depends only on its immediate neighbors (nearest-neighbor approximation), considering that the stability is essentially related to base stacking and hydrogen bonding. The base pairs considered are the standard Watson–Crick pairs, G-C and A-U, as well as the often functionally important wobble pair G-U (5, 6).

When a single sequence is available, computational methods rely on the assumption that the native secondary structure is based on the two-dimensional structure with the lowest energy, or at least belongs to one of the suboptimal predicted two-dimensional structures (7). Stereochemistry requires that at least three nucleotides separate two paired strands. As mentioned above, an additional constraint is the lack of prediction of pseudoknots. Thus, because efficient algorithms are usually based on the decomposition into substructures (which is mathematically not possible in the presence of pseudoknots), one solution is to account for pseudoknots in a second step, either visually or by algorithmic fudging.

Efficient computer programs use $O(N^3)$ recursive algorithms based on dynamic programming principles to fold sequences containing up to one thousand bases. A dynamic programming algorithm solves the problem by combining solutions corresponding to subproblems. It solves every subproblem just once and then saves the answers in a table, thereby avoiding the work of recomputing the answer every time the subproblem is encountered. The dynamic programming approach of RNA folding was first proposed by Nussinov and Jacobson (8) on the basis of the decomposition of a structure into base-paired structural elements (Fig. 2). An elegant decomposition into elementary structures proposed later by Zuker (Fig. 1) has made it possible to consider more complete thermodynamic data, at the price of increased computational time and storage requirements, depending on the way in which energy is assigned to loops (7). Both the free energies of the base pairs and additional experimental data are encoded in the energy function, resulting in the fast computation of the optimal two-dimensional structure.

Figure 2. Illustration of the principles underlying the dynamic programming approach. (**a**) The simplest recurrence proposed by Nussinov (8) for maximizing the number of base pairs. The same principle is applied by programs developed by Zuker (7), which include a more complex recurrence including loop consideration. (**b**) A schematic view of the principle of recurrence. For each increasing *i*, ¼, *j* subsection, the variable *k* is allowed to assume each position from *i* to *j*–1 to test the ability of base *k* to pair with base *j*. (**c**) At each point, the total number of base pairs in the section *i*, ¼, *j* is computed. For each subsection, the maximum number of pairs that can be formed is saved in $M(i, j)$, and the value of *k* that yields this number is saved in $M(j, i)$. If *j* cannot pair with any *k* in the subsection, $M(i,j) = M(i,j–1)$. The maximum number of base pairs that can be formed in the folding of the example is given by reading $M(14, 1)$. (**d**) The secondary structure is obtained by reading in the upper half matrix partners that give the maximum number of pairs in the considered subsection.



Nevertheless, the predictions depend strongly on the thermodynamic parameters used, which argues either for a lack of reliability of the optimization approaches or for incompleteness and imprecision in the energetic parameters. Although a better knowledge of the underlying thermodynamic parameters would certainly lead to better predictions, it is worth remembering the starting assumptions and limitations of the mathematical modeling. First, the Watson–Crick and wobble base pairs are not the only base–base interactions occurring between two RNA strands: Various A-A or A-G pairs, Hoogsteen base pairs, or pyrimidine-pyrimidine pairings are frequently present in internal loops eg, loop E of eukaryotic 5 S rRNA (9) or the SECIS element in **selenocysteine**-coding mRNA (10) (see Figs. 3 and 4) or hairpin loops (eg, the thymine loop of transfer RNA (11) or the -GNRA-tetraloops (12)). The three-way junction of the hammerhead **ribozyme** is organized as well around a core of tandem sheared A-G pairs and a non-Watson–Crick A-U pair (13). With pseudoknots, one of the two constituting helices will, in a favorable situation, be predicted on the basis of its stability, and visual inspection of the remaining single-stranded regions normally points to the second helix. However, regions that should form noncanonical base pairs are not considered as such by the prediction programs, but as potential Watson–Crick base-pairing regions. Thus, depending on the relative weights of the various helices, such noncanonical regions will be involved in standard helices (or in "internal loops" penalized by positive free energy increments) leading to incorrect local (and sometimes global) predictions. The manual or automated analysis of energy dot plots (14-16) offers an alternative to test new folding models and to guide the RNA sequence folding according to available information. In short, those prediction programs should be primarily used for obtaining a solid framework on which further refinements can be applied.

The comparative approach is based on the assumption that the function and folding architecture have and, consequently, that a consensus secondary structure should be derivable by comparing RNA sequ of choice when a set of homologous sequences is available for RNA with the same biological functio arranged in groups and subgroups (ideally of similar size), either according to the phylogenetic class parsing. The overall robustness of the approach increases with the diversity of the sequences and the them, whereas the accuracy of each prediction depends on the number of covariation events in each g in an alignment consists of establishing the paired regions along each sequence, which should be arra lengths of the paired regions juxtapose vertically (see the example of Fig. 3). In a second step, the co bases can be highlighted by a vertical alignment with the inclusion of blanks or gaps in a fashion sim sequences (see Figs. 3 and 4).

Finding the conserved core of the secondary structure is a difficult task that brings together, within a of aligning sequences and assessing pairs. The first task is usually done by hand, with the help of cor similarity search (17, 18). The second task consists of searching for nucleotide interactions by measu RNA positions in the alignment (19, 20). It is most effective when an alignment is available but, at th or readjusting the alignment. Computationally expensive approaches that attempt to find a conserved convergent cycle, combining the alignment search and secondary-structure assessment, have also bee usually aligns one sequence to a hypothetical secondary-structure model (21).

3. Prediction of Tertiary Structure

Although structure is not yet sufficient to predict function, a proper understanding of the functional r macromolecule requires knowledge of its precise molecular organization in space. In the absence of structure, molecular modeling attempts to construct and propose a three-dimensional architecture for mixture of theoretical and experimental data. Hence, prediction methods range from the most mathe solely on computer algorithms, to the most pragmatic and operational ones, in which insights come a

experiment. Modeling is best considered a heuristic tool that should help in the rationalization of exp

RNA Synthesis

Until a few years ago, much more progress had been made in the chemical synthesis of oligo- and polydeoxyribonucleotides (**DNA** sequences) (see DNA Synthesis) than in oligo- and polyribonucleotides (RNA sequences). There are two main reasons for this. First, until fairly recently, there had been a very much greater demand for DNA than for RNA sequences in biological research. Secondly, due to the presence of the 2′-hydroxy functions, the chemical synthesis of RNA requires the use of an additional protecting group and is therefore inherently more complicated than the chemical synthesis of DNA. Nevertheless, in the past decade or so, significant progress has been made in synthesizing RNA sequences, in both solution and on a solid support. As in DNA synthesis, the three main factors to be taken into account in synthesizing RNA sequences are (1) the choice of suitable protecting groups, (2) the development of phosphorylation procedures that are suitable for introducing the internucleotide linkages, and (3) the RNA sequences themselves.

1. Protecting the 2′-Hydroxy Functions

Almost certainly the most critical decision that has to be taken in the chemical synthesis of RNA sequences is the choice (1) of the protecting group (R, as in **1**) for the 2′-hydroxy functions. This protecting group must remain intact until the final unblocking step (Fig. 1) at the end of the synthesis. It must then be possible to remove it under very mild conditions that do not promote the attack of the released 2′-hydroxy functions (as in **2**) on the vicinal (3′ → 5′)-internucleotide phosphodiester linkages, thereby leading to their cleavage or migration (Fig. 2).

A number of the groups that have been used to protect the 2′-hydroxy functions are removed hydrolytically either under basic or acidic conditions. If the 2′-protecting groups are removed under basic conditions, cleavage but not migration of the internucleotide linkages can occur (2). This is illustrated in Figure 2a. Under basic conditions, the initially formed 2′,3′-cyclic phosphate **3** undergoes further hydrolysis to give a mixture of the corresponding 2′- and 3′-phosphates (**5** and **6**, respectively). If the 2′-protecting groups are removed under acidic conditions, both cleavage and migration of the internucleotide linkages can occur (2). This is illustrated in Figure 2b. In the context of RNA synthesis, cleavage of the internucleotide linkages is clearly undesirable, in that it inevitably leads to diminished yields. However, phosphoryl migration, which gives rise to material with one or more (2′ → 5′)-internucleotide linkages (as in **8**), is a much more serious matter. Even in the case of relatively low molecular weight oligoribonucleotides, it is virtually impossible to remove isomeric contaminants containing unnatural (2′ → 5′)-internucleotide linkages, and thereby obtain pure RNA sequences. Therefore, if acid-labile groups are used to protect the 2′-hydroxy functions in the synthesis of RNA sequences, such protecting groups must be removed under conditions of acidic hydrolysis that are mild enough to avoid the occurrence of phosphoryl migration.

Some of the groups that have been used most widely and indeed most successfully to protect the 2′-hydroxy functions in the chemical synthesis of RNA sequences are illustrated in Figure 3. Several of these protecting groups [ie, the tetrahydropyran-2-yl (Thp, **9**), 4-methoxytetrahydropyran-4-yl (Mthp, **10**), and 1-(2-fluorophenyl)-4-methoxypiperidin-4-yl (Fpmp, **13**) groups] are acetal systems that undergo hydrolysis under mild conditions (especially in the case of the Fpmp **13** group) of acidic hydrolysis (13). These protecting groups have the considerable advantage that they are completely stable under the ammonolytic conditions that are needed to remove virtually all of the other protecting groups from fully assembled RNA sequences. The 2-nitrobenzyl protecting group **11** (4) is removed photolytically (at wavelengths > 280 nm) and is, of course, also stable to ammonolysis. The *tert*-butyldimethylsilyl (TBDMS **12**) protecting group (5), which has been used very widely in the automated solid-phase synthesis of RNA sequences, has the advantage that it can be removed in the final unblocking step under nonacidic conditions. However, there are at least two distinct disadvantages associated with the use of the TBDMS protecting group. First, it is partially removed under the standard ammonolytic unblocking conditions (concentrated aqueous ammonia, 55°C). Second, as the TBDMS group readily undergoes base-catalyzed migration (6) from the 2′- to the 3′-hydroxy function of a ribonucleoside (and vice versa), particular care has to be taken in the preparation of the appropriate monomeric building blocks. Otherwise the synthetic RNA sequences will inevitably be contaminated with material containing (2′→5′)-internucleotide linkages.

Figure 3. Some protecting groups for the 2′-hydroxy functions in RNA synthesis.

Apart from the particular problem associated with 2' protection, the principles governing the chemica same as those governing the synthesis of DNA sequences. Similar protecting groups are used for the internucleotide linkages, and the same three principal phosphorylation methods (ie, the phosphotries phosphonate approaches) that are used in the DNA synthesis are also used in the synthesis of RNA s case of DNA synthesis, of these three phosphorylation methods only the phosphotriester approach (1 synthesis of RNA sequences, and the phosphoramidite approach (8-11) again appears to be the meth phase synthesis.

2. Solution-Phase RNA Synthesis

Before a really satisfactory procedure for automated solid-phase synthesis had been developed, relati sequences were prepared by the phosphotriester approach in solution. As an example of this approac used successfully (7) in the preparation of the 3′-terminal decamer, nonadecamer, and heptatriaconta $tRNA^{Ala}$ is illustrated in outline in Figure 4. The achiral Mthp group **10** was used to protect the 2′-hy and the methoxymethylene group was used to protect the 2′,3′-terminal vicinal diol system (as in **15** functions (as in **14** and **16**) were protected with acyl groups [such as the 2-(dibromomethyl)benzoyl (removable under what were effectively very mild basic conditions. Internucleotide linkages were pro (Ar, **19**), and the adenine, cytosine, guanine, and uracil residues were protected as in **20, 21, 22**, and uracil residues were protected on *O*-6 and *O*-4, respectively, with aryl groups to prevent the occurrer coupling steps. Coupling (Fig. 4, step i) was effected with 1-(mesitylene-2-sulfonyl)-3-nitro-1,2,4-(1 pyridine solution. After the fully protected RNA sequences had been assembled, unblocking was eff unblocking step (step ii), the 2-chlorophenyl protecting groups were removed from the internucleotic *O*-aryl groups were removed from the guanine and uracil residues by treatment with (*E*)-2-nitrobenz tetramethyl-guanidine **26**. All of the acyl protecting groups were then removed by treatment with co iii). Finally, the Mthp **10** and the 2′,3′-terminal methoxymethylene protecting groups were removed acidic hydrolysis. Solution-phase synthesis is labor-intensive and is likely to compete with automate below) only if relatively large quantities of RNA sequences are required, say, for chemotherapeutic p robust than the Mthp **10** group, and is also removable under milder conditions of acidic hydrolysis. T solution-phase oligonucleotide synthesis it would be advisable to replace the Mthp by the Fpmp or a protecting group.

RNA World

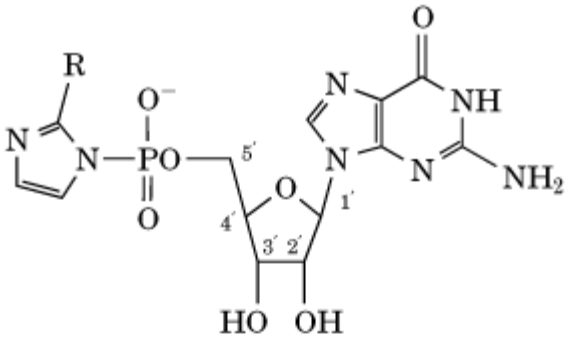
The "RNA World" is a term coined in 1986 by Walter Gilbert to describe the hypothesis that the origin of life proceeded through a stage that did not require DNA (1). The evidence from modern biochemistry that RNA is the more ancient nucleic acid obtains from many different inferences, including: 1) the 2′-deoxyribose nucleotides are synthesized enzymatically from the corresponding ribose precursors in modern biochemistry, 2) the DNA base thymine is formed by thymidylate synthase from the corresponding uracil nucleotide, and 3) RNA oligonucleotides function as primers in DNA biosynthesis. The molecular biology of DNA points repeatedly to the requirement for pre-existing RNA components, suggesting that the evolutionary origin of DNA depended on an ancient world in which RNA was the library of genetic information storage. In this view, DNA arose as a more stable vector by virtue of its superior resistance to self-cleavage, associated with the 2′-hydroxyl group, and the ability of thymine to circumvent the deleterious thermal and photochemical addition reactions typical of uracil.

A major boost to the supposed primacy of RNA was the discovery by Thomas Cech and Sidney Altman in the early 1980s that RNA could also serve a catalytic function as a so-called "ribozyme." Beginning with the self-splicing of introns, the types of reactions promoted by ribozymes has expanded with the help of *in vitro* selection techniques to include various ligation processes that mimic the action of RNA polymerases (2). An important step toward the emergence of a true "replicase" has come with the creation of a ribozyme that catalyzes elongation of a primer sequence by 11 to 14 nucleotides, with fidelities from 92.0% (for the incorporation of adenosine) to 99.96% (for guanosine) in a mixture of nucleoside triphosphates (3). Not only can ribozymes promote the formation of peptide bonds (4), but the recently unveiled X-ray structure of the ribosome suggests that an adenine base within an RNA chain (instead of an amino acid in a protein) plays the primary catalytic role in the active site: thus, the ribosome is itself a ribozyme (5).

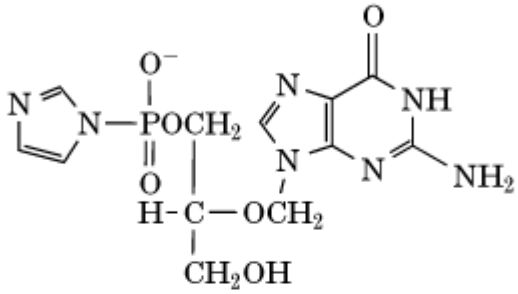
1. Oligomerization of Phosphorimidazolides

The origin of the RNA world has posed a formidable challenge. Self-replication must have preceded the evolution of ribozymes, and, thus, Leslie Orgel and his coworkers (6) have extensively studied the non-enzymatic template-directed oligomerization of activated nucleotides (eg, Ia in Fig. 1). Modern biochemistry employs nucleoside triphosphates, in which pyrophosphate serves as the leaving group, but these compounds react too slowly in laboratory simulations. A seminal discovery in 1980 was the zinc-catalyzed formation of oligoguanylates up to 40 nucleotides in length using a polycytidylate template; moreover, the internucleotide linkage in the presence of this metal ion was predominantly the "natural" 3′-5′ bond (7). Activated precursors containing 2-methylimidazole (Ib in Fig. 1) gave even better results without the need for added metal ions; subsequent work in Orgel's group established the fidelity of template copying at better than 99% for the Watson-Crick base when present in a mixture with the other three nucleotide phosphorimidazolides (8). While the precursors were chosen for their chemical efficacy rather than their prebiotic relevance, the results established that template-directed replication of a polynucleotide did not require the presence of a complex protein polymerase.

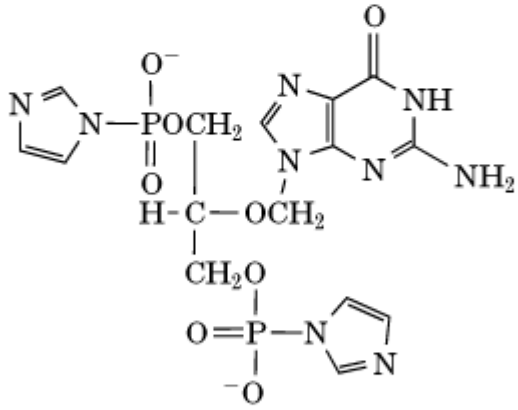
Figure 1. Activated guanine nucleosides and analogs: **(a)** guanosine 5′-phosphoimidazole (R = H) and guanosine 5′-phospho-2-methylimidazole (R = CH_3); **(b)** 9-[(1-hydroxy-3-phosphoimidazole-2-propoxy)methyl]guanine; **(c)** 9-[(1,3-diphosphoimidazole-2-propoxy)methyl]guanine; **(d)** PNA guanine dimer.



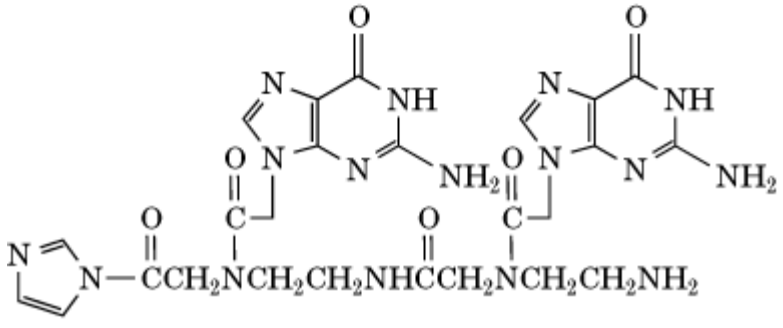
(**a**)



(**b**)



(**c**)



(**d**)

Despite the aesthetic appeal of this model system, Orgel and his associates have highlighted serious

limits to the templates and activated nucleotides that can be used. 2-Methylphosphorimidazolides prepared from a mixture of D- and L-guanosine do not oligomerize efficiently on a polycytidylate template due to chain termination by the "wrong" stereoisomer (9). Polyuridylates cause problems because of their tendency to form triple helices with adenine derivatives, while polyguanylates assemble into tetraplexes that inhibit replication (10). Mixed templates of guanosine and cytosine work as long as the amount of cytosine is high, but research on the deoxyribonucleotide series has shown that thymidine (and, by implication, uridine) effectively blocks the reaction (11). Because the goal of any self-replicating RNA model requires that the product also serve as a template, the problems of thymine (and uracil) arise whenever adenine is present in the strand being replicated. If these results with DNA analogs apply to their RNA counterparts, then the implications for the RNA world could be: 1) a smaller set of bases was employed early in the origins of replication (with severe limits on the amount of information storage); 2) a different suite of bases was used (with the attendant difficulties for the requisite transition); or 3) a natural catalyst (as yet unidentified) was necessary to achieve the conformation for thymine-containing templates to be replicated. Current research on the second and third alternatives may provide a solution to this dilemma.

Clay minerals on the early Earth could have played a role in the origin of the first oligonucleotide templates. In a remarkable series of papers by James P. Ferris and his colleagues (12), montmorillonite has been shown to promote the oligomerization of nucleoside phosphorimidazolide monomers: oligonucleotides up to 11 U long with a predominance of 3′-5′ linkages have been obtained from the activated adenosine derivative. The chain length can be extended further (up to the 50-mer) by repeated feeding of the oligoadenylates with additional adenosine phosphorimidazolide (13). The pyrophosphate-linked diadenosine (AppA) appears to be an intermediate in the reaction, and its presence as a starting material augments the regioselectivity of the oligoadenylate product. Montmorillonite also promotes the self-condensation of uridine phosphorimidazoles (14) and cytidine phosphorimidazolides (15), but the linkages are mainly of the non-biological (2′ to 5′) type. An intriguing observation is that a mineral-bound template of exclusively 2′,5′-oligocytidylate is a catalyst for the reaction of activated guanosine nucleotides (15). These results demonstrate that naturally occurring minerals cannot only accelerate such reactions but, in some cases, control the orientation of the monomers such that the products contain the biochemically important 3′-5′ internucleotide bonds.

2. Pre-RNA Alternative Worlds

A major question in the study of the origins of life is what might have preceded the RNA world, and much attention has centered on simpler monomers that possess fewer stereocenters (or even none). The glycerol derivative (II) shown in Figure 1 is attractive because glycerol is a product of prebiotic simulations, and the proposed nucleotide analog has only one stereogenic carbon, but the activated phosphate undergoes a facile intramolecular cyclization that prevents template-directed polymerization (16). A related structural analog, the 1,3-diphosphoimidazolide (III), does react catalytically on a polycytidylate template to give pyrophosphate-linked oligomers up to the 20-mer (17).

Other models for the pre-RNA world have sought to avoid the problems associated with phosphate (low reactivity and dilute natural concentrations) through peptide-linked nucleic acids (PNAs). Although the specific monomer units employed by Nielsen and his colleagues (18) are not asserted to be prebiotic compounds, he and Orgel have demonstrated that the guanosine PNA dimer (IV) undergoes oligomerization up to the decamer on a decadeoxycytidine template. Interestingly, the reaction of the phosphoimidazolide (but not 2-methylimidazolide) of guanosine is promoted by a complementary cytosine-containing analog, thus showing that information transfer between peptide nucleic acid and RNA (in either direction) is feasible. However, studies of autocatalysis in oligopeptide ligation test the assumption that chains of amino acids by themselves cannot replicate (19, 20).

In conclusion, RNA oligonucleotides up to 50 base units long can be synthesized on clay mineral surfaces, and this size lies within the lower regime in which catalytic activity becomes feasible. Self-replication of polynucleotides is possible without the need for enzymes, but only cytidine-rich templates can be efficiently copied. The challenge is to find pathways to this RNA world, either with the discovery of new catalysts or through a genetic takeover from a nucleic acid analog that is truly "prebiotic."

RNA-Binding Proteins

RNA is structurally more versatile than **DNA** and has more diverse biological roles. It is an informational molecule that serves as genetic material and the mediator of genetic information from

DNA to **protein**, it also plays a vital structural role in many ribonucleoprotein particles and, as is now recognized, can itself have catalytic activity. Whereas in the hypothetical RNA world, RNA would have acted unaided by other macromolecules, RNA almost invariably functions in modern organisms associated with RNA-binding proteins, a wide variety of which have now been identified. Although many RNA-binding proteins are uncharacterized structurally and do not fall into known categories, **primary sequence** analysis has led to the identification of a number of recurring RNA-binding **motifs** in functionally diverse RNA-binding proteins (1, 2). Interestingly in most cases, these are structurally and therefore probably evolutionarily distinct from **DNA-binding** motifs. RNA molecules are classified into various types based on their function or localization, such as transfer RNA (tRNA), messenger RNA (mRNA), **ribosomal** RNA (rRNA), viral RNA (vRNA), **small nuclear RNA** (snRNA), and small cytoplasmic RNA (scRNA). Table 1 gives some examples of RNA-binding proteins associated with each form, and Table 2 summarizes with examples the known RNA-binding motifs. Understanding how RNA-binding proteins specifically interact with their target RNA to form functional complexes is a key problem in structural biology, that has ramifications throughout molecular biology from transcription to **protein biosynthesis** and from replication of **viruses** to development of **embryos** and genetic disease .

[b] M. Görlach, M. Friedrichs, G. Dreyfuss, and L. Mueller (1992) *Biochemistry* **31**, 9254.

Some of the important questions concerning the nature of protein-RNA recognition can be illustrated by considering tRNAs (see Transfer RNA). They function as adaptor molecules that specify amino acid residues corresponding to particular triplet **codons**. There are 20 aminoacyl-tRNA synthetases, one for each amino acid, and each of these enzymes must specifically recognize and aminoacylate *only* its cognate tRNA with its cognate amino acid (3, 4). In contrast, the prokaryotic elongation factor Tu (EF-Tu), which introduces aminoacylated tRNA (aa-tRNA) into the A-site of the ribosome, binds to all aa-tRNA (except initiator-Met tRNA and **selenocysteinyl**-tRNA) and hence must recognize features common to all elongator aa-tRNAs (5). These are two extreme examples of tRNA recognition mechanisms that are essential in maintaining the fidelity and efficiency of protein biosynthesis. The various tRNA are transcribed as precursor RNA molecules and must be processed correctly by specific nucleases and a surprisingly large number of different base-modifying enzymes to form mature molecules. These modifying enzymes also have diverse specificities. Some recognize almost all tRNA [eg, tRNA (m^5U54)methyltransferase]. Others recognize a subset of tRNA (eg, tRNA-guanine transglycosylase), even a unique tRNA species.

A wide variety of RNA-binding proteins are involved in producing, processing, transporting, translating, and degrading mRNA, the most abundant single-stranded RNA in cells. mRNA in eukaryotes is **capped** at the 5′ end and **polyadenylated** at the 3′ end, and **introns** must be correctly excised by the **splicing** machinery. Mature mRNAs are transported from the nucleus to the

cytoplasm for translation. **Gene expression** is regulated at the transcriptional level and also at the translational level by a variety of mechanisms mediated by mRNA-binding proteins. The controlled **degradation** of mRNA is also an important process, involving a complex set of endo- and exonucleases. All of these processes must interact precisely with a large number of specific or nonspecific RNA-binding proteins and enzymes.

RNA is an essential structural and functional component of many ribonucleoproteins (RNP). Assembly of these RNP requires specific recognition of RNA structure and/or base identity by RNP protein subunits. The ribosome itself contains rRNA molecules, which are matured by splicing and modifying enzymes in the nucleolus in association with small nucleolar RNP (snoRNP). The rRNA may actually play the key catalytic role in peptidyl transfer. Pre-mRNA splicing is a complicated regulated process, involving a number of small nuclear RNPs containing snRNA that form a dynamic complex known as the spliceosome. The substrate of the spliceosome is not naked RNA, but pre-mRNA (also known as heterogeneous nuclear RNA, **hnRNA**) complexed with various proteins that form particles known as hnRNP. The mammalian signal recognition particle (SRP) is an scRNP consisting of a 300-nucleotide 7 S RNA associated with six protein subunits. It binds to signal peptides at the N-terminal end of **secreted proteins** as they emerge from the ribosome and directs the nascent-chain/ribosome complex to receptors on the endoplasmic reticulum membrane in eukaryotic cells. Systems homologous to SRPs are found in all living cells. Ribonuclease P, a tRNA-processing endonuclease, is an RNP in which the RNA component plays the catalytic role. Telomerase is a complex enzyme consisting of template RNA and protein subunits that adds multiple repeats of a particular sequence onto the ends of chromosomal DNA. Many viruses contain RNA as their genetic element, and virally-coded RNA -binding proteins play essential roles in the very diverse modes of replication and assembly of viruses.

How do RNA-binding proteins recognize their RNA-binding sites? RNA is distinguished from DNA most readily by the presence of the ribose 2′-OH and because the extended RNA double helix is predominantly in the **A-form** and has helical parameters significantly different from DNA, which is normally in the **B-form**. These general features permit nonspecific double-stranded RNA-binding proteins to recognize their correct nucleic acid substrate (eg, dsRNA-dependent protein kinase). On the other hand, specific RNA-binding proteins have more difficulty recognizing undistorted A-form RNA, which is characterized by a deep, narrow **major groove** and a shallower **minor groove**. The bases in the major groove are not readily accessible to protein side chains for specific recognition by **hydrogen bonding** except near the beginning or ends of helices. By contrast, the readily accessible minor groove contains less information for base discrimination. This problem is in reality bypassed by the fact that most cellular RNA is single-stranded, which forms irregular structures comprising short helices resulting from **Watson-Crick pairing** of short complementary stretches interspersed with hairpins, internal loops, bulges, or **pseudoknots** . Many RNA-binding proteins specifically recognize irregular RNA structures whose bases are more exposed for hydrogen bonding or stacking interactions with protein side chains. Indeed the irregularities may be specifically induced or enhanced by the protein/RNA interaction. Some RNA molecules fold further into complex tertiary structures (eg, tRNA) whose unique three-dimensional shape may be sufficient to define specific backbone interactions with an RNA-binding protein (eg, seryl-tRNA synthetase recognizing $tRNA^{Ser}$).

1. Domains and Motifs Found in RNA-Binding Proteins

The majority of the known RNA-binding proteins have modular structures that contain an RNA-binding **domain** combined with other auxiliary domains (1, 2). Four RNA-binding sequence motifs have been found in RNA-binding proteins from diverse species: therefore, it is considered that they arose early in evolution. These correspond to (1) the RNP domain, (2) the KH domain , (3) the dsRNA-binding domain, and (4) the S1 domain . X-ray crystallography has shown or NMR that they contain an a/b fold similar to those found in some ribosomal protein subunits, and it has been suggested that these RNA-binding motifs may have evolved from ribosomal proteins. This might

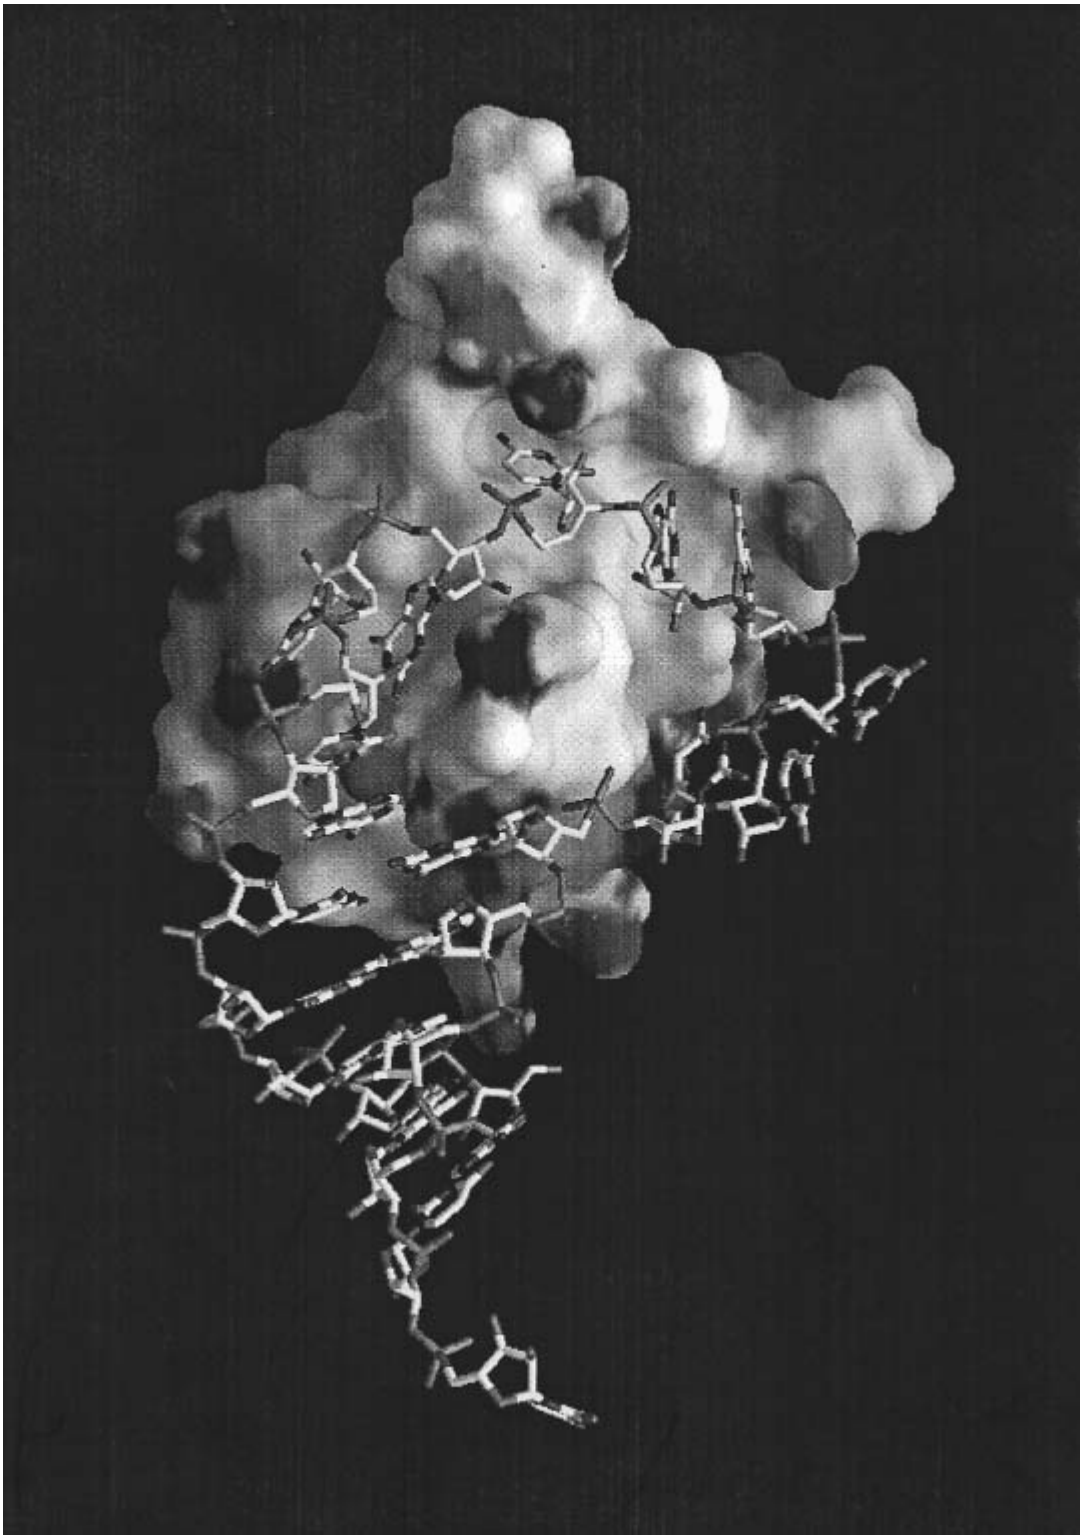
help to explain why RNA-binding domains are generally distinct from DNA-binding domains. Notable exceptions are the **zinc finger**, OB fold, and **homeodomain**. It is an interesting observation that many known RNA-binding proteins are all b or a/b proteins that contain an exposed b-sheet. The crystalline structure of the complex between U1A protein and an RNA hairpin discussed later suggests why a b-sheet is a good RNA-binding surface.

1.1. RNP Domain

The RNP domain, also known as RNA recognition motif (RRM) or RNP-consensus sequence (RNP-CS) type RNA-binding domain, is found in more than 200 distinct RNA-binding proteins from diverse species (1, 2, 6). It is also the second most common protein sequence motif in the entire genome of the nematode *Caenorhabditis elegans*. These facts suggest that this module appeared early in evolution. The RNP domain is about 80 amino acid residues long and contains two highly conserved short sequence motifs called RNP octamer (RNP1) and RNP hexamer (RNP2). Some proteins contain only a single RNP domain, but others contain multiple copies. For example, the protein that binds to the polyadenylate (poly A) tail of mRNA in eukaryotes contains four tandem copies of the RNP domain.

The three-dimensional structure of the RNP domain first determined for U1A spliceosomal protein, indicated that it consists of a four-stranded antiparallel b-sheet flanked on one side by two a **-helices**. The RNP1 and RNP2 motifs are located in the two middle b-strands of the sheet, and the side chains of the three highly conserved aromatic residues within RNP1 and RNP2 are projected onto the surface of the b-sheet (in U1A one of these residues is replaced by a glutamine) (7). U1A protein is a protein component of U1 snRNP, a large RNA/protein complex involved in pre-mRNA splicing, and binds to an RNA hairpin that contains 10 nucleotides in the loop. The crystal structure of a complex between U1A protein and an RNA hairpin representing its binding site has been determined at 1.9 Å resolution (8). The RNA hairpin loop binds to the surface of the b-sheet as an open structure, and the first seven nucleotides of the loop are fitted into a groove formed on the surface of the b-sheet (Fig. 1). The polypeptide loop between the b2 and b3 strands protrudes through the RNA loop. The bases of the seven nucleotides are splayed, and the protein-RNA contacts are made almost exclusively by RNA bases. These seven bases stack onto an adjacent base, a protein side chain, or both and also form an intricate hydrogen-bond network with protein side chains and the amide and carbonyl groups of the protein main chain. U1A protein also binds to the 3′-untranslated region of its own pre-mRNA and prevents its polyadenylation by directly interacting with poly-A polymerase. The binding site contains two internal loops, each with the AUUG(C/U)AC heptamer found in U1 snRNA hairpin II (6, 9, 10).

Figure 1. Crystal structure of a complex between U1A spliceosomal protein and its hairpin RNA binding site in U1 snRNA (8). The contact surface of the protein molecule is shown, whereas the RNA is a skeletal model. The AUUGCAC sequence in the ten-nucleotide loop fits into the groove on the surface of the b-sheet and binds tightly through stacking and hydrogen bond interactions with the protein.



1.2. Double-Stranded RNA-Binding Domain (dsRBD)
The dsRBD is a short sequence motif found in multiple copies in RNA-binding proteins from diverse origins including *Escherichia coli*, *Drosophila*, *Xenopus*, and mammals. In the *Drosophila* embryo, Staufen protein binds to maternal bicoid mRNA and plays an important role in establishing the anterior-posterior polarity through mRNA localization (11). *E. coli* ribonuclease III is an important enzyme involved in processing ribosomal and transfer RNA. The dsRBD is also found in **adenosine deaminase**, which is a key enzyme in RNA Editing, and in the double-stranded RNA-dependent protein kinase, which plays an important role in viral gene expression. The NMR structures of

dsRBD from RNase III and Staufen protein show that the module contains a three-stranded antiparallel b-sheet that has two a-helices packed on one side (11, 12). The dsRDB shows strong similarities to the N-terminal domain of *Bacillus stearothermophilus* ribosomal protein S5 at the levels of both amino acid sequence and three-dimensional structure (11). This strongly suggests that dsRBD may have evolved from a ribosomal protein. It is not yet known how this domain binds RNA, but site-directed mutagenesis experiments suggest that loops between b1 and b2 and between b3 and a2 may be involved in RNA-binding. The major groove of dsRNA is narrow and deep, and the bases are not accessible by protein side chains for sequence-specific interactions. It is likely that each dsRBD binds to the minor groove or to the phosphate backbone in the major groove. Biochemical experiments suggest that a set of dsRDB, together with some auxiliary domains, may recognize a structural feature of folded RNA.

1.3. KH Domain

Heterogeneous nuclear ribonucleoprotein (hnRNP) K is one of the nuclear proteins that bind to precursors of mRNA (1). There are three copies of a sequence motif within hnRNP K, and homologous sequences have been found in many proteins from diverse species, from bacteria to man, that interact with RNA. Human Fragile X (FMR1) gene contains two copies of the KH domain. A mutation in one of these is responsible for severe hereditary mental retardation (1, 13). The natural RNA target of the FMR1 gene product has not been identified, but the mutation that causes severe hereditary mental retardation abolishes the binding of poly(U) to the FMR1 protein. This suggests that the ability of FMR1 to bind to RNA is essential for its *in vivo* function. Two proteins that contain three copies of the KH domain are associated with the 3′-untranslated region of a-**globin** mRNA. These proteins affect the *in vivo* half-life of the a-globin mRNA. Ribosomal protein S3 from *E. coli* and other bacteria contains the KH domain, suggesting that the KH domains found in higher organisms have evolved from a ribosomal protein (1). The NMR structure of the KH domain from human vigilin has an a/b structure that contains a three-stranded b-sheet with three a-helices (14).

1.4. S1 Domain

Ribosomal protein S1 from *Escherichia coli* contains six copies of a short sequence motif of approximately 80 amino acid residues. S1 protein is directly involved in RNA binding because it can be **cross-linked** to mRNA in the translational initiation complex. The S1 domain has been found in proteins from bacteria and eukaryotes, including polynucleotide phosphorylase, initiation factor 1 (IF1), NusA, **ribonucleases** II and E from *E. coli*, yeast RNA helicase PRP22, eukaryotic initiation factor eIF2a, and eIF2a kinase inhibitor. An NMR study of the S1 domain of polynucleotide phosphorylase shows that this domain consists of a five-stranded antiparallel b-barrel (15).

1.5. MS2 Bacteriophage Coat Protein

One of the best studied examples of an RNA-binding protein is the MS2 **bacteriophage** coat protein. The MS2 phage contains a genomic RNA 3569 nucleotides long, packaged into an icosahedral protein shell that consists of 180 copies of the coat protein. A capsid protein dimer binds to an RNA hairpin formed near the ribosomal-binding site of the virally encoded **replicase** gene, thereby inhibiting translation of the replicase mRNA. The interaction also triggers assembly of the coat protein and packaging of the genomic RNA. A synthetic RNA hairpin that represents the binding site was soaked into a crystal of the empty phage particle, and its structure was determined to 2.8 Å resolution (16). The RNA, which contains a **tetraloop** and a bulged adenosine, binds to the surface of the continuous b-sheet across the dyad axis. The side chain of a tyrosine residue stacks onto a cytidine in the tetraloop, and the bulged adenosine and an adenosine in the tetraloop bind to equivalent sets of residues from each subunit.

1.6. Zinc-Containing RNA-Binding Proteins

Transcription factor IIIA is a transcriptional activator of the 5 S rRNA gene, but it also binds to its gene product 5 S to rRNA, and functions as a storage or transport protein (17). It contains nine **zinc fingers**, each of which folds into a domain that contains two b-strands and one a-helix stabilized by the coordination of two histidine and two cysteine residues to a zinc ion. Crystallographic analyses of zinc finger proteins in complex with dsDNA show that the a-helix fits into the major groove of the

DNA and forms many sequence-specific contacts with the DNA bases (18). It is believed that 5 S rRNA folds into a branched double helix that contains many bulges which may widen the major groove of RNA to permit entry of the recognition helices. The HIV nucleocapsid protein is another example of a zinc-containing, RNA-binding protein. Others are *E. coli* alanyl-tRNA synthetase and tRNA guanine transglycosylase (28).

1.7. Other RNA-Binding Modules

The bases of the anticodon loops of tRNA ^{Asp} and tRNA^{Lys} are splayed over the surface of a b-barrel domain of their cognate tRNA synthetases and are recognized in a sequence specific manner (see later) (19, 20). Many structural homologues of this b-barrel domain, which is known as the *OB-fold*, have been found in proteins that bind oligonucleotides (both ssRNA and ssDNA) or oligosaccharides (21).

The Sm proteins that form the core of spliceosomal small nuclear ribonucleoprotein particles (snRNP) contain a conserved sequence motif. It is predicted that this domain has an a/b fold, but its structure is yet to be determined (2). Some hnRNP proteins contain multiple repeats of an Arg-Gly-Gly (RGG) sequence that are believed involved in RNA binding (1).

The crystal structure of the SRP 14 / 9 heterodimer, which binds to the *Alu* domain of the mammalian signal recognition particle RNA, has been determined. SRP9 and SRP14 are structurally homologous and contain the same a-b-b-b-a fold, related to but distinct from the dsRNA-binding module. The heterodimer has pseudo two-fold symmetry and is saddle-like, comprising a strongly curved six-stranded amphipathic b-sheet. The four helices are packed on the convex side, and the exposed concave surface is lined with positively charged residues.

Both HIV tat and rev proteins bind the TAR and RRE elements, respectively, to their target RNA sequences, by arginine-rich peptides. The solution structure of a 14-residue arginine-rich peptide from BIV tat complexed with BIV TAR has been determined by NMR (26). The peptide forms a b-hairpin that interacts in the RNA major groove.

2. tRNA-Binding Proteins

2.1. Aminoacyl-tRNA Synthetases

The fidelity of protein synthesis depends to a large extent on the extreme specificity with which aminoacyl-tRNA synthetases charge their cognate tRNA with their cognate amino acid. In *E. coli*, there are at least 46 different tRNA molecules that have anticodons which correspond to the various amino acids. The seryl-tRNA synthetase, for example, has to charge the six serine isoacceptors (including one for selenocysteine) selectively and ignore the others. Because tRNA superficially have similar secondary and tertiary structures, what is the molecular basis for the specific recognition between aminoacyl-tRNA synthetases and tRNA? In many cases, extensive biochemical studies have revealed the so-called tRNA identity elements (see Aminoacyl tRNA Synthetases).

A more detailed picture of specific tRNA recognition and catalysis by aminoacyl-tRNA synthetases is emerging from crystallographic studies of aminoacyl tRNA synthetases complexed with various combinations of their three substrates: ATP, cognate amino acid, and cognate tRNA, plus the activated amino acid intermediate, the aminoacyl-adenylate. Now, crystal structures are known of 14 of the 20 aminoacyl tRNA synthetases, five of which are in complexes with cognate tRNA (3, 4). The three systems, for which the most extensive structural data exists on protein-tRNA recognition, are the class I glutaminyl system and the class II aspartyl and seryl systems. These show strikingly different modes of specific synthetase-tRNA interaction but share certain general features, including a fairly large synthetase-tRNA interactive interface characterized by (1) nonspecific backbone contacts, often involving basic residues, both of which increase binding affinity and aid correct positioning and orienting the tRNA; (2) discriminatory base-specific interactions restricted to a few regions, principally the anticodon and the acceptor stem. The second general feature is mutual induced fit by which protein-RNA contacts are made as a result of conformational changes in either

or both macromolecules. This includes ordering of protein loops and reorienting and stabilizing domains (eg, SerRS), base-pair breaking in the acceptor stem, and 3′-end distortion (eg, $tRNA^{Gln}$) and destacking of bases in the anticodon loop (eg, $tRNA^{Gln}$, $tRNA^{Asp}$).

2.2. Glutaminyl-tRNA Synthetase (GlnRS)

GlnRS is a monomeric class I synthetase whose specificity for $tRNA^{Gln}$ is largely determined by interactions with identity elements in the tRNA acceptor stem and anticodon stem-loop, both of which have severe distortions from the structure found in uncomplexed tRNA. In the *E. coli* complex, the tRNA anticodon stem is extended from five to seven base pairs by two extra non-Watson–Crick base pairs (23). The three anticodon bases (CUG) are splayed to fit into three separate recognition pockets formed at the interface between the distal two b-barrel domains of the protein. In the active site of the synthetase, the tRNA is oriented so that specific interactions can be made within the acceptor stem's minor groove to identity determinants in base pairs 2 and 3. On the other hand, the tRNA 3′-end reaches the catalytic center only by forming an unusual hairpin turn. This conformation requires breaking the first U1-A72 base pair and is stabilized, in part, by a hydrogen bond between the discriminator base G73 and the phosphate of A72.

2.3. Aspartyl-tRNA Synthetase (AspRS)

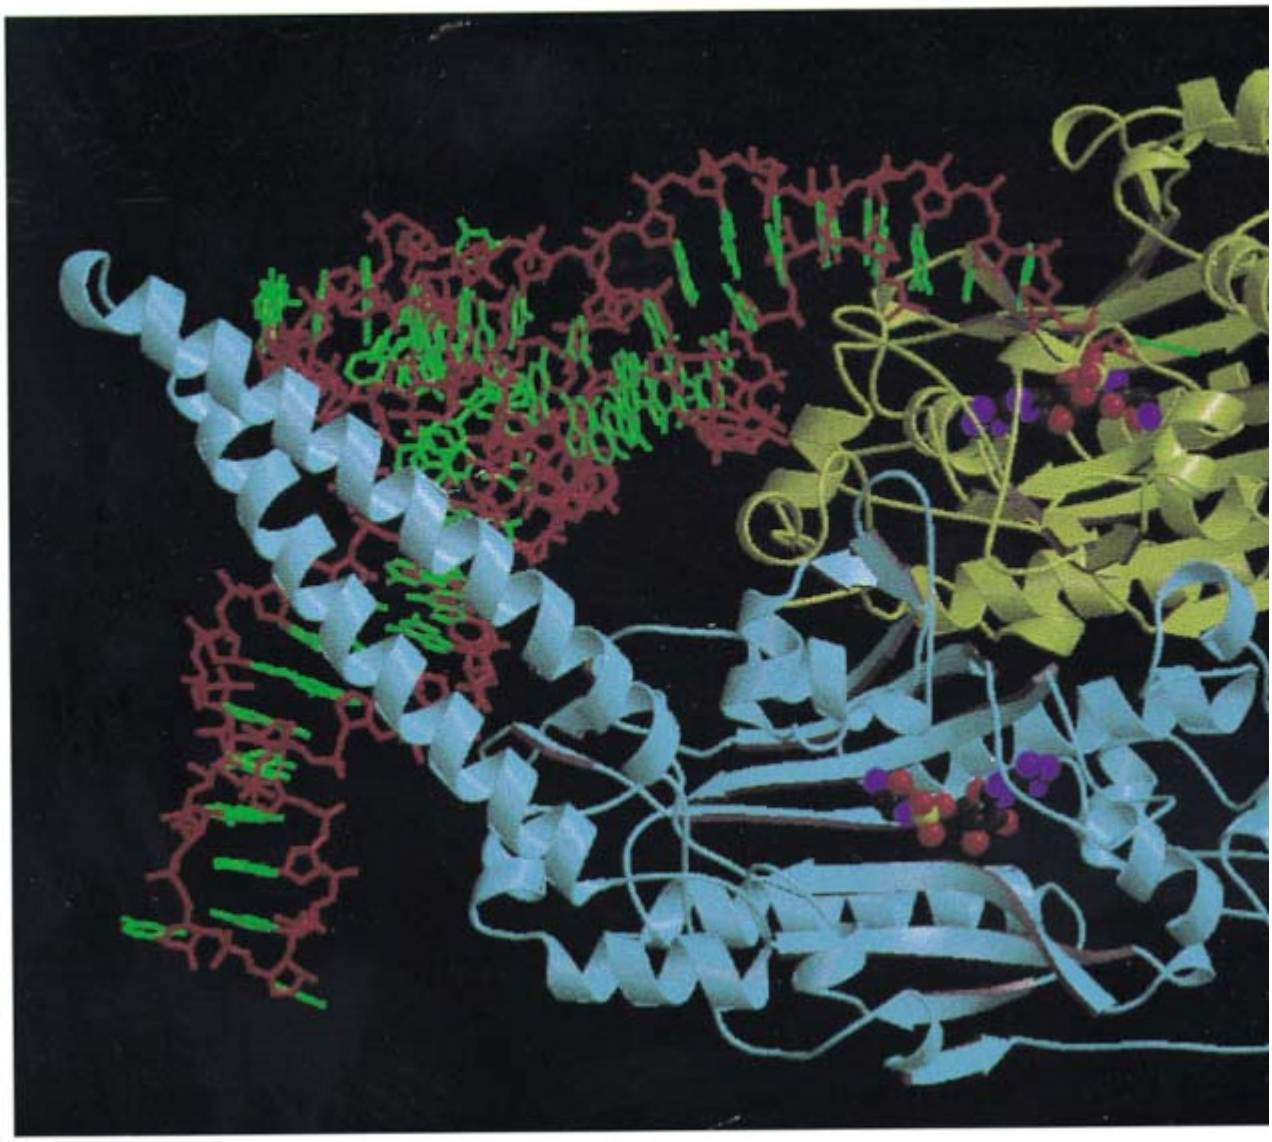
AspRS is a dimeric class IIb synthetase that binds two tRNAs symmetrically, although each tRNA interacts predominantly with only one subunit. In contrast to class I, class II synthetases interact with the acceptor stem of their cognate tRNA from the major groove side (27) by the so-called motif 2 loop, which in yeast AspRS makes base-specific interactions with the discriminator base G73 and base pair U1-A72 (19). The major groove side recognition also means that the single-stranded 3′-end of the tRNA enters the synthetase active site without significant distortion from its normal helical path, again in strong contrast to class I. Anticodon recognition by AspRS is performed by an N-terminal, five-stranded, b-barrel domain (OB fold) (21). The normal compact structure of the free tRNA anticodon loop undergoes a large conformational change, and the five anticodon loop bases are exposed to the exterior. The three anticodon bases (GUC) lie across the b-sheet surface and are recognized by specific hydrogen bonding interactions (19). Recent crystallographic results on another closely related class IIb synthetase complexed with its cognate tRNA, *T. thermophilus* lysyl-tRNA synthetase, show a very similar interaction between the anticodon of $tRNA^{Lys}$ (CUU) and the N-terminal, b-barrel domain of LysRS (20). Whereas the central U35 interacts identically in the two systems (by stacking with a conserved phenylalanine residue and hydrogen bonding with conserved glutamine and arginine residues), the specificity for base 36 and to a lesser extent for base 34 is idiosyncratic for each synthetase.

2.4. Seryl-tRNA Synthetase (SerRS)

SerRS is also a dimeric class II synthetase, but its mode of tRNA recognition differs significantly from that of AspRS (Fig. 2). SerRS is characterized by a unique 100-residue, N-terminal domain that is folded into a 60 Å long, solvent exposed and flexible, antiparallel coiled coil, known as the helical arm (24, 25). The variety of serine anticodons from two distinct groups means that the serine isoacceptors share no common anticodon base. Thus the anticodon is not an identity element of $tRNA^{Ser}$, whereas the long variable arm is, a feature shared only by $tRNA^{Leu}$ and $tRNA^{Tyr}$. The main features of the recognition of $tRNA^{Ser}$ by *T. thermophilus* SerRS are (1) the tRNA binds across the two subunits of the dimer; (2) upon tRNA binding the helical arm of the synthetase is stabilized in a new orientation and binds between the TYC loop and the long, variable-arm of the tRNA; (3) contacts with the tRNA long, variable-arm backbone extend until the sixth base pair, explaining the need for a minimum length of the tRNA variable arm; (4) the synthetase makes many backbone contacts, but few base-specific interactions, and is principally recognizing the unique shape of $tRNA^{Ser}$. The unique shape of $tRNA^{Ser}$ is largely determined by bases 20A and 20B inserted into the D-loop, both of which play novel roles in tertiary interactions in the tRNA core. In particular, the base of G20B is stacked against the first base pair of the long variable arm and thus defines the spatial orientation of the latter; (5) the anticodon stem loop is not in contact with the synthetase; (6)

the motif 2 loop of SerRS (longer than that of AspRS) makes base contacts down to the fourth base pair within the acceptor stem's major groove, but they are, however, only weakly discriminatory (25).

Figure 2. Overall view of the ternary complex of seryl-tRNA synthetase, $tRNA^{Ser}$(GGA), and a nonhydrolyzable analog monomer 1 is in yellow, and monomer 2 is in blue. Only the backbone and its secondary structure are shown (arrows are tRNA backbone is in red, and the bases are in green. The tRNA is viewed looking down the anticodon stem, which is no in the figure. The long variable arm of the tRNA crosses the helical arm of monomer 2 perpendicularly and emerges at th the Ser-AMS molecule is represented by spheres. See color insert.



2.5. Elongation Factor EF-Tu

EF-Tu is a **G-protein** that, in the activated GTP-bound state, binds all aminoacylated elongator tRNA with higher affinity than uncharged tRNA and delivers them to the ribosome. The crystalline structure of the ternary complex of yeast $tRNA^{Phe}$, *T. aquaticus* EF-Tu and GDPNP has recently been determined and reveals how activated EF-Tu contacts relatively limited and conserved regions of aa-tRNA (5). The only parts of the aa-tRNA in contact with EF-Tu are the aminoacylated CCA end, the 5′-phosphate, and the T-stem helix. The long stem of the L-shaped tRNA projects away

from the protein, so that the entire complex is extremely elongated. The CCA-3′ end binds in a cleft between domains 1 and 2 of EF-Tu, and conserved residues from domain 2 interact with the base and phosphate of A76. Main-chain hydrogen bonds from EF-Tu are made to the ester group linking the carboxyl group of the amino acid to the 3′-OH of the ribose and to the free amino group of the amino acid. The amino acid itself projects into a pocket formed between domains 1 and 2. The tRNA 5′-phosphate is bound by conserved basic residues from helix B of domain 1 and from domain 2. One side of the T-stem helix is packed against a depression between domains 1 and 3. The contacts are made by nonconserved residues from domain 3.

It has been pointed out that the EF-Tu.GTP.tRNA ^{Phe} ternary complex extraordinarily similar in shape to that of the elongation factor EF-G.GDP binary complex. This mimicry suggests that the two complexes might bind to the same ribosomal state.

ROESY Spectrum

A conventional nuclear Overhauser effect (NOE) experiment in nuclear magnetic resonance (NMR) spectroscopy involves detection of changes in the intensities of NMR signals associated with a particular spin of the molecule being examined, when other spins are perturbed in some way. The changes in signal intensity are the result of altered populations of nuclear spin energy levels associated with both sets of spins and reflect their physical proximity. There may be magnetic interactions between spins while they are in coherent states and these may lead to changes of signal intensity. This second kind of Overhauser effect is detected in a "rotating frame" NOE (or ROE) experiment. The ROE may be determined in a one-dimensional format or be incorporated into multidimensional experiments. A two-dimensional (2D) ROE experiment is often referred to as ROESY (rotating frame Overhauser effect spectroscopy). In such a 2D experiment, the appearance of a cross peak at the chemical shift coordinates (A, B) requires that there be a ROE between the spins characterized by these chemical shifts (s_A, s_B). The power of experiments that produce ROEs or NOEs is that changes in signal strength are strongly dependent on the distance between interacting spins. Thus, the observation of a ROE or NOE provides a constraint that can be used to define the tertiary structure of the macromolecule being studied.

For the standard NOE experiment wherein the detected signal intensity changes arise from alterations of spin energy level populations, the effect is given by

$$f_I\{S\} = I_p/I_0 - 1 \qquad (1)$$

where $f_I\{S\}$ indicates the NOE on the signal from spin I when there is a perturbation of level populations associated with spin S: I_0 is the normal intensity of the signal for spin I observed from a sample at thermal equilibrium before the analyzing RF pulse, and I_p is the intensity of the same signal when there has been a perturbation of spins S before the analyzing pulse. The value of $f_I\{S\}$ depends on the gyromagnetic ratios of spins I and S, how these spins move in the sample, the strength of the magnetic field used for the NMR experiment, and the details of how the energy level populations associated with spin S are perturbed during the course of an experiment. Values of $f_I\{S\}$ ranging from 0.5 to -1.0 are possible when both I and S are protons. It should be noted that, given the definition of $f_I\{S\}$, some set of experimental conditions may exist for which $f_I\{S\}$ becomes zero. Under these conditions, there is little or no change in signal intensity, even though spins I and S

might be very close to each other. These conditions are typically experienced when the mass of the molecule under study is in the range of 500–2000 D.

In contrast, the ROE on signal intensities is always positive for near-neighbor nucleus-nucleus interactions and thus remains detectable under all experimental conditions (1-3). This very significant advantage is countered, however, by the need to correct the experimental data for various artifacts and by the possibility that coherence transfers may produce effects that are unrelated to the ROE. Analysis of ROE data in conjunction with conventional NOE data may provide important insights into existing chemical exchange processes (4). Although most ROESY experiments with biological macromolecules involve interactions between hydrogen ^{1}H atoms, useful heteronuclear ROESY experiments also are feasible (5). The elements of the ROESY experiment can be built into experiments that produce three-dimensional or higher NMR spectra. (See also Nuclear Overhauser Effect (NOE), NOESY Spectrum.)

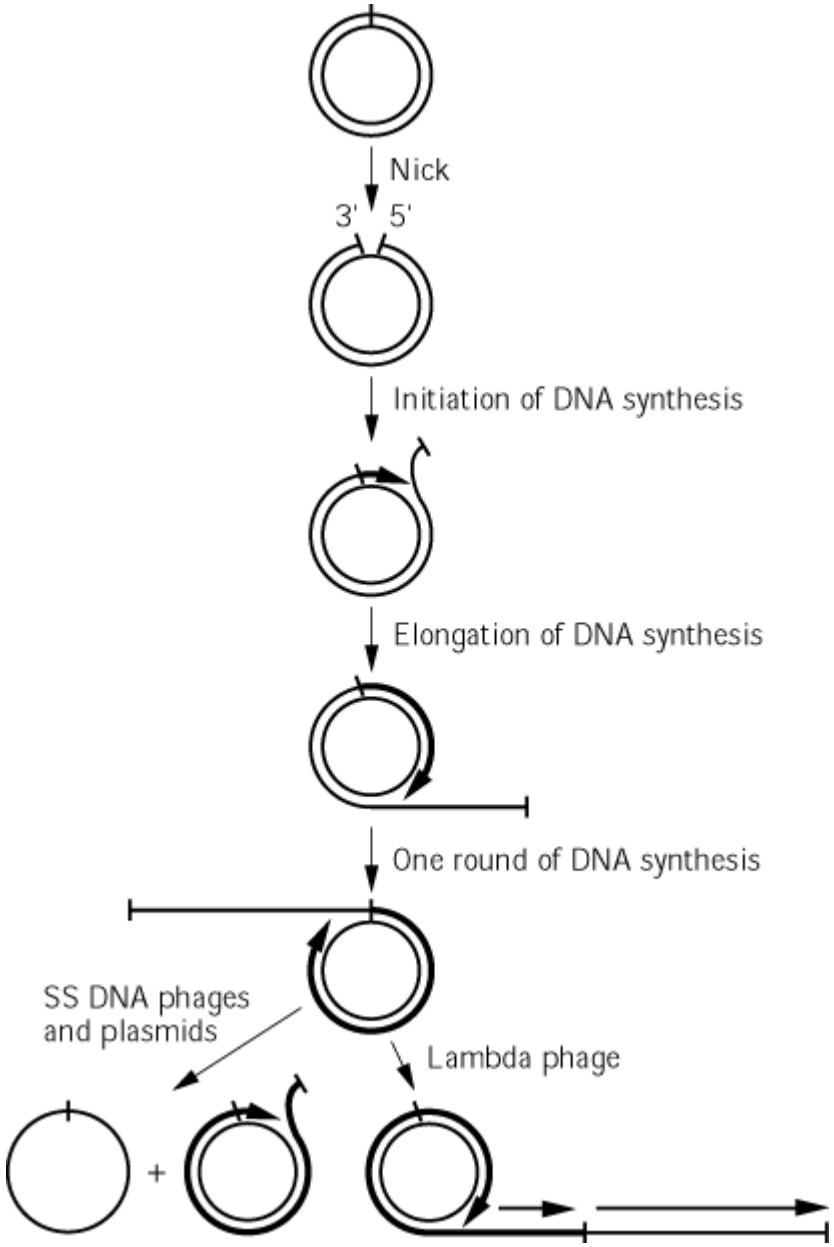
Rolling Circle DNA Replication

In DNA replication, the **DNA polymerase** cannot initiate the synthesis of a new DNA strand and must rely on a priming device. In general, an RNA primer is synthesized at or near a replication origin to start synthesis of the **leading strand**. However, a DNA primer terminus can be generated by a **nuclease**-generated nick at a specific place in some circular duplex DNA, and replication will then proceed unidirectionally, as shown in Figure 1. This mode of replication is called *rolling circle replication* and is found for replication of the replicative form (RF) form of **bacteriophage** single-stranded genomes of Gram-negative bacteria and of the multicopy **plasmids** of Gram-positive bacteria (see Single-Stranded DNA Replication). Rolling circle replication is also observed in the late stage of the replication of the lambda phage genome and in the process of the **conjugative** transfer of bacterial plasmids.

Figure 1. Scheme for rolling circle replication (see text for details).



DNA synthesis initiates using the free 3′-OH end at the nick as a primer, and a replication fork proceeds around the template. In the process, the newly synthesized strand displaces the old strand from the template. In the case of replication of the RF form of single-stranded phage **genomes** and of plasmids of Gram-positive bacteria, the displaced old strand is cleaved off after one round of replication and is converted into the circular, double-stranded form. In contrast, in phage lambda replication, the replication fork proceeds a number of revolutions around the template without cleavage of the displaced strand, and the displaced strand becomes double-stranded as it is peeled off. The linear concatemer thus created is cleaved into one unit length and packaged into the phage particles. In the conjugation process of plasmids, the displaced strand is transferred into the new cell.

The initial nick of rolling circle replication is introduced by an **endonuclease** specific for each system. The similarity of the amino acid sequences of the initiator endonucleases and of the proteins (known as relaxases) involved in the initiation and termination of conjugative DNA strand transfer clearly indicate that they are evolved from a common ancestor (1, 2).

Rossmann Fold

In the 1970s, Rossman and colleagues (1, 2) identified, analyzed, and characterized the similarity between the protein structures of lactate dehydrogenase and malate dehydrogenase, two enzymes that bind the dinucleotide NAD. Both protein structures incorporate two b–a–b–a–b protein motifs, and each half of the bound dinucleotide binds to one of these units. The b–a–b–a–b structural motif, which forms a parallel **b-sheet** surrounded by **a-helices**, is referred to as either a Rossmann fold or a **mononucleotide-binding motif**.

R_0T Curve

1. DNA–RNA Hybridization

During purification of messenger RNA, its quantity and the extent of purification can be determined by **hybridization** techniques. This also permits determining the size of the mRNA independently by gel electrophoresis.

Hybridization involves **annealing** a large excess of RNA with double-stranded DNA previously **radiolabeled** by **nick translation** or during its synthesis. Such labeling techniques result in a high specific radioactivity, so the necessary excess of RNA can be obtained easily. Heating double-stranded DNA denatures it to its single-stranded components and slow cooling of these single strands permit renaturation. This technique is used in **C_0t curves** to characterize DNA samples. Hall and Spiegelman (1) demonstrated that the same experiment can be performed with heat-denatured DNA and the corresponding mRNA, and slow cooling produces DNA–mRNA hybrids that were observed in cesium chloride density gradient centrifugation. When mRNA was heated with genetically unrelated DNA, no hybrid molecules were formed.

1.1. Kinetics of Association

DNA–RNA hybridization is a second-order reaction (see Kinetics). If t is the time, D the concentration of single-stranded DNA in moles of nucleotides/liter, R the concentration of excess mRNA in the same units, and k the rate constant for the reaction, then the equation describing the reaction is the following:

$$dD/dt = -kDR$$

The value of k is expressed in units of $M^{-1}s^{-1}$.

DNA self-reassociation is avoided by using a low concentration with RNA in excess. Then the RNA hybridizes much faster than the DNA, and its concentration remains practically constant throughout the reaction. The reaction follows pseudo-first order kinetics, and the equation above simplifies to the following:

$$\frac{dD}{dt} = -kR_0$$

R_0 is the mRNA concentration at $t = 0$.

By substituting $D = D_0$ at $t = 0$, the integrated equation becomes

$$\ln \frac{D_0}{D} = kR_0t$$

When 50% of the DNA (cDNA) strands have been converted into DNA-RNA hybrids, at $t = t_{1/2}D$ becomes $D_0/2$, and R_0t becomes $R_0t_{1/2}$. This yields

$$\ln \frac{D_0}{D_0/2} = kR_0t_{1/2}$$

from which the value of k can be derived by

$$k = \frac{\ln 2}{R_0t_{1/2}}$$

Therefore the velocity of the association reaction is inversely proportional to the value of $R_0t_{1/2}$, which itself is directly related to the size of a pure RNA or DNA molecule.

1.2. Determining mRNA size and evaluating a given mRNA in an RNA mixture

Knowing the size a of a given mRNA, the unknown size x of another mRNA is determined by the following equation:

$$\frac{\text{Size of mRNA}\alpha}{\text{Size of mRNA}x} = \frac{R_0t_{1/2}(\text{mRNA}\alpha)}{R_0t_{1/2}(\text{mRNA}x)}$$

For ovalbumin mRNA, which is 2000 nucleotides long, the $R_0t_{1/2}$ value is $4 \times 10^{-3}M^{-1}s^{-1}$. For prolactin mRNA (900 nucleotides long) the $R_0t_{1/2}$ value is accordingly smaller: $1.8 \times 10^{-3}m^{-1}s^{-1}$ (2).

The values of $R_0t_{1/2}$ allow determining the fraction of a certain mRNA in a mixture by comparing hybridization of the corresponding cDNA with the corresponding “pure” mRNA and with the same mRNA in a mRNA mixture. Because the size of the desired mRNA is constant, its reassociation rate depends only on its concentration in the mixture, according to the equation

$$\frac{R_0t_{1/2}(\text{“pure” mRNA})}{R_0t_{1/2}(\text{unknown sample})} = \frac{\%\text{mRNA (unknown sample)}}{\%\text{mRNA (pure mRNA)}}$$

The course of hybridization is monitored by determining the number of DNA–RNA hybrids at various reaction times. This is done in two ways (2):

1. by applying the reaction mixture to a chromatography column of **hydroxyapatite** in 0.05 *M* **phosphate buffer** at pH 6.8 and at a temperature of 60°C. The single-stranded DNA elutes with 0.14 *M* phosphate buffer, whereas the double-stranded DNA–RNA molecules elutes with 0.45 *M* phosphate buffer.
2. by digestion with S1 nuclease, which digests single-stranded DNA, whereas RNA–DNA hybrids remain unaffected and are precipitated with trichloroacetic acid.

2. Determining the Number of Different Sequences in mRNA Transcribed from a cDNA Library

To judge whether a **cDNA** library is representative, ie, whether the number of different clones carrying a particular cDNA insert reflects the relative fraction of the corresponding mRNA molecules in the cell from which the library has been prepared, the number of different mRNA sequences in the mRNA population is determined. This is done by hybridizing highly labeled cDNA with an excess of mRNA. The amount of hybridized DNA at any time t is plotted as a function of R_0. The kinetic curve yields the number of kinetic classes of mRNA molecules and their $R_0 t_{1/2}$ values. The values are corrected to obtain the values that would have been obtained if each of the classes had been considered on its own. The values are also corrected for the nonspecific poly-dA sequences in the cDNA from the mRNA poly A tails, which do not contribute to hybridization. Then the corrected $R_0 t_{1/2}$ values are used to determine the number of different sequences in each kinetic class by comparing them with the values of mRNA of known complexity ((3),(4)).

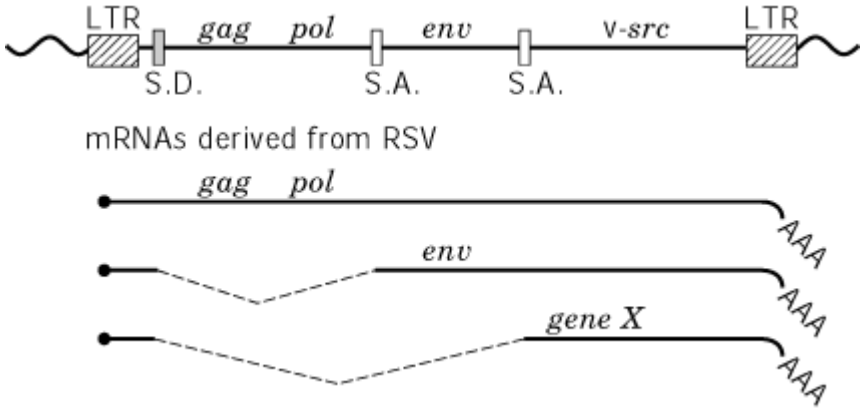
Rous Sarcoma Virus (RSV)

Rous sarcoma virus (RSV) was discovered in the extract of chicken sarcoma by Dr. P. Rous in 1911 as the first infectious reagent that causes tumors, and it is now known to be the prototype oncogenic **retrovirus** (*Oncovirinae*). It is widely accepted that ALV (avian leukosis virus), a replication-competent retrovirus carrying the **genes** *gag* (internal structural proteins), *pol* (**reverse transcriptase** and DNA **endonuclease**) (see HIV (Human Immunodeficiency Virus) and Hepatitis B Virus), and *env* (envelope glycoproteins), had once picked up a gene present in the chicken chromosome, now designated as cellular ***src*** (c-*src*), during its replication cycle as a rare event. RSV therefore carries an extra gene designated viral *src* (v-*src*) (because it is derived from c-*src*) at the extreme 3′ region of the genome, and it can be expressed from a subgenomic messenger RNA produced by RNA splicing (Fig. 1). By changing from c-*src* upon its integration into the virus genome and by

accumulation of mutations during the subsequent propagation of virus, this virus gene had acquired the ability to cause neoplastic transformation in chickens. High-level expression of c-*src*, however, does not cause such transformation. The products of both the v-*src* and c-*src* genes are now known to be **tyrosine-kinases**, with molecular weights of 60 kDa, and $p60^{v-src}$ has much higher kinase activity than does $p60^{c-src}$.

Figure 1. Proviral DNA structure of Rous sarcoma virus. The line at the top indicates the chromosomal DNA containing proviral DNA. SD, splicing donor site; and SA, splicing acceptor site. Three transcripts are produced from the LTR promoter, as shown below.



This prototype virus, however, is exceptional among RNA tumor viruses in that it is replication-competent. All the other oncogenic retroviruses acquired proto-**oncogenes** at the expense of a part of their genomes that is essential for virus replication, and they therefore require the association of other replication-competent virus such as ALV (often called helper virus) for their propagation. Because of the advantage of this exceptional genome structure, RSV has been historically used in laboratory for the analysis of neoplastic transformation in cell culture; virus titers, which were originally assayed by sarcoma formation in the injected chicken, are now determined much more easily by formation of a focus (a group of transformed cells) in infected chicken embryo fibroblasts (CEFs). RSV-infected CEF assume refractile morphology and acquire the ability to grow in soft agar (anchorage-independent growth). These phenotypes unique to cellular transformation are maintained even after cell divisions, because the virus genome is also replicated as a proviral DNA that is integrated into the host chromosome.

One of the breakthroughs in oncogene research was the isolation of unique **temperature-sensitive mutants** of RSV. These mutant RSVs were replication-competent independent of the temperature, but the transformation phenotypes of the infected cells were temperature-dependent. At 37°C, infected cells assume fully transformed morphology, while cells become flatter and assume very similar morphology to that of uninfected CEF at 40°C to 41°C. These observations led to the discovery of **oncogenes** and revealed the following basic ideas about them:

1. RSV encodes a gene responsible for the initiation of cellular transformation (the oncogene now known to be v-src, described above).
2. The oncogene is not necessary for the viral replication.
3. Continuous function of the oncogene is necessary for the maintenance of cellular transformation. (This observation excluded another hypothesis, the “hit and run theory,” in which the virus infection process is supposed to cause irreversible phenotypic changes to the host cells.)

It is also noteworthy that RSV-based avian retrovirus vectors are now widely used as a powerful tool for basic research. By transfecting plasmid DNA carrying a proviral DNA in which the v-src sequence was substituted with an exogenous gene, replication-competent virus vectors expressing the exogenous gene can be recovered from the culture fluid of the transfectants and used to introduce foreign genes into several avian primary cultures, embryos, or adults quite efficiently.

S-Adenosyl-L-Methionine

S-Adenosyl-L-methionine (AdoMet), one of nature's most interesting biological objects, is a sulfonium compound, first described by Cantoni (1), that is synthesized in every cell from L-methionine and adenosine triphosphate (ATP) by *methionine adenosyl transferase* (MAT).

$$\begin{aligned} &L\text{-methionine} + \text{Adenosine} - \mathrm{P}_\alpha\mathrm{P}_\beta\mathrm{P}_\gamma \\ &\rightarrow S\text{-adenosyl-}L\text{-methionine} + \mathrm{P}_\alpha\mathrm{P}_{\beta\mathrm{i}} + \mathrm{P}_{\gamma\mathrm{i}} \end{aligned} \qquad (1)$$

MAT catalyzes a most unusual reaction where ATP serves as the donor of its adenosine moiety, while its triphosphate chain is cleaved nonrandomly by the intrinsic triphosphatase activity of MAT itself, with the a and the b phosphates yielding inorganic pyrophosphate (PP_i) and the g phosphate yielding orthophosphate, P_i (2). It is noteworthy that the triphosphatase activity of MAT is stimulated by AdoMet (3). MAT is found in every cell, and the amino acid sequences of enzymes isolated from species that are separated by more than a billion years in evolutionary divergence (see Divergent Evolution), such as *Escherichia coli* (4) and humans (5, 6), exhibit an extraordinary degree of homology.

Elucidation of the structure of AdoMet as a sulfonium compound and clarification of the mechanism of its biosynthesis revealed that, in the reaction catalyzed by MAT, the chemical energy of the pyrophosphate bonds in ATP is utilized for the biosynthesis of a new class of energy-rich compounds. At physiological pH, the free energy of hydrolysis of a sulfonium compound is equivalent to that of the pyrophosphate bond in ATP (see Adenylate Charge; Free Energy Relationships), and the reaction is essentially irreversible, because it is accompanied by the release of a proton (7).

AdoMet was first identified as the source of methyl groups for biological transmethylation reactions (8), but it was anticipated that the energetic equivalence of the bonds linking the three ligands to the sulfur atom would enable AdoMet to function biologically as a source of either alkyl or adenosyl groups, thereby endowing AdoMet with a unique biochemical versatility (9). Experimentally, Tabor et al. (10, 11) made the important discovery that *S*-adenosylpropylamine, a sulfonium compound resulting from the enzymatic decarboxylation of AdoMet (12), can serve as a donor of propylamine in the synthesis of **spermidine** from putrescine, and of **spermine** from spermidine (11). AdoMet decarboxylase is particularly interesting from the mechanistic point of view, since it has a covalently bound pyruvate that is required for activity (13). AdoMet decarboxylase and the

propylaminetransferases are widely distributed in nature having been found in bacteria, yeast (14), and vertebrates. The synthesis of polyamines is of great biological importance although, quantitatively, it is less significant than biological transmethylation.

The biochemical availability of the groups linked to the sulfonium center of AdoMet was demonstrated by Nishimura et al. (15), who showed that AdoMet can serve as a donor of the aminobutyryl group to S-RNA, and more recently by Knappe (16) and by Reichardt and collaborators, who demonstrated that AdoMet can serve as an adenosine donor (17, 18). Finally Adams and Yang (19, 20) discovered in fruit ripening that AdoMet is cleaved to thiomethyl-adenosine and 1-aminocyclopropane-1-carboxylic acid. This reaction is of great biological significance, in that 1-aminocyclopropane-carboxylic acid is further metabolized to ethylene, a plant hormone that initiates fruit ripening and regulates many aspects of plant growth and development. Thiomethyl-adenosine is cleaved phosphorolytically to adenine and thiomethyl ribose 1-phosphate, in the first step of a salvage pathway that results in the regeneration of methionine (21).

In these reactions, AdoMet functions as a donor of the three ligands attached to the sulfonium atom. In addition, it has been shown that its 6 amino group is utilized in the synthesis of 7,8-diaminopelargonic acid, an intermediate in the synthesis of biotin (22). The mechanism of this reaction is entirely unknown, but it demonstrates the biochemical versatility of AdoMet.

In addition, AdoMet plays a role as a positive or as a negative allosteric effector (see Allostery) in the regulation of the key reactions that affect the metabolism of *homocysteine* . This amino acid can either be remethylated to methionine by 5-methyl-tetrahydrofolate (see Aminopterin, Methotrexate, Trimethoprim, and Folic Acid) or conjugated with serine to yield cystathionine. As an inhibitor of methylene-tetrahydrofolate reductase (23, 24), AdoMet regulates the availability of methyl-tetrahydrofolate, the key intermediate needed for the methylation of homocysteine in the *de novo* synthesis of methionine, whereas as an allosteric effector of cystathionine synthase (25) AdoMet favors commitment of homocysteine to the transulfuration pathway.

Quantitatively, AdoMet's role of serving as a methyl donor predominates. With the exception of the *de novo* synthesis of methionine, AdoMet is the sole source of the methyl groups utilized by a myriad of substrate-specific methyltransferases for the synthesis of a great variety of compounds, such as creatine, phospatidylcholine, yeast sterols, plant alkaloids, fungal and bacterial antibiotics, ubiquinone, triterpenes, lignins, and methyl chloride. AdoMet is also the source of the methyl groups required for the post-translational modification of proteins and nucleic acids.

Inversion of configuration at the stereospecific sulfonium center is a constant feature of the enzymatic methyl group transfer reactions (26-29). This indicates that methyltranferases, and by extrapolation alkyltransferases in general, operate by a mechanism involving direct transfer of the methyl, or alkyl, group from the sulfonium atom to the acceptor substrate, thus precluding a methylated intermediate or a ping-pong mechanism (see Enzymes).

S-Adenosyl-L-homocysteine (AdoHcy) is a product (30) and consequently a competitive inhibitor (31, 32), of all the reactions in which AdoMet participates as a methyl donor. AdoHcy also regulates fruit ripening by inhibiting the formation of ethylene (33) from AdoMet. In eukaryotes and most prokaryotes, the only pathway for the further metabolism of AdoHcy is catalyzed by *adenosylhomocysteine hydrolase* (AdoHcyase), an enzyme that, as first shown by de la Haba and Cantoni (34), catalyzes the reversible hydrolysis of AdoHcy to homocysteine and adenosine. The equilibrium of this reaction lies far in the direction of synthesis; physiologically, however, the reaction proceeds in the hydrolytic direction because homocysteine and adenosine are efficiently removed by *methionine synthase* and by adenosine deaminase, respectively. It was shown by Eloranta (35) that in most tissues the activity of AdoHcyase is 100 to 1000 times greater than the activity of MAT and that consequently the intracellular concentration of AdoHcy is 20 to 100 times smaller than that of AdoMet.

The mechanisms regulating the utilization of AdoMet by many different competing reactions are not well understood. Many methyltransferases have been purified and studied in detail. The kinetics of most are relatively simple, and the physiological activity of these enzymes appears to be related directly to the availability of methyl acceptor substrates, to their affinity (K_m) for AdoMet, and to their inhibition constant (K_i) for AdoHcy. Comparison of these parameters in a number of enzymes revealed that the kinetic features of different methyltransferases can be very different, and they appear to vary independently. This led to the suggestion that the intracellular ratio of AdoMet/AdoHcy, also known as the "*methylation ratio*" ," might play a key role in the regulation of AdoMet utilization (36).

The validity of this hypothesis can be explored by modulating experimentally the intracellular AdoMet/AdoHcy ratio. This ratio will decrease whenever inhibition of the enzymes responsible for the removal of adenosine and/or homocysteine shifts the equilibrium of AdoHcyase towards AdoHcy synthesis, or when removal of AdoHcy generated by methyltransfer reactions is prevented by inhibition of AdoHcyase. It is also possible to take advantage of the broad specificity of AdoHcyase for adenosine by supplying adenosine analogs, like 3-deazaadenosine (DZA), that, being adenosine deaminase-resistant, can be converted to 3DZAHcy (37). Modulation of the AdoMet/AdoHcy ratio or the generation of analogues containing groups other than adenosine in response to the administration of various AdoHcyase inhibitors and/or substrates, indicates that in different tissues the physiological responses may be ascribed to the inhibition of specific methyltransferases (38). These results therefore appear to support the hypothesis that the utilization of AdoMet by various competing reactions is regulated by the intracellular AdoMet/AdoHcy ratio. It should be noted, however, that interpretation of these experiments is complex because the accumulation of AdoHcy and/or of other analogues may also result in an increase in the intracellular level of AdoMet, due to feedback inhibition of AdoMet-dependent methyl or alkyl transferases.

Unexpectedly and most importantly, AdoMet has been found to be a safe and effective agent in the treatment of certain forms of clinical depression (39, 40). While it has been clearly established that administration of AdoMet results in a significant increase in the concentration of AdoMet in the cerebrospinal fluid (CSF) (41), it has not been determined whether the therapeutic effects of AdoMet are related to its ability to function as a methyl donor. In the absence of an animal model for depressive disorders, it has unfortunately been possible only to formulate hypotheses to account for the mode of action of AdoMet in such illnesses.

S1 Nuclease

S1 nuclease is a 32-kDa **nuclease** that is specific for hydrolyzing of single-stranded **RNA** or **DNA**

molecules into 5′-mononucleotides. It is a zinc-requiring metalloprotein that is inactivated by chelating agents, such as EDTA and citrate, and by phosphate concentrations as low as 10 mM. Its enzyme activity is optimal at pH 4.0 to 4.3, halved at pH 4.9, and negligible above pH 6.0. The protein is thermostable (1) and resistant to several **denaturing** agents, such as urea, **SDS**, and **formamide** (2, 3). Digestion of single-stranded DNA is five times more efficient than that of single-stranded RNA, and 75,000 times more efficient than digestion of double-stranded DNA. The low level of cleavage of double-stranded DNA is minimized by increasing the ionic strength to about 0.2 M salt (2, 4-6), whereas it is increased by negative **supercoiling** of the double-helical DNA, UV irradiation, and depurination (3, 6-9).

Because S1 nuclease does not degrade double-stranded DNA or DNA–RNA hybrids, it is used widely to remove single-stranded regions from such duplexes. It is extremely useful for (1) measuring the extent of specific **hybridization** between single strands of DNA and/or RNA; (2) probing the existence of duplex DNA regions; (3) removing **cohesive**, **sticky ends** generated by restriction enzymes from single-stranded protruding DNA; (4) increasing the specificity of nucleic acid hybridization (10); (5) localizing intron, exon boundaries; (6) isolating of duplex regions in single-stranded viral genomes (11, 12); (7) probing strand breaks in duplex DNA molecules (2, 9, 13); (8) cleaving double-stranded regions that have lower duplex stability (14, 15); (9) localizing inverted repeat sequences (14, 15); (10) introducing deletion mutations at **D loop**s in duplex DNA; and (11) mapping the genomic regions involved in interactions with DNA-binding proteins (16). Its most frequent use in mapping DNA sequences that encode RNA is described further here, because it exemplifies the potential and limits of the technique.

1. Mapping DNA sequences that encode RNA

A method for mapping RNA molecules onto the DNA templates from which they were **transcribed** was first described by Berk and Sharp (17, 18). The rationale is illustrated in Figure 1. An RNA transcript R is complementary to *n* nucleotides of the coding strand of a DNA, D. Hybridization of the denatured DNA and RNA leads to a hybrid duplex molecule that has single-stranded overhangs. These are removed by digestion with S1 nuclease. The size of the resulting DNA fragment, that is, the value of *n*, can be determined by subjecting it to electrophoresis on a polyacrylamide gel like those used in DNA sequencing. S1 nuclease does not remove the poly A track or the -cap of eukaryotic messenger RNA when they are base-paired, but the 5′-cap structure, it has been thought, sterically hinders S1 digestion of single-stranded mRNA at the phosphodiester bond adjacent to the first nucleotide (19). When mapping is done with an end-labeled probe, one can determine the polarity and the map position of the RNA on the corresponding DNA sequences (19). This strategy is very useful for mapping the 5′-end of mRNA transcripts, thereby identifying promoter sequences (Fig. 2), and mapping the exons in spliced eukaryotic mRNA (Fig. 3).

Figure 1. Rationale for S1-nuclease mapping

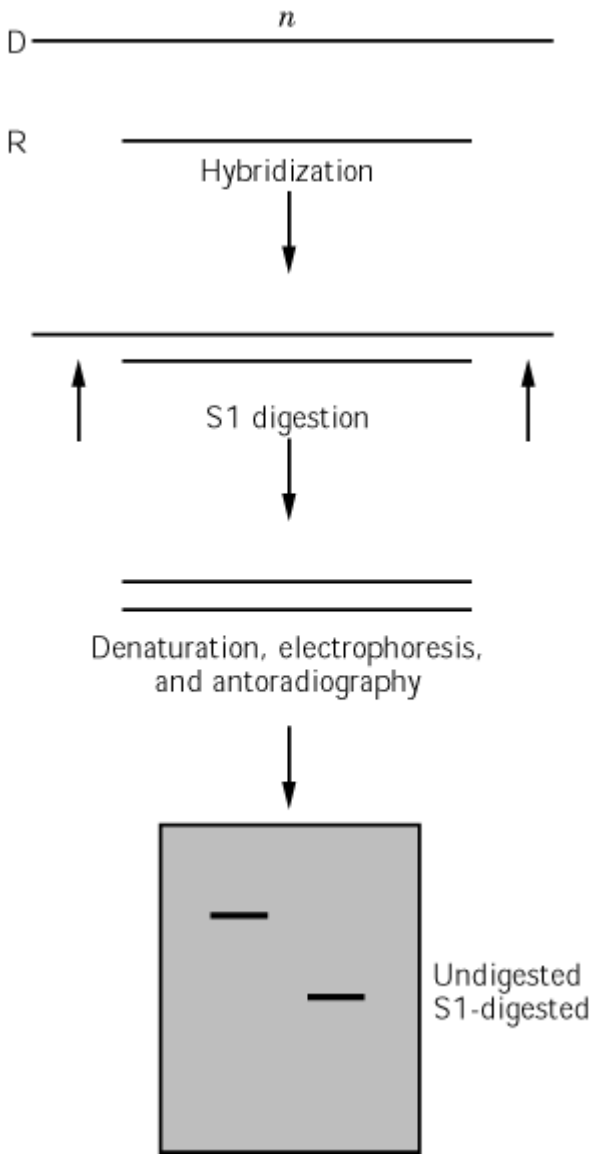

Figure 2. Mapping of 5′-proximal promoter sequences. Promoter sequences localized upstream of the 5′ terminus of eukaryotic spliced RNAs can be mapped after hybridization of RNA preparations with a labeled DNA template (corresponding to the coding strand) that contains the putative promoter sequences (as suggested by DNase hypersensitivity, sequence analysis, etc.). In this example, a DNA fragment XYZ encodes an RNA complementary to sequence YZ. The promoter sequences are localized in X. The 5′-end of the RNA delineates the X-Y junction. The first step consists of preparing a single-stranded, 5′-labeled DNA probe (XY) that contains the 5′-proximal promoter sequences and does not cover the 3-end of the RNA molecule. This conserves the 5′-labeled end (the dark sphere) after S1 digestion. Then, this DNA strand (top) is hybridized to the mRNA (bottom). The DNA and RNA overhangs are digested by S1 nuclease, and hybridized regions are protected. The S1- digested hybrid is denatured before to analysis by denaturing gel electrophoresis. Only the labeled DNA fragments are visualized by autoradiography. Left lane: control undigested labeled probe (XY); right lane: S1-digested sample in which only the protected Y region of labeled probe is protected. The length of the protected DNA fragment (Y) is smaller than that of the initial probe (XY). The difference in size (X) identifies the starting point (5′-end) of the RNA molecule.

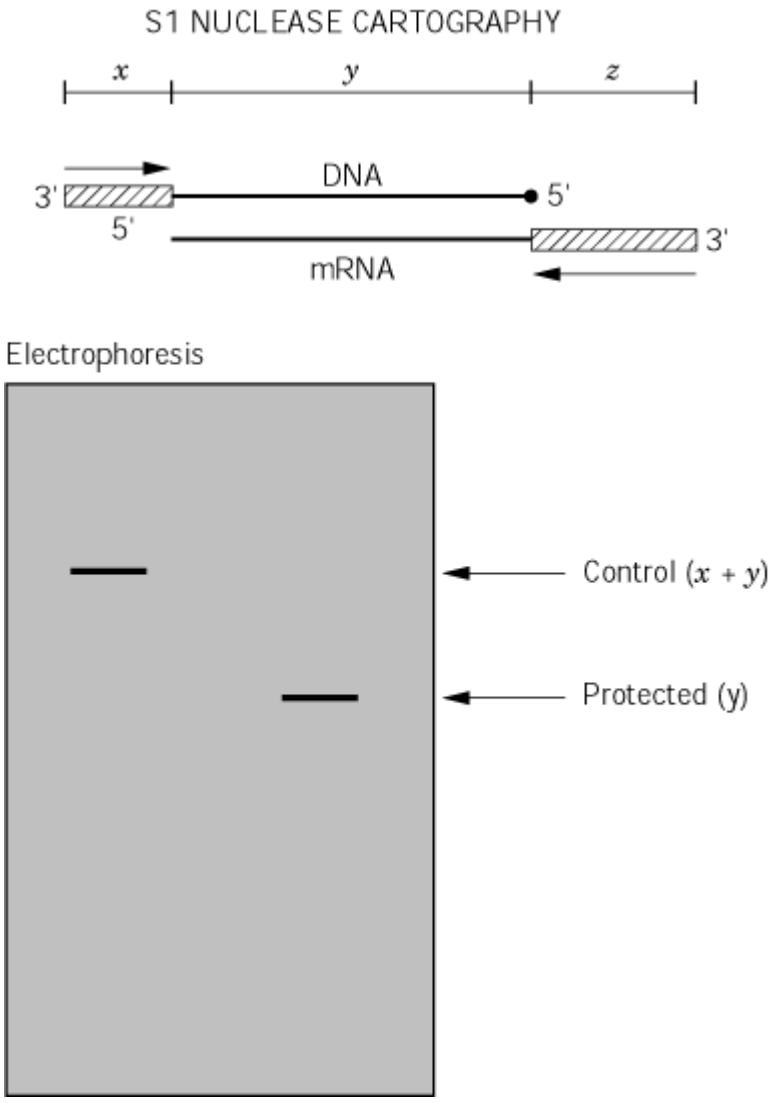

Figure 3. Mapping exon-intron junctions. In this example, a spliced mRNA composed of two exons is hybridized with the complementary, labeled DNA template (coding strand). Following hybridization of complementary sequences, a loop of single-stranded DNA (corresponding to the intron) is generated. Upon incubation of the partial DNA–RNA duplex with S1 nuclease, the free 3′- and 5′-proximal DNA overhangs and the loop are digested. The size of the resulting DNA–RNA hybrid, which contains only exon sequences, is determined by gel electrophoresis in a nondenaturing buffer. Establishing the individual sizes of the two exons requires gel electrophoresis under denaturing conditions to dissociate the hybrid strands. Only the labeled DNA fragments are observed by autoradiography.

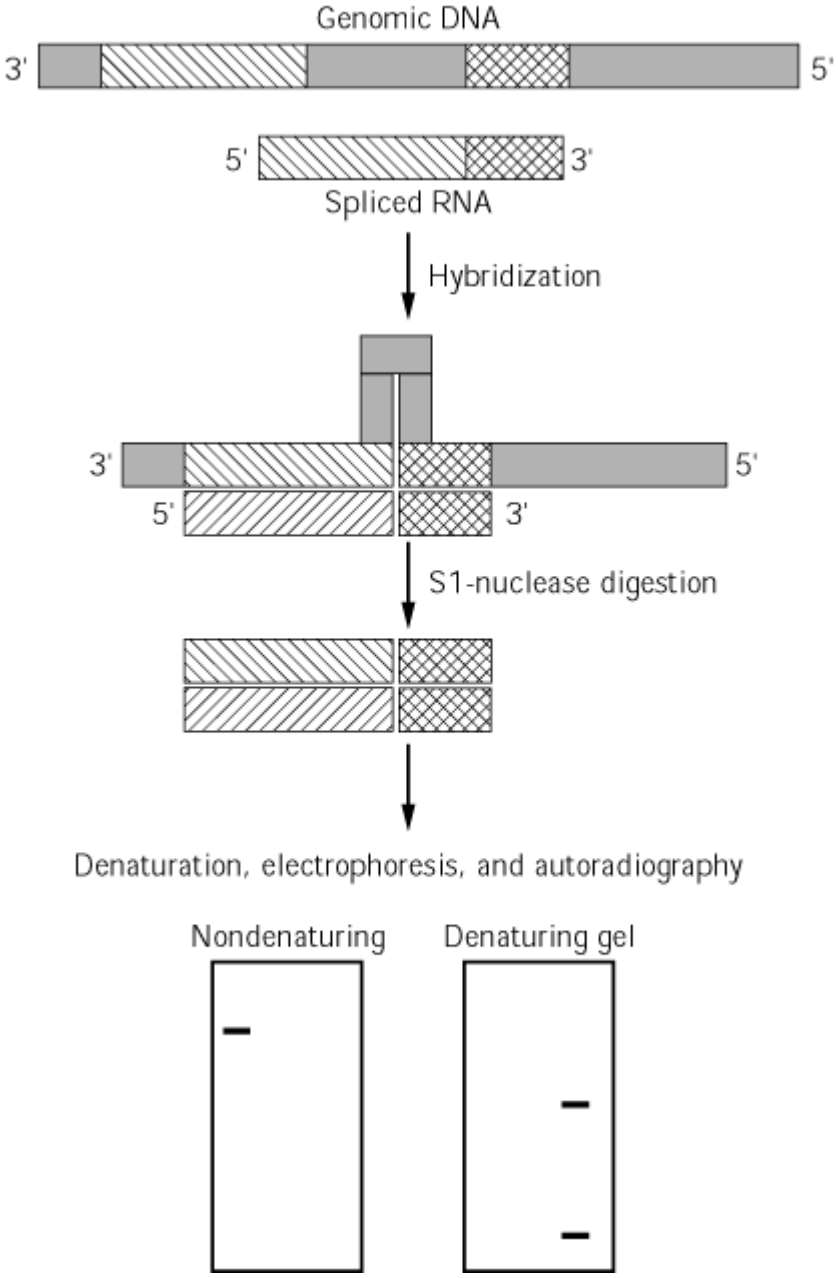

Labeling the DNA fragmant

Determining the size of the S1-resistant DNA fragment relies on measuring a difference in size between the initial DNA probe and the protected segment. The DNA is usually detected specifically by autoradiography, which requires that it be **radiolabeled** and that the label be within the protected segment and survive the S1 nuclease digestion. Cloned DNA fragments are labeled uniformly or specifically at either the 5′- or 3′-termini. Labeling at the 5′-terminus is usually done with **polynucleotide kinase** in the presence of g-^{32}P-ATP, whereas 3′-labeling is achieved with a^{32}P-nucleoside triphosphates and either the **Klenow fragment** of *Escherichia coli* **DNA polymerase** I, T4 polynucleotide kinase, or nucleotidyl terminal transferase.

2. Preparing single-strand templates

The previous labeling methods label both strands, so it is necessary to purify the labeled coding strand or to use conditions that favor hybridization between the RNA and DNA strands (see later). Generally, the best results are obtained with separated strands. After denaturation, the two strands of a DNA fragment may be separated by electrophoresis in polyacrylamide or agarose gels if they

have different base compositions. It is not possible to predict how each strand will migrate, however, so the S1 mapping must be done with each strand. Hybridization of polyUG to the denatured strands may accentuate differences in their electrophoretic mobilities (20, 21). The double-stranded DNA fragment is digested asymmetrically from its two ends, so that the two single strands have different mobilities after denaturation (see Fig. 3). Alternatively, single-stranded DNA may be isolated by cloning in filamentous **bacteriophage** or plasmid vectors based upon such phage (see DNA Sequencing).

2.1. Use of Double-Stranded DNA Fragments

The rate of hybridization of RNA molecules to single strands of DNA is similar to that of DNA single-strand renaturation (22, 23). Therefore, the rate of hybridization is maximal in the presence of a high salt concentration (1 M NaCl) and a temperature corresponding to the **melting temperature** (T_m) of 25 to 30°C. In practice, hybridization is often done in the presence of formamide to decrease the T_m and to hybridize at a lower temperature (24, 25). The melting temperature of duplex DNA molecules can be calculated (26) from the base composition, the ionic strength, and the formamide concentration by using the equation

$$T_m(°C) = 81.5 + 0.5(\%G + C) + 16.6\log[Na^+] - 0.6(\%\text{formamide}) \quad (1)$$

At high concentrations of formamide (70 to 80%), the T_m of a DNA-DNA duplex is 5 to 10°C lower than the T_m of the corresponding RNA–DNA hybrid (26). Under such conditions, a hybridization temperature between these two T_m values considerably favors association of the RNA with its coding DNA strand. Most RNA–DNA hybridizations are done at temperatures between 40 and 60°C with a buffer that provides constant pH and ionic strength, such as 0.04 M NaCl and 1 mM EDTA. To establish the optimal conditions for hybridization, the T_m of the DNA duplex used should be determined experimentally. Then, hybridization with the RNA is done at a temperature 2 to 4°C higher. The best results are usually obtained when excess DNA is used. Under such conditions, RNA–DNA hybridization is nearly complete in 3 hours with adenovirus 2 DNA (35 kbp) at a concentration of 10 µg/mL (27). Extrapolating, it can be predicted that nearly complete hybridization of a DNA that has *n* kilobases will be obtained under similar conditions in 3 hours at a DNA concentration of (*n*/3.5) mg/mL.

In practice, the labeled, double-stranded DNA and the RNA molecule are mixed and reextracted together once. After resuspending the pellet in a “double-strand hybridization buffer” of 50 mM PIPES (pH 6.4), 1 mM EDTA, 0.4 M NaCl, 80% formamide, the mixture is incubated at 65°C to denature the nucleic acids. Then, it is transferred to the appropriate temperature for hybridization.

2.2. Use of Single-Stranded DNA Fragments

The probe and the target single-stranded DNA are resuspended in a “single-strand hybridization buffer” of 0.3 M PIPES (pH 6.4), 30 mM EDTA, 2.5 M NaCl, and incubated as before.

Salt Bridge (Salt Linkage, Ionic Bond)

A salt bridge is a pair of ionized groups with opposite charge that are in very close proximity in a macromolecule and contact each other at their **van der Waals radii**. The ion pair is stabilized by attractive electrostatic interaction and may even have some hydrogen bond character. Intra- and intermolecular salt bridges are frequently observed in proteins (1) and at protein–protein and protein–nucleic acid interfaces (2).

Saltatory DNA Replication

Particles of **SV40 virus** are produced in **permissive** simian cells. Infection of nonpermissive rodent cells by SV40 results in integration of the viral genome into the host chromosome. The transformed rodent cells have no free SV40 genomes, but SV40 genomes are produced when these nonpermissive cells are fused with permissive simian cells. The chromosomes from the monkey cells provide replicative functions not present in the rodent cells, making SV40 DNA replication possible in the heterokaryons. Repeated rounds of initiation of DNA replication from the integrated SV40 replication origins result in polytenization of that region (see Polytene Chromosome), which may liberate a linear DNA duplex containing the integrated SV40 genome. The liberated DNA will then **recombine** with itself to form a circular viral genome. In cell lines with tandem duplications of the integrated SV40 DNA, the efficiency of infectious virus formation is increased because of the terminal duplication of the liberated linear DNA. In the absence of tandem duplication, cyclization by nonhomologous recombination may form mutants with the deletion of viral DNA or insertion of host DNA (1).

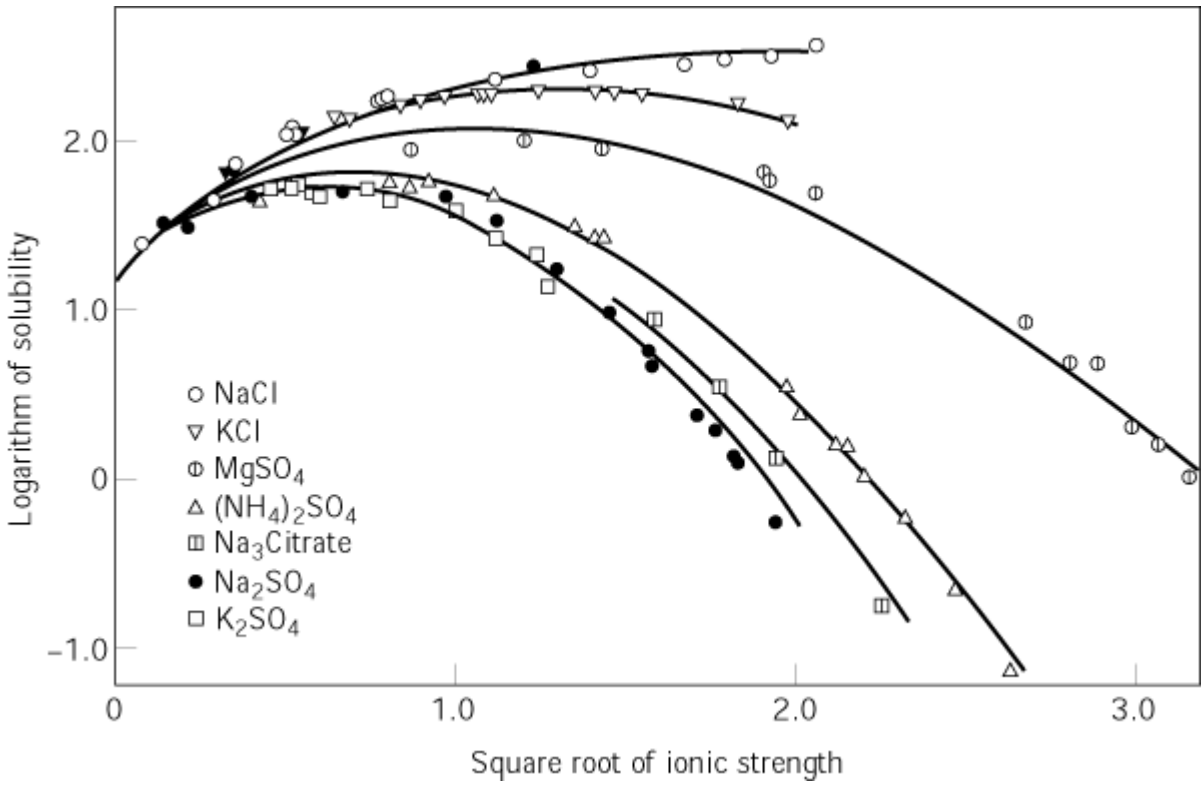
Salting In, Salting Out

The effect of salts on protein solubility is described by the salting in, salting out effect (1): The dependence of the solubility of a protein on salt concentration is one in which, for any salt, at low salt concentration the solubility of a protein increases; then, after the protein passes a point of maximal solubility, the further addition of salt reduces its solubility (see Precipitation). Typical patterns are shown in Figure 1 (2).

Figure 1. The solubility of carboxyhemoglobin in various electrolytes at 25°C. (Reprinted from (2) with permission of The American Society of Biological Chemists.)



This complex dependence has been decomposed into two contributions (3). At low salt concentration, proteins are salted in; in other words, their solubility increases. For any protein, this is independent of the nature of the salt and is simply the consequence of the fact that proteins carry positively and negatively charged groups on their accessible surface. These are surrounded by an atmosphere of the ions of the salt, which increases the solubility according to the simple *Debye–Hückel equation*. Thus, if s_s and s_w are the solubilities of the protein in salt solution and pure water, respectively, the salting in is described by the following equation:

$$\log(s_s/s_w) \simeq Z^2 \ell I^{\frac{1}{2}} \qquad (1)$$

where Z is the net charge of the protein, I its ionic strength, and ℓ a combination of constants.

At high salt concentration (approximately > 0.5 M), salting in becomes saturated, and the effect of salting out takes over, ie, the protein solubility decreases, following the law that the logarithm of the solubility (S, usually given in units of grams of protein per 1000 cm^3 of solvent) is linear in salt concentration expressed as ionic strength:

$$\log S = \beta - K_s I \qquad (2)$$

where b and K_s are empirical constants. The parameter K_s, called the salting out constant, is characteristic of the particular salt. The order of salting out effectiveness is close to invariant for most proteins and follows the Hofmeister series (2). The magnitude of K_s is defined by the preferential interaction of the particular salt with the protein, as

$$K_s = (1/2.303RT)(\partial\mu_{pr}/\partial m_s)_{T,P,m_{pr}} \quad (3)$$

where m_s is the molal concentration of the salt (3). Salts that induce preferential hydration (*negative* binding in equilibrium dialysis; see Binding) reduce the solubility of proteins. Conversely, a solvent system that shows preferential binding increases the solubility of proteins.

Salvage Pathways To Nucleotide Biosynthesis

Most **nucleotide** biosynthesis in most cells occurs via the nearly ubiquitous *de novo* synthetic pathways, starting from amino acids and their derivatives (see Purine Ribonucleotide Metabolism and Pyrimidine Ribonucleotide Metabolism). However, most cells possess capabilities for taking up nucleosides and nucleobases and converting them to nucleotides. Because these processes involve reutilization of previously synthesized purine and pyrimidine rings, they are called *salvage pathways*. These pathways are much shorter and simpler than the *de novo* pathways. On the other hand, there is much more variability from organism to organism, and from tissue to tissue in the same organism, in salvage synthetic capabilities. The metabolic importance of salvage pathways has come to light, first, along with the realization of the serious consequences of hereditary deficiencies in certain salvage enzymes and, second, with the many ways in which salvage pathways are being exploited to create or enhance the effectiveness of chemotherapy against a variety of diseases.

1. Transport of Nucleosides and Nucleobases

Substrates for salvage pathways can come from intracellular nucleic acid degradation (see DNA Degradation In Vivo). For most cells, however, salvage precursors are derived from the extracellular environment. An extreme example is protozoan parasites, which derive all their nucleic acid precursors from salvage substrates in the blood of infected organisms. In fact, these parasites have evolved to the extent that they completely lack *de novo* pathways and are totally dependent on salvage (1, 2); development of specific salvage inhibitors now constitutes one of the most active research areas of biochemical parasitology.

Nucleosides are hydrophilic molecules and do not readily diffuse through membranes; to an extent, the same is true for nucleobases. Thus, most cells contain specific **transporter** systems, which take up these molecules by **facilitated diffusion** (3, 4). In recent years, however, concentrative transport systems have been described, especially for nucleosides. These systems depend on sodium and involve cotransport of the nucleoside with Na^+. Most animal cells contain a broad-specificity nucleoside transporter that functions by facilitated diffusion, the active transport systems being limited primarily to specialized cells, for example, those that take up and use adenosine as a physiological regulator. The nucleobase transport systems are less well characterized, and the

question of whether cells contain multiple base transporters or a single broad-specificity transporter has not yet been resolved.

2. Salvage Pathways

Nucleobases are anabolized by phosphoribosyltransferases , which use 5-phosphoribosyl-1-pyrophosphate (PRPP),

$$\text{Base} + \text{PRPP} \rightleftharpoons \text{Ribonucleoside monophosphate} + \text{pyrophosphate}$$

while nucleosides are anabolized primarily by kinases.

$$\text{Ribonucleoside} + \text{ATP} \longrightarrow \text{Ribonucleoside monophosphate} + \text{ADP}$$

$$\text{Deoxyribonucleoside} + \text{ATP} \longrightarrow \text{Deoxyribonucleoside monophosphate} + \text{ADP}$$

Nucleosides can also be salvaged by a nucleoside phosphorylase followed by a phosphoribosyltransferase.

$$\text{Nucleoside} + \text{P}_\text{i} \rightleftharpoons \text{Base} + \text{ribose} - 1 - \text{phosphate}$$

$$\text{Base} + \text{PRPP} \rightleftharpoons \text{rNMP}$$

In principle, this route could be used for nucleotide synthesis, starting with a base, given that nucleoside phosphorylases are readily reversible. However, these enzymes generally act within cells in the direction of nucleoside degradation.

Salvage enzymes vary considerably in tissue distribution and specificity. Mammalian cells salvage purines primarily at the free base level through the action of two phosphoribosyltransferases: hypoxanthine guanine phosphoribosyltransferase (HGPRT), which converts hypoxanthine and guanine to inosinic acid (IMP) and GMP, respectively; and adenine phosphoribosyltransferase (APRT), which specifically converts adenine to AMP. HGPRT is the enzyme missing in cells of males suffering from Lesch–Nyhan syndrome (see Purine Ribonucleotide Metabolism). Pyrimidines, by contrast, are more likely to be salvaged at the nucleoside level. In the *de novo* pathway, orotic acid is converted to orotidylate by a phosphoribosyltransferase, but comparable pyrimidine salvage enzymes are of extremely limited distribution.

Protozoa that rely on nucleotide salvage pathways, particularly for purines, bear a distinctive set of enzymes— nucleoside hydrolases. These organisms take up purine nucleosides from the blood of infected animals, for example, and then hydrolyze the nucleoside to ribose plus the base; the base is then salvaged by a phosphoribosyltransferase (5). Because the nucleoside hydrolases are quite distinct from known proteins, they are being explored as targets for drugs that would specifically inhibit the growth of an infecting parasite by blocking this salvage route, which is essential for the parasite but not the host.

As discussed more thoroughly below, nucleoside and base analogues are widely used as antiviral, antimicrobial, and anticancer drugs. Because of the interest in developing or improving the

effectiveness of drugs that act as DNA synthesis inhibitors, there has been particular emphasis on the deoxyribonucleoside kinases (6). Four such enzymes, with overlapping specificities, are found in human cells. Properties and subcellular distributions of these enzymes are summarized in Table 1. It is of particular interest that deoxycytidine kinase (dCK) is also the principal enzyme for utilization of purine deoxyribonucleosides (the K_m values are much higher for the purines than for deoxycytidine; hence the name of the enzyme).

Table 1. Properties of the Human Deoxyribonucleoside Kinases

Enzyme Cycle Regulation	Natural Substrates	Intracellular Distribution	Cell Cycle Regulation
Deoxycytidine kinase (dCK)	dCyd, dAdo, dGuo	Cytosol	Constitutive
Thymidine kinase 1 (TK1)	dThd, dUrd	Cytosol	S-phase-specific
Thymidine kinase 2 (TK2)	dThd, dUrd, dCyd	Mitochondria	Constitutive
Deoxyguanosine kinase (dGK)	dGuo, dAdo, dIno	Mitochondria[0]	Constitutive

Source: Arnér and Eriksson (6)

A key to understanding some clinical disorders is knowledge of the tissue distribution of salvage enzymes. For example, the immunodeficiency state that results from adenosine deaminase deficiency can be related to this factor (see Purine Ribonucleotide Metabolism). Most or all tissues in an affected individual accumulate adenosine and deoxyadenosine as a result of the genetic block to purine catabolism. Nucleoside salvage enzymes are particularly active in the reticuloendothelial system, where apoptosis leads to degradation and reutilization of cell components, including nucleic acids. Thus, blood cells accumulate excessive amounts of ATP, and in particular, dATP, which interferes with white cell proliferation as part of the immune response, through its inhibition of ribonucleotide reductase.

A salvage enzyme of considerable interest is the family of thymidine kinases specified by herpes viruses. As exemplified by the herpes simplex thymidine kinase, these enzymes have two distinctive properties. First, they are bifunctional enzymes, with thymidylate kinase activity as well. Thus, the enzyme is evidently designed to catalyze two sequential reactions. Second, the nucleoside kinase activity has much broader substrate specificity than most cellular nucleoside kinases. As discussed below, antiviral chemotherapeutic strategies exploit this distinctive property.

3. Salvage Enzymes as Selectable Markers

Because nearly all cells possess *de novo* nucleotide synthetic capabilities, the salvage enzymes are usually not required for cell viability. In addition, a large number of nucleobase and nucleoside

antimetabolites are available, most of them inhibitors of specific enzymes (see Nucleotides, Nucleosides, And Nucleobases). These factors create favorable conditions for the use of salvage enzymes as selectable genetic markers, ie, genetic characteristics that promote the selective survival or growth of desired cell types. For example, the mammalian enzyme encoding HGPRT is widely used as a selectable marker in genetic analysis. 6-Thioguanine is metabolized by HGPRT to give the thiol analogue of inosinic acid, which is toxic. Cells lacking HGPRT can be selected for because they grow in 6-thioguanine-containing medium, while other cells are killed. Hence, one can estimate mutation rates by culturing wild-type cells in the presence of thioguanine and enumerating the cells that grow. Another advantage of this gene for genetic analysis is that it is carried on the X-chromosome. Thus, in male-derived cell lines, only one mutation, rather than two independent events is required to give the resistant phenotype.

A comparable selectable marker is the gene encoding thymidine kinase. 5-Bromodeoxyuridine is anabolized similarly to thymidine;

$$\text{BrdUrd} \rightarrow \text{BrdIMP} \rightarrow \text{BrdUDP} \rightarrow \text{Brd UTP} \rightarrow \text{DNA} \qquad (1)$$

However, incorporation of bromodeoxyuridine into DNA is a lethal event. Thus, thymidine kinase deficiency leads to a BrdUrd-resistant phenotype. Because most large DNA viruses encode a thymidine kinase, this is a useful system for manipulating viral genes, for example, the use of vaccinia virus as a vector in the generation of multivalent vaccines (7).

On the other hand, one can select for the presence of active salvage enzymes. The best example is the use of "HAT medium" in **somatic cell** genetic analysis and in preparing monoclonal antibodies. These techniques involve fusing cells of different origins and culturing in HAT medium to select for those cells that have undergone fusion. HAT is an acronym for the medium's constituents,—hypoxanthine, aminopterin, and thymidine. Aminopterin inhibits dihydrofolate reductase, blocking the synthesis of tetrahydrofolate needed for *de novo* synthesis of purine nucleotides and thymidine nucleotides. Thus, cells can grow in HAT medium only if they express active thymidine kinase and HGPRT, for salvage synthesis of thymidine and purine nucleotides, respectively. In monoclonal antibody production, one of the cell lines to be fused lacks thymidine kinase, and the other lacks HGPRT. Thus, only cells resulting from a fusion event have functional copies of both enzymes and can grow.

A final example relates to the use of a selectable marker to force expression of a nonselected marker. For cloning into expression systems in mammalian cells, one often incorporates into the cloning vector the *Escherichia coli xpt* gene, which encodes a distinctive phosphoribosyltransferase that acts on xanthine and guanine. During and after transformation of cells with the recombinant DNA, the cells are cultured in the presence of mycophenolic acid, which blocks *de novo* guanine nucleotide synthesis by inhibiting IMP dehydrogenase, the enzyme that converts IMP to XMP (which would then be converted to GMP). Thus, the only cells that can grow are those that have taken up and expressed the *xpt* gene, which bypasses this metabolic block. Being carried on the same vector, the gene of interest is also cloned and/or expressed, even though its expression was not directly selected for.

4. Salvage Enzymes and Molecular Pharmacology

A large number of antiviral, antibacterial, antiparasitic, and anticancer drugs act by inhibiting or otherwise manipulating pathways in nucleotide metabolism and thereby interfering with nucleic acid synthesis. Several examples are cited in Nucleotides, nucleosides, and nucleobases. In most cases, the active species is a nucleotide. Because nucleotide molecules are charged, and because specific transport systems for nucleotides don't exist, these molecules penetrate membranes poorly, if at all.

Therefore, in order to generate a therapeutically effective nucleotide intracellularly, its precursor must be administered extracellularly as a nucleobase or nucleoside analogue. Effective use of such drugs demands extensive understanding of salvage pathways in the target cell, subcellular distribution of the enzymes involved, degradative enzymes that might compete with the pathway leading to the desired nucleotide analogue, levels of the target enzyme, and cell-cycle regulation of all the enzymes involved (8).

As an example of the factors involved, consider the fluorinated pyrimidines, 5-fluorouracil (FUra) and 5-fluorodeoxyuridine (FdUrd), analogues used for four decades in treating various cancers. It was established in 1958 (9) that these drugs are converted *in vivo* to 5-fluorodeoxyuridine monophosphate (FdUMP), an analogue of deoxyuridine monophosphate, the substrate for thymidylate synthase (Fig. 1; see Deoxyribonucleotide Biosynthesis And Degradation), and that FdUMP is a potent inhibitor of thymidylate synthase and, hence of DNA replication. Figure 1 shows also the metabolic pathways that both activate these analogues and divert them from their desired endpoint (10). From the figure, one can see that coadministration with FdUrd of a thymidine phosphorylase inhibitor should increase the effectiveness of the analogue by blocking its catabolism. Note that there are multiple routes for activation of FUra; note also that FUra can enter pools of RNA precursors which, in principle, could limit its selectivity by diminishing the specificity of its effect against DNA synthesis. There is evidence, however, that, in some tumors, the effectiveness of FUra actually depends in part on its incorporation into RNA, where it stimulates translational miscoding.

Figure 1. Metabolism of fluorinated pyrimidines by salvage and other enzymes. dR-P is deoxyribose 5′-phosphate, dR-1-P deoxyribose-1-phosphate, and R-1-P ribose-1-phosphate. Enzymes are 1, thymidylate synthase; 2, dihydrofolate reductase; 3, serine transhydroxymethylase; 4, thymidine kinase; 5, thymidine phosphorylase; 6, uridine phosphorylase; 7, uridine kinase; 8, uridylate kinase; 9, nucleoside diphosphate kinase; 10, ribonucleoside diphosphate reductase; 11, RNA polymerase.

Sarkosyl

Sodium *N*-lauroylsarcosine, or Sarkosyl, is a detergent that is structurally related to **SDS**, except that Sarkosyl has an additional polar and rigid peptide bond linkage within the **hydrophobic** backbone (Fig. 1). Such rigidity added to the N-terminus of the hydrophobic chain could lead to a decrease in its ability to be inserted freely into hydrophobic membrane bilayers and proteins. This could explain why Sarkosyl is milder than SDS in its ability to **denature** and disrupt membrane and protein structures. Because of a similar difference in side-chain structure, the bile acid detergent CHAPS is rendered milder than the strongly denaturing sodium cholate, which inactivates integral membrane proteins, such as the serotonin 1A receptor (1). The relatively mild nature of Sarkosyl has been exploited at least in a few cases. Important examples include the purification of *Escherichia coli* **RNA polymerase** sigma factors by solubilizing inclusion bodies (2) and the solubilization and purification of the scrapie protein, the prion PrP^{Sc} (3, 4). Although comparison of the structural features of Sarkosyl with those of other detergents suggests that it might be effective in solubilizing functionally active membrane proteins, the major use of Sarkosyl has been to isolate **DNA** and **RNA**. The principal reason for this is that Sarkosyl is highly efficient in dissociating nucleosomes and ribosomes (5). The detergent also denatures **nucleic acids** and inhibits certain enzymes, such as **deoxyribonucleases** and **ribonucleases**, which could degrade these molecules.

Satellite DNA

The regions adjacent to the centromeres in chromosomes of higher **eukaryotes** are composed of very long blocks of highly repetitive DNA, in which simple sequences are repeated a thousand times or more. Often, these repeated sequences have a base composition very different from that of the remainder of the DNA, so they can be separated from the bulk DNA by cesium chloride density gradient centrifugation of slightly fragmented DNA. For this reason, such DNA is referred to as *satellite DNA* . The localization of satellite DNA near the centromeres allows localization of the centromeres by **in situ** *hybridization* and autoradiography in squashed **metaphase** cells, using **radiolabeled** RNA copies of the satellite sequence (2).

Different satellites can occur in the same species. For example, **Drosophila** *virilis* possesses three centromeric satellites (1) whose sequences are highly related. None of these satellite sequences is a pure repeat of the basic consensus sequence. The reason behind the evolution of several sequences is not clear.

Usually, satellite DNA is not transcribed into messenger RNA, as it lacks **promoter** sites where RNA chains can be initiated. **DNA polymerase** must recognize the satellite sequences, however, because the DNA from centromeres is replicated at the same rate as the rest of the chromosomal DNA. It is assumed that the satellite sequences bind particular proteins essential for the centromere's function of holding the daughter chromatids together during metaphase, such as playing a role in the assembly of the kinetochores responsible for their attachment to the mitotic spindle or guiding the topoisomerase that eventually separates the sister chromatids (see DNA Topology). Thus satellite sequences are examples of structural rather than genetic regions of DNA.

Satellites

Satellites are subviral agents that depend for their replication on co-infection of a host cell with a helper virus (HV). The **nucleotide sequences** of the nucleic acids of satellites are substantially different from those of their HV or their hosts, although some satellites may share with their HV short sequences, often at the termini. Thus, satellites are different from defective interfering particles or RNAs, which are wholly derived from the genome of the HV. One chimeric replicon with sequences derived from both a satellite and a HV has been described (1). The relationship between helper virus and satellite is usually specific in that only one HV species, or a group of related species, can sustain the replication of a particular satellite species; on the other hand, a particular HV may sustain the replication of different, unrelated satellites. There is no correlation between the taxonomic relationships of satellites and those of their HVs. Thus, satellitism may have evolved independently several times. The presence of the satellite may modulate the level of accumulation and the pathogenicity of the HV. Because of these properties, satellites can be considered as molecular parasites of their HVs. Satellites are not needed for the normal multiplication of HVs, but there are satellite-like RNA molecules that may be necessary for completion of the HV's life cycle under natural conditions. Examples are the satellite-like single-stranded RNAs associated with groundnut rosette umbravirus or with beet necrotic yellow vein benyvirus, which are needed for transmission of the HV by their respective aphid or fungal vector.

Satellites are a heterogeneous group, rather than a single taxonomic unit. There are satellites that encode proteins that are expressed *in vivo*, and others that are noncoding. When the encoded protein is a structural protein that encapsidates the satellite nucleic acid, the satellite is called a *satellite virus* . Satellite viruses are found as distinct nucleoprotein components in preparations of the HV. The first satellite virus was described in 1962 associated with tobacco necrosis virus (TNV) (2). Satellites that do not encode their structural proteins are called *satellite nucleic acids*. The first satellite nucleic acid was described associated with tobacco ringspot nepovirus in 1969 (3). The different groups of satellite viruses and nucleic acids, and their abbreviations, are listed in Table 1.

Table 1. Satellites and Their Types, with Indication of Size of Nucleic Acid and Accession Number of Typical Sequence Variants[a]

Satellite	Size (nt)	Accession
Viruses		
Subgroup I		
Tobacco necrosis satellite virus (STNV)	1239	J02399
Panicum mosaic satellite virus (SPMV)	826	M17182
St. Augustine decline satellite virus (SSADV)	824	L10083
Tobacco mosaic satellite virus (STMV)	1058	M24782
Maize white line mosaic satellite virus (SMWLMV)	1168	M55012
Subgroup II		
Chronic bee-paralysis associated satellite virus (CPVA)	~ 1100	NR
Nucleic acids		
ssRNA satellites		
Large satRNAs with messenger properties		

Arabis mosaic nepovirus (ArMV) large sat-RNA	1104	D00664
Chicory yellow mottle nepovirus (CYMV) large sat-RNA	1165	D00686
Grapevine bulgarian latent nepovirus (GBLV) sat-RNA	~ 1500	NR
Grapevine fanleaf nepovirus (GFLV) sat-RNA	1114	D00442
Myrobalan latent ringspot nepovirus (MLRV) sat-RNA	~ 1400	NR
Strawberry latent ringspot nepovirus (SLRV) sat-RNA	1118	X69826
Tomato black ring nepovirus (TBRV) sat-RNA	1374	X05689
Bamboo mosaic potexvirus (BaMV) sat-RNA	836	L22762
Small linear satellite RNAs		
Turnip crinkle carmovirus (TCV) sat-RNA	230	X12749
	355[b]	X12750
Cucumber mosaic cucumovirus (CMV) sat-RNA	335	M18872
Peanut stunt cucumovirus (PSV) PSV sat-RNA	393	Z98198
Pea enation mosaic enamovirus (PEMV) sat-RNA	717	U03564
Tobacco necrosis necrovirus (TNV) small sat-RNA	620	NR
Chicory yellow mottle nepovirus (CYMV) small sat-RNA	457	D00721
Artichoke mottled crinkle tombusvirus (AMCV)sat-RNA	~700	NR

Solanum nodiflorum mottle sobemovirus (SNMV) sat-RNA	377	J02386
Subterranean clover mottle sobemovirus (SCMV) sat-RNA	332	M33000
Velvet tobacco mottle sobemovirus (VTMoV) sat-RNA	366	J02439
dsRNA satellites		
M satellite of *Saccharomyces cerevisiae* virus L-A	1801	U78817
Satellite of *Trichomonas vaginalis* virus T1	497	U15991
ssDNA satellites		
Tomato leaf curl geminivirus (TLCV) sat-DNA	682	U74627

[a] nt, nucleotides; ss, single-stranded; ds, double-stranded; NR, not reported.

[b] A chimeric replicon with sequences derived from both satellite and helper virus.

1. Satellite viruses

All known satellite viruses have a single-stranded RNA of 800 to 1200 nucleotides. In addition to the open reading frame (ORF) encoding their coat protein, some satellite viruses contain further ORFs; it remains unclear if the encoded products have any role *in vivo* (4). The structure of their isometric,

17-nm diameter particles, built of 60 protein subunits, differs from that of their HV. The particle structures of STNV, STMV and SPMV (see Table 1) have been determined at high resolution by X-ray crystallography (5). In spite of the different structures of the TNV virus particle and of the coat protein of its satellite STNV, both are able to bind specifically to zoospores of the vector fungus *Olpidium brassicae*.

Best-characterized are the satellites of the tobacco necrosis satellite virus (STNV) subgroup. The 1000- to 1200-nucleotide RNA of STNV has no methylated cap structure or genome-linked protein (Vpg protein) at its 5′-end. Unlike most plant virus RNAs, it has a phosphorylated 5′-terminus. Interference with the accumulation of the TNV has been described for STNV. The particles of STNV may also contain a noncoding satellite RNA of about 620 nucleotides, which depends on TNV for its replication and on STNV for its encapsidation. This is a good example of the complexity of the dependence relationships in satellitism.

Satellite viruses are also found associated with chronic bee-paralysis virus (CPV) (6). Its RNA consists of three species, about 1.1 kb, which can be encapsidated in 17-nm isometric particles built of coat proteins encoded by the satellite or by CPV. The satellite interferes with CPV replication.

2. Satellite nucleic acids

Satellite nucleic acids are single-stranded RNA, single-stranded DNA, or double-stranded RNA satellites associated to viruses of the same type of nucleic acid. Most of the characterized satellites are associated with plant viruses, and most are single-stranded RNA.

2.1. Single-Stranded RNA Satellites

These are classified into three subgroups.

(i) Subgroup I includes *satellites with messenger properties* . The RNA molecules are between 0.8 and 1.5 kb in size. These satellites encode nonstructural proteins that are expressed *in vivo*. The most studied satellites of this subgroup are those associated with nepoviruses. Large single-strand RNA satellites of nepoviruses have a 3′-terminal Poly Asequence and a 5′-terminal Vpg protein that, in the analyzed instances, is indistinguishable from that on the HV genome and, therefore, is encoded by it. The encoded nonstructural proteins of different satellite RNAs share some conserved domains, and in some cases have been shown to be needed for replication of the satellite RNA. It may be speculated that these proteins are needed to adapt the virus replication complex to the satellite RNA. For most large satellite RNAs of nepoviruses, an effect on the accumulation or pathogenicity of the HV has not been shown. This may depend on the experimental system: the large satellite RNA of ArMV was shown to modulate the symptoms of the HV, depending on the species of host plant. Another satellite RNA in this subgroup has been found associated with bamboo mosaic potexvirus. The encoded nonstructural protein is not essential for satellite replication (7). Interestingly, this protein shares significant sequence similarity with the structural protein of the satellite virus of PMV, suggesting an evolutionary relationship between the satellite virus and the satellite RNA.

(ii) The second subgroup of single-stranded RNA satellites are *small, linear RNAs*, of less than 800 nucleotides and with no circular forms. Although they may contain potential ORFs, and *in vitro* translation products have been described for some variants of the satellite RNA of CMV, evidence is strong that these molecules are noncoding RNAs. Thus, their biological functions must depend on the RNA structure, which would mediate the direct interaction of the satellite RNA with components of the HV and/or the host plant. Experimental analyses of secondary structure have been done for the satellite RNAs of CMV and TCV, and there is evidence that several have highly-paired secondary structures. This may account for the high survivability of satellite RNAs *in vivo* and *in vitro*, as well as for their high infectivity. Most satellite RNAs in this subgroup modify the symptoms induced by the HV. The most frequent modification is symptom attenuation, but modulation to more severe symptoms (eg intense chlorosis or necrosis) also occurs. Symptom modulation depends on the triple interaction between the strain of satellite RNA, strain of HV, and species or genotype of the host

plant. For the satellite RNA of CMV, there has been an extensive analysis of symptom determinants in the satellite RNA. For the satellite RNAs of CMV and TCV, the HV and host determinants have been identified as well. The presence of the satellite RNA often results in depression of the accumulation of the HV, but the relationship between this and the attenuation of symptoms is unclear: depression of HV accumulation also occurs when the interaction between satellite RNA and HV results in symptom exacerbation. Also, for some combinations of satellite RNA and HV, symptom attenuation is not accompanied by a reduction in the accumulation of the HV. The satellite RNA may also interfere with movement of the HV within the infected plant, as shown for the satellite RNA of TCV (8).

(iii) The third subgroup of single-stranded RNA satellites are *small circular RNAs*. These satellite RNAs actually occur as both circular and linear molecules. The HV may encapsidate circular forms (for sobemoviruses) or linear forms (for nepoviruses and luteoviruses). In both cases, replication is through a rolling circle mechanism (see Rolling Circle DNA Replication). Small circular single-stranded RNA satellites interfere with the accumulation and symptoms induced by the HV. These satellites have been described under the heading Virusoids.

The single-stranded RNA satellites may replicate by different mechanisms than their HV. Thus, the replication machinery of the HV must be adapted to the replication of the satellite RNA. Satellite-encoded factors (for the large, encoding satellites) or unidentified host factors may play a role in modifying the virus replication complex. It is to be noted that for those systems that have been analyzed in detail, the efficiency of satellite RNA replication depends on the HV, as well as on the host plant.

Because of the attenuation of the symptoms of the HV, single-stranded RNA satellites have been proposed as efficient agents for the biocontrol of HV-induced plant diseases, both in classical cross-protection programs and by engineering transgenic plants. The high genetic variability of satellite RNAs under experimental and natural conditions, and the possibility of their evolution from attenuating to highly pathogenic types, should be considered when evaluating the potential risks of such control programs.

2.2. Double-Stranded RNA Satellites

Other nucleic acid satellites are the double-stranded RNA satellites associated with viruses in the family *Totiviridae*. Of these, the best studied are the M satellites, which are responsible for the killer phenotype and for immunity to the killer toxin associated with the L-A virus of *Saccharomyces cerevisiae*. The multiplication of the M satellite depends on both the helper virus L-A and on host chromosomal genes.

2.3. Single-Stranded DNA Satellites

A 682-nucleotide, circular, single-stranded DNA satellite has been found associated with tomato leaf curl geminivirus (TLCV). The satellite DNA contains no ORF, is encapsidated in TLCV particles, and is totally dependent for its replication on the replication-associated protein of TLCV. It shows no sequence similarity with the HV DNA, except for a motif that is universally conserved in geminiviruses and involved in single-stranded DNA replication, and for the binding site for the replication-associated protein. At odds with most RNA satellites, this satellite DNA can be supported by distantly related geminiviruses (9).

Satellites have been considered interesting models to approach the analysis of fundamental aspects of virology, such as virus replication, encapsidation, pathogenesis, recombination, and variability. Also, the often complex dependence relationships between satellites and HV pose interesting questions about evolution. Because of this, much research has focused on satellites. Still, major questions remain largely unanswered: (i) how satellites are replicated by the replication machinery of the HV, (ii) how they affect the accumulation (ie, replication and/or movement) of the HV, (iii) how they modify symptoms of the HV, and (iv) what is their origin, evolution, and fate in populations of their HV.

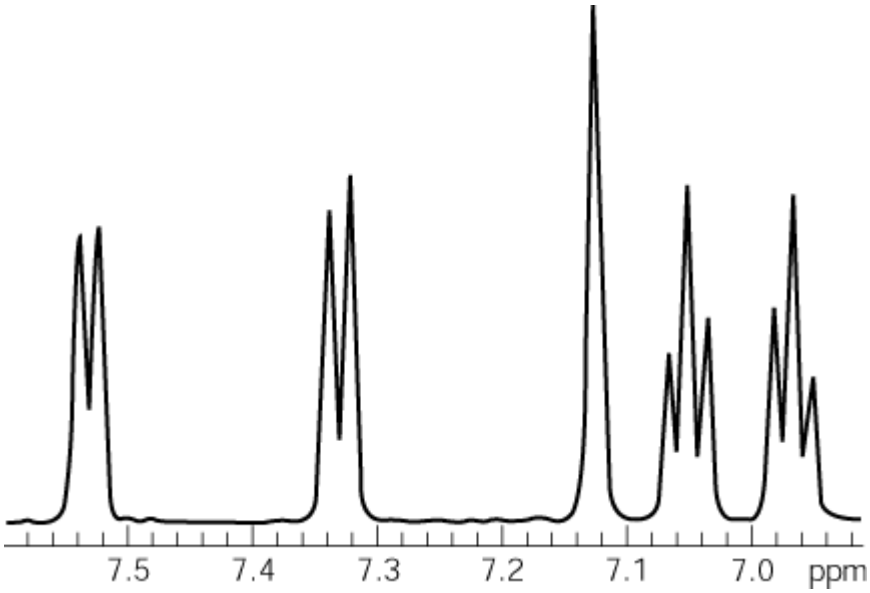
Scalar Coupling

Nuclear magnetic resonance (NMR) spectra of liquid or gaseous samples of a molecule are usually more complex than would be expected based on the number of chemically distinct nuclei in the molecule. The additional complexity (fine structure) in the spectra arises from spin-spin coupling, also called J-coupling, spin-spin splitting, or scalar coupling. The exact resonance frequencies of NMR transitions associated with a particular nucleus depend on the magnetic field at that nucleus, which is the sum of many components. The largest part is provided by the magnetic field of the NMR instrument, as modified by the chemical shift effects of the electrons of the subject molecule and the electrons of surrounding molecules. (See Chemical Shift.) Smaller contributions to the total magnetic field are made by other nuclei in the vicinity of the subject nucleus. Surrounding nuclei are usually “spin 1/2” nuclei and, according to quantum mechanics, these nuclei can have only a “spin-up” or “spin-down” state. Either of these states will potentially contribute to the magnetic field experienced at a neighboring nucleus, with the result that the NMR signals associated with that nucleus may be a collection of signals (a multiplet). Each line of the multiplet represents a particular combination of neighboring nuclear-spin orientations. Analysis of multiplet structure can provide important details of a molecule, because scalar coupling effects are dependent on the number and

relative orientations of the coupled nuclei. Scalar coupling is a necessary condition for coherence transfer experiments such as correlation spectroscopy (**COSY**) and total correlation spectorscopy (**TOCSY**), and it is fundamental to **isotope-filtering** NMR experiments.

Consider the one-dimensional proton NMR spectrum of N-acetyltryptophan shown in Figure 1. The proton (hydrogen atom) attached to C-4 of the indole ring of this molecule has a shielding parameter that corresponds to 7.53 ppm. The NMR spectrum of proton H-4 is more complicated than would be expected because H-4 feels the orientation of adjacent proton H-5. Two possible orientations exist for H-5, so H-4 experiences two different magnetic fields, and these are represented in the proton NMR spectrum as two signals at slightly different frequencies.

Figure 1. A portion of the proton NMR spectrum of *N* -acetyltryptophan corresponding to the protons attached to the indole ring, obtained at 500 MHz. (The full spectrum is given in Figure 3 of NMR.) The acetylated amino acid was dissolved in d_6-DMSO.



The size of the scalar coupling effect is measured in terms of a parameter called the scalar coupling constant, or spin-spin coupling constant, usually symbolized J and always measured in Hz. Subscripts may follow the J that denote the identities of the spins whose interaction is represented by the coupling constant. A superscript may precede the J that indicates the number of chemical bonds that separate the interacting nuclei. Experiments show that J can be either positive or negative. Not all NMR experiments are sensitive to the sign of J, however, and often only the magnitude of J is discussed. In the case of proton H-4 of *N*-acetyltryptophan, the spin-spin coupling interaction between H-4 and H-5, represented by the symbol $^{2}J_{H_\beta H_{\beta'}}$ has a value for the coupling constant of about +7Hz.

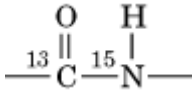
The value of a spin-coupling constant depends on several factors, including the gyromagnetic ratios of the interacting nuclei and the nature of the chemical bonding between them. The larger the product of the gyromagnetic ratios of the coupling partners, the larger the J_{AB}. A tendency exists for coupling constants to decrease with the number of intervening bonds, that is, $^{1}J_{AB} > {}^{2}J_{AB} > {}^{3}J_{AB}$. $^{3}J_{AB}$ has an important dependence on the dihedral angle between the first and third covalent bonds, which can be the source of useful stereochemical information. Table 1 indicates the ranges observed for various spin coupling constants between spin 1/2 nuclei that make up biological macromolecules.

Table 1. Typical Values for Coupling Constants, ($^{n}J_{AB}$)

Chemical System	J, Hz
 (**1**)	$^{2}J_{HH}$, –15 to –10
 (**2**)	$^{3}J_{HH}$, 2 to 12 (depends on dihedral angle)
 (**3**)	$^{3}J_{HH}$, 7 to 9 (*ortho*) $^{4}J_{HH}$, 1.5 to 2.5 (*meta*) $^{5}J_{HH}$, 0 to 1 (*para*)
^{13}C-H	$^{1}J_{CH}$, 125 to 250 (depends on carbon hybridization)
^{13}C-C-H	$^{2}J_{CH}$, –5 to 5
 (**4**)	$^{1}J_{CC}$, ~55
 (**5**)	$^{1}J_{CC}$, 30 to 40
^{15}N-H	$^{1}J_{NH}$, 80 to 100
	$^{1}J_{CN}$, ~11

(**6**)

$^{1}J_{CN}$, ~15



(**7**)

A detailed understanding of the spin-spin coupling phenomenon requires a quantum-mechanical treatment. An important result of such an analysis is that J-coupling between nuclei that have the same chemical shift is not observable experimentally in most of the commonly performed NMR experiments with liquids. Thus, the spin coupling constant between two protons of a methyl group, which is a two-bond proton-proton interaction ($^{2}J_{HH}$), is not observable in a standard one-dimensional proton NMR spectrum.

An observed spin-spin coupling constant of $^{n}J_{AB}$ is potentially made up of two types of contributions. Interactions between the A and B nuclei and the electrons that bind A and B to each other and to the remainder of the molecule provide the means whereby the orientation of one nuclear spin is sensed by the other. There are several possible mechanisms by which nuclei-electron interactions can take place; in all cases, the fine structure introduced by them, as reflected by J values, is independent of the laboratory magnetic field used for the NMR experiment (B_o) and, for all practical purposes, independent of the orientation of the molecule being studied in this magnetic field. A direct through-space interaction between spin 1/2 nuclei is also possible. This nuclear dipole–nuclear dipole interaction is strongly dependent on internuclear distance and on orientation of the molecule relative to B_o. Importantly, in samples where sufficient molecular motion exists so that all possible orientations relative to the magnetic field are rapidly sampled, this contribution to spin-spin coupling averages to zero, leaving only the electron-mediated contributions. These are the conditions that normally obtain in nonviscous solutions at magnetic fields less than ~12 T and normal laboratory temperatures. In organized systems (such as liquid crystals) or in very high magnetic fields, sufficient ordering may exist so that the dipole-dipole contribution to J is not completely averaged away, and an appreciable structure-dependent contribution to the observed coupling constant through this mechanism will be present.

Often, the multiplet structure produced in an NMR spectrum by J-coupling is undesirable because it provides no useful information. A variety of experimental techniques, generally known as decoupling, can be used to remove the effects of spin-spin coupling from an NMR spectrum. Under decoupling conditions, the spectrum is simplified, perhaps reduced to single peaks at the positions corresponding to the chemical shifts (shielding parameters) of the nuclei being examined. Bear in mind, however, that decoupling methods do not remove spin-spin couplings. These are fundamental aspects of the electronic and geometrical properties of the sample that cannot be removed by external intervention. Only the effects of spin coupling—multiplicity in NMR spectra—are removed by a decoupling procedure. The ^{13}C spectrum shown in Figure 4 of NMR was obtained with proton decoupling. Because proton-^{13}C spin coupling effects are absent from the spectrum, the spectral line positions depend only on the ^{13}C chemical shifts.

Scanning Electron Microscopy

The scanning electron microscope (SEM) has been used for three decades to produce direct, 3-D topographic images of biological samples. Until recently, the resolution in SEM has been too low to directly observe most macromolecules. Advances in specimen preparation, which are sufficient to preserve fine structural details at the molecular level, and instrumentation have extended the possible spatial resolution from 5–10 nm to 2–4 nm. In the SEM, the image is constructed by using a fine electron beam that is raster scanned over the surface of a specimen. Secondary electrons from the specimen are emitted through excitation caused by the primary electrons in the beam striking the specimen. The intensity of the secondary electrons is detected and used to modulate the brightness of another electron beam synchronously scanned over the surface of a cathode ray tube (1). Even though its resolution does not approach that routinely attained in the TEM, the high-resolution SEM (HRSEM) has the advantage of high contrast and high signal-to-noise. However, it must be noted that the SEM provides information only about the surface, whereas the TEM will provide information about the internal structure as well. To increase HRSEM signal yield, enhance contrast, and reduce charging artifacts, coating the specimen with a thin metal layer is performed. However, it is possible to view the fractured surface of a frozen hydrated specimen directly in the SEM without coating the surface with metal (2). For high-resolution work, the metal coat must be thin, with a grain size small enough to reduce decoration artifacts while still producing a high-resolution secondary electron signal.

The preparation of biological specimens can be broadly divided into two methods, chemical and cryo. Though easier to perform, chemical fixation is slower than cryofixation and consideration of pH and osmotic strength must be made. Furthermore, the more widespread adoption of high-pressure freezing to inhibit ice crystal formation has made cryofixation more attractive. One advance that has permitted cryo-HRSEM to characterize biological specimens at near molecular resolution is the employment of an in-lens field emission gun as the source of the electron beam (3). The beam diameter from such a gun is less than 1 nm. However, practical resolution has not achieved this dimension because of the nature of the metal coat and beam damage during observation in the HRSEM. Furthermore, the resolution is limited by the penetration of the electron beam into the specimen, since secondary electrons are emitted from a volume around the site at which the probe meets the specimen. HRSEM can be performed at either low voltage with bulk specimens, or high voltage with thin specimens. The low-voltage electron beam penetrates less deeply into bulk specimens, resulting in the high-contrast signal being generated at only a few nanometers radius from the point of beam impact. Hence, high topographic spatial resolution can be achieved (1). On the other hand, the beam diameter can be made smaller at high voltage, therefore representing a greater potential for high-resolution scanning of thin specimens (4).

HRSEM is being used more often to probe finer details of biological specimens than in the past. Cryo-HRSEM has been used to visualize surface features on reovirus particles (5). It was found that because SEM imaged only the surface of each particle, obscuring of structural detail by the internal structure or by the opposite surface was avoided, an important consideration with large structures such as viruses. Further results with cryo-HRSEM provided evidence that topographical views of actin filaments, microtubules, and clathrin cages could show individual subunits, thus permitting identification by molecular morphology (6). The success in visualizing the 3-D surface architecture of these cytoskeletal elements was attributed to controlled freeze-drying, thin metal coating, cryo-transfer and cryo-observation. In order for SEM visualization to be accomplished, the ice surrounding frozen samples must be removed, either by freeze-drying (ice sublimation in a vacuum) or freeze-substitution (ice dissolved by a chemical solvent), followed by critical point drying. It was found for cytoskeletal structures that freeze-drying provided a superior topography. HRSEM of mitochondria showed a greater variation of cristae morphology than previously recognized and also elucidated how serial-section TEM produced unreliable results because of limited resolution (7).

Scanning Hypothesis

Most cellular messenger RNAs initiate translation via a scanning mechanism in eukaryotes. According to the scanning hypothesis (1), eukaryotic ribosomes bind to the 5′ end of the mRNA and subsequently migrate along the mRNA until they encounter an AUG codon embedded in an appropriate context, whereupon translation initiation occurs. One of the first steps in initiation of translation of most mRNAs in mammalian cells is recognition of the -Cap structure and the interaction with it of eIF-4F. At some point in this process, the small ribosomal subunit with associated factors binds to the mRNA and scans to the initiation codon. The scanning model postulates that the 40S ribosomal subunit stops at the first AUG if that codon occurs in a favorable context. But if the first AUG codon occurs in a suboptimal context—for example, in the absence of the critical purine at position –3 or a G at position <+4—some 40S subunits will bypass the first AUG and initiate instead at a downstream site. Two independently initiated proteins may thus be produced from one mRNA by context-dependent leaky scanning. Sometimes ribosomal leaky scanning is used for protein expression. For example, translation of the hepatitis B virus *pol* gene from the viral pre-genome RNA involves such a mechanism (2).

In addition, internal start codons in eukaryotes can be reached by a reinitiation mechanism, originally thought to be the exclusive trait of eubacterial ribosomes. Reinitiation at a downstream codon may be possible when the 5-proximal AUG triplet is followed shortly by a terminator codon and fails to form the proper initiation complex (3).

A similar mechanism of ribosomal scanning is used for translational reinitiation in eubacteria (4). According to this scanning model, the terminated but not released ribosome reaches neighboring initiation codons by lateral diffusion along the mRNA. This ribosomal scanning-like movement is bidirectional, has a radius of action of more than 40 nucleotides in the model system used, and activates the first encountered restart site. The ribosomal reach in the upstream direction is less than in the downstream one, probably due to dislodging by elongating ribosomes. The proposed model has parallels with the scanning mechanism postulated for eukaryotic translational initiation and reinitiation. There are no data to indicate that the two kinds of scanning are basically different. A quantitative difference between prokaryotic and eukaryotic ribosomal scannings is the distance that can be screened. In eukaryotes, this is far greater, in both the 5′-Cap-directed and in termination-dependent states.

Scanning Probe Techniques

Scanning probe microscopes provide a unique window to the microworld of cells, subcellular structures, and biological macromolecules . A common feature of all scanning probe microscopes is that the image of a specimen surface is obtained by using a sharp probe scanning in the near field. The specimen surface is scanned while maintaining a very close spacing between the sample and the probe (Fig. 1). Such scanning produces a very short depth of focus on the molecular scale. As a result, the physical features and physicochemical properties of only the top layers of rigidlybound molecules are imaged. The lateral (x and y) resolution in an scanning probe microscope image of inorganic molecules is typically 20 Å and, with the best instruments and the right sample, can be better than a few angstroms. The height (z) resolution is typically less than 1 Å. The scanning probe instruments described here include scanning tunneling microscopy, atomic force microscopy (AFM), and magnetic force microscopy. Of these, AFM has the greatest potential for biological studies because it can image the three-dimensional (3-D) surface structures of a wide array of native biological specimens in a liquid environment and thus provides an avenue for observing biochemical and physiological processes at molecular resolution in real time. In addition to imaging molecular structures, AFM is also an exquisite sensor of molecular forces, such as hydrogen bonds and **van der Waals** and electrostatic interactions. In addition, by applying a controlled imaging force, surfaces can be altered (nanodissection), created (nanomachining), or moved (nanotransplant) in real time. In its very short period of existence, AFM has imaged biological structures ranging in size from whole cells to macromolecular complexes, such as chromosomal **DNA**, proteins in extended 2-D arrays, individual multisubunit proteins, various other biological macromolecules, and a variety of membranes. Dynamic processes, such as polymerization or dissolution of macromolecular complexes and crystal growth, and physicochemical properties, such as elasticity, viscosity, and various chemical forces in biological specimens, have been studied.

Figure 1. Schematic illustration of the basic operating principles of scanning probe microscopes, in particular the atomic force microscope (AFM) and scanning tunneling microscope (STM). The interaction between a probe tip and the specimen surface is measured continuously while raster scanning in the X and Y directions. With a feedback system, the height (Z position) of the sample is adjusted to keep the tip-specimen interaction force constant. For STM, the interaction force is measured by measuring the tunneling current between the tip and the specimen surface. In AFM, the extent of interaction is measured in terms of the forces of interaction between the specimen surface molecule and the probe, which is usually a tip attached to a cantilevered spring.

Scanning Transmission Electron Microscopy

The scanning transmission electron microscope (STEM) combines the imaging mode of the scanning electron microscope with the specimen characteristics of the conventional transmission electron microscope (CTEM). In the STEM, the electron source, usually a small field emission tip, is demagnified by electron lenses to produce a very small electron probe which is scanned across the specimen in a raster pattern. Unlike the SEM, the STEM is used with thin specimens, and electrons that pass through the specimen are detected and either displayed on a cathode ray tube whose scan is synchronized with the scan of the electron probe, or the signal is digitized and stored in computer memory. CTEMs can be adapted to become STEMs, but the resolution of these hybrid microscopes is not as good as either a dedicated CTEM or a dedicated STEM. A dedicated STEM can produce a probe of 0.2–0.3 nm and hence has resolution roughly equivalent to a CTEM.

A STEM can be used to image the same types of specimens as CTEMs, macromolecules, viruses, thin sections, and so on, but have little advantage over the CTEM at the cost of increased complexity, purchase price, and maintenance of dedicated STEMs. The STEM, however, has an

established niche in molecular biological applications of microscopy through accurate and precise mass measurements of individual macromolecules and complexes (1, 2). The principle of mass determination relies on quantifying a specimen's differential capacity to scatter electrons elastically. Quantitative image processing is performed on STEM dark-field images of unstained specimens. Unstained particles produce a dark-field signal that is proportional to their local mass density which means that not only the total mass of an individual molecule can be determined, but its resolved domains can also be determined by integrating over appropriate regions of the image (3).

The STEM attains relatively high spatial resolution of different mass elements by the use of a field emission source of electrons. Electrons that pass through the thin specimens used in STEM are collected by a detector placed below the specimen. Since elastically scattered electrons used for mass measurements are scattered over a wide angular range, they can be selectively detected with an annular detector placed below the specimen. Unscattered and inelastically scattered electrons pass through a hole in the center of the annular detector and can be recorded separately by a second circular detector placed below. STEM overcomes limitations in mass analyses, such as impurities, low amount of material, large size of the macromolecule or complex, and conformational variability and polymorphism found in more traditional methods (eg, chromatography, sedimentation, small-angle X-ray, or **neutron scattering**). Because of the STEM's high spatial resolution for mass measurements, discrete subpopulations can be distinguished within a mixed population and treated separately for statistical measurements. STEM also has the advantage of invariant mass measurements regardless of conformation or viewing geometry. Incisive mass specification can be made with as few as 100 molecules with an accuracy of 1–2% (4).

In addition to determining the total mass of a molecule, it is often feasible to measure the mass distribution within it; this is referred to as *mass-mapping*. Distinct features resolvable in images can be classified and computer averaged, thus increasing the signal for more precise mass-mapping with extended resolution. For example, molecular edges can be localized to within 0.5 nm and the radial distribution of density within complexes can be accurately determined (5). The versatility of mass-mapping can be appreciated from the determination of masses ranging from single protein subunits to large viruses (2). An instructive example of the potential of STEM mass analysis was made with isolated gap junction membranes (see Gap Junction and Membranes) to determine the protein composition of the hexameric unit (6).

Scanning Tunneling Microscopy

1. Principle of Operation

The scanning tunneling microscope (STM), invented by the Nobel prize winners Binnig and Rohrer, is a scanning probe technique that provides information at atomic resolution about structures that are electrically conducting. STM is based on the quantum mechanical principle that electrons travel

across the classically forbidden energy potential zone (i.e., tunnel) from one surface to another without physical contact if there is overlap in their probabilities of finding their positions, as determined by their electron density functions at the two surfaces. In such a situation, applying a small potential difference between the corresponding surfaces causes electrons to tunnel through the potential barrier that exists between the surfaces of the sample and the probe, which gives rise to the tunneling current. The tunneling current density i through a planar potential barrier at small voltages V is inversely proportional to the exponential power of distance and can be approximated by

$$i = Ax \exp[(\phi)^{1/2} \times s] \quad (1)$$

In this expression, f is proportional to the average potential barrier height of the two surfaces, and s is the tunnel distance in angstroms. The constant A contains several important features, such as the applied bias voltage V. For a greater applied bias voltage V, the effective barrier height becomes a function of V. For a nonplanar barrier, like the barrier between a conducting surface and an STM tip, the tunneling current cannot be described so easily because, in addition in these circumstances, the current is extremely sensitive to the tip-sample separation and is manifested by an exponential dependence on the tunnel distance s. Generally, the possibility of finding any tunneling current beyond a few angstroms from a weakly conducting surface, such as a biological material, and for a small bias potential, is negligible.

2. Modes of operation

The most commonly used STM operating mode is "constant current topography" imaging. In this mode of imaging, the tunneling current is kept at a constant value by feedback electronics, and the change in the scanner height necessary to maintain constant tunneling current is registered as topographic information (see Fig. 1 of Scanning Probe Techniques). Such height change is registered at each lateral x-y coordinate as the tip scans over the surface. This mode is most suitable to measuring the topography of nonflat surfaces. Because of the finite reaction time of the feedback, however, the scan speed is limited. Another way of operating the STM is the "constant height mode." For this mode, the height of the probe is fixed, and the tunneling current is measured at each x-y coordinate during the scanning. This mode allows much faster scanning of atomically flat surfaces because the feedback does not have to respond to surface features. This is important because fast scanning allows dynamic studies. It also minimizes data acquisition time, and image distortion caused by thermal drift and creep in the piezo scanner.

STM images give pure topographic information about surfaces only when the surface has uniform electronic properties because it actually measures the electronic structure of the sample and probe via barrier heights. The resolution is limited primarily by the size, shape, and mechanical stability of the tip and is on the order of 1 Å laterally, and 0.1 Å vertically.

STM can be operated in a more **spectroscopic** mode, measuring current-voltage characteristics. For each lateral position of the probe, the feedback is temporarily disabled after which the tunneling current is measured while ramping the bias voltage. The variation in the tunneling current at specific bias voltages can be visualized by constructing real-space images of surface electronic states. Spatially resolved current-voltage curves have been used to examine the electronic structure of semiconductor and metallic surfaces. The energy resolution of the spectroscopic imaging mode is influenced by several factors. Some of these factors are the thermal limit, which depends on the width of the edge of the Fermi distribution of the electrons in the electrode surfaces; an energy-dependent lifetime broadening of electronic states; and the uncertainty principle, which plays a role because the lateral resolution and tip radius are both of the order of angstroms.

3. Mechanical design

The mechanical design of a STM system can be modified for specific experimental needs. The most general criteria that must be satisfied by a STM setup are (1) an x, y, and z scanning range that allows for a scanning window sufficiently large to find and identify features of interest; (2) a resolution of 0.1 Å laterally and 0.01 Å in the z-direction; and (3) rigid construction of the tip-sample junction part with high resonance frequency to minimize vibrational disturbances. The scanners use mostly polycrystalline ceramic materials, like lead zirconate titanate and barium titanate.

The operating environment of STM studies depends on the nature of the contamination. Most inert samples are imaged in air, but for more accurate and reliable studies on clean surfaces, a STM situated in a vacuum chamber may be necessary. The mechanical construction in this case is more complicated because of the need for vibration isolation in the vacuum chamber, for in situ cleaning, and for possible use of Auger electron spectroscopy in the same chamber which is low-energy electron diffraction. Another approach that imposes harsher requirements on a piezo scanner is STM imaging in cryogenic conditions because the low temperature reduces the piezoelectric response of the ceramics.

4. Probe preparation

The physical shape, size, and chemical identity of the STM probe employed influences the resolution obtained in a STM scan and also the electronic structure. Three important properties make a “good” probe for STM. First, a large blunt macrostructure ensures high mechanical resonance frequency, leading to low hysteresis and an increase in the data acquisition rate. Second, the microstructure of the tip at the very apex needs a single site of atomic approach to the sample. If this is not met, multiple tip imaging occurs because electrons tunnel through several points on the tip apex. Third, the purity of the tip is important because any impurities may lead to barriers through which electrons do not tunnel. Most STM tips are made of metal wires, such as tungsten, platinum-iridium, or gold. Platinum-iridium tips are used most because platinum is inert to oxidation, produces a pure tip, and iridium adds stiffness to the probe. They are cut and sharpened in different ways, from simply using a wire cutter to ion milling or electrochemical etching.

5. Applications

The first STM work was done on conducting or semiconducting surfaces. A precise image of the atomic arrangements of those surfaces was obtained, mostly with the STM running in ultrahigh vacuum, primarily to avoid contamination from gases, mainly oxygen, and organic materials present under ambient conditions. Although it is difficult to image thicker biological samples with STM, small molecules like aromatic molecules, fatty acids, hydrocarbons, and liquid crystal molecules are routinely imaged. Energy levels between the various electron orbitals can be precisely calculated in some cases, and the use of a substrate like graphite can shift these orbitals in the adsorbed liquid crystalline molecules. Numerous similar applications of STM are described elsewhere.

Although attempts have been made to obtain structural information about larger biological macromolecular specimens, which are nonconducting, the mechanisms of image generation and their interpretation are unclear. Some of the early imaging of large molecules, such as **DNA**, with STM were later proven to be artifacts, when it was found that features that look very similar to a double-helical DNA strand could be obtained from a clean sample of graphite. More recently, a new way of imaging DNA and possibly other macromolecules with STM was described. The technique imaged DNA and tobacco mosaic virus on mica surfaces under a relative humidity of 65% and found clear images with a tunneling current in the subpicoampere range. The electrical conductivity is explained by a layer of water on the surface that has conductivity five times higher than bulk water.

Scatchard Plot

The Scatchard plot is a graphical method of analyzing equilibrium **ligand binding** data (1). It is used to determine the number of ligand-binding sites on a **receptor**, whether these sites show **cooperative** interactions, whether more than one class of site exists, and the respective affinities of each site. The experimental parameters used for a Scatchard plot are the free ligand concentration [L] and the average number of ligand molecules bound to a receptor, n, at a particular ligand concentration at equilibrium. The formal definition of n is

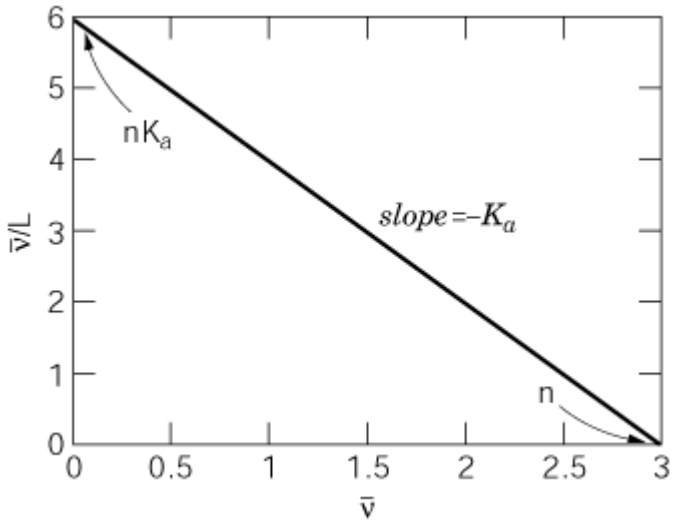
$$\bar{\nu} = \frac{\text{moles bound ligand}}{\text{moles receptor}} = \frac{\sum_{i=1}^{n} i[\mathrm{R}_i]}{\sum_{i=0}^{n} [\mathrm{R}_i]} \qquad (1)$$

where n is the maximum number of ligands that can bind and $[\mathrm{R}_i]$ is the concentration of the receptor species with i ligands bound. In the simplest case, of a receptor with a single class of noninteracting sites, receptor–ligand binding follows the Scatchard equation:

$$\frac{\bar{\nu}}{[\mathrm{L}]} = nK_a + \bar{\nu}K_a \qquad (2)$$

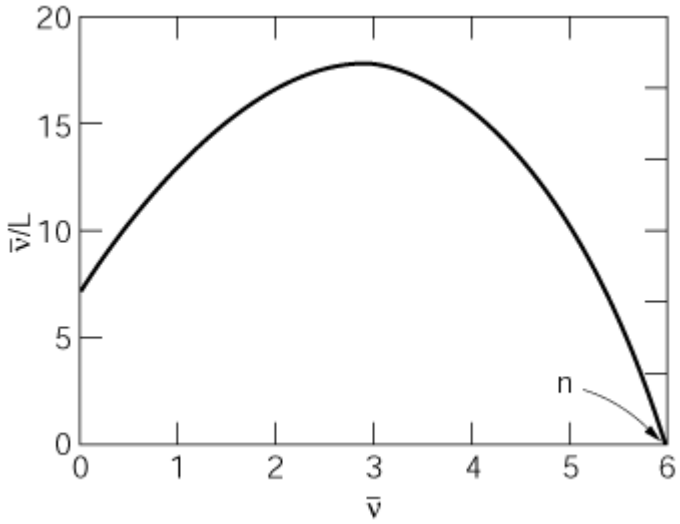
A linear plot results, as shown in Figure 1. The intercept on the abscissa equals the total number of binding sites in the receptor, and the slope equals $-K_a$, where K_a is the intrinsic equilibrium **association constant**.

Figure 1. Scatchard plot for a receptor with three equivalent, noninteracting ligand-binding sites.



Nonlinear Scatchard plots are diagnostic of several more complex types of ligand–receptor interaction. A plot that is concave downward indicates positive **homotropic** cooperativity between binding sites on an **allosteric** receptor. An example is shown in Figure 2. The abscissa intercept again equals the maximum number of binding sites. The curvature of the plot corresponds to the degree of cooperativity in the system studied, but it is difficult to obtain an experimentally meaningful parameter from the curvature by inspection. Nevertheless, the linearity of Scatchard plots is very sensitive to cooperative interactions, and the downward-concave form of the plot in Figure 2 is considered diagnostic of allosteric proteins.

Figure 2. Scatchard plot for a receptor that exhibits cooperative ligand binding. The example illustrates a molecule that follows the Monod–Wyman–Changeux **concerted model** of allostery, with six binding sites and 10-fold preferential binding to the R state.

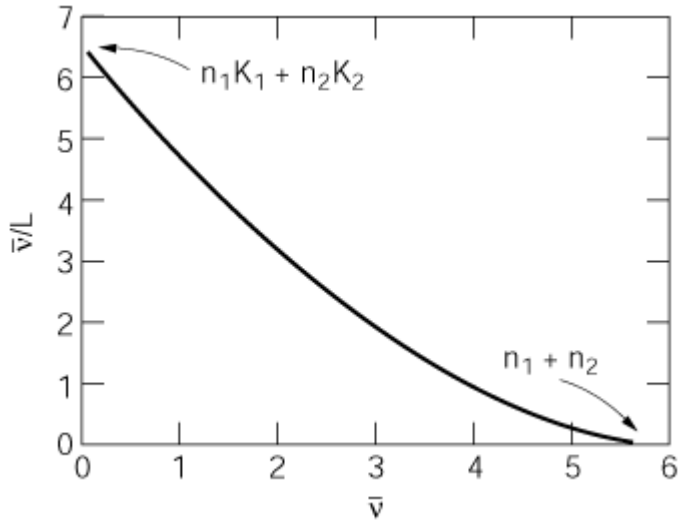


A second type of nonlinear Scatchard plot arises when multiple classes of binding sites with distinct affinities are present on a receptor. For receptors with multiple (m) classes of noninteracting sites, the Scatchard equation becomes a sum:

$$\frac{\bar{\nu}}{[L]} = \sum_{j=1}^{m} \frac{n_j K_j}{1 + [L]K_j} \qquad (3)$$

where n_j and K_j are the number of sites and association constant of the jth class. The corresponding Scatchard plot (Fig. 3) is multiphasic, superficially resembling a linear combination of simpler plots. The abscissa intercept equals the total number of binding sites on the receptor, but further interpretation of multiphasic Scatchard plots is difficult.

Figure 3. Scatchard plot for a receptor with two classes of ligand binding sites, three high affinity, and three low affinity sites. The sites do not interact, and the affinities differ by a factor of 10.



Several limitations of Scatchard analysis have been recognized. One is that n and n/[L] both contain experimental errors; hence calculating the slope and intercept of a linear Scatchard plot by simple least squares is not statistically valid. A better approach for statistical analysis is to fit n as a function of [L] directly to the equation for a binding model (2). In addition, nonlinear Scatchard plots are notoriously difficult to interpret. Scatchard analysis amplifies the prominence of binding data obtained at low ligand concentrations. These data can distort extrapolations to the total number of binding sites that will be filled at a saturating ligand concentration (3). Another source of overinterpretation stems from the fact that binding behavior consistent with multiple classes of sites is also consistent with other binding models (4). In the case of multiphasic plots like that in Figure 3, discerning the true molecular properties of a receptor requires independent experiments, in addition to Scatchard analysis.

Scattering Intensity Distribution

The scattering of light, X-rays, or neutrons by atoms in matter provides information on the structure and dynamics of the material being sampled. The scattering experiments depend upon measuring the scattering intensity distribution, generally as a function of scattering angle. Presented here is a brief description of the theory for the elastic, coherent scattering of X-rays and neutrons. Coherence refers to the fact that the amplitudes of the scattered waves are additive and hence can produce interference. Elastic scattering means that there is no energy difference between the incident and scattered waves. When X-rays or neutrons are scattered coherently and elastically by atoms, the scattered waves interfere in a manner related to the spatial distribution of the atoms in the sample. This interference provides the foundation for small-angle scattering and crystallography applications. The basic principles of light scattering are the same as those for X-rays, but the wavelengths are much longer and different formalisms are used. Light scattering is therefore discussed as a separate topic in this series.

X-rays and neutrons can be considered as plane waves with wavelengths, l, and can be represented as

$$\Psi(z) = e^{ik_i z} \tag{1}$$

where k_i = 2p/l is the amplitude of the incident wave vector which is taken to be in the direction z. A wave scattered by an atom at a position in space designated by the vector **r** will be a spherical wave of the form

$$\Psi(\mathbf{r}) = -\frac{A}{r} e^{i\mathbf{k}_f \cdot \mathbf{r}} \tag{2}$$

where $\mathbf{k}_f$ is the scattered wave vector, and A is the scattering amplitude for the atom. X-rays are electromagnetic radiation and are scattered via interactions with the electrons in a sample. Thus, for X-rays, A is proportional to the number of electrons in the atom and is generally designated as f. Because X-ray wavelengths are of the same order as the dimensions of the electron clouds of the scattering atoms, there is an angular dependence to X-ray scattering amplitudes. Neutrons are neutral particles and are scattered by atomic nuclei. Neutron scattering amplitudes are generally given in units of length and are designated as b. Because nuclei have dimensions much smaller than the wavelengths of neutrons used in scattering experiments, b values have no dependence on scattering angle. The total coherent scattering from a molecule made up of atoms is the summation of the coherent scattering over all atom pairs (i,j):

$$\sum_i \sum_j A_i A_j e^{-i\mathbf{Q}\cdot\mathbf{r}_{ij}} \tag{3}$$

where $r_{ij} = \mathbf{r}_i - \mathbf{r}_j$. **Q** is the scattering vector equal to the difference between the incident and scattered wave vectors ($\mathbf{k}_f - \mathbf{k}_i$); its amplitude is 4p(sin q)/l, where 2q is the scattering angle (Fig. 1). **Q** is also the momentum transfer vector. In scattering experiments, one can describe molecules as continuous density distributions rather than sums of discrete point atom scatterers. Scattering densities are calculated as the sum of the scattering amplitudes of atoms within a finite volume element divided by its volume, SA_i/V. The total coherent, elastic scattering, $I(\mathbf{Q})$, from a molecule in a vacuum then can be written as

$$I(\mathbf{Q}) = \left| \int \rho(\mathbf{r}) e^{-i\mathbf{Q}\cdot\mathbf{r}} d^3\mathbf{r} \right|^2 \tag{4}$$

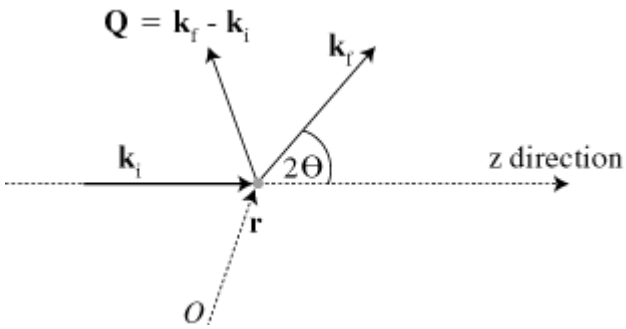
where r(**r**) is the scattering density distribution within the molecule, and the integration is over the volume of the molecule. For a randomly oriented molecule in a solvent with scattering density r_s, equation (4) becomes

$$I(Q) = \left\langle \left| \int \Delta\rho(\mathbf{r}) e^{-i\mathbf{Q}\cdot\mathbf{r}} d\mathbf{r} \right|^2 \right\rangle \tag{5}$$

$$= \int\int \Delta\rho(\mathbf{r}_1)\Delta\rho(r_2) \frac{\sin Q|\mathbf{r}_1 - \mathbf{r}_2|}{Q|\mathbf{r}_1 - \mathbf{r}_2|} d\mathbf{r}_1 d\mathbf{r}_2 \tag{6}$$

The brackets ⟨¼⟩ indicate averaging over all orientations of the particle, and Dr(**r**) = r(**r**-r_s) is the scattering density difference or "contrast" between the molecule and the solvent (1, 2). Equation (6) is known as the Debye equation 3 and is the basic equation for scattering. The total scattering intensity distribution for a solution of monodisperse molecules will be directly proportional to both the number density (concentration) and the square of the molecular weight of the particles. Analysis of the scattering intensity distribution at small angles (small-angle scattering) yields structural parameters such as the radius of gyration, R_g, molecular weight, M, and the vector length distribution function, $P(r)$, for the scattering particle. Contrast variation techniques involve the deliberate manipulation of contrast in order to increase the information content of the scattering experiment. For polydisperse solutions, or a solution of nonidentical particles, the time- and ensemble-averaged scattering intensity distribution function is measured; hence average structural parameters are determined.

Figure 1. Geometrical representation of the scattering vector **Q. k** $_i$ and $\mathbf{k}_f$ are the incident and scattered wave vectors, respectively, of a wave that interacts with an atom at a point **r** from an arbitrary origin *O*.



For scattering from samples ordered in one, two, or three dimensions, the scattering from an individual molecule is convoluted with the repeating lattice structure to yield a diffraction pattern that has discrete intensity maxima. These diffraction patterns can give information on the repeat distances in the lattices, as well as provide higher resolution structural information on the ordered molecules. For well-ordered three-dimensional crystals, complex diffraction patterns are obtained that can be indexed according to the crystal lattice indices h, k, l. The unit cell scattering is described mathematically in terms of the square of the structure factor F_{hkl}, which is the ratio of the radiation scattering by any real sample to a point scatterer at the origin:

$$I(Q_{hkl}) = F_{hkl}^2 = \left| \int_j A(Q)_j e^{-2\pi i(hx_j + ky_j + lz_j)} \right|^2 \qquad (7)$$

where x, y, and z are the coordinates of each atom in the crystallized molecules in one unit cell, and the summation is over all atoms. Diffraction data from three-dimensional crystals of biological polymers (proteins, polynucleotides) can be used to solve the structure of the crystallized polymer at high resolution (crystallography) if one knows both the phases and amplitudes of the structure factors F_{hkl}. The structure factor amplitudes are readily calculated as the square root of the measured intensities of the diffraction peaks. These amplitudes are combined with experimentally and/or theoretically deduced model phases in order to calculate (by Fourier transformation) an electron density distribution function that is usually interpreted using the known contiguous sequence of chemical groups in the polymer.

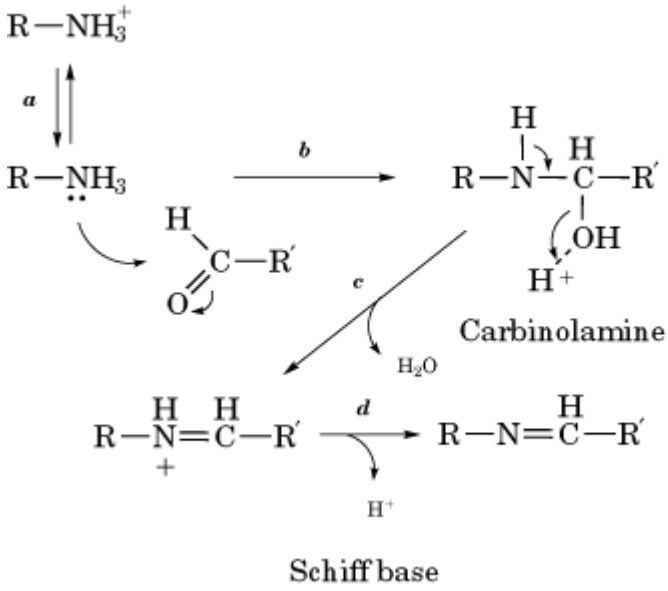
Schiff Base

Schiff bases (also known as Schiff's bases, imines, or azomethines) are unsaturated compounds formed by the condensation of amino groups with aldehydes or ketones (1-4): **(Eq. 1)**



(1)

The amine will be reactive in its un-ionized form and may require deprotonation (step *a*). The free amino group adds to the carbonyl group (step *b*) to form an intermediate known as a carbinolamine. It loses water (step *c*) to form an *N*-protonated Schiff base, which may lose a proton (step *d*). All the reaction steps reach equilibrium, often quite rapidly. Because the pK_a of the protonated Schiff base is usually low whereas that of a protonated primary amino group is high, the equilibria will be pH-dependent. Consider formation of a Schiff base by reaction of an unprotonated amine with a carbonyl compound to give an unprotonated Schiff base, with formation constant K_f at high pH. If the pK_a value of the amine is 10 and that of the Schiff base is 5, it is easy to show that the formation constant for reaction of the protonated amine to form protonated Schiff base at low pH, eg, below pH 3, will be only $10^{-5}K_f$. Consequently, the Schiff base will not be formed to a significant extent at low pH. If, however, the pK_a of the amine is unusually low, or if the Schiff base proton is held by a hydrogen bond not present in the free amine, a Schiff base may be quite stable at neutral pH. This is the case for Schiff bases of pyridoxal phosphate.

Schiff bases are chemically reactive, and various adducts can be formed. Especially popular is a reaction with a borohydride ion, which reduces the double bond of the Schiff base, converting the labile imine linkage to a stable secondary amine. This reaction has proved useful in linking pyridoxal phosphate to amino groups of enzymes or substrates, in attaching aldehydes to amino groups of receptors, and so forth (5, 6).

Schiff bases participate in many biological processes. In a common class of aldolases, protonated Schiff bases are formed with ketone substrates such as fructose 1,6-bisphosphate. The protonated imine serves as an electron-accepting group that facilitates carbon-carbon bond cleavage by the enzyme (Fig. 1**a**). (7, 8) A similar function is found for bacterial acetoacetate decarboxylase (Fig.

1**b**) (9). The Amadori rearrangement, prominent in carbohydrate chemistry, including nonenzymatic glycation and the Maillard browning reaction, also proceeds through a Schiff base mechanism (Fig. 1**c**). (10, 11) The Mannich condensation useful in organic synthesis (3, 12) is an addition reaction of a quaternary Schiff base, often derived from formaldehyde, with a carbanionic center **(Eq. 2)**.

Figure 1. Participation of Schiff bases in three biologically important reactions: (**a**) type I aldolase; (**b**) beta-oxoacid decarboxylase, eg, acetoacetate decarboxylase; (**c**) Amadori rearrangement.

Scrapie

Scrapie is the archetype of the transmissible spongiform encephalopathies (TSE), a closely related group of rare and fatal neurodegenerative diseases affecting humans and other mammals. They are of particular scientific interest because the transmissible infectious agent appears to be a single type of protein molecule, the prion protein, rather than an organism containing **nucleic acid** (1, 2). The diseases are also unique in that they are both hereditary and infectious. Their importance has been further highlighted in the past 10 years by the recognition that they can be transmitted across the species barrier, from cattle to humans, in contaminated foodstuffs. The characteristic signs of the disease include dementia, progressive loss of locomotion coordination (ataxia), and wasting, leading inevitably to death. Postmortem histological examination of the brain (3, 4) shows a spongiform appearance with amyloid plaques surrounding the voids. The incubation times of the diseases tend to be long; in mice it is about 1 year, in sheep about 5 years, and in humans it may be 10–50 years, depending on the disease strain. The spongiform encephalopathies can be transmitted between animals by a number of different routes. The most effective, and useful in laboratory studies, is by intracerebral inoculation of tissue homogenate. Other routes include feeding (5) and the inadvertent intramuscular injection (6) of infected material during medical treatment and corneal grafting (7). In the United Kingdom, scrapie may have been transferred from sheep to cattle (as bovine spongiform

encephalopathy (BSE)) on a large scale, and thence to the human population (as new-variant Creutzfeldt–Jakob disease) (8) through infected beef products, so far on a small scale.

The spongiform encephalopathies include the following:

Scrapie: a disease of sheep and goats whose altered behavior prior to death includes the obsessive scraping of the fleece, hence the Scottish dialect name of "scrapie." It has been known for at least 250 years and is endemic in all countries except Australia and New Zealand. Experimental sheep-to-sheep transfer of scrapie by inoculation was first carried out 60 years ago, and it is thought that natural transmission occurs through pasture contaminated with placental tissue carrying the agent, but vertical transmission, ewe-to-lamb, is disputed. There is no evidence of direct transmission from sheep to humans. Scrapie can be bred out of flocks, indicating it has a genetic component. Similar diseases include transmissible mink encephalopathy in mink and chronic wasting disease in muledeer and elk. Spongiform encephalopathies have been reported in the United Kingdom in domestic cats and several types of deer, possibly from feeding with infected sheep or cattle remains.

Bovine spongiform encephalopathy (BSE), or "mad cow" disease: a disease of cattle first recognized in 1986 originating in, and largely confined to, the United Kingdom. The United Kingdom has reported 168,000 cases of BSE in the period 1986–1997 in an epidemic that peaked in 1992–1993 and is now diminishing rapidly. Other European countries have reported no more than a few hundred cases, often of cattle imported from the United Kingdom, but no cases of BSE have been found in the United States, which has nearly 100-fold more cattle than the United Kingdom. For commercial or political reasons, BSE cases are likely to be reported conservatively in every country. Epidemiological evidence suggests that BSE originated from the feeding (5) of inadequately rendered sheep remains from scrapie-containing flocks, but a spontaneous origin in cattle herds has not been entirely ruled out. The practice of using meat and bone meal in cattle feeds had been common for several decades, but reductions in the severity of the rendering conditions permitted by the U.K. government in the late 1970s and early 1980s apparently allowed the infectious scrapie agent to escape destruction and to pass into cattle. It is also known that BSE is transmissible from cow-to-calf (vertical transmission) at a very low rate.

1. Human Spongiform Encephalopathies

There are five recognized diseases in the human population associated with TSEs.

Creutzfeldt–Jakob Disease (**CJD**): a rare and fatal neurodegenerative disease in humans first described in Germany in the early 1920s independently by H. G. Creutzfeldt and A. Jakob. It normally affects people above 60 years of age and is presented as a rapidly progressive dementia, with a characteristic electroencephalogram signature. CJD may have one of three origins: hereditary transmission as an autosomal, dominant trait; acquisition by ingestion; or acquisition by an iatrogenic route, such as surgery, corneal transplant, or growth hormone injection. The majority of cases are sporadic (85%), 10–15% are familial, and the remainder are iatrogenic. The incidence of CJD is given as about 1 per million per year, with little geographic variation. It is possible, however, that CJD is rather more common than this because of its misdiagnosis as Alzheimer's disease (9) (see Amyloid Precursor Protein), with which it shares a remarkable number of etiological and pathological similarities (10).

New-variant CJD, or v-CJD: appears to be distinct from normal CJD (8) and thus far limited to the United Kingdom. Cases have appeared from 1996 at a rate of about 10–20 per year. The new variant affects an age group below 40 years, it progresses more slowly than classic CJD, and the brain plaques are very similar to those of BSE in cattle brains. It is now thought to be a human form of BSE resulting from the ingestion of infectious cattle tissue. In view of the major epidemic of BSE in the U.K. cattle herds, and the prolonged incubation period, a parallel increase in cases of v-CJD at a later stage in the human population in the United Kingdom cannot be ruled out.

Kuru: most probably a sub-form of CJD, discovered in Papua, New Guinea, but now extinct. It is likely that its transmission was associated with ritual tribal practices of eating the brains of ancestors.

Gerstmann–Straussler–Scheinker disease: a very rare inherited midlife disease in humans manifest by ataxia.

Fatal familial insomnia (**FFI**): another very rare human midlife inherited disease in which dementia follows difficulty in sleeping.

It is evident that all these diseases are closely related and may represent essentially the same disease in different hosts. The nature of the transmissible agent has been very controversial. The initial assumption that it was a slow-acting **virus** has been eroded, as no virion could be isolated, no antibody reaction observed, and, most compelling of all, by the ability of the infectivity to survive irradiation, heat, and enzyme treatments that should destroy nucleic acids. In its place, the prion hypothesis was proposed by Prusiner in 1982 (2) that posited a proteinaceous infectious particle as the scrapie agent (see Prion). The essence of the prion hypothesis is that the prion protein (PrP) exists in two states, a normal, cellular form (PrP^{C}), and a pathologic scrapie form (PrP^{Sc}). The normal and scrapie forms of the prion differ not covalently but in the three-dimensional fold of their polypeptide chains (11). Spectroscopic examination has demonstrated that the PrP^{C} molecule is a predominantly **alpha-helical** protein, whereas PrP^{Sc} molecule has much more beta-sheet structure. Moreover, PrP^{C} is sensitive to **proteolysis**, but PrP^{Sc} has a large proteinase resistant core, which spontaneously forms insoluble amyloid fibrils. Scrapie diseases result from the ability of the scrapie form of the prion (PrP^{Sc}) to induce the structurally quite different cellular form (PrP^{C}) to take up the structure of the PrP^{Sc} form in a chain reaction (12). In this way the scrapie form of the prion protein can effectively replicate itself, and also act as an infectious agent, capable of the induction of more scrapie prions in other hosts.

That a single protein molecule could be responsible for a group of inherited and communicable diseases was a radical idea naturally attracting much skepticism. However, a great deal of experimental verification of the prion hypothesis has been obtained (12), and it has recently received the imprimatur of the Nobel committee. It seems highly probable that the prion protein is indeed the source of the infectious scrapie agent, although the viral hypothesis has still not been entirely abandoned. One of the aspects that encourages retention of the viral origin of the scrapie diseases is the issue of "strains" (3, 4) (see Prion). It is known that scrapie prions appear as multiple strains that differ somewhat in their disease expression, for example, Gerstmann–Straussler–Scheinker disease, FFI, and different subtypes of CJD (see list above) are expressed by different point mutations in the prion gene. When these different prion strains are inoculated into mouse brain containing only the single type of mouse prion, the resultant scrapie prions exhibit the characteristics of the inoculated strain. In viral diseases, these different disease signatures would be encoded on the viral DNA/RNA, but in the prion hypothesis they are thought to be encrypted on scrapie prion proteins in the form of slightly different three-dimensional folds of their polypeptide chains. These different folds are assumed to be capable of being "imprinted" on the same cellular prion proteins in their conversion to the scrapie form (14), thereby expressing the particular strain of the infection. A similar line of argument has been used to explain why prions are able to cross some species barriers, but not others (15). The experimental evidence suggests that infection crosses species barriers more easily when the host prion proteins have a closer amino acid homology with the infecting prions. For example, **transgenic** mice carrying both mouse and hamster prion genes express more mouse prions when inoculated with mouse prions, and more hamster prions when inoculated with hamster prions. This suggests that prions preferentially recruit homologous prion proteins. Similarly, the spread of scrapie from sheep to cows may be facilitated because the sequences of sheep and cattle PrP differ at only seven positions. It is probable, however, that it is the locations as well as the number of differences that is crucial: how else to explain that scrapie can pass from sheep to cattle, and then to humans, while scrapie cannot apparently pass directly from sheep to humans?

The prion hypothesis has taken our understanding of the scrapie diseases a considerable way forward, and in doing so has added some radically new concepts about protein structure to molecular biology. The weight of evidence is quite strongly in its favor, but nevertheless some important aspects of the role of prions in molecular mechanisms of the scrapie diseases remain to be uncovered. For example:

1. What is the precise nature of the infectious scrapie agent?
2. In what molecular complex the does the structural conversion of the prion proteins take place, and how does the "imprinting" of prion strains occur within it?
3. How are the neurotoxic effects of scrapie prions expressed?
4. How does the agent pass from the gut to the brain?
5. What is its relation to Alzheimer's disease?

More radical ideas will be needed to answer these questions—or to overturn the prion hypothesis.

SDS-PAGE

Electrophoresis of fully **denatured** and dissociated polypeptide chains derived from proteins by binding of, and saturation with, the negatively charged detergent **SDS**, usually designated SDS-PAGE, is by far the most popular mode of gel electrophoresis in polyacrylamide gels (usually abbreviated PAGE). There are two reasons why SDS-PAGE is preferred: (1) it provides the resolving capacity and **molecular sieving** of PAGE, especially when conducted as disc electrophoresis (Fig. 1); and (2) it can give an estimate of the molecular weight of each polypeptide chain on the basis of electrophoresis at a single gel concentration. Molecular weights are often measured for protein using this technique alone, but it must be remembered that the results are valid only to the extent that the following simplifying conditions apply:

1. All SDS-denatured proteins tend to have the same net negative charge density: The binding of SDS to the protein usually masks the intrinsic charge of the protein and because of the bound SDS, gives it a standard negative charge density, that is largely independent of pH.
2. All SDS-denatured proteins tend to have the same conformation: The binding of SDS, when coupled with reduction of any disulfide bonds and dissociation into individual polypeptide chains at high temperatures, produces a conformation like a random coil for all SDS-polypeptides; therefore, mobility differences due to specific protein conformations are abolished.
3. The mobility is inversely proportional to the size of the polypeptide chain: Because the surface charge densities of proteins are equalized [see (1)], the Ferguson plots of all SDS-polypeptides should intersect at zero gel concentration; in this case, the ratios of the mobilities for all proteins at various gel concentrations are the same.
4. The mobility is inversely proportional to the logarithm of the molecular weight: A plot of log (molecular weight) versus migration distance is linear except at very large and very small molecular weights. Such a linear plot provides a simple means of deriving the molecular weight of an unknown protein (such as rhodopsin in the example of Fig. 2) by comparison to a set of standard proteins.

Figure 1. SDS-PAGE patterns of polypeptides derived from total cell extracts of various strains (numbered) of Achromobacter. Lane X contains the protein standards (from top to bottom) ovotransferrin (77 kDa), albumin (66 kDa), ovalbumin (43 kDa), carbonic anhydrase (30 kDa), and myoglobin (17 kDa). The polyacrylamide gel was of 10% (w/v) acrylamide, 2.7% Bisacrylamide, in a discontinuous Tris-chloride-glycinate buffer system [Fig. 2, M. Costas (1990) *Electrophoresis* **11**, 382].

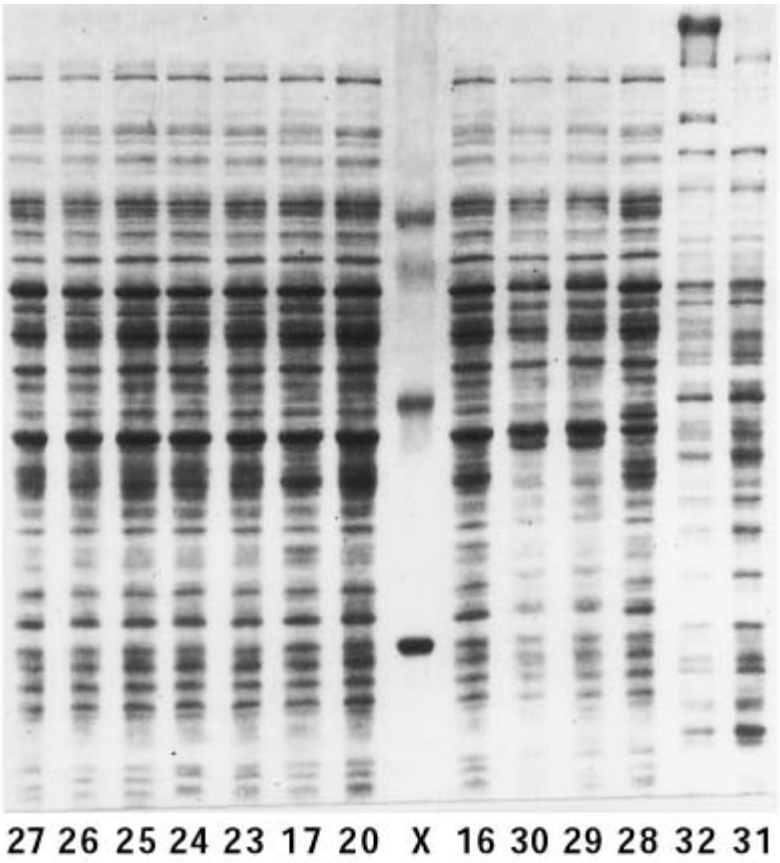

Figure 2. Standard curve of log(molecular weight) versus relative distance migrated in SDS-PAGE. Twelve standard proteins of known size were separated by SDS-PAGE in polyacrylamide gels of six different concentrations. The protein of molecular weight to be determined was rhodopsin. [Fig. 2 of R. N. Frank and D. Rodbard (1975) *Arch. Biochem. Biophys.* **171**, 1–13].

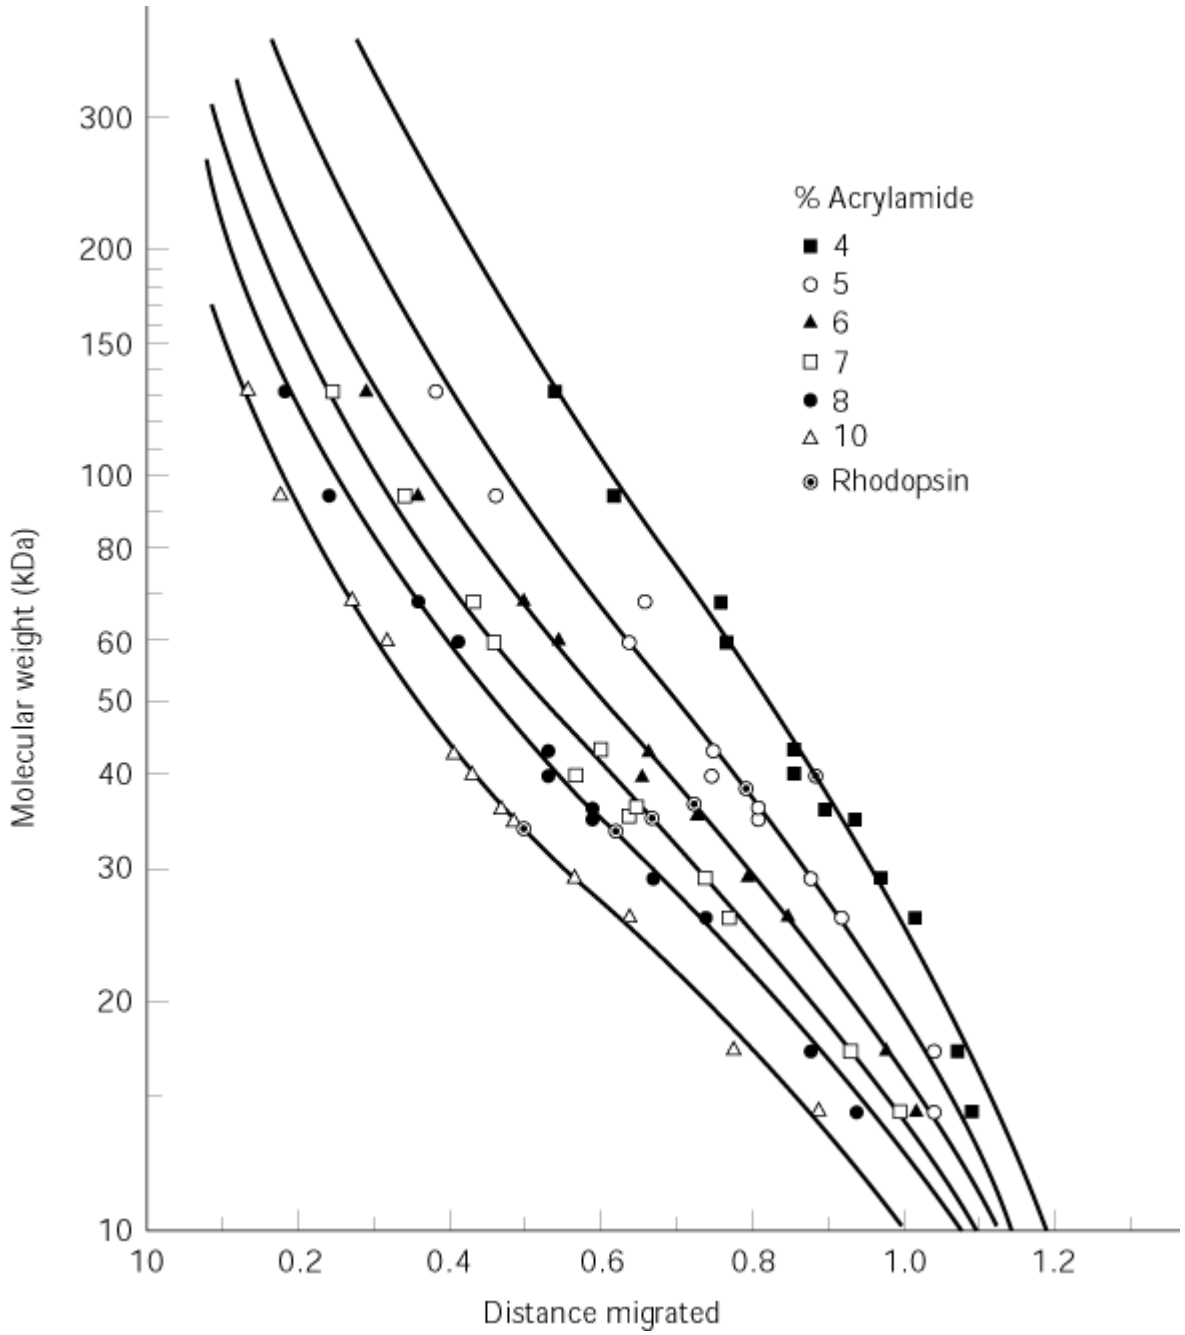

The four simplifying conditions of SDS-PAGE given above are, however, not entirely or always valid, since:

1. The mobilities are usually constant between pH 7 and 11 but not at lower pH values.
2. The derivatization of proteins with SDS produces polypeptides of uniform random-coiled conformations only when the reaction conditions are sufficiently severe. In particular, the reaction time needs to be sufficient, which in many cases requires prolonged boiling with SDS. Once conformational uniformity and an approximately uniform net charge are attained (see condition 3 above), the mobilities and separations are more reproducible than those of native proteins.
3. Equalization of the surface charge densities of polypeptides by reaction with SDS is incomplete for proteins with extreme net charges or for those containing glyco-, lipo-, or nucleo-moieties. Such incomplete saturation of the protein surface with SDS accounts for the failure of the Ferguson plots of many SDS-polypeptides to intersect at or near the ordinate (1).

4. When the charge densities among proteins are not fully equalized by derivatization with SDS, the ratio of mobilities between size standards and unknowns becomes dependent on gel concentration. Therefore, the molecular weight obtained from a comparison with the mobilities of standards will vary with gel concentration; in that case, accurate molecular weights of SDS-polypeptides, like those of native proteins, can be derived only from the slope of a Ferguson plot (2).
5. Even if surface charge and conformational equalization among proteins are established for particular proteins, the sigmoidal nature of the plot of log(molecular weight) versus migration distance (Fig. 2) needs to be recognized (2). Thus, the approximation of linearity in the central segment of the sigmoidal curve needs to be restricted to a relatively narrow range of migration distances.

There are other common problems with SDS-PAGE:

1. Its SDS concentrations are greater than the critical micelle concentration (cmc), so that the SDS is present as micelles. Micellar SDS bound to the tracking dye unstacks at high gel concentrations in disc electrophoresis; so a tracking dye that marks the moving boundary front at low gel concentrations fails to do so at high concentrations (1).
2. Polyacrylamide is oxidative, and so disulfide bonds may be re-formed after proteins enter the gel; also, oxidation of agents used to reduce any disulfide bonds in the original sample may introduce artifactual new components in the gel pattern.
3. There is no theoretical understanding of SDS-PAGE in discontinuous buffer systems that takes account of moving boundaries set up by monomeric or micellar SDS and its complexes with buffer constituents.

For the foregoing reasons, it is always advisable to establish the accuracy of any important molecular weight value by Ferguson plot analysis.

Sec Mutants/Proteins

A compelling approach to any biological process is to generate mutants that affect it. One such process is protein secretion. Almost all cells in almost all organisms are capable of secreting proteins. Thus it is possible to study secretion in two of the organisms most amenable to genetic analysis, *Escherichia coli* and *Saccharomyces cerevisiae*. Mutants in bacteria and yeast with defective secretion have been called sec mutants.

Proteins are secreted from bacteria by translocating them in an unfolded state directly from the cytoplasm across the plasma membrane into extracellular space. The sec mutations in *E. coli*, therefore, affect the unfolding process (secB, Table 1), the translocase or pore in the plasma membrane through which the nascent protein passes (*sec*Y, *sec*E, *sec*G, etc.), and the motor that drives the protein through the pore (*sec*A).

Yeast, like all eukaryotic cells, translocate newly synthesized proteins across the membrane of the endoplasmic reticulum (ER). This process closely resembles translocation across the plasma membrane in bacteria. The protein must be kept unfolded by a **molecular chaperone** (Table 1) and is translocated through a pore whose basic constituents are **homologous** to the *sec*Y, *sec*E, and *sec*G proteins in *E. coli* (Table 2). There is no eukaryotic equivalent of the ATP-driven (adenosine triphosphates) translocating machinery, encoded in *E. coli* by *sec*A.

Table 1. Mutations Affecting Chaperones

Name	Organism	Location	Notes
*Sec*B	*E. coli*	Cytoplasm	Delivers protein to *sec*B
*DNA*JK	*E. coli*	Cytoplasm	?
*Gro*E	*E. coli*	Cytoplasm	Affects pre-**b-lactamase**. GroEL and GroES together form a complex multisubunit structure (chaperonin)
Ffh	*E. coli*	Cytoplasm	Part of bacterial ribonucleoprotein signal recognition particle (SRP) complex; interacts with 4-5S RNA
*sec*65	yeast	Cytoplasm	Homologue of 19-kDa protein of mammalian SRP.Required for assembly of integral membrane proteins
*SRP*54	Yeast	Cytoplasm	Homologue of 54-kDa protein of mammalian SRP,also a GTPase
Ssa 1-4	Yeast	Cytoplasm	Members of yeast **heat-shock** protein family required for ATP-dependent posttranslational translocation
*Kar*2p	Yeast	Lumen of ER	Analogous to mammalian BiP, required for translocation into ER
*PDI*1	Yeast	Lumen of ER	A protein disulfide isomerase that catalyzes disulfide bond formation asthe nascent chain enters the ER
*FkB*2	Yeast	Lumen of ER	**Peptidyl proline** *cis-trans* isomerase

Table 2. Mutations Affecting Membrane Translocation

Name	Organism	Location	Notes

*sec*Y, E, G	*E. coli*	Plasma membrane	Forms transmembrane channel
*sec*A	*E. coli*	Cytoplasm	ATP-driven shuttle, pushing protein through translocon.Recognizes newly synthesized protein, complexed with secB
*sec*D, *sec*F	*E. coli*	Plasma membrane	Accessory proteins for bacterial translocon
*sec*61, 62, 63	Yeast	ER	Forms transmembrane channel Homologue of mammalian 61p, a, b, g
SRP 101	Yeast	ER membrane	A GTPase that acts as receptor for a signal recognitionparticle (SRP); homologue of mammalian a-subunits
*ft-s*Y	*E. coli*	?	Bacterial homologue of SRP receptor

In eukaryotes, protein secretion also requires membrane traffic from the endoplasmic reticulum to the **Golgi complex**, and from there to the plasma membrane. Each of the two membrane trafficking steps involves segregating cargo proteins from endogenous proteins, forming a carrier vesicle, and fusing the carrier vesicle with the appropriate target. The same categories of proteins are involved in each step: namely, sortases, coating molecules, and SNARE complexes to allow fusion. There are also conserved Gtpases (guanosine triphosphate hydrolases) that regulate the coating and targeting steps. Finally, the movement of carrier vesicles sometimes requires cytoskeleton elements, and so secretion can be perturbed by mutations that affect the cytoskeleton.

The steps at which sec mutants act are described in the entries protein secretion, exocytosis, and secretory vesicles/granules. Indeed, much of our understanding of these topics has come from analysis of mutants defective in secretion. For convenience, mutations are listed here by their function. It is doubtful that all mutations that affect secretion have been identified, but the overall patterns seem to be clear.

In several cases, yeast mutations that affect secretion were not isolated through a direct screen for a secretion deficiency. Instead, they were selected as mutations that acted as **suppressors** of a deficiency, or as giving synthetic lethality when combined with a weak secretion-deficiency allele. In other cases, they were identified by homology to a mammalian protein of known function. Finally, some were products of other selections but were found also to have a “sec” phenotype. Thus not all of the mutants listed in Tables 1 and 2 have the conventional designation of sec followed by a number or letter.

1. Chaperones

Molecular chaperones are proteins that help keep newly synthesized proteins unfolded until they pass through the transmembrane channel and then help fold them correctly after translocation. Representative examples are given in Table 1.

2. Membrane Translocation

The newly synthesized proteins cross membranes via a proteinaceous channel. Proteins that recognize the signal peptides help present the newly synthesized protein to the channel. Mutations

are found in channels and in the receptors that recognize signal peptides.

3. Budding from the endoplasmic reticulum

In eukaryotes, newly synthesized proteins leave the ER in a coated vesicle. The COPII coatomers are clearly involved in the ER to Golgi pathway. Since the *ret*1 mutation blocks retrieval of dilysine-containing ER proteins from the Golgi, COPIs are involved in intra-Golgi or Golgi to ER traffic. Mutants in COPI may only affect ER to Golgi traffic indirectly. Cargo can be selected from ER-resident proteins by specific "sortases" such as *SHR*3 or *emp*24. (See Table 3.)

Table 3. Mutations in ER to Golgi Traffic

Name	Organism	Location	Notes
*SHR*3	Yeast	ER membrane	A sortase required specifically for amino-acid **permease** export from the ER
*emp*24	yeast	ER membrane	Required for invertase secretion. Believed to be a carrier molecule
*sec*23/24	Yeast	Cytosol	Form a heterodimer; *sec*23p has GAP activity. With *sec* 13/31, form a COPII coat on ER-budding vesicles
*sec*13/31	Yeast	Cytosol	Form heterodimers. With *sec*23/24p, form a COPII coat on ER-budding vesicles
*saur*1	yeast	Cytosol	A yeast GTPase, homologous to ARF1, which mediates coating and uncoating
*sec*12	yeast	ER membrane	Sar1 exchange factor
RET 1/*sec*26	yeast	ER membrane	Homolog of the a-, b-, b′-, and g-subunits of *sec*27, *sec*21 mammalian coatomer (COPI)
*ARF*1/2	yeast	ER membrane	Yeast homologues of the small mammalian GTPase, ARF1

4. Fusion of ER-Derived Carrier Vesicles with Golgi Membranes

ER-derived vesicles fuse with the *cis*-Golgi network. Recognition appears to be mediated by specific SNAREs. There is also a parallel recognition pathway involving another small GTPase, *ypt*1 or *rab*1, which, like all *rab* proteins, has an isoprene addition to its *C*-terminal tail. (See Table 4.)

Table 4. Mutations Affecting Fusion with Golgi Membranes

Name	Organism	Location	Notes

*Bct*1	Yeast	ER carrier vesicle	Similar in structure to a v-SNARE
*Bos*1	Yeast	ER carrier vesicle	Suppressor of *bet*1 mutations. Required for fusion competence. Homologue of synaptobrevin/VAMP
*sec*22	Yeast	ER carrier vesicle	v-SNARE
*ypt*1	Yeast	ER carrier vesicle	A small ras-like GTPase, homologue of mammalianrab1
*bet*2	Yeast	Cytoplasm	A geranyl geranyl transferase for *ypt*1
*sec*18	Yeast	Cytoplasm	An ATPase required for all fusion reactions; homologue of NSF (*N*-ethylmaleimide sensitive factor)
*sec*17	Yeast	Cytoplasm	Peripheral membrane protein that binds *sec*18p to membranes; homologue of a-SNAP
*end*2	Yeast	Golgi membranes	Receptor for proteins carrying HDEL sequence; homologue of mammalian KDEL receptor
*sed*5	Yeast	Post-ER structures	A putative t-SNARE; homologue of mammalian syntaxin
*sly*1	Yeast	Golgi membranes	Homologue of *sec*1,which interacts with syntaxin at the cell surface

5. Golgi to Plasma Membrane Traffic

The basic requirements for transfer between Golgi and plasma membrane are identical to those that are involved in ER to Golgi traffic, since the steps of vesicle formation and selective vesicle fusion are common to both. Sometimes the same proteins—for example, *sec*17p (a-SNAP), *sec*18p (NSF) (NEM-sensitive factor), and ARF1 (ADP–ribosylation factor)—are common to both steps. Table 5 shows mutations that affect exocytoses.

Table 5. Mutations that affect Exocytosis

Name	Organism	Location	Notes
*Snc*1,2	Yeast	Secretory vesicles	Homologues of VAMP/synaptobrevin. Redundant geneproducts
*sec*7	Yeast	Golgi	Peripheral membrane protein believed to coat Golgi-derived carrier vesicles
*kex*2	Yeast	Golgi membrane	Serine proteinase that cleaves protein precursors in lumen of Golgi that have Lys–Arg or Arg–Arg sequences. Homologue of mammalian furin
*kex*1	Yeast	Golgi	Removes the two basic residues after

		membranes	*kex*2 has made its proteolytic cleavage
*sec*1	Yeast	Plasma membrane	Homologue of *nsec*1, which binds tightly to syntaxin. Mutants cause secretory vesicle accumulation
*sec*9	Yeast	Plasma membrane	Homologue of SNAP-25
*sec*8,	Yeast	Cytoplasm	Forms a large 19S complex required for *sec*15, etc. exocytosis, in addition to SNAREs
*sec*4	Yeast	Secretory vesicles	A small GTPase of the ras family
*DSS*4	Yeast		A **guanine nucleotide exchangeprotein** acting on *sec*4
*act*1	Yeast	Cytoplasmic cytoskeleton	Mutants cause accumulation of 100-nm secretoryvesicles
MYO-2Yeast		Cytoplasmic cytoskeleton	A novel yeast myosin of the class V-type; causes accumulation of 100-nm vesicles

Second Messengers

In most cases of hormonal signal transduction, the a subunits of heterotrimeric G proteins interact directly with one or more effector proteins in the plasma membrane, to induce the release of soluble second messengers that in turn amplify the hormonal signal into the cell. While the number of effectors continues to grow, four distinct types have been studied in detail: adenylate cyclases, phospholipases, **ion channels**, and phosphodiesterases. All of these enzymes are known to be transmembrane proteins, or proteins that closely associate with the plasma membrane, and they interact with receptor systems to generate second messengers, especially cyclic AMP, diacylglycerol, **inositol phosphates**, and **calcium**.

1. Effectors of Signal Transduction

1.1. Adenylyl Cyclase

The first well-characterized effector system in signal transduction centered around the discovery of cyclic AMP as a second messenger by Sutherland et al. It is now known that adenylyl cyclases are a large multigene family, with a conserved basic structure. Thus far, nine basic forms of adenylate cyclase have been identified, with different sensitivities to calcium, G proteins, and regulation by **phosphorylation** (1). Like many ion channels and other membrane transporters, the adenylyl cyclases are characterized by 12 a-helices: One intracellular loop occurs between the sixth and seventh transmembrane domain (C1), and another (C2) occurs at the *C*-terminal tail. The amino terminus of the protein is also thought to be intracellular. While the a-helices diverge significantly between the family members, the intracellular loops are conserved. The C1 and C2 regions are thought to contain the catalytic activity of the enzyme and to be responsible for much of its regulation.

In addition to regulation by both the a and bg subunits of heterotrimeric G proteins, some forms of adenylate cyclase are also subject to regulation by the diterpene forskolin, by calcium/calmodulin, and by **phosphorylation** catalyzed by several kinases. It has been speculated that the Gasubunitinteracts directly with the C1 and/or C2 domains of cyclase, although it remains unclear how the inhibitory actions of G proteins are mediated. Calmoldulin is thought to interact with the amino-terminal region of C1 in adenylate cyclase I, whereas phosphorylation by CAM kinase in adenylate cyclase III is thought to occur in the *C*-terminal tail (1) (see Calcium Signaling).

1.2. Phospholipases

Another second messenger system that plays a key role in the regulation of cellular function involves the generation of small molecules derived from phospholipid metabolism. The hormone-sensitive enzymes that catalyze these reactions are phospholipases. The phosphatidylinositol cycle in particular (see Inositol Lipids and Phosphates) results in the generation of two potential second messengers, the membrane-associated diacylglycerol, which can activate protein kinase C, and inositol trisphosphate, which can lead to the mobilization of intracellular calcium levels.

1.3. Ion Channels

There are many examples of **ion channels** that are regulated by heterotrimeric G-protein Ga subunits in a manner analogous to that described for adenylate cyclase and phospholipase C (2). Numerous studies have focused on voltage-gated Na^+, K^+, and Ca^{2+} channels in different tissues, particularly endocrine and neuronal cells. In general, receptors linked to slow synapses in the central nervous system are coupled to ion channels through G proteins. These changes in ion permeability are slower than those induced by ligand-gated channels (see text below) and are generally longer-lasting. In many cases, ion channels are regulated by Gi subunits.

The voltage-sensitive ion channels that are regulated by G-protein interactions have been the subject of extensive investigation. While there has been significant progress in elucidating the subunit structures of these channels and their regulation by various toxins, the molecular details of G-protein interaction remains cloudy. Probably the best-studied system has been the regulation of K^+ channels by the muscarinic acetylcholine receptor. In this case, the binding of acetylcholine to the receptor activates a Gi protein, leading to the dissociation of ai from bg. It is then thought that ai can directly activate the K^+ channel, although bg subunits can interact with the channel as well (2, 3).

1.4. Phosphodiesterases

Cyclic nucleotide phosphodiesterases (PDEs) are a large superfamily of enzymes that play an important role in the termination of cyclic AMP (cAMP) and cyclic GMP (cGMP) signaling. Some forms of PDE specifically recognize one cyclic nucleotide, while others are less specific. The best-studied of these enzymes are the cGMP-specific forms of PDE. These enzymes are regulated directly by G proteins, such as rhodopsin in rod outer segments. In this system, the activation of rhodopsin by light leads to activation of the heterotrimeric G protein known as transducin. In its GTP-bound, activated state, transducin abinds directly to cGMP PDE, inducing its activation through the release of the gsubunit of PDE (4). For the other isoforms of PDE, the modes of regulation are less well established, although some may involve feedback **phosphorylation**.

2. Targets

Many of the effects of second messengers on cells are mediated by the activation of protein **tyrosine kinases** and **serine-threonine kinases**. Indeed, protein **phosphorylation** is the major currency by which signals are transmitted in cells. While there have been over 1000 protein kinases identified to date, only a subset are thought to be activated by soluble second messengers. The second messenger-activated kinases can be categorized based on the upstream processes that lead to their regulation. They are protein kinase A (or cyclic AMP-dependent protein kinase), protein kinase C, and CAM kinase, which is a critical target in calcium signaling .

Secondary Structural Prediction Of Proteins

The **secondary structure** of proteins is the two-dimensional arrangement of the **polypeptide** backbone, defined primarily by a network of hydrogen bonds. The two most common and most regular secondary structures are the alpha-helix and the beta-sheet . The beta-sheet is made up of b-strands arranged in either parallel or antiparallel fashion. The goal of secondary structural prediction is a relatively modest aspect of **protein structural prediction** to infer the location of a-helices and b-strands along the polypeptide chain without necessarily determining how the latter associate into a b-sheet. Therefore, the prediction problem is formally no longer two-dimensional, but it is addressed to the correspondence between two linear strings, the amino acid sequence and the linear sequence of elements of secondary structure in the sequence. The secondary structure is often denoted by letters: A, a-helical; B, b-stranded; C, coil or other conformations. Any predictive algorithm produces a string of A's, B's, or C's along the sequence being analyzed, and then this outcome must be compared with the real secondary structure, when known. The success rate of the prediction is measured simply as the percent of residues that were predicted correctly, counted on a residue-by-residue basis. The random level of the three-state predictive accuracy might be expected to be close to 33%, but it is actually about 40%, because of an uneven distribution of the three states in known structures: on average, the coil is the most abundant, and the b-strand the rarest.

A wide variety of predictive methods have been developed to date, but the basic logic of most of them is like that developed by Chou and Fasman (1). It is assumed that individual amino acid residues have their own intrinsic propensities to form a-helix, b-strand, or coil conformations. For example, every alanine residue has a certain propensity for A, B, and C conformations, and every valine has different propensities, as do the other amino acid residues. These propensities are assumed to be additive along a sequence, to give a propensity for any segment of residues to adopt each conformation. The propensities for individual residues are estimated from the known protein structures. This type of logic can be extended to a “directional” propensity (2), which incorporates the influence of near-neighbor residues, or it can be extended to pairs (3) or triplets (4) of residues. Neural networks and genetic algorithms operate similarly, predict the secondary structural state of the central residue in each window of about 10 residues, and take into account the influences of all the residues within the window on the conformational state of the central residue (5). The parameters used are estimated by the computer “learning” from the known protein structures using the neural network algorithm. The simple application of neural networks, assuming only the input and output layers, is almost identical in logic to the directional propensity method (6), but it becomes more complicated upon adding “hidden layers” inserted between the input and output layers. The “hidden Markov” method (HMM) is another technique that was developed in informatics theory and applied to protein secondary structural prediction (7).

The number of parameters required for the simple method of Chou and Fasman (1) is only 60 (20 amino acids × 3 states each), about 1000 for the “directional” propensity (20 amino acids × 17 positions of neighboring residues × 3 states) (2), and more than 10,000 for the method using residue-

pair propensities (20 × 20 amino acid pairs × 10 positions × 3 states) (3). Only 29 protein structures with a total of about 6,000 residues were known at the time Chou and Fasman developed their method (8). This was sufficient to derive the 60 parameters for their method but was dubious for the second method and very insufficient for the third. As the size of the structural databases increased, much more data became available, making it possible to derive reliable parameters for more complex methods, and the predictive accuracy has also increased. Whereas the initial predictive accuracy for the Chou–Fasman technique was a significant 55% or less (9, 10), that figure has now reached 70% or more (11, 12). For example, a neural network composed of five independent networks can use a number of homologous sequences aligned with each other (11). Such a treatment is logical because proteins that have homologous sequences adopt basically the same fold. So using a number of them increases the information available (see Homological Modeling). The predictive methods just described use as input only the local sequence information, such as the neighboring residues within a narrow window. Recently, algorithms to incorporate global features of the input sequence have also been developed (13, 14). Thus, secondary structure predictions are still under development, and the structural database is growing by 40% each year.

How much further can the predictive accuracy increase? It is almost certain that 100% accuracy is impossible. One of the reasons is simply technical. Assignment of secondary structure in real protein structures involves some ambiguity because the local structure can be irregular. The computer program DSSP (15) is widely used to assign the ranges of a-helix and b-strands along a polypeptide chain automatically from the atomic coordinates of the structure determined experimentally. X-ray crystallographers, on the other hand, often assign the secondary structure by manual inspection and record their own assignments in the Protein Data Bank (PDB) file (16). It would not be correct to consider one assignment more correct than the other. The DSSP assignments sometimes appear too strict to the eye, although they are the more objective, so long as the atomic coordinates of the model are correct. When these two types of assignments are compared with each other in 200 well-resolved and unrelated structures, the percentage of identical three-state assignments is about 90%. This figure may indicate the upper limit to the predictive accuracy.

Secondary Structure, Protein

Protein structure is classified in a hierarchical manner into primary structure, secondary structure, tertiary structure, and quaternary structure . The secondary structure of a protein refers to the **backbone conformation** of the polypeptide chain. There are several different types of secondary structure elements found in proteins, including the regular a-helix and b-sheet as well as the nonregular omega loops and turns that reverse the direction of the polypeptide chain. Regular secondary structure is defined by repeating backbone dihedral angles and hydrogen bonds of the peptide backbone. Nonregular secondary structure does not have repeating backbone angles, and the backbone hydrogen-bonding pattern is irregular.

The peptide backbone dihedral angles around the N–C_a and C_a–C bonds are referred to as phi (f) and psi (y), respectively. Only certain combinations of f/y angles are allowed due to steric restraints imposed by the amino acid side chain; f is almost always negative (see Ramachandran Plot). The **glycine residue**, with only a hydrogen for its side chain, has a high degree of backbone conformational flexibility and can adopt f/y angles that are forbidden for other amino acid residues (for example, positive f angles). Generally, over 90% of nonglycine amino acid residues in a protein structure have backbone conformations close to those of the a or b types of secondary structure. This can be visualized in the Ramachandran plot, which shows the allowed combinations of f/y angles as discrete regions or areas and is used to plot observed f/y combinations for each residue in a protein structure.

Different types of secondary structure have different f/y combinations and different hydrogen bond patterns. For example, the a-helix has f and y angles of close to –60°and –50°, respectively, and is stabilized by (*i*+4) hydrogen bonds—that is, hydrogen bonds formed between the backbone carbonyl oxygen of one residue *(i)* and the backbone nitrogen of another located four residues further on in the sequence (*i*+4). In contrast, the b-strand structure is characterized by an almost fully extended polypeptide backbone conformation (f and y angles of close to –120°and 140°, respectively) that forms hydrogen bonds with backbone atoms of adjacent b-strands to form b-sheets.

In the absence of a complete three-dimensional structure of a protein, its secondary structure may be predicted or determined experimentally. **Secondary structure prediction** is based on the observation that individual amino acid residues have different tendencies to form a-helices, b-sheets, or turns. The sequence of amino acid residues in a protein, its primary structure, is therefore used to predict its secondary structure. Circular dichroism measurements of a protein can be used to estimate the relative proportion of each type of secondary structure in a protein, and nuclear magnetic resonance (NMR) can be used to assign the secondary structure type for each amino acid residue.

The three-dimensional structures of proteins consist of many thousands of atoms and are very complex. Often, their structures are represented simply by showing the backbone trace of the protein, with the secondary structure components identified (Fig. 1).

Figure 1. Representation of the backbone structure of the oxidoreductase protein thioredoxin (1) showing the secondary structure elements. a-Helices are shown as blue coils, and b-strands are shown as green arrows. Loops and turns are in yellow. This figure was generated using Molscript (2) and Raster3D (3, 4). See color insert.

Secretion Vector

A secretion vector is a specialized expression **vector** (see Expression Systems) that directs the production of protein for locations other than the cytoplasm. Transport out of the cytosol can be achieved by fusing the gene of interest with a nucleotide sequence encoding the signal peptide of a

readily **secreted protein**. The use of a secretion strategy has many potential advantages, including high yields, simplified purification, improved stability; escape from cytoplasmic proteins, especially proteinases, prevention of toxicity; avoidance of an N-terminal methionine residue extension (mainly a problem in **prokaryotic** expression systems); and localization in a more oxidizing environment where disulfide-bond formation may proceed and the protein may fold correctly, alleviating formation of inclusion bodies (which is mainly a problem that occurs on overexpression of a protein of **eukaryotic** origin in a prokaryotic host).

Secretion vectors can be designed for a broad spectrum of hosts, including both **Gram-negative** and Gram-positive bacteria, hosts ranging from primitive eukaryotes to higher eukaryotes, including mammals.

1. Gram-negative Bacteria

In Gram-negative bacteria, such as *Escherichia coli*, proteins can be targeted to the **periplasm** (the compartment between the cytoplasmic and the outer membrane), the outer membrane, or the culture medium. By definition, export takes place in the first two cases, whereas only in the latter case does true secretion occur. Proteins directed to the periplasm can be specifically released by osmotic shock treatment, providing an enrichment of the protein. Three pathways exist for protein targeting in Gram-negative bacteria: the type I pathway (also known as the *single-step pathway*, the *signal sequence–independent pathway*, or the *hemolysin pathway*); the type II pathway (also known as the *two-step pathway* or the *general secretion pathway*, or GSP); and the type III secretion pathway.

1.1. Type I Pathway

In the type I pathway, the proteins are translocated across both the cytoplasmic and the outer membrane in a concerted manner. The best-known protein secreted in this way is hemolysin. The signals targeting the proteins to the type I pathway are located at the carboxyl end of the molecule, but there is disagreement on the **consensus sequence** of this "secretion signal." The genes essential for type I secretion in *E. coli* include *hlyB*, *hlyD*, and *tolC*. The first two are not found in laboratory strains of *E. coli* but can be introduced into them. The key element in this pathway, the carboxy-terminal domain of the hemolysin protein, can be fused to a "passenger" protein. The resulting **fusion protein** will, in many cases, be efficiently secreted into the extracellular medium. If the native form of the protein of interest is required, a specific proteinase cleavage site should be introduced between the "passenger" and the "carrier." A drawback of this pathway is the unpredictability of what makes a good passenger (1).

1.2. Type II Pathway

Most secretion vectors use the type II pathway, in which the protein to be secreted is equipped with an amino-terminal **signal sequence** (also known as a *leader sequence* or *presequence*). This sequence marks the protein for transport through the cytoplasmic membrane, which is accomplished by the **Sec protein** complex in *E. coli* and presumably by **homologous** pathways in other species. These signal sequences share characteristic features with the signal sequences directing proteins to the extracellular medium in Gram-positive bacteria or the lumen of the endoplasmic reticulum (ER) of eukaryotes: the N-terminal region is rich in positively charged amino acid residues, the core domain is hydrophobic, and the C-terminal region contains the signal recognized by a signal peptidase, which removes the signal peptide during the translocation process. The signal sequences of secreted *E. coli* proteins, such as OmpA, maltose-binding protein, alkaline phosphatase, and b-lactamase, have been used with success for the export of heterologous proteins. As another example, the **promoter** and secretion signals of staphylococcal protein A (SpA) have been shown to be functional also in the Gram-negative *E. coli*. Protein A fusions are secreted to the periplasm of the bacteria and, in some cases, to the culture medium; from there, they can be readily purified by immunoglobulin G affinity chromatography (see Fusion Gene, Fusion Protein).

Proteins to be secreted through the outer membrane reside temporarily in the periplasm, where folding and assembly are carried out, before transport through the outer membrane can take place

(2). In principle, the fusion of a signal sequence to the protein of interest should direct the protein into the periplasmic space. Not all proteins are compatible with the type II pathway, however. In some examples, chimeric heterologous proteins are incorrectly folded, which blocks their transport into the periplasm. The overexpression of various **molecular chaperones**, eg, **DnaK/DnaJ** or various components of the Sec system, will, in some cases, relieve this problem. In other cases, however, more specific folding catalysts are needed. If the folding process in the periplasm is inefficient, the accumulated, misfolded proteins may induce the **heat-shock** response, leading to increased proteolysis.

In general, the success of a secretion strategy using a bacterial host is most likely with proteins that are naturally secreted bacterial exoproteins. More problems are often encountered when the protein of interest is of eukaryotic origin, and the magnitude of the problems seems to correlate with the size of the protein in question. Certain large eukaryotic proteins require the addition of post-translational modifications in order to be secreted properly. Also, the assistance of accessory factors not present in the bacteria may be needed.

1.3. Type III Pathway

The type III pathway is present in certain pathogenic bacteria and has been found to secrete proteins involved in virulence toward animals and **plants**. The signal sequence involved in this pathway is positioned at the N-terminus of the proteins. It does not have the characteristics of a classical signal peptide, however, and is not cleaved off during the translocation.

1.4. Leakage through the Outer Membrane

Another mode of secretion is semispecific secretion, in which the expression of a recombinant protein in the periplasm causes the outer membrane to destabilize and become permeable, allowing the protein to diffuse from the cell in a partly specific manner. The production level using this approach can be rather high, but the bacteria will often be killed by the destruction of their outer membrane. A similar result is obtained by the use of so-called leaky mutants with a defective outer membrane, from which the periplasmic proteins are slowly released (3). Another approach to inducing limited leakage of the outer membrane utilizes the coexpression of the bacteriocin release gene (4). Protoplast type L-forms of various bacteria, including *E. coli*, lack the outer cell wall and the periplasmic space, which permits direct secretion of recombinant proteins into the extracellular medium (5).

2. Gram-positive Bacteria

The outer membrane of Gram-negative bacteria presents a strong barrier to the secretion of proteins. Gram-positive bacteria do not have this outer membrane to prevent exported proteins from being released from the cell. Gram-positive *Bacillus* have become very popular hosts for expression, mainly as a result of their potential to secrete proteins directly into the culture medium. Signal sequences of Gram-negative (type II pathway) and Gram-positive microorganisms share the same structural features. One of the serious disadvantages of using *B. subtilis* as an expression host is the secretion of high levels of proteinases. Proteinase-deficient strains that grow normally have been constructed, but particularly susceptible proteins may still be difficult to produce. Another *Bacillus* species, *B. brevis*, has an advantage over *B. subtilis* in that its level of extracellular proteinase activity is very low (6). Mammalian proteins are often toxic to *B. brevis*, and it is therefore necessary to screen a large number of transformants for particular clones that produce the mammalian protein in large amounts. Furthermore, the productivity is highly dependent on growth conditions (eg, medium composition and temperature), and these have to be optimized individually for each new protein produced.

3. Eukaryotic Secretion Systems

The eukaryotic secretory pathway is similar to the type II pathway of Gram-negative bacteria. The emergence of the signal peptide from the ribosome synthesizing the protein to be secreted causes its

binding to the signal-recognition particle (SRP) and cessation of translation. The resulting complex is targeted to the rough endoplasmic reticulum (ER) via an interaction with the SRP receptor. Translation of the protein is then resumed, and the polypeptide chain is translocated across the ER membrane into the lumen of the ER, where the signal peptide is processed by the ER membrane-bound signal peptidase. Now maturation of the protein starts, including its folding and addition of post-translational modifications. This includes quality control to ensure that the protein fold is compatible with the secretion machinery. If this is found not to be the case, the protein is degraded, and this stage is where the major loss of heterologous proteins takes place. As the next step, the protein is transported in **vesicles** to the Golgi apparatus, where further maturation occurs. Finally, the protein is transported in vesicles to the cell wall and secreted into the extracellular medium. Heterologous proteins have a propensity for folding incorrectly in the ER, either because the levels of factors required for proper folding/processing are too low to handle the increased throughput or because the enzymes required to perform the authentic post-translational modifications are lacking. As an example, disulfide-bond formation catalyzed by protein disulfide isomerase (PDI) takes place in the ER lumen.

To ensure efficient secretion, it is usually advisable to choose the leader sequence of a homologous or closely related, naturally well-secreted protein. However, examples exist in which a signal sequence of a more distantly related species turned out to be the most efficient, such as the human versus honeybee signal sequence in the baculovirus/insect cell system (7). The precise natures of signal sequences are not fully understood. It is not possible to graft such signals onto a particular gene and to guarantee efficient export or secretion of the resulting product. Proteins that are not normally secreted may contain sequences that are incompatible with the export apparatus, and the attachment of a signal sequence to such a protein may kill the host cell.

As mentioned earlier, a secretion or export strategy may solve a protein degradation problem but, in some cases, it may also worsen the problem. Overloading the secretion machinery may block secretion and cause precursor molecules to accumulate, leading to the induction of a **stress response**; this often involves the production of several proteinases.

A special variant of secretion allows the display of peptides and proteins on the surface of a cell (8). This demands that the corresponding gene be fused to, or inserted into, the gene encoding an outer membrane protein or a cell surface structure. Such cells may be useful as live vaccines, as whole cell adsorbents, in biocatalysis or bioremediation, or in drug hunting. Also, the study of protein–ligand interactions may be facilitated. In eukaryotes, intracellular targeting to **organelles**, such as mitochondria or the nucleus, is another option that permits the study of the effects of a recombinant protein within a specific subcellular location (9).

Even though several examples of the successful application of a secretion strategy exist, a more thorough understanding of secretion mechanisms is required before predictable manipulations of secretion systems can be made to secrete native recombinant proteins that are not naturally targeted to the extracellular compartment.

Secretory Vesicles/Granules

Enzymes, growth factors, extracellular matrix proteins, and signaling molecules are all secreted by cells by fusion of a secretory vesicle with the plasma membrane, releasing the vesicular contents (see Exocytosis). All cells have constitutive secretory vesicles, which carry newly synthesized proteins directly from the Golgi complex to the cell surface (see Protein Secretion). Dedicated secretory cells, such as neuronal, endocrine, and exocrine cells, divert classes of secretory proteins out of the constitutive pathway into a specialized class of secretory vesicles, the secretory granules (1), which are stored in the cytoplasm until the cell receives an appropriate stimulatory signal. The term *granule* is a historical misnomer, deriving from the observations of early morphologists, who saw the granular content in their electron microscopy, before the limiting membrane was seen. The protein concentration of secretory granules can be so high, about 0.1 g/ml, that the proteins condense to give secretory granules a solid core that is dense in electron micrographs. A commonly-used alternative name is therefore dense core secretory granule or vesicle. Granulocytes and platelets also have dense core secretory granules that resemble, but are not identical to, those of neurons and endocrine and exocrine cells. Dense core secretory granules are all examples of secretory vesicles derived from the biosynthetic pathway, whose main function is to carry newly synthesized proteins to the cell surface (2). A fourth major group of secretory vesicles, the synaptic vesicles, are generated by endocytosis from the cell surface (3, 4). Because they do not form at the **Golgi complex**, synaptic vesicles cannot contain newly-synthesized proteins. Instead they secrete small molecules, such as acetylcholine, glutamate, glycine, catecholamines, and g-amino-butyric acid, which they take up directly from the cytoplasm using specialized membrane **transporters**.

Regulated secretory vesicles accumulate in the cytoplasm because their exocytosis is normally inhibited. The accumulation of such vesicles in the cytoplasm is a defining morphological feature of endocrine and exocrine cells, granulocytes, and neurons. An appropriate extracellular signal can remove the inhibition, leading to a massive release of the contents stored in the cytoplasmic vesicles. It is the capacity of such cells to trigger release from a stored pool that gave rise to the term *regulated* secretory vesicles, to contrast them with constitutive secretory vesicles, whose exocytosis occurs in the absence of an extracellular stimulus.

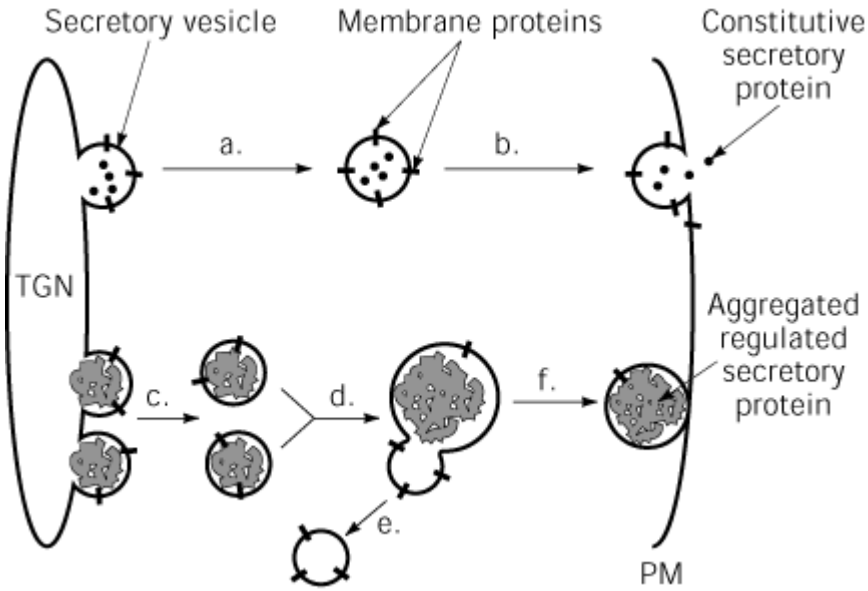
1. Secretory Granules from Endocrine Cells

1.1. Formation

In endocrine cells, proteins in the *trans* region of the Golgi complex, the *trans*-Golgi Complex, are segregated into two export pathways. Whereas some exit by the conventional constitutive route, others are segregated into the specialized regulatory pathway. Proteins that are segregated into a regulated pathway have a feature absent from constitutively secreted proteins. Thus, if a chimera is made of a regulated pathway protein and a constitutive pathway one, the chimera is sorted into the regulated pathway (5). The feature that allows regulated pathway proteins to be sorted away from other secreted proteins may not be the usual **signal sequence**, a short stretch of contiguous amino acids residues, but it appears to be a region that encourages the formation of large protein complexes in the milieu of the *trans*-Golgi complex (6). An exception to this might be the hormone pro-opiomelanocortin, which has been reported to have a signal peptide recognized by a receptor (7). Condensation of proteins that will become the contents of secretory granules can often be seen in the lumen of *trans*-Golgi complex membranes, prior to secretory granule formation.

To form an immature secretory granule, a portion of the *trans*-Golgi network pinches off, trapping an aggregate of the secretory granule proteins. Several of these immature granules may fuse to give a precursor that contains all of the content of a secretory granule, but an excessive amount of membrane. To mature, excess membrane is removed from the secretory granule by a series of vesiculation steps (Fig. 1). The immature secretory granule retains some of the features of the Trans Golgi Network, since the excess membrane includes proteins that are destined to go to prelysosomal compartments (8). Maturation of the secretory granule requires coating molecules, clathrin, and the heterotetrameric adaptor, AP1, recruited to the membranes by the small GTPase, adenosyl ribosylating factor-1 (ARF-1) (9, 10), as in the case of other coating events in membrane traffic (see Protein Secretion).

Figure 1. Formation of constitutive and regulated secretory vesicles. (a–c) Both constitutive and regulated secretory vesicles bud from the *trans*-Golgi complex (TGN). (b) Constitutive secretory vesicles go directly to the cell surface, where they immediately fuse with the plasma membrane (PM) and release their protein contents. (c) Immature regulated secretory vesicles are formed by budding aggregates of regulated secretory proteins from the TGN. (d) Immature secretory vesicles fuse to form larger granules, (e) from which excess membrane and proteins can be retrieved and trafficked elsewhere in the cell. (f) The now mature secretory granule goes to the PM, where its exocytosis is blocked until the cell receives the proper signal to release its specialized proteins.



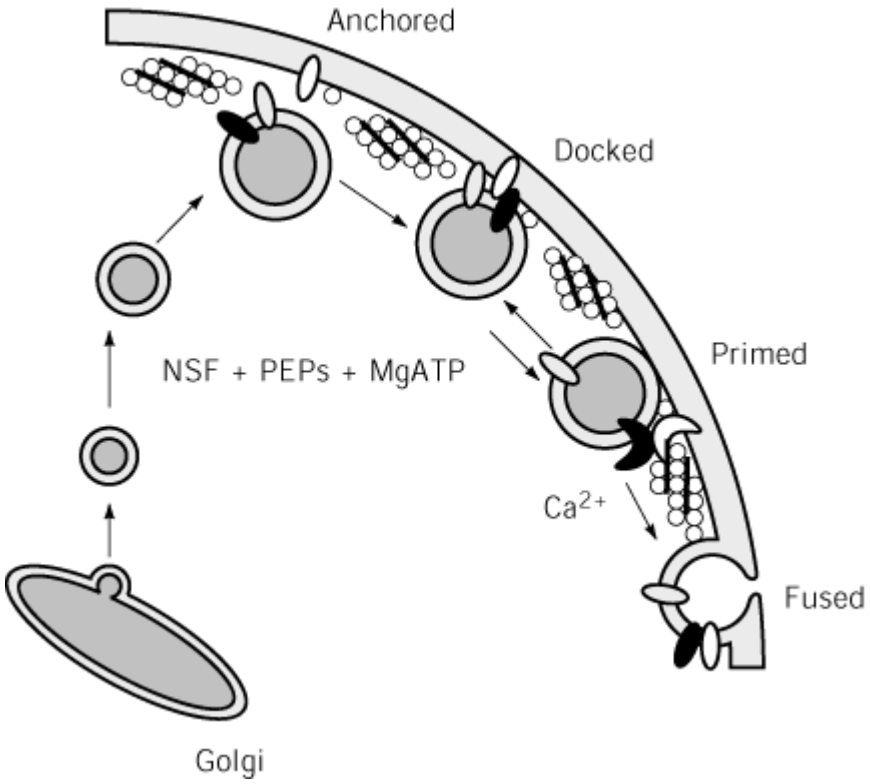
The core of the secretory granule contains proteins specific to the class of endocrine cells, (eg, hormones such as insulin or growth hormone). Most secretory granules also contain two other classes of protein, independent of their hormone content. One of these is the chromogranins: highly charged, and often sulfated, proteins that facilitate the condensation of hormones into a proteinaceous core (6). The second is a family of furin-related proteinases (see Protein Secretion) that act to convert prohormones into their biologically-active forms (11). These prohormone convertases act on prohormones after they have been sorted into secretory granules. Prohormone convertases and chromogranins also have sorting domains that target them to the regulated pathway rather than the constitutive pathways. The exact nature of the sorting domain remains obscure. Unlike retention signals for the endoplasmic reticulum, or internalization signals from the plasma membrane, no amino acid sequence motif has yet been identified for the sorting of convertases.

1.2. Docking and Fusion of Secretory Granules

To release their protein contents, secretory granules must first make contact with the plasma membrane, a process called docking. Then the secretory granule membrane fuses with the plasma membrane, a process called exocytosis (qv). Before docking occurs, the secretory granule migrates from its site of formation, the *trans*-Golgi network, to the plasma membrane. Movement is along microtubules, probably mediated by a "plus-end" directed motor protein of the kinesin family (1). Disrupters of microtubule structure, such as colchicine or vinblastine, inhibit the regulated secretion of hormones. The next step in reaching the cell surface requires the secretory granules to pass through the layer of cortical cytoskeleton comprised of actin, which underlies the plasma membrane. This process, mobilization, requires that the cortical cytoskeleton be temporarily removed. Actin-depolymerizing enzymes, such as gelsolin, have been linked to the mobilization process (12). Finally, the secretory granules can associate with the plasma membrane, ready for exocytosis. The molecular links between secretory granules and the plasma membrane are not known, but they are sufficiently strong that they can survive homogenization.

Some of the steps involved in the fusion reaction are now known. Two of the first steps require ATP. Before the secretory granule is competent to fuse, the phosphatidylinositol phospholipids in the cytoplasmic leaflet of its phospholipid bilayer must be correctly phosphorylated (see Inositol Lipids and Phosphates). This requires a phosphatidylinositol 5′ kinase to be present in the cytosol. The reaction is facilitated by a phosphatidylinositol-transfer protein present in the cytoplasm (13, 14) (Fig. 2).

Figure 2. Docking and fusion of secretory granules. Secretory granules travel from the Golgi, where they are formed, to the plasma membrane, where they become anchored once they pass through the layer of cortical actin cytoskeleton. Interaction between proteins (probably SNAREs) on the opposing membranes allows the vesicles to dock there. Vesicles become primed for exocytosis by two ATP (adenosine triphosphate)-dependent steps, dissociation of the SNARES by NSF (NEM-sensitive factor) and remodeling of the phospholipids by the PEPs (priming of exocytosis proteins). Influx of Ca^{2+} from nearby Ca^{2+} channels triggers fusion of the vesicles with the plasma membrane and exocytosis of the vesicle contents. [Redrawn from Fig. 4e in A. Banerjee, V. A. Barry, B. R. GasGupta, and T. F. J. Martin (1996) *J. Biol. Chem*. **271**, 20223–20226.]



In addition to correctly phosphorylated phospholipids, the secretory granule must have a functional v-SNARE (15) (see Exocytosis). Treatment of secretory cells with tetanus toxin, which is a v-SNARE-specific endopeptidase, blocks exocytosis (16). The secretory-granule v-SNARE forms a complex with two t-SNAREs, syntaxin and SNAP-25. This complex must be dissociated by the ATPase, *N*-ethylmaleimide sensitive factor, prior to the fusion event (17).

The third requirement for exocytosis is an increase in cytoplasmic calcium concentration (see Calcium Signaling). Hormone release is triggered when an external signal triggers the opening of a **calcium channel**, raising the internal calcium level from its usual 0.1 µM to about 5 µM (18). The elevated calcium triggers exocytosis by interacting with a membrane-bound protein on the secretory granule, presumably synaptotagmin (19).

1.3. Exocrine Secretory Granules

Exocrine cells are epithelial cells dedicated to protein secretion from their apical surfaces. They include cells of the exocrine pancreas and the intestine, which secrete digestive enzymes, mammary gland cells secreting casein, and mucin- and saliva-secreting cells. These cells exhibit polarized secretion (that is, secretion through a specialized region of the plasma membrane). In addition, exocrine cells are characterized by the very large size of their secretory granules, often called zymogen granules. Their size is such that they can be seen readily in the light microscope. Early morphologists noted the disappearance of zymogen granules on stimulation of exocrine cells and the appearance of their content extracellularly. Before the phenomenon of exocytosis was discovered, it was assumed that the extracellular signal caused the "granules" to dissolve in the cytoplasm, allowing the proteins to appear extracellularly by unknown transport mechanisms. This view of exocrine secretion remained in vogue for a remarkably long time, even after exocytosis was discovered.

What is known of zymogen granule formation and exocytosis shows strong parallels with what is found in endocrine cells. The contents of the zymogen granules begin to condense in the *trans*-Golgi network. Sorting signals for targeting proteins into zymogen granules must exist (20), and

aggregation is likely to participate (21). The large exocrine secretory granules grow by the fusion of many smaller immature granules. The granules also have a member of the synaptobrevin family of v-SNAREs that is required for exocytosis (22). Targeting to apical membranes appears to be due to selective expression of the appropriate t-SNARE (syntaxin) on the apical surface (23).

In addition to having polarized secretion, secretion exclusively via the apical membrane into the lumen of the gland or the gut, exocrine cells differ from endocrine cells in showing piggy-back exocytosis. This means that once an exocrine secretory granule has fused with the apical plasma membrane, a second secretory granule can fuse with the membrane of the first secretory granule, and so on. As a result, massive exocytosis leads to a highly convoluted apical plasma membrane.

1.4. Secretory Granules in Cells of Hematopoietic Lineage

Cells of the hematopoietic lineage, stem cells, have a form of regulated exocytosis that differs in some ways from what is found in endocrine and exocrine ells. First, the secretory vesicle resembles a **lysosome** more than a secretory granule. In cytotoxic T lymphocytes, it contains cathepsins and membrane markers of lysosomes. It can contain small vesicles and so resembles a multivesicular body, which is a lysosomal precursor. Sorting of granzymes to the storage vesicles involves the **mannose phosphate receptor**, which normally sorts lysosomal enzymes (24, 25). Secretion in cytotoxic T lymphocytes is polarized in an unusual way. The Golgi complex and microtubule-organizing center rotate around the nucleus until they face the target cell. Finally, exocytosis from mast cells, neutrophils, and cytotoxic T lymphocytes is readily stimulated by GTPgS. It seems likely that protein secretion from hematopoietic cells should be seen as a modification of the conventional lysosomal pathway and is thus only superficially similar to regulated secretion from endocrine cells.

1.5. Constitutive Secretory Vesicles

The constitutive secretory vesicle was initially defined on the pathway for the externalization of membrane proteins in regulated secretory cells. Exported proteins that lack a sorting domain directing them to the regulated pathway also take the constitutive pathway. In cells such as fibroblasts or **antibody**-secreting lymphocytes, there is no major post-Golgi pool of secreted proteins. Proteins arrive at and are released from the cell surface a few minutes after leaving the Golgi complex, instead of being stored for as long as several days in secretory granules, as is common for the regulated pathways. Cells with no post-Golgi storage capacity are usually considered to have only constitutive secretion.

Because the constitutive secretory vesicles are short-lived, it has been difficult to purify enough of them to characterize them biochemically.

Formation of constitutive secretory vesicles in the *trans*-Golgi complex requires a coating mechanism. The early observation that their formation is blocked by **brefeldin** A (26) is consistent with the recruitment of coats by the small GTPase, ADP-ribosylation factor (27). One potential brefeldin A-sensitive coating molecule is p200 (28).

1.6. Synaptic Vesicles

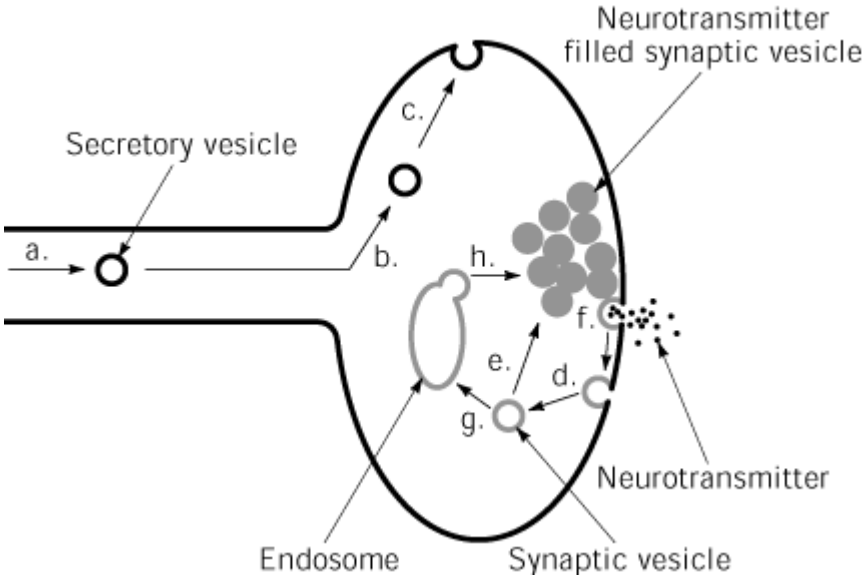
Two cell types dedicated to intercellular signaling are endocrine cells and neurons. Both cell types store their chemical signals in secretory vesicles and release them by exocytosis on stimulation. The crucial difference between the two systems is speed. While an endocrine response can take minutes, communication between neurons takes a millisecond. The properties of the synaptic vesicle make most sense when they are seen as ultra-high-speed secretory vesicles.

1.7. Formation of Synaptic Vesicles

Formation of synaptic vesicles is one of the fastest membrane trafficking events known. Each stimulus causes the release of about 1% of the synaptic vesicles stored in the nerve terminal. Since stimuli can arrive at the terminals at a rate of up to 50 per second, the vesicle pool would be depleted in seconds if there were no efficient way to replenish it (29). Since it can take days for membranes to arrive at the nerve terminal by axonal transport from the cell body, synaptic vesicles

need to be made locally at the nerve terminal. To do this, the membrane proteins of the synaptic vesicle are retrieved after neurotransmitter release and recycled quickly back into fresh synaptic vesicles. The biosynthetic machinery is sufficiently fast to replenish the complete store of nerve terminal synaptic vesicles in 10 to 20 seconds (29). Nerve terminals adapt the process of endocytosis present in all cells. For example, **dynamin**, a large GTPase that polymerizes rapidly into helical structures, is required for the formation of clathrin-coated vesicles in all mammalian cells (30), while AP2 is a heterotetrameric adaptor protein that recruits clathrin coats to plasma membrane proteins awaiting internalization. Mutations in dynamin or in AP2 prevent synaptic vesicle formation (31). Clathrin-coated vesicles are abundant in nerve terminals and contain almost exclusively synaptic vesicle membrane proteins. The synaptic vesicles may form directly from the plasma membrane or from a short-lived endosomal intermediate in the nerve terminal (Fig. 3).

Figure 3. Formation of synaptic vesicles. Synaptic vesicle proteins are synthesized in the cell body and (a) transported through the secretory pathway and down the axon of the neuron to the (b) nerve terminal, where they are (c) fused with the plasma membrane. In the nerve terminal, synaptic vesicle proteins undergo multiple rounds of exo/endocytosis. Synaptic vesicles are (d) formed by endocytosis, (e) filled with neurotransmitter, and (f) fused with the plasma membrane to release neurotransmitter in response to stimuli. They may form directly (d–f) from the plasma membrane or (d, g, h) through an endosomal intermediate.



When they have formed, they are quickly filled with neurotransmitter to concentrations as high as 0.4 M. To concentrate the neurotransmitters to this extent, synaptic vesicles have a transporter with 12 transmembrane-spanning regions that makes use of a transmembrane proton electrochemical potential, generated by a **proton pump** in the synaptic vesicle plasma membrane. Several drugs of clinical significance, such as amphetamines and reserpine, interfere with the uptake of neurotransmitter by the transporter (32).

1.8. Docking and Fusion of Synaptic Vesicles

The newly formed and filled synaptic vesicle quickly joins the pool of synaptic vesicles in the nerve terminal. These vesicles are not free to diffuse in the nerve terminal but are restricted to a region of the active zone, the site of synaptic vesicle exocytosis. The actin-binding protein synapsin is believed to restrict the free movement of synaptic vesicles (33). Of the vesicles in the vicinity of the active site, about 10% are docked at specific docking sites on the nerve-terminal plasma membrane (34). Although protein-containing dense core secretory granules (also called dense core synaptic vesicles) can be found in nerve terminals, they cannot dock at the synaptic vesicle release sites. Docked synaptic vesicles are separated from the plasma membrane by less than the width of a membrane.

Release of neurotransmitter by exocytosis requires the synaptic vesicle v-SNARE, called synaptobrevin or VAMP, and two t-SNAREs on the plasma membrane, syntaxin and synaptosome-associated protein-25 (SNAP-25) (see Exocytosis). Drosophila mutants defective in synaptobrevin or syntaxin do not have normal synaptic transmission (35, 36). Furthermore, it is now known that the blocks in neurotransmitter release caused by bacterial neurotoxins are due to their endoproteolytic activity on the three SNARE molecules (37) (see Exocytosis). Although neurotransmission is blocked by the bacterial neurotoxins, the vesicles can still dock at the plasma membrane, showing that the SNAREs are not essential for docking (38). The t-SNAREs syntaxin and SNAP-25 are not localized to the active sites and so cannot by themselves specify the site of docking of synaptic vesicles (38).

The small rab3 GTPases are associated with the resting synaptic vesicle and dissociate from it when the synaptic vesicle fuses with the nerve-terminal plasma membrane (39). **Knockout** mice defective in rab3A have no apparent defect in docked vesicles, but they are unable to mobilize synaptic vesicles as efficiently from the reserve pool to the docked pool (33).

1.9. Regulation of Synaptic Vesicle Exocytosis

Synaptic vesicles docked at active zones fuse with the plasma membrane within 100 μs after an electrical stimulus reaches the nerve terminal. The voltage change caused by the electrical signal opens voltage-sensitive calcium channels in the nerve terminal, and the calcium that enters triggers synaptic vesicle fusion. An important finding was that the cytoplasmic calcium concentration has to reach 50 μM before fusion is triggered (34). Since such calcium concentrations are found only in close proximity to calcium channels, the docking/fusion site and the calcium channels are physically linked to each other. Indeed, it is the calcium channels that define the location of the active zones of vesicle fusion. After a round of exocytosis, the nerve terminal needs to be reset to be capable of a second exocytotic event in about 10 ms. In particular, the calcium concentration at the release site must quickly return to near normal (0.1 μM). This is accomplished by rapid diffusion of calcium away from the release site at the mouth of the calcium channel (40).

The synaptic vesicle uses the calcium-binding protein synaptotagmin as a sensor to detect changes in cytoplasmic calcium. Mouse knockout mutants lacking synaptotagmin lose almost all calcium-dependent exocytosis from nerve terminals (41). The fusion machinery is normal in such mice, because they can still release neurotransmitter in the absence of calcium, when stimulated by hyperosmolarity in the bathing fluid or by the toxin of the black widow spider, a-latrotoxin. Thus synaptotagmin is a regulator of the fusion machinery.

Sedimentation Coefficient (*S*-Value)

During centrifugation, the rate of movement, or the velocity of sedimentation, of a macromolecule through a solution under the influence of a centrifugal field (w^2s) can be characterized by its sedimentation coefficient , or *s*-value. As a macromolecule sediments, it moves at the velocity

$$v = dr_b/dt = r\omega^2 s \qquad (1)$$

where *r* is the radial position of the boundary at time *t* and w is the angular velocity of the centrifuge rotor in radians/sec. Specifically, the *s*-value is defined as the velocity of movement divided by the centrifugal field strength $r\ w^2$. Then the *s*-value is given by

$$s = v/r\omega^2 \qquad (2)$$

The *s*-value can be calculated graphically or by computer (see Sedimentation Velocity Centrifugation). When characterizing macromolecular sedimentation, it is important to measure the value of *s* from different experiments at several different macromolecular concentrations to evaluate the effects of intermolecular interactions (1, 2). In the simplest case of nonideality , where the sedimentation of one molecule interferes with another, the *s*-value decreases with increasing macromolecular concentration.

The *s*-value and the diffusion coefficient *D* are sufficient to determine the **molecular weight** ($M_{s,D}$, see Sedimentation Velocity Centrifugation) of a molecule from the Svedberg equation :

$$M_{s,D} = \frac{s}{D}\frac{RT}{(1-\bar{v}\rho)} \qquad (3)$$

where *R* is the gas constant, *T* the absolute temperature, r the density of the solvent, and *v* the partial specific volume of the macromolecule (see Sedimentation Velocity Centrifugation). Finally, the *s*-value is a function of the shape of the macromolecule and of its frictional coefficient (1, 2), and it depends on the solvent viscosity. The *s*-value is also sensitive to temperature because the viscosity of water is strongly temperature-dependent. Thus, macromolecular *s*-values (and also diffusion coefficients) are routinely corrected to water as the solvent and at a standard temperature (20°C), designated $s_{20,w}$ and $D_{20,w}$, respectively.

The *s*-value has the dimensions of time and it is usually expressed in Svedberg units *S*($1\ S = 1\times10^{-13} s$).

Sedimentation Equilibrium Centrifugation

Sedimentation equilibrium experiments measure the radial distribution of molecules at chemical and hydrodynamic equilibrium under a constant centrifugal force (see Centrifugation). This equilibrium distribution is determined by the opposing tendencies of the molecules to sediment and to **diffuse** (see Sedimentation Velocity Centrifugation). Consequently, the technique permits direct measurement of the **molecular weight** of the molecule in solution and of M_w and M_z, the weight- and z-average molecular weight distributions (see Analytical Ultracentrifugation). It is also one of the few direct methods, other than titration **calorimetry** and equilibrium dialysis, for accurately measuring the binding constants between macromolecules.

The behavior of an ideal solute at sedimentation equilibrium (Fig. 1) and infinite dilution obeys an exponential (Eq. (1)) relationship and its linear transform (Eq. (2)):

$$C_r = C_m e^{\left\{\frac{M_w o^2(1-\overline{v}\rho)(r_i^2-r_m^2)}{2RT}\right\}} or C_r = C_m e^{\{Mw C_0(r_i^2-r_m^2)\}} \quad (1)$$

$$\ln C_r = \frac{M_w o^2(1-\overline{v}\rho)(r_i^2-r_m^2)}{2RT} + \ln C_m \quad (2)$$

where C_r and C_m are, respectively, the concentrations of the solute at radius r_i and at the meniscus r_m, M_w is the molecular weight of the solute and v its partial specific volume, w is the angular velocity of the rotor, r is the density of the solvent, R is the gas constant, T the absolute temperature, and the C_0 term is the combined set of equation constants $[w^2(1–nr)/2RT]$. In the linear transform of Eq. 2 (Fig. 2), the apparent solute weight-average molecular weight is defined by the slope of the plot of ln C_r versus $(r^2_i - r^2_m)$. Deviations from linearity are typically caused by solute paucidispersity, polydispersity, and/or nonideality (see Analytical Ultracentrifugation). For most dilute samples of otherwise homogeneous proteins, polydispersity can arise from self-association of solute monomers into larger oligomeric forms or from the dissociation to monomers from a normally oligomeric protein.

Figure 1. Sedimentation equilibrium profile scanned by absorption optics. The raw data are plotted as sample absorbance (sample solution minus reference solution) versus radial distance from the center of rotor rotation. The figure inset depicts the sample and reference channels of the middle of a three-channel centrifuge centerpiece. The sample and reference solution menisci are indicated.

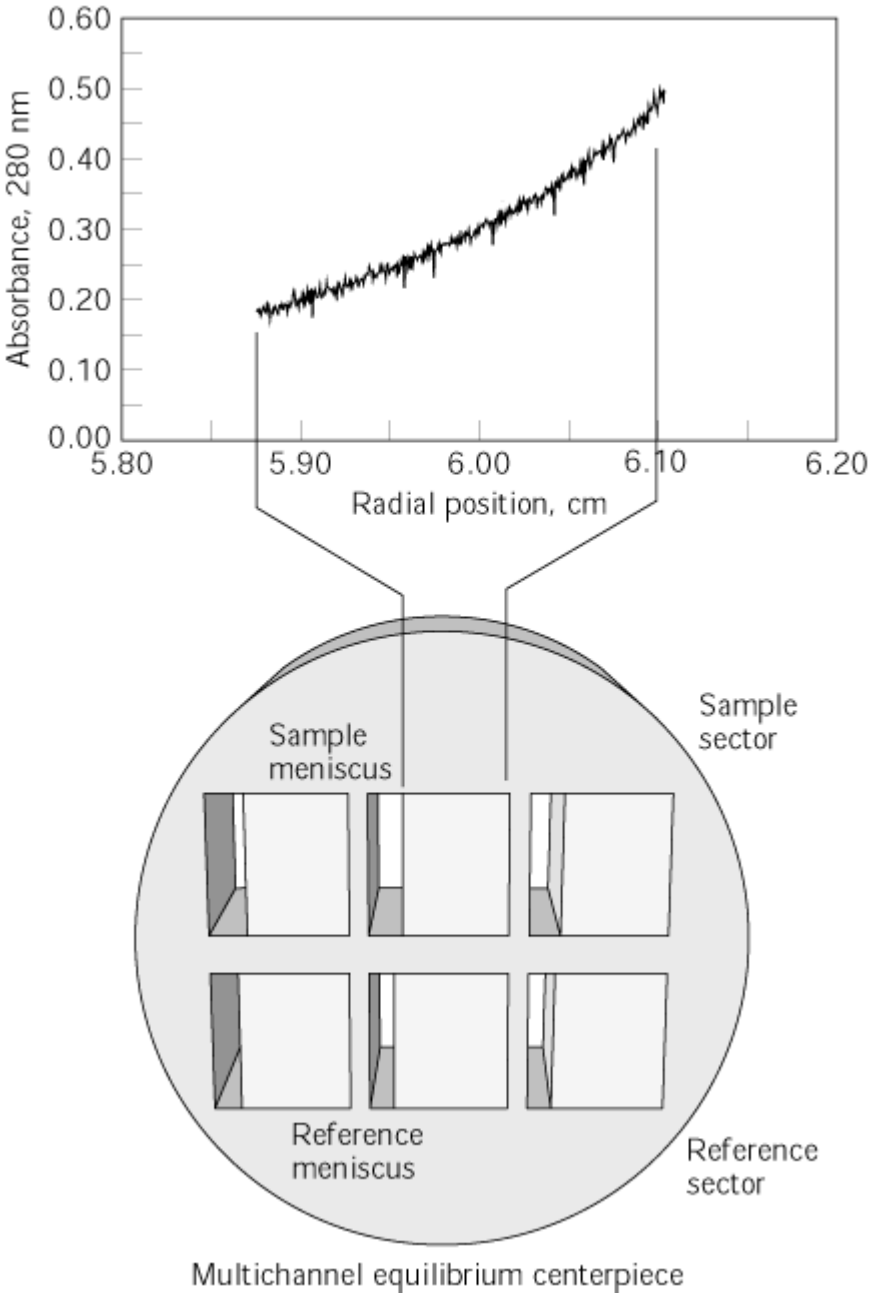

Figure 2. Analysis of sedimentation equilibrium data. In the upper panel, the data for a single sedimenting monodisperse protein are plotted according to Eq. (2) and fitted to a straight line (solid line). The slope of the line is directly proportional to the solute weight-average molecular weight M_w. In the lower panel, the same data are plotted according to Eq. (1), fitting them to a single exponential (solid line).

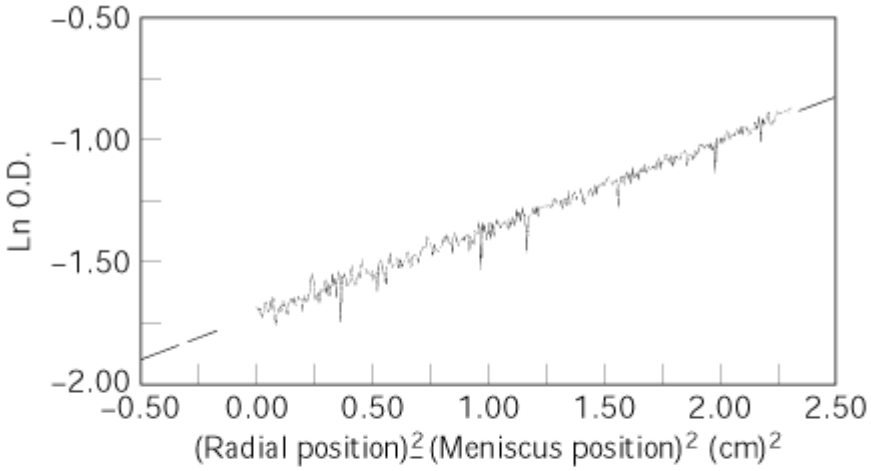
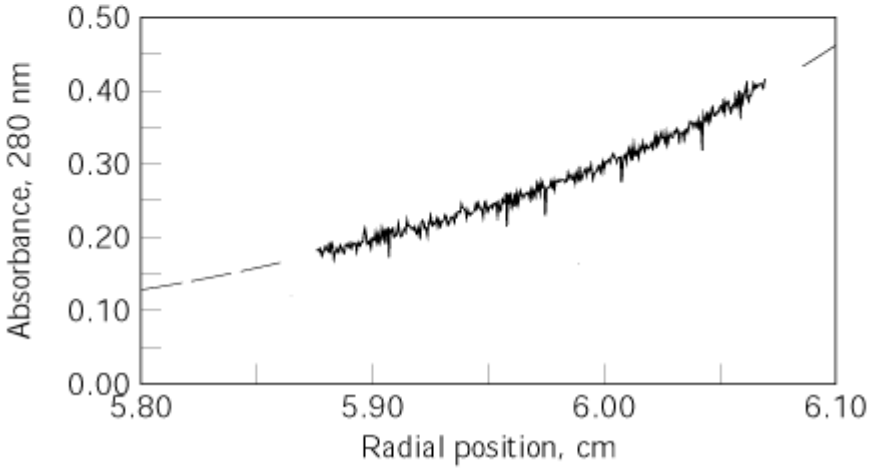


(a)



(b)

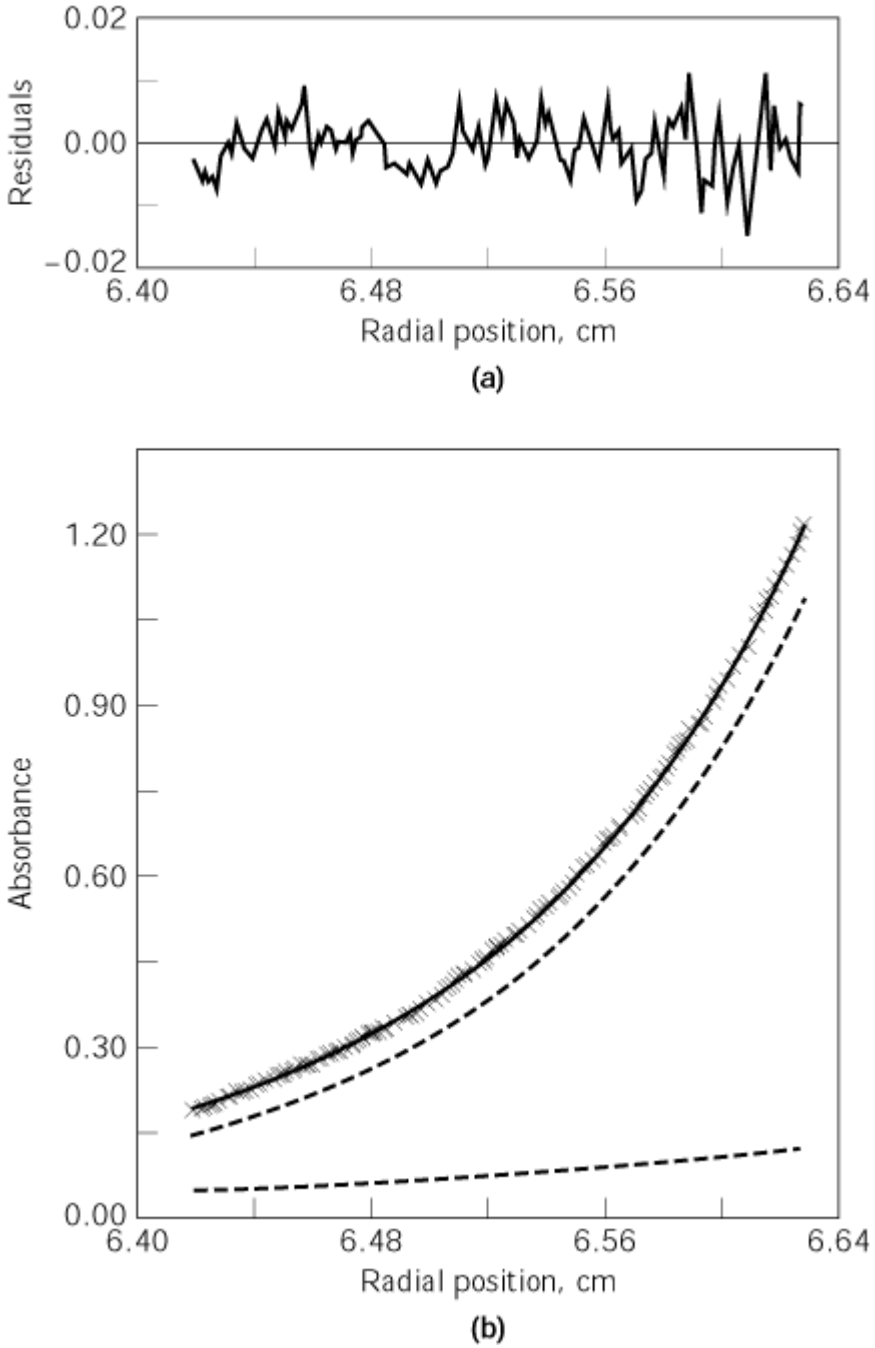
The distribution of each species in a polydisperse solution during centrifugation is described by an equation of the form of Eq. (1). Rather than dealing with logarithmic transformations of data in Eq. (2), the preferred analysis involves using best-fit exponential sums, as in Eq. (3) (1, 2). For example, at equilibrium, the distribution of total protein concentration between a monomer and a dimer as a function of radial position is described as follows:

$$P_{r^2} = A_{11}e(C_0 \cdot \overline{M}_w \cdot r^2) + A_{12}e(2 \cdot C_0 \cdot \overline{M}_w \cdot r^2) \quad (3)$$

where r^2 is the square of the radial position relative to the sample meniscus and (P_r^2) is the absorbance at that radial position. The monomer molecular weight (M_w) for the two-term fit, along with the preexponential constants, are allowed to change during data fitting. The fitting routine iteratively adjusts the values of these coefficients to minimize the difference between the observed data and values calculated from the analytical expression. The number of exponential terms employed in the fitting routines is determined by analysis of both goodness-of-fit parameters (usually the chi-square value) and visual examination of the residual differences between the fitted sums and the actual data set. Such a fit is illustrated in Fig. 3. Thus, this analysis permits evaluating the molecular weights and the radial distributions of the components in solution. The radial distributions of the individual species present can be used to calculate binding constants directly for

the association of the solution components (3). It can be thought of as combining mass transport (under the influence of the centrifugal field) with equilibrium dialysis (3).

Figure 3. Fit of two exponential terms for a monomer and a dimer to sedimentation equilibrium data for the association of the subunits of **cytomegalovirus proteinase** (Ref. 4, with permission). Lower panel: raw data (x), fitted exponential sums of monomer (----, lower shallow dashed curve) and dimer (---, upper steep dashed curve). The thick black steep curve passing through the raw data points (x) is the calculated sum of monomer and dimer at each radial position. Upper panel: residual differences between the fitted sum of the two exponential terms and the actual data.



Unlike indirect techniques that correlate changes in solute spectroscopic properties (such as **absorbance**, **fluorescence** or circular dichroism) upon binding, which are often assumed to represent two-state events (free versus bound), sedimentation equilibrium analysis requires no such assumptions. In a carefully performed experiment, both completely bound and free states can exist,

literally side-by-side, in the same centrifuge cell. Along with such techniques as isothermal titration **calorimetry**, where the actual thermochemical energetics of ligand binding are measured, sedimentation equilibrium analysis is one of the few direct techniques capable of such measurements.

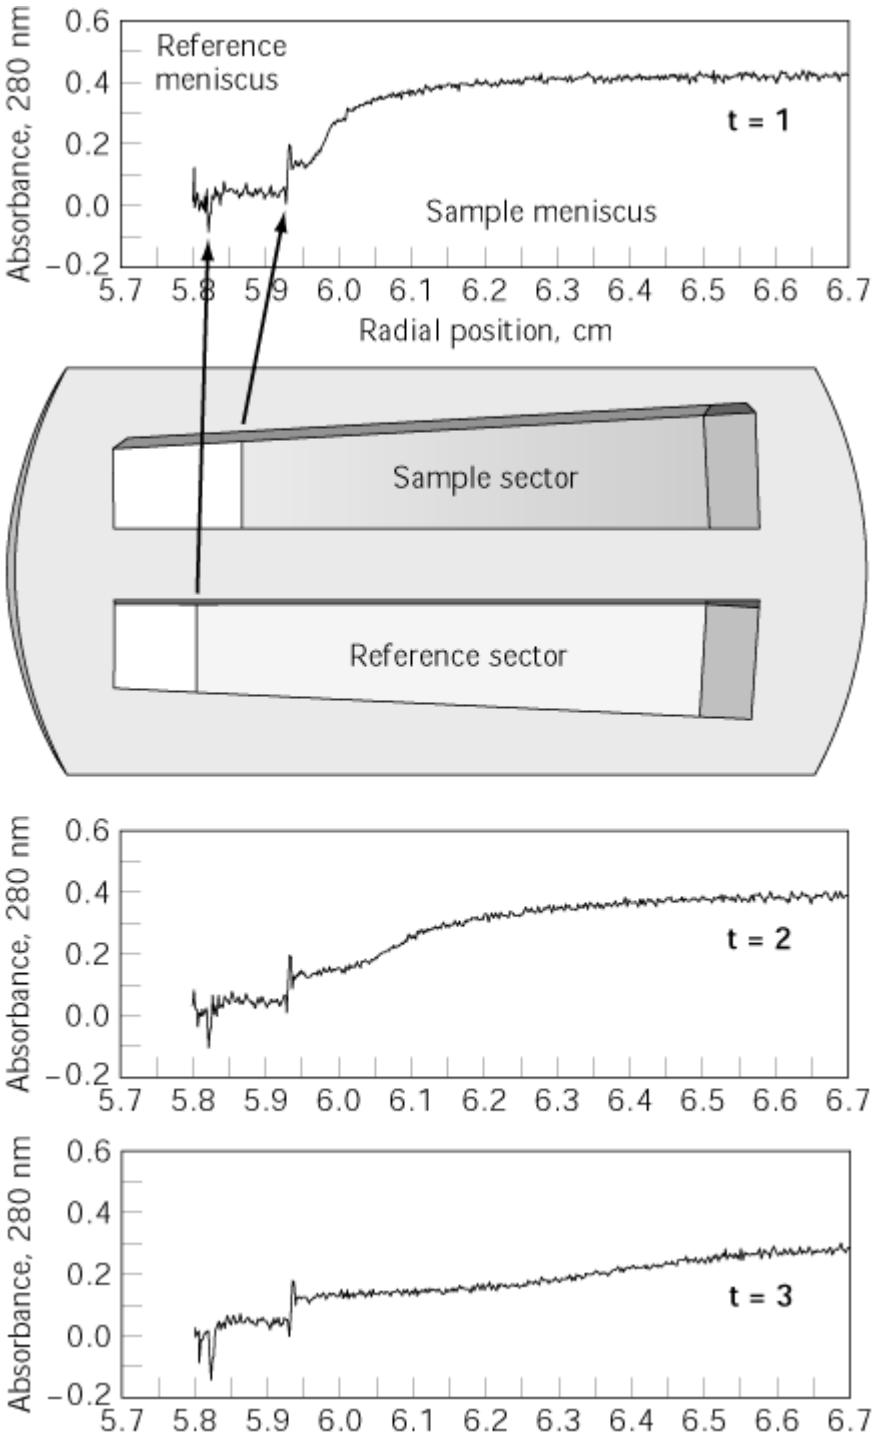
Sedimentation Velocity Centrifugation

Sedimentation velocity centrifugation experiments measure the rate of movement of molecules through solution under centrifugal force and permit determining the sedimentation coefficient of a single macromolecule or the individual time-average distributions in a solution containing multiple sedimenting components. In addition to dynamic light scattering analyses, sedimentation velocity experiments are also useful for estimating the diffusion coefficients and **frictional coefficients** of the macromolecules and their size in terms of the radii of equivalent spherical molecules. From a single, short, sedimentation velocity run, it is possible to measure both the sedimentation and diffusion coefficients and to combine them to calculate $M_{s,D}$, the sedimentation velocity-derived **molecular weight**. Finally, such information can be used with results from other physical measurements to evaluate the shape and hydration of a macromolecule in solution (1, 2).

1. Simple Graphical Analytical Methods

A sedimentation velocity experiment is illustrated in Figure 1. A sample of macromolecule is placed in one side of a centrifuge cell with only the buffer in the other side. It is centrifuged at a rate sufficient to sediment the macromolecule, depleting it at the meniscus and accumulating it at the bottom of the cell. At varying times, the sample cell is scanned for its absorbance at a wavelength where the macromolecule absorbs, giving the profile of the macromolecular concentration versus radial position. A series of profiles at different times represents the moving boundary of molecules sedimenting from the meniscus through the solution under the influence of the centrifugal field.

Figure 1. Sedimentation velocity experiment profiles at three different times (t = 1 to 3) in a centrifugation run scanned by absorption optics. The sample and reference solution menisci are indicated. The figure inset depicts the sample and reference channels of the centrifuge centerpiece.



The basic principle of sedimentation velocity is straightforward. The velocity of movement of a sedimenting boundary is defined by

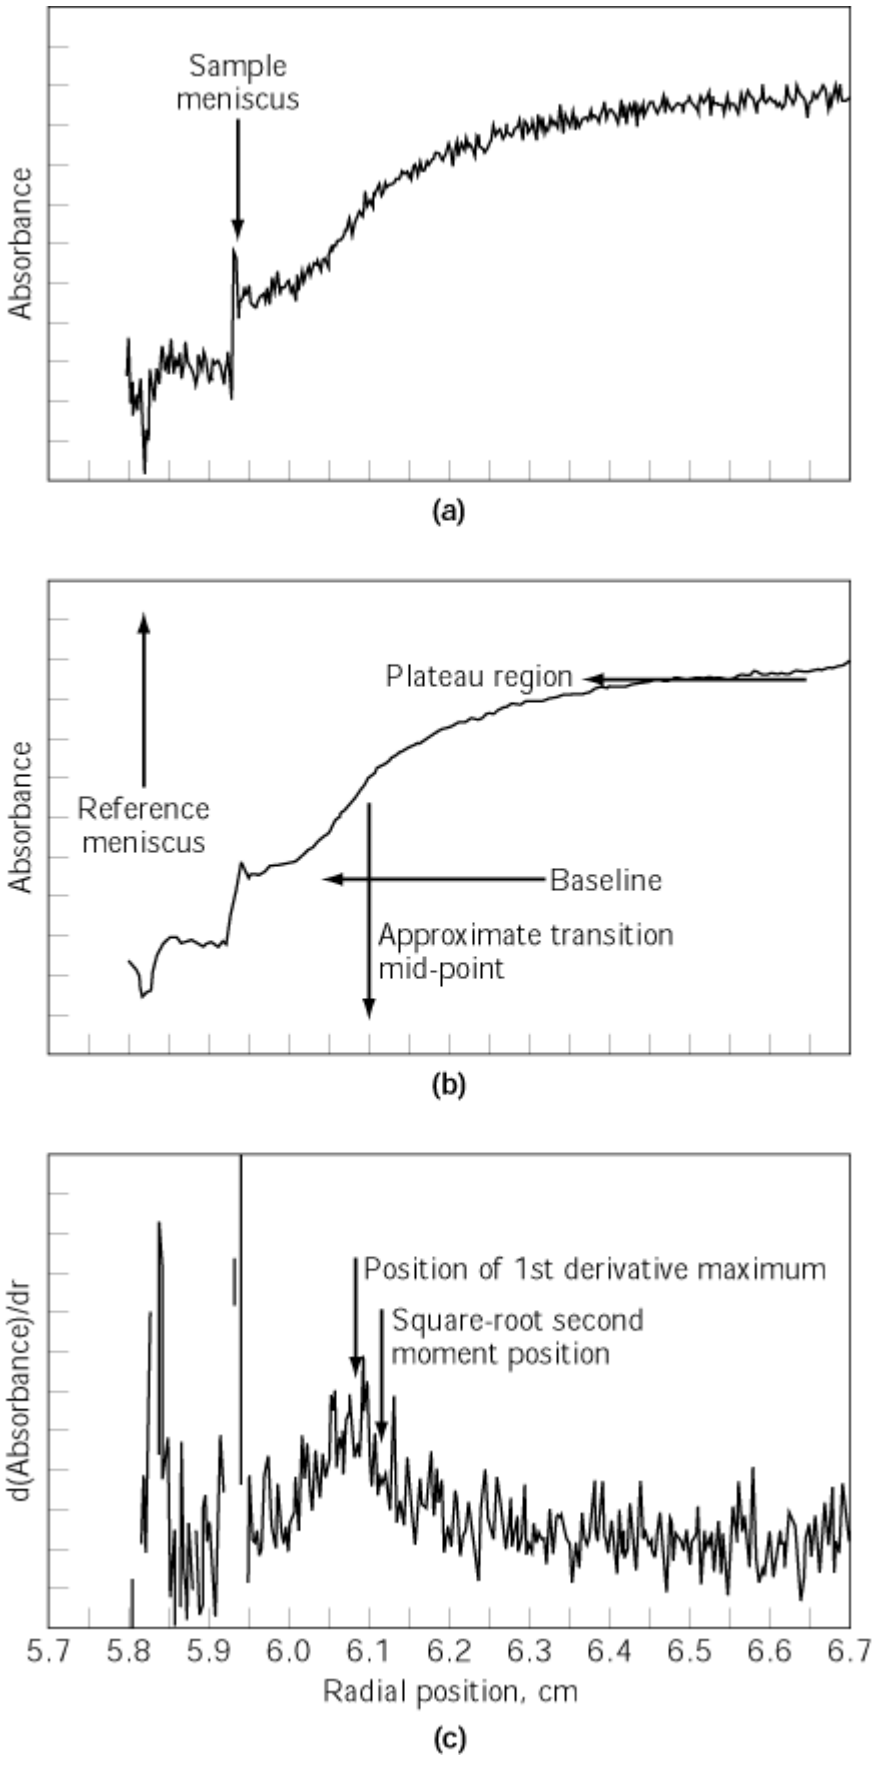
$$v = dr_b/dt = r\omega^2 s \quad (1)$$

or in its integrated form

$$\ln\left(\frac{r_{b(t)}}{r_{b(t_0)}}\right) = \omega^2 s(t - t_0) \qquad (2)$$

where $r_{b(t0)}$) is the position of the sedimenting boundary at time zero, $r_{b(t)}$ is the position of the sedimenting boundary at the time of measurement, w is the angular velocity of the rotor in radians/sec, and s is the sedimentation coefficient. The sedimentation coefficient can be determined from Eq. (2) by a plot of ln $[r_{b(t)}/r_{b(t0}]$ versus $(t–t_0)$. There are typically three graphical/computer methods to choose the position of the sedimenting boundary (Figure 2). The first is simply to estimate or calculate the $r_{b(t)}$ value at the midpoint of the sedimenting boundary based on the (height) distance between the plateau region and the absorbance baseline of the sedimenting sample. The second is to use a first-derivative transformation of the data and to choose the $r_{b(t)}$ value at the peak position of the first derivative of each scan. The third and most accurate method for single-scan analysis using Eq. (2) is calculating the second-moment $r_{b(t)}$ boundary position (3).

Figure 2. Three different ways of analyzing sedimentation velocity data to identify the position of the sedimenting boundary. Raw data scans (upper panel) or smoothed data scans (middle panel) are evaluated at various times for the approximate values of $r_{b(t)}$ at (1) the transition midpoint (middle panel), (2) first-derivative maximum (lower panel), or (3) second-moment boundary position (lower panel) and plotted according to Eq. (2).



2. Computer-Based Analysis Methods

Until recently, graphical linear-fit analyses employing sedimentation velocity Eq. (2) have, been the most widely applied methods for analyzing sedimentation velocity data. Readily availability modern software for computerized graphical analysis has led, however, to the easy application of sophisticated hydrodynamic analytical methods to sedimentation velocity data to account for both the sedimentation and the diffusion of the macromolecule. In this way, it is possible to obtain values for both the sedimentation coefficient *s* and the translational diffusion coefficient *D*. For example, now two powerful analytical methods can be routinely applied to velocity data with only a modest investment of time and mathematical expertise.

2.1. Single-Scan Fitting to the Lamm Equation

One method now in common use is based on forms of Faxén's two-component solution to the *Lamm equation* (4). The useful expressions are as follows:

$$c = [(c_0 e^{-\tau})/2]\left(1 - \Phi\left\{\frac{1-(xe^{-\tau})^{1/2}}{[\varepsilon(1-e^{-\tau})]^{1/2}}\right\}\right) \qquad (3)$$

where $x = (r/r_0)^2$, $t = 2s\omega^2 t$, $\varepsilon = 2D/s(\omega r_0)^2$, F is the error function of the term enclosed in brackets, and *s* and *D* are, respectively, the sedimentation coefficient and the diffusion coefficient. Under suitable conditions (4), Eq. (3) can approximate the concentration profile of the sedimenting solute boundary closely (i.e., *c* versus *r*, as illustrated in Fig. 3). Recently, Behlke and Ristau (5) have described a very useful extension of this method, and Demeler et al. (6) demonstrated its value in modeling the sedimentation behavior of *n*-component samples. A short review of recent advances in this approach is provided by Laue (7).

Figure 3. Sedimentation velocity analysis of a 40-residue, b-amyloid peptide (Ref. 9 with permission). The absorbance profiles of the sedimenting peptide are given by the original curves after seven different times of centrifugation. In (**a**), the solid smooth lines indicate a single-component fit of the Lamm Eq. (3) to the data. The inset shows the values of *s* and *D* obtained from the scans at different times. In (**b**), the smooth solid lines represent a two-component fit (with two sedimenting species) of the Lamm Eq. (3) to the sample data. The inset represents the *s* and *D* values for the two different components at the various scan times. The sedimentation coefficients are in units of Svedbergs, and the diffusion coefficients are in units of Ficks.

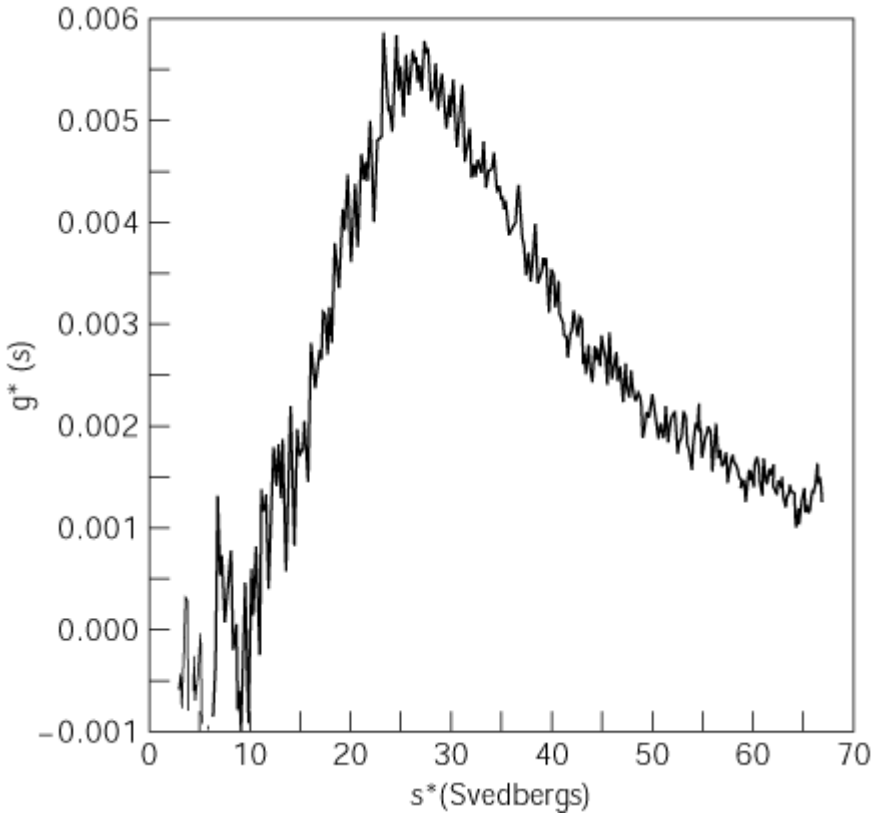
2.2. Sedimentation Coefficient Distribution Analysis

A second modern approach, termed $g^*(s)$ analysis, was developed and has recently been reviewed by Stafford (8). Rather than analyzing a single scan, it uses a set of scans in a centrifugal run to compute the distribution of sedimentation coefficients of the various components of the sedimenting solute. This approach is extremely useful in analyzing otherwise poorly defined multicomponent samples. Because of this, it has found wide application in studying the size distributions of "real-world" samples of aggregated peptides (Fig. 4) and in defining the oligomeric state of recombinant proteins (9).

Figure 4. The apparent distribution of sedimentation coefficients for the data of Fig. 3 (Ref. 9 with permission). Whereas the data of Figure 3 show two sedimenting components of about 28S and 64S, the $g^*(s)$ analysis shows that the sample of b-peptide is better represented as a distribution of species ranging from about 10S to 70S. The amyloid b-peptide and its aggregated forms may play a role in familial Alzheimer's disease.



3. The Sphere-Equivalent Radius

As indicated above, fitting to the Lamm equation yields the values of both s and D. One way of converting these sedimentation/diffusion coefficient values into more familiar terms is to employ the relationship between the diffusion coefficient and the **frictional coefficient** of the sedimenting particle (see Table 2 of Centrifugation). Although the details of the relationships between the frictional coefficient and molecule shape are beyond the scope of this discussion (see references 2, 10, 11 and Diffusion for more thorough treatments), a simple approximation is possible and is often very useful as a molecular "yardstick." The diffusion coefficient of a sphere is directly proportional to temperature and inversely proportional to the Stokes' law frictional coefficient. Thus, knowing the viscosity of the solvent, it is possible to compute the radius of the equivalent sphere r_{sphere} of the solute particle under study. This is typically done using the diffusion coefficient obtained from fitting to the Lamm equation. Alternatively, D can be estimated using the simple ratio of area/height

of the first derivative of the sedimenting boundary (Fig. 1), as described by Fugita (4):

$$(A/H)^2 = D(2\pi/s\omega^2)[\exp(2s\omega^2 t) - 1] \quad (4)$$

Equation (2) provides the sedimentation coefficient *s*, while Eq. (4) gives the value of *D*. Using the relationship between the frictional coefficient and the diffusion coefficient and combining all of the various constants, it can be shown that r_{sphere} in nanometers is equal to $(7.323\times10^{-9})\times(T$in kelvin/$D$in cm^2/sec) for a particle in a solvent with the viscosity of water. Thus a diffusion coefficient of 1 Fick, or $1.0\times10^{-7}cm^2$/sec, represents an r_{sphere} of 21.5 nm at 20°C in water. Using this relationship with some typical proteins, it is possible to estimate their diameters from just their measured diffusion coefficients. For example, hen egg-white lysozyme has a diffusion coefficient of $11.2\times10^{-7}cm^2$/sec (10) and an r_{sphere} of ~1.9nm at 20°C in water, and bovine serum albumin has a diffusion coefficient of $6.97\times10^{-7}cm^2$/sec (10) and an r_{sphere} of ~3.1nm at 25°C in water. For comparison, the **X-ray crystallographic** structure of hen lysozyme has rough dimensions of 3.0×3.0×4.5nm.

4. $M_{s,D}$, The Molecular Weight Derived from Sedimentation Velocity Data

The molecular weights of solutes are measured most accurately by sedimentation equilibrium centrifugation, but the sedimentation and diffusion coefficients obtained from sedimentation velocity experiments can be combined to give an approximate molecular weight (2, 10, 11) from the expression

$$M_{s,D} = \frac{s}{D}\frac{RT}{(1-\bar{v}\rho)} \quad (5)$$

where *R* is the gas constant, *T* the absolute temperature, *r* the density of the solvent, and *v* the partial specific volume of the macromolecule. It is most useful to calculate the $M_{s,D}$ values during the sedimentation velocity phase of an analytical ultracentrifugation run profile. This is especially true for runs using "long-column" centerpieces (Fig. 1) and extended equilibrium run times (>48hours). However, it is also sometimes useful for data collected with multichannel equilibrium centerpieces, even though the time to equilibrium is shorter because of the reduced column height in the centerpieces. Because the value of $M_{s,D}$ can be calculated quickly (within a few minutes), it is often useful in choosing the final speed for the sedimentation equilibrium phase of a centrifugation run after the high-speed, velocity phase of the run (see Analytical Ultracentrifugation).

Selection, Genetic

Selection is the process by which organisms with certain traits gain reproductive advantage over organisms of the same population without those traits. Provided that the traits are heritable, selection increases the prevalence of the selected traits in the population, ie, the population becomes adapted to the selective conditions. The source of heritable variation is mutation, so selection is the differential **reproduction** of mutant individuals. Selection has somewhat different connotations depending on whether it is used in a genetic sense or in an **evolutionary** sense.

In genetic usage, selection almost always means allowing only individuals with a given trait, usually mutants, to reproduce. Thus, selection allows the researcher to isolate an extremely rare mutant so long as the mutant has a selectable **phenotype**. A common example is antibiotic resistance in **bacteria**, which is caused by a mutation or the acquisition of a **plasmid** or transposable element carrying drug resistance. In the presence of the antibiotic, the resistant bacteria survive and give rise to **clones** of resistant progeny, whereas sensitive bacteria are killed. Likewise, with the proper selection, rare cells or organisms with other desirable characteristics can be harvested from a large population. Typical genetic selections are for amino acid **prototrophies**, for the use of specific carbon sources or for suppression of a conditional lethal mutation. The unwanted individuals do not have to die, but only fail to reproduce.

Selection is distinguished from two other genetic manipulations, *enrichment* and *screening*. Enrichment is also a selective process, but unwanted individuals do not fail to reproduce (and in this way it is more like natural selection, see later). Typically, several rounds of enrichment for growth on a poorly used substrate, for example, are needed to obtain a reasonably pure culture of mutant cells better able to use the substrate. Screens, on the other hand, are nonselective but allow the researcher to identify the desired cell or organism. For example, a typical step in cloning a gene is to insert it into a plasmid so that another gene, for which an easy assay exists, is disrupted. Genes are commonly cloned into the *lacZ* gene, which encodes **beta-galactosidase**. Cells with active b-galactosidase turn blue on medium containing X-gal (5-bromo-4-chloro-3-indolyl-b-D-galactopyranoside), so the progeny of cells receiving the disrupted *lacZ* gene containing the cloned gene are white and can be isolated for further analysis (see Operons).

Selections are often devised to find cells that have gained a trait, whereas screens must usually be used to identify cells that have lost a trait. But there are notable exceptions. For example, mutations that inactivate nonessential genes are selected with toxic analogues of the normal enzyme's substrate. And part of the intellectual challenge of genetics is to devise selection procedures to find desired genes or proteins. Recently, the yeast two-hybrid system for identifying interacting proteins has been used to select for inactivating mutations by making a successful interaction toxic to the cell (1).

In **evolutionary** usage, selection is the process by which adaptive changes take place in populations over time. Natural selection increases the mean fitness of a population by enriching it for more fit individuals and decreasing the prevalence of less fit individuals, thus producing changes in the frequencies of the genetic alleles associated with variation in fitness. There are two ways in which fitness is measured: (1) the number of offspring an individual produces; and (2) the change in the frequency of a certain allele with time. Because selection operates on the whole organism, the first of these has more evolutionary meaning. However, an organism's phenotype is the totality of its traits, each of which may or may not contribute to its fitness. Selection operates to favor particular traits encoded by particular genetic alleles. While this is what is usually meant by evolution, it is not necessarily true that all of the traits of a population are adaptive. Neutral genetic alleles can become prevalent in a population by chance, a process known as genetic drift.

Although fitness can be measured absolutely, a more meaningful measure is relative fitness, i.e., the fitness of individuals with a particular **genotype** relative to individuals with another genotype. The strength of the selective pressure on individuals with a given genotype, the selection coefficient, is one minus their relative fitness. Note that the selective pressure can be positive or negative, but because the fittest genotype is usually given the value of 1, the selection coefficient takes values of 0 to 1. Negative selection eliminates variants from the population, whereas positive selection favors them. Fitness can be defined only for a given set of conditions. Today's fittest genotype may be at a disadvantage if conditions change.

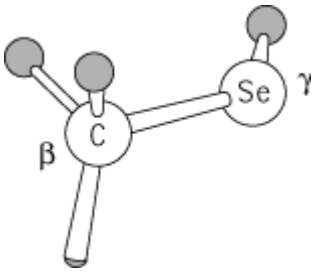
Selenocysteine

The side chain of the amino acid *selenocysteine* differs from cysteine only in having a selenium atom in place of the sulfur of Cys:



This amino acid residue is generally abbreviated as Sec, and its selenol group is an essential component in the active sites of a few important enzymes in both prokaryotes and eukaryotes, such as formate dehydrogenase and glutathione peroxidase. The Sec residue occurs at a specific position in every polypeptide chain of these enzymes. It is inserted during **protein biosynthesis** using the genetic code of the messenger RNA and can be considered the 21st amino acid of proteins.

The gene sequences for proteins with Sec residues indicate that the **codon** specifying the selenocysteine residue is UGA, one of the normal termination codons. In the appropriate context, however, this codon is **translated** using a special transfer RNA specific for selenocysteine. In both **bacteria** and **eukaryotes**, this tRNA is charged initially with serine (see **AMINOACYL TRNA SYNTHETASES**), which is then converted enzymatically to selenocysteine. This conversion is catalyzed by a specific enzyme, using the intermediate selenophosphate, which is produced from selenide and ATP by selenophosphate synthetase, also generating orthophosphate and AMP. Although bacteria produce free selenocysteine, the amino acid is apparently not used in protein biosynthesis.

Whether a UGA codon is translated as Sec or as a termination signal is dependent on other sequences in the mRNA. In prokaryotes, the 40-base sequence immediately downstream from the UGA must be present, and this sequence is believed to adopt a **stem-loop structure** . Analogous structures are believed to be important in eukaryotes, but in this case the sequence responsible is in the 3′ untranslated region of the mRNA. In bacteria, a special translation elongation factor is required; it acts in place of EF-Tu, and transports the selenocysteyl-$tRNA^{Sec}$ to the ribosome.

A selenol group normally ionizes with a pK_a of 5.2, so it would be fully ionized at physiological pH; in contrast, cysteine thiol groups have considerably higher pK_a values and are only slightly ionized at pH 7. Consequently, the selenol and thiol groups have different chemical properties, and the enzymes containing selenocysteine residues are much less active if these residues are replaced by cysteine.

Selenomethionine

Selenomethionine (Se-methionine) differs from the normal amino acid methionine only in that it has a selenium atom in place of the normal sulfur atom. Selenomethionine can be incorporated biosynthetically into proteins in place of methionine. In practice, this is most facile using

microorganisms that cannot synthesize methionine and depend on its presence in the growth medium. Selenomethionine is simply added instead.

The presence of selenomethionine residues is very useful in protein X-ray crystallography. The change of S (16 electrons) into Se (34 electrons) is an ideal isomorphous replacement and can be applied to solve the phase problem in protein X-ray crystallography. This requires X-ray data for the native protein and for its Se-methionine derivative. However, even more important is the application of this derivative in the multiple wavelength anomalous dispersion technique (see **MAD**) by taking advantage of the relatively strong anomalous dispersion of the Se atom near its K-absorption edge (0.98 Å) (1).

Self-Assembly

1. Definition

Self-assembly is the formation of a well-defined, complex structure under equilibrium conditions spontaneously from noncovalent interactions between two or more molecular components. Self-assembly encompasses the self-association of proteins and **nucleic acids**, such as the formation of different forms of a double-stranded **DNA** double helix from two complementary polydeoxynucleotide strands (see Reassociation, Nucleic Acids), the association of multiple copies of the same polypeptide chain (see Oligomeric Proteins, Quaternary Structure), the formation of complexes comprised of more than one type of polypeptide chain (ie, *heteromultimeric* proteins), and the reconstitution of an infectious **viral** particle, comprised of one or more proteins, plus nucleic acid.

Self-assembly can also be viewed as part of a more general topic of *supramolecular* assembly or self-organization, which encompasses the formation of a wide variety of structures with masses greater than 1 MDa and sizes greater than 10 nm. These include pathogens such as viruses; large **multienzyme complexes** involved in biosynthetic pathways (eg, *pyruvate dehydrogenase*) and in **protein degradation** (eg, the proteasome); multiprotein complexes that bind to nucleic acids and are active in DNA replication, **RNA biosynthesis** and **protein biosynthesis** (eg, nucleosomes, polymerases, spliceosomes, ribosomes), transmembrane protein complexes (eg, acetylcholine receptor, respiratory enzyme complexes, photosynthetic reaction centers); and the protein complexes encaging transport **vesicles** (**clathrin**-coated vesicles and circulating **lipoproteins**).

The foregoing definition of self-assembly implies that all the necessary information is encoded within the covalent structures of the components and hence requires complete reversibility of the assembly process. Reversibility is demonstrated *in vitro* by the reassembly of the completely dissociated structure upon return to the initial solution conditions. Dissociation into individual molecules can be effected in many different ways: (a) increased hydrostatic pressure, (b) addition or removal of specific **ligands**, such as **coenzymes**, substrates, **allosteric** effectors or other **prosthetic** groups, (c) decrease in concentration, (d) alteration of pH, temperature, or ionic strength, and (e) the addition of dissociating and denaturing **chaotropic** agents such as urea, guanidinium salts, and

detergents (neutral, cationic, or anionic). At present, overexpression in ***Escherichia coli*** of the individual wild-type or mutagenized subunits makes it possible to elucidate the pathways of self-assembly and the roles in the self-assembly process of various protein **domains** within each subunit.

Although self-assembly of a limited number of supramolecular structures has been demonstrated to occur *in vitro*, it is now known that the assembly of many large, complex supramolecular structures *in vivo* requires various cellular factors and generally involves several steps, some of which are irreversible. Self-organization of intracellular spatial structures encompasses self-assembly and almost certainly occurs under conditions that are distant from the equilibrium conditions under which the latter is studied *in vitro*.

2. Historical Perspective

Historically, the concept of self-assembly arose primarily from the work on the reconstitution of **tobacco mosaic virus** (**TMV**) by H. Fraenkel-Conrat and R. Williams. In 1955 they were able to reassemble its isolated RNA and protein components into a native-like, infectious rod-like particle, consisting of exactly 2130 identical protein subunits (each of 158 amino acid residues) stacked in a helical array around a single-stranded RNA molecule comprising 6390 nucleotides. A subsequent key development was the demonstration in 1961 by C. Anfinsen and colleagues that the enzyme **ribonuclease A** (a single polypeptide chain of 124 residues) could regain its four disulfide bonds and three-dimensional structure, plus the resulting enzymatic activity, from the completely unfolded, reduced, and inactive form. This was recognized to indicate that all the necessary information for the reversible folding of a polypeptide chain into a well-defined three-dimensional structure resided within its sequence of amino acids (see **Protein folding**). Subsequently, in 1968, M. Nomura and collaborators accomplished the complete reassembly of the 30S ribosome from a mixture of 30 proteins and the 16S rRNA. This and numerous other studies of multimeric proteins and enzymes provided a firm molecular basis for the concept of self-assembly. The observations of intracellular arrays of linear polymers of cytoplasmic proteins, microtubules, intermediate filaments, and actin filaments in the early 1970s provided the impetus for investigations of the structure and assembly of supramolecular spatial structures responsible for the maintenance of cell morphology and the related processes of cell movement, division, and differentiation.

3. Intermolecular Forces Responsible for Self-Assembly

Although the covalent structure of each component encodes all the information necessary for its three-dimensional structure and its interactions with the other components in the self-assembly process, the intermolecular forces involved in both processes are all noncovalent, being energetically weaker than covalent bonds by more than an order of magnitude (<10kcal/mol vs ~100kcal/mol). These intermolecular forces represent both specific, geometrically directed interactions, like hydrogen bonds and salt bridges (which may be regarded as hydrogen-bonded ion pairs), and relatively nonspecific **electrostatic** and van der Waals interactions, including the hydrophobic effect. The resulting energetic stabilization depends on the amount of accessible surface area buried in the contact between the interacting components and, most critically, on the complementarity in the chemical nature and shapes of the interacting surfaces.

4. Role of Subassemblies and Assembly Pathways

Simultaneous encounter and assembly of three or more independent molecules is most unlikely on kinetic grounds, and self-assembly usually occurs by the stepwise interactions of pairs of molecules or subassemblies. In the case of a relatively simple, hypothetical assembly system consisting of only three components A, B, and C, there are three possible pathways for the formation of the ABC assembly via formation of the subassemblies AB, AC, or BC. One of the three pathways may be the only pathway that is used because it is kinetically and energetically most favorable, perhaps through a nucleation event involving the formation of one of the initial binary complexes. Pathways and subassemblies can play an important role in determining the accuracy of the final assembly structure

(1). For example, forming a homooligomer of 1000 subunits via stepwise addition of individual subunits with a probability of being correct of 0.999 for each step (ie, only a 0.1% error rate) is only 0.368 (0.999^{1000}). However, if two subassemblies of 500 subunits are formed first and then associate to the final oligomer, the probability of correct assembly rises to 0.605. The two optimum assembly pathways would be from 25 subassemblies, each of 40 subunits, or from 40 subassemblies, each of 25 subunits (1). Furthermore, a 50% probability of assembling the correct 1000-mer structure using the optimum pathways requires that each step in the assembly occurs correctly with a probability of at least 0.99. This value is decreased (ie, there is an increased probability of obtaining the correct structure), with an increase in the number of different subassemblies—for example, to 0.98 with self-association to 10-mers, followed by self-assembly of 10-mers into 100-mers, followed in turn by self-assembly of 100-mers to the correct 1000-mer. Thus, successful assembly of a multisubunit structure can be favored by maximizing the number of subunits per subassembly and the total number of subassemblies. The existence of subassemblies can also increase the speed with which a multisubunit structure can be assembled. If each subunit or subassembly addition in the foregoing example requires 1 s, then the assembly of the 1000-mer by stepwise addition would take 999 s to complete; from 40 subassemblies of 25 subunits each, only 63 s (39+24) would be necessary (1).

In view of these simple considerations, it is reasonable that assembly of large spatial structures occurs via well-defined pathways and involves the formation of specific subassemblies. A. Klug and collaborators worked out the details of TMV assembly from the coat protein and the single-stranded RNA. The initiation event was found to be the interaction with a hairpin loop of the RNA of a self-assembled two-layer disc of 34 protein subunits. This was followed by an elongation phase of the self-assembly process proceeding in both directions through further addition of discs of protein subunits (2).

5. Experimental Methods of Investigating Self-Assembled Structures

The detailed structures of small and large proteins, of unassembled viral capsid protein oligomers, and of many capsids themselves have been determined to high resolution by X-ray crystallography. The development of cryoelectron microscopy and three-dimensional image reconstruction (see Single Particle Reconstruction) techniques capable of achieving a resolution of 1 nm and better has provided a very powerful method for the investigation of supramolecular assemblies. Cryoelectron microscopy can be used with large particles that are unstable, short-lived or present in quantities too small for crystallization. The two methods complement each other, in that X-ray crystallography can provide high-resolution structures of individual components, and cryoelectron microscopy provides lower resolution structures of the large complexes consisting of these components (3). Furthermore, immunoelectron microscopy can localize epitopes within protein subunits participating in a supramolecular structure, providing a method to identify specific protein subunits in the structure. With capsids, immunoelectron microscopy can be used to assist in the mapping of the movement of protein subunits during capsid maturation.

6. Advantages of Assembled Structures

Self-assembly of multisubunit protein complexes provides a number of structural and functional advantages over equally large, single-chain proteins (4, 5).

1. Coding efficiency: Less genetic information is required to build a small protein subunit, with a concomitant reduction in biosynthetic error.

2. Quality control via association and dissociation of subunits: Errors in subunit synthesis are minimized, because mutated subunits can be excluded from the assembly process.

3. Enhancement of function through the association/dissociation equilibria of the subunits: assembly of monomers to the active complex at locations distant from the site of monomer synthesis and the

ability to either transmit or respond to allosteric regulatory signals via intersubunit communication (allostery).

4. The self-assembly and dissociation of multisubunit structures can be driven by small alterations in external conditions (in pH, ion concentration, etc.), thereby providing the possibility of added refinement in their functions.

5. Multimerization can provide specificity for interaction of the complex with another partner in supramolecular structures: many proteins involved in the regulation of gene transcription form homo- and heterodimers by more than one mechanism, thereby enabling them to bind to the substrate DNA with exquisite specificity.

7. Self-Assembly *In Vivo* is More Complex than Self-Assembly *In Vitro*

Since Anfinsen's seminal experiments, the duration of refolding of some proteins *in vitro* was found to be reduced in the presence of the catalysts peptidyl prolyl cis–trans isomerase and protein disulfide isomerase. Furthermore, the inability of insulin and some other protein hormones to refold following complete unfolding was shown by D. Steiner in 1974 to be due to **proteolytic** cleavage subsequent to the folding of a precursor form. Although substantial information had been accumulated by 1987 on the self-assembly of many homo- and heteromultimeric protein complexes (6), as well as of viruses, the first intimation of the involvement of additional factors in self-assembly was the finding that the plant enzyme, **ribulobisphosphate carboxylase**, required **molecular chaperone** proteins for proper folding and assembly of its two different subunits, L and S, to the final L_8S_8 form. Although the molecular chaperones primarily inhibit misfolding and misassembly and do not direct assembly per se, it has become apparent that the narrow definition of self-assembly provided at the outset has very limited applicability to the self-organization of the many large supramolecular assemblies *in vivo*. It needs to be emphasized that the self-organization of large cellular structures and their maintenance requires a dynamic interplay between assembly and regulatory processes; not only are their pathways multistep processes, but they also occur under nonequilibrium conditions.

8. Control of Self-Assembly

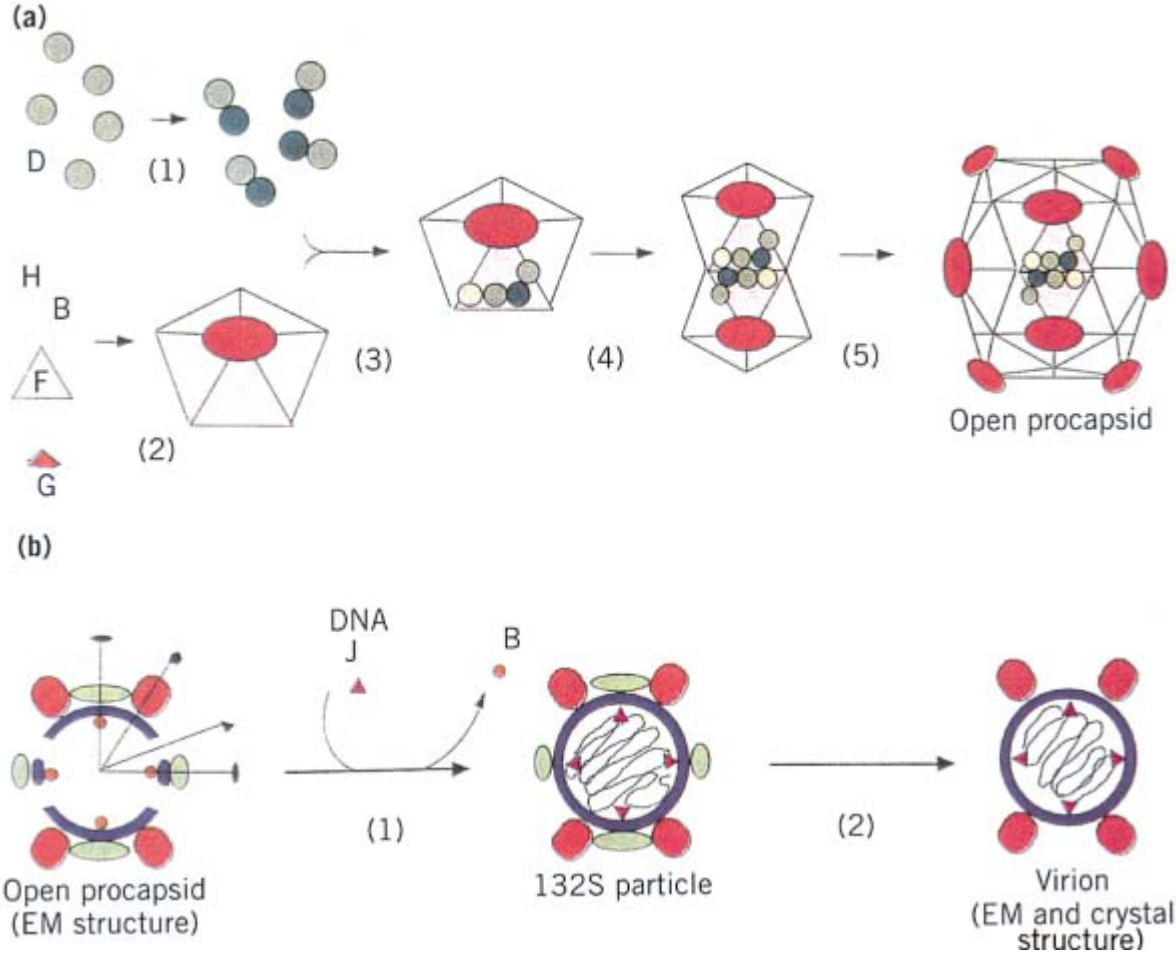
Self-assembly *in vitro* and the assembly of supramolecular structures *in vivo* proceed via specific assembly pathways, not by random association of various components, and generally require a nucleation event, which could be the formation of a dimer or higher complex. The first step results in a conformational alteration, which creates the sites for subsequent addition of protein subunits, leading to a protein-determined cooperative assembly pathway, also called *conformational switching* (7). In the case of TMV, the nucleation event triggers a conformational change in the bound disc of 34 protein subunits that provides binding sites for the stepwise addition of further subunits of the coat protein. It is not yet clear which of the observed differences between the structures of polymerized coat protein with and without the single-stranded RNA lead to the creation of the preferential binding sites.

In the case of TMV and other simple viruses, the length of the RNA appears to determine the length of the tubular coat protein particles formed: The ratio was found to be constant at about 20 bases of RNA per 1 nm length of assembled structure. This control mechanism can be regarded as a case of template-assisted assembly, which occurs widely. Another possible example may be the roles as protein rulers played by the giant muscle proteins **titin** and nebulin, both multidomain proteins ~1 μm long, in the assembly of **myosin** and actin filaments, respectively. It is also possible for the template to be removed prior to completion of the assembly. Well-known examples of the second possibility occur widely in **herpesviruses** and tailed **bacteriophages**, where scaffolding proteins direct the assembly of capsid coat proteins, by forming a three-dimensional scaffold onto which the shell is assembled with correct **icosahedral symmetry**. This is followed by the exit of the

scaffolding polypeptides and their subsequent reutilization or their removal via proteolysis. Because the scaffolding proteins in these cases are not part of the final assembly, they can be considered to act as chaperones.

Conformational alterations resulting at one or more steps of the assembly process appear to be a widely applicable regulatory mechanism. One example is conditional assembly, wherein the protein complex provides a signal for subsequent processing; an example is the homo- and heterodimeric forms of cystine-knot growth factors, which nucleate the assembly of different multisubunit receptor complexes. Another is the major cooperative conformational changes that occur during procapsid assembly and maturation of double-stranded DNA bacteriophages. Covalent alterations, predominantly **proteolysis**, have been found to occur during the formation of the infectious virions of many viruses, particularly the more complex ones. Proteolysis makes the assembly irreversible, it may lead to conformational alterations required for subsequent association or increased stability, and it could be necessary for the removal of scaffolding proteins (7). Figure 1 illustrates the complex pathway of the icosahedral *E. coli* bacteriophage FX174 capsid assembly based on recent X-ray crystallographic and cryoelectron microscopic work (8).

Figure 1. The assembly pathway of bacteriophage FX174. (**a**) Assembly of the open procapsid. Two scaffolding proteins, B and D, are required for the formation of the 108S, 36-nm-diameter procapsid from pentameric intermediates containing proteins F, G, and H. (1) The scaffolding D protein (green) forms asymmetric dimers (light and dark green); (2) the main capsid protein F forms pentameric precursors, complexed with proteins B, G, and H; (3) the D dimers bind to the pentamers in at least two distinct steps, resulting in an altered conformation of one of the D subunits (very light green); (4) dimerization of the pentameric precursors occurs through the binding of D dimers and requires protein B; (5) generation of the complete icosaheral open procapsid. (**b**) Maturation of the open procapsid presented in cross section, showing the scaffolding protein B (orange); one fivefold, one threefold and two twofold symmetry axes are indicated. (1) Packaging of DNA and J protein, accompanied by removal of B protein, leads to 132S particles; (2) removal of the external scaffolding protein D from the 132S particle generates the mature infectious virion. EM, electron microscopy; crystal, X-ray crystallography. (Adapted from Ref. 8, with the permission of Dr. M. G. Rossman and the journal *Nature*.) See color insert.



In addition to the use of templates, regulation of self-assembly can be achieved by the binding of additional proteins to the self-assembling structure to stop the process. For example, the lengths of actin filaments *in vivo* are precisely controlled: 0.06 μm in the erythrocyte membrane skeleton and 1.1 μm in the sarcomeres of skeletal muscle. Control of actin oligomerization is achieved by capping—that is, the binding of different proteins or protein complexes to the two distinct ends of each actin filament.

9. Self-Organization of Lipid Bilayers and Membrane Proteins

Phospholipids, triacylglycerols, and cholesterol, which constitute the membranes of cells and intracellular organelles, are amphipathic molecules consisting of a hydrophilic group attached to a larger **hydrophobic** moiety, the latter being either a long fatty-acid chain or a fused nonaromatic ring system in the case of cholesterol. They have the ability to self-organize spontaneously *in vitro* into structures in which their polar groups form the interface with water, excluding their hydrophobic moieties from the aqueous environment: spherical micelles, **vesicles**, and **lipid** bilayers. It should be pointed out that lipid micelles and bilayers are not precisely defined structures, and their sizes can be variable. All cell membranes and intracellular organelle membranes are lipid bilayers. Some of the large, complex viruses are enclosed by a lipid bilayer that is acquired from the plasma membrane of the infected host cell. The self-assembly of **lipoprotein** particles and of membrane-bound structures, such as **receptors**, represents processes in which the constituent nascent polypeptide chains interact cotranslationally with the membrane. Many membrane proteins will insert spontaneously and correctly into artificial lipid bilayers and liposomes, yet still require chaperones and insertional machinery *in vivo*.

10. Nanostructures and Supramolecular Chemistry

The constant drive toward increasing miniaturization of electronic components has led to a general and intense interest in nanostructures, which are assemblies of bonded atoms that have dimensions in the range of 1 to 100 nm. In addition to physical micromethods for forming nanostructures, nanochemistry encompasses the synthesis and characterization of ultralarge molecules and molecular assemblies that can be achieved through covalent polymerization, self-organization, controlled formation of covalent bonds, and molecular self-assembly (9). The latter two topics represent supramolecular chemistry, a discipline involving the self-assembly into ordered structures of synthetic inorganic and organic molecules and synthetic **peptides** and **polypeptides**. The origin of this rapidly evolving area lies in the seminal work carried out by Lehn, Cram, and Pedersen, followed by the discovery of fullerene, a self-assembled structure of 60 carbon atoms, by Smalley, Curl, and Kroto.

Efforts have been made by organic chemists to obtain large, supramolecular complexes via self-assembly of synthetic organic monomers, using either templates or directed interactions. Several growing areas include the design of artificial and mimetic proteins using self-assembly on templates, as well as metal-ion-assisted assembly, self-assembly of designed peptides into biopolymers having desirable material properties, and the use of self-assembled monolayers for fundamental studies of protein adsorption and cell adhesion.

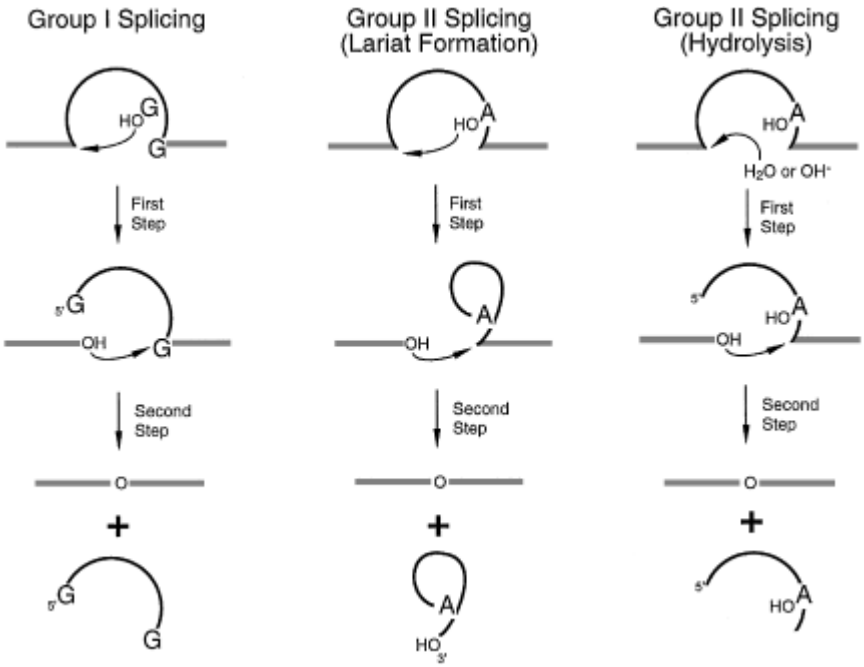
Self-Splicing Introns

Group I and group II introns are two distinct classes of self-splicing **RNA** molecules that contain their own active site for **intron** removal and exon ligation (see RNA Splicing). These two classes of ribozymes are distinguished by their mechanisms of splicing and by their unique structures (1).

1. Reaction Mechanisms

Both classes of self-splicing introns perform two consecutive transesterification reactions in the process of exon ligation. The first step of splicing in a group I intron involves nucleophilic attack at the 5′- splice site by the 3′-OH of an exogenous, bound guanosine cofactor (Fig. 1) (reviewed in Ref. 2). This reaction adds the guanosine onto the 5′-end of the intron and releases the 5′-exon. The second step is analogous to the reverse of the first step. Following a conformational rearrangement of the active site in which the exogenous guanosine is replaced by the G nucleotide at the 3′-terminus of the intron, the 5′-exon attacks the 3′-exon boundary. This releases the intron and ligates the 5′ and 3′-exons. Both the first and second steps of the splicing reaction are fully reversible because no net energy is consumed. The result of these reactions is that the flanking exons are ligated and the intron is released as a linear molecule with an uncoded G at the 5′-end.

Figure 1. Two-step reaction mechanisms for the self-splicing group I and group II classes of introns.



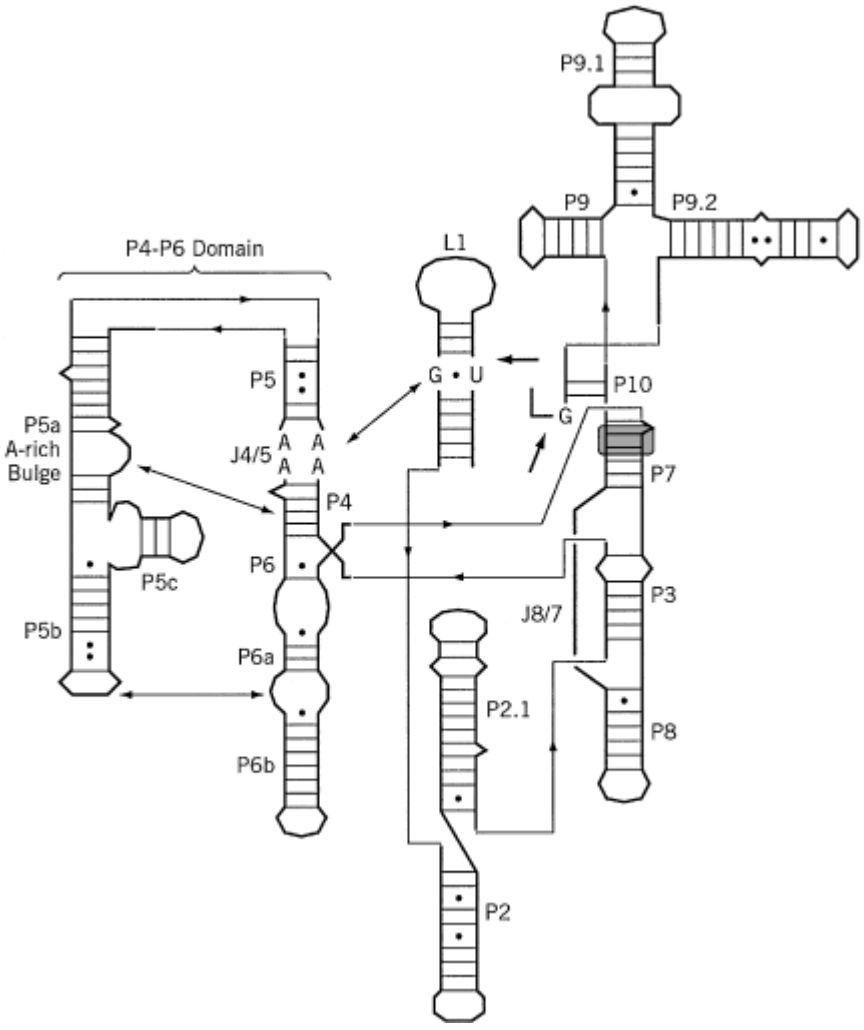
Unlike the group I introns, a group II intron utilizes an internal nucleophile for the first step of splicing (reviewed in Ref. 3) (Fig. 1). The 2′-OH of a highly conserved bulged A nucleotide located within domain 6 of the intron attacks the 5′-splice site. This results in release of the 5′-exon and formation of a **lariat structure** whose 5′-end of the intron is covalently attached to the 2′-OH of the bulged A. Alternatively, the 5′-exon can be released by hydrolysis in which water is the nucleophile. The second step of splicing involves attack by the 5′-exon on the 3′-splice site. This results in ligation of the flanking exons and release of the lariat or linear intron. The reaction catalyzed by the

group II intron follows the same mechanism as that employed in the more complex process of messenger RNA precursor splicing catalyzed by the spliceosome (4). For this reason, it has been proposed that group II intron splicing is an evolutionary precursor to pre-mRNA splicing.

2. Structures

Group I and group II introns catalyze their self-splicing reactions by folding into a distinct tertiary structures comprised of many conserved secondary structural elements (5, 6). The hallmarks of a group I intron include a common secondary structure of 10 paired segments (termed P1–P10) (Fig. 2) and several single-stranded joiner (or J) segments between the double helices (5). The "catalytic core" of the intron is made up of about 120 nucleotides that are highly conserved among group I introns isolated from a broad diversity of biological sources. The conserved nucleotides are clustered within paired regions P4, P6, P3, and P7 and the joiner regions J3/4, J4/5, J6/7, and J8/7. There is also a universal requirement for a G · U **wobble pair** at the 5′-exon boundary. The intron includes a guanosine binding site located in the major groove of the P7 helix, an internal guide RNA sequence that base pairs to the 5′-exon to form the P1 helix, a catalytic cleft within joiner regions J4/5 and J8/7 that orients the P1 helix into the active site for nucleophilic attack, and a terminal G nucleotide that defines the 3′-splice site. Although these elements are quite distant within the intron's linear sequence, they converge spatially within the tertiary structure to catalyze the two splicing steps.

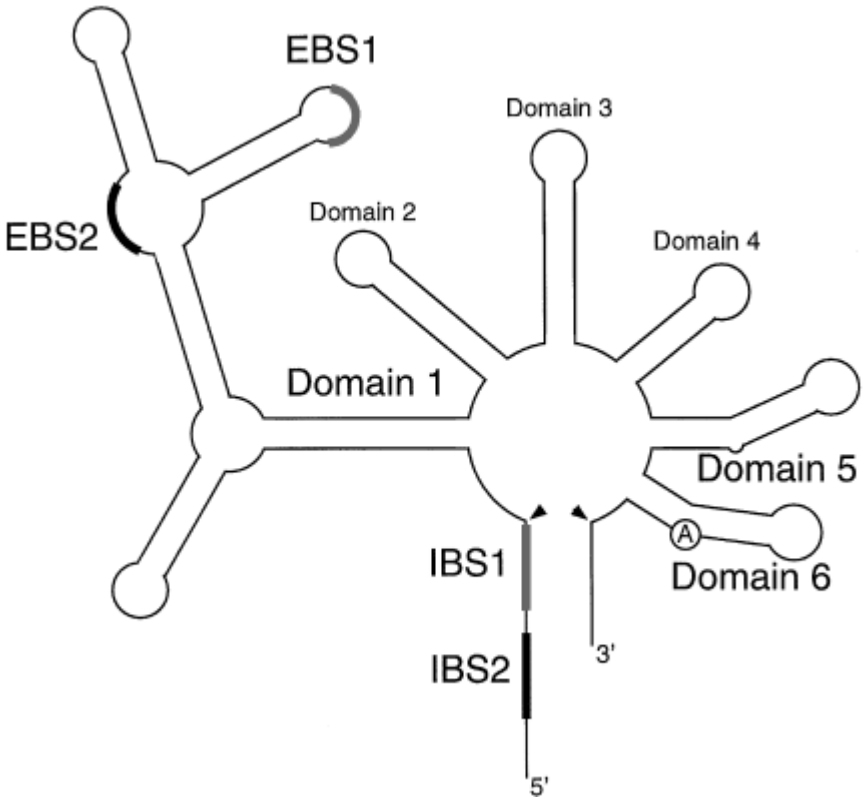
Figure 2. Secondary structure of the *Tetrahymena* group I intron showing the conserved helices P1–P10, the 5′ and 3′ splice sites (large arrows), and the guanosine binding site (gray box). The double-headed arrows indicate a few sites of tertiary interaction between different regions of the intron.



An excellent example of this structural convergence was observed within the P4–P6 domain of the *Tetrahymena* group I intron (7). The crystal structure of this independently folding domain of the intron was recently reported (8). This 160-nucleotide fragment is the largest RNA structure currently known and provides numerous insights into the molecular basis of RNA folding (see RNA Structure). The structure is formed from two long helical segments (helices P6, P4, P5 and helices P5b, P5a) that pack side by side. A bend of about 150° between the helices allows the two helical elements to form two extensive arrays of tertiary interactions. These contacts form between the minor groove of the P4 helix and the A-rich bulge of P5a and between the GAAA tetraloop of P5b and a tetraloop receptor in P6a/6b. Several new motifs of RNA structure and for metal binding were identified within this folding domain, including the "A-platform" and the "ribose zipper" (8, 9). When viewed from the side, the P4–P6 helix is essentially one RNA helix thick. It comprises about half of the intron active site but does not include the P1 helix or the guanosine binding site. Models have been proposed for the complete structures of four different group I introns.

Although there are substantially fewer conserved nucleotides, a group II intron also has a distinct structure (6) (Fig. 3). The intron is organized into six double-helical domains (D1–D6) that originate from a central wheel. Each of the domains has a particular function in the activity of the intron, although D1, D5, and D6 form the intron core. Domain 1 is an extended multihelical element that includes two looped regions (termed EBS1 and EBS2) complementary to two sites in the 5′-exon (termed IBS1 and IBS2). Interdomain interactions also allow domain I to serve as the scaffold upon which the intron active site is built. In contrast to domain 1, domain 5 is a relatively small (34-nucleotide) helical element, yet a large percentage of the phylogenetically conserved nucleotides is concentrated in this domain. It constitutes the catalytic center of the group II intron. D5 catalyzes 5′-splice site hydrolysis even when the domain is added *trans* to the rest of the intron (10). The chemical groups responsible for this catalytic enhancement map into the major groove of the D5 helix in the nucleotides surrounding a conserved G · U wobble pair (11). Domain 6 includes the branch-point adenosine whose 2′-OH nucleophilically attacks the 5′-splice site.

Figure 3. Schematic secondary structure of the group II intron. The bulged A, which acts as the nucleophile in the first step of splicing, is circled in Domain 6. The complementary sequences (EBS and IBS) between Domain I of the intron and the 5′-exon are shown as shaded lines. Arrows represent the splice sites.



3. Biological Occurrence

Group I introns are found within **genes** for mRNA, **ribosomal** RNA, and transfer RNA (1). They are extremely widespread across phylogeny and have been found in mitochondrial, chloroplast, and nuclear **genomes** of diverse eukaryotes, although they have not yet been observed in vertebrates. The discovery of a group I intron in **T4 bacteriophage** was the first example of RNA splicing observed in a prokaryote. Group I introns have also been found in eubacterial genomes. There are currently more than 450 examples of group I introns in the genomic databases. All known group II introns are located within eukaryotic organelles, including plant and fungal mitochondrial DNA and the majority of introns in plant chloroplasts (1).

4. Metals in Folding and Catalysis

Both group I and group II introns are metalloenzymes, which require divalent metal cations for activity (12). Although the metal specificity varies substantially among group I introns, it is usually satisfied by Mg^{2+} or Mn^{2+}. Group II splicing is substantially less efficient and requires nonphysiological concentrations of monovalent and divalent cations (as high as 2.0 M KCl and 100 mM $MgCl_2$), which play both structural and catalytic roles. A dramatic example of divalent metals in RNA folding is in the P5abc subdomain of the *Tetrahymena* group I intron. Three Mg^{2+} ions coordinate to separate phosphate groups within the subdomain (13). This allows the RNA to fold inside-out, that is, the phosphates point into the structure and the nucleotide bases point out to the solvent. Some structural metals in RNA can often be substituted with polycations, such as **spermidine** or cobalt hexamine, which emphasizes the importance of charge neutralization in RNA folding.

Biochemical evidence has implicated two metal ions in the chemical transition state of group I intron splicing (14, 15). One of these metals activates the nucleophile, and the second stabilizes the leaving group during the transesterification reaction. These metal-binding sites are highly selective and

cannot be substituted with a generic polycation. A two-metal active site has also been proposed for the group II intron reaction mechanism, although the evidence for this mechanism is not as complete (11). A ribozyme active site that has two metal ions is analogous to those seen in protein polymerases that catalyze the transesterification reactions of replication and transcription (16).

5. Accessory Protein Factors

Although some group I and group II introns undergo efficient self-splicing *in vitro*, several have no *in vitro* splicing activity. This is true of the majority of the group II introns that have been isolated. Splicing of these introns is likely to be promoted by accessory protein factors that assist the RNA in forming the appropriate active structure. For example, the group I intron in *Neurospora* pre-rRNA has no self-splicing activity unless complexed with the CYT-18 accessory protein (17). Even the yeast mitochondrial group II introns that have *in vitro* splicing activity require nuclear genes to splice efficiently *in vivo* (18).

6. Multiple-Turnover Catalysis

Both the group I and group II introns can be converted into ribozymes capable of multiple-turnover catalysis. The group I intron was converted to a true enzyme by eliminating the 3′-splice site and breaking the connection of the 5′-exon to the rest of the intron. An oligonucleotide analog of the 5′-exon was added to the ribozyme as a substrate (19) where it bound the internal guide sequence within the intron and was cleaved in a reaction equivalent to the first step of splicing. In this form, the ribozyme is not covalently altered during the reaction, and the RNA can cleave multiple substrates. Under multiple-turnover conditions where the substrate is in excess of the ribozyme concentration, the rate-limiting step is not the chemical reaction but release of the 5′-exon (20). A multiple-turnover form of the group II intron was created by deleting the 3′-exon and domains 4 and 5 (10). Upon adding independent domain 5, 5′-splice site hydrolysis of the truncated RNA was catalyzed. Analysis of this construct demonstrated that the chemical step is slower than the association or dissociation rates for substrate binding (21).

Semi-Conservative DNA Replication

The double-helical model of **DNA** proposed by Watson and Crick in 1953 predicted how the molecule could self-duplicate, by assembling deoxyribonucleotides according to the complementary Watson–Crick base-pair rule of A to T and G to C on the two separated strands used as templates. In other words, the double helix predicts a *semi-conservative* mode of DNA replication in which each of the original two strands is conserved in the two-daughter double-stranded DNA. Semi-conservative replication was demonstrated in an ingenious experiment by Meselson and Stahl in 1958 using CsCl density gradient centrifugation to separate DNA with different densities by labeling with a heavy isotope (1). The principle of the method is that each large molecule, like a nucleic acid or protein, attains its specific buoyant density in a solution of high density like 6 *M* of CsCl. When such a solution is subjected to ultracentrifugal force, it generates a concentration gradient along the gravity axis, so large molecules in the solution move to the concentration of the solute corresponding to their buoyant densities and there form sharp bands.

Escherichia coli was grown in $(NH_3)_2SO_4$ labeled with heavy nitrogen ^{15}N for several generations, to make high-density DNA labeled with ^{15}N in both strands, ^{15}N : ^{15}N. The culture was then shifted to a medium containing a rich nitrogen source of normal density, ^{14}N. According to the semi-conservative mode of replication, newly synthesized DNA should contain a hybrid density, one strand heavy and one strand light, ^{15}N :^{14}N. All the DNA molecules are expected to have hybrid density after one generation growth in light nitrogen, and a third molecule of ^{14}N : ^{14}N would appear in the following generations. As expected, the three types of molecules varying in densities were identified, and changes of molecular species from one to the other during the growth of cells after the shift from the heavy to the light medium were exactly as expected from the model (Fig. 1). The Meselson–Stahl experiment not only proved the semi-conservative replication of DNA, but it also demonstrated directly that DNA is composed of two strands, as the molecule of hybrid density produced two types of single-stranded molecules differing in density upon **denaturation** by heat or alkali. The semi-conservative replication found in *E. coli* is ubiquitous in all genomes that are composed of double helical DNA, from **plasmids** to humans.

Figure 1. Demonstration of semi-conservative DNA replication. (**a**) Cells grown in ^{15}N medium and containing chromos

were further incubated in ^{14}N medium for 2.0 generations. Chromosomes after the various generations indicated are drav strand synthesized in the ^{14}N medium. (**b**) DNA fragments isolated from each cell population are illustrated schematicall chromosome is divided in six fragments (in reality into more than 1000 fragments). (**c**) The DNA preparation in (**b**) is ce obtain three discreet bands of DNA with different buoyant densities. The amount of DNA in each band is determined by graphically. HH corresponds to heavy (grey)/heavy (grey), HL to heavy (grey)/light (black) and LL to light (black)/light

Seminal Ribonuclease

Bovine seminal ribonuclease (BS-RNase), or simply “seminal ribonuclease”, as the enzyme is present only in the seminal plasma of cattle and water buffalo bulls, is an eccentric enzyme and

protein in many ways, not the least of which is its absence in all other mammals investigated thus far. It is the only dimeric RNase of the entire **ribonuclease A superfamily** of more than 100 homologous members (see Homology) (1); it is present in seminal plasma at extremely high concentrations (over 1.5 mg/ml); it is endowed with surprising special biological functions distinct from, but dependent on, its catalytic action, including a cytotoxic action selective for tumor cells, an immunosuppressive action, and an aspermatogenic action. The structural and biological properties of the enzyme have been extensively reviewed (2). BS-RNase can be isolated as a soluble protein from bull seminal plasma, or extracted from bovine seminal vesicles, where it is produced (3). It has also been prepared as a recombinant protein in *Escherichia coli* (4) and in eukaryotic cells (5).

1. Structural Properties of Seminal RNase

The subunit of BS-RNase shares with RNase A from bovine pancreas, the archetype of the vertebrate RNase A superfamily, more than 80% of its amino acid residues. BS-RNase differs in that its two subunits are linked non-covalently, as well as by two disulfide bonds, which bridge Cys31 and Cys32 of one subunit with Cys32 and Cys31, respectively, of the partner subunit. Seminal RNase is a homodimer; however, Asn67 of the sequence is readily deamidated (see Deamidation) in one or in both subunits, so that BS-RNase as isolated is a mixture of three components: one with intact Asn67 in both subunits, one with Asn67 deamidated in one subunit, the third with Asn67 deamidated in both subunits (6, 7).

The tertiary structure of BS-RNase subunit is the classical RNase A fold: a kidney-shaped structure, comprising a three-stranded curved beta-sheet, in which the N-terminal **alpha-helix** (helix-I) is inserted, linked to helix-II by a linker peptide segment. A third a-helix runs across the subunit. X-ray crystallography analysis of BS-RNase (8) has shown that each subunit is not autonomous, in that its tertiary structure is constructed with the N-terminal a-helix from one subunit, and the main protein body from the other. Biochemical studies (9) have shown that the intertwined structure (termed MXM) is not the only quaternary structure available to covalently linked seminal RNase chains. The protein also can adopt another quaternary conformation T (termed M = M) in which each subunit folds onto itself, without interchange of parts between subunits. The two quaternary forms are in equilibrium with each other in solution, with the intertwined structure as the more stable form, present in a ratio of 2 to 1 with the other form (9).

Although the enzyme is isolated as a covalent dimer, and its special biological actions depend on its dimeric structure, selective reduction of its intersubunit disulfide bonds, followed by protection of the exposed thiol groups and mild treatment with urea, dissociates the dimer into stable, enzymatically active monomers (10). When the urea treatment is omitted, only the M = M form (with no interchange of parts between subunits) dissociates (9). Upon refolding, after complete **denaturation** and reduction, BS-RNase chains fold first into superactive monomers (11), which later associate into M = M dimers; these eventually transform partly into, and equilibrate with, the MXM form of dimers (9). Thus BS-RNase unfolds in a 3-state transition, in that a stable, folded monomer is an equilibrium intermediate between the associated dimer and the unfolded monomer (see Protein Folding In Vitro). This finding may have an evolutionary significance, as refolding may recapitulate the evolutionary history of a protein (12). It has been hypothesized that an ancestor of the **gene** encoding the uniquely dimeric RNase encoded a stable monomer, which after destabilizing genetic alterations could then find a lower free energy minimum, and thus a new level of stability, in the association with an identical monomer. The key genetic alterations probably occurred within the stretches of sequence encoding the linker peptide connecting helix-I and -II and the helix-II, which compose the intersubunit interface. In particular, these would include substitutions providing the evolved protein chain with a Pro19 residue in the linker peptide, and Leu28, Cys31 and Cys32 residues in helix-II. These residues have been demonstrated in a protein engineering experiment to be essential for the transformation of a monomeric RNase such as RNase A into a stable dimeric and biologically active RNase (13, 14).

2. Biological Properties of Seminal RNase

As an enzyme, BS-RNase is unique among the vertebrate RNase A superfamily in that it is endowed with **allosteric** properties (15, 16). In the second, hydrolytic step of the ribonuclease reaction, the substrate regulates the enzyme activity allosterically, with **negative cooperativity** at low concentrations, and positive **cooperativity** at high concentrations. In contrast, the first catalytic step, the transphosphorolyis of the phosphodiester bonds, follows typical **Michaelis-Menten kinetics**. On the other hand, this finding can hardly be reconciled with the extracellular nature of the enzyme, and with its high concentration in seminal plasma.

Of greater interest biologically is the ability of the enzyme to degrade effectively both single- and double-stranded RNA, under conditions in which most homologous extracellular RNases only cleave single-stranded substrates (17). This activity is due not only to the dimeric structure of the enzyme, and to its high positive net charge (18, 19), but also, and more specifically, to the presence at key positions of the seminal RNase chain of residues Gly38 and Gly111, which in the RNases with low or no activity on double-stranded RNA are replaced by acidic residues (20).

Also of interest is the resistance of seminal RNase to the cytosolic **ribonuclease inhibitor**, which is clearly due to its dimeric structure (21). The docking of a sensitive monomeric RNase, such as RNase A (22), involves the very protein surface that becomes a subunit interface in dimeric BS-RNase. Thus when dimeric BS-RNase dissociates, as presumably happens in the more reducing environment of the cytosol, the protein becomes sensitive to the action of the cytosolic RNase inhibitor (23).

As anticipated above, the interest in seminal RNase is also directed towards its surprising and diverse biological functions. It has been proposed (24) that they are mere reflections in laboratory assay systems of the actual physiological action of the enzyme, which is yet to be conclusively deciphered. On the other hand, the high concentrations of the enzyme in seminal plasma, and the disappearance of immunosuppression in bull semen deprived of the enzyme, have led to the hypothesis (25) that the immunosuppressive activity of the enzyme is the basis for its real physiological action, which consists in the immune protection of the non-self sperm cells in the female host.

Given the general interest in the antitumor action of seminal RNase since its early discovery (26), many efforts have been directed towards the elucidation of the structural and functional determinants of this activity and of its mechanism of action. The dimeric structure of the protein and the integrity of its catalytic function have been found to be essential, since neither monomeric nor inactivated derivatives of the protein display antitumor activity (27), as is the interchange of N-terminal a-helices between subunits (28, 29). This is also apparent from the results of the site-directed mutagenesis experiments cited above, by which monomeric RNase A, devoid of antitumor action, was transformed into a dimeric protein with antitumor activity (13, 14). The antitumor activity is correlated with the interchange of parts between subunits, and both depend on the simultaneous presence in the subunit chains of a Pro19 residue at the linker segment connecting the exchanged helix-I to helix-II, of the Cys31 and Cys32 residues responsible for the intersubunit disulfide bonds, and of Leu28 residue, which participates in a **hydrophobic** interaction at the intersubunit interface.

Some of the steps of the targeting pathway of the protein have also been defined: the protein is first secreted and concentrated on the extracellular matrix, where it is bound specifically; then it is internalized by non-receptor mediated endocytosis; through unknown pathway(s), it is eventually delivered to the cytosol, where it specifically degrades **ribosomal** RNA, thus blocking **protein biosynthesis**, and leading to the death of the cell.

Besides the immunosuppressive activity, the other “special,” ie, noncatalytic, bioactions of seminal RNase are its aspermatogenic, antitumor, antiviral, and embryotoxic activities (2). Perhaps the most interesting of them is the antitumor activity, discovered by Josef Matousek and coworkers (26) almost 30 years ago. Thus, it is not surprising that many efforts have been directed towards the elucidation of the structural and functional determinants of this activity and its mechanism of action

(30). The main determinants have been proposed to be the integrity of the catalytic action and the dimeric structure of the protein (27). The former is clearly related to the ability to degrade rRNA, which the seminal enzyme exerts in malignant, but not in normal, cells (31). As for the significance of the dimeric structure in the protein antitumor action, this has been related to its ability to evade as a dimer the neutralizing effect of the cytosolic RNase inhibitor (see above). The main data leading to this conclusion are: 1) The higher cytotoxic activity of the MXM form (29) compared with that of the M=M form; the latter, upon reduction of the intersubunit disulfides by the cytosolic reducing environment, dissociates into monomers, whereas MXM remains a dimer, albeit non-covalent, hence, resistant to the cytosolic inhibitor (32); 2) Monomeric non-cytotoxic RNases can be made cytotoxic by rendering them resistant to the inhibitor (33, 34).

As for the mechanism of anti-tumor action of seminal RNase, a more complete picture is emerging. The protein first accumulates at the extracellular matrix, where it binds with high affinity to specific, saturable, reversible binding sites (31), and then it is internalized by nonreceptor mediated endocytosis and packaged in endosomes; it reaches the *Trans*-Golgi Network (TGN), and, eventually, the cytosol (A. Bracale et al, unpublished results), where it degrades rRNA. This engenders a block of protein synthesis and apoptotic death (35). The observation that TGN and cytosol are reached by the protein only in tumor cells justifies the selectivity of the anti-tumor action of seminal RNase, but it does not shed light on the reason why this toxic pathway is followed by the enzyme only in tumor cells. Clearly, the resistance to the cytosolic inhibitor does not explain all seminal RNase cytotoxic potential and its selectivity.

Semliki Forest Virus

Semliki Forest virus (SFV) is a member of the **virus** genus *Alphavirus* in the family *Togaviridae*. SFV was originally isolated in Western Uganda in 1942 from mosquitoes, *Aedes abnormalis*, and since then it has also been found in African and Eurasian countries. In nature, SFV circulates between birds and mosquitoes, while experimentally SFV has a wide host range of mammalian, avian, and insect cells. In rare cases, SFV causes rash, fever, or arthritis in humans. SFV and Sindbis virus, the prototype alphavirus, are most extensively studied molecular biologically among the 26 members in the genus.

The genome is a positive-strand RNA molecule with 11,422 nucleotides, excluding the cap and the

3′ poly(A) tail. The virion is 70 nm in diameter and consists of a nucleocapsid 40 nm in diameter, which contains the genomic RNA encapsidated with 240 copies of capsid (C) protein, and a surrounding lipid bilayer membrane that anchors 80 spikes, each composed of three hetrotrimers units (240 in total) formed by **glycoproteins** E1, E2, and E3. Both the nucleocapsid and envelope spikes are arrayed in a $T = 4$ symmetry. The **sedimentation coefficient** of the virion is 280S (in water at 20°C), and the buoyant density in sucrose is 1.22 g/mL.

The **genes** for four nonstructural proteins required for viral RNA replication and transcription—nsP1, nsP2, nsP3, and nsP4, are positioned in that order in the 5' two-thirds of the genomic RNA and are **translated** initially as polyprotein P1234. P1234 is cleaved into intermediate and four mature proteins by a papain-like thiol proteinase, located in the *C* -terminal half of nsP2. Genetic and biochemical studies, as well as amino acid sequence analysis, indicate that nsP1 has capping enzyme activity, nsP2 has a nucleoside triphosphate-binding RNA helicase activity in the *N*-terminal half and a proteinase activity in the *C*-terminal half, and nsP4 is the viral **RNA polymerase**. The functions of nsP3 have not been elucidated, but it is a component of the replication complex and is **phosphorylated** *in vivo*.

The genes for the structural proteins C, E3, E2, 6K, and E1 are positioned in that order from the 5′ terminus and are expressed from a subgenomic RNA that is collinear with the 3′ one-third of the genome and is transcribed from an internal **promoter** on the full-length complementary strand. The structural proteins are translated as a polyprotein and processed into mature products by capsid autoproteinase at the C—E3 bond, by cellular signal peptidase at the E2–6K and 6K–E1 bonds, and by a cellular proteinase at the E3–E2 bond.

The virions enter the host cells by receptor-mediated endocytosis, followed by fusion of the viral envelope with a host endosomal membrane, triggered by low pH. After release of the nucleocapsid into the cytoplasm, disassembly of the nucleocapsid appears to be triggered by its binding to ribosomes. Subsequent RNA replication and transcription occurs entirely in the cytoplasm. The regulatory mechanism of plus-strand and minus-strand RNA synthesis was elucidated from studies with Sindbis virus. Four nonstructural proteins are translated as polyprotein P1234, in which **proteolytic** cleavage at the nsP3–nsP4 bond occurs rapidly in *cis* (intramolecularly), and the resulting P123 and nsP4 form a replication complex for full-length minus-strand RNA synthesis. Polyprotein P123 is unstable due to its intrinsic proteinase activity, and the cleaved products together with nsP4 form a stable replication complex for plus-strand genomic and subgenomic RNA synthesis. At late stages of infection, when the nsP2 proteinase concentration has increased, the nsP2–nsP3 bond of nascent polypeptide chain is cleaved, preventing formation of the P123–nsP4 complex and shutting off minus-strand RNA synthesis. Plus-strand genomic and subgenomic RNA synthesis continues, because this replication complex is composed of fully cleaved, metabolically stable products. On the other hand, structural proteins are translated from subgenomic RNA, which is produced in a large excess over the genomic RNA. Capsid proteins and a genomic RNA molecule assemble to form a nucleocapsid. The assembled nucleocapsid interacts with the cell plasma membrane, which is occupied by the viral glycoproteins. Mature virus particles are released from the cell membrane by budding.

Full-length complementary DNA of the SFV genome was **cloned** immediately downstream of a bacteriophage **RNA polymerase** promoter in a plasmid **vector**. Transcription of the cDNA insert with a bacteriophage RNA polymerase generates infectious RNA *in vitro*, which leads to production of infectious virions upon transfection of host cells. This "infectious" cDNA clone has proved to be a powerful tool for molecular genetic analysis of SFV replication and pathogenesis. The full-length clones have been also successfully used for development of transient expression systems, so that genes of interest can be expressed in the cytoplasm of the transfected or infected cells.

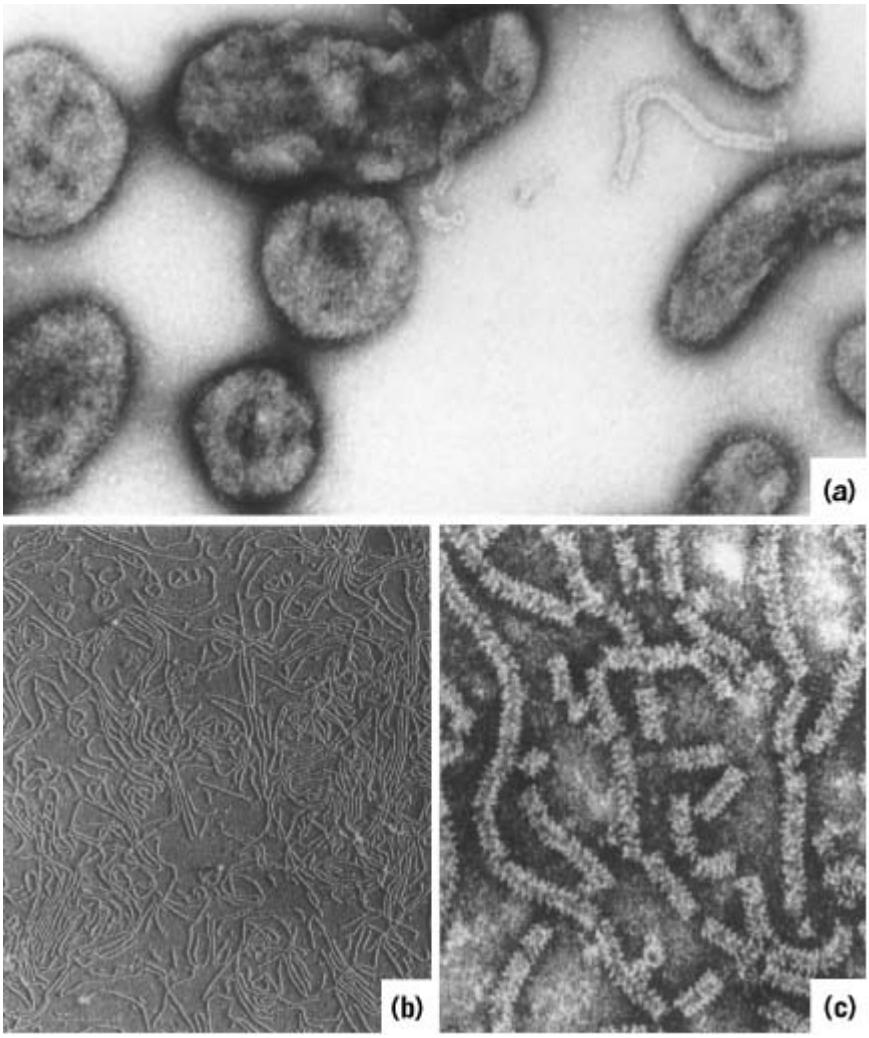
Sendai Virus

Sendai virus (murine parainfluenza virus 1) belongs to the genus *Respirovirus* in the subfamily of *Paramyxovirinae* of the family *Paramyxoviridae*. The **virus** particles are 150 nm or more in diameter, and they are pleomorphic but usually spherical in shape (Fig. 1). The genome is a single molecule of linear, single-stranded, negative-sense RNA of 15,384 nucleotides. The genome RNA is tightly associated with the nucleocapsid (N) subunit proteins and **RNA polymerase**, which consists of a phosphoprotein (P) and a large (L) protein, forming a helical ribonucleoprotein complex (RNP) or nucleocapsid (Fig. 1). The virion consists of the RNP surrounded by a lipid envelope, which is derived from the host cell plasma membrane and contains two virus-specific **glycoproteins**, the hemagglutinin-neuraminidase (HN) and the fusion (F) protein. These glycoproteins are present as homooligomers, forming spike-like projections of 8 nm in length. HN binds to the receptor sialic acid residues on the host cell surface, whereas the F protein facilitates virus entry by mediating fusion of the viral envelope with the host cell plasma membrane. F is derived from the biologically inactive precursor F_0 glycoprotein through proteolytic processing by a host cell endoproteinase.

There is a matrix (M) protein layer between the envelope and RNP. The M protein is important for assembly and stabilization of the virion structure.

Figure 1. Sendai virus particles. Sendai virus virions were negatively stained with uranyl acetate (**a**). RNPs were revealed by shadowing (**b**) and negative staining (**c**). Magnifications: (**a**) ×130,000, (**b**) ×16,000, (**c**) ×220,000. (Courtesy of Dr. Y. Hosaka.)



The genes encoding the individual proteins are organized in the viral genome in the order 3′-leader-N-P-M-F-HN-L-trailer-5′. The short terminal leader and trailer regions contain the **promoters** for replication. The RNP, but not the naked RNA, can serve as template for both transcription and replication. The **RNA polymerase** enters the 3′ terminal region and generates each mRNA successively by a stop–start mechanism controlled by the specific *cis*-acting signals present at each gene boundary. Therefore, the viral gene expression is generally monocistronic, although expression of the P gene is a notable exception. The P messenger RNA directs the synthesis of not only P protein, but also a nested set of accessory proteins, C′, C, Y1, and Y2, collectively referred to as C proteins, by using multiple initiation codons in the +1 reading frame relative to that of P. The P gene further generates an mRNA encoding another accessory protein, V, by cotranscriptional RNA editing featuring the insertion of a single guanine residue at a specific site. The P and V proteins thus have the same amino-terminus but differ in their carboxyl-terminal halves. After translation of the mRNAs and accumulation of viral proteins, the same RNA polymerase copies the same RNP template, but somehow ignores all junction stop–start signals and the editing site, to generate antigenomic RNP with a full-length positive strand RNA. This RNA serves as the template to generate genomic RNP. All replication steps take place in the cytoplasm, and maturation occurs by budding from the plasma membrane.

Sendai virus was first isolated in 1952 in Sendai, Japan, by inoculating mice with the autopsy lung tissue from a newborn child with pneumonia. In 1955 it was initially named hemagglutinating virus of Japan (HVJ) by the Japanese Society for Virology. The question soon arose, however, as to whether it was the causative agent of a human disease, because the virus was found to be prevalent

worldwide in mice and other rodents and to cause enzootic or epizootic infections in these animals. Indeed, no direct evidence supporting the involvement of Sendai virus in any human disease is yet been available. Instead, the Sendai virus system in the mouse has been widely used as a model for studying acute respiratory infections. Recently, a technology has been established that allows infectious virus to be generated solely from cDNA, permitting the genetic engineering of Sendai virus. This technology is not only solving previously unsettled issues, including the roles of the Sendai virus accessory proteins, but also opening the possibility to use Sendai virus as a novel expression vector.

Senescence

Tissue homeostasis is regulated not only through the elimination of excess cells by apoptosis, but also by the inability of most cells to proliferate infinitely; at some stage, their further growth is arrested. Thus, cell populations are consistently replenished by a small pool of proliferating stem cells, with the daughter cells they produce eventually arresting, limiting the number of cells within the population. The maintenance of cell survival in the absence of division is termed *senescence*; a senescent cell is essentially a cell that is genetically dead. For long-lived animals, senescence is a sensible option because reducing the number of cells with the capacity to divide also reduces their capacity to both mutate and form tumors (see Cell Death). Senescence is tightly regulated, with clear differences existing between proliferating and senescent cells in the proteins expressed (1). Some of the proteins involved in regulating senescence also regulate apoptosis, but the link between these two pathways, if indeed there is one, is unclear.

Primary cells in culture will undergo a finite number of passages before terminally arresting (2, 3) (see **Cell growth**). Once in this state, cells cannot be triggered to reenter the cell cycle, suggesting that each cell must have a clocklike mechanism that counts each division and arrests this cell after the critical number of doublings (3-5). This clock like mechanism is now believed to occur in the **telomeres** of chromosomes (6-9). Telomeres are, however, not the only mechanism through which senescent cells are arrested. Senescent cells have alterations in the expression of proteins that regulate the cell cycle. In particular, senescent cells express low levels of cyclins and cyclin-dependent kinases (cdk), have no phosphorylated (active) **retinoblastoma** (Rb) protein and express elevated levels of the cell-cycle inhibitor p21. Senescent cells also express particular senescent genes, as shown by the complementation analysis of immortalized cells (10). **Cell fusions** between transformed cell lines can result in the hybrid cell either remaining immortal or becoming senescent. If the fused cells remain immortalized, they must contain the same genetic mutation allowing

immortalization, whereas the senescent hybrid cells must have different immortalization mutations and are therefore assigned to different complementation groups. Several putative genes that regulate senescence have been identified using this method, but their function is not yet known (1).

The regulation of cellular senescence has been described in two stages, mortality stage 1 (M1) and mortality stage 2 (M2), which are controlled by two different mechanisms. This model was derived to explain the behavior of cells transfected with inducible SV40 large T-antigen. Proteins from a variety of tumor **viruses**, including T-antigen, E1A and E1B from Adenovirus type 5, and E6/E7 from human papilloma virus, extend the life span of fibroblasts in culture. Cells expressing these proteins have effectively bypassed the first stage of senescence, because these proteins sequester both p53 and Rb, two proteins thought to be critical for arresting cells in M1 (11, 12). SV40 large-T antigen-transfected cells do not reach senescence; instead, they enter *crisis*. During crisis, cells exhibit both mitosis and apoptosis and, because death outweighs proliferation, the population is eventually lost. Only rarely does an immortalized cell emerge from crisis.

Both p53 and Rb have well-described roles in cell-cycle control (13-17) (see Cell Cycle). Activation of p53 results in either G_1 arrest, preventing cell replication in the presence of DNA damage (18, 19), or apoptosis (20, 21). Several functions have been ascribed to p53, including the control of transcription and **replication**, either of which may contribute to growth suppression. The induction of cell-cycle arrest by p53 is likely to be facilitated by its induced expression of $p21^{Waf-1/Cip-1}$ (22-24), which efficiently inhibits the activities of the cyclin-dependent kinases (25), one of which, cdk-2, phosphorylates Rb, inhibiting its interaction with the transcription factor E2F (25-27). Thus, the removal of p53 and Rb eliminates two interlocked cell-cycle inhibition steps, allowing uncontrolled cellular progression; furthermore, mutations within these cells will be undetected due to the absence of functional p53. Not only will this cooperation suppress the M1 phase of senescence, it will also prevent apoptosis, suggesting that the regulation of M1 and apoptosis overlap.

Cells that evade M1 progress instead to the M2 crisis. Only a cell that gains a mutation in one of the M2-regulating genes is able to overcome crisis and emerge as an immortalized cell. M2 is thought to be regulated by telomere shortening. The hypothesis proposed is that telomere shortening triggers the M1 phase and cells are arrested by p53 and Rb. However, in large T-antigen-expressing cells, M1 arrest is suppressed. Hence, the telomeres continue to shorten, leading to the chromosomal damage that triggers M2 and crisis (12). Cells that evade M2 are thought to enable the reexpression of telomerase, an outcome that is also found in many tumor cells. Thus, an understanding of the mechanistic pathways that facilitate senescence is critically important if the ways in which tumor cells become immortalized are to be fully understood.

Sephadex, Sepharose, Sephacryl

Sephadex, Sepharose, and Sephacryl are trade names for three types of **gel-filtration** matrices made by the Pharmacia Fine Chemicals Company (1). Sephadex is a bead-formed gel prepared by cross-linking dextran with epichlorohydrin. The gel is extremely hydrophilic due to the large number of hydroxyl groups, and it therefore swells readily in water and electrolyte solutions. The G-types of Sephadex differ in their degree of cross-linking and hence in their degree of swelling and their fractionation range. Sephadex also swells in dimethylsulfoxide and formamide. Sephadex is insoluble in other nonaqueous solvents (unless it is chemically degraded). It is stable in water, salt solutions, organic solvents, and alkaline and weakly acidic solutions. Sephadex does not melt, and it may be sterilized wet at neutral pH or dry by autoclaving for 30 minutes at 120°C without affecting its chromatographic properties.

Sepharose is a bead-formed gel prepared from agarose by a purification process that removes the charged polysaccharides and gives a gel with only a very small number of residual, charged groups (see Electroendosmosis). Sepharose is stable in water and salt solutions over the pH range 4 to 9 and in the absence of oxidizing agents. It melts by heating above 40°C, and the bead structure may be irreversibly damaged by freezing. Cross-linked Sepharose, as prepared by reaction with 2,3-dibromopropanol under strongly alkaline conditions, is called Sepharose CL. It has greatly increased thermal and chemical stability. For example, Sepharose CL is used in aqueous media in the pH range 3 to 14.

Sephacryl is prepared by covalently cross-linking allyl dextran with *N*,*N*′-methylene bisacrylamide (see Polyacrylamide) and gives a rigid gel with a carefully controlled range of pore sizes. It is usually used in aqueous solutions. However, its gel structure allows replacing the water with organic solvents that have a much smaller effect on pore size than in the case of Sephadex. Sephacryl is insoluble in all solvents unless it is chemically degraded. It may be used in the range pH 2 to 11, with eluents containing detergents (eg, SDS), and with structure-breaking media, such as 6 M **guanidinium** chloride and 8 M urea. Sephacryl does not melt and may be autoclaved repeatedly at 120^{o}C and neutral pH without significantly affecting its chromatographic properties.

Sequence Analysis

Sequence analysis is devoted to the extraction of information contained in nucleic acids and proteins, and is one of the most important areas of bioinformatics. Many of the sequence-analysis methods are aimed at the prediction of functional and structural features in biological sequences. Given the availability of complete genomes for several organisms, and thus of their entire gene pools, prediction of individual protein structure, function, and interactions can now be complemented by methods that reconstruct entire biochemical pathways and other cellular processes.

Nevertheless, computational approaches are only beginning to contribute to the closure of the gap between genotypic and phenotypic information (1). As yet, too little is known about the signals in

genomic *DNA*, so elementary processes such as gene regulation cannot currently be predicted from sequence alone. Computational methods do better on the prediction of protein-coding genes, although this is a complicated process: Coding sequences comprise only 3% of the human genome. Therefore numerous, often weak, signals have to be combined (**promoters**, RNA splicing junction and branch sites, polyadenylation signals, etc.) in order to recognize exons and **introns** and to assemble the putative exons into complete genes (2). Database searches using sequence similarity are amongst the most powerful tools in this process, because ever more **homologues** of newly sequenced genes are found to be already stored in publicly available databases. However, because gene prediction methods currently only have an accuracy in the range 60% to 80% (3, 4), wrongly assembled proteins are accumulating in databases. Falsely annotated coding sequences, together with direct sequencing errors, frequently cause major problems in analysis of protein sequence data (5, 6).

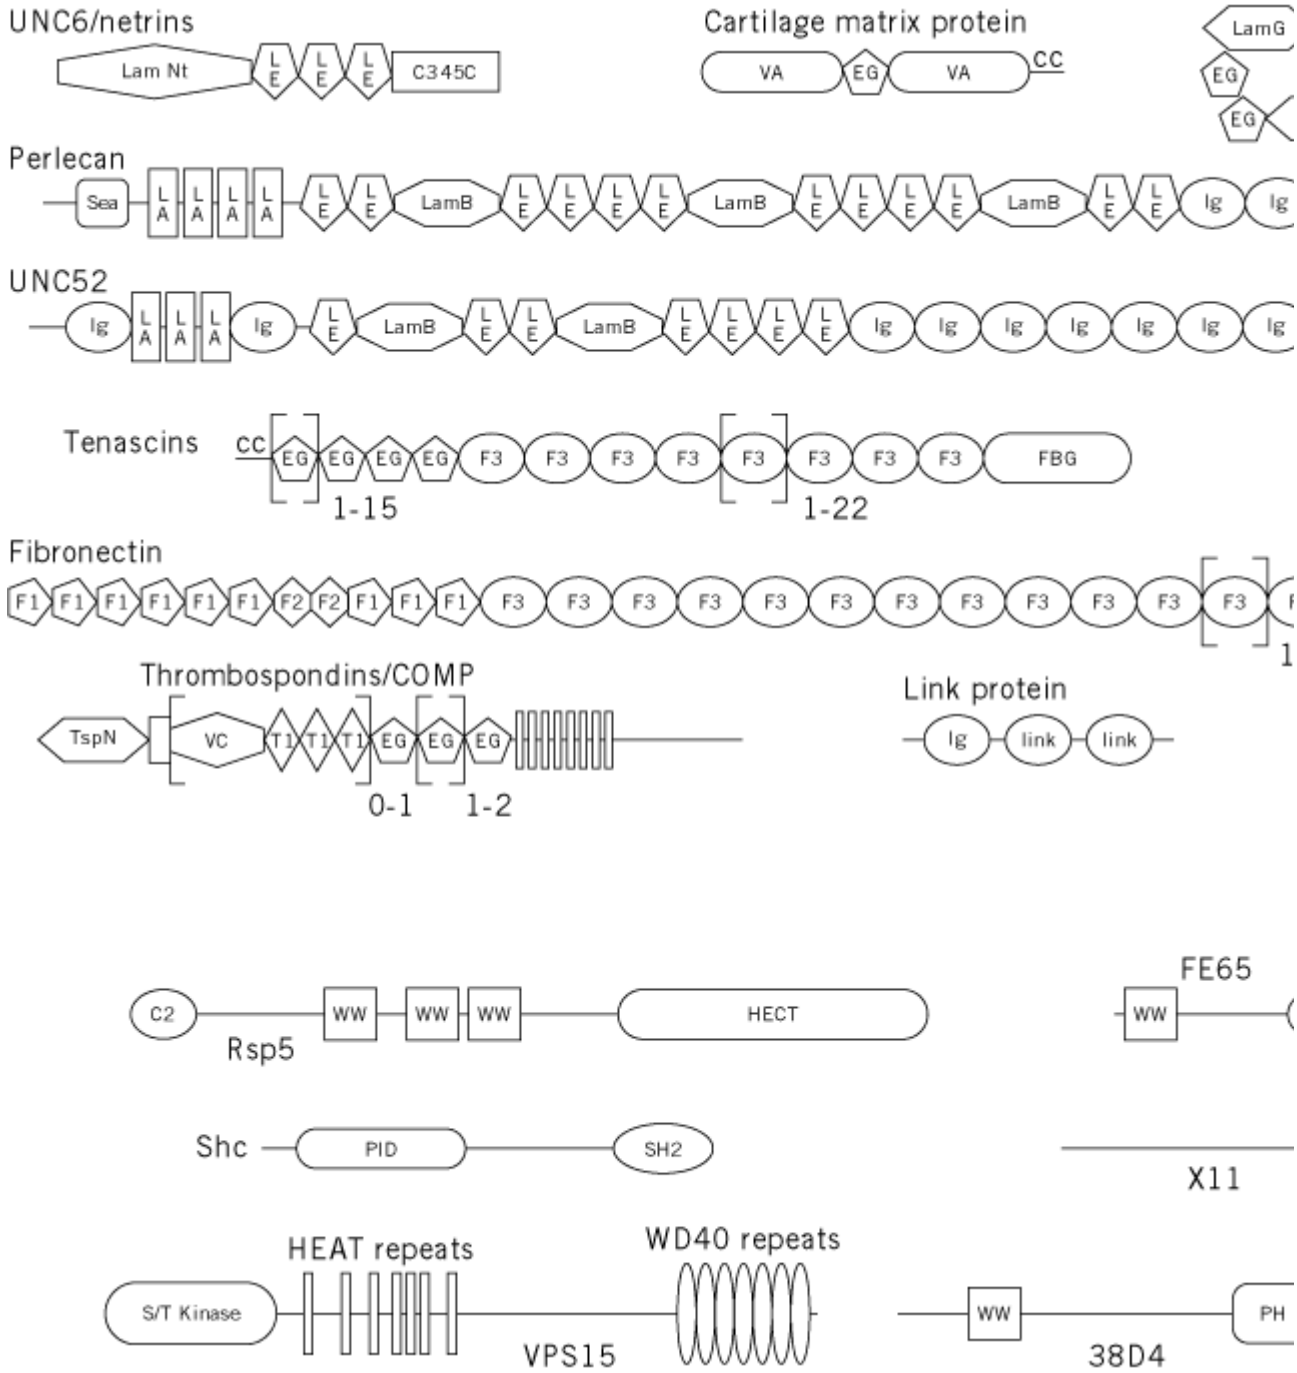
When a gene is identified and translated into a protein using the genetic code, a variety of fast methods can be applied to identify its intrinsic features (4). Examples are the prediction of **transmembrane** regions and, more specifically, of **signal peptides**. Typically, these methods **thread sequences** of interest against precomputed weighting matrices (but more sophisticated algorithms may use trained **neural networks**, hidden Markov models, etc.). Other intrinsic features of proteins that should be characterized are nonglobular regions, internal repeats, **secondary structure**, and **posttranslational modifications**. Nonglobular regions of proteins include **coiled coil** or other fibrous elements, transmembrane regions, short internal repeats and segments of random coil. These regions usually show a strong compositional bias in favor of certain amino acid residues (7). Nonglobular regions should usually be filtered out before a database search is carried out, because most algorithms are optimized for the identification of globular regions (8).

Sequence database searches are often the best way to obtain features indicative of individual protein function. If a homologue with a known tertiary structure can be identified, structural information can also be transferred from the hit to the query (see **Homology modeling**). Database searches are best done in an iterative procedure: If the first scan revealed some significantly similar proteins in the database, reciprocal searches with the clear homologues should be done and all proteins identified this way should be aligned together in order to utilize family information (9). Sequence conservation within an alignment is a valuable source of information about **divergence** of sequences and their evolution, as well as of functional and structural features. More often than not, several homologues are found within one species; that is, the query sequence belongs to a multigene family. Based on a multiple alignment (and given a certain expectation for the grouping of the sequences according to our current understanding of species evolution), phylogenetic trees can be built that help to discriminate **orthologous** from paralogous genes—that is, the equivalent genes in different species, as distinct from homologous but nonequivalent genes belonging to the same multigene family (10). Moreover, the conservation within aligned sequences can be used to perform much more sensitive database searches in order to identify distant relatives. For this purpose, the entire alignment can be used as query, using the full family information, although it is often useful to restrict the further searches to particularly conserved local regions, protein motifs (9, 11). A highly conserved motif often hints at a functional site, usually overlayed on a conserved structural unit. Motifs are often sufficient to predict the presence of a functional activity, so sequences can also be scanned against motif databases that contain signatures of well-characterized protein families (12).

A complication in the elucidation of individual protein function and structure is the modular architecture of many proteins; that is, they contain several functionally and structurally independent building blocks, called autonomous **domains**. Ideally, definition of domains should form the basis of all analyses of genes and proteins, but it is often hard to deduce the domain structure if only the sequence is known. A domain is best described in structural terms, because physical parameters can be applied (ie., ratio of diameter versus surface area) that provide clear thresholds for domain definitions (9, 11). The average size of proteins in databases is more than 300 amino acid residues, yet globular domains only rarely exceed 200 residues in length; hence the majority of proteins contain more than one domain. If proteins are known to harbor a certain domain, or such a domain has been identified in a database search, it is advisible to perform separate searches with the

remaining parts of the proteins. Homologous domains can be found in a diverse set of proteins with unrelated overall functions, as exemplified in Figure 1. Therefore, genetic mechanisms must have existed (and presumably still do) that allowed their horizontal spread within genomes. For animals, exon shuffling appears to be one such mechanism, especially with regard to extracellular proteins (13), but, because it requires introns, this cannot be the driving force for the fast evolution of certain modular bacterial proteins (especially in soil bacteria), many of which show **horizontal transmission** between genomes. Both plasmid transfer and efficient recombination mechanisms are likely to contribute to the horizontal transfer of domains between bacterial genomes.

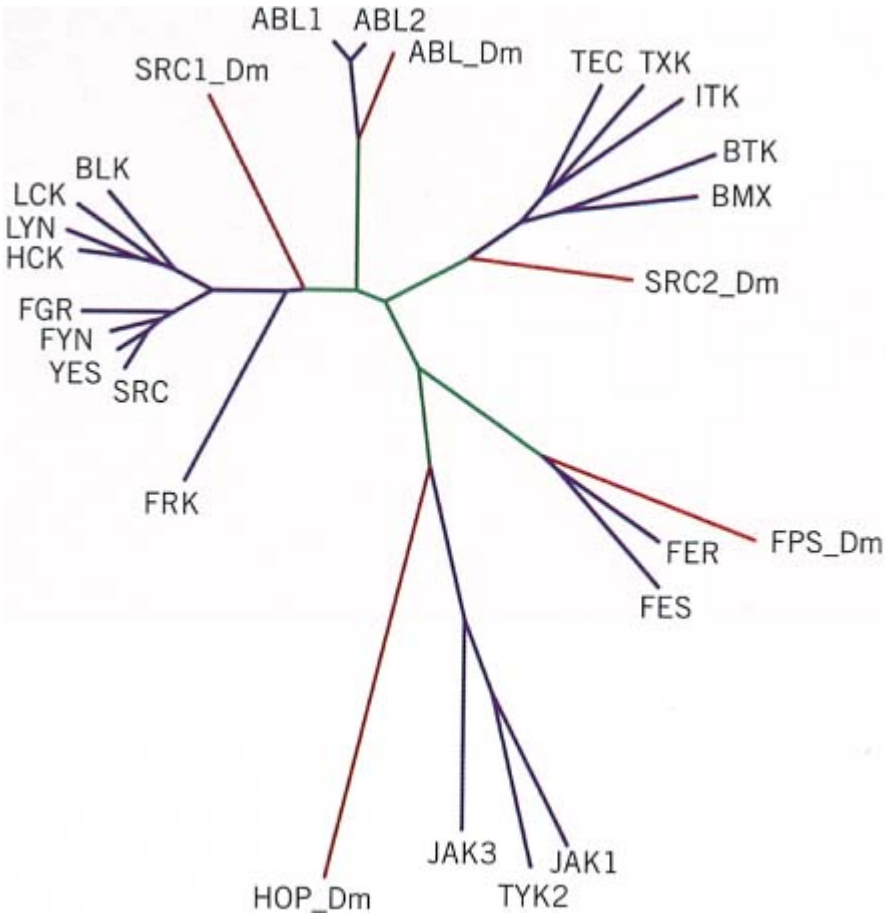
Figure 1. A selection of multidomain proteins. Most eukaryotic extracellular proteins are partly or wholely assembled fr
while more than 50 widespread cytoplasmic signalling domains are known to date (31). In the nucleus, there is an extens
chromatin-associated domains. These sets of domains are together estimated to occur in more than 20,000 human protei
human proteins.



The domain phenomenon also has to be considered when comparing whole genomes, with the aim of identifying orthologues and thence reconstructing metabolic pathways. This has become feasible now that several complete bacterial genomes are available, while, especially for *Escherichia coli*, a vast amount of biochemical knowledge has also been generated. The comparative analysis of entire genomes is rather new, though progressing quickly (14-16). Orthologues from different species are collected, and newly incoming bacterial genomes can be scanned against those collections for the purpose of annotation. Databases of known pathways are becoming linked to sequence information and apparent gaps in, or the absence of, certain pathways have then to be interpreted. Secondary metabolism in a bacterium can then be confined to a restricted number of "leftover genes" that are not present in other bacteria.

In addition to following the evolution of genes and proteins, it is now becoming possible to analyze the evolution of entire genomes. One important result to have emerged from extensive sequence analyses is that the vertebrate genome is essentially octaploid (a fourfold genome amplification, because somatic cells are already diploid). This would be accounted for by two consecutive genome duplications in the vertebrate common ancestral lineage. It is routinely found that a given gene in the model organism *Drosophila* has up to four counterparts in human or mouse, called tetralogues, because, although they are paralogues, they are all orthologous with respect to *Drosophila* (17). In some cases, individual tetralogues may have been lost by deletion, as is documented within the *Hox gene* clusters. Figure 2 shows the situation for a set of human and *Drosophila* **tyrosine kinases**. As a consequence of **polyploidy**, tetralogous genes originally had an essentially total functional overlap. Although their functions may have diverged subsequently (especially for extracellular proteins), there are many instances of vertebrate functional redundancy, most clearly indicated by the effect of mouse gene knockouts with notoriously small phenotypic effects—for example, for ***Src***, MyoD, RXR, and so on. Functional redundancy enormously complicates analyses of, for example, signaling pathways and gene regulation: It becomes essential to obtain the full set of redundant genes and proteins. Until such time as a complete vertebrate genome sequence is determined, the expressed sequence tag (EST) databases [large collections of randomly sequenced complementary DNAs (18)] are a vital resource for identifying tetralogues.

Figure 2. Neighbor-joining tree prepared from an alignment of human and *Drosophila* tyrosine kinases, showing multiple human kinases for each related *Drosophila* kinase. Branches leading to human kinases are colored blue; to *Drosophila* kinases, red; with green for branches that precede the split of the human–*Drosophila* lineages. The least divergent human groups, such as the ABL and SRC groups, are likely to have the most conserved and overlapping functions. The more diverged BTK group has incompletely overlapping functions. *Drosophila* orthologues were not yet known for the SRC and LYN tetralogies. Local chromosomal gene duplications may account for some of the multiple human genes; thus the BTK group exceeds the tetralogy with five known members, but BTK and BMX are close together on the X chromosome, implying a relatively recent duplication. See color insert.



Vertebrate tetraploidy is only one of very many polyploidies that have occurred in eukaryotic evolution. Polyploidy is probably one of the main routes to the establishment of multigene families (although not the only one) (19). For example, the full sequence for the genome of Baker's yeast revealed traces of an ancient genome duplication, estimated to have occurred 100 million years ago (20). Many other medium- to large-scale genetic events will also be revealed as more genomes become completely sequenced. Genetic mechanisms leading to inversions, slippage, plasmid operon mobility, and so on, will in future be better detected and quantified.

As the amount of sequence data increases, analyses rely more and more on sophisticated databases and knowledge retrieval systems. Therefore, adequate computer hardware and network facilities are becoming essential even to experimental biologists. Amongst the academic disciplines, biologists are indisputably the single greatest beneficiaries of modern computer networking developments such as the World Wide Web (WWW), which has allowed legions of web servers to become accessible to any biologist with a personal computer and telephone line. Because of continual development in sequence analysis tools, many programs and web servers in common use at the time of writing are likely to be replaced in the near to medium term. Therefore only those that the authors regard as having longer-term utility, or particular current importance, will be mentioned by name in this section.

1. Searching Sequence Databases

As well as the sequences themselves, the databases contain annotation that can provide very useful information about the sequences—and increasingly, cross-links to other forms of databases (or other biological resources)—which may not be based on primary sequence information—for example, tertiary structure databases or medical databases. Therefore tools have been developed for two vital

forms of database retrieval; firstly, by sequence similarity and, secondly, by keyword search through the text annotation. In practice, sequence-based searches are likely to induce information extraction, and vice versa, so the tools are highly complementary.

1.1. Search by Sequence Similarity

Underlying similarity searches is the concept of *homology*, which implies that sequences have diverged from common ancestral genes and genomes; hence traces of the evolutionary history may still be seen in the present sequences. Typically, both functional and structural contraints apply to the sequences, so that conservation within a set of related sequences mirrors those contraints, and current database search methods tend to be optimized to identify these signals.

The sensitivity of the search methods is inversely related to their computational speeds, which are primarily determined by the algorithm that is used for aligning sequences. Searches for identical sequence matches are useful for checking whether a newly isolated cDNA or protein is already known from other experimental approaches. For (nearly) identical sequences, very fast methods can be used to find database matches. Searches for more divergent sequence matches are undertaken in the hope of finding related genes or proteins that can shed light on the possible functions of the query sequence. The fast search programs of the BLAST (8, 21) and FASTA (22) series, which first find ungapped matches and then use more sensitive routines in matching regions, may be accessed via the web but are fast enough to be installed and run on workstations. More sensitive searches using single sequences or multiple alignments [as profiles or hidden Markov models (HMMs)] for the input query, as well as dynamic programming algorithms such as Smith–Waterman (23) for the search, are mostly used in central facilities because of their larger CPU requirements. Fortunately, the most sensitive alignment methods are increasingly being ported to fast dedicated machines that can be accessed by web servers.

1.2. Statistical Analysis of DB Matches

Many programs provide statistics for the significance of matches in the search output (24, 25). These can be helpful for assessing whether a match is true or false and are essential for automatic large-scale analyses, in order to be able to apply thresholds and cutoffs. Common indicators of statistical significance are *E* and *p* values (*E*, expected ratio of false positives; *p*, probability of a chance match; they can be converted into each other using $p = 1–e^{–E}$). While they are a useful indication for the significance of a hit (8, 21), it is important to be aware that they are based on assumptions that very often do not hold. For example, they are affected by choice of amino acid mutation matrix and assume an unbiased amino acid composition in the database and that both query and database proteins are devoid of low-complexity regions. Also, the values are dependent on the size of the database so that, as data accumulate, the increased noise level causes increased *p* and *E* values for a given hit over time. On the other hand, it should be noted that there is a compensatory effect filling the finite space of real sequences: For any given protein, the chance of a database containing a sufficiently close and detectable homologue steadily increases.

HMM-based searches are able to provide intrinsic probabilities that a given match is related to the query. This is expected to become very useful (26). Nevertheless, whether these values are more robust than the current *E* and *p* values will depend on the approximations in the HMM. For example, an HMM that does not have a good model for reduced sequence complexity will be just as error prone as any other statistic.

1.3. Retrieval of Information from Databases

Modern sequence analysis packages contain integrated retrieval systems that try to add biologically relevant information to the hit detected by database sequence similarity searches. Biological context often helps in the evaluation of weak similarities. Species information and functional information, including cellular localization and tissue expression patterns, are examples of the useful features that add value to the sequence data itself.

Molecular biological databases originated as stores for DNA and protein sequences and

macromolecular structures. However, increasingly diversified databases reflecting different functional criteria are appearing and will continue to proliferate. Databases for single organisms, for mutations causing human inherited diseases, for biochemical pathways, and for developmental pathways are obvious topics. The most practically useful databases must include extensive cross-indexing to other classes of databases. In this respect the Swiss–Prot protein sequence database, with links to many other databases, provides a pioneering example of the standards that need to be met (27).

Efficient retrieval of database entries requires fast text matching and keyword indexing strategies. These biological needs are providing a stimulus for computational methods development in database retrieval, as exemplified by the Sequence Retrieval System (SRS), which combines efficient indexing, a flexible parsing language, and extensive database cross-links, to provide a powerful general database query tool (28). SRS, installed at many web sites, and the ENTREZ and PubMed servers at the NCBI (29) together provide universal network access to many different biological databases.

1.4. World Wide Web

WWW servers have been set up for most forms of sequence analysis. They offer advantages to the biological community in that central sites can offer services to users everywhere. Web servers may be at places where analysis programs are being actively developed and thus offer the latest, most sensitive methodology and/or they may be sites that are well equipped with powerful computers, so that computationally demanding jobs can be offered. However, the WWW also has some disadvantages. There is an increase in system complexity: web interaction requires two computers, a network, and compatible web software all to be functioning. To run stably, web sites have a high maintenance load. They may disappear when the person responsible leaves an institute. Stable servers are most likely to be found at the larger bioinformatics institutes, such as the NCBI in the United States, the EBI and EXPASY in Europe, and the many sites providing facilities at the national level. Some tasks are poorly suited to web servers, which must turn around jobs rapidly to allow heavy access. For example, web servers offering multiple-sequence alignment tend to be highly restrictive, because the calculation time progresses arithmetically with respect to the number of sequences and, worse still, increases proportionately to the product of the sequence lengths. A web site cannot afford to be blocked by giant alignment tasks, so these have to be done on a local machine. Such disadvantages mean that it is likely that local computational resources will continue to play an important role in sequence analysis, and users will still need to install and run analysis programs directly.

Sequence Codes

Nucleotide sequences do not only encode the primary structures of proteins . Numerous sequence-directed processes and sequence-dependent structures and interactions also exist. The corresponding sequence instructions are “read” from the DNA or RNA molecule, each in its own way, via one or another specific molecular interaction or a whole network of such interactions. In the case of the triplet genetic code, the reading device is the ribosome, in a complex combination with transfer RNAs and various protein factors (see **Protein biosynthesis**). In the case of gene splicing, the sequence signals are recognized by the spliceosome, which, in addition to the nuclear RNA transcript, involves various small nuclear RNAs and proteins (see RNA Splicing). Numerous, relatively simple sequence-specific DNA-protein and RNA-protein interactions also exist, in which the respective sequences are read by a single protein (see DNA-Binding Proteins and RNA-Binding

Proteins).

The existence of codes other than the classic translation triplet code is already suggested by the degeneracy of the triplet code. Eight amino acids are actually encoded by doublets, with the third bases of the codons being arbitrary, ie, fully degenerate. Seven amino acids are encoded by triplets, with the third base being either C or U, and five amino acids have degenerate A or G in the third positions of their triplets. Three of the amino acids (Leu, Ser, and Arg) are encoded by two sets of triplets each, with two different doublets in the first and second positions. Only two residues, Met and Trp, are each encoded by a single, nondegenerate triplet. Such freedom in the choice of codons allows significant changes in the nucleotide sequence without changing the encoded protein sequence. This, in principle, makes it possible to utilize the interchangeable bases of the mRNA sequence for purposes, other than protein coding, eg, for some additional, different sequence codes (1).

Despite their traditional classification as noncoding, sequences other than those for protein coding carry some important information as well (2). Among numerous examples are cases of sequence conservation. Comparison of human and mouse T-cell receptor alpha locus sequences—about 80 kbp each, both largely noncoding—shows greater than 70% similarity (3). High conservation is also observed in the 5′ and 3′ untranslated regions, as well as in the **introns** (4). Such conservation of the noncoding sequences suggests that they actually do encode some message(s).

Each sequence-specific interaction, either complex or simple, is represented by a specific sequence pattern. Visual or computer recognition of a given pattern in the sequence allows location of corresponding functional sites (regions) in the long DNA or RNA molecules. The pattern therefore serves as a code for recognition of the sites in the sequences. The code can be defined as a sequence pattern that corresponds to one or another biological or biomolecular function. The code can be general, even universal, of broad use in various species, or specific, eg, species or gene specific. For example, the triplet code is general, but the sequence pattern responsible for recognition of *Escherichia coli* DNA by Lac repressor represents a specific code.

Among known general sequence codes other than the triplet code are transcription signals in **promoters**, such as TATAAA-box in eukaryotes and TATAAT- and TTGACA-boxes in bacteria (see TATA Box), coding for the initiation of transcription. Another widely known sequence code is the gene-splicing code, the GT-AG rule (see RNA Splicing) and some sequence preferences around the intron-exon junctions. Eukaryotic sequences around these junctions resemble to varying degrees the **consensus sequences** agGUaag and $y_{10–15}$ncAG, where the capitalized nucleotides are most conserved, n is any nucleotide, and y is a pyrimidine. The splicing code is likely to contain some other as-yet undetected sequence features, as the current computer recognition algorithms based on the above patterns are not as precise as the natural gene-splicing process.

A complex set of sequence rules describes details of the shape of DNA that are important for DNA-protein interactions and DNA folding in the cell. The DNA structure is not monotonously uniform. It is modulated by sequence-dependent local deviations from the standard geometry, which, for example, may accumulate to a net DNA curvature. The first manifestation of the intrinsic DNA curvature was observed in the predicted 10.5 base sequence periodicity. Local deflections of the DNA axis at certain dinucleotide steps, primarily at AA(TT) dinucleotides, repeated at the DNA helical pitch distance, result in an accumulating unidirectional deflection of the DNA axis, making it curved. The first experimental indication of the existence of DNA curvature was the anomalous **electrophoretic** mobilities of certain DNA fragments (5). More direct experimental evidence was provided by electron microscopy of the curved DNA (6) and by making small circles of DNA with designed periodic sequences (7). The sequence rules to describe the DNA curvature or the generally nonplanar sequence-dependent **writhe** of DNA are not yet fully developed. The simplest description is based on the original wedge model. The geometry of every base-pair step in this model is described by three angles: wedge roll, wedge tilt, and twist. The full set of these angles for all

dinucleotide steps has been estimated from the available experimental data. Following the sequence and deflecting the DNA axis at every step according to the wedge and twist angles from the table of the dinucleotide "codons," one can calculate the predicted path of the DNA axis for any given sequence.

The chromatin code is a set of rules directing sequence-specific positioning of the nucleosomes. Although nucleosome positioning may also involve several other factors (8), the sequence plays a substantial if not a major role. Sequence-dependent deformational anisotropy (bendability) of DNA appears to be an underlying principle of the nucleosome sequence specificity. The anisotropy can be ascribed to certain sequence elements periodically distributed along the nucleosome DNA, following the DNA helical repeat. In particular, these are dinucleotides AA and TT, as in the case of DNA curvature, however, with different phase relationships between the dinucleotides (9). Other dinucleotides, such as CC(GG) (10), TA, and perhaps some additional sequence elements (11), also contribute to the nucleosome sequence pattern. Further elucidation of the chromatin sequence code is important for understanding the role of the nucleosomes in gene expression (12).

A unique property of the nucleotide sequences is the superposition of the codes they carry—that is, a given base in a given position along the sequence may be involved simultaneously in several messages of the same or a different nature as was theoretically predicted in 1971 (1). For example, the coding sequences of the genome of hepatitis B virus massively overlap, so that the same regions of the sequence simultaneously code for two different proteins with different amino-acid sequences (13). The promoters of 5S **rRNA** genes are located within the genes themselves (14). The sequences at the ends of the exons are involved not only in the protein coding but also in the gene splicing sequence patterns (15). Many other cases of such overlapping are known; these are only immediate simple examples of a general phenomenon of superposition of many different sequence codes. Such overlapping is possible owing to degeneracy of the codes, well exemplified by the triplet code, so that alternative base combinations may be used simultaneously to satisfy several superimposed messages. Of course, an informational limit for such superposition, should exist, in which the degeneracy becomes insufficient to accommodate all messages without loss of quality. One current theory, by Zuckerkandl, on the nature of the intervening sequences is based on the notion of spatial separation of two otherwise conflicting sequence messages—protein-coding pattern and sequence determinants of the chromatin structure (2). The intervening sequences are proposed to have been introduced to take the load of the chromatin code, whereas the exons would remain primarily responsible for the protein-coding function.

Sequence Databases

A sequence database is a repository of all publicly available **nucleotide sequences** or amino acid sequences that are experimentally determined by DNA sequencing and protein sequencing methods. The primary nucleotide sequence databases, which comprise the International Nucleotide Data Banks, are GenBank by the U.S. National Center for Biotechnology Information, EMBL by the European Bioinformatics Institute, and DDBJ (DNA Data Bank of Japan) by the Japanese National Institute of Genetics. These three databases have virtually the same content, for they daily exchange data received from individual researchers and large sequencing centers. The primary protein sequence databases are SWISS-PROT by the University of Geneva and Protein Information Resource (PIR) by the National Biomedical Research Foundation in Georgetown University, and its collaborators in Germany and Japan. The contents of these two are not the same; SWISS-PROT is a well-curated database, whereas PIR contains a superfamily classification. Because the majority of protein sequences are now determined from DNA sequences, the protein databases also rely on direct submissions to the Nucleotide Data Banks. A third database Protein Research Foundation (PRF) in Japan also covers peptide and protein sequences reported in the literature. The sequence databases can be viewed as a collection of entries, each of which is uniquely identified by its entry name or accession number. The content of an entry generally consists of definition, source, references, and other text information, a table describing the biological features of the sequence data, and the information about the sequence itself. Because of the expansion of the sequencing of entire genomes and of complementary DNA (cDNA), most of the databases are updated daily and released over the Internet. The WWW address is shown in Table 1for each of the organizations that produce the primary sequence databases.

Table 1. WWW Addresses for the Sequence Databases

Database	Address
GenBank	www.ncbi.nlm.nih.gov
EMBL	www.ebi.ac.uk
DDBJ	www.ddbj.nig.ac.jp
SWISS-PROT	expasy.hcuge.ch
PIR	www-nbrf.georgetown.edu
PRF	www.prf.or.jp

Amino acid sequence determination became possible when Frederick Sanger sequenced insulin in 1953 (1). In the mid-1960s, Margaret O. Dayhoff initiated an effort to collect protein sequence data to study molecular evolution . Her collection was not fully computerized but was published in the series *Atlas of Protein Sequence and Structure* between 1968 and 1978 (2). The PIR database was established in 1984 as a descendant of her collection. In 1977, Sanger published the first complete genome sequence of a tiny virus, bacteriophage f**x174** (3). This was the beginning of the era of DNA sequencing. The sequence databases of GenBank at the Los Alamos National Laboratory and EMBL at the European Molecular Biology Laboratory were officially launched in 1982, and DDBJ joined in 1984. Over the years, these databases have undergone transitions to cope effectively with ever increasing amounts of sequence data. Originally, it was the databases' responsibility to find, enter, and annotate published sequences, but now it is the authors' responsibility to annotate and submit the data, and to obtain the accession number because many journals require data submission as a precondition of publication. The main use of the sequence databases is homology searches to retrieve related sequences (see Bioinformatics). Because there are multiple databases for the same type of data and because there are identical sequences in the same database, attempts are being made to derive computationally a nonredundant set of sequences from multiple sources. The sequence databases also form a backbone resource from which other value-added databases are developed.

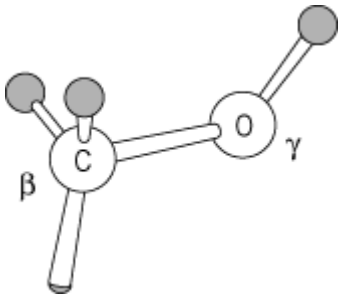
Serine (Ser, S)

The amino acid serine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to six **codons**—UCU, UCC, UCA, UCG, AGU, and AGC. This is unique, in that the first four codons are not interchangeable with the last two by single base substitution mutations, so there are two types of serine codons. Ser represents approximately 6.9% of the residues of the proteins that have been characterized. The seryl residue incorporated has a mass of 87.08 Da, a van **der Waals volume** of 73 $Å^3$, and an accessible surface area of 122 $Å^2$. Ser residues are changed frequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with alanine, threonine, glycine, and asparagine residues.

The side chain of Ser is dominated by its hydroxyl group:



This hydroxyl group is normally no more reactive chemically than is that of ethanol, so there are few chemical reactions that can modify Ser residues in a protein specifically and readily. The only useful general reaction is acetylation with acetyl chloride in aqueous trifluoroacetic acid. When in the appropriate environment, however, and with a potentially reactive group held in the correct position, the Ser hydroxyl group can function as a potent nucleophile, as occurs in the serine proteinases .

The hydroxyl group is very polar and hydrophilic and can function as either a donor or acceptor in hydrogen bonds. Consequently, Ser residues can be fully buried in protein structures, and about 22% are, especially if their hydroxyl group is paired in a hydrogen bond. The Ser hydroxyl group is situated sterically to interact with polar groups of the polypeptide backbone, which affects its conformation and reactivity. For example, peptide bonds adjacent to Ser residues are especially susceptible to acid hydrolysis. Ser residues also moderately favor the **alpha-helical** conformation in model peptides, and they are particularly adept in serving as the terminal "capping" residue at the end of the a-helix, when the hydroxyl group of the side chain participates in hydrogen bonding with the backbone. In folded protein structures, Ser residues occur most frequently at reverse turns, again because the hydroxyl group can hydrogen bond with the backbone.

In native proteins, Ser residues are frequently **post-translationally modified** by the addition of oligosaccharides (see O-Glycosylation) and phosphate groups.

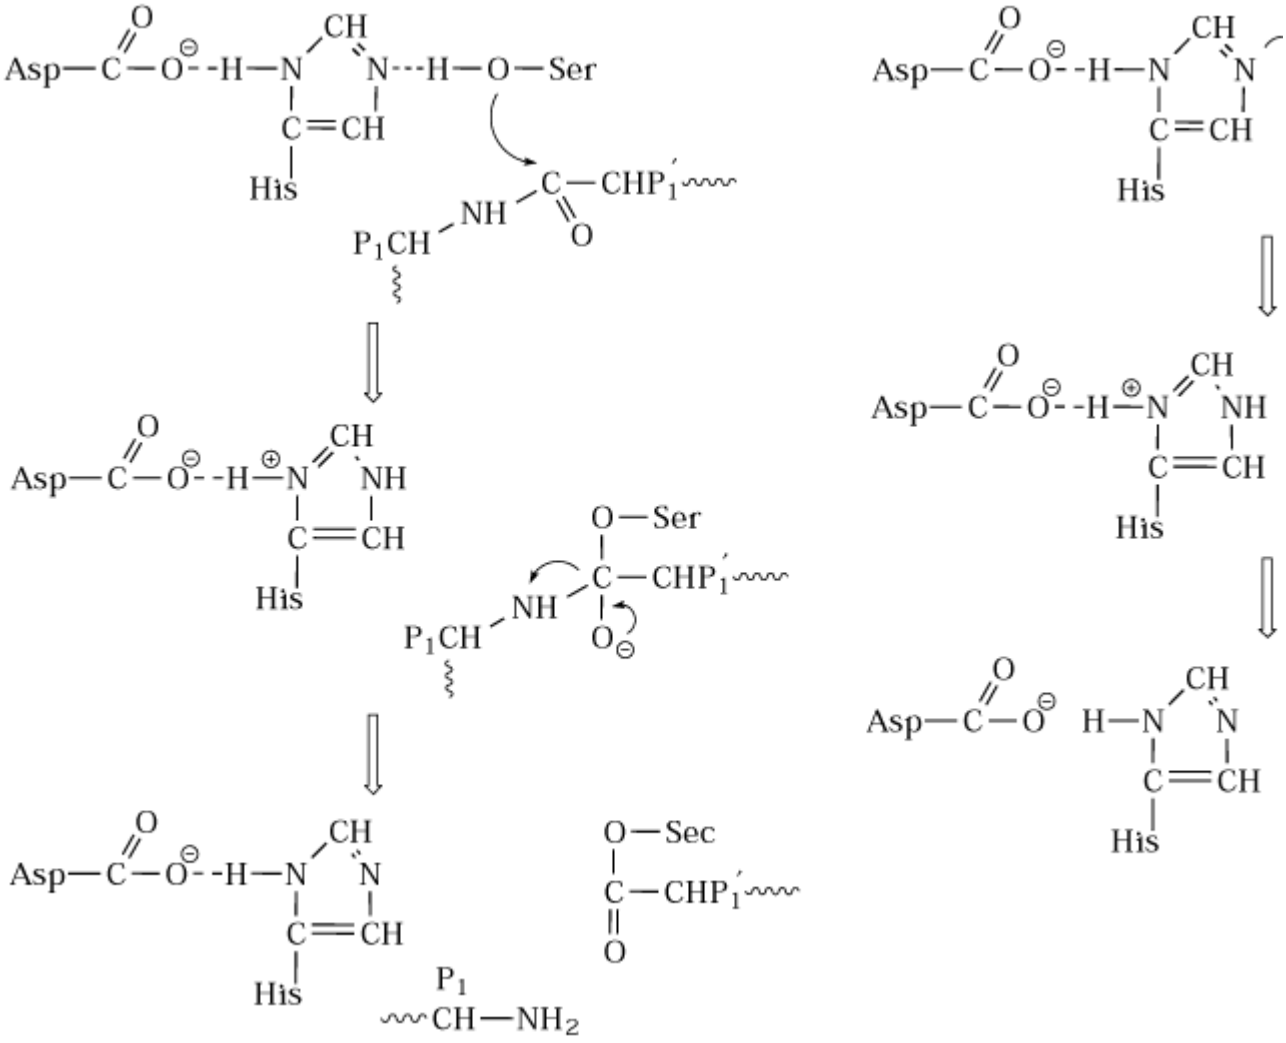
Serine Proteinase

The term *serine proteinase* defines a class of proteolytic enzyme (one that catalyzes the hydrolysis of peptide bonds in proteins) in which the hydroxyl group of a serine residue participates in the catalytic process (E.C. 3.4.21) (1). The three-dimensional structure of the serine proteinase (2) brings together what is called a "catalytic triad," wherein a carboxyl group of an aspartic acid residue is aligned with the imidazole side chain of a histidine residue, which in turn interacts with, and thereby activates, the serine hydroxyl group. When a substrate (protein or peptide) binds to the active site of the serine proteinase (the region of the enzyme where catalysis occurs), the serine hydroxyl group interacts with the carbonyl group of the peptide bond that is to be hydrolyzed and forms an acylenzyme (Fig. 1). Subsequent hydrolysis of this acylenzyme involves the imidazole side chain again and a water molecule, and this completes the proteolytic event. Members of this family are also referred to as *alkaline proteinases* because they tend to act optimally at a pH close to 8.

Figure 1. Schematic representation of the catalytic reaction of serine proteinases. On the left, the active-site serine residu and histidine components of the catalytic triad, attacks the carbonyl carbon in the peptide bond of the substrate. In a subs bond, the particular peptide attacked is determined by the ability of the enzyme to recognize P_1 and P_1', which are the pr amino acid side chains. The resulting tetrahedral intermediate is converted to an acyl-enzyme intermediate, with formatic the carbonyl carbon of the acyl intermediate is attacked by an activated water molecule to form another tetrahedral interr carboxyl product, with regeneration of the starting enzyme.



There are two evolutionary families of of serine proteinases. One includes the notable examples of **trypsin**, **chymotrypsin**, and elastase, digestive enzymes secreted by the pancreas. These three proteins have rather similar amino acid sequences, indicative of divergent evolution from a common ancestor, and almost identical three-dimensional structures. They act on a wide range of proteins, but each has a unique specificity: Trypsin cleaves bonds where a lysine or arginine residue contributes the scissile carbonyl group; chymotrypsin requires an aromatic or bulky **hydrophobic** side chain; and elastase acts only adjacent to small, uncharged side chains.

The second class of serine proteinases includes bacterial proteins related to subtilisin. They have completely different amino acid sequences from the trypsin family and are not **homologous** to them. Nevertheless, they have the exact same "catalytic triad" arrangement. This is a clear indication of what is known as **convergent** evolution.

Serine proteinases are involved in blood clotting, where activation and localization of function

require exquisitely fine tuning. Indeed, the presence in plasma of the serpin class of **serine proteinase inhibitors** (3) to prevent clotting throughout the vasculature is essential for hemodynamic homeostasis. On the other hand, another serine proteinase, tissue plasminogen activator, can be useful in treating heart attack and stroke victims because it catalyzes the formation of **plasmin**, yet another serine proteinase that dissolves unwanted blood clots.

In addition to protein inhibitors, serine proteinases are characteristically inhibited by a variety of reagents that chemically either block the reactive serine hydroxyl group or modify the histidine imidazole group. The classic serine reagent is diisopropylfluorophosphate (**DIPF**), an early nerve gas whose action originally defined serine proteinases. Phenylmethane sulfonylfluoride (see PMSF (Phenylmethylsulfonyl Fluoride)) is easier to work with and has become widely accepted as a serine proteinase inhibitor. Chloromethyl ketones (see TLCK (N-P-Tosyl-Lysine Chloromethyl Ketone) or TPCK (N-P-Tosyl-Phenylalanine Chloromethyl Ketone)) have been designed to be inhibitors of trypsin and trypsin-like serine proteinases or chymotrypsin and chymotrypsin-like serine proteinases, respectively. More recently, 3,4-dichloroisocoumarin has been proposed as a very potent catalytic mechanism-based inhibitor of all serine proteinases (4).

Serine Proteinase Inhibitors, Protein

Serine proteinase inhibitors, protein are arguably the most intensely studied of protein enzyme inhibitors. Serine proteinase inhibitors are proteins that inhibit only enzymes that are serine proteinases [see Proteinase Inhibitors, Protein]. There are a few exceptions. Inhibitors of this type are not all homologous. Indeed, a large number of families of protein inhibitors of serine proteinases were described (Table 1). It should be noted that the division into animal, plant, and microbial inhibitors is far from absolute. As an example, a leech protein [see Eglin C] is a member of the potato I family. Similarly, there are plant serpins. Nonetheless, the division seems convenient, indicating as it does the source of most known members of the family. Another caveat should be borne in mind. Families of proteins are structurally related groups. It does not follow that all the members of the family are proteinase inhibitors. For example, ovalbumin, while a serpin, is not a proteinase inhibitor. Neither are several other serpins. Some members of the bovine pancreatic trypsin inhibitor (Kunitz) family, such as dendrotoxins and bungarotoxins, act as K^+ and Ca^{2+} channel blockers. It seems unlikely that the dendrotoxins and the Ca^{++} blockers are efficient inhibitors of proteinases. It seems more likely that inhibitors were recruited to serve as toxins, although the opposite scenario can also be contemplated. Some authors discuss the possibility that in those families, such as the cereal family, where there are only a few inhibitors, the inhibitory properties may have arisen accidentally.

The mechanism of association of serine proteinases with their protein inhibitors has been a matter of great interest. This mechanism, which is well understood for a large subset of those inhibitors called standard-mechanism inhibitors and listed in Table 1 in bold, is given in equation (1).

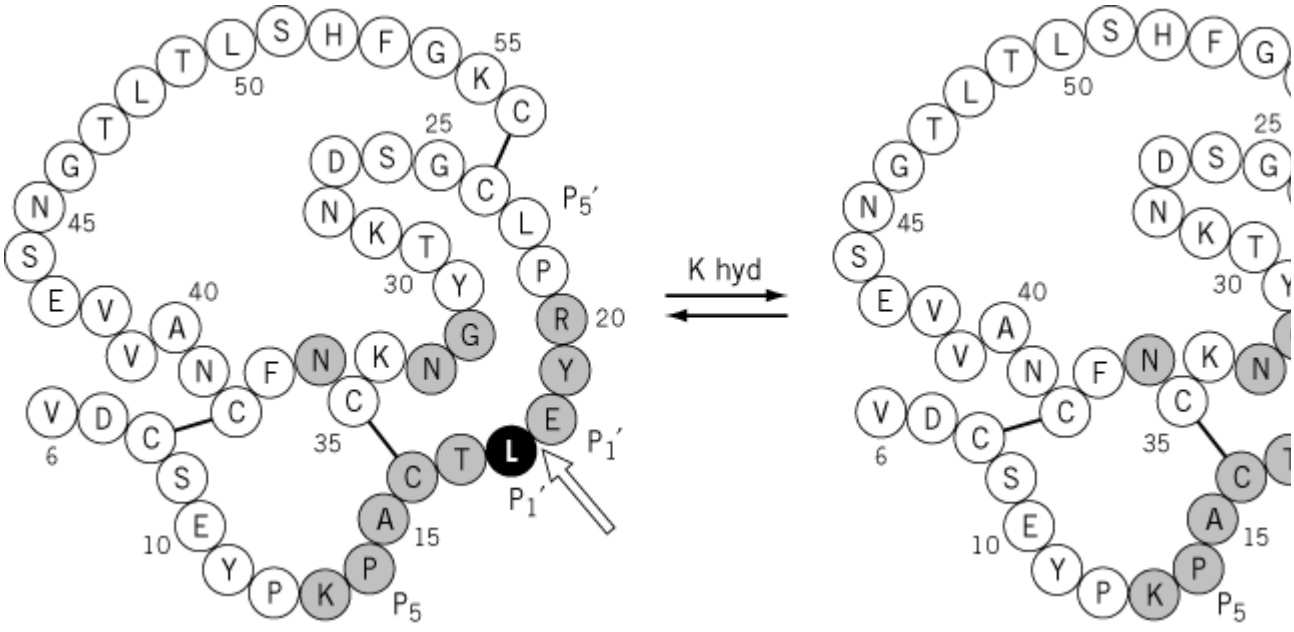
$$E + I \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} C \underset{k_{on^*}}{\overset{k_{off^*}}{\rightleftharpoons}} E + I^* \qquad (1)$$

where E is the enzyme (serine proteinase) and C the stable proteinase inhibitor complex. I, the virgin inhibitor, has all its peptide bonds intact, whereas I^*, the modified inhibitor, has one specific peptide bond hydrolyzed (Fig. 1). With less than a stoichiometric amount of enzyme added, I and I^* attain equilibrium, given by K_{hyd}.

$$K_{hyd} = \frac{(I^*)}{(I)} \qquad (2)$$

Equation (1) asserts that the complex C is the same substance whether made by mixing $E+I$ or $E+I^*$. In addition, it turns out that, for the great majority of standard-mechanism inhibitors, I and I^* are equally effective thermodynamically. This is because, for most inhibitors, the equilibrium constant for reactive site peptide bond hydrolysis [eq. (2)] is very close to unity at neutral pH.

Figure 1. The amino acid sequence of virgin (left) and of modified (right) turkey ovomucoid third domain, a standard-m canonical protein inhibitor of serine proteinases. In most such inhibitors, the equilibrium constant K_{hyd} is the near unity a The residues are numbered sequentially from Val [6] and also (Schecter and Berger notation) from the reactive site peptide by an arrow in the virgin inhibitor. Leu [18] (in black) is the P_1 residue and Glu[19] the P_1'. The shaded residues make conta enzyme in complexes. The bars between C residues indicate disulfide bridges. The sequence from Lys[14] (P_6) to Arg[21] (P contiguous contact loop; a portion of it from P_4 to P_3' is the canonical region.



The detailed nature of C was solved by many X-ray crystallographic structure determinations. In all these complexes, the reactive site peptide bond is intact. The oxygen atom OG1 of the catalytic serine of the enzyme makes a very close approach to the C atom of the P_1 residue of the inhibitor (for the Schecter and Berger notation, see Fig. 1). The distance is shorter than for van der Waals closest approach but longer than C—O covalent single bond. This close approach suggests a tetrahedral intermediate. The peptide bond remains planar, however, and the C atom is trigonal, not tetrahedral. The O atom of the P_1 residue inserts into the oxyanion hole (Fig. 2), and the N atom

donates a hydrogen bond to the enzyme. About a dozen residues of the inhibitor make close contacts with the enzyme. They consist of a (sequentially) contiguous set surrounding the reactive site and of a few discontiguous residues. The latter set seems very different in different families and occasionally even in subfamilies. A portion of the contiguous set comprising the P_4 to P_3' residues is called the canonical set. The canonical residues are said to have closely similar fy angles in free inhibitors and in complexes with all cognate enzymes but, most importantly, in all inhibitor families (see Table 2). It appears that all canonical inhibitors exhibit the standard mechanism and vice versa.

Figure 2. Diagrammatic representation of the interaction between the active sites of serine proteinases and standard-mechanism canonical protein inhibitors: (left) for the subtilisin class of enzymes and (right) for the chymotrypsin class o enzymes exemplified by *Streptomyces griseus proteinase B*, SGPB. In both cases, an imperfect, antiparallel beta structur is formed between enzyme and inhibitor. In the chymotrypsin group, one strand of the enzyme interacts with the combin loop of the inhibitor. In subtilisin, there are additional interactions at P_4 and P_2 with another strand of the enzyme. (Fror C. A. McPhalen and M. N. G. James (1988) *Biochemistry* **27**, 6582–6598.)

Serine proteinases exhibit many different specificities. Words such as *trypsinlike, chymotrypsinlike*, and *elastaselike* have become commonplace descriptors. The protein inhibitors combine with all these enzymes, but the strength of association differs greatly. In some cases, K_a is so small (K_I so great) that the inhibitor is said to be ineffective. In other cases, very strong inhibition is observed. Aside from discriminating between different substrate specificities of enzymes, inhibitors from some families, eg, BPTI (Kunitz), appear to inhibit enzymes only of the chymotrypsin group of serine proteinases. Others inhibit members of both the chymotrypsin group and the subtilisin group, eg, PSTI (Kazal), ovomucoids, and so forth. It is highly likely that the chymotrypsin/subtilisin discrimination is a consequence of the family's scaffolding. In contrast, the better-studied substrate specificity is caused by the nature of the inhibitor's residues that make contact with the enzyme (shaded in Fig. 1). The simplest of these is P_1, the primary specificity residue. This residue, on complex formation, becomes embedded in the primary specificity S_1 pocket of the enzyme. When P_1 is Lys and Arg, strong inhibition of trypsin is anticipated and frequently found. P_1 Tyr, Trp, Phe, Leu, and Met (in that order) are optimal for chymotrypsin. Ala and Leu for porcine pancreatic elastase and Cys, Leu, and Met for *Streptomyces griseus* proteinases A and B. Glutamic acid–specific proteinase from *Streptomyces griseus*, Glu SGP, is strongly inhibited by avian ovomucoid third domains with P_1 Glu and Asp. The strength of interaction and specificity of inhibitors does not depend solely on the nature of P_1. The other contact residues (Fig. 1), in aggregate, contribute much more to the strength and specificity of association than P_1 does. The effects of contact residue changes in various positions in the inhibitor on the free energy of association are nearly additive. The

conclusions about the effect of contact residues on inhibition emerged both from the study of natural inhibitors, where hypervariability of contact residues is observed, and from intentional changing of these residues by recombinant DNA technology or by chemical and enzymatic modification. In the recombinant approach, the design of protein inhibitors to become strong or specific inhibitors of a new target enzyme became a paradigm of protein engineering technology. Recently, phage display has often been employed to aid in rapid screening of the set of contact residues. Probably even more striking is the manipulation of the contact residues by nature in the process of evolution. In most proteins, both structurally and functionally important residues are conserved among closely related species. This is not the case for several families of prote in inhibitors of serine proteinases. Here, the structurally important residues are still conserved, but the functional enzyme-inhibitor residues are often the most variable in the inhibitor molecule. The term *hypervariability* of the reactive site region was adopted from the antibody literature, where hypervariability describes the variation between numerous antibodies in the same individual. Among the inhibitors, the term is used to describe the variation of one inhibitor among closely related species. Positive Darwinian selection was invoked as the driving force maintaining hypervariability among inhibitors from related species. The suggestion is controversial.

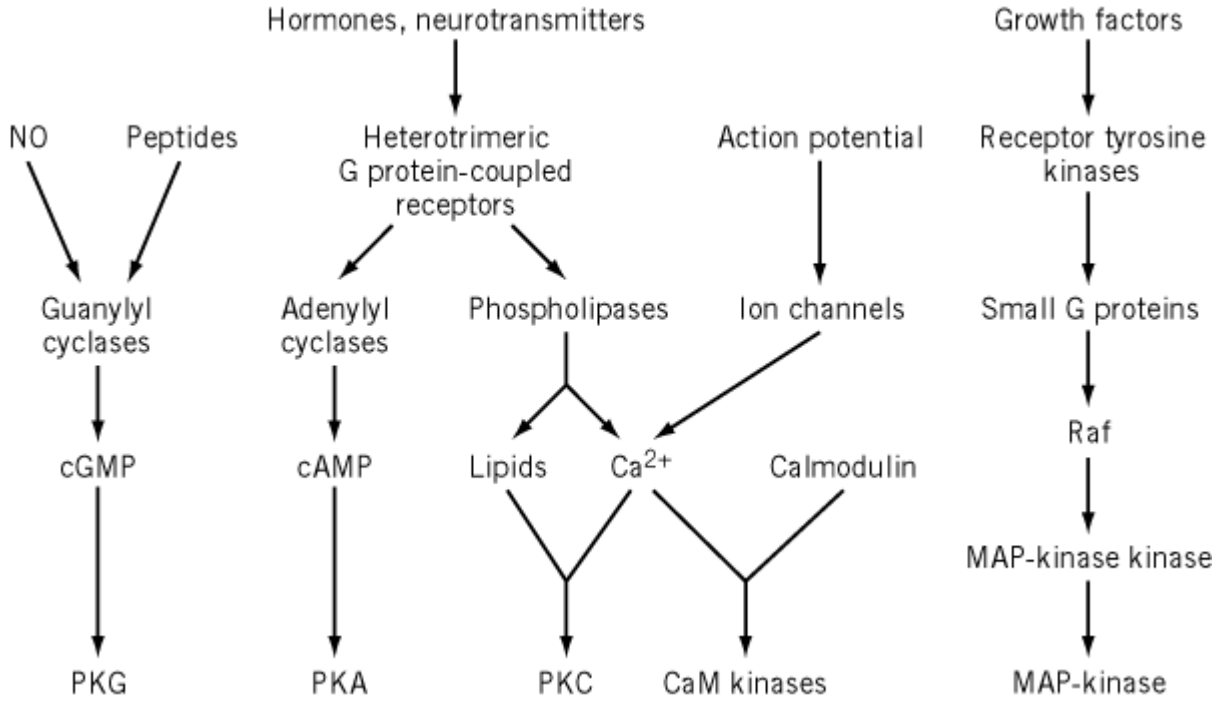
Serine/Threonine Kinases and Phosphatases

Serine and threonine are the amino acid residues in proteins that are most commonly phosphorylated. Their phosphorylation is used as a regulatory device in many signal transduction pathways of prokaryotic and eukaryotic cells. The presence of a phosphate group instead of an hydroxyl group on a serine or a threonine side chain modifies dramatically its size and charge. Phosphorylation can have important consequences on the properties of the protein in the vicinity of the phosphorylated residue or can lead to global rearrangements of the protein. Phosphorylation of proteins on serine or threonine residues is the result of a dynamic equilibrium between the activities of the kinases and **phosphatases** acting on these residues. Almost all serine/threonine protein kinases (Ser/Thr kinases) have a conserved catalytic **domain** that is a member of a very large gene family, which contains also tyrosine and dual-specificity protein kinases (1). Phosphoserine/phosphothreonine protein phosphatases (Ser/Thr phosphatases) are metal-requiring enzymes that belong to two highly conserved gene families (2-5). Both Ser/Thr kinases and phosphatases are tightly regulated within cells by intracellular and extracellular signals. Major pathways activating Ser/Thr kinases in response to extracellular stimuli are illustrated schematically in Fig. 1. In many instances, their precise localization is also tightly controlled by specific targeting sequences or by interaction with anchoring proteins or targeting subunits (6-8).

Figure 1. Examples of regulation of Ser/Thr kinases by extracellular signals in higher eukaryotes. Various signals such as hormones, neurotransmitters, nitrous oxide (NO), growth factors, or action potential can activate signal transduction pathways, leading to the stimulation of protein kinases, including cGMP-dependent protein kinase (PKG), cAMP-dependent protein kinase (PKA), protein kinase C (PKC), Ca^{2+}/calmodulin-dependent protein kinases (CaM kinases), and mitogen-activated protein kinases (MAP kinases). These kinases phosphorylate a number of protein substrates including enzymes, transcription factors, cytoskeletal proteins, receptors, and ion channels, the phosphorylation of which is responsible for the biological effects of the extracellular signals. The pathways are highly simplified, and the numerous cross-talks that take place between them are ignored.



1. Ser/Thr Kinases

1.1. Structure and Regulation

Most Ser/Thr kinases have in common a conserved catalytic domain, whose three-dimensional protein structure is well-characterized by X-ray crystallography (9, 10). Schematically, this catalytic domain comprises a small lobe, mostly of b-sheet, a large lobe mostly of a-helix, and a cleft between the two, in which catalysis takes place. The small lobe is involved in ATP binding, and the large lobe is involved in substrate binding. For the kinase to be active, a critical loop of the large lobe, termed the *activation loop* or *T loop*, must be positioned correctly. This requires in many cases the phosphorylation of the loop on one or several residues. In some cases (eg, cAMP-dependent protein kinases, or protein kinase A) this phosphorylation is constitutive. In others (eg, MAP kinases) phosphorylation is a major regulatory step carried out by an activating protein kinase. In addition to this conserved catalytic domain, Ser/Thr kinases comprise other domains that are highly variable from one kinase to the other. These domains play a role in targeting and in oligomerization, as well as in regulation. In several cases, the regulatory domain contains a substrate or a pseudosubstrate sequence that obstructs the catalytic site when the Ser/Thr kinase is in an inactive state. Activation, usually by binding of a regulatory molecule, removes this intramolecular inhibition, allowing access of substrates to the active site. Activation can also occur, usually under nonphysiological conditions, following limited **proteolysis**, which releases a free, constitutively active catalytic domain. There are a very large number of Ser/Thr kinases, which have been classified on the basis of the sequence of their catalytic domain (Table 1) (1). Usually, this classification is in good agreement with the mode

of regulation of the Ser/Thr kinases, and it will be used here for an overview of this family of enzymes.

---

[a] Classification based on Ref. 1.

1.2. The AGC Group

This group comprises cAMP-dependent protein kinases (PKA), cGMP-dependent protein kinases (protein kinase G, PKG), protein kinase C (PKC), and related enzymes. PKA was the first protein kinase identified to be regulated by a second messenger, cyclic AMP (cAMP). PKA is the main target for cAMP in eukaryotic cells and is probably the most extensively studied protein kinase. The catalytic (C) and regulatory (R) subunits are coded by separate **genes** and form a heterotetramer (R_2C_2) (11, 12). Upon binding of cAMP (two molecules of cAMP per catalytic subunit), the two catalytic subunits are released, and they phosphorylate neighboring proteins or diffuse to the nucleus, where they phosphorylate proteins involved in gene transcription. PKG is activated in a similar manner, but the catalytic and regulatory domains are located on the same polypeptide chain. PKCs form a subfamily of Ser/Thr kinases characterized by the optional presence of **zinc-finger motifs** (C1 domain) and a Ca^{2+}-phospholipid-binding domain (C2 domain) (13-15). The C1 domain provides a binding and activation site for diacylglycerol and for its nonmetabolizable structural analogues, the carcinogenic **phorbol esters** derived from croton oil. The C2 domain allows a Ca^{2+}-dependent interaction of the enzyme with membrane phospholipids. Whereas the subgroup of "classical" PKCs have both C1 and C2 domains, the "novel" PKCs lack the C2 domain, and the "atypical" PKCs lack the C2 domain and one of the two zinc fingers of the C1 domain. Other kinases in this group include PKB (also known as Akt), which is recruited to the membrane by interaction of its **pleckstrin homology** domain with phosphatidyl-inositol-2,3,4-P_3 (see Inositol Lipids and Phosphates) and is phosphorylated by an activating kinase (16, 17). As such, it mediates some of the actions of **phosphatidylinositol-3-kinase**. Another interesting group of enzymes are the G-protein-coupled receptor kinases (GRK), which phosphorylate rhodopsin or seven-transmembrane-domain receptors when they are in the ligand-bound form, controlling their desensitization (18, 19).

1.3. The CaMK Group

This group comprises Ca^{2+}/**calmodulin**-activated enzymes (or CaM kinases). Two types of CaM kinases have been characterized: those that have a narrow substrate specificity (eg, phosphorylase kinase, myosin light-chain kinase, eEF2 kinase) and those that have a broad substrate specificity (CaM kinases I, II, and IV) (20). In addition to activation by the binding of the Ca^{2+}/calmodulin complex, CaM kinases I and IV are activated by a different Ca^{2+}/calmodulin-dependent enzyme, constituting a Ca^{2+}/calmodulin-activated protein kinase cascade (21). CaM kinase II stands apart in this group, because of its oligomeric structure (8 to 12 subunits) and biochemical properties, which endow it with an interesting capability to integrate Ca^{2+} transients (22). The AMP-regulated protein kinase is structurally related to CaM kinases, but is CaM-independent. It plays an important role in metabolic controls (23).

1.4. The CMGC Group

The cyclin-dependent protein kinases (CDKs) are critical regulators of the cell cycle that are activated by a combination of factors, including phosphorylation of the activation loop,

dephosphorylation of amino-terminal residues, and interaction with proteins whose levels vary during the cell cycle, the cyclins (24-27). The MAP kinases (mitogen-activated protein kinases) form a group of protein kinases that contain essentially only the catalytic domain (28, 29). They are activated by phosphorylation of the activation loop on both a threonine and a tyrosine residue by a specific group of dual-specificity protein kinases, the MAP-kinase kinases. These MAP-kinase kinases are themselves activated by phosphorylation of their activation loop, by a third group of activating kinases, in a characteristic kinase cascade that has been highly conserved during evolution. Some MAP kinases (also called ERKs, extracellular signal-regulated kinases) are activated in response to growth factor stimulation. Others, such as Jun-N-terminal kinase (JNK), or p38, are implicated in cascades activated by cytolsines and cellular stress (eg, osmotic shock, tumor necrosis factor) and are sometimes known as SAP kinases (stress-activated protein kinases) (see Ref. 28 for a discussion of the nomenclature of MAP kinases). The same group also includes glycogen-synthase kinase-3 (GSK3), which is not only involved in the control of glycogen synthesis, as its name implies, but also in differentiation, cell survival, and other functions (30). Protein kinase CK2 is a ubiquitous and highly conserved enzyme, existing as a dimer of catalytic and noncatalytic subunits. Although it has numerous substrates, its regulation and function are still poorly understood.

1.5. Miscellaneous Ser/Thr Kinases and Dual-Specificity Protein Kinases

Several protein kinases (eg, Raf, p160-ROCK, PAK) interact with the GTP-bound form of small G proteins (such as Ras, Rho, or Rac, respectively). This interaction allows their translocation to the plasma membrane, which is often completed by phosphorylation by activating kinases. Raf activation triggers the ERK pathway by phosphorylating MEK, the dual specificity kinase that activates ERK (31). Related enzymes are involved in the activation of other dual-specificity MAP-kinase-kinases that phosphorylate and activate SAP-kinases JNK or p38. Protein kinases activated by heme or by double-stranded RNA play a role in the control of **protein biosynthesis** and antiviral defenses, respectively. Protein kinase CK1 is a highly conserved monomeric enzyme, whose regulation and function are poorly understood. Some Ser/Thr kinases have a **transmembrane** segment and are activated by binding of a polypeptide chain to their extracellular domain, in a manner similar to the activation of growth-factor tyrosine kinase receptors (32). These Ser/Thr kinases include receptors for transforming growth factor b, activin, and inhibin.

1.6. Ser/Thr Kinase Inhibitors

A number of Ser/Thr kinase inhibitors have been discovered and/or designed. Some are peptide pseudosubstrates, usually based on the sequence of the inhibitory domain of the kinase itself or of an associated protein. The best-known example is the PKA inhibitor (termed PKI or Walsh inhibitor) naturally expressed as a small regulatory protein that may be involved in the nucleocytoplasmic traffic of PKA (33). The other group of Ser/Thr kinase inhibitors is comprised of nonpeptide compounds that interact either with the protein kinase catalytic domain or with the regulatory domain, preventing its activation (eg, binding sites for cAMP in PKA or for diacylglycerol in PKC). Such inhibitors are powerful tools for studying phosphorylation pathways in intact cells and may provide interesting therapeutic leads (28, 34, 35).

2. Ser/Thr Phosphatases

On the basis of sequence analysis, Ser/Thr phosphatases belong to two gene families, but they are all metalloenzymes and have a similar structural organization (5, 36). In many cases, they are found as catalytic subunits that interact with other subunits responsible for their targeting and regulation (2, 3, 36, 37). Ser/Thr phosphatases are also classified according to their functional properties, which were determined before the cloning of their complementary DNAs (see Refs. 38 and 39 and Table 2).

Table 2. Protein Phospho-serine and Phospho-threonine Phosphatases

Classification Based on Sequence	Classification Based on Function
PPP gene family	**Protein phosphatases 1** *Inhibited by phospho-inhibitor 1 and inhibitor 2*
PPP1C	Protein phosphatases 1 (PP1)
	Protein phosphatases 2 *Resistant to phospho-inhibitor 1 and inhibitor 2*
PPP2C	Protein phosphatase 2A (PP2A) *Insensitive to divalent cations*
PPP3C	Protein phosphatase 2B (PP2B) = calcineurin *Activated by Ca^{2+}* and *Ca^{2+}/calmodulin*
PPM gene family	Protein phosphatase 2C (PP2C) *Activated by Mg^{2+}*
Other phosphatases from the PPP family Related to PP1: PPY, Ppz, Ppq Related to PP2A: PPX (PP4), PP6 (Sit4, Ppe) PP5 (contains a tetratricopeptide repeat)[a]	

[a] *Source*: References 39, 43, and 47.

2.1. PPP Group

This gene family includes several of the best-characterized Ser/Thr phosphatases. The PP1 subfamily is comprised of a catalytic subunit that interacts with a number of other proteins including targeting subunits (eg, for glycogen particles, myofibrils, and dendritic spines) and inhibitor proteins (2, 3, 40). The activity of some of the inhibitor proteins acting on these phosphatases can be regulated by phosphorylation. For example, inhibitor-1 and DARPP-32, two related proteins, are potent inhibitors of PP1 only when they are phosphorylated by PKA, providing a mechanism by which extracellular signals that increase cAMP levels can inhibit a protein phosphatase (41). Enzymes of the PP2A subfamily are heterotrimers comprised of a catalytic subunit and two regulatory subunits (42). Like PP1, PP2A is mostly regulated by interaction with other proteins. A number of naturally occurring toxins including okadaic acid, calyculin, microcystin LR, and tautomycin produced by various microorganisms (dinoflagellates, cyanobacteria, etc.) are potent inhibitors of PP1 and PP2A (34). These compounds, which are usually membrane permeant, can be environmental hazards, but they are also extremely useful tools to study the role of PP1 and PP2A in biological processes. The CDNAs for several novel Ser/Thr phosphatases related to PP1 or PP2A have been **cloned** recently (43) (Table 2). Although PP2B is structurally related to PP1 and PP2A, it is far less sensitive to the toxins listed above. PP2B is expressed ubiquitously in eukaryotic cells, but it is particularly abundant in brain; it was independently isolated as a major brain Ca^{2+}/calmodulin binding phosphatase and called *calcineurin* (44). PP2B/calcineurin is a heterodimer, comprised of a catalytic subunit (A) and a Ca^{2+}-binding subunit related to calmodulin (B). Calcineurin is activated by binding of Ca^{2+}/calmodulin to A and of Ca^{2+} to B; hence it is a phosphatase that responds directly to Ca^{2+} transients. Calcineurin is inhibited by the complex between the immunosuppressant drugs

cyclosporin A and FK506, in combination with their intracellular receptor proteins, the immunophilins (cyclophilin and FK-binding protein, respectively) (45). These drugs are used to prevent rejection following organ grafting and act by blocking the Ca^{2+}-dependent, calcineurin-mediated activation of **interleukin**-2 transcription in lymphocytes.

2.2. The PPM Gene Family

This group of phosphatases is less well-characterized than the PPPs. It corresponds to the PP2C enzymes, which are activated *in vitro* by high concentrations of Mg^{2+} (39). In cells, they appear to be monomeric and little is known about their regulation. PP2C has a very widespread expression among eukaryotes, and it may have relatives in prokaryotes (see Ref. 46). The lack of a specific inhibitor, however, has hindered study of the functional role of this enzyme.

Serotype

Microorganisms express at their surface a large array of molecules, including polysaccharides, that are frequently the target of **antibodies** produced by the host immune response. This is the case of extracellular pathogens, like staphylococci or streptococci, that may express one or the other of a large collection of polysaccharides, differing from each other by a limited number of monosaccharide units. These small differences are sufficient to be recognized by different antibodies. The individual antigenic specificities so defined are given the name of *serotypes*. Serology of bacteria has been extensively developed for many years, so that microbiologists have a long list of identified serotypes that are of importance for diagnosis, prognosis, and treatment of a number of infectious diseases. For example, one single bacterial species such as *Salmonella enteritidis* may have 2000 distinct serotypes; *Streptococcus peumoniae*, which causes bacterial pneumonia in humans, has nearly 100. Each strain, with its characteristic serotype, behaves as a discrete antigen, which provides a way for the bacteria to escape the immune system by antigenic variation. Whenever mutants occur in a pathogen, it may acquire an unexpected virulence and spread dangerously over very large populations of people or animals.

Serpins

Serpins is an acronymic name given to a family of **serine proteinase inhibitors** that share a complex, but well-conserved, tertiary structure (1-3). Members of the family are diversely present in eukaryotes, plants, and **viruses**, and are evident in everyday life, from the foam protein of beer—the barley Z proteinase inhibitor—to the white of the breakfast egg—the noninhibitory serpin ovalbumin. Most notably, though, the serpins are the principal proteinase inhibitors in human plasma; antithrombin controls the proteolytic blood clotting cascade; C $_1$-inhibitor controls **complement** activation; the plasminogen activator inhibitors, PAI-1 and PAI-2, control fibrinolysis; and a_1- **antitrypsin**, also known as a_1 proteinase inhibitor, modulates connective tissue restructuring. Altogether, the inhibitory serpins make up approximately 10% in molar terms, of the proteins in human plasma. Also present in plasma, although in smaller concentrations, are other serpins that have lost their inhibitory activity but have taken on other functions vital to life; examples are the vasopressor peptide source angiotensinogen, and the thyroxine- and **corticosteroid**-binding globulins. The reason for the evolutionary success of the serpins is their possession, uniquely among the many families of serine proteinase inhibitors, of a mobile reactive-site loop (Fig. 1). It is the ability of this loop to change its conformation profoundly (4) that enables the serpins to bind to their target proteinases as a virtually irreversible complex (5-7). The possession of alternative folding topologies also explains the variety of other functions that have evolved among members of the family (8). It provides the evolutionary advantage of the potential to modulate inhibitory activity, as occurs in the spontaneous refolding of the fibrinolysis inhibitor PAI-1 (9) or on the conformational activation of antithrombin by heparin (10). This flexibility of fold carries with it a price, as serpins, because of their complicated mechanism of action, are especially vulnerable to mutations affecting their conformational mobility (11). In humans, such mutations in serpins are a significant cause of disease, including familial emphysema, cirrhosis, thrombosis, and allergic hypersensitivity.

Figure 1. Mobility of the reactive loop of serpins (black) and its ability to refold as the central strand of the A b-sheet of the molecule (gray shaded bands). (**a**) The noninhibitory serpin ovalbumin has a relatively fixed helical loop; (**b**) a $_1$-antitrypsin has a loop in the optimal inhibitory—canonical—conformation; (**c**) in antithrombin the loop is partly inserted into the A-sheet, with the reactive center arginine in an inaccessible internal orientation; (**d**) the latent inactive conformation of antithrombin has a completely inserted intact loop; (**e**) cleavage of a_1-antitrypsin (shown in **b**) at its reactive center gives immediate insertion of the amino-terminal section of the loop; (**f**) peptides homologous to the reactive loop sequence can insert into the A-sheet displacing and disordering the reactive loop. (Crystallographic structures, with the F-helix removed for clarity, as detailed in Ref. 8.)

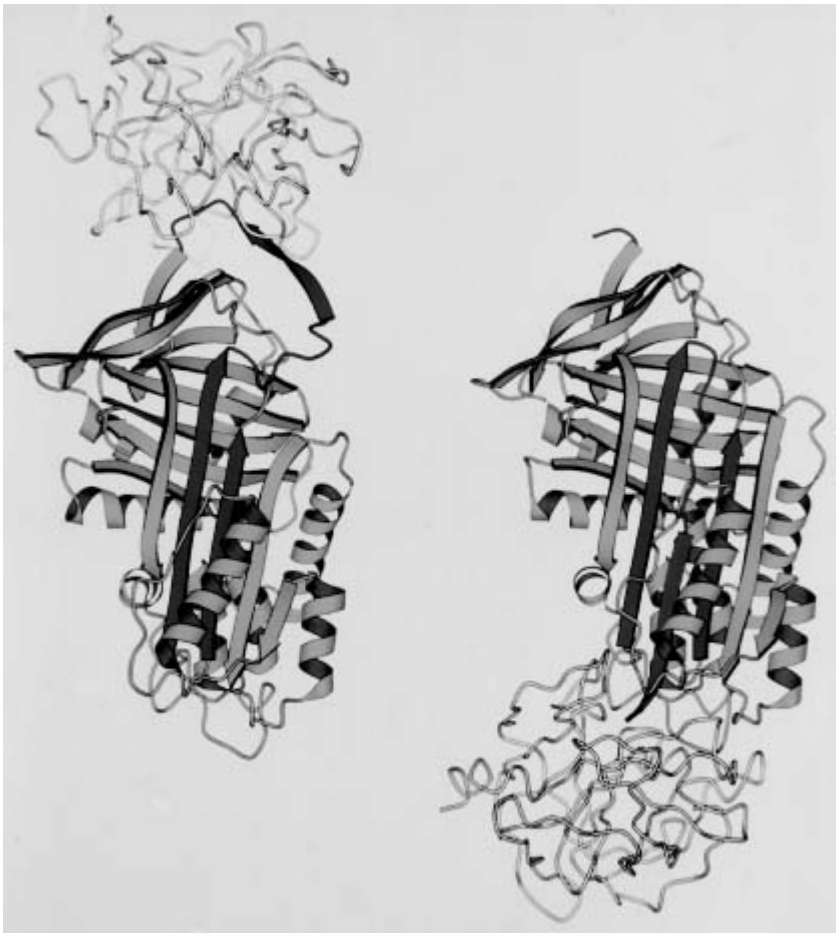
1. Structure and Function

There are now more than 300 known members of the serpin family, all of which share the same core protein structure of some 400 amino acid residues folded in nine alpha-helices and three beta-sheets. Considerable variations can occur at the *N*-terminus of the molecule, as with the glycosaminoglycan-binding extensions in antithrombin and another anticoagulant serpin, heparin cofactor II, and the long glycosylated extension in C_1-inhibitor. Similarly, functional **domains** have been added to the *C*-terminus, as in the plasma fibrinolysis inhibitor a_1-antiplasmin. The central core of the molecule, however, is remarkably conserved, with almost superimposable backbone outlines from one serpin to another (3). The dominant feature of the molecule is the A b-sheet, which changes from a five-stranded conformation in the active inhibitory state to a six-stranded sheet in the inactive, complexed form of the molecule. This remarkable change, illustrated in Figure 1, results from the movement of the reactive site loop of the molecule, hinged at the end of beta-strand 5, from an externally exposed position to insertion as the central, strand 4, of the sheet. This shift in conformation is accompanied by an equally remarkable increase in molecular stability, typically from a $\mathbf{T}_m$ **(melting temperature)** of 56°C in the inhibitory form to 100°C or more in the inserted, six-stranded, form. This stressed to relaxed, $S \rightarrow R$ change (12), was first shown to occur on **proteolytic** cleavage of the reactive-site loop, a process that is now realized to model the shift accompanying complex formation with the cognate proteinase. The $S \rightarrow R$ change in stability also occurs when the intact loop is incorporated into the A-sheet, as with the spontaneous transition of PAI-1 to the six-stranded latent conformation, or the inducible transition to the latent form in antithrombin, a_1-antitrypsin, and a_1-antichymotrypsin (13).

In the active inhibitory form of the serpins, the peptide loop containing the reactive center is exposed at the pole of the molecule. This peptide loop presents the reactive-center peptide bond—denoted the P_1–P'_1 bond—as an ideal substrate. The cognate proteinase cleaves this bond to form an acyl-enzyme linkage that is stabilized by the rapid insertion of the amino-terminal portion of the reactive loop P_1–P_{14} into the A-sheet (5). This movement of the loop takes with it the linked proteinase to the opposite pole of the molecule (Fig. 2) thereby distorting and rendering inaccessible the acyl–enzyme bond, hence giving a stable, virtually irreversible complex of the two. Although no X-ray crystallography structure of the complex has yet been identified, there is support for this mechanism from numerous observations with both natural and **site-directed mutations** (14). Mutations in the hinges of the reactive loop slow the rate of loop insertion, with a proportionate shift of the interaction of the serpin with the proteinase, changing from inhibitor to substrate.

Figure 2. Mechanism of inhibition. A model based on the structure of intact (15) and cleaved (4) a_1-antitrypsin, showing on the left how an outlined serine proteinase precisely docks with the canonically conformed reactive loop of a_1-antitrypsin. On the right, cleavage with formation of an acyl-enzyme linkage is believed to result in a 70-Å shift of the proteinase driven by the insertion of the cleaved loop as the fourth strand of the A-sheet. (Figure prepared by J. P. Abrahams.)



Although there is uncertainty as to the final locking conformation of the complex, there is now a firm structural basis for the initial docking of inhibitor and proteinase. This had been a puzzle as in comparison to other families of serine proteinase inhibitors, the conformation of the reactive-site loop of the serpins is mobile and variable, from the totally exposed and well-ordered a-helix of ovalbumin to the partly obscured and A-sheet-inserted loop of antithrombin (Fig. 1). The other nonserpin families of serine proteinase inhibitors are all much smaller molecules, which have diverse, but tightly fixed, conformations of their exposed reactive loops. The surprising finding is that, although these other families of serine proteinase inhibitors have evolved separate and unrelated structures, they all share the same canonical conformation that makes a complementary fit with the active-site cleft of the serine proteinases. The structure of wild-type a $_1$-antitrypsin (15) has confirmed that the reactive loop of the serpins can also adopt this same precise conformation, and in the case of a$_1$-antitrypsin, but not other serpins, the loop is held in this canonical loop conformation by side-chain hydrogen bonds to the body of the molecule. Thus the general mechanism of complex formation can be divided into two stages (Fig. 2). The first is docking, with the approach of the proteinase to the serpin inducing a shift in the inhibitory loop to the canonical conformation, followed by cleavage at the P_1–P'_1 peptide bond, to give an acyl–enzyme linkage. The second change, immediate to the first, is to the locking conformation, with complete insertion of the P_1–P_{14} loop into the A-sheet and transport of the proteinase some 60–70 Å to the distal pole of the molecule.

2. Modulation by Glycosaminoglycans (Heparin)

Antithrombin is the principal inhibitor of coagulation of human plasma, but its activity is relatively limited, until it binds to the heparan sidechains that line the microvasculature. Heparin, an animal

extract, is the therapeutic equivalent of the heparans; both are glycosaminoglycans containing a core pentasaccharide fragment that binds to the D and A helices of antithrombin. Crystallographic structures (10) of antithrombin and its complex with heparin reveal an elegant mechanism of activation and illustrate the way in which the mobile structure of the serpins has been adapted by evolution to modulate their function.

The reactive loop of antithrombin differs from that of other serpins in being partially inserted into the A-sheet, with an inward orientation of the reactive-center arginine residue, rendering it inaccessible to proteinases. The molecule as a whole is in a constrained conformation that is released on the binding of heparin, with a closure of the A-sheet, a shift of the D helix, and an elongation of both the D and A helices. This shift of the molecule from its constrained state results in the expulsion from the A-sheet of the reactive loop, which is then freed to take up the inhibitory conformation, with exposure of the reactive-center arginine. This conformational change fully activates antithrombin as an inhibitor of factor Xa, but in addition, the longer-chain heparins provide a bridging template for an even greater acceleration of the inhibition of thrombin.

A related but intriguingly different mechanism also takes place with the activation of heparin cofactor II. This binds another glycosaminoglycan, dermatan sulfate, to give a similar conformational activation, but with a supplementary contribution from the *N*-terminal extension of the inhibitor (16). The interaction of heparin with antithrombin also involves linkage and movement of the unstructured *N*-terminus, but this is more markedly so with heparin cofactor II. The much longer *N*-terminus of heparin cofactor II contains a sequence **homologous** to that of the thrombin inhibitor from leech, hirudin (17). Hirudin binds directly to an anion-binding site on thrombin, sterically blocking the active-site cleft of thrombin. There is good evidence (16) that, on activation with dermatan sulfate, the amino-terminus of heparin cofactor II moves to give a hirudin-like linkage and an analogous blockage of the active site of thrombin.

3. Molecular Pathology and Conformational Disease

More than 100 different mutations have now been identified in the plasma serpins as being responsible for associated diseases (11). In many cases, these affect specific functional domains, such as the heparin-binding site in antithrombin or the reactive site itself. By far the largest group of dysfunctional mutations, however, are those that affect the mobile mechanism of A-sheet opening and reactive-loop hinging and insertion. Such mutations can cause a spontaneous $S \rightarrow R$ transition to give the formation of the inactive latent form, or, if the change occurs at higher concentrations of the serpins, to allow the opening of the A-sheet with intermolecular linkage between the reactive loop of one molecule and the A-sheet of the next. These structurally well-defined mechanisms of monomeric transitions and of loop-sheet polymerization provide the best-defined examples of what is now being recognized as a new clinical entity—the conformational diseases (18).

The pathological transition of the active inhibitor to the latent form is most apparent with the mutants of antithrombin where the occurrence of the transition results in thrombosis. The most frequent example of such changes in the serpins, however, is observed with the common genetic variants of plasma a_1-antitrypsin (19); 1 in 10 people of northern European descent are carriers of either the severe Z-deficiency variant or the milder S variant. Homozygotes for the Z variant are likely to develop the degenerative lung disease emphysema in early adult life, and in childhood they are at risk of developing a fatal liver cirrhosis. Homozygotes for the Z mutation accumulate a_1-antitrypsin in the endoplasmic reticulum of their hepatocytes. The blockage of processing results in a plasma deficiency of a_1-antitrypsin and consequently a failure to protect the lung tissue against the elastase released by inflammatory white cells. The mutation in Z antitrypsin results in the replacement of conserved Glu342 (residue P17) by a lysine. This site is at the base of the hinge of the reactive-center loop, and the effect of the mutation is to destabilize the A-sheet and hence favor the insertion of the loop from another Z antitrypsin molecule, to give loop-to-sheet polymerization (20). This results in the accumulation of intracellular tangles of fibrils at the site of synthesis in the liver, with

consequent cell death and eventually the development of liver cirrhosis.

4. Cell Biology and the Serpins

There is now increasing interest in a large subclass of the serpins that have intracellular or pericellular functions (21). A consistent, though not invariable, finding in this subclass is the presence on the reactive loop of residues that readily oxidizes: cysteine or methionine residues. The likely reason is to confine the inhibitory activity of these serpins to the reducing environment of the cell and its immediate pericellular radius. The proximity to intracellular proteolytic processes makes these serpins candidate regulators of cell growth, differentiation, and death. The intra- and pericellular serpins can be divided into two main categories: those that resemble the chicken egg protein ovalbumin and those encoded by poxviruses (22).

In recent years an increasing number of ovalbumin-type serpins have been described that share the properties of lacking a conventional secretion signal peptide for protein secretion, having a truncated *C*-terminus and possessing a similar overall gene structure. Several of these proteins have been described in human tissues, and, although in most cases their intracellular function is uncertain, some important clues are beginning to emerge. A good example is PI9 (a granzyme B inhibitor) that is expressed in the cytosol of activated T cells and natural killer (NK) cells and is thought to protect these killer cells from their own pro- **apoptotic** proteinase, granzyme B (23, 24). Other intracellular serpins may protect cells from thiol proteinases of **lysosomes** (25).

The idea that intracellular serpins could regulate cell growth was strengthened by the identification of maspin, a serpin that is expressed in mammary epithelial cells and downregulated on malignant differentiation. When transformed cells are induced to express maspin, their migratory capacity is markedly reduced (26). The mechanism for this effect is unclear, as this serpin is found both intra- and extracellularly. Furthermore, it is uncertain whether maspin is capable of acting as a proteinase inhibitor. Other intracellular serpins include plasminogen activator inhibitor 2, squamous cell carcinoma antigens 1 and 2, monocyte–neutrophil elastase inhibitor, and bomapin (present in haemopoietic cells) (22).

The other group of intracellular serpins is expressed by poxviruses. Orthopoxviruses produce three serpins: SPI-1, SPI-2 (*crmA*), and SPI-3. Studies of viruses deficient in one or other serpins suggest that they have different activities. SPI-2 (*crmA*) inhibits the caspase interleukin 1-b–converting enzyme, thereby preventing production of mature interleukin 1 by the host cell and dampening the immune response to infection (27). When overexpressed in mammalian cells, SPI-2 (*crmA*) inhibits Fas- and tumor necrosis factor–mediated apoptosis, but it is uncertain whether this effect occurs physiologically (28). SPI-1 inhibits virus-induced apoptosis, and SPI-3 surprisingly seems to modulate cell–cell fusion during **virus infection** (29, 30).

Serum Albumin

Serum proteins are operationally classified into a, b, and g fractions, plus albumin, according to their relative mobilities upon electrophoresis at pH 8.6. With an isoelectric point of 4.9, serum albumin is the most acidic protein in serum, except for a small amount of pre-albumin, and the only albumin. Human serum albumin (HSA) and bovine serum albumin (BSA) are two of the most studied

proteins, because of their abundance, and the most popular standard proteins in many protein assay systems. Some of the important physical constants of bovine serum albumin are given in Table 1(1).

Table 1. Physical Parameters of Serum Albumin

Property	Bovine	Human	Rat
Molecular weight			
From composition	66,267	66,439	65,871
From physical data	66,700	69,000	64,300
Sedimentation coefficient (S)			
Monomer	4.5	4.6	4.2
Dimer	6.7	6.7	
Diffusion coefficient ($10^{-11}m^2s^1$)	5.9	6.1	
Partial specific volume (cm^3/g)	0.733	0.733	
Intrinsic viscosity (cm^3/g)	0.041	0.042	
Refractive index increment (578 nm, $\times 10^3$)	1.90	1.89	
Optical absorbance (279 nm, 1 mg/ml)	0.667	0.531	0.59

Reproduced from (1) with permission.

Albumin is the most abundant protein in the serum, occurring at a concentration of about 35 to 45 gL and comprising almost 50 to 60% of the total plasma proteins. Because of this and its relatively small molecular weight, it accounts for about 80% of the colloid osmosis of the blood. Albumin is produced in the liver as pro-albumin at the rate of approximately 120 to 200 mg/kg body weight daily for an adult male and 120 to 150 mg/kg for a female. In the first several years after birth, the production level is highest at 180 to 300 mg/kg weight. Albumin is one of the most soluble proteins and can be dissolved up to a concentration 30% (*w*/ *v*) in water. To prepare serum albumin, the globulins of serum are precipitated at 50% saturation of ammonium **sulfate**, the remaining solution is adjusted to pH 4.4, and the precipitate is collected and dialyzed against water. Most such preparations contain various degrees of micro-heterogeneity: (1) mercaptoalbumin with one thiol group and nonmercaptoalbumin, with the thiol group blocked covalently, (2) different combinations of disulfide bonds due to disulfide interchange reactions, (3) varying amounts of bound fatty acids and other ligands that are mostly insoluble in plasma in the absence of albumin.

Human serum albumin is made of 585 amino acid residues, and its three-dimensional protein structure is known (2, 4) (Fig. 1). It is usually a monomeric protein, with a molecular weight of 66,300, although some dimer is almost always present. It has 17 disulfide bonds and a single cysteine thiol group. The amino acid sequence shows the presence of three regions with high sequence similarities, residues 1 to 191, 192 to 384, 385 to 585, and these correspond to three **domains** in the native conformation (Fig. 2). The gross structure of albumin may be approximated by a prolate of revolution with the major and minor axes being 4.1 and 14.1 nm, respectively. About 50% of the amino acid residues are in the **alpha-helical** conformation.

Figure 1. The three-dimensional structure of human serum albumin. It is composed of three homologous regions.

Based on PDB data.

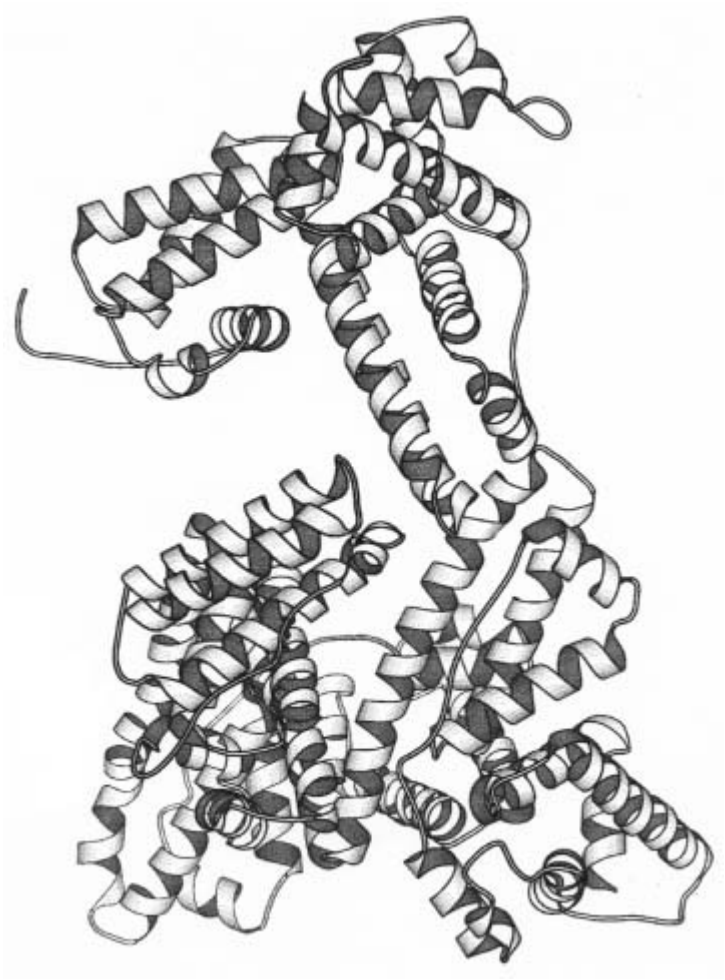

Figure 2. A model of serum albumin, emphasizing the tandem repeat of three semiglobular units that are related to each other in primary and tertiary structures and in function. Reproduced from (3) (Fig. 5, p. 179) with permission.

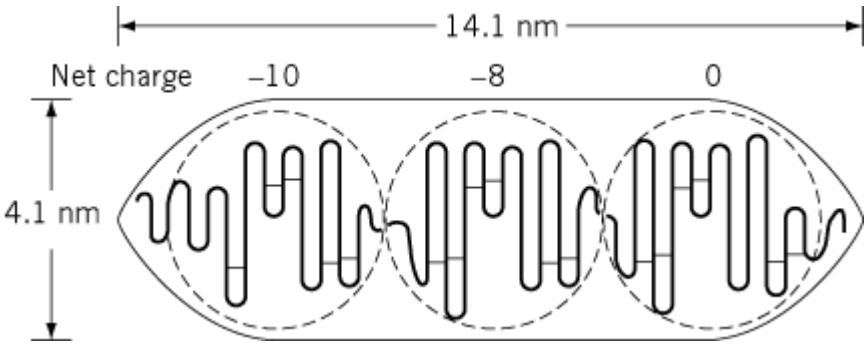


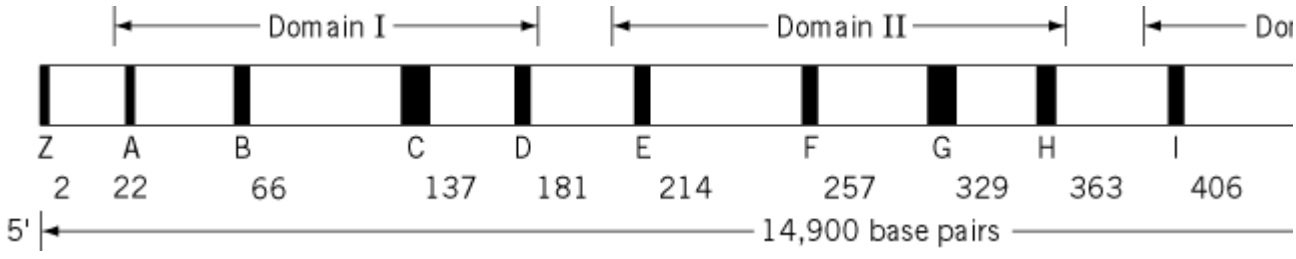
Serum albumin is relatively stable against **denaturants** such as urea or **guanidinium** chloride, but at pH 4 to 4.5 it changes from the native N state to a structurally loose and electrophoretically fast-moving species known as the F state. The transition from N to F accompanies an increase of about 40 titratable carboxyl groups that are apparently masked in the N state. The N state is stable in alkaline solution up to pH 10 to 11 (3).

Serum albumin functions as a carrier of insoluble long-chain fatty acids (mainly stearic, palmitic, and oleic acids) having two very strong and five strong binding sites, with association constants of 1.1×10^8 and $4.0 \times 10^6 M^{-1}$, respectively. Other ligands known to bind to albumin include bilirubin, chloride ion, testosterone, salicylic acid, phenoxymethyl- penicillin, and synthetic dyes. The function of albumin may be replaced by other blood proteins, mainly those in globulin fractions, since it has been shown that some patients of analubinaemia who completely lack serum albumin have led almost normal lives.

Only one copy of the albumin **gene** has been detected in the human and rat genomes. The gene for a-fetoprotein is in close proximity. The albumin gene consists of 15 exons separated by 14 **introns** and is 16,000 base pairs long, even though the total coding region for albumin requires only 1830 base pairs. The protein is initially produced as pro-albumin, which has an extra hexapeptide, Arg—Gly—Val—Phe—Arg—Arg, at its N-terminus. It is synthesized in the liver and secreted into the blood after cleavage of the hexapeptide. Substitution of the penultimate Arg residue prevents cleavage of the hexapeptide from pro-albumin, but its secretion into the blood is not hampered. The average half-life of albumin in blood is about 19 days.

The structure of the albumin **gene** is given in Fig. 3. In the case of humans, the gene is located at the proximal end of the long arm of chromosome 14, in bands q11-22 (5), where the genetically linked a-fetoprotein and vitamin D-binding protein genes are also located. In the case of mouse, the albumin and a-fetoprotein genes are in tandem on chromosome 5, and the gene for a-fetoprotein lies 13.5 kbp downstream of the albumin gene, showing a close genetic linkage. The albumin gene has 15 exons and 14 **introns**. Expression of the albumin gene is codominant, with both genes present in the diploid genome showing copenetrance. **Polymorphism** of human albumin is rare. Bisalbuminemia, where both the normal albumin A and a variant are present in the plasma, occurs with a frequency of 0.0003 to 0.001. In a variant called albumin B, Gly570 is substituted by Lys, and in albumin Mexico-2, Asp550 by Gly. Proalbumin with unexcised hexapeptide has also been found in the circulation, together with normal albumin. Variations in the amino acid sequence in the hexapeptide pro-region are also known. Familial dysalbuminemic hyperthyroninemia, in which there is an abnormally tight binding of thyroxin by albumin, is caused by a single amino acid replacement. In more severe cases, analbuminemia, patients show a complete lack of circulating albumin. By using a strain of rats that have a similar lack of albumin, it has been shown that the animals have an intact albumin gene, but the processing of the **transcriptional** products to messenger RNA (mRNA) is prevented (see RNA Splicing). Analbuminaemia humans and rats may seem healthy under normal conditions, but their health can be threatened under stress or disease conditions (3).

Figure 3. The gene structure of rat serum albumin. The solid bars labeled with capital letters are exons, and the 14 intror correspond to the terminal amino acid residue in each exon. Reproduced from (3) (Fig. 9, p. 209) with permission.



The counterpart of serum albumin in the fetal serum is a glycoprotein known as a-fetoprotein, which has limited sequence similarity with albumin. Phylogenetically, albumin is found in the serum of amphibians and higher vertebrates, and less frequently in bony fish (3).

Serum Dependence

A large number of serum-free media for tissue culture of cell lines have been developed (1, 2), and many of these are now commercially available, but the bulk of cell culture on the laboratory scale is still carried out in the presence of serum. Serum provides the cells with growth factors, attachment factors, hormones, nutrients, minerals, and trypsin inhibitor activity. It also buffers the medium against pH fluctuations and traces of toxins. On the other hand, it is a poorly defined natural product that carries the risk of contamination with **viruses** and mycoplasma, is variable in quality and constitution, is sometimes in limited supply, and adds complexity to the isolation of cell products from the medium. Over the past 20 years, several recipes have been generated for the replacement of serum, usually with defined supplements containing selenium, insulin, transferrin, steroids, and lipids, and often with additional minerals and intermediary metabolites. The main advantages of these serum-free recipes are definition, reproducibility, and selectivity for the cell type that may be propagated. Serum dependence is also a feature that is most strongly expressed in normal cells, as one of the recognized features of Neoplastic Transformation is a reduction in the requirement for serum, reflecting the increase in autonomous growth control typical of transformed cells.

1. Constitution of Serum

Data on serum analysis are traditionally derived from clinical laboratories and depend on conventional analyses and assays based on the major constituents, and those that show fluctuations that are of interest in diagnosis of disease or nutritional deficiency. It is now possible, however, to obtain data from serum suppliers, with greater emphasis on those constituents of greater significance to cell culture, and whose determination usually requires immunoassays or functional bioassays.

The major constituents of serum are listed in Table 1. There are undoubtedly other constituents that may be of importance, but these are the main ones that have been identified. Those that have been shown to be required in serum-free medium, in addition to the regular constituents found in serum-containing medium, are given in boldface type. The major roles of these constituents are listed in Table 2.

Table 1. Constituents[a] of Serum

	Concentration Range of Each [b]	
Albumin	20–50 mg/mL	
Amino acids	0.01–1.0 μ*M*	
Calcium	4–7 m*M*	
Chlorides	100 μM	
Cholesterol	10 μM	
Fatty acids	0.1–1.0 μ*M*	
Fetuin		In FB only
Fibronectin	1–10 μg/mL	
Globulins	1–15 mg/mL	
Glucose	0.6–1.2 mg/ml	
Growth Factors: EGF, PDGF, IGF,FGF, IL-1, IL-6, Insulin	1–100 ng/mL	
Hydrocortisone	10–200 n*M*	
Hexosamine	0.0–1.2 mg/mL	Highest in human
Iron	1–10 μ*M*	
Lactic acid	0.5–2.0 mg/mL	Highest in FB
Linoleic acid	0.01–0.1 μ*M*	
Phospholipids	0.7–3.0 mg/mL	
Polyamines putrescine,spermidine	0.1–1.0 μ*M*	
Potassium	5–15 m*M*	
Proteinase inhibitors:a_1-antitrypsin, a_2-macroglobulin	0.5–2.5 mg/mL	
Protein, total	40–80 mg/mL	
Pyruvic acid	2–10 μg/mL	
Selenium	0.01 μ*M*	
Sodium	135–155 m*M*	
Total lipids	2–10 mg/mL	
Transferrin	2–4 mg/mL	
Tri-iodotyrosine		
Urea	170–300 μg/mL	
Vitamins	10 ng–10 μg/mL	
Vitamin A	10–100 ng/mL	
Zinc	0.1–1.0 μ*M*	

[a] Constituents inbold type are those that have been used to supplement serum-freemedia.

[b] Concentrationrange is very approximate and only intended to convey the order ofmagnitude.

Table 2. Major Functions of Serum in Cell Culture

Function	Constituent
Mitogenic activity	Growth factors, platelet-derived growth factor(PDGF) and insulin-like growth factors (IGF-1,IGF-2)
Attachment factors	Fibronectin, fetuin
Antagonize trypsin used in subculture	a_1-Antitrypsin,a_2-macroglobulin
Bind toxins	Albumin
Detoxify free radicals	Selenium
Stimulate nutrient uptake, eg, glucose and amino acids	Insulin
Bind and transport iron	Transferrin
Provide intermediary metabolites	Pyruvate, a-ketoglutarate, adenosine, etc
Viscosity to buffer cells against mechanical damageduring manipulation	Albumin

Many of the growth factors in serum are derived from platelets; hence serum from naturally clotted blood is usually superior to serum separated from the cellular constituents by centrifugation. The growth factors released by platelets include platelet-derived growth factor (PDGF) and transforming growth factor b (TGFb), which have effects that are cell-type-specific. PDGF is a mitogen for mesodermally derived cells, such as fibroblasts, and glial cells, such as astrocytes; TGFb is cytostatic for many epithelial cells. Hence, the presence of serum is likely to favor fibroblastic cells, rather than epithelium, in cultures from normal tissues, and this has added weight to the argument in favor of using serum-free selective media to grow normal epithelial cells. Transformed cells may be exceptional, as they often produce a spectrum of autocrine growth factors, giving them a degree of autonomous control over mitogenesis. In addition, they may also produce TGFa, which reverses the cytostatic effect of TGFb and gives it a mitogenic and transformation-like effect. The inhibitory effect of TGFb can also be reduced by the presence of a feeder layer of 3T3 primitive embryonic mouse mesodermal cells, which appears to degrade or block activation of TGFb in cocultures with epithelium. Such feeder layers are frequently used to generate cultures of epithelial cells, such as epidermal keratinocytes (3), in serum-containing medium.

Growth of cells in the absence of serum frequently requires modification of the substrate to enable cell attachment and, for normal cells at least, the cell spreading that is necessary for cell proliferation. This modification can be a simple chemical treatment with, for example, poly-D-lysine, which neutralizes the negatively charged plastic and produces a slight positive charge. The incorporation of **spermidine** or putrescine into the medium (4) may play a similar role. Other protocols require extracellular matrix constituents, such as collagen, fibronectin, or laminin (5), which will interact with specific integrin receptors on the cell surface and promote adhesion to the substrate. In many cases, the cells may be capable of generating these matrix constituents themselves, as is suggested by the improved survival of cells reseeded into the flask from which they were released by **trypsin** treatment, or on to a substrate conditioned by other cells, such as vascular endothelium (6). It has been suggested that serum contains many such attachment factors that condition the substrate, modify its charge, and allow attachment of extracellular matrix molecules important in cell adhesion. Fibronectin is known to be present in serum, although in a modified form, and may participate in this.

2. Effect of Transformation

Reduced serum dependence is frequently used as a criterion for the identification of transformed cells. While normal cells will block at a restriction point in the G_1 phase of the cell cycle in the absence of serum and will re-enter cycle when serum is restored (7, 8), transformed cells will tend to progress into S phase regardless of the serum concentration, although they may arrest at later points in the cycle because of nutritional deficiencies. This distinction is created by the reduced dependence of transformed cells on exogenous growth factors (see Neoplastic Transformation) as a result of the expression of autonomous control mechanisms, such as autocrine growth factor production, for example, PDGF b-subunit in gliomas (9), or modifications in signal transduction leading to unregulated, permanently active induction of mitogenesis, such as *ras* mutations in colon carcinoma (10) (see Oncogenes, Oncoproteins).

Transformed cells are also able to proliferate without the degree of cell spreading required with normal cells, even to the extent of proliferating in suspension. Hence, there is reduced dependence on attachment factors present in serum for cells to initiate proliferation. Transformed cells are not devoid of cell adhesion molecules (CAMs), but they frequently have modifications affecting the selectivity of attachment and, possibly more important, alterations to the extracellular domain, which modify the interactions with the actin cytoskeleton, which, in turn, may make redundant cell spreading and the formation of adhesion plaques.

3. Serum-Free Media

Although serum supplementation is still widely used, there are several problems associated with the use of serum, most of which derive from its variability and undefined nature. Although a fairly precise analysis can be performed of the major constituents of serum, it is the minor constituents, those present in small amounts, but with high specific activity, that are difficult to detect and most likely to be variable. Some of these are listed in Table 1 and include hormones and growth factors. Although batch testing minimizes this problem, each batch has a limited shelf life, and it is unlikely that the next batch will be identical. Hence, although the nutritional content and physical properties of serum can be reproduced fairly accurately, the signaling content cannot, giving rise to considerable physiological variation from batch to batch. With the dramatic increase in the use of cell culture by the pharmaceutical industry, acute worldwide shortages have been avoided only by the development of low serum or serum-free formulations by drug companies, many of which, unfortunately, are not available in the public domain. In order to meet the requirements of Good Laboratory Practice (The United Kingdom Compliance Programme: Department of Health, London, 1989) and Good Manufacturing Practice (Medicines Control Agency, “Rules and Guidance for Pharmaceutical Manufacturers and Distributors 1997,” The Stationery Office Ltd., London, 1977), pharmaceutical companies have also been obliged to address the problems of viral contamination, which most research laboratories still choose to ignore. As the elimination of viruses from serum has proved to be extremely difficult, the obvious alternative is serum-free media, which have the additional advantages of minimizing the risk of mycoplasma infections and reducing the contamination of cell products with serum proteins, thereby facilitating downstream processing.

One of the major advantages of serum-free media has been the development of media that are selective for individual cell types. The range is now quite extensive, and many are available commercially from companies such as Bio Whittaker, Sigma, Invitrogen (Gibco), and ICN. Some examples are given in Table 3; for a more extensive list see Barnes et al. (11), Freshney, (12), Davis, (13) and Jayme and Gruber (2).

Unfortunately, a move to serum-free medium is not without its difficulties. Individual recipes may be required for each cell type maintained, and the time required to develop media for specific cell types is quite significant, possibly several years. The problem is diminishing with an increase in the supply of serum-free media from commercial sources, but it is still substantially more expensive than serum-containing media and may be beyond the reach of laboratories on modest budgets. There are also problems with subculture, as serum is normally responsible for the inhibition of trypsin that is used to liberate cells when they are reseeded. Trypsin damage can be reduced by using purified trypsin at a reduced temperature (14) and/or by incorporating a trypsin inhibitor in the medium at reseeding.

The major additions to medium to replace serum are insulin, selenium, and iron-saturated transferrin, and these are to be found in most serum-free formulations. In addition, hydrocortisone, **cholera toxin**, or isoprenaline are often added to increase proliferation of epithelial cells. Hydrocortisone probably acts by increasing attachment via the induction of proteoglycans, which may also activate **cytokines** and growth factors (15, 16), cholera toxin and isoprenaline increase the intracellular concentration of cyclic AMP, which is mitogenic in some epithelial cells. Lipid precursors, such as cholesterol and linoleic acid, ethanolamine, and phosphoethanolamine, high density **lipoproteins** (HDL), and crude lipid preparations, such as soya bean lipid, are often included and may contribute to the biosynthesis of membranes or second messengers. Thiol compounds such as b-mercaptoethanol are often used to inhibit oxidative stress induction from free radicals. In addition to

insulin and hydrocortisone, other growth factors and hormones include epidermal growth factor (EGF), fibroblast growth factor (FGF), **insulin-like growth factor**-1 (IGF-1, somatomedin C) and -2 (IGF-2, multiplication stimulating activity (MSA)) (17), PDGF, follicle-stimulating hormone (FSH), prolactin, tri-iodotyrosine, estradiol, and prostaglandins such as PGF_{2a};. In addition to selenium and iron, other trace elements include copper, zinc, manganese, molybdenum, tin, nickel, vanadium, and silicon. Finally, in the absence of the detoxifying effect of serum proteins, there is a requirement for highly purified reagents and water.

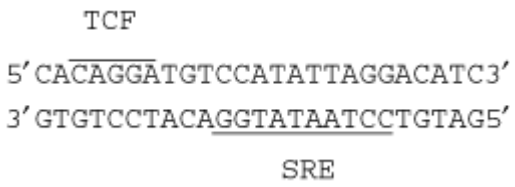
Serum Response Element

The serum response element (SRE) was originally identified within the **promoter** of the c-fos **proto-oncogene** and is responsible for the activation of this **gene** following addition of serum to cultured cells (1). Subsequently an SRE was also identified in a number of other genes whose transcription is enhanced by treatment of cells with serum or growth factors (2, 3). The SRE has a **consensus sequence** of the form CC A/T_6 GG, in which two C residues are followed by a run of six residues

that can be either A or T and then followed by a further two G residues. The sequence of the SRE within the c-Fos promoter is illustrated in Figure 1.

Figure 1. Structure of the c-Fos SRE and the adjacent binding site for TCF. The SRE is underlined and the TCF site is overlined.



Subsequent studies demonstrated that the SRE acts by binding a ubiquitous 67-kDa protein known as the serum response factor (SRF). Although the binding of SRF to the SRE is essential for the response to growth factors in serum, it is not sufficient for this to occur. Thus, further studies identified a 62-kDa protein known as ternary complex factor (TCF), which could only bind to the SRE in partnership with SRF and was required for SRE function (4). Subsequent studies identified TCF as a member of the *ets* family of DNA-binding proteins (5). Although a binding site for this factor is located adjacent to the SRE in the c-Fos promoter (Fig. 1), TCF cannot bind to this site unless it has also formed a protein-protein interaction with SRF bound at the SRE. Hence binding of TCF to its binding site is dependent on the prior association of SRF with the SRE.

Interestingly, TCF is a substrate for **phosphorylation** by a number of different kinases that are activated following addition of serum or growth factors to cultured cells. Such phosphorylation enhances both the ability of TCF to associate with SRF and its ability to activate transcription (6). Hence the addition of serum or growth factors to cells results in kinase activation, which in turn stimulates the activity of TCF and hence causes gene activation by the SRF/TCF complex bound to the SRE and its adjacent sequences.

Sex

Biological evolution is driven by the natural selection of the fittest individuals that pass their own **genes** on to the next generation. At the very early stages of the biological evolution, **reproductive** success was enhanced by the invention of a polarity within a species. In higher **eukaryotes**, this has led to the two forms of beings within one species, the male and female sexes. The evolutionary advantage of sexual reproduction is not obvious at first sight because the investment is twice as high as with asexual reproduction (1). However, the reproductive success of this strategy in most eutherians is superior to asexual reproduction. The most important advantage of sexual reproduction is the enlarged basis for natural selection. In systems without sexual reproduction and recombination, as in **prokaryotes**, genetic adaptation to a changing environment is achieved by a high **mutation** rate and a short generation interval. The phenomenon of genetic recombination during gametogenesis and fertilization, however, introduces a variability that would otherwise necessarily depend solely on the mutation rate of the genome (2). Even more important in asexual reproduction, the risk of losing beneficial mutations from the population is enhanced by deleterious mutations (1, 3). Therefore, the invention of genetic recombination and sex seems to be one of the basic requirements for the evolution of individuals with longer generation times; consequently, it is responsible for the diversity of higher species.

Sexual reproduction enables a selection that occurs not only on a single path but independently in the two sexes. Further, selection may be different in the two sexes. This has led to distinctly different sex-specific strategies between males and females (see Male; Female). Regarding a common male behavior, it is a prevalent strategy of males to attempt to spread their genetic information widely in the population. Because all males do so, they suffer from severe competition for females. Especially in higher mammals, this has led to population structures in which some males are dominant enough to transfer their genes on a big scale while the other males remain inferior with no reproductive success at all. This competition has influenced the male **phenotype**. This becomes apparent in the development of male germ cells that are specialized to spread genetic information.

In females, the sex selection is different. The chance to reproduce is limited by the number of **oocytes** that reach the stage of ovulation. The reproductive success in females does not depend so much on competition within females, and so the risk of achieving no reproductive success is considerably lower than in males. On the other hand, the total reproductive success of females in a life span cannot be as high as reproductively successful males because the female's investment in its offspring is generally greater and resources are limited. In many species, females therefore exhibit a phenotype that is adapted not for producing high numbers of gametes but more so to the preservation and the successful raising of the offspring. Even in animals with extracorporal fertilization, the investment of the female is still greater than in the male. This is because the female produces the egg and gene products necessary for the initial growth and differentiation of the new individual. In mammals, the high investment of the female becomes apparent in the long period of maternal care during pregnancy.

1. Sex Determination

Sex can be determined on a **chromosomal** level using cytogenetic techniques. During the **meiosis** of spermatogenesis, when the reduction of the **diploid** to the haploid genome occurs, sex chromosomes are divided; as a consequence, haploid spermatozoa carry either an **X-** or a Y-Chromosome. After fertilization, when the two haploid genomes join, either two X-chromosomes or one X- and one Y-chromosome come together to form either a female or a male, respectively. It is hitherto still usual to attribute the heterogametic sex to the male. **Crossing-over** between the X- and Y-chromosomes is very rare, and the sex-determining factor is almost always located on the Y-chromosome in mammals. In birds, on the other hand, the heterogametic sex is the female. An arrangement of ZW

chromosomal constitution determines female, while ZZ determines male.

At the molecular level, the sex determining factor is a major gene (SRY) that acts as a transcription factor. The SRY gene belongs to a conserved gene family (4). This gene is necessary in mammals for the formation of a male **phenotype**. The conservation among species appears to be greatest in the **HMG** box (high mobility group domain), which encodes a DNA-binding domain and is closely related to the SOX gene family (5). Mutations within this domain go together with sex reversal in XY females (6). Interestingly, almost no sequence similarity is observed in the other regions of the gene or protein, indicating either that these sequences have evolved in species differently or that they are not involved in sex determination (7).

The sex is not determined in all species by the presence of a Y-chromosome carrying the SRY gene. Sex determination can depend on the presence or absence of genes or on their heterozygous or homozygous state. In a number of insects, sex determination is based on the number and the homozygous or heterozygous status of **alleles**. In honeybees, homozygosity of certain alleles leads to male individuals (the drones), which are produced **parthenogenetically**. In most animals, the genetic sex is the basis for the physiological development of the two sexes, as it induces the hormonal and, subsequently, the gonadal sex, as well as the behavioral sex.

Hormonal sex can be determined by measuring the levels of the sex-specific hormones, eg, the amount of testosterone. The levels of hormones have a considerable effect on the phenotypic appearance. During embryogenesis, a cascade of gene products, especially testosterone and MIS (Mullerian-inhibiting hormone), which are expressed by the embryonic testis, influence the undifferentiated sex glands in such a way that they develop a functionally active testis (8). The seminiferous tubules of the developing testis are responsible for the expression of a hormone that subsequently affects the development of the final reproductive tract. Mullerian ducts undergo a regression on MIS expression and form Wolfian ducts. In mammals without the testis-determining factor, the primordial urogenital tract develops to Mullerian ducts to give a female phenotype.

Hormones influence not only the gonadal sex during embryogenesis but also the behavioral sex of adults. High levels of testosterone increase aggression; also, behavioral changes dependent on the function of the estrogen receptor have been reported (9). In most cases, genetic, chromosomal, gonadal, and behavioral sex go together, although aberrations, such as the hermaphrodite, are also reported.

SH2, SH3 Domains

Src homology (SH) domains 2 and 3, SH2 and SH3, are protein **domains** that bind to phosphotyrosine-containing sequence motifs and proline-rich motifs, respectively. The SH2 domain was originally identified as a conserved amino acid sequence in the noncatalytic region of **tyrosine kinases** encoded by viral **oncogenes** such as v-*src*, v-*yes*, and v-*fps* (1) (see SRC Genes). The most conserved sequence, however, was that of the catalytic region of these kinases, which was referred to as the Src homology 1 (SH1) domain. The SH3 domain is also present in the noncatalytic region of many tyrosine kinases, but it was originally found as a sequence similarity between phosphatidylinositol-specific phospholipase C and a novel viral oncogene product, Crk (2). Both SH2 and SH3 domains are now known to be present in a wide variety of signal transduction molecules and have been shown to mediate protein–protein interactions (3).

Three-dimensional structures of several SH2 and SH3 domains have been elucidated. The SH2 domains consist of two a-helices, with a core of antiparallel b-sheet in between. The binding of phosphotyrosine-containing peptide to SH2 is bifurcated. The primary interaction is between the phosphotyrosine and basic residues of the SH2 structure. The second interaction, which confers the ligand specificity of each SH2 domain, is provided by the recognition of amino acid residues immediately carboxyl terminal of the phosphotyrosine. The SH3 domains contain a five-stranded antiparallel b-sheet that forms two **hydrophobic** pockets. SH3 ligands have the minimal **consensus sequence** X-Pro-Pro-X-Pro, where X tends to be an aliphatic residue. Each X-Pro pair binds to one of the two hydrophobic pockets of SH3 in either orientation (ie, amino to carboxy terminal or carboxy to amino terminal). Some SH2- and SH3-containing proteins are composed of only SH2 and SH3 domains. These proteins are believed to function as phosphotyrosine-dependent adaptor proteins. Examples of SH2 and SH3 proteins are shown in Figure 1.

Figure 1. Schematic structures of SH2 and SH3 proteins. Illustrated are five enzymes (c-Src and Syk tyrosine kinases: PLCg, phospholipase C_g; PTP1D, protein-tyrosine phosphatase 1D; and GAP120), three adapter proteins (c-Crk, Shc, and Grb2), and one transcription factor (Stat). SH2 and SH3 domains are shown by hatched and gray bars, respectively. KD represents the kinase domains of c-Src and Syk tyrosine kinases. PLC and PTP are the catalytic domains of phospholipase Cg and protein-tyrosine phosphatase 1D, respectively. GAP is the domain of GAP120 that is responsible for Ras GTPase activation; PH, the pleckstrin-homology domain that binds to phosphoinositides; PTB, the phosphotyrosine-binding domain that is structurally distinct from the SH2 domain; DBD, DNA-binding domain.

Shine–Dalgarno Sequence

To initiate protein biosynthesis in bacteria, a bacterial 30S **ribosomal** subunit binds to a specific site on messenger RNA that is located 5 to 10 bp upstream of the initiation codon. This ribosome-binding sequence is called the Shine–Dalgarno sequence (or S–D sequence), which is named after its discoverers, J. Shine and L. Dalgarno (1). As shown in Fig. 1, it consists of seven or fewer nucleotides that are complementary to the 3′ terminus of bacterial 16S rRNA. The diversity of the number of the complementary bases in the S–D region (3 to 9 bases) or of the distance separating it from the initiator codon (5 to 9 bases) accounts, in part, for differences in mRNA translatability. Much evidence supports the idea that the S–D sequence binds to the 16 S rRNA and controls the frequency of translation initiation. For example, oligonucleotides complementary to the 3′ terminus of 16S rRNA inhibit translation, and base substitutions in the S–D sequence that reduce the

complementarity to 16S rRNA severely restrict translation, while compensatory changes in the 16S rRNA sequence restore the translatability. It is known in several cases that gene expression is regulated at the translational level by sequestering or exposing the S–D sequence with a regulatory protein or mRNA structure. Although most of the bacterial genes use the S–D sequence to mark the initiation site, there are several exceptions that do not use a S–D sequence. In these cases, alternate sequences that are complementary to other sites of the 16S rRNA are located immediately upstream or downstream of the initiation codon. The latter signal is referred to as the downstream box (2).

Short-Chain Dehydrogenases/Reductases SDRS

The SDRs are a large family of dehydrogenase and reductase enzymes that includes insect alcohol dehydrogenase and **hormone**-converting and regulatory enzymes in humans and all living forms. They frequently have subunits with ~250 residues and a sequence Tyr-X-X-X-Lys at the active site. For examples, references and further details, see Alcohol Dehydrogenase (ADH).

Shotgun Experiments

Shotgun experiments are based on the theory of "randomly divide up into manageable fragments and conquer." Shotgun experiments use a genomic library or a cDNA library as a source of individual clones that, as far as possible, represent the entire genome or the entire messenger RNA complement of an organism. It is important for any subsequent experiment that the library be constructed to maximize the probability that any one DNA or mRNA sequence in the starting material is

represented at least once among clones in the library. In practice, this ideal is hard to achieve, because for various reasons certain DNA sequences are hard to clone and are omitted from the library. These reasons include nonuniform distribution of restriction enzyme sites and the presence of repetitive DNA and poison sequences. Therefore shotgun experiments are experiments that use as a starting material a library cloned in so as to be inclusive and unbiased. Different types of shotgun experiments are described below.

1. Shotgun cloning

Shotgun cloning, one type of shotgun experiment, is an important technique for analyzing whole genomes or any DNA molecule too large to be analyzed directly. The DNA is randomly fragmented into smaller pieces by methods, such as mechanical shearing or partial digestion with a restriction enzyme, and then cloned into a suitable **vector** (see Cloning). Mechanical shearing is the most random and thus the most unbiased method of fragmenting DNA because the DNA sequence has no effect on breakage sites. However, sheared DNA cannot be cloned directly. The sheared ends must be filled in and linkers must be added before the DNA is cloned into a vector (see Fill-In Reaction and **Linker fragment**). The set of recombinant vectors that together contain the shotgun-cloned DNA are termed a **library**. Such libraries can be used in a number of different types of shotgun experiments, such as shotgun sequencing, or isolating individual genes or functional sequences, such as **origins of replication** or **promoters** (see Cloning) (1-3). An example of a typical shotgun cloning experiment is the following: *Bacillus subtilis* DNA was shotgun cloned into the **plasmid** pBR322, the *B. subtilis* library was mobilized into a cold-sensitive mutant of *Escherichia coli*, and a fragment of *B. subtilis* DNA that suppressed the mutant *E. coli* **phenotype** was identified (4).

2. Shotgun Sequencing

The theory behind shotgun **sequencing** is that by sequencing large numbers of random library inserts, the original shotgun cloned sequence is pieced together by using the overlaps between the different clones to order them (5). Shotgun sequencing is used to sequence smaller fragments of DNA, such as **yeast artificial chromosome** (YAC) inserts or **cosmid** inserts, to identify genes known to be contained in the fragment of DNA, or it can be used to sequence entire genomes. Many of the procedures involved in shotgun sequencing have been automated, including isolating of the DNA from random clones, carrying out the sequencing reactions, and reading the sequence. A number of entire bacterial genomes have recently been sequenced by shotgun methods, including *Archaeoglobus fulgidus*, the first sulfur-metabolizing organism to have its genome sequenced (6). In the case of *A. fulgidus*, several different libraries were used in the sequencing strategy, including a small-sized insert library and a medium-sized insert library, each created by randomly shearing genomic DNA, and a large-sized insert lambda phage library created by partially digesting genomic DNA with a restriction enzyme. Because some parts of the genome are more difficult to clone than others, using different libraries created by different methods that select for differently sized DNA molecules is useful to ensure that all sequences are represented in at least one library. The final genomic sequence of *A. fulgidus* was based on randomly determining 29,642 sequences from the three libraries. The average sequence was determined 6.8 times. Even with such sequencing redundancy, other methods, such as combinatorial **PCR** or primer walking, were needed to fill in gaps in the sequences (6).

A technique termed “ordered shotgun sequencing ” has been described for yeast artificial chromosomes (YACs) that reduces the redundancy of shotgun sequencing. A YAC is subcloned into plasmids, and the ends of the plasmid inserts are sequenced and analyzed for overlaps. Plasmid inserts with minimal overlaps are sequenced fully in the first round and then the next set of plasmids to be sequenced is also chosen for minimal overlap with the ends of the previously sequenced plasmids (7). A similar method of ordered shotgun sequencing has been proposed as the strategy for sequencing the human genome. Human bacterial artificial chromosome libraries (BACs) would be generated, BAC ends would be sequenced, and BACs with minimal overlap would be sequenced fully by shotgun sequencing (8).

3. Other “shotgun experiments”

As mentioned, use of the word “shotgun” to describe an experiment implies that a library is randomly screened to obtain a gene or genes of interest or that random library clones are analyzed (eg, by sequencing) to provide a representative survey of the entire library. Such general usage of the word “shotgun” results in a wide variety of different “shotgun experiments” in the literature. In one unusual shotgun experiment, “shotgun **antisense**” was used to create mutants and identify genes in *Dictyostelium* by transforming random antisense cDNA clones into *Dictyostelium*. Clones conferring interesting **phenotypes** were selected for further analysis (9). In another example, a novel V-ATPase was isolated by “shotgun screening” an expression library with an antiserum against the V-ATPase (10). In a different type of experiment, “shotgun analysis” of cDNA populations was used to identify tissue-specific genes (11).

Sickle Cell Disease

Sickle cell disease results from homozygosity for a glutamic acid to valine mutation in the b-globin polypeptide chain of hemoglobin (Hb), producing sickle cell Hb (Hb S). Red cells with only Hb S form sickle shapes under low oxygen pressure. These can block circulation in capillaries and also cause problems in the spleen. There is no very effective treatment. Most persons who are homozygous for Hb S die young. The frequency of Hb S is high in African populations and in some groups in India and Arab countries. Heterozygotes appear to have an advantage with respect to falciparum malaria, thus countering the low survival of homozygotes. The Hb S mutation has arisen independently five times.

1. Clinical Picture and Genetics

Sickle cell disease (sickle cell anemia) was first described in 1910 by J.B. Herrick. It is the major inherited disorder in most populations of African descent. It also occurs in the Mediterranean region and in some Arabic and Indian groups. Its most characteristic feature is the distorted shape of deoxygenated erythrocytes. They acquire large projections, suggesting the shape of a sickle to early observers. These sickled cells can clog capillaries, leading to even lower oxygenation and complete blocks in circulation. Both oxygenated and deoxygenated red cells in a person with sickle cell disease have increased adherence to vascular endothelium, a property that increases the likelihood of exposure to low oxygen pressure in capillaries.

The blocked capillaries, which can occur anywhere in the body, produce a variety of consequences, depending on the organs involved. Heart damage, brain damage, and damage to the intestinal tract are common occurrences. Renal damage results in inability to concentrate urine. The interruption of blood supply can be very painful, and sickle cell disease is characterized by painful crises as one or another tissue is affected. In many young children, the collection of sickled cells in the spleen causes loss of splenic function and leads to septicemia, a common cause of death. The anemia associated with loss of red cells and decreased production of hemoglobin causes increase in bone marrow and results in bone deformity. A “tower skull” is often seen in patients. Eventually, most patients succumb, usually in the teenage years.

The genetic basis of sickle cell anemia was established in 1949 James V. Neel. Familial clustering had been noted earlier, but the blood of many persons in these same families would sickle without other evidence of disease. Eventually it was recognized that persons whose red cells sickle in vivo are homozygous for a gene that is benign in the heterozygous state. Red cells of heterozygotes sickle in the more stringent anaerobic conditions used in the laboratory but not in vivo. If the allelic variations at this genetic locus are represented by *A* and *S*, the three possible genotypes are *AA* (homozygous wildtype), *AS* (heterozygous carrier), and *SS* (homozygous affected). Heterozygotes are often described as having *sickle cell trait*, as opposed to the sickle cell disease/anemia of homozygotes. There are no well-documented problems associated with heterozygosity for Hb S.

2. Molecular Genetics

In 1949, L. Pauling and coworkers compared the electrophoretic mobility of hemoglobin (Hb) from persons with and without sickle cell disease and found that the sickle cell Hb migrates more slowly toward the positive electrode under mild alkaline conditions, indicating a more positive net charge. Hb from heterozygotes showed two populations of molecules, one of which matched normal Hb (Hb A) and the other of which matched sickle cell Hb (Hb S). Thus there is a simple correspondence between the three genotypes and the three electrophoretic patterns.

Vertebrate Hb's are tetrameric, consisting of two each of two related but distinct polypeptide chains. In normal adult human Hb, the chains are labeled a and b, and the molecular formula is written a_2b_2. The two types of chain are products of separate genes, the a-globin gene (*HBA*) being on human chromosome 16 at 16pter-p13.3 and the b-globin gene (*HBB*) on chromosome 11 at 11p15.5. In 1956, Vernon Ingram demonstrated that the only difference between Hb's A and S is replacement of one glutamic acid by valine. Subsequently it was shown that the replacement is in amino acid residue six of the b chain. The N-terminal sequence for the b chain of Hb A is Val-His-Leu-Thr-Pro-Glu-Glu-Lys-, and that for Hb S is Val-His-Leu-Thr-Pro-Val-Glu-Lys. The Hb S allele can therefore be designated *HBB, GLU6VAL*.

These N-terminal segment of the b chain that includes this amino acid substitution lies on the exterior of the folded globin. The replacement of glutamic acid by valine creates a new nonpolar site. This allows deoxygenated Hb S in high concentrations to aggregate into fiberlike structures that form

a gel and that align to distort the cell shape and make the cells subject to rupture. In heterozygotes, in which a majority of the Hb is Hb A, sickling does not occur under physiological conditions but can be induced if the oxygen pressure is lowered sufficiently. Even in persons who are homozygous for Hb S, a small increase in fetal hemoglobin (a_2g_2) can interfere with sickling and ameliorate the symptoms of sickle cell disease.

3. Population Genetics

In view of the fact that most persons with sickle cell disease do not survive to reproduce, one would expect the frequency of the Hb *S* allele to be very low. Yet, in West Africa, the Hb *S* allele frequency can be as high as 15%. The expected frequency of homozygotes is 2.25% and of heterozygotes is 25.5%. The proportion of Hb *S* alleles in homozygotes and therefore subject to strong negative selection would be 15%. The frequency of this allele in the population should decrease rapidly over time. However, it does not.

The explanation appears to be the selective advantage of heterozygotes because of their greater resistance to falciparum malaria as compared to the normal Hb *AA* population. Whatever the initial allele frequencies, eventually the number of Hb *S* alleles lost through sickle cell disease will equal the excess number of Hb *A* alleles lost because of malaria. This *balanced polymorphism* involving falciparum malaria and sickle cell disease in Africa also occurs with falciparum malaria and other hemoglobin disorders, including Hb C and b-thalassemia in West Africa and Hb E, Hb Constant Spring, and a-thalassemia in Southeast Asia. Approximately 8% of African-Americans are heterozygous for Hb *S* and some 6 per thousand are affected with sickle-cell disease. Because falciparum malaria does not occur in the U.S., the frequency of the Hb *S* allele should diminish, although very slowly.

4. Origins of the Hb S Mutations

Did the single nucleotide substitution that constitutes the Hb S mutation occur once and spread because of selection, or did it occur multiple times? This question can now be answered because of the availability of a number of polymorphic DNA markers that lie in the vicinity of the *HBB* locus. Because these markers are close to each other, recombination during meiosis is very rare, and a particular combination of "alleles" at these marker loci is transmitted as a unit, called a *haplotype*. There are several hundred possible combinations of marker variations, but only a portion have been observed worldwide. Any one population will have a number of haplotypes, some of which will be shared with other populations, depending on the prehistoric origins of the populations and the migrations and hybridizations that have occurred.

When a mutation occurs, it necessarily occurs within a specific haplotype combination. The nucleotide substitution in codon 6 of the b-globin gene, if it arose only once, should occur in association with a single haplotype or in related haplotypes that could have arisen by rare recombination events from the original haplotype. On the other hand, if the mutation occurred more than once, it should be found in distinctive haplotype backgrounds.

Analysis of Hb *S*/haplotype combinations indicates that the mutation must have occurred at least five times. Four are found predominantly in Africa and are designated Bantu, Benin, Senegal, and Cameroon. A fifth is found in the populations of India and Saudi Arabia in which the sickle cell gene occurs. The Hb S allele in Sicily and other Mediterranean areas occurs with the Benin haplotype, which is otherwise very rare there. This suggests an African origin for the Mediterranean alleles.

There is some difference in severity of sickle cell disease also associated with haplotypes. Persons homozygous for the Arabian haplotype are least severely affected and those with the Bantu haplotype are the most severely affected. Because the Hb S mutation does not differ among the haplotypes, it is likely that regulatory elements in the b-globin complex vary, perhaps resulting in

more or less fetal hemoglobin that interferes with sickling.

5. Diagnosis and Treatment

The diagnosis of homozygosity for Hb *S* is readily accomplished by gel electrophoresis of red cell lysates from blood of newborns or adults. Examination of Hb in fetal red cells cannot be used routinely for diagnosis because of the low production of b-globin during this period. Direct examination of DNA has made prenatal diagnosis possible, however. Most earlier procedures were based on the fact that the DNA sequence for codons 5 to 7 is 5′-CCTGAGGAG-3′ in the case of Hb *A* and 5′-CCTGTGGAG-3′ for Hb *S*. The restriction enzyme MstII cleaves at the sequence CCTNAGG, which is present in Hb *A* but not in Hb *S*. Thus the restriction fragment patterns will differ for the two alleles. The difference can be observed using a Southern blot with an appropriate b-globin probe. Several variations on polymerase chain reaction (PCR) amplification of the altered DNA segment have also been developed. These have the advantage of requiring minute quantities of DNA, such as single cells from an in vitro-fertilized 8-cell embryo or from rare fetal cells in the maternal circulation.

Effective treatment of sickle cell disease has yet to be developed. Current approaches have been directed toward increasing the level of fetal Hb, which interferes with sickling. Hydroxyurea increases fetal Hb and has some beneficial effect on sickling, but the levels required and the uncertain long term effects have been problems. Nevertheless, it is the treatment of choice at present. Bone marrow replacement should be effective but generates its own major problems.

Side Chain

Side chain is the general term to describe the variable part of a polymer, the functional group(s) attached to the constant or regularly repeating backbone. Different kinds of polymers have different kinds of side chains. For homopolymers, the side chains are all chemically equivalent (for example, polyacrylamide has amide side chains). Copolymers have two or more types of side chains and can be very complex. Biological examples of copolymers include the **nucleic acids** and proteins. In the nucleic acid **DNA**, which has a sugar phosphate backbone, there are four possible side chains corresponding to the purine and pyrimidine bases **cytosine**, **adenine**, **thymidine**, and **guanine**. Proteins are even more complex, with 20 possible amino acids, each with a different side chain on the polypeptide chain backbone. The 20 different protein side chains are chemically very diverse, including polar, nonpolar, aromatic, sulfur-containing, positively charged, and negatively charged functional groups. Further complexity is possible for protein side chains through post-translational modifications, such as **phosphorylation**, N-glycosylation, O-glycosylation, sulfation, and disulfide

bond formation, that modify the side-chain chemistry. The order or sequence of amino acids, and therefore of side chains, in a polypeptide chain influences both the structure and function of the protein. Furthermore, the large variety of available amino acids leads to an immense number of possible side-chain combinations. This diversity in amino acid building blocks is the basis for the enormous range of protein structures and functions.

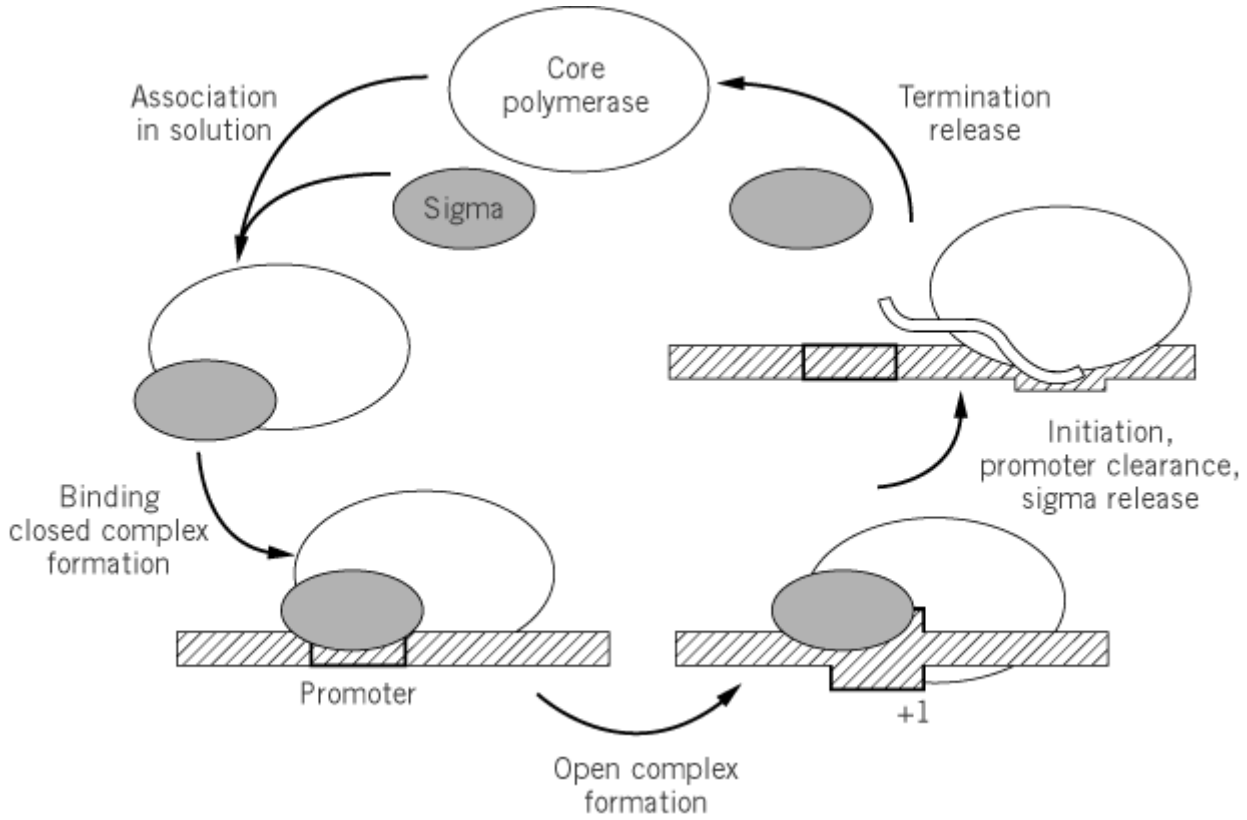
Sigma Factors

Sigma factors are subunits of the DNA-dependent **RNA polymerase** (RNAP) holoenzyme from eubacteria that are required for initiation of transcription at specific **promoters** (1, 2). Sigma factors function in a number of roles during transcription initiation: (i) They bind to the core RNAP; (ii) inhibit nonspecific transcription; (iii) recognize specific DNA sequences at the promoter; (iv) contribute to promoter melting; (v) interact with certain transcriptional activators; and (vi) play a critical role in promoter clearance (Fig. 1). Sigma factors therefore bind to the nonspecific core RNAP and convert the enzyme into a form that is specific for initiation. Consistent with s; factors playing a role only during initiation, the factor is released from RNAP during the transition from initiation to elongation.

Figure 1. The cycle of interaction between s factor and core RNA polymerase showing the steps of transcription initiation.



Sigma factors were originally identified as a dissociable subunit of the *Escherichia coli* RNAP required for promoter recognition (1). The first s; factor to be identified was the major vegetative s^{70} factor required for recognition of most *E. coli* promoters. Transcriptional studies in *Bacillus subtilis* and its bacteriophage led to the identification of multiple alternative s factors that alter promoter recognition, thereby being capable of changing the patterns of transcription. It is now clear that all eubacteria have multiple sigma factors that control genes for specific functions. These functions include: **sporulation**; response to **heat shock**; entry into and maintenance of stationary phase; expression of **flagella** genes; and control of nitrogen metabolism. Some s factors are specific for classes of bacteria, including the factors involved in sporulation and flagella synthesis, whereas other s factors, such as those that control nitrogen metabolism, heat shock, and the stationary phase response, are found throughout the bacterial world.

1. Overview of Sigma Function

As shown in Figure 1, s factor-dependent initiation of transcription can be described as a cyclic process. First, the core RNAP associates with a s factor in the absence of DNA. This association alters the conformation of both the RNAP and the s factor, allowing the holoenzyme to recognize and bind specific promoter DNA sequences. Eubacterial promoters are comprised of sequences upstream of the start site of transcription that are recognized by s factors (see below for specific examples). The RNAP initially binds to these recognition sequences, to form a closed complex with the double-stranded DNA of the promoter. After initial binding, the DNA strands are separated, forming an open promoter complex, which is competent for initiation of transcription. The early stages of transcription are only slightly processive, and the enzyme dissociates readily. Many short RNA transcripts are produced while the RNAP maintains contacts with the promoter. When the nascent transcript reaches a critical length, the RNAP undergoes an important transformation, called *promoter clearance* . This process is marked by dissociation of the s factor from the transcription complex and the concomitant release of contacts with the promoter. At this point, the core RNAP enters an elongation mode of transcription, while the released s factor is free to interact with a new

core RNAP. After termination of transcription, the core RNAP is released from the DNA and can reassociate with a sigma factor to initiate a new round of transcription.

2. Classes of Sigma Factors

2.1. The s^{70} Family

Most s factors are similar at the amino acid sequence level to the *E. coli* s^{70} factor identified originally and constitute a large family of related proteins. The s^{70} family has been divided into three groups (1). Group 1 includes the primary s factors. These factors direct the transcription of most of the genes required for exponential growth, and they are therefore essential for cell survival. Group 2 s factors are not essential for growth, but are quite similar at the amino acid sequence level to Group 1 s factors. This group includes the s^{38} (s^{S}) stationary phase s factor found in *E. coli* and many other bacteria. Group 3 includes the alternative s factors. They are required for transcription of certain regulons and have diverged considerably (usually with less than 30% sequence identity) from the Group 1 s factors. Group 3 s factors can be further divided into five closely related clusters. Three of the five clusters include sporulation-specific s factors, while the remaining two clusters consist of flagellar and heat-shock s factors. Alignments of the s^{70} family have identified four regions of high conservation ((1-4), see Fig. 2A). These regions have been further subdivided as functional information has been obtained. The primary or Group 1 s factors contain all four of these regions, whereas alternative s factors may contain only a subset. Regions 2 and 4, which are implicated in DNA binding, are conserved in many of the s factors, whereas regions 1 and 3 are often absent from the alternative and phage-encoded s factors. The functions of the conserved regions in the s^{70} class of factors are described below.

Figure 2. Features of selected s factors. (**a**) *Escherichia coli* s^{70}. Conserved regions (numbered 1–4) are labeled above the bar depicting the primary structure of s^{70}. Conserved subregions are shown as shaded boxes. Regions of known function are shown as lines below the s^{70} sequence. The data used to derive this figure came from references 1, 2, 13, 20, 22, 23, and 27. (**b**) Summary of selected sigma factors from *E. coli, B. subtilis*, phage T4, and yeast mitochondria (24, 36, 43). Consensus promoter recognition sequences of the s factors are shown. Nucleotide spacing between the recognition elements is indicated where applicable.

(b)

2.2. The s^{54} Family

A second class of s factors is similar to *E. coli* s^{54} (3, 4). These s factors have very little amino acid sequence similarity to the s^{70} family. s^{54} recognizes a unique class of promoter elements characterized by the presence of unique sequences at nucleotides 2 12 and 2 24 relative to the transcription start site (Fig. 2). Unlike the s^{70} class of factors, s^{54}-containing holoenzyme is incapable of forming an open complex on its own. Activation of the RNAP and open complex formation requires an activator protein bound upstream of the promoter. When the activator protein is **phosphorylated** in response to an environmental signal, it triggers open complex formation, in a process that requires ATP hydrolysis. After promoter clearance, s^{54} remains associated with the promoter DNA (5). Unlike s^{70}, s^{54} can bind some promoters in the absence of core RNAP. The s^{54} family of s factors therefore undergoes a unique cycle of transcription distinct from that of the s^{70} family.

s^{54} can be divided into three regions, designated I to III, respectively: the *N*-terminal region; a poorly conserved acidic central region; and a long *C*-terminal region. Region I contains only the *N*-terminal 25 to 50 amino acid residues. This region is glutamine-rich and is required for activation. Certain mutations in this region permit transcription in the absence of activator proteins (6). Region II is required for binding to core RNAP (7). And finally, Region III is a promoter-binding domain (8). A **helix–turn–helix** motif in this domain is required for recognition of the 2 12 region of the promoter (9).

3. Functional Domains of Sigma Factors

3.1. Interactions with DNA

One of the main functions of s factors is to bind DNA, directing initiation of transcription to the promoter. For a number of years, it was not certain whether s factors bound DNA or altered the structure of the core RNAP to allow the enzyme to bind DNA. The discovery of multiple s factors with unique recognition sites supported the idea that the different s factors directly recognized the promoter DNA. Current data suggest that the majority, if not all, of contacts with the promoter in its 2 10 region are made by the s subunit (10). A critical development for s-specific DNA binding came from genetic analyses of promoter mutants with altered recognition sites (1, 2). These studies identified compensatory alterations in s factor genes that suppress promoter sequence alterations, confirming that s factors make direct contacts with the DNA. Suppressor mutation studies revealed that two regions of s are critical for binding DNA (see Fig. 2a). Region 4.2 recognizes the 2 35 element of the s^{70} promoter. This region is predicted to form a helix–turn–helix motif similar to that found in many DNA-binding proteins . Two residues in the second a-helix of this motif affect promoter binding in *E. coli* s^{70} and *B. subtilis* s^{A}. Furthermore, mutations that switch the promoter specificities of *B. subtilis* s^{B}, s^{F}, and s^{G} also map to this region. The second DNA-binding region, 2.4, recognizes the 210 element of the promoter. Genetic studies have identified amino acid residues in this region that make specific contacts with bases in the 210 region of the promoter. Recent structural studies have confirmed earlier speculation that this region forms a DNA-recognition a-helix (11).

Intact s^{70} does not bind to promoter DNA, but direct recognition can be observed after removal an *N*-terminal inhibitory region (12). Subregion 1.1 (see Fig. 2a) prevents the s factor from binding to DNA in the absence of core RNAP by direct interactions with the *C*-terminal region of s that includes subregion 4.2 (13). Binding of s factor to core RNAP must alter the inhibitory effect of this domain. In support of this idea, recent evidence suggests that the core RNAP makes direct contact with region 1.1 (see "Sigma-Core Interactions," below). Inhibition of DNA binding by the *N*-terminal regions of sigma factors may be a common mechanism of regulation. Although they have no obvious amino acid sequence similarity to region 1.1 of s^{70}, the *N*-terminal regions of *E. coli* s^{32} and *B. subtilis* s^{K} also alter the ability of these factors to bind DNA (13).

Recent work has revealed that base-specific recognition of the 2 10 region of the promoter is directed through interactions with the nontemplate strand (10, 14). *E. coli* RNAP holoenzyme can bind single-strand oligonucleotides containing the consensus 2 10 region of the nontemplate strand, but not of the template-strand. However, whether the holoenzyme first recognizes double-stranded DNA and then later converts the binding to single-strand interaction is not known. Alternatively, single-strand binding may be the only base-specific interaction, after melting of the DNA by holoenzyme. In either case, specific binding to the nontemplate strand would leave the template strand accessible to the catalytic center of the RNAP.

3.2. Sigma-Core Interactions

The complex interactions between the sigma subunit and the core RNAP play a critical role in the regulation of the transcriptional cycle. In the previous section, we reviewed the requirement for core RNAP to unmask the sigma DNA-binding activity. Additional regulatory interactions have been observed (2). For example, binding of s^{70} decreases the affinity of core RNAP for nonpromoter DNA by at least 10^4-fold. Furthermore, the affinity of s for core is relatively high (**dissociation constant** of about 2 nM). However, the affinity decreases more than 10^3-fold after the transition to the elongating form of core RNAP. Association with s factor also greatly alters the structure and conformation of the core RNAP. This conclusion is supported by low-resolution structure studies of the core and holoenzyme (15, 16). Both the core and holoenzyme contain a channel presumed to bind the template DNA, but the channel of the core RNAP is closed. Association with s factor

appears to open the channel of the holoenzyme, making it accessible to DNA for promoter binding. The transition to the closed form of the core RNAP after release of s factor is thought to contribute to the processive nature of the elongation complex, serving to "clamp" the RNAP to the DNA.

Despite the importance of the s-core interaction, little is known about the specific amino acid residues that mediate this association. Recent work has indicated that several of the conserved regions of s factors are required for this interaction (see Fig. 2a). For a number of years, region 2.1 has been implicated in core binding. Deletion analysis of s^{70} identified a segment of 30 residues that may contribute to interaction with core RNAP (17). This segment forms an a-helix (18) and contains most of subregion 2.1. Mutational studies have reinforced the importance of region 2.1 in core interaction and have identified additional regions of s that are required for interaction with the core RNAP. Many of these studies involve single amino acid substitutions in s factors that significantly reduce the interaction with the core RNAP. Site-directed mutagenesis of specific regions of sigma factors has confirmed the importance of amino acid residues in subregion 2.1 and also identified subregion 2.2 as important for core interaction (19-21). Additional core-binding mutants have been identified by the analysis of defective s^{32} alleles (22). Mutations in subregion 4.2 and *C*-terminal to 2.4, in a region known as the RpoH-box, were found to be defective for core interaction. Several other mutants in subregions 3.1 and 4.1 were identified that had core-binding defects that were apparent only when in competition with s^{70} for core binding.

An additional study footprinting proteins has confirmed that the interface between s and core RNAP is not simple. Footprints of s^{70} alone and bound to core RNAP showed that regions 1.1, 2, 3, and 4.2 are all protected by interaction with core (23). While these studies show that multiple regions of the s subunit contact the core RNAP, there may be some differences between s factors in their core binding sites, because the s^{32} RpoH box is not conserved in other s factors. However, subregion 2 probably plays a pivotal role in core binding, because this region has been implicated in core binding in many s factors. Interestingly, similarities to s^{70} region 2 have been identified in the core-binding region of s^{54}, the otherwise unrelated s factor. A small region in s^{54} is nearly identical to residues found in subregion 2.1 of s^{70}. Mutations in this conserved patch of residues demonstrate that this region is required for the s^{54}-core interaction (7). This work suggests that the two types of s factors may have a common core binding site, despite their very different properties and lack of overall amino acid sequence similarity.

4. DNA Melting By Sigma Factors

Early predictions of how s factor would bind to promoter DNA were based on comparisons to single-stranded DNA binding proteins, which use aromatic amino acid residues to interact with exposed bases and basic residues for charge neutralization and stabilization of the bound complex. Sigma factor subregion 2.3 contains many aromatic and basic amino acids and was therefore predicted to be involved in interactions with single-stranded DNA at the promoter (24). This prediction was consistent with photocrosslinking experiments that showed contact between s^{70} and the 2 3 position of the nontemplate strand (25). Evidence for single-stranded DNA binding was provided by mutagenesis of specific residues in region 2.3 in a primary s factor (s^{A} of *B. subtilis*) (26). Many of these mutations impair DNA melting by the RNAP holoenzyme. However, the melting defect can be overcome by raising the reaction temperature or by using a **supercoiled** template. Several of the mutant s factors exhibit a *trans*-dominant lethal phenotype *in vivo* consistent with their defect in DNA melting (26).

A recent investigation of s^{70} region 1, already implicated in autoinhibition of DNA binding and interactions with core RNAP, has identified an additional possible role in DNA melting (27). Deletion of region 1.1 resulted in reduced rates of open complex formation and formation of the initial transcribing complex. Deletion of both regions 1.1 and 1.2 resulted in a more severe

phenotype. The mutant holoenzyme complex arrests after initial binding to the promoter. These results suggest that region 1, as well as subregion 2.3, plays a critical role in the early stages of open complex formation.

5. Sigma Factors of *Escherichia Coli*

In eubacterial cells there are several different sigma factors that bind to the core RNAP to direct transcription of distinct subsets of genes. Therefore, in addition to the intrinsic strength of each promoter DNA sequence, the degree to which each of approximately 4000 genes is transcribed is in part determined by the properties of s factors. In *E. coli*, seven s factors (s^{70}, s^{32}, s^{28}, s^{F}, s^{S}, s^{54}, and FecI) have been identified (28, 29). Each *E. coli* promoter is recognized by one or more of the different s factors. A summary of some features of several *E. coli* s factors is presented in Figure 2b. Most genes expressed in exponentially growing cultures are transcribed by the s^{70} holoenzyme. This s factor binds a bipartite promoter with recognition sequences centered at nucleotides 2 10 and 2 35 relative to the start site of transcription. Promoters recognized by alternative s factors have distinct recognition sequences, but with similar spacing between the recognition sites.

Genes responsive to heat shock are transcribed by s^{32} (s^{H}) and s^{24}(s^{E}) (24, 30). s^{32} is the main heat-shock s factor and is expressed at low levels during steady-state growth. Expression and stability of s^{32} is dramatically increased upon a shift to high temperature. The other heat-shock s factor, s^{24}, is responsive to extracytoplasmic stress signals (31). s^{54} is responsible for transcription of genes in response to a number of signals, including availability of nitrogen (3, 4). As described above, s^{54} requires input from additional binding proteins to activate transcription in response to extracellular signals. s^{38} (s^{S}) is required for survival of starvation in stationary phase. Some genes required for stationary phase can only be transcribed by the s^{38} holoenzyme; other genes that are expressed in exponential growth or stationary phase can be recognized by either s^{70} or s^{38} (32). It has been proposed that s^{38} is also important for expression of genes in stationary phase cells, based in part on the observation that the intracellular level of s^{38} increases with decreases in cell growth rate (28). s^{28} is required for synthesis of **flagella** and chemotaxis genes.

The most recent sigma factor identified in *E. coli* is FecI, which responds to external stimuli to regulate a small set of genes required for ferric citrate transport (29). Although homologues of these sigma factors are found in most bacteria, including *B. subtilis* as described below, there are some interesting exceptions. For example, the complete sequence of *Treponema pallidum* (33), an obligate human parasite and the causative agent of syphilis, demonstrated that this organism lacks homologues of s^{38} and s^{32}. The parasitic lifestyle of this organism apparently does not require response to starvation or heat stress.

6. Sigma Factors of *Bacillus Subtilis*

The gram-positive bacterium *B. subtilis* has more s factors than the **gram-negative** *E. coli*, reflecting the central role these factors play in the complex sporulation pathway of *B. subtilis* (24, 34-36). In *B. subtilis*, there are 11 known sigma factors; five are required for sporulation, and the other six are used only during vegetative growth. The main vegetative sigma, s^{43} (s^{A}), although it is missing 245 amino acid residues between conserved regions 1 and 2 found in s^{70}, is 50% identical to *E. coli* s^{70} and recognizes similar promoters. Like *E. coli, B. subtilis* contains alternative s factors that regulate **stress response**, stationary-phase growth, and flagellar biosynthesis (34). In the case of the flagellar genes, the *B. subtilis* s factor can substitute for *E. coli* s^{28} to support flagellar expression. Furthermore, *B. subtilis* SigL is homologous to s^{54} and similar in function (37). Finally, *B. subtilis* sigX can complement an *E. coli* fecI mutant, although sigX does not appear to regulate ferric citrate utilization in *B. subtilis* (38). Therefore, in a least several cases, the alternative s factors of *E. coli*

and *B. subtilis* are analogous.

In Figure 2B, the consensus promoter elements are shown for three of the five *B. subtilis* s factors that are required for sporulation (36). s^H is the only sporulation s that is also active in vegetative cells. In addition to regulating genes required for the initiation of sporulation, s^H regulates stationary-phase genes and genes needed for sporulation competence. The four remaining sporulation s factors are expressed only during the sporulation program. Two s factors (s^F and s^G) function within the prespore, while the other two (s^E and s^K) function within the mother cell. In both cell types, one s factor regulates early spore development, while the other becomes active later during sporulation

7. Anti-Sigma Factors and Competition between Sigma Factors

Studies of transcription in *E. coli* show that there are approximately 2000 core RNAP molecules per cell in exponential cultures (39). At any given time, roughly two-thirds of the core RNAPs are engaged in transcriptional elongation, leaving 600 or 700 RNAP molecules free for interaction with a s factor. On the other hand, there are about 700 molecules of s^{70} in the cell, in addition to lesser amounts of the alternative s factors. Therefore, there is likely to be competition between the primary and alternative s factors for interaction with core RNAP. Direct competition between s factors for access to RNAP is also involved in the case of **T4 phage** replication, where transcription of late genes is controlled by the phage-encoded s factor gp55. The fact that gp55 competes very poorly with s^{70} for core interaction led to a proposal that a s antagonist might participate in the T4 developmental process (40). Subsequent investigations identified a 10-kDa T4 phage-encoded protein that binds to s^{70} and inhibits its activity. This protein, named AsiA, belongs to a now fairly large and growing group of proteins known as *anti-s factors*.

The anti-s factors are an unrelated collection of proteins that bind s factors to regulate their activity, often in unique ways. For example, after the formation of flagella, the anti-s factor FlgM of *S. typhimurium* binds to s^F and inhibits its further activity (41). While the flagellum is being synthesized, however, the FlgM protein is actively transported through the immature flagellar tubes and out of the cell. This provides a unique mechanism for regulating the complex developmental program of flagellar formation. Anti-s factors have now been identified for a number of s factors including: inhibitors of *B. subtilis* sporulation factors s^F and s^B; *E. coli* heat shock s factors s^{32} and s^{24}; and a possible inhibitor of *E. coli* s^{70} in stationary-phase cultures (2, 39). Gene regulation in eubacterial cells is therefore modulated by both the presence of different types of s factors and by their interactions with anti-s factors.

8. Sigma Factor Relatives in Phage and Eukaryotes

Sigma-like factors have been identified in the bacteriophage T4 and SPO1 (1). These factors interact with the host core RNAP to direct transcription of middle and late genes in the phage genome. The bacteriophage SPO1 s factors, gp34 and gp28, have regions somewhat similar to regions 2, 3, and 4 of the cellular sigma factors. The T4-encoded sigma, gp55, has some weak amino acid sequence similarity to region 2 of the s^{70} family. It is interesting that, consistent with the lack of a similarity to conserved region 4, which is required for recognition of the 2 35 element of the bacterial promoter, gp55 recognizes promoters with only a 2 10 consensus (see Fig. 2b).

Two factors with weak but significant sequence similarity to s factors have been identified in eukaryotic cells. One factor, RAP30, is a component of the required RNA polymerase II initiation factor TFIIF. Like s factors, RAP30 binds stably to its RNAP (see also text below) and promotes binding of the RNAP to the promoter, while reducing the affinity of the enzyme for nonpromoter DNA (42). A second s-like factor, Mtf1p, is required for initiation of mitochondrial transcription in

yeast (see Fig. 2b) (43). A number of similarities between Mtf1p and s factors have been noted, including release of the factor shortly after initiation of transcription. However, Mtf1p binds to an RNAP that is homologous to the T7 phage single-subunit RNAP, rather than to a multisubunit RNAP.

Core-binding studies of the phage and eukaryotic factors provide additional evidence for their similarity to s factors. The core-binding sites of RAP30 and gp55 have been mapped to regions similar to s regions 2.1 and 2.2, which are required for core binding in s factors. Remarkably, human RAP30 also has the ability to interact with the *E. coli* core RNAP (44). The interaction of RAP30 with core RNAP can be disrupted by the addition of s^{70}, suggesting that the two factors bind to the same region of the RNAP. Like s factors, multiple regions of Mtf1p are required for binding to the core (45). The Mtf1p core-binding regions include regions similar to subregions 2.1, 2.2, and 3 of the eubacterial s factors, which, as described above, have also been implicated in s-factor-core RNAP interactions.

9. Concluding Remarks

Although s factors are used throughout the eubacterial world to direct core RNAP to certain promoters, in both archaea and in the eukaryotic nucleus the unrelated **TATA box**-binding protein (TBP) appears to be the critical determinant for identification of promoters. However, recent work has revealed that multiple forms of TBP exist, and additional factors modulate the activity of the major TBP at different promoters in ways that are specific for tissue and developmental stage (46, 47). At some level, therefore, the regulation of gene expression by s factors described in this brief review is used in all forms of life. In addition, the cyclic interactions of initiation factors with a nonspecific core RNA polymerase are also found in all types of cells (see RNA Polymerases, DNA-Dependent). The study of s factors therefore continues to provide important lessons for transcriptional regulation of all genes.

Signal Peptidase

Signal peptidases are the enzymes that cleave signal peptides from pre-proteins during their translocation across membranes (see Protein Targeting, Intracellular). The type I signal peptidases that are present in eubacteria are simple monomeric proteins, but the signal peptidases of the endoplasmic reticulum and mitochondria exist as multisubunit complexes. Whereas detailed analyses of signal peptides have been ongoing for more than 20 years, the structure and function of the individual subunits of these protein complexes has become clearer only through more recent studies.

1. Endoplasmic Reticulum Signal Peptidase

Unlike eubacterial representatives of the type I signal peptidase family, purified ER signal peptidase is a multisubunit protein complex, thus leading to its alternative name signal peptidase complex (SPC) (1). The SPC purified from the ER membrane of canine pancreas contains five membrane-bound subunits (2). Naming of these subunits has been based on their size as measured by gel electrophoresis (see SDS-PAGE). The subunits are SPC25, SPC22/23, SPC21, SPC18, and SPC12 (Table 1). SPC22/23 migrates on SDS-PAGE gels as two distinct species exhibiting molecular masses of 22 and 23 kDa. This heterogeneity is due to SPC22/23 being the only **glycoprotein** subunit of the complex. SPC18 and SPC21 are highly homologous to each other (Fig. 1) and bear limited homology to eubacterial leader peptidase: The homology is confined to five distinct regions, denoted A through E (Fig. 2). Because two of these five regions contain probable active-site residues in the eubacterial type I enzymes (indicated by an asterisk), the mammalian SPC may contain two catalytic subunits. The remaining SPC subunits show no apparent homology to type I signal peptidases.

Figure 1. Alignment of the amino acid sequences of SPC21, SPC18, and Sec11p. Sequence identity is indicated by using capital letters.

Figure 2. Regions of homology in the type I signal peptidase family. Regions A through E show the strongest homology among proteins in the type I signal peptidase family. Sequence identity is indicated using capital letters. Amino acids thought to make up the catalytic serine/lysine dyad of eubacterial signal peptidases are indicated using an asterisk. The sequences displayed are from *E. coli* (Lep), the canine ER (SPC21 and SPC18), the ER of the yeast *S. cerevisiae* (Sec11p), and the mitochondrial inner membrane of the yeast *S. cerevisiae* (Imp1p and Imp2p).

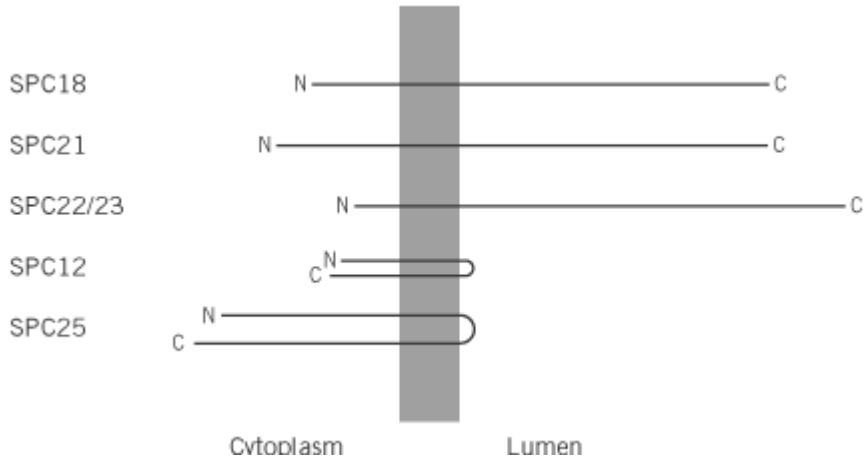
Table 1. Homology (% Identity and % Similarity) Between ER Signal Peptidase Subunits from Canine and Yeast Cells

Canine	Yeast	Identity (%)	Similarity (%)

SPC18	Sec11p	48	75
SPC21	Sec11p	45	75
SPC12	Spc1p	24	63
SPC25	Spc2p	20	55
SPC22 / 23	Spc3p	22	55

Membrane topology studies of the SPC subunits reveal two distinct groups: single-spanning proteins orienting their C-termini to the ER lumen and proteins containing two membrane-spanning segments (3, 4). Proteins in the first group, SPC22/23, SPC21, and SPC18, possess much larger lumenal domains than cytoplasmic domains (Fig. 3). SPC25 and SPC12, which represent the second topological group, are oriented predominately toward the cytoplasmic side of the membrane. Because the catalytic site of the SPC is located on the lumenal side of the membrane, it is thought that SPC25 and SPC12 do not contribute significantly to the catalytic site. This hypothesis is supported by the fact that a functional signal peptidase containing only two subunits has been purified from the ER of hen oviduct (5). These two subunits are homologous to the SPC22/23 and SPC18 subunits of the canine SPC.

Figure 3. Membrane topologies of the subunits of ER signal peptidase from canine cells. The deduced topologies of the SPC18, SPC21, SPC22 / 23, SPC12, and SPC25 subunits are represented. The diagram depicts the relative sizes of the cytoplasmic and luminal domains of each subunit but is not drawn to scale.



ors to proteins resident within the ER, transported from the ER to another compartment of the secretory pathway, secreted from the cell, and resident within the **lysosome**. The function of the SPC subunits has been elucidated in the yeast *Saccharomyces cerevisiae*. The first of the signal peptidase genes to be cloned from yeast was *SEC11*, which encodes the 19-kDa subunit (6). This gene has adopted the *SEC* (for secretion; see Sec Mutants/Proteins, Proteins) nomenclature because *SEC11* was identified in a selection for mutations inhibiting protein secretion. That *sec11* mutations inhibit secretion is due to the fact that defects in cleaving signal peptides can result in abnormal maturation of the cargo and, consequently, retention of immature precursors in the ER lumen (see Unfolded Protein Response). The genes encoding the other yeast subunits are named by the more conventional SPC nomenclature and are numbered, starting with *SPC1*, according to the order in which the genes have been isolated (see text below). Sequencing of the *SEC11* gene demonstrates that the corresponding protein, Sec11p, is highly related (~45% identity and ~75% similarity) to two subunits of the canine enzyme, SPC18 and SPC21 (Fig. 1) (7). This high degree

of homology is greater than that found for the other SPC subunits (Table 1). In addition, gene-disruption analyses have shown that Sec11p is essential for cell growth, and *sec11* temperature-sensitive mutations inhibit cleavage of signal peptides in yeast cells incubated at the nonpermissive temperature (6). Consistent with these observations, Sec11p appears to contain the five distinct regions of homology typified by proteins in the type I signal peptidase family (Fig. 2), suggesting that Sec11p contains all or part of the catalytic site.

A high-copy **suppressor** of a *sec11* mutation has been isolated and found to encode the SPC12 homologue Spc1p (8). Overexpression of Spc1p permits growth of *sec11* temperature-sensitive mutant cells at their nonpermissive temperature. Spc1p shares 24% identity and 63% similarity with SPC12 at the primary structure level (Table 1). Sequence analysis of the cloned *SPC1* gene predicts a molecular weight for the encoded protein of 11 kDa and a topology like its mammalian homologue. Despite its presence in the partially purified SPC and homology to mammalian SPC12, Spc1p is not required for cell growth or signal peptidase activity in yeast cells. It is plausible, however, that another polypeptide can replace Spc1p functionally, although analysis of the complete genome of *S. cerevisiae* has revealed no other SPC12 homologue. The only phenotype found to be associated with the *spc1* null mutant is that expression of high levels of a membrane protein fragmented by signal peptidase (see text below) causes a partial accumulation of uncleaved precursors in mutant cells. This finding suggests that Spc1p may be important for efficient signal peptidase activity.

Spc2p (21 kDa) has been identified by comparing open reading frames in the yeast genome to the sequence of canine SPC25 (9). Spc2p shares 20% identity and 55% similarity to SPC25, and it co-purifies with Sec11p, supporting the idea that Spc2p is the SPC25 homologue (Table 1). The *SPC2* gene has been disrupted and, as with the *SPC1* gene, found to be nonessential for cell growth and signal peptidase activity under normal laboratory conditions. Furthermore, disruption of both *SPC1* and *SPC2* in the same cell is nonlethal. To date, the only phenotype associated with the *spc2* null mutant is that cell viability and signal peptidase activity are diminished at high temperatures. A specific function for Spc2p is suggested by the fact that the mammalian homologue, SPC25, can be cross-linked to the b-subunit of the translocon (Sec61p complex; see Endoplasmic Reticulum), suggesting that Spc2p may form a bridge between signal peptidase and the ER translocation machinery and thereby ensure co-translocational signal peptide cleavage (10).

The *SPC3* gene has been isolated using a suppressor approach similar to the analysis that yielded *SPC1* (11). The *SPC3* gene product, Spc3p, is 22% identical and 55% similar to SPC22/23 of the mammalian SPC (Table 1). The calculated molecular mass of the Spc3p polypeptide chain is 21 kDa, but it migrates on SDS-PAGEgels as a 25-kDa polypeptide. The difference between its calculated and apparent molecular masses is due to the presence of two *N*-linked glycans on the Spc3p polypeptide (see N-Glycosylation) (12). That Spc3p is a **glycoprotein** is consistent with the fact that it is homologous to SPC22/23. Furthermore, Spc3p is present in the partially purified SPC from yeast cells. Disruption of the *SPC3* gene is lethal to yeast, and *spc3* temperature-sensitive mutations inhibit cleavage of signal peptides at the nonpermissive temperature (11). The data thus indicate that two subunits, Sec11p and Spc3p, are required for ER signal peptidase activity in yeast cells.

The subunit compositions of the ER signal peptidases that have been purified from mammalian cells and partially purified from yeast cells are summarized in Table 1. The mammalian SPC contains five subunits, but the yeast SPC has four (12, 13). The major difference between these enzymes is the presence of two Sec11p-type subunits in the mammalian SPC (SPC18 and SPC21), accounting for the extra subunit. The presence of two Sec11p homologues appears to be unique to higher eukaryotic systems, because analysis of the complete sequence of the *S. cerevisiae* genome reveals only one Sec11p-type protein. The SPC purified from hen oviduct contains two subunits that correspond to the two essential subunits of the yeast SPC, namely, Sec11p and Spc3p (5). Why the purified avian SPC contains only two subunits is probably explained by differences in the

purification procedures used. Based therefore on genetic data in the yeast system and biochemical evidence from the avian system, Sec11p and Spc3p seem to form a two-subunit core enzyme that is responsible for the signal peptide cleavage reaction. The core enzyme from the ER is the only type I signal peptidase known to contain two polypeptide chains unrelated to each other. As discussed below, the mitochondrial type I signal peptidase also contains two subunits, but these subunits are homologous to each other.

1.2. Protein Fragmentation by ER Signal Peptidase

It appears that ER signal peptidase functions in the fragmentation of several abnormal membrane proteins. The internal site(s) cleaved are usually placed after a **transmembrane** segment that is oriented so that the *C*-terminus of the transmembrane segment is placed on the lumenal side of the ER membrane (14, 15). The types of proteins that are fragmented in this manner include a number of chimeric membrane proteins, a mutated membrane protein (the invariant chain of the **major histocompatibility** antigen), and an unassembled membrane protein subunit (the H2 subunit of the human asialoglycoprotein receptor). The presence of a small uncharged amino acid, particularly at the 2 1 position, seems to be important for cleavage at these internal sites, similar to the "rules" governing cleavage of *N*-terminal signal peptides. In addition, because the membrane proteins recognized by signal peptidase are abnormal, cleavage sites that are probably cryptic within proteins undergoing normal maturation may be exposed in an abnormal protein.

The subunit requirements for the fragmentation reaction are the same as for signal peptide cleavage. That is, both Sec11p and Spc3p are required for fragmentation, whereas Spc1p and Spc2p are not. The kinetics of the two processes, however, differ dramatically when monitored *in vivo*. Signal peptides can be cleaved while the protein cargo is still being synthesized on a ribosome (see Translation), meaning that signal peptide cleavage is often a co-translational process. On the other hand, protein fragmentation by signal peptidase occurs several minutes after the fully synthesized polypeptide chain enters the ER lumen (15). As the fragmentation process proceeds rather slowly, other maturation events, such as glycosylation, can precede fragmentation. This raises the possibility that recognition of a fragmentation site may be affected negatively by modifications present at or near a cleavage site or by folding events that bury a potential cleavage site within the structure of the protein.

2. Mitochondrial Type I Signal Peptidase

The mitochondrial type I signal peptidase cleaves the second signal located after the matrix targeting signal of proteins disposed to the mitochondrial inner membrane. Mitochondrial type I signal peptidase (named IMP, for inner membrane proteinase) is bound to the inner membrane of mitochondria and is oriented so that its catalytic site is located within the intermembrane space, which lies between the inner and outer mitochondrial membranes. The IMP contains two subunits, Imp1p and Imp2p, both of which are catalytic and bear the five distinct homology regions characteristic of type I signal peptidases (Fig. 2) (16, 17). Imp1p and Imp2p differ, however, in that Imp1p cleaves signal peptides containing the unconventional amino acid asparagine at the 2 1 position, whereas Imp2p cleaves conventional signal peptides containing a small uncharged residue at this position.

3. Catalytic Mechanism of ER and Mitochondrial Type I Signal Peptidase

The eubacterial type I signal peptidases appear to utilize a serine/lysine dyad for catalysis (1). Because serine and lysine residues in Imp1p and Imp2p align with the catalytic serine and lysine residues of their eubacterial counterparts, both subunits of the mitochondrial enzyme may contain a serine/lysine catalytic dyad (Fig. 2). In contrast, despite the functional relationship between ER and eubacterial type I signal peptidases, the Sec11p-type subunits contain a histidine residue that aligns to the catalytic lysine residue of leader peptidase (Fig. 2). From this, the following models are plausible but have not yet been tested: (i) ER signal peptidase utilizes a histidine residue for

catalysis, meaning that ER signal peptidase belongs to a subfamily that is functionally related to the type I enzymes. (ii) ER signal peptidase utilizes a serine/lysine dyad, and therefore current sequence alignments have failed to match catalytic residues in Sec11p to those present in the eubacterial enzymes. (iii) One or more catalytic residues are contained in Spc3p, the other essential subunit of ER signal peptidase.

Signal Peptide

Signal peptides are cis -acting sequences that effect the transport of polypeptide chains from the cytoplasm to a membrane-bound cellular compartment (see Protein Targeting, Intracellular). There are various targeting signals present in eukaryotic cells, and they exhibit much diversity at the primary structure level, accounting for the specificity required in routing proteins to different organelles. Many signal peptides are cleaved after targeting is achieved, including the type found in precursors targeted to the endoplasmic reticulum (ER) membrane and the **mitochondrial** inner membrane. This type of signal peptide is cleaved by enzymes resident within these two organelles that are related functionally to the type I signal peptidases present in eubacteria. Unlike their eubacterial counterparts, however, the ER and mitochondrial signal peptidases exist as multisubunit complexes. It has also been shown that defects in the signal peptide cleavage event are linked to some human diseases.

1. Structures of Signal Peptides

1.1. Endoplasmic Reticulum

Signal peptides of protein precursors targeted to the ER membrane are cleaved by ER signal peptidase. As depicted by the example shown in Figure 1, targeting to and translocation across the ER membrane of the yeast pheromone precursor prepro-a-factor results in cleavage of its signal peptide, thereby liberating the cargo pro-a-factor. The signal peptide of this precursor, like many others targeted to the ER, is placed at the *N*-terminus and has a typical length of 19 amino acid residues, although signals containing 40 or more residues have also been observed (1). Consistent with this variation in length, there is only modest conservation in the primary structures of various signal peptides, leading to the idea that only common structural features may be important to their function and recognition. Indeed, a general motif is apparent that consists of three regions: (i) a positively charged stretch of amino acids (the n-region), (ii) a central **hydrophobic** core (the h-region), followed by (iii) a polar amino acid stretch that includes the cleavage site (the c-region) (Fig. 2).

Figure 1. The signal peptide cleavage event. The diagram depicts the precursor prepro-a-factor in the process of being cleaved by ER signal peptidase, also termed signal peptidase complex (SPC). Shown here is the cotranslational cleavage of a signal peptide, although some precursors, including prepro-a-factor, can also be cleaved post-translationally.

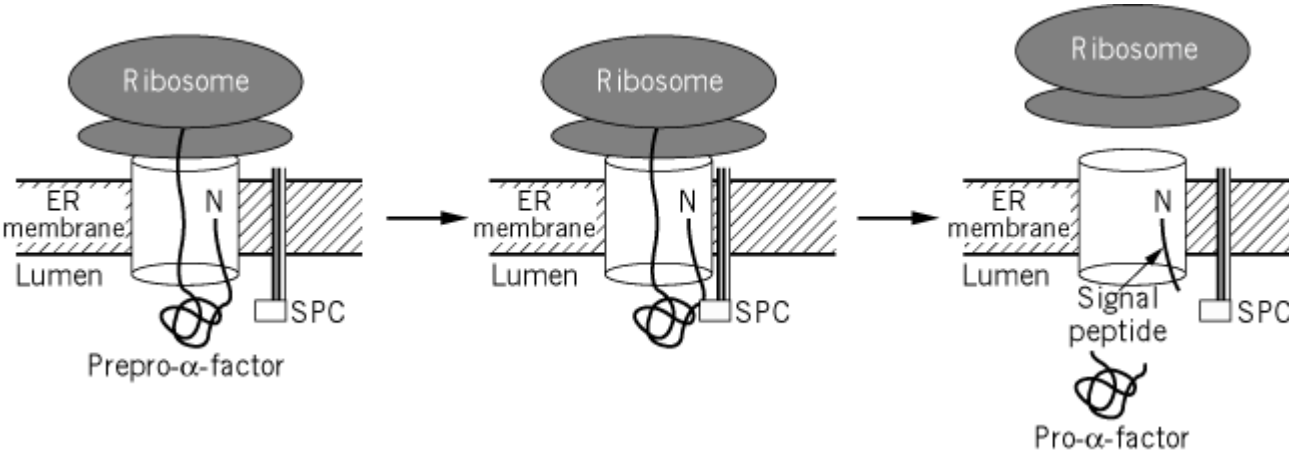

Figure 2. Sequence of a typical signal peptide. The amino acid sequence of the signal peptide from prepro-a-factor and the partial amino acid sequence of pro-a-factor (cargo) are depicted. The positions of the n-region, h-region, and c-regior of this typical signal peptide are indicated by arrows. Representative amino acids in the signal peptide (starting with 21) and the cargo (starting with 11) are indicated.

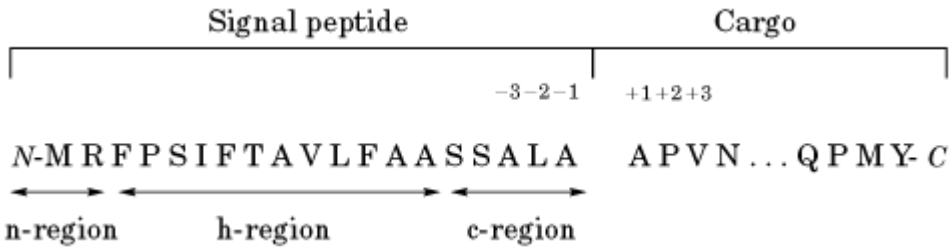

The length of the n-region can vary considerably, from only 1 residue to almost 20. The net charge of the n-region can also vary, but it is often found to be about 12, including the charge of the *N*-terminal amino group. The h-region has an average length of 12 residues and is hydrophobic. Mutagenesis studies have, in fact, revealed the importance of an uninterrupted stretch of uncharged amino acids within the h-region (2). The c-region exhibits less variation, the average length being 5 to 6 residues (1). At the *C*-terminus of the c-region is the cleavage site, which marks the *C*-terminal end of the signal peptide. Within the c-region, there is a requirement for small uncharged amino acids at the 21 and 23 positions from the cleavage site. Evidence also exists that one or more amino acid residues located within the *N*-terminal part of the cargo is important for determining the site of cleavage by signal peptidase (3).

1.2. Anchor Sequences of Membrane Proteins.

Signal peptides that function in targeting many membrane proteins to the ER membrane are often found internally within the polypeptide chain, and they are not cleaved after targeting in normal situations (4). These internal signal peptides have a dual role, in that they also help to anchor the polypeptide chain within the lipid bilayer, thus explaining the alias signal/anchor sequences. Signal/anchor sequences span the membrane in an N(cytoplasm)–C(lumen) orientation. Their structure is like that of cleavable signals, except that they have an extended hydrophobic region containing 18 or more amino acid residues that is necessary to span and become anchored to the lipid bilayer, and they may lack a signal-peptide cleavage site.

1.3. Mitochondria Inner Membrane

Signal peptides like those found in proteins targeted to the ER are also present in proteins of the mitochondrial inner membrane. Unlike ER targeting signals, however, these inner-membrane signals are not found at the *N*-terminus of the polypeptide chain. Instead, the *N*-terminal position is occupied by a matrix targeting signal that directs all or part of the polypeptide chain to the mitochondrial matrix, where cleavage by a metalloproteinase occurs. Upon cleavage of the matrix signal, the inner-membrane signal is then exposed at the *N*-terminus, where it targets the polypeptide chain to the mitochondrial inner membrane. The structure of the inner membrane signal is like its ER counterpart: It contains a hydrophobic h-region flanked on either side by polar (sometimes charged) sequences. Why the mitochondrial inner-membrane signal does not target proteins to the ER may be due to a dominance of the mitochondrial matrix signal over the second signal. One important difference between mitochondrial inner-membrane signals and other signal peptides cleaved by type I signal peptidases is that some inner-membrane signals contain the unconventional amino acid asparagine at the –1 position.

2. Signal Peptides in Disease

Proteolytic removal of *N*-terminal signal peptides is often required for proper maturation of the protein cargo. It therefore seems plausible that mutations inhibiting the cleavage event in humans might be responsible for some inherited diseases. There are at least two diseases that appear to result from the defective cleavage of specific signal peptides. A mutation causing substitution of the –1 alanine with threonine of the pre-pro-vasopressin signal peptide leads to inefficient cleavage by ER signal peptidase and is a possible cause for familial central diabetes insipidus (5). A mutation that results in a glycine to arginine substitution at the –3 position of human coagulation factor X inhibits cleavage by ER signal peptidase and is linked to a severe bleeding diathesis (6). A third inherited disease also appears to result from a signal peptide mutation. A change of cysteine to arginine at the –8 position of the pre-pro-parathyroid hormone alters the hydrophobic nature of the h-region (7). Because both targeting to the ER membrane and cleavage are inhibited by this mutation, it is unclear whether only one or both of these defects is responsible for the disease phenotype.

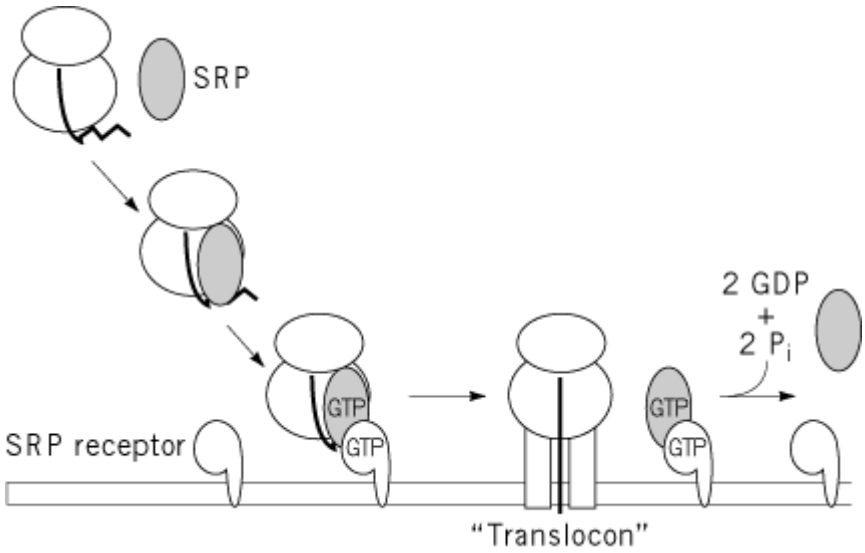
Signal Recognition Particle

The signal recognition particle (SRP) is a small cytoplasmic ribonucleoprotein that plays a crucial role in intracellular protein sorting (see Protein Targeting, Intracellular). In mammalian cells, essentially all proteins that are secreted or that are routed through the secretory and endocytic pathways depend on SRP to initiate their journey. All of these proteins contain either N-terminal **signal peptide sequences** or **transmembrane** regions that earmark them for translocation across, or integration into, the membrane of the endoplasmic reticulum (ER). SRP recognizes these sequences as soon as they emerge from ribosomes during translation (1, 2) (Fig. 1). The binding of SRP causes a transient inhibition of further polypeptide elongation, or "translation arrest" (3). Subsequently, SRP guides or "targets" the ribosome-bound nascent polypeptide chains to transport sites in the ER (4). There, the release of the nascent chains and their insertion into protein transport channels ("translocons") is facilitated by an interaction between SRP and the heterodimeric SRP receptor (SR)

(5-8). Once the nascent chain is inserted into the translocon, translation resumes, and the growing polypeptide chain is fed gradually into the lumen of the ER. Finally, SRP dissociates from the membrane, and the entire cycle is repeated. Although SRP initiates the protein sorting process by acting as an adaptor between the translation and transport machineries, it plays no direct role in transport per se. An SRP-based co-translational targeting mechanism presumably evolved in part to ensure that translocation begins before polypeptide chains are large enough to fold tightly and to become translocation-incompetent as a result.

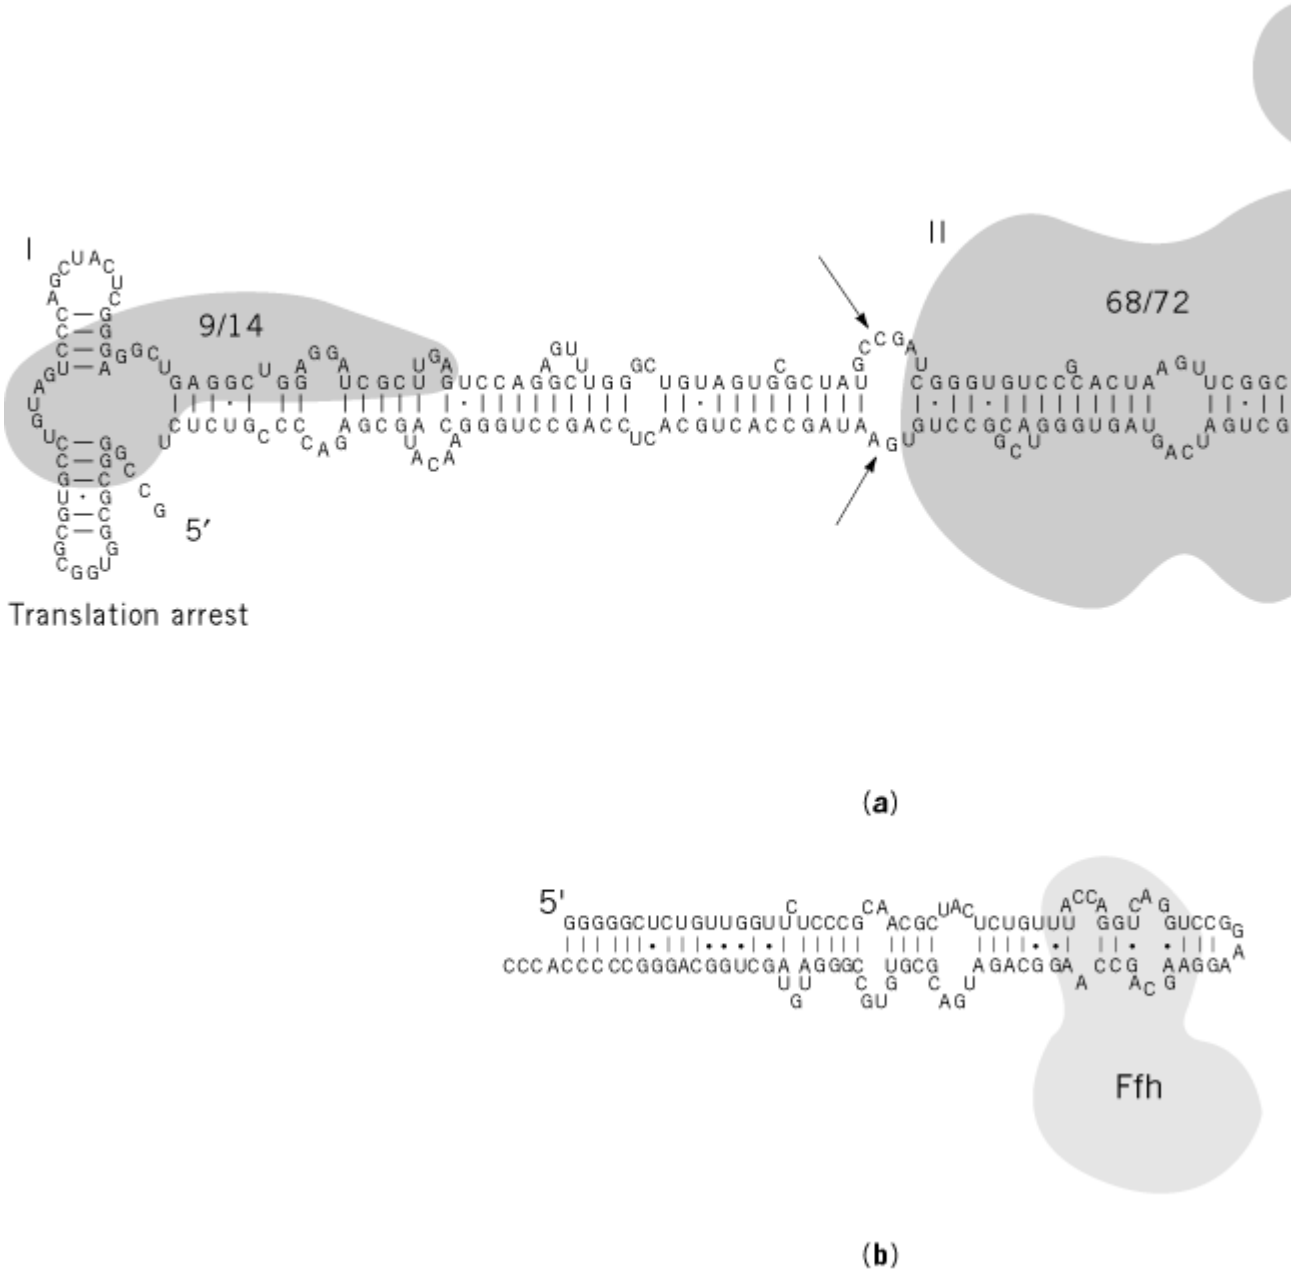
Figure 1. The SRP targeting cycle. As described in the text, SRP binds to targeting sequences as they are synthesized and then inhibits further polypeptide elongation ("translation arrest"). SRP-ribosome-nascent chain complexes then travel to the ER, where an interaction between SRP and the SRP receptor catalyzes the release of the nascent chain and its insertion into the translocon. Translation of the polypeptide chain resumes at that point. Finally, SRP dissociates from the membrane, and the cycle is repeated. GTP binds to both SRP54 and the SRP receptor a-subunit when SRP arrives at the ER membrane and facilitates a regulated release of the nascent chain. GTP hydrolysis at the end of the targeting cycle promotes dissociation of SRP from the ER membrane.



SRP was first identified in mammalian cells and purified on the basis of its ability to support the translocation of secreted proteins into small ER vesicles called "**microsomes.**" The particle is composed of six polypeptide chains of 9, 14, 19, 54, 68, and 72 kDa and a single, highly base-paired **RNA** of approximately 300 nucleotides (7SL RNA) (9, 10). The sedimentation coefficient of SRP in sucrose gradients (11 S) is much smaller than would be expected for a 300-kDa spherical particle (see Hydrodynamic Volume), suggesting that it has a rod-like shape. Examination of SRP by electron microscopy confirmed that it has an extended structure (11). The shape of SRP suggests that it may need to bridge a considerable distance in order to perform its various functions. Consistent with this notion, the translation arrest and signal recognition activities appear to reside at opposite ends of the particle (see text below and Fig. 2).

Figure 2. The structure of SRP. (**a**) Mammalian SRP has an elongated, rod-like structure. Treatment of the intact particle in cleavage of the 7SL RNA (arrows) and produces two discrete domains ("*Alu* domain" and "S domain"). The *Alu* doma mediates translation arrest. The S domain contains all of the other protein subunits. SRP54 binds to targeting signals and receptor. The region of SRP RNA contacted by each subunit was determined by chemical and enzymatic footprinting an facilitate comparison of SRP RNA molecules from different species, the RNA has also been divided into four structural encompassing the 5′ and 3′ ends, II is the main stem, and III and IV are the stem-loop structures that diverge from domai bacteria and Mycoplasma is a much smaller particle that contains a ~100 nucleotide RNA (4.5 S RNA) and a homologue that contains the protein binding site is very closely related in sequence and structure to the equivalent region in domain

from *Annu. Rev. Cell Biol.* **10**, Copyright 1994.)



Significant progress has been made in obtaining a detailed structural and functional map of SRP. The particle can be divided into two discrete domains by limited **nuclease** digestion (Fig. 2) (12). One domain, which contains both the 5′ and 3′ ends of the RNA and a heterodimer of the 9- and 14-kDa subunits (SRP9 / 14), is required for SRP to mediate translation arrest. This domain is called the "*Alu* domain" based on the homology of the RNA sequence with the *Alu* family of repetitive DNA elements (see Alu Sequences). X-ray crystallographic analysis has shown that SRP9 and SRP14 are structurally related and that together they form an **RNA-binding** surface comprised of a concave beta-sheet lined with positively charged amino acids (13). The second domain of SRP is called the "S domain" and contains the remainder of the polypeptide chains and RNA. The 54-kDa subunit (SRP54) binds to signal sequences and to SR (14-16). This protein can be separated into two segments by limited **proteolytic** digestion, one which contains a GTPase activity ("NG domain"), and one which contains an usually large number of methionine residues ("M domain") (17). The

function of the other three subunits is less well understood, and their amino acid sequences have proved uninformative. The 19-kDa subunit (SRP19) is required for efficient binding of SRP54 to 7SL RNA (18). The 68-kDa and 72-kDa subunits bind to the RNA as a heterodimer (SRP68 / 72), although only SRP68 clearly contacts the RNA directly (19). Based on a variety of data, SRP68 / 72 has been proposed to play a role in the interaction of SRP with SR or, alternatively, to influence the affinity of SRP54 for GDP (20, 21). Although the protein subunits bind to 7SL RNA with high affinity (22), SRP can be disassembled easily, and the purified components can be mixed together to reconstitute a completely functional particle (18).

SRP54 binds to signal sequences and transmembrane segments with a high degree of specificity. Many studies indicate that SRP54 recognizes the relatively long stretches of **hydrophobic** amino acids found in these targeting sequences. For example, SRP binds to the signal sequence of preprolactin efficiently, but the binding is abolished when the leucine residues are replaced by the hydrophilic amino acid analogue b-hydroxy leucine (1). Although signal sequence binding has been mapped to the M domain of SRP54 (17, 23, 24), the mechanism by which signal sequences are identified correctly on the basis of hydrophobicity in spite of considerable variation in amino acid sequence has not been fully elucidated. The crystal structure of the M domain reveals a hydrophobic groove formed by several alpha-helices that is likely to be the signal sequence-binding pocket (25). The groove is lined with methionine residues, which differ from other large hydrophobic amino acids in that their side chains can adopt several different energetically favorable conformations. It has been proposed that the "flexible" methionine residues impart a great deal of plasticity to the signal sequence-binding pocket and thereby allow SRP54 to bind to hydrophobic sequences that vary greatly in amino acid composition (26).

The binding and release of signal sequences by SRP is a highly regulated process that involves the participation of several GTPases. In addition to SRP54, both subunits of SR have GTPase activity (16, 27). The observation that the GTPase domains of SRP54 and the SR a-subunit (SRa) are highly **homologous** has led to the proposal that these two domains participate in a homotypic binding reaction (26). Prior to contact between the SR and the complex SRP-ribosome-nascent chain, the GTP binding sites of both SRP54 and SRa appear to be empty (17, 28). A concerted binding of GTP by SRP54 and SRa subsequently stabilizes the interaction between SRP and SR (Fig. 1), and a tight SRP-SR complex is formed in the presence of nonhydrolyzable GTP analogues (28, 29). The binding of GTP is coupled to release of the signal sequence and its insertion into the translocon. Finally, hydrolysis of GTP by both proteins facilitates dissociation of SRP from the membrane (29). Because SRP54 and SRa have a very low affinity for GDP (17, 30), they may return to a nucleotide-free state spontaneously. The SRP54-SRa "concerted switch" presumably serves to prevent premature release of the signal sequence and to ensure proper coupling between protein targeting and protein translocation. The SR b-subunit (SRb) GTPase may also play a role in coordinating the two processes, but this possibility remains to be explored.

1. The Evolution of SRP Structure and Function

Analysis of a large number of genomes has shown that SRP and SR are widely distributed in all three kingdoms of life. Indeed, it is likely that all cells contain SRP. During the course of evolution, however, the particle appears to have undergone several significant size reductions (21). Higher eukaryotes and archaea have SRP RNAs that are similar in size and structure, suggesting that the "primordial" 7SL RNA was approximately 300 nucleotides in length. Gram-Positive Bacteria, such as *Bacillus subtilis*, however, have SRP RNAs that lack a segment called domain III (Fig. 2). Many **gram-negative** organisms and Mycoplasmahave an even smaller SRP RNA of about 100 nucleotides ("4.5 S RNA") that corresponds to domain IV of 7SL RNA, but the remainder of the RNA seems to be missing altogether (Fig. 2). Despite considerable sequence divergence among the different SRP RNAs, all are predicted to be highly base-paired and all contain a highly conserved sequence motif in domain IV that mediates the attachment of SRP54 (31-33). The only exception is the unusually large 600-nucleotide scR1 RNA of *Saccharomyces cerevisiae* SRP, which cannot be aligned with other SRP RNAs using **secondary structure prediction** programs.

Like SRP RNA, SRP54 is also very highly conserved; homologues have been clearly identified in all organisms that have been examined. The *E. coli* SRP54 homologue (designated "Ffh" for fifty-four homologue) has been shown to form a complex with 4.5 S RNA *in vivo* (34). Purified *S. cerevisiae* SRP has subunits that are homologous to SRP19, SRP68, SRP72, and SRP14, a 7-kDa protein that may correspond to SRP9, and an additional 21-kDa protein not found in higher eukaryotes (35). Unlike SRP54, these proteins are not highly homologous to their mammalian counterparts. Significant evolutionary drift may explain why genes that encode these subunits have not been identified in the genomes of microorganisms in which their existence is predicted by the presence of a large SRP RNA.

SRa is also ubiquitous in nature, but SRb has been identified only in eukaryotes. Like its eukaryotic counterpart, the *E. coli* homologue of SRa ("FtsY") forms a tight complex with Ffh in the presence of the GMP analogue GMP-PNP (36), suggesting that interaction among components in the SRP targeting pathway is also conserved.

Despite the changes in SRP structure during evolution, recent studies indicate that the targeting function has been highly conserved. Bacterial SRP facilitates the transport of proteins across the cytoplasmic membrane, which is evolutionarily related to the eukaryotic ER and contains a homologous translocation machinery. Although it might seem surprising that an SRP that has lost most of its subunits would perform a similar function, a particle consisting of only mammalian SRP54 and *E. coli* 4.5 S RNA promotes protein translocation into microsomes under certain experimental conditions (37). Yeast and bacteria differ from mammalian cells, however, in that many proteins can use SRP-independent targeting pathways to gain access to the protein secretion pathway. Depletion of SRP in *S. cerevisiae* has a profound effect on the translocation of some proteins, but only a small effect on others (38). In that organism, SRP-dependence correlates well with the hydrophobicity of the signal sequence (39). In bacteria, even fewer proteins require SRP to traverse the cytoplasmic membrane. Inhibition of SRP function in *E. coli* blocks the insertion of many integral membrane proteins into the cytoplasmic membrane, but has essentially no effect on protein secretion (40, 41). SRP-independent targeting can occur post-translationally, and its prevalence in rapidly growing organisms suggests that they favor efficient export over the high degree of control afforded by SRP. **Molecular chaperones** such as hsp70 and the *E. coli* SecB protein (see Sec Mutants/Proteins) play an important role in SRP-independent targeting (42, 43), probably because they help to maintain proteins in a loosely folded, translocation-competent conformation.

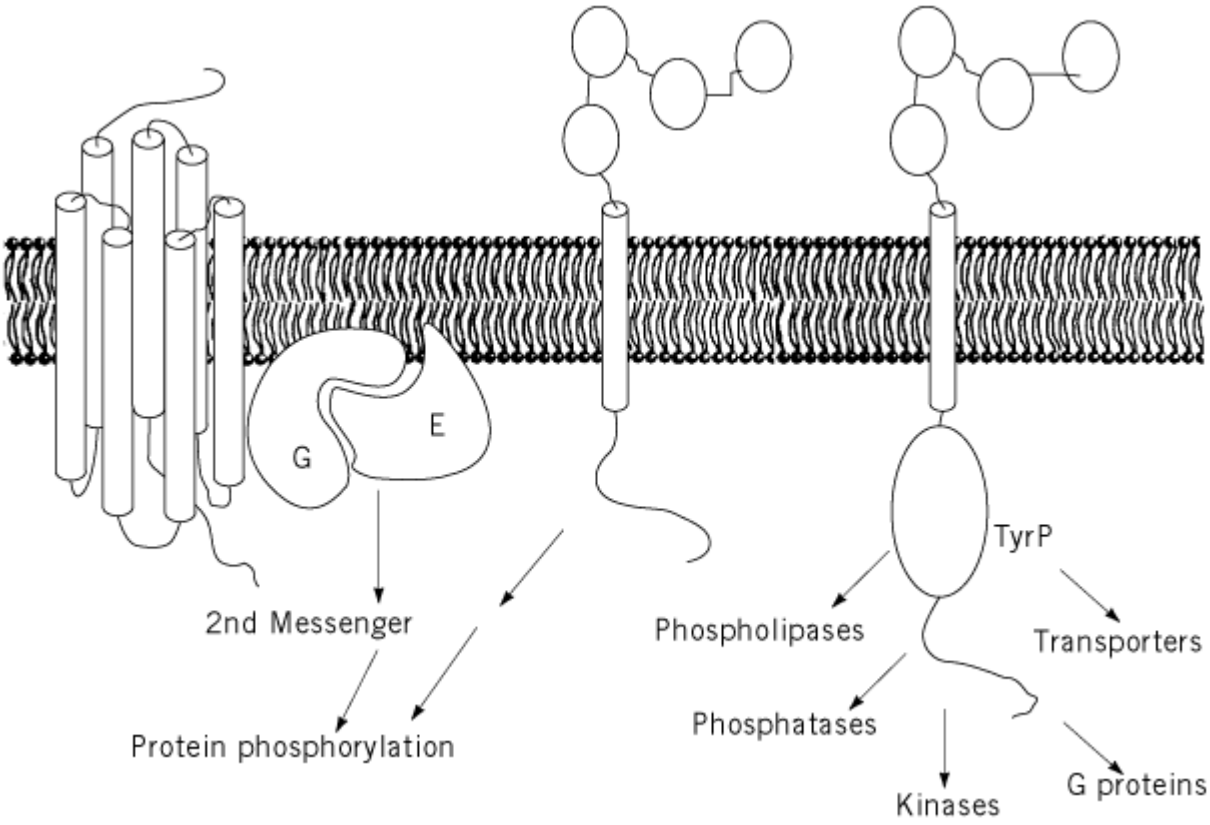
Signal Transduction

Signal transduction encompasses a wide variety of biochemical processes that mediate the response of a cell to extracellular stimuli. These processes have been most extensively characterized in endocrine and neuronal cells, whose primary function is cellular communication. On the other hand, signal transduction governs the regulation of metabolism, growth, differentiation, and death in virtually all cells. In simple terms, signal transduction from the plasma membrane can be organized into three discrete components: receptors, effectors, and targets. Cell-surface receptors are bifunctional proteins that traverse the plasma membrane, interacting with extracellular molecules and transmitting information to the cytoplasmic portion of the membrane. This information is conveyed by an intermediary system, referred to as an *effector*, that generates different types and combinations of intracellular messengers. Second messenger systems generate further specificity in the response and provide an amplification of the extracellular signal. Finally, these messages are received by their intracellular targets, which often are enzymes that may undergo covalent modifications, altering their activity. In reality, signal transduction systems are complex networks of convergent and divergent pathways, with cross-talk mechanisms and feedback loops, allowing different hormones to elicit their characteristic effects on cells.

The precise relay systems used by receptors can be predicted to some extent by their structure and distribution. In general, there are four types of receptors that generate signals (Fig. 1): (i) G-protein-coupled receptors (GPCRs); these receptors are known to interact with a family of GTP-binding transducing molecules, which in turn regulate the activities of a variety of membrane proteins. (ii) **Ion channels**; these receptors allow the flow into the cell of specific ions, and they are directly regulated by ligand binding. (iii) Receptors with intracellular enzyme activities; such receptors bind ligands on the extracellular surface, resulting in the activation of an intracellular enzyme activity, such as a protein kinase. These receptors typically have a single **transmembrane** region, along with large extracellular and intracellular **domains**; many of these proteins are receptors for growth factors. (iv) Receptors lacking enzyme activities; these receptors also contain a single transmembrane domain, typically bind to **cytokines**, and interact specifically with intracellular proteins that modulate a variety of processes.

Figure 1. Structures of receptors involved in signal transduction.



Dramatic advances have been made in our understanding of the molecular mechanisms involved in signal transduction. It appears that many of the important components in signaling pathways have been identified, and studies on their structure and function are likely to produce a fairly detailed picture of what role they play in governing cell growth, differentiation, and survival. However, we still have much to learn regarding the molecular mechanisms that ensure specificity in signal transduction, especially regarding the temporal and spatial relationships of different pathways to each other, as well as the intrinsic limitations on signaling, and ways in which pathways cross-communicate within cells.

The details of signal transduction are described in G-protein-coupled receptors; Second messengers; Heterotrimeric G proteins; Phosphorylation; Phospholipases; Protein kinases A and C; Calcium signaling; Tyrosine kinase receptors; Ion channel receptors; MAP kinases; Phosphatidylinositol kinases; Receptors linked to tyrosine kinases; JAK/STAT signaling.

Silencer, Gene

A silencer is a cis-acting regulatory sequence that lowers the rate of initiation of transcription of eukaryotic genes. Silencer elements have been identified from a variety of organisms. The first and best-characterized silencer was identified near the promoters for mating-type genes at the HML and HMR loci in the yeast *Saccharomyces cerevisiae* (1). The yeast-mating-type genes, a and a, at HML and HMR are transcriptionally silent and become active only when they replace the mating-type allele present at the MAT locus during the process known as mating-type switching. The silenced mating-type genes require E regulatory sites known as HMLE and HMRE, respectively. Molecular

analyses have identified a DNA element at the E regulatory site, called the silencer, capable of repressing transcription of a target **promoter** in *cis*. This element comprises binding sites for regulatory proteins. Interactions of the silencer element with these proteins are necessary and sufficient for forming the repressive chromatin structure (2, 3). This element was named a silencer because of its similarity to transcriptional enhancers, despite their opposite effects on transcription: (i) it functions in either orientation; (ii) it exerts a silencing effect relatively independently of its position with respect to its target promoter; (iii) it is capable of repressing promoters other than its normal target. Subsequently, however, the term silencer has been also used to describe negatively acting regulatory elements that do not conform to the criteria used in the original definition (4).

Silent Mutation

A silent mutation is a mutation that changes a **codon** into another codon that specifies the same amino acid because of the degeneracy of the genetic code. By definition, a silent mutation can only be a base substitution mutation. If a silent mutation comes to fixation in a population or subpopulation, it is called a synonymous substitution.

Silver Stain

Silver stains are used for the visualization of proteins and nucleic acids on polyacrylamide gels and blotting matrices. They have achieved widespread application because of their great sensitivity (1, 2). Most silver stains can detect proteins and nucleic acids in the nanogram range. This level of detection surpasses by 10- to 100-fold those that can be achieved with the commonly used nonfluorescent organic stains, such as the Coomassie brilliant blue stains for proteins. Silver stains are also employed in applications that previously employed **radiolabeling** because they can achieve comparable levels of detection without the environmental and economic concerns associated with the use of radioisotopes (1). The ability of silver stains to detect proteins and nucleic acids depends on a differential oxidation-reduction potential that is contingent on the presence of proteins or nucleic acids in the gels or membranes. This differential oxidation-reduction potential in the gel or

membrane permits selective reduction of ionic silver to the metallic state, resulting in the visualization or detection of proteins or nucleic acids (3). For example, if a site containing a protein or a nucleic acid has a higher reducing potential than the surrounding gel or matrix, the protein will be positively stained. Conversely, if the protein-occupied site has a lower reducing potential than the surrounding gel or matrix, the protein will appear to be negatively stained. It is possible to alter these relative oxidation-reduction potentials by changing the chemistry of the staining procedure so that proteins separated on polyacrylamide gels stain either negatively or positively (4).

1. Silver Stain Protocols

There are three basic silver-staining protocols (3): (1) the diamine or ammoniacal stains, (2) the non-diamine chemical reduction stains, and (3) the silver stains based on photo-development.

The diamine or ammoniacal stains maintain silver ion concentrations at a low level by the formation of silver diamine complexes with ammonium hydroxide. Image development is initiated by acidification of the ammoniacal silver solution, usually with citric acid in the presence of formaldehyde. The citric acid lowers the concentration of free ammonium ions. This results in the liberation of silver ions for reduction by formaldehyde to metallic silver, modulated by the presence of nucleic acid or protein. The diamine or ammoniacal silver stains have proved particularly useful for the staining of proteins separated on polyacrylamide gels that are thicker than 1 mm.

Nondiamine chemical reduction stains use silver nitrate to provide silver ions for reaction with protein and nucleic acid sites under acidic conditions. Image development is initiated by placing the gel in an alkaline solution, utilizing sodium carbonate and/or hydroxide and other bases to maintain the alkaline pH, while the silver ions are selectively reduced to metallic silver with formaldehyde. The formic acid produced by the oxidation of formaldehyde is buffered by the sodium carbonate. This type of stain is relatively rapid and simple to perform. The nondiamine stains generally work best with gels 1 mm or less in thickness.

Photodevelopment silver stains depend on the energy from photons of light to reduce ionic silver to metallic. The presence of proteins or nucleic acids in the gel or on the membrane enhance the photoreduction of ionic to metallic silver in gels impregnated with silver chloride. Photodevelopment stains are very rapid and simple. They can permit the visualization of protein patterns within 10 minutes after an electrophoresis separation. However, current photodevelopment protocols lack the sensitivity of the other silver-staining methods.

It is also possible to combine these protocols. For example, by combining photodevelopment with a nondiamine stain, a protocol was developed to detect proteins and nucleic acids on membranes. This combined protocol relies on the formation of silver halide precipitates in gels or on membranes, and it employs light to initiate the formation of silver nucleation centers on the silver halide crystals, followed by the use of a chemical development to deposit additional silver on the silver nucleation centers. This protocol provides a silver stain that is rapid and sensitive. It can detect proteins and nucleic acids in the nanogram range on thin membranes in under 15 minutes (5).

2. Quantitative Applications of Silver Stains

In silver staining, the accumulation of metallic silver generally displays a reproducible but limited linear relationship between the density of silver in the developed image and the concentration of protein or nucleic acid on the gel or membrane ((2),45). For most proteins, the linear portion of this relationship extends over a range of concentrations from 0.02 to 2 ng/mm^2. Above 2 ng/mm^2, saturation generally occurs. Saturation can be recognized by the occurrence of bands or spots with centers that are less intensely stained than the regions near the edges. As the staining-response curve for each protein species may vary, quantitative comparisons between different gels should be limited to bands or spots of the same protein on each gel. For example, the actin spot on one gel should be

compared only with an actin spot on another gel and not with a transferrin spot. Furthermore, gels to be compared should be run under similar conditions (eg, percentage acrylamide, stacking gel specifications), as migration distance may affect band or spot compression which, in turn, may influence the staining reactions.

The specific silver-staining curve displayed by each protein species is not limited to silver detection methods; similar unique responses have also been demonstrated with Coomassie blue and with the commonly used Lowry protein assay. These protein-specific staining curves arise because of the unique collection of reactive staining groups contained in each type of protein. By studying amino acid homopolymers, individual amino acids, and peptides of known sequence, it has been determined that the principal reactive groups are the free amino groups and the sulfur atoms (see Cysteine (Cys, C) and Methionine (Met, M) residues) contained by the proteins (5, 6). The importance of the basic amino acids has been further substantiated by studies of the relationship between the specific amino acid contents of proteins and their ability to stain with silver. Studies of silver-staining reactions of nucleic acids and their precursors indicate that the **purine** bases may be important. However, because individual nucleoside and nucleotide derivatives stain poorly, silver stains may require cooperative effects between several functional groups on the same molecule to form complexes with the silver ions prior to their reduction to metallic silver (5). Despite complexities due to the variations in the staining response and to the difficulties in controlling staining end points, it has been possible to compare proteins found in one gel with those in another gel quantitatively, using computerized image analysis and densitometry. The identification of proteins that occur in the same amounts in different samples has proved helpful because these proteins can serve as normalization standards (7). The identities of silver-stained proteins may also be determined directly from the stained gels by the use of **mass spectroscopy** (8).

3. Historical Perspective

Silver staining was introduced in 1979 as a general protein detection method for proteins separated by polyacrylamide gel electrophoresis (PAGE) (1, 2). However, the observation that silver nitrate, the main ingredient of silver stains, can blacken organic substances was reported as early as the twelfth century by one of the great alchemists, Albert the Great (Albertus Magnus), the eldest son of Count von Bollstädt. Although there were numerous experiments between the twelfth and nineteenth centuries concerning the ability of silver nitrate to stain organic materials, ranging from artistic applications to the development of "invisible inks," the first modern science application is credited to Krause. He used it, in 1844, to stain fresh tissue for microscopic analysis (9). Soon thereafter, Golgi and Cajal revolutionized our understanding of the central nervous system by their analysis of sections of the human brain, stained with silver (10, 11). Whether the use of silver to enhance histological imaging was initiated by the development of silver-based photography is not known, but there was clearly a cross-fertilization of ideas. These early efforts with silver staining occurred just as the revolution of photographic imaging was beginning. Although Scheele recognized, as early as 1777, that the blackening of silver chloride crystals by light was caused by the formation of metallic silver, it wasn't until 1839 that William Fox Talbot utilized this ability of light to reduce ionic silver to metallic as the basis of the photographic process (12). By 1862, experiments to enhance the photographic process resulted in the introduction of organic reducing agents to help with the development of images that were initiated by exposure of silver halides to light. Cajal participated in these early experiments to enhance photographic techniques, and some of the protocols were clearly adapted to his development of histological stains. One of the main compounds that Cajal used for developing his photographic images and later for his histological stains, formaldehyde, is currently used in many of the silver-stain protocols for the visualization of proteins and nucleic acids separated by gel electrophoresis.

13. J. M. Eder (1945) *History of Photography*, trans. E. Eptean, Columbia University Press, New York, pp. 22–24. This book provides considerable historic information on the use of silver in image formation, particularly the early history. Although it is concerned primarily with photography, many of the principles apply to the silver staining of proteins and nucleic acids on gels.

Simulated Annealing

Simulated annealing is a general procedure for finding a solution to an optimization problem (1, 2). Nuclear magnetic resonance (NMR) experiments can be used to produce constraints on the possible **secondary structures** and tertiary structures of a biological macromolecule. The experimental observations usually include nuclear Overhauser effects (NOEs), which provide information about the distances between pairs of nuclei of the molecule, and three-bond coupling constants, which can provide estimates of dihedral angles. Constraints may also be produced by experiments that define the orientation of chemical shift tensors or dipolar interactions within the molecular framework. Determination of the three-dimensional structure consists of finding a conformation that is consistent with all constraints. This is a kind of optimization problem; simulated annealing thus provides a method for finding tertiary structures that are consistent with known constraints.

The use of simulated annealing for determination of tertiary structure is based on the type of empirical molecular force field that is usually used in molecular modeling. Such a force field is a collection of mathematical expressions that attempt to account for the energies associated with the deformation of chemical bonds, nonbonded van der Waals interactions between atoms of a molecule, and electrostatic interactions between charged groups of the structure. Molecular modeling programs usually contain a facility for conformational energy minimization. This feature uses an algorithm to adjust the positions of the atoms of a molecule so that the total energy, computed using the force field of the program, is at a minimum.

The simplest approach to finding a molecular conformation consistent with a set of NMR constraints is to include a term in the molecular force field that adds nothing to the total energy of the molecule when a given constraint is satisfied, but adds a large, unfavorable energy contribution when that constraint is violated. With such terms present, the process of energy minimization will tend to drive the molecule toward a conformation in which all constraints are satisfied. The defect in this procedure is that, although all energy minimization algorithms are capable of finding a minimum energy, no way exists to guarantee that it will be the conformation of lowest energy. Significant energy maxima (barriers) may separate local energy minima from the global minimum, and these must be overcome before the conformation that satisfies all constraints represented in the force field is identified. Simulated annealing is useful at this stage of optimization problem.

If the mathematical expressions in a force field can be differentiated, it is possible to calculate the force experienced by any atom of the molecule for any specific conformation. By employing Newton's second law ($F = ma$), one can calculate the acceleration of each atom and, therefore, the change of position of an atom with time. Using a molecular force field in conjunction with the solution of a family of equations that embody the second law is the basis for molecular dynamics simulations.

The method of simulated annealing is based conceptually on the behavior of materials as they undergo the transition from the liquid state to the solid. If a sample starts at high temperature and is cooled rapidly, a polycrystalline or amorphous material may be obtained. This disordered sample represents a material that is not is its lowest free energy state. If the liquid is cooled slowly (annealed), a single crystal can often be formed. In the crystal, molecules are ordered in a way that represents the conformation of lowest possible energy, that is, the global minimum energy.

A direct proportionality exists between the kinetic energy of a system of moving particles and the temperature of the system. To find the global energy minimum for a system that includes NMR constraints, a molecular dynamics simulation is run in which the system is subjected to a schedule of temperature changes. The system is held at a high temperature for a period of time and then cooled slowly. It is hoped that during the high temperature phase, there will be sufficient motions of the atoms of the structure that barriers separating local minima from the global minimum are overcome. The cooling phase of the calculation potentially “anneals” the system into the conformation representing the global energy minimum—presumably the conformation in which experimentally derived constraints are best satisfied. In practice, several cycles of heating and cooling (annealing) are used, and the best schedule for these must often be worked out by trial-and-error. (See also Distance Geometry.)

Sines

Distinctive families of both short and long interspersed DNA elements, *SINEs*, and Lines, respectively, are repeated within genomes, in addition to the abundant primate family of short repeats called Alu sequences. SINEs are typically shorter than 500 bp and occur on the order of hundreds to thousands of times within each genome. Each family of SINEs comprises a set of segments that are nonidentical but closely similar in length and sequence. The members of any given family are dispersed throughout the genome. SINEs are detected by probe hybridization using **radiolabeled** probes. They are found between **genes**, inside introns and within satellite DNA, but never in regions coding for protein. SINEs are the major component of dispersed repetitive DNA in all mammalian genomes. Most SINEs contain an intragenic **RNA polymerase** III **promoter** that initiates transcription at the 5′ end of the repeated DNA sequence and which, it has been proposed, facilitates the transposition and amplification of these sequences by an RNA-intermediate mechanism.

The term SINEs is restricted to short **retroposons**, which have internal RNA polymerase III promoter sites in a region derived from a structural RNA (usually a transfer RNA), that are amplified via cDNA intermediates and then enter the host genome. There is considerable evidence that these DNA transposable elements result from self-primed **reverse transcription** of their RNA transcripts with subsequent DNA integration. In contrast to retroviruses and retrotransposons, SINEs do not encode the enzymes, such as reverse transcriptases, required for their amplification. Thus it is presumed that they borrow these enzymes from other sources. In the human genome, however, two families of mobile elements have been identified which have the sequence characteristics of transposons that move directly from DNA to DNA, rather than requiring the reverse transcription of an RNA intermediate. One type of element comprises a coding region for a transposase flanked by short terminal repeats of 31 or 32 bp (1).

Alu sequences are a type of SINE but, in contrast to Alu sequences, the other SINEs are not confined to primates. SINEs have been characterized in the genomes of many organisms, including mammals and other vertebrates (*Xenopus borealis*), salmonid fishes, in many **plants**, in the nematode *Caenorhabditis elegans*, in several filamentous **fungi** of the genus *Podospora*, and in Dictyostelium*discoideum*. A SINE of 470 bp, occurring in 100 copies per haploid genome, isolated and characterized in *Magnaporthe grisea*, the rice blast fungus, as an insertion element within an inverted repeat transposon, shows the typical features of a mammalian SINE. At its 5′ end, a secondary structural analysis reveals a tRNA-related region that could fold into a tRNA-like cloverleaf structure (2). DANA, the first SINE isolated from *Danio rerio*, the zebrafish, is unique in its substructure of distinct cassettes. In contrast to classical SINE elements, it appears to have been assembled by insertions of short sequences into a progenitor tRNA-derived element. Once associated with each other, these subunits are amplified as a new transposable element with such success that DANA-related sequences form 10% of the modern zebrafish genome (3). Three different kinds of SINEs were isolated and characterized in *Octopus vulgaris*. Two of them seem to have been derived from $tRNA^{Arg}$, and the third is from a tRNA that could not be identified because of sequence divergence from the original tRNA sequence (4).

A family of SINEs described in the hamster genome constitutes approximately 0.3 to 0.5% of the genome. The repeats are about 300 bp long and are highly divergent (differing by up to 30% from the **consensus sequence**). In contrast to the usual SINEs, the repeats are not flanked by short direct repeats and lack sequences corresponding to the RNA polymerase III promoter (5). Other SINEs had already been found highly homologous to tRNA genes, which suggested that many SINE mammalian families are amplified tRNA pseudogenes (6).

Single Particle Reconstruction

Many biological macromolecules are very difficult to crystallize and thus are not amenable for electron or X-ray crystallography. Fortunately, techniques have been developed over the past two decades for image averaging and three-dimensional reconstruction of individual macromolecules with low or no symmetry. Presently, the attainable resolution for reconstructing these molecules in 3-D is 1.5–4 nm. Radiation damage of biological material remains the principal problem, since low-dose imaging requires averaging of thousands of individual images in order to boost the specimen signal to a level sufficient to allow construction of an atomic model. In theory, low-dose images provide enough information about the position and orientation of individual macromolecules or assemblies to provide atomic resolution if the molecular weight is greater than ~10^5dal and more than 10,000 particles are averaged (1). However, the quality of the best images as yet does not match theoretical calculations, which means that the molecular weight limit and the number of averaged particles required for atomic resolution may need to be an order of magnitude higher. The limitation in resolution comes about because of inaccuracies in determining the five orientation parameters needed to align low-dose images that are inherently noisy. Larger molecules or assemblies can be more accurately aligned simply because more orientational information is produced by the imaging process. The poor image contrast at high resolution of ice-embedded specimens needs to be overcome before atomic resolution can be challenged. This low contrast is thought to be caused by blurring of the image due to charging of the specimen by the electron beam and to beam-induced specimen movement (2).

Computer analysis of single-particle images was developed initially from methods to align individual images of macromolecules based upon cross-correlation functions versus a common reference. For 2-D images, three alignment parameters must be determined, a rotational orientation angle and two translational vectors. These can be determined from a rotational cross-correlation function (performed on the modulus of the Fourier transform of the images, since this function is translationally invariant) and from a subsequent translational cross-correlation function, respectively (3). Typically a second alignment procedure is performed using the averaged structure from the first alignment as a reference in the second. A second major development in single-particle methods was the use of correspondence analysis (a type of multivariate statistical analysis) to determine the most significant factors by which a collection of images varies (4). Typically images of identical molecules will cluster into groups that differ in their orientations, and if the orientation of each group can be determined, a 3-D reconstruction can be calculated using established computer algorithms such as the filtered backprojection. The strategy for collecting different tilted views of a specimen varies, but one common approach is the “random conical tilt” procedure (5). In this example, two electron micrographs are recorded of an area containing dozens or hundreds of molecules. The first micrograph is a low-dose exposure with the specimen grid tilted at some predetermined angle; the second exposure is a higher-dose exposure of the untilted grid. The higher-dose image is used to

identify individual particles and the orientations using cross-correlation alignment and correspondence analysis. From this information, the same particles can be identified in the low-dose, high-tilt exposure, and their orientations can be calculated knowing the orientations of the untilted views, the known tilt angle, and the orientation of the tilt axis. The 3-D structure of the molecule can then be calculated from the various images of the molecules identified in the low-dose image.

Although performed at relatively low resolution, single-particle approaches have provided significant insight into the operation of large macromolecular complexes. The structure and function of ribosomes have been explored (6-8), which has also produced the sites of association of the 30S and 50S subunits (9) and a direct visualization of tRNAs bound to the 70S ribosome (10, 11). Other large complexes studied in 3-D are the NADH–dehydrogenase complex (see Dehydrogenase (12)), the calcium release channel/ryanodine receptor (13, 14), the nuclear pore complex (15), and hemoglobins (16, 17). Not all structural characterizations need to be performed in 3-D as evidenced by the ligand and subunit locations found in 2-D in photosystem I and II (18, 19).

Single-Stranded DNA Binding Protein

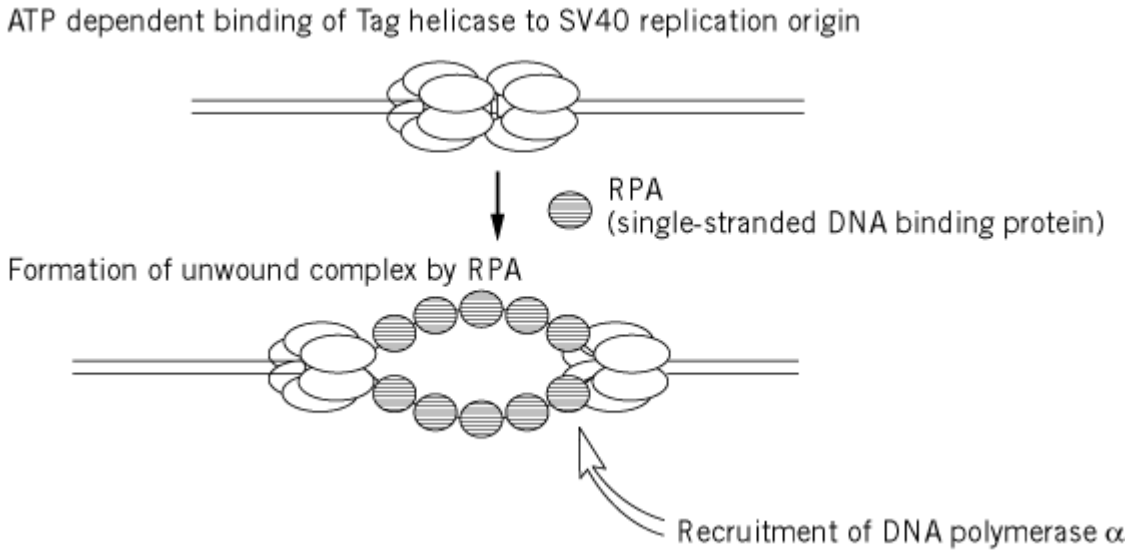
During several **DNA** metabolic reactions, double-stranded DNA is converted to single-stranded DNA temporarily by the actions of DNA helicase or **exonucleases**. The exposure of a single-stranded DNA region is necessary for enzymes or the complementary DNA strand to interact with the region, but this also produces regions that form unfavorable **secondary structures** and are susceptible to attack by **nucleases**. To avoid such problems and make the enzyme reactions efficient, all organisms have single-stranded DNA binding proteins (SSBs) that preferentially bind only single-

stranded DNA. Due to their involvement in vast tasks, they appear to be multifunctional and one of the major players in various cellular processes.

The first discovery of SSB was **bacteriophage** T4 gene32 protein. Affinity chromatography of T4 phage-infected cell lysate on single-stranded DNA cellulose successfully identified a protein that bound strongly and preferentially to single-stranded DNA (1). Genetic studies had shown that the gene product was essential for recombination and DNA replication, indicating the importance of this type of **DNA-binding protein** in these processes. Following this discovery, many SSBs were identified from various systems, eg, from *Escherichia coli*, bacteriophages, and **viruses**. Although there are almost no similarities in their protein structures, they commonly bind to single-stranded DNA with more than 10^3 times greater affinity than to duplex DNA and have a crucial rule in DNA metabolism. In general, their binding to single-stranded DNA is **cooperative**; this means that each molecule prefers to bind adjacent to another molecule along the DNA strand. As a result, many molecules of SSB coat DNA and make it an active target for many enzymes (2). This aspect of SSBs sometimes induces the **denaturation** of duplex DNA under physiological conditions, so that they were initially called unwinding or **helix-destabilizing proteins**. This function is distinguishable from DNA helicase action, since the denaturation of duplex DNA by SSB does not require ATP hydrolysis. SSB interacts with the backbone of single-stranded DNA rather than the bases. Thus, the binding is almost nonspecific for the DNA sequence, and the bound DNA is extended. The extended conformation facilitates base pairing of complementary strands and increases the rate of **DNA polymerase** migration; this function explains the requirement of SSB for replication and recombination.

SSBs have been sought from eukaryotic cells, and several single-stranded DNA-specific binding proteins were identified, but none of them were obviously demonstrated to be involved in DNA metabolism. The essential cellular SSB was first identified from human cell extracts as a component essential for *in vitro* SV40 virus DNA replication and named RPA (replication protein A, also called RFA or HSSB; for a review, see (3)). During the replication reaction, RPA interacts with the viral-coded initiator protein, large T Antigen, and in collaboration with its helicase activity forms a replication origin unwound complex (Fig. 1). Another interaction between RPA and DNA polymerase a/primase facilitates the recruitment of this polymerase on the unwound DNA and initiates DNA synthesis. In the following DNA elongation step, RPA stimulates DNA polymerases through either specific or nonspecific interactions (4). Therefore, RPA has critical roles throughout this viral DNA replication and will have the same function during chromosomal DNA replication. Related to this point, studies by immunostaining with anti-RPA **antibodies** have revealed the tight interaction of RPA with the replication apparatus. RPA is localized in the nucleus, exists in the replication foci prior to the initiation of DNA synthesis, and remains there during **S phase** (5).

Figure 1. Unwinding of the SV40 virus replication origin by SV40 T-antigen and RPA.



Unlike prokaryotic SSBs, which are monomers or oligomers of identical subunits, human RPA has three heterogeneous subunits of 70, 32, and 14 kDa. This oligomeric structure is conserved among eukaryotic SSBs, so homologous SSBs in heterotrimeric complexes have been identified in all tested eukaryotes from yeast to human (3). Since eukaryotes have several specific cellular processes, such as the mitotic cell cycle, DNA damage signaling, chromatin formation, and transcription activation, this complex structure of RPA might reflect its extra roles in these processes, in addition to DNA metabolism. For example, RPA interacts directly with nucleotide excision repair proteins XPA, XPG, and XPF (xeroderma pigmentosa group A, G, and F proteins) and plays crucial roles in damage recognition and cleavage (6). Another type of RPA-interacting protein includes transcription activators such as GAL4, VP16 (7), and tumor suppressor p53 protein (8), suggesting the involvement of RPA in transcription regulation. Indeed, RPA has been isolated as a transcription factor for several genes in yeast (9). In addition to protein–protein interactions, the 32k-Da subunit of RPA is **phosphorylated** in a cell-cycle-dependent manner and by DNA damage. An up-shift of the mobility of the 32-kDa subunit in gel electrophoresis was observed upon the phosphorylation that takes place efficiently in the presence of single-stranded DNA (10). Although the phosphorylation of RPA has been studied intensively, no direct evidence to connect it with the modulation of RPA functions could be obtained. However, if we consider this specific phosphorylation, the localization of RPA in nuclei, and its interaction with several important factors for various cellular processes, we see that eukaryotic single-stranded DNA-binding proteins are not merely DNA metabolic proteins, but will also play a role in coordinating DNA metabolism with several cellular processes.

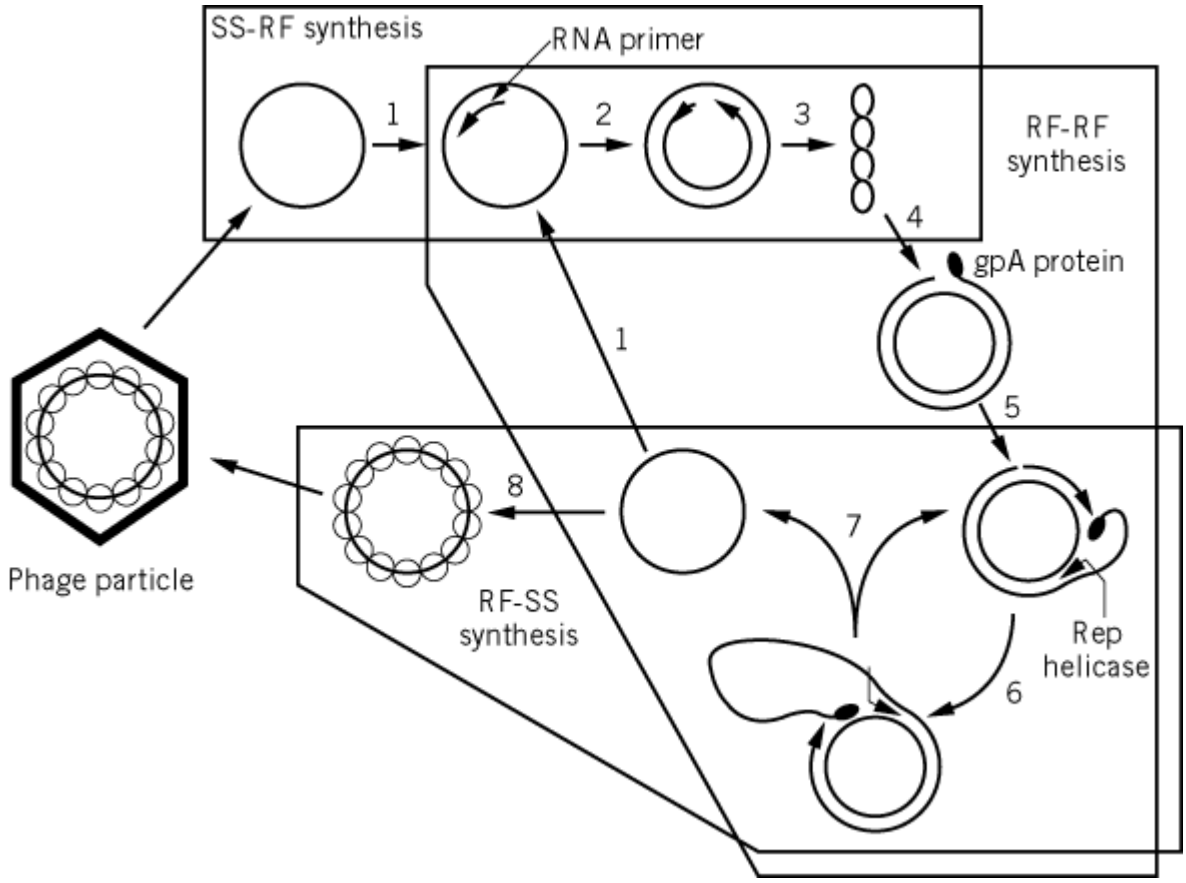
Single-Stranded DNA Replication

Certain small **bacteriophages** contain a circular, single-stranded **DNA** (ssDNA) as genome. Replication of the single-stranded DNA has been characterized extensively for two groups of *Escherichia coli* phage, filamentous phages represented by M13 and spherical phages represented by fX174 (1). Their replication can be divided into three steps (Fig.1);(1) conversion of the ssDNA genome to a double-stranded form, called the replicative form (RF); (2) multiplication of RF DNA by rolling circle replication; and (3) generation of ssDNA genome for packaging into phage from the RF DNA. Thus, replication of the ssDNA genome depends on the synthesis by DNA polymerase of a complementary strand in a sophisticated manner.

Figure 1. Scheme for single-stranded DNA replication of *E. coli* phage fx174. Three stages of the replication, SS → RF, RF → RF and RF → SS synthesis, are indicated by boxes (see text for details).



1. Conversion of ssDNA into Double-Stranded RF Form

Immediately after infection by the ssDNA genome (the plus strand), synthesis of the complementary strand (the minus strand) begins using host enzymes. As all the phage mRNA is synthesized using

the minus strand as template strand, no phage messenger RNA is synthesized at this stage. Synthesis of the minus strand is primed using an RNA primer made at a specific site on the plus strand, called minus *ori* or single-strand *ori* (sso), (step 1 in Fig. 1). Then the host elongation proteins synthesize the minus strand from the primer terminus. Three different modes of priming are known: by **RNA polymerase** (2), by DnaG primase (3), and by a seven-component *primosome* (4). A general feature of minus *ori* is an extensive region of **secondary structure**, which probably stabilizes the recognition sequences for the primer synthesis against melting by single-stranded DNA binding protein (SSB). After completion of the minus-strand synthesis, the initial product is a duplex circular DNA (RFII) consisting of an intact viral DNA and a nearly full-length linear complementary DNA plus the RNA primer (step 2 in Fig. 1). Then DNA polymerase removes the RNA primer and fills the resultant gap. Subsequently, the nick is sealed by DNA Ligase, and the duplex DNA is converted to the superhelical form (RFI) by the action of DNA gyrase (step 3 in Fig. 1) (see DNA Topology). The RFI DNA serves as a template for RNA transcription, and the production of phage proteins begins.

2. Rolling Circle Replication of RF DNA

Multiplication of RF DNA is initiated by introducing a nick by an initiator **nuclease** encoded in the phage genome at a particular site in the plus strand (plus *ori* or double-strand *ori*, dso) (step 4 in Fig. 1). The free 3′-OH end at the nick site serves as a primer and is elongated by DNA polymerase III holoenzyme, as the host Rep DNA helicase peels off the existing plus strand (step 5 in Fig. 1). When synthesis of the new plus strand reaches the plus *ori* (step 6 in Fig. 1), the nick is introduced again at the junction of the old and newly synthesized plus strand, to form linear ssDNA of one unit length (step 7 in Fig.1). The linear form is then converted into the circular form, a further reaction catalyzed by the initiator nuclease. Thus, one round of the rolling circular replication produces one new plus strand, and it is used as a template to form another RF DNA.

The molecular mechanism of action of the initiator nuclease of ssDNA phage has been best characterized for that of fX174, gpA (product of gene A) (5). The gpA nuclease recognizes and binds to a specific sequence in the plus *ori* and introduces a nick in a nearby sequence. Then the gpA protein covalently attaches to the 5′-P end at the nick by a phospho bond to a **tyrosine residue**, and the energy liberated by the cleavage of the DNA strand is stored in the protein–DNA complex (see step 4 in Fig. 1). GpA has affinity for the host Rep DNA helicase and recruits it to the nicked site. Furthermore, the interaction locks the gpA protein to the template throughout the replication (see steps 5 and 6 in Fig. 1). When synthesis of the new plus strand reaches the regenerated plus *ori*, the gpA nuclease introduces a second cleavage in the plus strand, and the 5′-P group of the old strand attached to the gpA protein is transferred to the newly created 3′-OH end, to produce circular ssDNA. At the same time, the new 5′-P end is transferred to the Tyr residue of the gpA protein, and the next cycle of the rolling circle replication begins (see step 7 in Fig. 1). The fX174 circle is synthesized in about 10 sec, and 20 or more ssDNA circles are released from a single rolling circle intermediate. It should be noted that **supercoiling** of the template is required for the first cleavage, whereas the second cleavage occurs on the relaxed template. An explanation for this difference may be that the supercoiling is required for specific binding of the gpA protein to the template and that, since the gpA is already bound to the DNA, recognition of the nicking site is sufficient for the second cleavage.

Covalent linkage between the initiator nuclease and DNA strand is not observed for filamentous phage, and the mechanism by which the energy liberated by the cleavage is stored is not clear in this case. Their rolling circle replication is limited to a single round.

3. Generation of ssDNA Genome for Packaging

Accumulation of supercoiled RF DNA provides the many copies of the template for transcription of **genes** encoding phage structural proteins and phage proteins necessary for the assembly of phage particle. When a certain amount of such proteins has accumulated, synthesis of the minus strand (SS

to RF synthesis) is inhibited, and the accumulated single-stranded plus (viral) DNA is packaged into the phage particles (step 8 in Fig. 1). This switch from RF synthesis to phage assembly depends on accumulation of a specific phage gene product. For example, gp5 protein of filamentous phage blocks the minus strand synthesis by coating the displaced viral strand, to form the nucleoprotein precursors for packaging.

4. Similar Replication Mode of Plasmids of Gram-Positive Bacteria

Single-stranded DNA phage have not been reported for Gram-positive bacteria. However, many small plasmids of Gram-positive bacteria follow in essential detail the pattern and strategy used by ssDNA phage of Gram-negative bacteria for multiplication of RF DNA (6). These plasmids encode an initiator protein that introduces a site-specific nick and produce a single-stranded circle as replication intermediate. The ssDNA is converted to the double-stranded form by the host enzymes, as is the case for the SS to RF conversion of ssDNA phages. The similarity in the amino acid sequences of the initiator endonucleases of the two groups and of their recognition sequences clearly indicates that they have evolved from a common ancestor (7).

Site-Directed Mutagenesis

Site-directed mutagenesis is a method used to alter the **nucleotide sequence** of cloned **DNA** at a pre-defined position or *site*. This method is one form of *in vitro* mutagenesis, because it involves a series of biochemical steps using purified reagents and is performed on **cloned** DNA in a small test tube. Site-directed mutagenesis can be used to change only a single base pair, to change a few base pairs, or to create more extensive sequence changes, such as deletions and insertions. The ability to create site-directed mutations in cloned DNA largely became possible with the advent of methods to synthesize oligonucleotides, short segments of DNA, to create the desired DNA changes (see DNA Synthesis). Although methods using chemical modification of DNA can create site-directed mutations in cloned DNA (see Mutagenesis), site-directed mutagenesis is most easily and precisely accomplished using an oligonucleotide; hence, the method is often termed *oligonucleotide-directed mutagenesis*. This entry describes the basic principles of oligonucleotide-based site-directed mutagenesis and highlights a number of procedures currently in use.

1. Site-Directed Mutagenesis is a Powerful Tool for Studying Nucleic Acids and Proteins

The ability to alter cloned DNA at will provided molecular biologists with a powerful tool with which to study the role of cloned DNA in cellular processes. Prior to the development of site-directed mutagenesis, biologists' only source of DNA variants was from rare spontaneous mutations that occurred randomly *in vivo* or from imprecise methods for *in vitro* chemical mutagenesis of cloned DNA. In contrast, oligonucleotide-based site-directed mutagenesis changes the sequence of a DNA fragment precisely as designed by the molecular biologist. Cloned genes can be studied in a biological system by comparing the function of the normal gene to variants containing site-directed mutations.

This revolutionary technique is not limited to the study of **genes**. Because the flow of genetic information is normally DNA → RNA → protein (according to the central dogma), site-directed mutagenesis of a cloned DNA fragment can also be used to study **RNA** and proteins. For example, site-directed mutagenesis has been used to uncover nucleotides in messenger RNA precursors that direct the RNA splicing of **introns** (1), to characterize amino-acid residues critical for protein–protein interactions (2), and to probe the **catalytic** mechanism of enzymes (3). There are many additional examples where site-directed mutagenesis has helped to solve basic problems of biology, and it has also been applied in the biotechnology industry to generate novel therapeutics.

Since the first report of oligonucleotide-based site-directed mutagenesis (4) by M. Smith and colleagues in 1978, site-directed mutagenesis has developed into a number of related methodologies that are now part of every molecular biologist's toolbox. Kits containing the reagents and protocols needed to conduct site-directed mutagenesis are commercially available and make the technique relatively straightforward to perform. In 1993, the method was recognized as being truly revolutionary by the award of the Nobel Prize for Chemistry to Smith for his "fundamental contributions to the establishment of oligonucleotide-based, site-directed mutagenesis and its development for protein studies" (5).

2. Two General Methods for Oligonucleotide-based Site-directed Mutagenesis

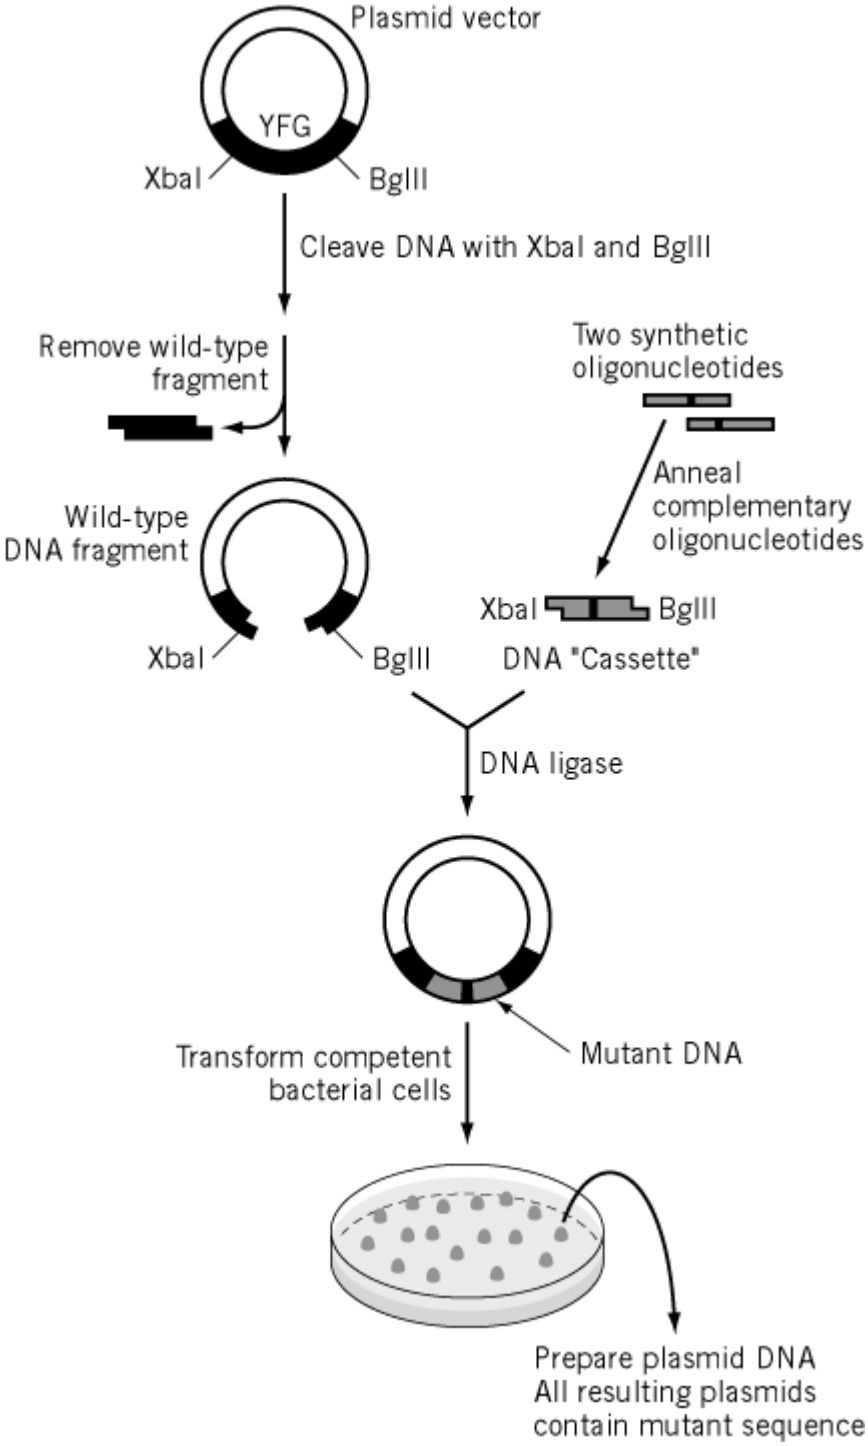
Current procedures for oligonucleotide-based site-directed mutagenesis can be grouped into two categories: (1) cassette mutagenesis and (2) enzymatic extension of a mutagenic oligonucleotide annealed to a DNA template. Cassette mutagenesis is, in practice, the simpler of the two approaches. As described in the next section, cassette mutagenesis is a derivative of total gene synthesis (6) in which a gene is constructed by ligating a series of synthetic oligonucleotides.

Site-directed mutagenesis by enzymatic extension of mutagenic oligonucleotides stemmed from research in the 1960s and 1970s on DNA polymerization *in vitro*, the genetics of bacteriophage wX174, and the preparation of synthetic oligonucleotides. Researchers were studying the ability of the enzyme **DNA polymerase I** from *Escherichia coli* to synthesize DNA in a test tube using an oligonucleotide primer hybridized to a single-stranded DNA template from wX174 **bacteriophage** (7). These experiments demonstrated that a single-stranded DNA template could be converted to a double-stranded molecule *in vitro* . Importantly, the DNA polymerase needed a short oligonucleotide primer to initiate DNA synthesis. Additional experiments on wX174 studied the ability of restriction fragments from wild-type wX174 annealed to a mutant form of wX174 to create wild-type phage by a process called *marker rescue* (8). These experiments, and research on oligonucleotide synthesis, led to the first site-directed mutagenesis experiment, where an oligonucleotide with only 12 nucleotides was used to change a single G to A in the wX174 DNA. Since the initial experiments on wX174 (4, 9), site-directed mutagenesis protocols have been developed for DNA fragments cloned into a variety of **vectors**. These methods can be subdivided further, depending on the particular DNA polymerase used. Early methods used DNA polymerases derived from *E. coli* or bacteriophage T4 or T7. Recent procedures have been developed for DNA polymerases from thermostable bacteria and the polymerase chain reaction (**PCR**). The details of these methodologies are discussed below.

2.1. Synthetic DNA Cassettes

In cassette mutagenesis (see Fig. 1), a restriction fragment from the cloned DNA of interest is replaced by another restriction fragment containing the desired nucleotide changes (10-12). The process begins by digesting the cloned DNA with one or two restriction enzymes to release a DNA fragment containing the (wild-type) sequence to be changed. The new (mutant) sequence is constructed from two synthetic, complementary single-stranded oligonucleotides, which are first mixed together in a buffered solution so they hybridize, thereby forming a duplex DNA molecule, but with cohesive, **sticky ends** to hybridize with restriction sites of the vector. To position the synthetic fragment back into the vector, the ends of the synthetic DNA must be the same as that in the wild-type fragment. The remainder of the cloned DNA in the vector is mixed with the synthetic fragment, and the two are ligated into place by the action of the enzyme DNA Ligasefrom bacteriophage T4. Following the joining of the two DNA molecules, DNA from the ligation reaction is introduced into competent *E. coli* cells, and recombinant molecules containing the desired mutation are selected.

Figure 1. Cassette mutagenesis. A plasmid containing a clone of your favorite gene (YFG; black segment) is cleaved with two restriction enzymes, eg, XbaI and BglII, each of which has only one restriction site in the entire plasmid. The reaction mixture is separated by agarose gel electrophoresis, and the larger fragment is purified from the gel. Two single-stranded oligonucleotides are synthesized by automated DNA synthesis. The sequences of the oligonucleotides are complementary to each other and differ from the wild-type sequence at only a single position (black stripe) containing the desired changes. The oligonucleotides are mixed in a solution that promotes hybridization of the two strands by virtue of their complementary sequences. The ends of the duplex fragment are single-stranded, cohesive, sticky ends that join with XbaI and BglII sites. The DNA cassette is mixed with the isolated fragment, and the two molecules are covalently joined by the action of T4 DNA ligase. The ligated DNA is transformed into *E. coli*, and drug-resistant colonies are selected. Plasmid DNA is prepared from individual bacterial colonies. Since the two linear fragments themselves cannot transform *E. coli*, all colonies contain plasmids with the mutant sequence.



Cassette mutagenesis generally results in nearly 100% of the resulting clones having the desired new (mutant) sequence. The difficulty with this method is that unique, conveniently spaced restriction endonuclease recognition sites to excise a small cassette in the desired place are often not present. In this case, one can turn to enzymatic extension methods.

2.2. Enzymatic Extension of a Mutagenic Oligonucleotide

The principle and end result of site-directed mutagenesis by oligonucleotide extension are similar to those of cassette mutagenesis: An oligonucleotide encoding the desired new DNA sequence is inserted into a cloned DNA fragment. In the basic method (Fig. 2), a short oligonucleotide, typically 20 to 40 nucleotides in length, is hybridized to its complementary sequence in a circular, single-

stranded, wild-type DNA template. The sequence of the oligonucleotide is designed so that the new (mutant) sequence is in the middle of the oligonucleotide and flanked by wild-type sequences on the ends. Upon annealing the oligonucleotide to the template DNA, the wild-type sequences within the oligonucleotide are perfectly complementary to the template DNA, but the mutant sequences are mismatched. The wild-type sequences need to be long enough so the oligonucleotide will form a stable duplex with the template DNA. Next, a DNA polymerase and nucleotide precursors (dNTPs) are added to synthesize the remainder of the complementary strand using the mutagenic oligonucleotide as a primer for DNA synthesis. In the past, derivatives of *E. coli* DNA polymerase were used in site-directed mutagenesis. Recently, DNA polymerases from bacteriophage T4 or T7 have replaced the *E. coli* enzyme. These DNA polymerases are more processive than the *E. coli* enzyme (see DNA Polymerase Sliding Clamps) and do not displace or proofread the mutagenic oligonucleotide, thereby improving the frequency of the mutant plasmids obtained.

Figure 2. Site-directed mutagenesis by enzymatic extension of a mutagenic oligonucleotide. A DNA fragment encoding YFG is cloned into a plasmid vector. Single-stranded DNA is prepared by one of several methods. A synthetic oligonucleotide is annealed to the DNA template. The sequence is perfectly complementary to the wild-type sequence of the template, except for the mismatched nucleotides (black dot) that contain the mutant DNA sequence. The remainder of the complementary strand is synthesized by a DNA polymerase using the mutagenic oligonucleotide as a primer. Upon completing the circle, the ends of the newly synthesized DNA strand are joined by DNA ligase, forming a heteroduplex of two covalently closed DNA molecules. One strand contains the mutant sequence, and the other contains the wild-type sequence. The heteroduplex DNA is introduced into competent *E. coli* cells. Drug-resistant colonies that contain plasmid DNA are selected. The two strands separate by DNA replication in the bacterial cells. Plasmid DNA is isolated from the bacteria and sequenced to identify clones with the desired mutation.

Once synthesis of the complementary DNA strand has proceeded completely around the circular template, the ends of the newly synthesized strand are joined enzymatically by T4 DNA ligase. In this way, a single-stranded DNA molecule is converted into a double-stranded molecule, where all sequences will be wild-type except the region containing the mismatched nucleotides. The resulting double-stranded *heteroduplex* DNA molecule, composed of one wild-type strand and one mutant strand, is introduced into competent *E. coli* cells, where the two strands segregate by DNA replication. Theoretically, each colony should contain both wild-type and mutant plasmids; in practice, however, only one sequence is often obtained from a colony due to mismatch repair prior to replication of the two strands. Generally, the frequency of mutant plasmids is lower than that of the wild type. This is most likely due to incomplete DNA replication *in vitro*. A number of selection or screening methods have been developed to enrich for plasmids with the desired mutation (see below).

3. Modifications and Improvements to Site-directed Mutagenesis Methods

The first oligonucleotide-directed mutagenesis experiments were performed using DNA from the single-stranded bacteriophage wX174. Because wX174 is not a convenient cloning vector, mutagenesis of cloned DNA fragments was performed using plasmids such as **pBR322** (13) or vectors derived from the filamentous M13 phage (14-17) and fd (18). The phage vectors offered an easy way to prepare a single-stranded DNA template. However, protocols were also developed for oligonucleotide-directed mutagenesis in double-stranded plasmid vectors (19, 20). In addition, **phagemid** vectors (21, 22) were developed that normally are double-stranded but can be induced to produce single-stranded phage-like DNA. These vectors facilitated template preparation for site-directed mutagenesis.

The early methods for oligonucleotide-directed mutagenesis resulted in a low frequency of plasmids with the desired mutation. Often, the fraction of mutants was less than 1 out of 100 plasmids. As discussed above, this was probably due to a variety of technical and biological problems. A number of methods were introduced to make it easier to find a plasmid carrying the desired mutant sequence. For some experiments, mutant molecules can be identified if the mutation happens to create or destroy a restriction endonuclease site. In a more general method, the double-stranded heteroduplex molecules were purified by centrifugation (17, 23). A simpler procedure was to make the mutagenic oligonucleotide **radioactive** and to use it as a hybridization probe (24). Under certain stringent conditions, the probe would hybridize with only mutant molecules and not with wild-type molecules. Other high-frequency mutagenesis methods used two oligonucleotide primers (25, 26); one was the mutagenesis oligonucleotide, and the other was positioned upstream. The second primer helped to complete synthesis of the complementary strand.

A powerful adaptation of the original procedure (27), developed by Kunkel in 1985, yielded mutants with efficiencies greater than 50%. First, the DNA vector was grown in a *dut*$^-$, *ung*$^-$ strain of *E. coli* that causes uracil to be incorporated into the DNA template. Single-stranded template was prepared and annealed with the mutagenic oligonucleotide; the complementary strand was synthesized using standard deoxyribonucleotide triphosphates. In this way, the mutant strand contains thymine and the wild-type strand contains uracil. The heteroduplex molecule is introduced into an *ung*$^+$ *E. coli* strain, where the wild-type strand is destroyed by uracil deglycosylase (the product of the *ung* gene) cleavage of sites containing uracil.

Several other methods are available that increase the efficiency of mutagenesis. One method incorporates thiophosphoryl nucleotides into the newly synthesized strand, allowing the wild-type strand to be converted into the mutant sequence *in vitro* (28). Yet another method uses a second primer that alters a restriction site or corrects a mutation in a drug-resistance marker (29, 30). In this

way, plasmids containing the desired mutation can be enriched by drug selection or restriction enzyme digestion. By most of these improved methods, the fraction of mutant molecules obtained was often greater than 50%. Once these highly efficient methods were established, mutants were identified simply by randomly picking one or two plasmids and subjecting them to DNA sequencing. Finally, the ability to perform multiple mutagenesis experiments in parallel has been addressed by the development of **solid-phase** mutagenesis methods (31). By this approach, the creation of site-directed mutants can be automated.

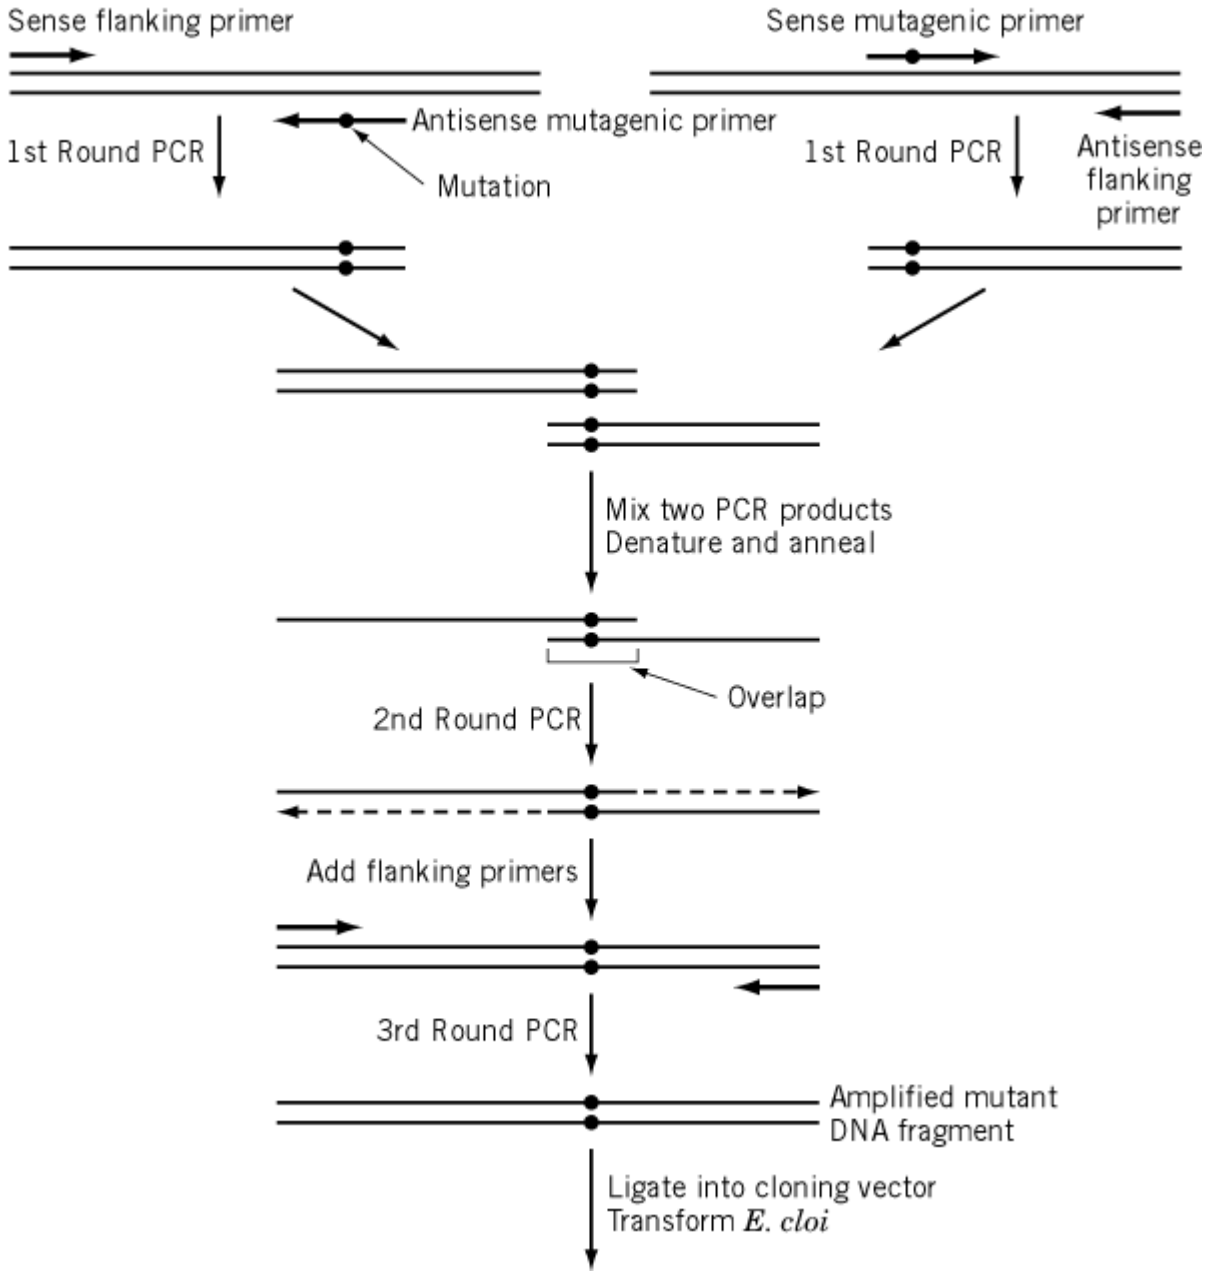
4. Oligonucleotide-Directed Mutagenesis using the Polymerase Chain Reaction

New approaches to molecular biology problems are constantly being developed; they are usually simpler, cheaper, and more efficient. Soon after the polymerase chain reaction (PCR) was reported (32), it was realized that it could be adapted to create site-directed mutants (reviewed in (33)). The PCR procedure was developed to amplify a segment of DNA from a minute amount of a DNA sample. The basic method uses two oligonucleotides as primers for DNA synthesis from a DNA template (see **PCR**). The advantage of using PCR for site-directed mutagenesis stems from its simplicity and speed. The disadvantage of PCR-based methods is the possibility of undesired mutations due to the error-prone nature of certain thermostable DNA polymerases. Today, there are dozens of variations for PCR-based site-directed mutagenesis. Several representative approaches are described here.

4.1. Overlap-extension Method

The *overlap-extension* method requires four oligonucleotide primers and three separate amplification reactions (34, 35). Two complementary mutagenic primers induce the mutation into the desired sequence of DNA, and two flanking primers amplify the mutant fragment and facilitate cloning of the PCR fragment into a suitable vector. By this approach (Fig. 3), a variety of mutations can be created, such as single base-pair changes, deletions, and insertions. First, two separate PCR reactions are set up in parallel. One reaction has the “sense” mutant primer and an “anti-sense” flanking primer 3′ to the mutation site. The other reaction contains the anti-sense mutant primer and the sense flanking primer 5′ to the mutation site. The two amplified fragments contain mutations at the 5′ or 3′ terminus, respectively. In the second round of amplification, the two fragments from the first round of PCR are purified, then used as templates for amplification using only the flanking primers. After amplification, the mutation is contained within the target DNA segment, which is cloned into appropriate vectors for DNA sequencing and subsequent functional studies.

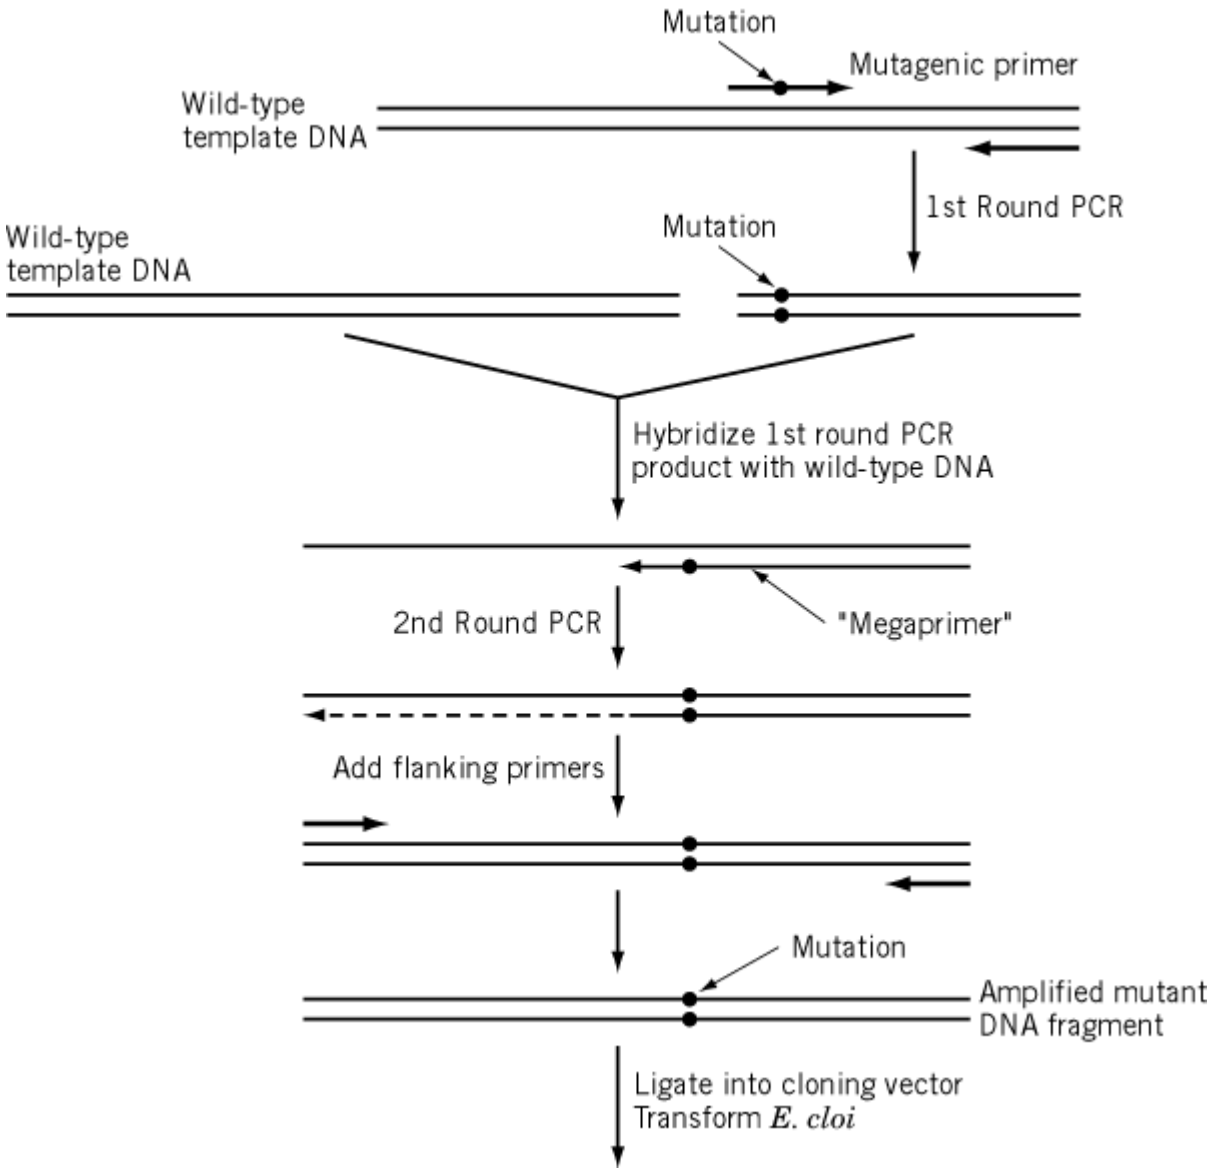
Figure 3. Site-directed mutagenesis by overlap-extension PCR. The two first rounds of PCR produced two overlapping fragments of the original template, both containing the mutation within the overlap region. These two PCR products are annealed and then subjected to a second round of PCR to generate the entire fragment with the mutation. The flanking primers contain the restriction sites for ligating the fragment back into the original vector.



4.2. Megaprimer Method

The *megaprimer* method uses only a single mutagenic primer to create mutations in the target template (36-38) (Fig. 4). In the first round of amplification, the wild-type template is amplified using either a sense or anti-sense mutagenic primer and an appropriate flanking primer. The amplified product is then used in a second round of PCR with wild-type template and the other flanking primer to create a fragment of the same length as the original target DNA containing the desired mutation. The key to this method is that the amplified product from the first round of PCR is used as a primer in the second round of PCR. Compared to the four-primer method, this procedure requires only a single mutagenic primer and yields more of the full-length product. This is probably due to the instability of the 10- to 20-basepair overlap between the two mutant templates during the second round of amplification when using the four-primer method. In the megaprimer method, the overlap between the template and mutagenic strands is more extensive.

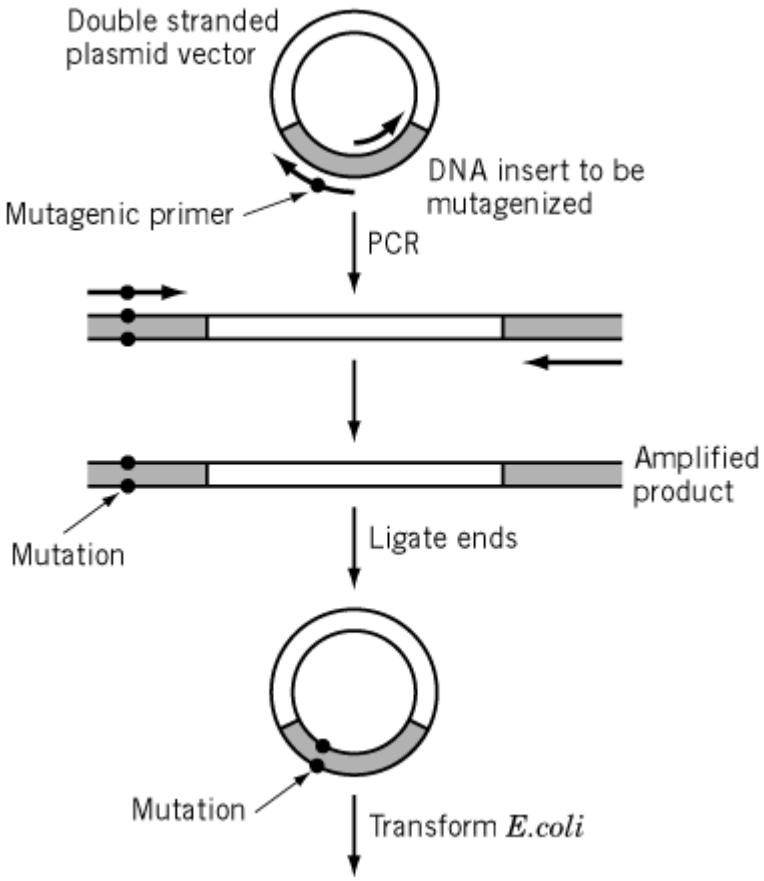
Figure 4. Site-directed mutagenesis by the megaprimer PCR method. The first round of PCR is used to make a fragment of the template DNA containing the desired mutation. This "megaprimer" is then hybridized to the wild-type template DNA, and a second round of PCR is carried out, to generate the entire molecule with the mutation. The flanking primers contain the restriction sites for cloning the fragment back into the vector.



4.3. Inverse PCR

A third approach, termed *inverse PCR*, uses only two primers to create the desired mutation (39) (Fig. 5). The key feature of this method is that in making the mutation, the entire vector is amplified. The two primers, one containing the desired mutation, extend on the circular template DNA in opposite directions. Amplification ultimately yields a linear, double-stranded DNA molecule containing the mutation at one end. Following amplification, the ends are ligated, and the resulting circular DNA molecule is transformed into *E. coli*. There are a number of variations of this method that improve the efficiency of mutagenesis (reviewed in 33).

Figure 5. Site-directed mutagenesis by inverse PCR. The vector is cleaved by a restriction enzyme at a single site, close to the site to be mutated. Two primers from the two ends of the linearized molecule, one containing the desired mutation, are used to amplify the linear molecule and produce molecules with the mutation. After ligating the ends to regenerate a circular molecule, the vector is used to transform *E. coli*.



The major disadvantage of PCR-based *in vitro* mutagenesis methods is the lower fidelity of Taq DNA polymerase in DNA polymerization than the phage polymerases used in the traditional methods. This can result in undesired mutations being incorporated into the amplified DNA fragment due to nucleotide misincorporation. If this happens in an early round of amplification, the undesired mutation will be present in a majority of cloned fragments. One simple way to alleviate this problem is to use fewer rounds of DNA amplification and conditions for the highest fidelity of DNA polymerization (40). Alternatively, the use of Pfu or Vent thermal stable polymerases, which are less error-prone than Taq polymerase, will result in fewer undesired mutations. Regardless of which method is used, the DNA sequence of the entire amplified fragment should be determined to ensure that only the desired changes have been made.

5. Evolution of Site-Directed Mutagenesis Applications

Initially, site-directed mutations were constructed one at a time, using a single oligonucleotide. However, multiple mutations can be generated using a *degenerate* oligonucleotide containing a mixture of related sequences. For example, an oligonucleotide that was degenerate at three adjacent positions was used to generate a series of proteins containing different amino acids at a selected position (11). *Doped* oligonucleotides are synthesized by spiking each nucleotide monomer with a small amount of the other three monomers. The resulting oligonucleotide will direct a variety of mutations over a defined window of the wild-type sequence (41, 42). The use of degenerate oligonucleotides is particularly powerful when used in conjunction with a genetic screen or selection (43, 44). A particularly powerful method for protein evolution, termed *DNA shuffling*, uses the polymerase chain reaction to generate proteins with novel or improved properties (45, 46).

6. Summary

In the 20 years since its original report, site-directed mutagenesis has evolved into a standard tool

with which to evaluate gene function. It can be accomplished by a variety of methods, many of which are now commercially available in kit form. Given the ease and speed by which site-directed mutagenesis experiments can be performed, the challenge has shifted from simply being able to construct a mutant to designing good experiments.

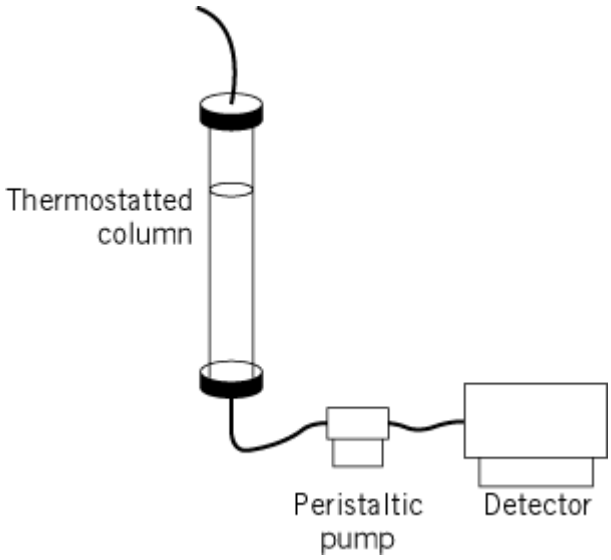
Size Exclusion Chromatography

Molecular biologists have recently become increasingly interested in purification and biochemical analysis of **gene** products that function in a broad range of biological systems. Size exclusion chromatography (SEC) provides a method for both analytical and preparative-scale separations of biological macromolecules . Historically, SEC has been referred to as gel filtration chromatography when applied to the separation of proteins in aqueous (native) conditions (1). The most common uses of SEC are for determination of the size of macromolecules and for their purification. A less appreciated, but very powerful, application of the method is for the analysis of the interactions of macromolecules, to determine their stoichiometries and energetics. In SEC, solutes are separated on the basis of their size. In the case of proteins, the molecular size or hydrodynamic volume is usually specified in terms of the Stokes Radius(1). SEC differs from other types of chromatography, such as ion-exchange or affinity chromatography, in that the analytes are not separated on the basis of their differential interaction with the column resin. In fact, an inherent assumption of gel filtration chromatography is that there are no interactions between the protein solute and the stationary phase. This entry provides descriptions of the SEC technique and of methods of analysis of SEC data.

The basic experimental apparatus for standard SEC is shown in Figure 1 (2). The size exclusion resin is packed into a column, which may be jacketed to maintain temperature *via* connection to a circulating water bath. Detailed discussion of commercially available resins is provided in molecular sieve resins. Protein samples to be analyzed by SEC are loaded onto the top of the resin as either a

small or large zone (see discussion below), and allowed to enter the resin at a flow rate determined by a pump connected at the column outlet. Once a sufficient amount of sample has entered the column, the sample is replaced by column buffer, and transport of the macromolecules proceeds. The eluted proteins can be detected most conveniently using an in-line detection system, most commonly a UV–visible **absorbance** detector. However, **fluorescence**, or even in-line scintillation counting of radioactivity, can also measure the protein eluted. Alternatively, the eluted material can be characterized after its elution and collection, using a very wide variety of techniques. Although standard low pressure chromatographic equipment has traditionally been used for SEC, the use of FPLC and **HPLC** systems has become increasingly popular for performing small-zone measurements (3). The utility of HPLC for large-zone experiments, however, has been rigorously demonstrated in only one case (4).

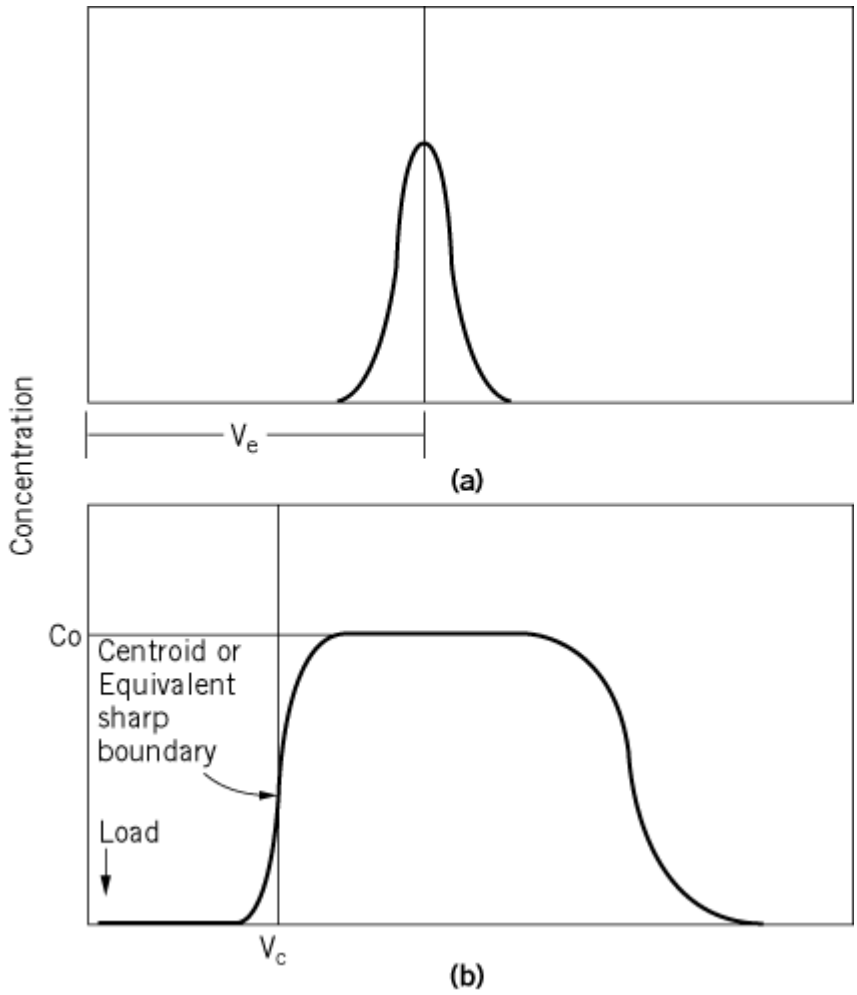
Figure 1. Schematic diagram of a standard low pressure gel filtration chromatography experimental setup. For a discussion of the experimental details, the reader is referred to Reference 2.



1. Zonal Analysis

The most common type of SEC experiment involves loading a small volume of solute onto the column. This is referred to as a small-zone experiment (Fig. 2a) or zonal analysis, and it may be used for either analytical or preparative separations. The volume of the sample used in this type of experiment is approximately 1–4% of the total column bed volume (1). As the sample flows through the column, its transport is accompanied by spreading of the zone as a result of diffusion. A single homogeneous peak detected at the exit port of the column should have a Gaussian shape, the apex of which defines the elution volume of the solute. Applying a mixture of solutes with different elution properties will result in multiple Gaussian-shaped peaks.

Figure 2. Schematic representations of results of (**a**) small-zone and (**b**) large-zone size exclusion chromatography: V_e—the elution volume of the small zone, C_o—the initial concentration of the loaded sample in the large-zone experiment, V_c—the centroid or equivalent sharp boundary of the leading edge of the large zone. This last term is analogous to the elution volume measured in the small-zone experiment.



2. Boundary Analysis of Large Zones

A second type of SEC measurement involves chromatographing a large volume of solute on the resin. This type of experiment, which is referred to as large-zone gel filtration chromatography, is especially useful for measuring protein–protein interactions (5, 6). One advantage of this technique over small-zone experiments is that dilution of the sample does not have to be considered. As a small zone of protein is transported through a column, the zone is diluted, so the concentration at the column outlet can be as much as 100-fold lower than that of the loaded sample. If dilution of the protein results in its dissociation, the oligomeric state of the protein at the point of elution may differ significantly from that of the loaded sample. This makes it impossible to interpret the results of small-zone experiments in terms of protein assembly equilibrium. In a large-zone experiment, in contrast, a sufficiently large volume of protein is loaded onto the column so that the edges of the zone, leading and trailing, are fed by a plateau of protein at the constant initial loading concentration (Fig. 2b). The elution volume for a large zone is determined from the centroid or equivalent sharp boundary of the leading or trailing edge of the zone. This elution position reflects the average size of the protein at its initial loading concentration. If a protein dissociates, its average size, as determined from its elution volume, will, according to mass action, decrease with zones loaded at decreasing protein concentrations. The data relating the measured partition coefficient to protein concentration are analyzed using appropriate mathematical models, to obtain the stoichiometry and energetics of the protein assembly process (6).

The information obtained from large-zone SEC experiments is thus analogous to that obtained from sedimentation equilibrium centrifugation measurements. The advantages of the SEC technique over

centrifugation are that the instrumentation is of only moderate cost, and consequently available to a larger number of laboratories, and that the method can be more readily applied to study of very tight macromolecular associations. This has been demonstrated in studies of the lambda phage cI repressor, for which dimerization equilibrium constants in the nanomolar range of concentration were measured by large-zone SEC (7). An excellent discussion of the application of large-zone analytical gel filtration chromatography for measurement of protein-protein interactions is provided in Reference 6.

3. Size Measurements by SEC

In order to obtain size information about a solute from an SEC experiment, the column must first be characterized in terms of the volumes accessible to analytes. The volume of an SEC column is divisible into three parts: (*1*) the volume external to the packing material, V_0; (*2*) the volume contained within the porous resin beads that is accessible to small molecules, V_i; and (*3*) the volume occupied by the packing material itself, V_g (1, 5). The values of V_0 and V_i are determined experimentally by measuring the elution volumes of, respectively, a large solute that is totally excluded from the interior of the resin and a small solute that has access to all pores of the resin. The elution volume, V_e, of a solute that is partially included in the pores of the gel filtration resin can be related to the void and internal volumes of a column by the following equation:

$$V_e = V_0 + \sigma V_i$$

where s is the partition coefficient of the solute or the fraction of the internal volume of the resin, V_i, that is accessible to the analyte. A detailed discussion that relates these measured volumes to the microscopic properties of the sieving resin is contained in molecular sieve resins.

It is the partition coefficient, s, that, when compared with the values measured for proteins of known size, provides information about the molecular size of an unknown macromolecule. If a series of proteins of known size or Stokes radius are subjected to SEC, a linear relationship between partition coefficient and size is observed (5). For proteins that are well approximated as hydrated spheres, a linear relationship between the elution volume and molecular weight will be observed (1, 5). One approach to analysis of SEC data to obtain information about the size of the protein was developed by Ackers (8). This relationship assumes that penetrable volumes within column packing material are distributed randomly with respect to the size of the protein that can penetrate them. The Stokes radius, *a*, for a protein in Å units (1.0×10^{-10}) is related to the inverse error function complement (erfc^{-1}) of s as

$$a = a_0 + b_0 \text{erfc}^{-1} \sigma$$

where a_0 and b_0 are calibration constants for a column and are obtained by chromatographing a series of proteins of known size or Stokes radius. Values of the inverse error function complement are compiled in tables provided by the National Institute of Standards and Technology (NIST), or they may be readily calculated (9). The Stokes radius for a protein obtained from SEC measurements will accurately reflect the radius of a spherically shaped molecule, but not all proteins are well modeled as spheres; approaches to deal with other shapes are given in Stokes Radius.

Slime Molds

Slime molds is a term commonly used to describe a group of soil amoebas that have the ability to use bacteria as a source of food. They are neither a mold nor a fungus, but rather organisms that share many basic biochemical and genetic mechanisms with higher eukaryotic cells. They can be readily cultivated in the laboratory, and a considerable array of techniques have been developed to manipulate them on a biochemical, genetic, and cellular level. To the molecular biologist, these organisms can present opportunities to examine the details of the regulation and function of systems common to higher organisms, but in a less complicated and more accessible setting.

The two species most studied in the laboratory are *Dictyostelium discoideum* (see Dictyostelium) and *Physarum polycephalum* (see Physarum). They both have the ability to change their basic cellular architecture in a programmed, developmental pathway to optimize their growth and survival. They differ in that *Physarum* has a number of vegetative forms, including a flagellated swimming form, a migrating amoeboid form, and a unique single large cell form containing many nuclei, called a plasmodium. When starved, it can develop into a variety of environmentally resistant forms, including spores. The *Dictyostelium* developmental program differs from that of *Physarum* in that the cells aggregate when starved and develop into a multicellular organism, called a slug. The cell walls do not fuse, and cells differentiate into unique types that perform different functions. If this faster moving slug fails to find better conditions, it can develop into a terminal fruiting structure containing resistant spores. The vegetative form of *Dictyostelium* is a single cell that uses amoeboid motility to find food.

Slime molds have been classified in the *Mycetozoa* phylum. There are three recognized subclasses: acellular (myxogastrid), cellular (dictyostelid), and protostelid. It has been proposed that slime molds are related to the multicellular eukaryotes, more closely to fungal and animal cells than to plants (1). Outside the laboratory, they can be found in forest detritus, where they occupy a unique niche, eating bacteria. In the laboratory, by combining genetic, biochemical, and cell biological techniques, these organisms have given investigators multifaceted approaches to problems that are intractable elsewhere.

Slow-Binding Enzyme Inhibition

Inhibitors have proved to be useful probes of chemical and kinetic mechanisms of **enzyme**-catalyzed reactions. The action of inhibitors has also provided background information for the development of specific bioactive compounds to act as chemotherapeutic agents or as herbicides. Most studies have been performed with classical inhibitors. These are substrate analogues that give rise to linear competitive inhibition with respect to the substrate through the reversible formation of **dead-end** complexes that can only dissociate back to the components from which they were formed. Usually, the kinetic investigations have been performed under conditions in which the concentrations of substrate and inhibitor are much greater than the concentration of the enzyme, and all the equilibria are set up rapidly, conforming to Michaelis-Menten kinetics. The rapid interaction of an inhibitor (I) at the active site of an enzyme (E) to form an EI complex is described by equation 1.

$$\mathrm{E} + \mathrm{I} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \mathrm{EI} \qquad (1)$$

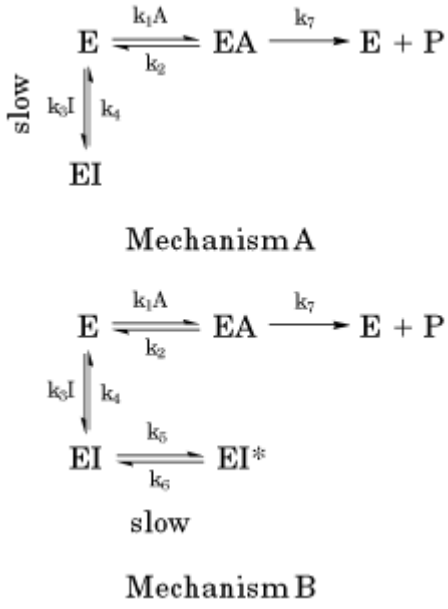
The **dissociation constant** (K_i) for the reaction, a thermodynamic quantity, is defined by the relationships given in equation (2).

$$K_i = \frac{k_4}{k_3} = \frac{(E)(I)}{(EI)} \qquad (2)$$

Rapid establishment of the equilibrium, on the time scale of a steady-state kinetic experiment of seconds to minutes, requires that the magnitudes of the apparent first-order rate constants for the formation of EI, $k_3 I_t$, and for the dissociation of EI, k_4, be relatively high, with values greater than about $1 s^{-1}$. If the binding is very tight, however, dissociation will be intrinsically slow; for example, if K_i is in the micromolar range, k_4 can be no greater than $10^{-6}\ k_3$ in units of s^{-1}. Consequently, a tight-binding inhibitor will tend to dissociate slowly and might not fulfill the requirements for rapid equilibration.

It has now been established that the equilibrium between enzyme, inhibitor, and the enzyme-inhibitor complex is not always set up rapidly, so that the inhibition becomes time-dependent. Compounds that behave in this manner have been referred to as *slow-binding inhibitors* (1). This term conveys the idea that binding, which is the establishment of all equilibria involving the inhibitor, occurs slowly on the steady-state time scale of seconds to minutes. Slow-binding inhibition resembles transient-state kinetics on a different time scale. The definition is an operational one, as it is always possible that the time to reach equilibrium could vary with the experimental conditions. The simplest scheme to illustrate slow-binding inhibition of an enzyme-catalyzed reaction is shown as mechanism A in Figure 1.

Figure 1. Kinetic mechanisms for the slow-binding inhibition of enzyme-catalyzed reactions by substrate analogues.



There are two reasons why formation of an EI complex might be slow. If the concentration of I required to demonstrate the inhibition is relatively low, the rate of forming EI (k_3I_t) would also be low. For example, if the values for K_i, I_t and k_3 are 10^{-9} M, 10^{-8} M and 10^6 $M^{-1}s^{-1}$, k_3I_t would be $10^{-2}s^{-1}$ and the half-time for the forward reaction 69 s. As $k_4 = K_i\, k_3 = 10^{-3}s^{-1}$, the half-time for the dissociation reaction will be 11.6 min. It should be noted that, for these calculations, it is assumed that the inhibitor concentration is at least 10 times that of the enzyme, so that tight-binding inhibition does not occur (see Active-Site Titrants). Analysis of slow-binding data for the mechanism under discussion will yield a true value for k_3, whose magnitude is comparable to that of the usual second-order rate constants for the interaction of enzymes and substrates. An alternative explanation for slow-binding inhibition conforming to mechanism A is that the inhibitor encounters barriers to its binding at the active site. The value of k_3 might then be sufficiently low to permit the monitoring, on a steady-state time scale, of the time-dependent inhibition.

A second mechanism to account for slow-binding inhibition is mechanism B in Figure 1, which involves the rapid formation of a collision complex (EI), with the inhibitor behaving initially as a classical competitive inhibitor (cf eqs. 1 and 2). The EI complex then undergoes a slow conformational change, or isomerization reaction, to form a more stable complex, EI*. The overall dissociation constant for the reaction, K_i*, would be defined as

$$K_i^* = \frac{(E)(I)}{(EI) + (EI^*)} = \frac{K_i k_6}{k_5 + k_6} \tag{3}$$

where $K_i = k_4/k_3$. The degree to which the initial binding is enhanced through the isomerization reaction will depend on the ratio k_5 / k_6. The absolute values of these rate constants must be such as to allow observation, on a steady-state time scale, of the isomerization as manifested by the slow increase in inhibition.

Under conditions in which the total concentration of a slow-binding inhibitor is at least 10 times greater than the total enzyme concentration and the reaction is started by the addition of enzyme, the progress curve in the presence of a single inhibitor concentration is described for either mechanism A or mechanism B by an integrated rate equation (eq. 4).

$$P = v_s t + (v_o - v_s)(1 - e^{-kt})/k \qquad (4)$$

For this equation, which contains both a linear term and an exponential term, P represents the concentration of product; v_s and v_o denote steady-state and initial velocities, respectively; k represents an apparent first-order rate constant whose meaning varies with the mechanism. Equation 4 predicts, and curve b of Figure 2 illustrates, that when the reaction is started by adding enzyme, there is an initial burst or transient phase. The velocity then settles down to a slower steady-state rate, as represented by the asymptote of the curve, because of the slow establishment of the equilibrium between enzyme, inhibitor, and the enzyme-inhibitor complex(es). If the enzyme is preincubated with the inhibitor and the reaction is started by the addition of substrate, equation 4 still applies. But there is now a slow decrease in the degree of inhibition, an apparent activation, because of the establishment of new equilibria that involve interactions of both substrate and inhibitor with the enzyme (Fig. 2, curve c); consequently, the initial velocity is less than the steady-state velocity. Whichever procedure is used to study the inhibition, the same steady-state velocity will be obtained. All this discussion assumes that the enzyme is not inactivated or activated by other phenomena.

Figure 2. Progress curves for an enzyme-catalyzed reaction in (a) the absence, and (b, c) the presence, of a slow-binding inhibitor. The reactions were started (b) by adding enzyme or (c) by adding substrate after preincubation of enzyme and inhibitor. The dashed lines represent steady-state rates in the presence of inhibitor.

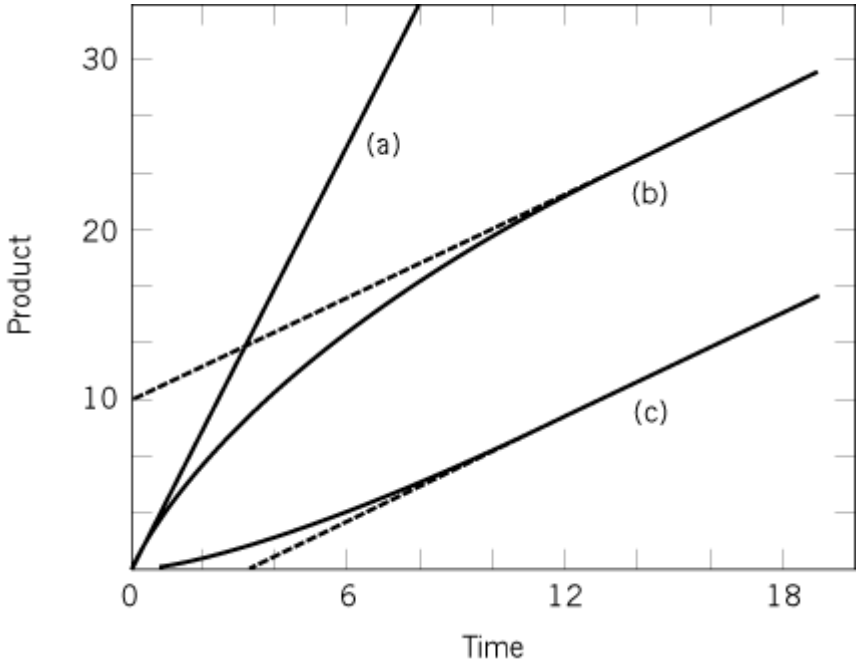


Figure 3 shows the basic types of plots obtained when reactions conforming to either mechanism A or mechanism B are run in the presence of different concentrations of a slow-binding inhibitor, and started by the addition of enzyme. The two families of curves are similar except that, for mechanism A, the initial velocity of the reaction is independent of the inhibitor concentration. By contrast, the initial velocity of a reaction that conforms to mechanism B is described by the equation for linear competitive inhibition (Table 1). This same general equation describes the variation with inhibitor

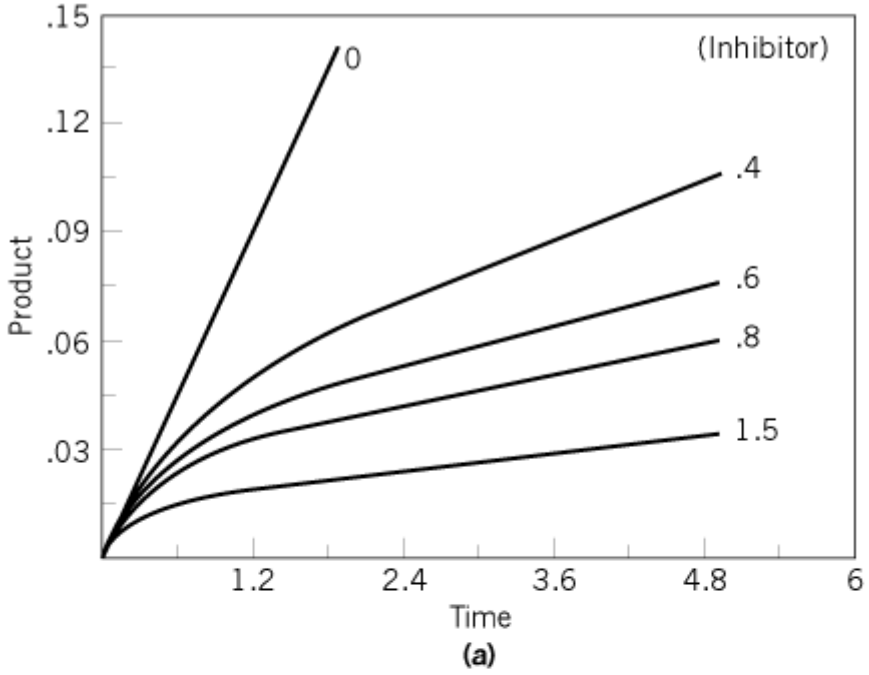
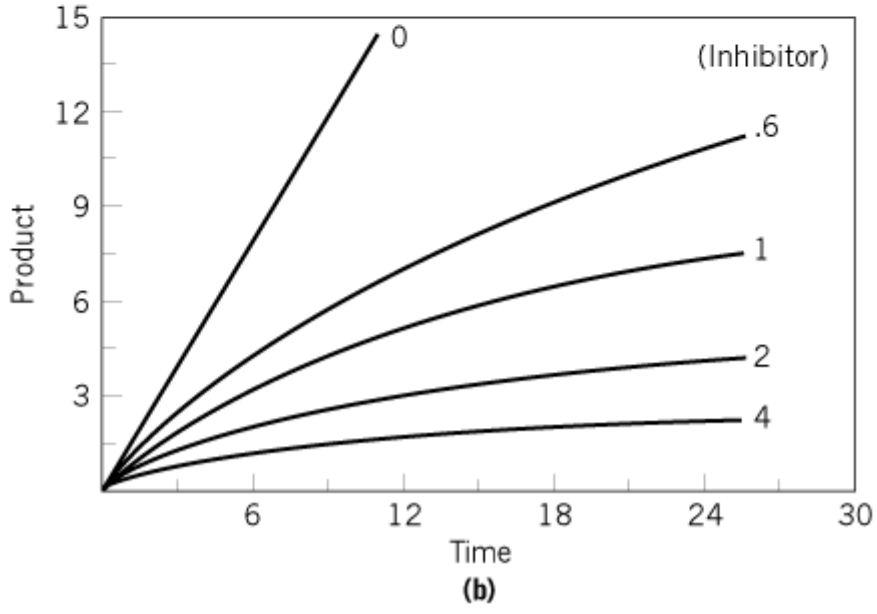
concentration of the asymptotes for each family of curves (Table 1). As the concentration of the inhibitor increases, so also does the rate at which the curves for the two mechanisms turn over. This is a function of the value for the apparent first-order rate constant (k), which increases with inhibitor concentration (Table 1). It will be noted that, in the presence of a fixed concentration of substrate (A), the variation of k as a function of inhibitor concentration is linear for mechanism A and hyperbolic for mechanism B. The linear plot has an intercept with the vertical ordinate equal to k_4. The hyperbolic plot has limiting values of ($k_5 + k_6$) and k_6 at infinite and zero inhibitor concentrations, respectively.

Figure 3. Progress curves for the slow-binding inhibition of enzyme-catalyzed reactions conforming to mechanisms (**a**) and (**b**). In each case, the reaction was starting by adding enzyme to a mixture of substrate and varying amounts of the inhibitor.





Slow-binding Inhibition Mechanisms [a]

Parameter in equation (4)	Mechanism A	Mechanism B
Initial velocity	v_o	$v_o = \frac{VA}{K_a(1+I/K_i)+A}$
Steady-state velocity	$v_s = \frac{vA}{K_a(1+I/K_i)+A}$	$v_s = \frac{VA}{K_a(1+I/K_i^*)+A}$
k	$k = k_4[1 + \frac{I}{K_i(1+A/K_a)}]$	$k = k_6\left\{\frac{1+I/[K_i^*(1+A/K_a)]}{1+I/[K_i(1+A/K_a)]}\right\}$
	$k_4 = kv_s/v_o$	$k_6 = kv_s/v_o$

[a] $K_i = k_4/k_3K^*_i = K_i[k_6(k_5+k_6)]$ (see Fig. 1)

Although values for the kinetic parameters associated with slow-binding inhibition can be determined by graphic procedures, it is greatly preferable to make an overall least-squares fit of the data to equations that describe mechanisms A and B, namely, equation 4, plus those listed in Table 1. This approach allows discrimination between the two mechanisms, as well as determination of values for each kinetic parameter, together with their standard errors. The nonlinear regression analysis involves using about 20 points from each curve and the utilization of a graphic procedure to obtain estimates of the *k* value for each curve (2, 3). The same basic approach is used for the study and analysis of slow-binding inhibition when an enzyme has multiple substrates. Analysis of inhibition data is simplified, however, if all substrates other than the one for which the inhibitor is an analogue are present at saturating concentrations.

There are several points to note about the detection and study of slow-binding inhibition (2). It will not be observed, on starting the reaction by adding the enzyme, if the rate of interaction of enzyme and inhibitor (mechanism A) or the rate of isomerization of the enzyme-inhibitor complex (mechanism B) are very slow relative to the rate of the reaction catalyzed. Therefore, the enzyme should also be preincubated with the inhibitor, and inhibition should be studied as a function of enzyme concentration. The ratio of the concentration of substrate to its K_m **(Michaelis constant)** should not be high; if it is, the concentration of free enzyme is reduced considerably and there is a concomitant reduction in the collision rate for enzyme and inhibitor. Thus, it could appear that the inhibition conforms to mechanism A rather than to mechanism B. With any progress curve investigation, it is important that there is no other inactivation of the enzyme. This can be confirmed by the observation of an extended linear asymptote or by the application of Selwyn's test (4). Reactions in the presence of the inhibitor should be run for a sufficiently long period, but not beyond the point at which the reaction in the absence of inhibitor ceases to be linear.

In the original formulation of mechanism B, consideration was not given to the possibility that the step for the formation of an initial collision complex between E and I was at steady state rather than at thermodynamic equilibrium (Fig. 1). Subsequent theoretical investigations have demonstrated the difficulties associated with the use of steady-state kinetic techniques to distinguish mechanism B from the more general but more complex mechanism B, with both steps involving the formation of enzyme-inhibitor complexes being at steady state equilibrium (5).

When a slow-binding inhibitor causes inhibition at concentrations comparable to that of the enzyme, the inhibitor is described as being of the *slow, tight-binding* type (1). The inhibition can still be described in terms of mechanisms A and B (Fig. 1), but the equations to describe the inhibition are more complex because of the change in the concentration of free inhibitor as the inhibition proceeds. The availability of a computer program that allows straightforward analysis of

slow, tight-binding inhibition data has facilitated the study of this type of inhibition (3). Consideration has been given recently to kinetic schemes for slow- and tight-binding inhibition where the inhibitor can also combine with an enzyme-substrate complex and influence the binding or the rate of product formation, or both (6) (see Competitive Inhibition and Noncompetitive Inhibition).

From a list of enzymes subject to slow-binding and slow, tight-binding inhibition (1), it appears that the predominant mechanism of inhibition is that described by mechanism B.

Small Cytoplasmic RNA (scRNA), Small Cytoplasmic RNP (scRNP)

The nucleoplasm and cytoplasm of eukaryotic cells contain a large number of small ribonucleoprotein (RNP) complexes, which are called small nuclear RNPs (snRNPs) and small cytoplasmic RNPs (scRNPs), respectively. They are composed of one or more proteins and a small stable RNA molecule (chain length <~300 nucleotides). The high abundance and the evolutionary conservation of RNA sequences within these small RNPs indicate that they have an important biological role. While a large body of information is available on the function of snRNPs in regulating nuclear RNA processing (see RNA Splicing), relatively little is known about the function of most scRNPs. Nonetheless, their cellular localization suggests a role in regulation of the last step of gene expression—that is, translation or disposition of newly synthesized proteins [reviewed by Baserga and Steitz (1)].

The discovery of the scRNPs was facilitated by **autoantibodies** present in sera of patients with autoimmune diseases in which antibodies against scRNPs components were found. The antibodies are usually targeted against a protein epitope, indicating that a common protein is associated with scRNPs of the same class. For example, **antibodies** against the 60-kDa Ro protein, which is a component of several scRNPs, also called Ro RNPs, were found in sera of patients with systemic lupus erythematosus (SLE) or with Sjögren's syndrome (2-6). Sera of such patients frequently contain autoantibodies against the 50-kDa La protein (2, 3). These antigens were termed Ro and La, based on the names of the patients in whom they were first identified (3).

1. Ro RNPs

The Ro RNPs were first identified with the aid of anti-Ro autoantibodies (6). They contain one molecule of small cytoplasmic RNA that belongs to a family called Y RNAs, to indicate their cYtoplasmic location, and are assembled with the 60-kDa Ro protein and the 50-kDa La protein. The Y RNAs sequences, as well as the sequences of the Ro and La proteins, have been conserved during

evolution. This, together with their high abundance (~10^5 copies per cell), suggests an important physiological role. However, their biological function is yet unknown [reviewed by Baserga and Steitz (1) and by Van Venrooij et al. (7)].

The Y RNAs are produced by transcription by **RNA polymerase** III. Four different Y RNA molecules, ranging in size between 69 to 112 nucleotides, were identified in humans and were termed Y1, Y3, Y4, and Y5 RNAs (Y2 is a truncated form of Y1). In different species, however, different numbers of types of Y RNAs were found associated in Ro RNPs. Thus, while humans and Xenopus cells contain all four types of Y RNAs, two types are found in mouse cells, and only one type is found in ***Caenorhabditis elegans*** (8-12).

The predicted secondary structure of sequenced Y RNAs can be drawn as a long base-paired stem composed of the 5′ and the 3′ ends of the molecule and an internal loop containing a pyrimidine-rich sequence (9, 13). Within the stem region, a highly conserved based-paired sequence with a bulged cytidine was proposed to be the binding site of the 60-kDa Ro protein (14, 15). The La antigen was proposed to bind to the 3′ oligo-uridylate sequence (15-17).

In *Xenopus* oocytes, the 60-kDa Ro protein is found also complexed with a heterogeneous population of 5S ribosomal RNA precursors that contain internal mutations. This binding is attributed to an alternative fold of the RNA in the mutant 5S rRNA. Because the mutant 5S rRNA precursors are processed inefficiently and are finally degraded, it was proposed that the Ro protein may function in a quality-control pathway of 5S rRNA biosynthesis (18, 19).

The 60-kDa Ro protein is an abundant and conserved protein that contains an RNA-recognition motif (RRM) (see RNA-Binding Proteins) of ~80 amino acid residues (10, 20). An additional protein of 52 kDa (Ro52), which is recognized by autoantibodies from patients with SLE and Sjögren's syndrome, has been proposed to be a component of Ro RNPs in human cells (21), but other reports indicate otherwise (22, 23). The 52-kDa protein does not bind directly to the Y RNA, but probably associates with the Ro RNP through protein–protein interactions (24).

The 50-kDa La autoantigen is a highly abundant phosphoprotein that is found complexed with a variety of small RNAs to form small RNP particles [reviewed by Van Venrooij et al. (7)]. These include precursors to 5S rRNA, transfer RNA, 7S RNA, and Ro cytoplasmic Y RNAs, which are transcribed by RNA polymerase III (8, 25, 26). The La protein has an RNA recognition motif (RRM) (27). Its binding to the above-mentioned small RNAs occur via this RRM and is directed, at least in part, to a short uridylate sequence at the 3′ end of the relevant RNA (15-17).

The La protein has been proposed to be involved in a number of physiological processes within the cell's nucleus. For example, experiments *in vitro* have indicated that the La protein is required as a transcription termination factor for RNA polymerase III transcripts (28-30), which is consistent with the protein's ATPase activity that can melt DNA/RNA hybrids *in vitro* (31). Nevertheless, its association with scRNPs suggests a cytoplasmic physiological function as well. This view is supported by **immunofluorescence** experiments showing that the La protein is localized in the cytoplasm at sites of translation (32).

2. Viral scRNPs

An example of viral scRNPs are complexes of VAI and VAII small adenovirus RNAs that are transcribed by RNA polymerase III and have the La autoantigen as a common protein partner. These viral scRNPs are highly abundant in infected cells (~10^8 copies per cell) and are found in the cytoplasm. The ~160-nucleotide VAI RNA plays a role in enabling **protein biosynthesis** late in the adenovirus life cycle (33). Due to its high abundance and its binding to the interferon-induced 68-kDa kinase, it competes effectively with the cellular components that are involved in the **interferon**-induced transcription shutdown of translation (34, 35).

3. Signal Recognition Particle (SRP)

Another class of scRNPs are the signal recognition particles (SRPs) that help translocation of secretory proteins during translation. Mammalian SRPs are composed of 7SL RNA of ~300 nucleotides in length, which is complexed with six proteins having molecular weights of 9, 14, 19, 54, 68, and 72 kDa, to form an 11 S RNP particle [reviewed by Walter and Johnson (36) and by Lutcke (37)].

The 7SL SRP RNA is an abundant transcript of RNA polymerase III (~10^6 copies per cell). It is a member of a class of mammalian intermediate-repeat sequences called short interspersed elements (SINES). The 7SL RNA has a remarkable sequence homology with the **Alu** family of repetitive sequences in primates and rodents. The "Alu domain" of the SRP consists of the Alu homologous region of 7SL RNA to which SRP9 and SRP14 are bound.

SRPs are required for cotranslational targeting of nascent secretory proteins to the endoplasmic reticulum. Translation of secretory proteins begins on ribosomes that are free in the cytosol. The SRP binds to the **hydrophobic** amino-terminal nascent peptide (15 to 30 amino acid residues) of the secreted nascent protein while it emerges from the large subunit of the ribosome. The binding arrests or delays the translation of the nascent polypeptide chain. The SRP then targets the nascent polypeptide–ribosome complex to the SRP receptor in the rough endoplasmic reticulum. The release of SRP from the signal sequence/ribosome complex requires GTP hydrolysis [reviewed by Walter and Johnson (36) by Lutcke (37), and by Bovia and Strub (38)]. Specifically, the 54-kDa protein, also called SRP54, binds directly to the signal peptide through a methionine-rich carboxyl-terminal domain. This protein is a GTP-binding protein, and when bound to the 7SL RNA it helps target the nascent chain by interacting with the heterodimeric SRP receptor. The function of the other proteins has not yet been characterized in detail. SRP19 aids the binding of SRP54 to the 7SL RNA, and the heterodimer SRP68/72 was proposed to interact with the a subunit of the SRP receptor. SRP68/72 and the Alu domain of SRP are required to confer elongation arrest activity of the particles.

The components of the SRP and SRP receptor were highly conserved during evolution. This is in accordance with their function in targeting proteins to the endoplasmic reticulum, which is shared by all eukaryotic organisms examined [reviewed by Wolin (39)].

4. Alu-Related scRNPs

Several Alu-related small RNAs were found to accumulate stably in the cytoplasm of rodent and primate cells. They are less abundant (10^3 to 10^4 copies per cell) and less well characterized than the above described scRNPs. Among them are the primate scAlu RNA (120 nucleotides), the rodent scB1 (140 nucleotides), and the BC200 RNA (200 nucleotides). The latter is expressed specifically in nerve cells by RNA polymerase III. These scRNAs have Alu-like sequences at their 5′ and 3′ ends, similar to the 7SL RNA, and can be drawn in a cruciform secondary structure. These Alu-like scRNAs are found complexed in small cytoplasmic RNPs and have been shown to bind the SRP14/19 heterodimer *in vitro*. Although the role of these scRNPs is yet unknown, a role in translation has been suggested [reviewed by Bovia and Strub (38)].

Small Nuclear Rnps (Snrnps)

In addition to the short conserved sequences at the branch site and the 5′ and 3′ splice sites, RNA splicing of nuclear pre-mRNA is dependent on the activity of a large number of trans- acting factors. These can be divided into two classes: the snRNPs, evolutionarily conserved ribonucleoprotein particles, and non-snRNP protein splicing factors (reviewed in Refs. 1 and 2). These *trans*-acting factors assemble in an ordered fashion onto the pre-mRNA substrate to form the spliceosome, wherein the catalysis of splicing occurs. The spliceosomal snRNPs play a central role in the recognition and alignment of the pre-mRNA splice sites during spliceosome formation and are also involved in the catalytic steps of splicing (see Spliceosome). The major spliceosomal snRNPs, which are involved in the removal of U2-dependent introns (the most abundant type of nuclear pre-mRNA intron), include U1, U2, U5, and U4/U6, and are named according to their snRNA component(s). Due to their greater abundance (2×10^5 to 10^6 particles per cell, compared with 50 to 100 in yeast), the major spliceosomal snRNPs have been best characterized at the biochemical and structural level in higher eukaryotes and will thus be emphasized in the following paragraphs. In addition to U1, U2, U5, and U4/U6, a minor class of spliceosomal snRNPs involved in the excision of U12-dependent introns (which represent a small minority of nuclear pre-mRNA introns) has also been recently identified. These include the U11, U12, and U4atac/U6atac snRNPs, which, unlike the ubiquitous major snRNPs, appear to be lacking in some eukaryotes (eg, in the budding yeast *S. cerevisiae*) (3-5). As a consequence of their low abundance (estimated at 10^3 to 10^4 particles per cell) and more recent identification, the minor spliceosomal snRNPs are presently not well-characterized and thus will not be discussed in detail here.

1. snRNA

The major spliceosomal snRNPs consist of one snRNA molecule (or two in the case of U4/U6) complexed with a number of proteins. The U1, U2, U4, U5, and U6 snRNAs are characterized by their small size (164, 187, 145, 116, and 106 nucleotides, respectively in humans), metabolic stability, and high degree of sequence conservation. They also contain a large number of modified nucleotides, such as pseudouridine and 2′- *O*-methylated nucleosides, and, with the exception of U6, possess a unique 2,2,7-trimethylguanosine -cap structure. In addition to their sequence conservation, the secondary structures of the metazoan snRNAs are also highly conserved such that a consensus secondary structure model can be generated for each of them. The sequence and most probable secondary structures of the human U1, U2, U4, U5, and U6 snRNAs are shown schematically in Figure 1. The majority of the U4 and U6 snRNAs interact by extensive base pairing to form a characteristic Y-shaped structure and are present in this form within the U4/U6 snRNP. The most highly conserved sequences of these snRNAs are typically single-stranded regions that either base-pair with the pre-mRNA or other snRNAs during spliceosome assembly (eg, the 5′ end of U1) or serve as binding sites for snRNP proteins (eg, the so-called Sm site; see text below). With the exception of U4 and U6, the major spliceosomal snRNAs are somewhat larger in yeast (eg, U1 and U2 are 568 and 1175 nucleotides long, respectively), and they therefore exhibit different secondary structures. It should be noted that the structures of most of the spliceosomal snRNAs are not fixed, but rather undergo conformational changes during splicing that reflect the dynamic nature of the splicing process. A prime example is the U6 snRNA, which first base-pairs with U4 in the U4/U6 snRNP and then, after the incorporation of the U4/U6 snRNP into the spliceosome, dissociates from this complex and basepairs with the U2 snRNA and the pre-mRNA (see Spliceosome). The U4 snRNA and the 5′ half of the U2 snRNA also undergo significant conformational rearrangements during splicing (6). During splicing, the spliceosomal snRNAs engage in multiple base pairing interactions with other spliceosomal snRNAs and with the pre-mRNA. These RNA-RNA interactions play essential roles in the selection and favorable alignment of the 5′ and 3′ splice sites for splicing catalysis (see Spliceosome). Some of the structural features of the complex RNA network that is formed during spliceosome assembly mimic RNA structures that are essential for the

autocatalytic splicing of group II pre-mRNA self-splicing introns. The spliceosomal snRNAs—in particular, U2, U5, and U6—thus appear to form, at least in part, the active sites of the spliceosome and take part directly in the catalysis of nuclear pre-mRNA splicing.

Figure 1. Sequence and secondary structure models of the human U1, U2, U5, and U4/U6 snRNAs. The consensus seco shown are the models of Guthrie and Patterson (15), and that of U2 was proposed by Ares and Igel (16). The conserved s of the common snRNP proteins) is underlined. The 5′ ends of the snRNAs possess a cap structure (2,2,7-trimethyl-guanc spliceosomal snRNAs (with the exception of U6, which possesses a monomethyl phosphate cap).

2. snRNP Proteins

The spliceosomal snRNAs are present in cells as discrete ribonucleoprotein complexes. In human cells, the U1 and U2 snRNAs are organized as a 12 S and 17 S particle, respectively. U4/U6 and U5 snRNAs can be isolated as individual 12 S and 20 S particles, respectively, but they also associate with one another to generate a 25 S [U5.U4/U6] tri-snRNP complex, and they are integrated into the spliceosome as such. The protein composition of the major spliceosomal snRNPs has been best characterized in HeLa Cellsand is summarized in Table 1. Proteins associated with the U1, U2, U5, and U4/U6 snRNPs fall into two classes. The first class consists of the so-called common or Sm proteins, denoted B′, B, D1, D2, D3, E, F, and G, which are tightly associated with all snRNP particles. The Sm proteins play an important role in the biogenesis of the snRNPs and are essential for their import into the nucleus (see text below). The second class is comprised of the particle-specific proteins, which associate with a particular snRNP particle or complex. These proteins exhibit a wide range of binding affinities, and their association with an snRNP particle is thus dependent on the ionic strength of the particle's environment. In addition to the eight common snRNP proteins, the metazoan U1 snRNA is associated with three proteins, designated 70K, A, and C. Under physiological conditions, the U2 snRNA is complexed with 12 U2-specific proteins, whose molecular weights range from 33 to 160 kDa (Table 1). With 16 specific proteins and two sets of common proteins, the 25 S [U4/U6.U5] tri-snRNP possesses the most complex protein composition of the snRNPs (Table 1). The vast majority of proteins identified in isolated HeLa snRNPs are also present in the spliceosome (7), and thus most spliceosomal proteins have an snRNP origin. The majority of the human snRNP proteins have now been **cloned** and sequenced, and several have been shown to perform essential functions during spliceosome assembly and the catalytic steps of splicing (see Spliceosome). For example, snRNP proteins (eg, U1-70K, U5-220 kD, and the U2-specific proteins comprising SF3a and SF3b) are involved in protein–protein interactions and protein–RNA interactions that facilitate the interactions of the U1, U2, and U4/U6.U5 tri-snRNPs with the pre-mRNA during spliceosome assembly. Furthermore, several snRNP proteins (eg, the 20 kD, 100 kD, 116 kD, and 200 kD U4/U6.U5 tri-snRNP proteins) appear to possess enzymatic activities, such as RNA duplex unwinding or protein isomerization activity, that potentially drive the many conformational changes that occur in the spliceosomal RNA and/or protein networks. In this way, snRNP proteins make important contributions to the assembly of the active sites responsible for the catalysis of splicing. However, whether snRNP proteins contribute directly to catalysis is currently an open question.

[a] The presence of a given protein in a particular snRNP is indicated by the various symbols. The 25 S [U4/U6.U5] tri-snRNP complex contains two sets of common proteins (E, F, G, D1, D2, D3, B, B′). Tri-snRNP proteins that also associate with U4/U6 snRNPs are indicated by a ( ), and those also present in U5 snRNPs are marked with a solid diamond. Proteins associated solely with the 25 S [U4/U6.U5] are marked with a solid square. SF3a is composed of the 60, 66, and 110 kDa U2-specific proteins, and SF3b consists of the 53, 120, 150, and 160 kDa U2-specific proteins. Additional information (including references) about the yeast *S. cerevisiae* common proteins and U1 snRNP specific proteins are reported in Ref. 8 and for the Prp proteins in Ref. 2. Snu246 is also referred to as Brr2p (17), Slt22p (18), and Rss1p (19) The identification of Prp3p and Prp4p as homologues of the U4/U6 90 and 60 kDa proteins is described in Refs. 12 and 20. Hsh49p and Cus1p are described in Refs. 21 and 22, respectively. (Courtesy of Claudia Schneider.)

Homologues of some of the HeLa U1, U2, U5, and U4/U6 snRNP proteins have also been identified

either genetically or biochemically in yeast (summarized in Table 1). Significant progress has recently been made in the biochemical characterization of snRNPs from the yeast *S. cerevisiae*. This has complemented, as well as extended, the somewhat limited information obtained through yeast genetic techniques. Biochemical characterization of the yeast U1 snRNP has demonstrated that it possesses a significantly more complex protein composition than the metazoan U1 snRNP, containing not only homologues of the U1-70K, A and C proteins, but also six additional yeast-specific proteins (8). Some of these additional proteins appear to mediate the bridging of the 5′ and 3′ splice sites during the earliest stages of spliceosome formation in yeast. Although the number of snRNP protein homologues that have been characterized at the molecular level in yeast is presently limited, there are striking examples of both structural and functional conservation between yeast snRNP proteins and their counterparts in evolutionarily distant organisms. This not only underscores the functional importance of the snRNP proteins in nuclear pre-mRNA splicing, but also confirms that many aspects of the splicing process are conserved between higher and lower eukaryotes.

3. snRNP Biosynthesis and Structure

The snRNPs undergo a complex pathway of biogenesis that involves their shuttling between the nucleus and cytoplasm. Subsequent to their transcription in the nucleus, the major spliceosomal snRNAs, with the exception of U6, migrate to the cytoplasm. In the cytoplasm, some of the nucleosides of the snRNAs are modified (primarily 2′ OH methylation and pseudouridylation) and their 5′ m^7G cap is hypermethylated to a 2,2,7-trimethylguanosine (m_3G) cap. Cap hypermethylation is dependent upon the formation of an snRNP core structure. Core snRNPs are formed by the association of the common snRNP proteins (B′, B, D3, D2, D1, E, F, G) with the Sm site, an evolutionarily conserved structural motif found in the U1, U2, U4, and U5 snRNAs (see Fig. 1). The Sm proteins form distinct heteromeric complexes (eg, E/F/G or B/D3) that interact with the Sm site in an ordered manner. Subsequent to core snRNP formation and cap hypermethylation, the snRNPs are translocated to the nucleus by an active, receptor-mediated process. The nuclear import pathway of the spliceosomal snRNPs is distinct from that of karyophilic proteins. snRNPs possess a bipartite nuclear localization signal that is comprised of the m_3G cap and the snRNP core structure. At least one of the receptors responsible for snRNP import, Snurportin1, which specifically recognizes the m3G cap, has recently been described (9). SnRNP assembly is completed in the nucleus, where most of the particle-specific proteins are thought to associate with the snRNPs.

Although the vast majority of spliceosomal snRNP proteins have already been identified in humans, and a growing number are rapidly being identified in yeast, significantly less information about structural aspects (ie, RNA–protein and protein–protein interactions) of the spliceosomal snRNPs is currently available. Because the snRNPs serve as spliceosomal subunits, information regarding their higher-order structure may provide much needed information about the three-dimensional structure of the spliceosome. Information about the general morphology of both the mammalian and yeast spliceosomal snRNPs has been obtained through electron microscopy. More detailed information about RNA–protein and protein–protein interactions within the snRNPs is, however, limited. The molecular characterization of snRNP proteins has revealed that they possess a variety of interesting structural motifs, which include, among others, RNA-binding and protein-interaction **domains** (eg, RRMs, RS, and WD-40 domains). The best-characterized interactions within the snRNPs are those formed between snRNP proteins containing an RNA-binding domain (eg, U1-70K, U1-A, U2-B″) and their cognate snRNA. The atomic structure of interactions between the U1-A protein and U1 snRNA, and between the U2-B″/U2-A′ proteins and the U2 snRNA, have been obtained by X-ray crystallography (10, 11). Well-characterized protein–protein interactions include those formed between U2-snRNP-specific proteins comprising the splicing factors SF3a and SF3b, as well as those among the Sm proteins. More recently, a number of novel snRNP protein–protein interactions have been reported that involve proteins associated with the [U4/U6.U5] tri-snRNP complex (12-14).

Small-Angle Scattering

Analysis of the small-angle scattering of X-rays, neutrons, or light is a valuable tool for studying the

structures and interactions of biological macromolecules in solution. Importantly, small-angle scattering experiments can be done on proteins and polynucleotides in a variety of solution conditions that mimic different physiological factors. Studies can be done on biological macromolecules and the assemblies they form over a very wide molecular weight range that encompasses the smallest proteins to the large animal viruses. The information obtained is inherently low-resolution, generally confined to molecular shapes. When neutrons are used with contrast variation, the shapes and dispositions of component structures in complexes can be obtained (see Neutron Diffraction And Scattering and Contrast Variation). Light scattering is fundamentally the same as X-ray scattering, except that the wavelengths are longer and there are differences in the theoretical formalisms (see Light Scattering).

1. Theory of Small-Angle Scattering

Small-angle scattering (also known as low-angle scattering, or sometimes solution scattering) results from the constructive interference of secondary waves that are scattered when a plane wave interacts with matter. The small-angle scattering intensity distribution from a particle in solution is maximum at zero scattering angle and falls off with a rate that depends upon the size and shape of the scattering particle. The larger the particle, the faster the falloff. Small-angle scattering generally refers to the elastic, coherent scattering of X-rays or neutrons, both of which have the properties of plane waves. Scattering theory assumes the wavelength of the radiation being used as a structural probe is smaller than the dimensions of the object being studied. X-rays and neutrons can be produced with wavelengths from 0.1 to 10's of Å (1 Å = 10^{-10}m), and hence they are useful for studies of biological molecules with dimensions from 10 to 1000's of Å.

The total scattering intensity distribution for a homogeneous solution of monodisperse, randomly oriented, noninteracting particles in a solution can be expressed as

$$I(Q) = \int\int \Delta\rho(\mathbf{r}_1)\Delta\rho(\mathbf{r}_2)\frac{\sin Q|\mathbf{r}_1 - \mathbf{r}_2|}{Q|\mathbf{r}_1 - \mathbf{r}_2|}d\mathbf{r}_1 d\mathbf{r}_2 \qquad (1)$$

where Q is the momentum transfer or scattering vector amplitude and is equal to 4p(sin q)/l (q is half the scattering angle and l is the wavelength of the radiation; note that Q is also called K, h, or q, and some authors prefer to use $s = Q/2p$). Dr(**r**) = r(**brb**)-r_s, and is the "contrast," or scattering density difference between the particle and solvent. A very useful function in small-angle scattering is the pair distance, or vector length distribution function $P(r)$, which is related to $I(Q)$ by a Fourier transformation:

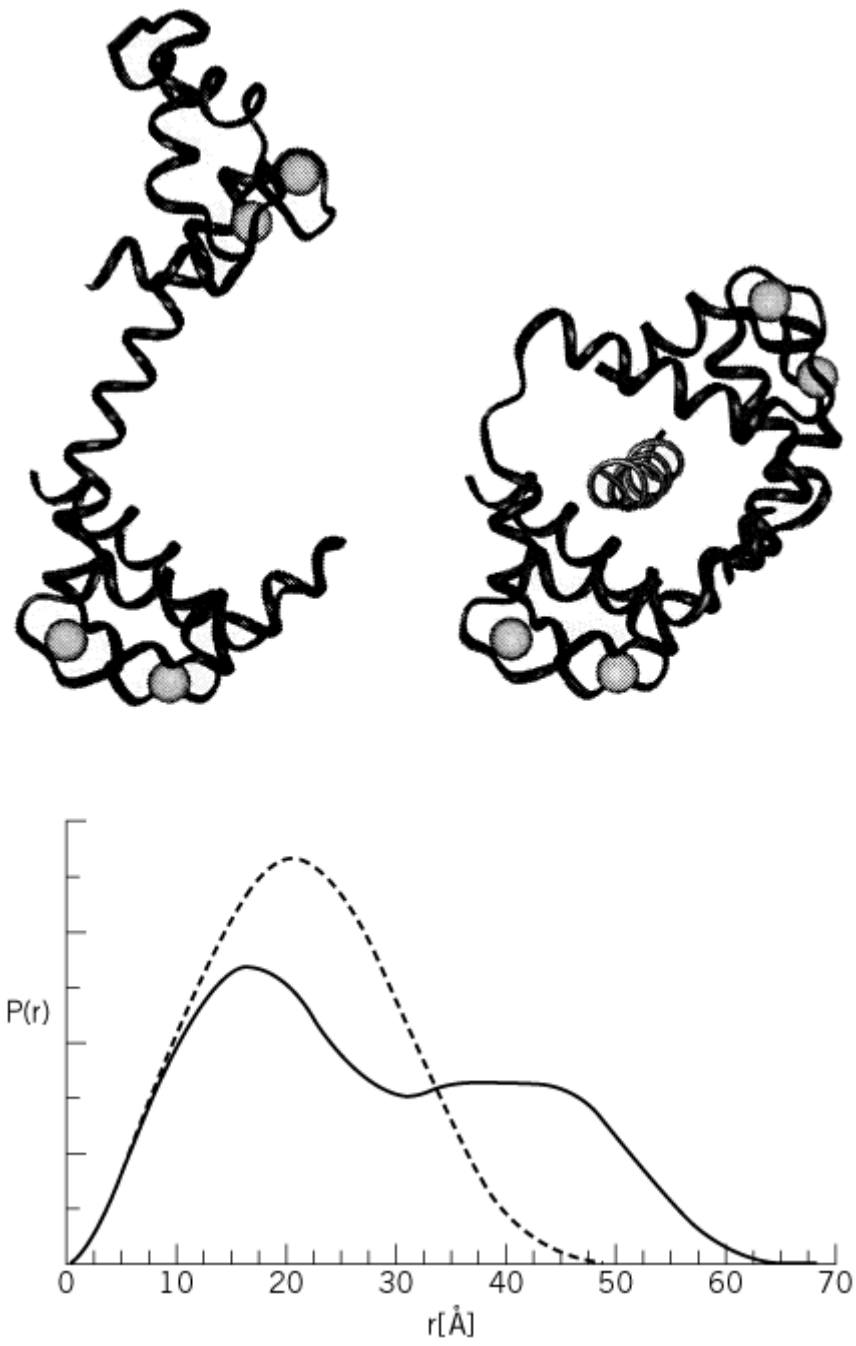
$$I(Q) = 4\pi \int P(r)\frac{\sin Qr}{Qr}dr \qquad (2)$$

$$P(r) = \frac{1}{2\pi^2}\int I(Q)Q \cdot r \sin(Q \cdot r)dQ \qquad (3)$$

$P(r)$ is the frequency of vector lengths connecting small-volume elements within the scattering particle, weighted by their scattering densities. $P(r)$ goes to zero at a value corresponding to the maximum dimension of the particle, d_{max}. Because $I(Q)$ can only be measured over a finite range of Q values, $P(r)$ is generally calculated using an indirect Fourier transform method in which the coefficients of the Fourier transform of a set of functions in real space are fit to the scattering data. Several such methods have been developed using different basis sets (1, 2); alternatively, a regularization method can be used (3). $P(r)$ is extremely sensitive to the symmetry of the scattering particle and to the relationships between domains or repeating structures. This effect is demonstrated in Figure 1, which shows the structures and corresponding model $P(r)$ functions for the calcium-

binding protein calmodulin and its complex with the peptide sequence of its binding domain in myosin light-chain kinase. The two globular domains of the uncomplexed calmodulin give rise to a $P(r)$ function with a maximum whose position is dominated by the most frequently occurring vector lengths within the individual domains, and a shoulder whose position is influenced by vector lengths between domains. The calmodulin complex is more compact and symmetric and has a correspondingly more symmetric $P(r)$, and its d_{max} is smaller. Small-angle scattering experiments showed this dramatic effect in 1989 (4), which has since been confirmed by high-resolution solution NMR studies (5) and has become a key element in our understanding of calcium/calmodulin enzyme activation (6).

Figure 1. Ribbon representations of the structures of the crystal form of calmodulin [*upper left* (22)], its complex with its binding domain from myosin light chain kinase (MLCK) determined by NMR [*upper right* (5)], and the corresponding $P(r)$ functions represented by solid and dashed lines, respectively. Calcium atoms are represented as spheres. Small-angle scattering experiments (4) detected this dramatic conformational collapse by calmodulin that occurs upon binding the helical MLCK binding domain and is effected by flexibility in the helix connecting the two lobes of calmodulin. This figure is based on work done at Los Alamos National Laboratory.



A parameter often used in the interpretation of small-angle scattering data is the radius of gyration, R_g, which can be calculated as the second moment of $P(r)$. The zeroth moment of $P(r)$ gives the forward scatter, $I(0)$, which, when normalized to the protein concentration expressed in units of mg/mL, is directly proportional to the molecular weight of the particle for particles of equal scattering density (7). If the $I(0)$ values are normalized to molar concentrations, they will be proportional to the square of the molecular weight. Because most proteins have similar X-ray scattering densities, protein standards known to be monodisperse in solution can be used to determine the molecular weight of the scattering particle and to evaluate possible sample aggregation. For neutron scattering, the data can be scaled absolutely and precise molecular weights calculated (8). For a monodisperse solution of particles, the volume, V, of the scattering particle can also be calculated using the Porod relation:

$$V = \frac{2\pi^2 I(0)}{Q_i} \tag{4}$$

where Q_i is the scattering invariant:

$$Q_i = \int_0^\infty Q^2 dQ\, I(Q) \tag{5}$$

2. Interparticle Interference and Solvent Effects

Small-angle scattering theory assumes there is no correlation in positions or orientation of the particles in solution. For a dilute solution (<10mg/ml of a small protein ~50 kDa) the average distance between particles is ~200 Å and long-range electrostatic interactions are generally canceled by the distribution of positive and negative charges on the surfaces of the protein molecules. For highly charged macromolecules, or for higher concentrations, this approximation may not hold. In these cases, the scattering function will be convoluted with an "interparticle" structure factor $S(Q)$ which is less than 1 at $S(0)$, oscillates around unity, and is strongly damped with increasing Q (9). $S(Q)$ has a first maximum at ~2p/r_0, where r_0 is the average distance between neighboring objects. The contribution of the interparticle structure factor to the total scattering will be diminution of the lowest-Q data, giving rise to an apparent reduction in the structural parameters derived from the scattering data. Often there is a linear dependence on particle concentration, c, to these interparticle interference effects, and they can be eliminated by extrapolating $I(Q)/c$ versus c to infinite dilution ($c = 0$). Alternatively, one can minimize interparticle interference by adjusting the solution conditions, such as the pH (moving closer to the isoelectric point for the molecule can reduce the net charge on the molecule) or ionic strength (counterions can effectively screen charges on the surface of the molecule). If attractive forces exist between particles, the interparticle structure factor $S(0)$ is greater than 1, and the scattering particles will appear larger than they are.

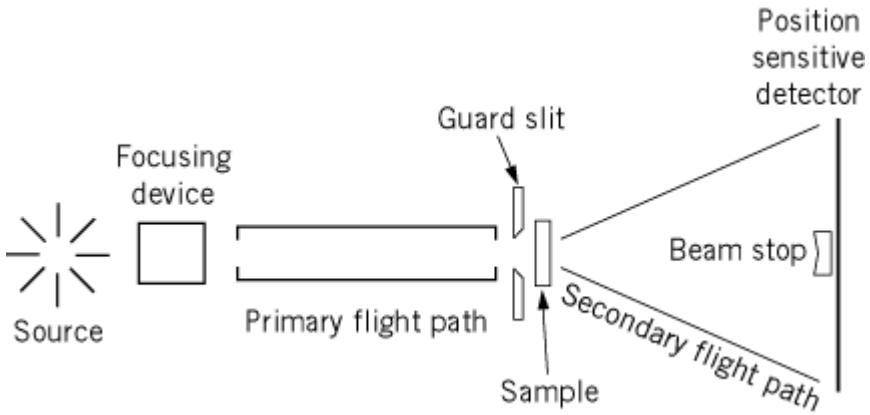
It is in general a good approximation to assume that a soluble protein in dilute aqueous buffer (<0.1 *M* salts) can be considered as a two-component solution of solvent and solute. In the case of highly charged molecules (such as DNA and very acidic or basic proteins in neutral pH solutions) with relatively high concentrations of salts, however, there can be preferential binding or repulsion of counterions to the surface of the protein that will effect scattering measurements (10). Such systems effectively have three components: solute, bulk solvent, and solvent at the surface of the solute. The effect on the scattering data is to make the scattering particles appear larger than they are.

3. The Experimental Setup

A small-angle scattering experiment is conceptually simple (Fig. 2). A source of radiation is required, followed by a collimated path (the primary flight path). In general the radiation is monochromatized, although instruments on pulsed neutron spallation sources have increased intensity and Q range using a "white" beam and time-of-flight methods to determine the wavelength of the neutrons arriving at the detector (11). In the case of X-rays, a focusing device is installed between the source and the primary flight path. Immediately after the exit aperture of the primary flight path, guard slits can be placed so as not to touch the beam, but to eliminate parasitic scatter from the experiment. The sample is placed immediately after the guard slits. Typically, sample volumes for X-ray experiments are quite small (~10 to 50 mL), while neutron experiments use larger beams and hence require larger sample volumes (~200 to 600 mL). The solute concentrations required for both X-ray and neutron experiments are similar, 1 to 10 mg/mL, depending on the molecular weight of the solute. Because of the molecular weight dependence of the scattering intensity, larger molecules can be measured using samples with lower solute concentrations. A position-sensitive detector is placed at some distance from the sample. This distance is

approximately equal to the primary flight path in order to minimize beam divergence. The path after the sample to the detector is called the secondary flight path. Detectors may be one- or two-dimensional position-sensitive devices. Because small-angle scattering from randomly oriented particles in solution gives rise to circularly symmetric scattering, two-dimensional detectors offer the opportunity for circular averaging in order to increase signal-to-noise ratio. The total flight path of the instrument is designed so that ideally, in the absence of a sample, the radiation enters the collimator and passes undeflected through the instrument, to be detected at a single point on the detector. In practice, this point is a small area due to beam divergence. For X-rays, highly polished mirrors with a slight bend can be used as focusing devices to increase the intensity of X-rays throughout the systems. There are no simple focusing devices for neutrons, and hence the collimation is designed simply to select neutrons whose path is already directed to a point on the detector. When a sample is placed in position, it is bathed in radiation, and a fraction of the radiation is deflected to give rise to the small-angle scattering pattern. Because the intensity of the scattered radiation is small, very sensitive detectors are used that cannot tolerate the high intensity of the undeflected beam, so a small beam stop is placed in front of the detector to absorb the direct beam. The sample-to-detector distance needs to be large enough to resolve very small angles of fractions of degrees. The greater this angular resolution, the larger the objects that can be studied. For a small-angle X-ray instrument with copper K_a radiation (l = 1.54 Å, 1 Å = 10^{-10}m), a 65- cm secondary path length, and an ionizing gas chamber linear wire detector, Q values as low as 0.006 $Å^{-1}$ can be measured, which allows study of objects with dimensions of 100's of Å. Larger molecular dimensions can be measured using instruments with longer flight paths and/or longer wavelength radiation. Neutron small-angle scattering instruments typically can select wavelengths over a fairly wide range (4 to 10 Å at reactors, 0.1 to 20 Å at pulsed neutron spallation sources) and can have variable sample-to-detector distances, ranging from 1 to tens of meters.

Figure 2. Schematic diagram of a small-angle scattering experiment geometry (not to scale). 2q is the scattering angle.



The theory of small-angle scattering assumes point sources of radiation and monochromatic (single wavelength) radiation. This is not true, in practice and in fact some instruments are designed to used a slit beam geometry and/or a range of wavelengths to increase the flux on the sample, which results in a “smearing” of the scattering pattern that affects both the amplitude and shape of the scattering profile. Corrections can be made for both factors. In general it is easier to “smear” the models used to interpret the scattering data rather than to desmear the data. In addition, error propagation can be done more rigorously in the former case.

4. Examples of Applications of Small-Angle Scattering

Significant advances have been made in a broad range of areas in structural biology based on X-ray or neutron small-angle scattering analyses. Small-angle X-ray scattering has been used to characterize molecular hinges in bilobal proteins that allow for cleft closure to initiate either ligand binding and/or substrate binding and catalysis (12, 13) and the conformational changes involved in biochemical regulation by calmodulin (6). Small-angle X-ray scattering has also contributed to our understanding of the degree of compaction in **protein folding** intermediates, such as molten globules (14-16). Small-angle neutron scattering and contrast variation has yielded a model structure showing the shapes and interactions of the muscle proteins troponin C and troponin I (17) that has implications for the calcium-sensitive "switch" mechanism that controls the contractile apparatus. In the late 1970s, the solution structure of the nucleosome core particle was determined using neutron small-angle scattering and contrast variation (18, 19). The important result of this landmark study was that the DNA was found to wind around the outside of the histone protein core, which has important implications for DNA accessibility in DNA replication and transcription mechanisms. Neutron small-angle scattering with deuterium labeling and contrast variation has also revealed the dispositions of the component proteins and/or nucleotides in the ribosomes (20, 21) that are the **protein biosynthesis** factories in cells (see Neutron Diffraction And Scattering).

Sodium Dodecyl Sulfate (SDS)

Of all the detergents used, SDS is probably the strongest **denaturing** one known. In addition, earlier studies have also shown that SDS is efficient in solubilizing both proteins and lipids present in cell membranes (1). However, the highly denaturing property of SDS almost precludes its use in obtaining solubilized membrane proteins in their active conformation. In a few cases, SDS has been used to solubilize amphiphilic peptides and small membrane proteins for solution-state nuclear magnetic resonance (NMR) analysis (2). SDS is widely used in SDS–polyacrylamide gel electrophoresis (SDS–PAGE) for analyzing denatured proteins based on their molecular weights. SDS–PAGE has also been used on a preparative scale in the purification of proteins for N-terminal protein **sequencing**, raising **antibodies** and diagnostic studies of inborn neurological disorders (3, 4). Following separation, gel slices that contain the protein bands (or spots, when the proteins are resolved by two-dimensional gel electrophoresis) are excised from the polyacrylamide gel, and the proteins are then separated from the gel by electroelution .

The essential principle of SDS–PAGE is that protein molecules are denatured in SDS such that the **hydrophobic** portions of the long-chain SDS molecules envelope the denatured polypeptide chain . Consequently, the native charge of any protein is completely masked by the negative charge on the SDS molecules, and all proteins adopt similar denatured conformations. Thus, once the charge and shape differences among all the different protein molecules are eliminated, the proteins move (under an electric field) through the polyacrylamide gel matrix according to their molecular weights, that is, the high molecular weight proteins move more slowly than the low molecular weight proteins.

Solvent Flattening

The result of a structure determination by X-ray crystallography is the calculation of an electron density map and the construction of a molecular model of the structure in this map. Protein crystals contain large amounts of solvent that occupy the voids between the protein molecules. This solvent has a dynamic character. Therefore, in a high-quality electron density map, the solvent region is flat and has a relatively low density, whereas the protein region has a higher density and is certainly not flat. However, if the map is of poor quality, the solvent region will contain peaks and valleys of density. In solvent flattening they are simply removed by modifying the density to a low, constant value. An important condition is that the regions occupied by the protein molecules can be identified

as regions with relatively high density and that the boundary between the protein and the solvent region can be traced (1, 2). This modified map is closer to the correct map than the first, preliminary electron density map.

From this improved map, structure factors including phase angles are calculated. Then, the calculated phase angles are combined with the observed structure factor amplitudes to calculate a new electron density map. This solvent flattening procedure is repeated until no further improvement is obtained.

Solvent Perturbation Spectroscopy

The absorption spectra of the aromatic amino acids (phenylalanine, tyrosine, and tryptophan) depend on their molecular environments. Alterations in the solvent can thus be used to change the environment of those aromatic side-chains in a folded protein that are exposed to the solvent (see Protein Structure). In principle, this provides a method to identify residues that are located at the protein surface.

In general, small shifts in the wavelength of absorption occur as a response to changes in the solvent: a blue-shift of the spectra to shorter wavelengths is observed when the polarity of the solvent increases and a red-shift when the polarity decreases. For example, the maximum of the absorption of the phenol chromophore is blue-shifted by about 3 nm when the solvent is changed from CCl_4 to water (1). The solvent perturbation method has, however, found only limited applications. First, the changes in absorbance are generally small; secondly, the changes in the nature of the solvent have to remain very small in order not to perturb the conformation of the protein under investigation. The exposure of tryptophan residues to the solvent is much more easily investigated by fluorescence quenching (see Fluorescence Spectroscopy).

Somatic Hypermutations

Somatic hypermutations are a unique mechanism used by B cells to amplify immunoglobulin (Ig) diversity and permit antigen to select clones that express high-affinity **antibodies**. The rate of such mutations is very high, generally estimated to be 1 per 1000 base pairs per cell division. At the onset of a primary immune response, antibodies are of the IgM isotype and are generally of moderate affinity, because they essentially result from the expression of germline genes that have rearranged their mosaic of VDJ and VJ gene segments for the heavy and light chains, respectively, and that have no or very few mutations. As a rule, **T-cell**-dependent antigens will induce a second wave of antibody production, now of the IgG isotype. This takes place in secondary lymphoid organs (such as spleen, tonsils, or lymph nodes) that have been colonized by some stimulated B cells, generating a germinal center, where active cellular interactions take place, including cooperation between T and B cells, which is an absolute prerequisite for the initiation of hypermutations. B cells divide rapidly, giving rise to a clonal amplification *in situ*. They present a blastic morphology and are known as centroblasts, which define the so-called dark zone of the germinal center. As the centroblasts actively divide, they accumulate somatic mutations that are localized mostly in the regions of the VH and VL segments that do interact with the antigen. As a result of these mutations, the array of affinities will be largely increased, and the organization of the germinal center will permit the antigen to select positively the B cells that express at their surface the immunoglobulins with the greatest affinities. At this stage, centroblasts cease to divide, and they become small nondividing centrocytes that accumulate in the light zone of the germinal center, where they actively interact with numerous follicular dendritic cells. As a result of this interaction, the selected centrocytes can now be directed toward either plasma cell differentiation or become long-lived B memory cells.

The molecular mechanisms that drive somatic hypermutations are still only partially understood. Very clearly, this is a specific feature of B cells; although T cells share many common features with B cells, they make their **T-cell-receptor repertoire** by **gene rearrangements** alone and do not mutate. Somatic mutations have long been suspected on mouse l chains, because it was known that only three Vl genes were present in this species. Comparing their genomic structure with that of complementary DNAs prepared from Igl-expressing plasmacytomas indicated that additional mechanisms had to operate to amplify the diversity. This was also extensively studied with large collections of monoclonal antibodies derived at various times after immunization of inbred mice against the nitro-iodo phenyl arsonate hapten. The number of nucleotide substitutions clearly increased with time. They were scattered all along the variable regions, with a clear accumulation in the hypervariable regions, which suggested that a selection mechanism had taken place. A puzzling observation was that mutations were limited to the **V region** . Compared with the rearranged genomic gene, it was apparent that mutations were found not only in the coding region, but also in the 5′- and 3′-untranslated flanking regions. More precise information was obtained by Neuberger and Milstein at Cambridge (1). First, it was shown with the mouse k chain model that mutations were strictly dependent on the presence of the **enhancer**-containing region, located at the 3′ position of the Ck gene. Second, it was demonstrated that if the Vk gene region was replaced in a construct by another gene, such as the b-**globin** gene, mutations still occurred in the inserted sequence, clearly demonstrating that the mutational events were not dependent upon the V region structure itself. The information that is lacking to date is the nature of the enzymatic mechanism that must generate these mutations. Despite intense efforts from several laboratories, this problem has still not been solved.

Somatic Mutation

Somatic mutations are heritable changes in the genome of the non **germ-line**, **somatic cells** of an individual. When cells carrying a somatic mutation divide, they give rise to **clones** that are also mutant. The proportion of mutant cells in the population depends on the timing of the mutation. If the mutations occur early in development, the ratio of mutants to **wild-type** in the somatic tissue population is high, whereas if the mutation arises late in development, the proportion of mutants is low. In addition, somatic mutations can give rise to cancer (see Neoplastic Transformation). Somatic mutations occur at high frequency in **antibody**-producing cells. Some of these mutations result in antibodies with higher affinity for the antigen, thereby improving the specificity of the antibody response (see Affinity Maturation).

Sonic Hedgehog

The sonic hedgehog (SHH) protein belongs to a family of intercellular signaling molecules involved in patterning, growth, and cell-fate specification during vertebrate embryogenesis. SHH derives its name from the ***hedgehog*** (*hh*) gene of *Drosophila*, a segment polarity gene that was identified in a large screen for mutations that disrupt embryonic development. The bristle pattern on the cuticle of hh mutant flies is aberrant, which gives them a rough or hedgehog-like appearance. Several *Hedgehog* (*HH*) **genes** have been **cloned** from chick, rodent, human, frog, and zebrafish, and are expressed in tissues that have patterning activity and at sites of epithelial-mesenchymal interactions all over the developing embryo. The HH signal transduction pathway is highly conserved from *Drosophila* to vertebrates, and mutations in the *SHH* gene and components of its signaling pathway are responsible for developmental defects and tumorigenesis in humans.

1. SHH Protein Biochemistry

The SHH gene encodes for a secreted protein that consists of a signal peptide, a highly conserved N-terminal region and a more divergent C-terminal **domain**. SHH is produced as a 45-kDa precursor protein that cleaves itself **proteolytically** to generate two fragments, a 25-kDa carboxy-terminal fragment and a 19-kDa amino-terminal, biologically active fragment (SHH-N). The proteolysis, which is **catalyzed** by conserved residues within the carboxy-terminal domain of the precursor protein, also results in the covalent addition of a cholesterol molecule to the C-terminus of the SHH-N fragment (1). The lipid modification of SHH-N has profound consequences for localization of the protein. Cholesterol-modified SHH-N remains associated with the cell that produces it, whereas unmodified SHH-N produced from truncated complementary DNA is freely diffusible. Cell association is important for the patterning functions of HH in development. It may create a high local concentration of the protein and may also restrict its domain of activity within a tissue (2).

2. SHH and Patterning in the Vertebrate Embryo

HH proteins play key roles in patterning many tissues in the developing vertebrate embryo. Indian HH and Desert HH, two other mammalian HH **homologues**, regulate bone development and spermatogenesis, respectively. SHH is expressed at numerous sites of epithelial-mesenchymal interactions in the developing embryo, including the gut, lung, hair, whisker, and tooth. It also plays a role in establishing some of the major axes in early embryonic development: left-right asymmetry of the body, dorsal-ventral polarity in the central nervous system, and anterior-posterior polarity in the limb. SHH also induces specific neuronal cell fates in the central nervous system and promotes proliferation in a number of tissues.

2.1. SHH and Left-Right Asymmetry of the Body

The vertebrate body plan is patterned along three axes, anterior-posterior, dorsal-ventral, and left-right. The establishment of left-right asymmetry is essential for normal development and the correct positions of the internal organs. In vertebrates the heart is normally on the left and the liver on the right. At early developmental stages in the chick embryo, SHH expression is restricted to the left side of Hensen's node (a signaling center), well before the appearance of morphological asymmetries. The left-sided SHH expression restricts the expression of nodal, a secreted molecule of the transforming growth factor b (TGFb) superfamily, to the left side of the node. Ectopic expression of SHH on the right side of the embryo induces nodal expression on the right side and alters the position of the heart. These results suggest that SHH is part of the molecular cascade that controls left-right asymmetry in the developing chick embryo.

2.2. SHH and Neural Tube Patterning

The embryonic nervous system consists of a tube of proliferating cells that extends along the anterior-posterior axis of the embryo. The anterior region of the neural tube gives rise to the brain, and more posterior regions give rise to the spinal cord. The neural tube is patterned along its dorsal-ventral axis by signals from the overlying surface ectoderm and from the underlying mesodermally derived notochord. Signals from the notochord ventralize the neural tube and induce three major cell types: floor plate cells at the ventral midline, motorneurons at the ventrolateral position, and interneurons at more dorsal locations. SHH is expressed in the notochord at the stage in which it mediates its inductive effects on the neural tube, and treatment with SHH recombinant protein mimics the effects of the notochord on floor plate and motoneuron induction in neural tube explants cultured *in vitro*. The floor plate and motorneurons do not develop in SHH-null animals, suggesting that SHH signaling is required to induce midline structures in the neural tube (3).

The effect of SHH on cell fate induction in the neural tube is concentration-dependent. High concentrations induce floor plate, intermediate concentrations induce motorneurons, and low concentrations induce interneurons. Graded SHH signaling also regulates the expression of transcription factors in the neural tube. Low concentrations of SHH initially repress the expression of paired domain transcription factors PAX-3 and PAX-7 in the ventral neural tube, generating a population of ventralized progenitor cells (see Pax Genes). Later, graded SHH signaling establishes regional differences in the expression of two additional transcription factors, Nkx2.2 and PAX-6. Nkx2.2 is induced ventrally, and PAX-6 is expressed in a gradient dorsal to the Nkx2.2 expression domain. The position of the different SHH-induced neuron subclasses correlates with the regional differences in transcription-factor expression along the dorsal-ventral axis of the neural tube. SHH may establish neuronal identity in the neural tube by differentially regulating the expression of transcription factors, thereby establishing different progenitor cell populations along the dorsal-ventral axis of the neural tube. The response of progenitor cells in the neural tube to SHH signaling also depends on their position along the anterior-posterior axis of the neural tube; SHH induces the development of cholinergic neurons in the forebrain, dopaminergic neurons in the midbrain, and motoneurons in the spinal cord. The different outcomes of SHH signaling may be due to differences in progenitor cell identity established by signals that pattern the neural tube along its anterior-posterior axis.

2.3. SHH and Developmental Defects in Humans

Disruption of the normal midline patterning in the forebrain in humans results in a condition known as holoprosencephaly (HPE). In alobar HPE, the most severe form of HPE, the forebrain fails to separate into left and right hemispheres, and these patients have cyclopia and severe facial anomalies. The developmental defects observed in humans who have HPE are similar to those observed in SHH-null mice, raising the possibility that some cases of HPE may result from genetic alterations that disrupt SHH signaling. Subsequently, it has been shown that mutations in the SHH gene itself are responsible for some cases of autosomal-dominant HPE. Most of the mutations are point mutations that result in premature truncation of the protein or alteration of highly conserved residues, suggesting that this form of HPE results from haploinsufficiency of the SHH gene.

2.4. SHH and Somite Patterning

The skeletal muscle of the body is derived from segmented arrays of mesodermal structures called somites. Signals from the notochord and neural tube pattern each somite into two compartments: the ventral sclerotome, which gives rise to the vertebrae and ribs, and the dorsal dermomyotome, which gives rise to the dermis and the myotome. SHH can substitute for notochord-derived signals in promoting the expression of sclerotome markers in explanted somites, and in combination with WNT (a secreted factor that is present in the dorsal neural tube, see Wingless Signaling), it also promotes myogenesis in explanted somites. Three lines of evidence suggest that, instead of acting as an inductive signal for sclerotome and myoblast development in the somite, SHH is required for the survival and expansion of cells of the somitic lineages. First, cells in the somites undergo programmed cell death when the notochord and neural tube are surgically ablated (4). Secondly, small numbers of myoblasts and sclerotome cells still develop in SHH-null mice (3). Thirdly, SHH stimulates the proliferation of sclerotome cells and myoblasts (5, 6).

2.5. SHH and Limb Development

Vertebrate limbs develop from the limb buds, which are outgrowths of the body wall. Each limb bud is patterned along three axes, proximal-distal, dorsal-ventral, and anterior-posterior. Patterning along the anterior-posterior axis is controlled by the zone of polarizing activity (ZPA), a group of mesenchymal cells located in the posterior limb bud. When the ZPA is grafted onto the anterior side of a limb bud, it induces a mirror-image duplication of the digits. SHH is expressed in the cells of the ZPA, and SHH protein mimics the limb-duplicating activity of the ZPA. The use of SHH to pattern the vertebrate limb is a striking example of conservation in evolution—hh also controls anterior-posterior patterning in the developing wing and leg in *Drosophila*.

2.6. SHH and Long-Range Signaling

Induction of the floor plate by SHH is a short-range interaction that requires contact with the SHH-expressing cells of the notochord. The induction of motoneurons and sclerotome, however, occurs over a longer distance and does not require contact with the notochord. Because SHH is tethered to the membrane via its cholesterol anchor, it is not clear how it mediates these long-range effects. One possibility is that SHH induces the production of a secondary signaling molecule, which then diffuses and acts at a distance to pattern tissues. In *Drosophila*, the long-range patterning effects of the hh protein are mediated by the induction of ***decapentaplegic***, a fly TGFb homologue. Although there is no evidence that motoneuron induction in the neural tube occurs via the production of a secondary signaling molecule, there is a correlation in many other tissues of the developing embryo between the expression of SHH and the expression of bone morphogenetic proteins (BMPs), secreted signaling molecules that belong to the TGFb superfamily. SHH and BMPs are expressed in adjacent domains in the lung, gut, tooth, hair, and other tissues, and overexpression of SHH induces BMP expression in the developing gut. This suggests that some of the patterning activities of SHH may be mediated by BMPs.

3. SHH Signal Transduction and Cancer

Although most of the information about the signaling pathway activated by SHH has come from genetic analysis of *Drosophila* development, the fundamental aspects of the pathway are conserved

in vertebrates. The SHH receptor is Patched (PTC), a transmembrane protein with 12 transmembrane segments that sits in a complex at the cell membrane with Smoothened (SMO), a seven-pass transmembrane protein. According to the current model, PTC is required to inhibit the activity of SMO, thereby repressing the expression of HH-induced target genes. SHH binding to PTC relieves the inhibition of SMO and allows it to activate downstream components of the SHH signal cascade, which include members of the GLI family of **zinc-finger** transcription factors. A paradoxical feature of SHH signaling is that it also up-regulates PTC expression. One explanation for this cellular response is that, in addition to regulating the activity of SMO, PTC may also sequester SHH and, therefore, limit its range of activity. Animals that have targeted disruptions of the PTC gene (7) have severe neural tube defects that include an expansion of the floor plate. This suggests that PTC activity is required to regulate SHH signaling during vertebrate development.

In addition to its patterning activities during embryogenesis, SHH also plays a role in growth control in a number of tissues, including the lung, sclerotome, retina, myoblasts, and skin. Several lines of evidence suggest that inappropriate activation of the SHH signaling pathway plays a role in human tumorigenesis. First, SHH target genes GLI and PTC are expressed constitutively in a number of human basal cell carcinomas (BCCs), the most common tumor type in humans, suggesting that the SHH signal cascade is activated in these tumor cells. Secondly, overexpression of SHH in the skin of transgenic mice is sufficient to induce BCCs. Thirdly, mutations in the PTC gene are associated with the autosomal-dominant condition basal cell nevous syndrome (BCNS): in addition to developmental defects, patients with BCNS have a high incidence of BCCs and meduloblastomas. Fourth, mutations in PTC and SMO (8) have been found in a high proportion of spontaneous BCCs and meduloblastomas. Taken together, these data suggest that components of the SHH signaling cascade are important targets for genetic alterations in human cancer.

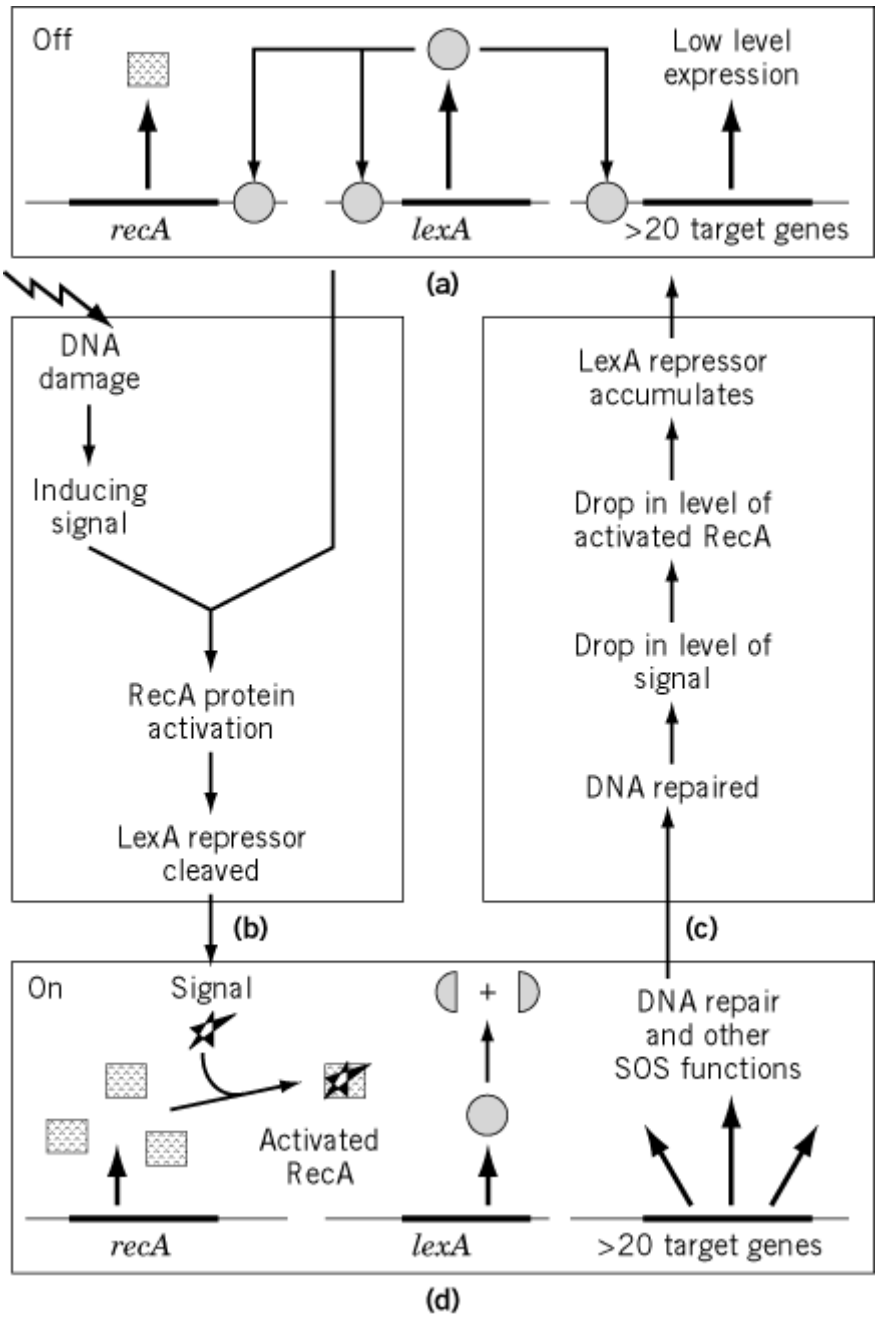
SOS Response

The SOS response is a global **gene** regulatory system used by **bacteria**, such as *Escherichia coli*, to respond to treatments that damage **DNA** or inhibit DNA replication . During this response, about twenty genes are expressed at increased rates. These genes are individually termed *SOS genes* and collectively the *SOS regulon*. Their expression is controlled by the interplay of two regulatory proteins: the LexA repressor, which inhibits expression of the SOS genes during normal cell growth (see also Repressors), and the **RecA** protein, which is activated by treatments that turn on the SOS response (Fig. 1). Activation of RecA leads in turn to inactivation of LexA by specific **proteolytic** cleavage (see LExA Repressor). It is thought that expression of the SOS genes helps the cell counteract the damage to the DNA, leading to repair of the damage and resumption of normal cell growth.

Figure 1. The SOS regulatory system. (**a**) State of the system during normal cell growth. The LexA protein is active and represses synthesis of RecA (left) and the SOS proteins (right). (**b**). Induction and transition to the induced state caused by DNA damage. The activated RecA protein causes the LexA protein to cleave itself into two pieces, which inactivates it as a repressor. (**c**). Induced SOS state. In the absence of active LexA, the *rec*A and SOS genes are expressed in large amounts. If the cell contains a l prophage, a prolonged stay in this state results in prophage induction. (**d**) Transition to the normal growth state. Activation of RecA is reversible, so that DNA repair leads to loss of RecA activation. The state of the system and the transitions between the two states are controlled by the level of RecA coprotease activity. Modified from Little and Mount (1982) with permission.



Although DNA is chemically stable, it can be modified by various agents in ways that alter its base-pairing properties (see Mutagenesis). Cells have a variety of mechanisms for repairing DNA (see DNA Repair). These mechanisms are expressed in *E. coli* at low levels that suffice to repair sporadic damage, but when the level of damage becomes high enough to threaten cell survival, the SOS system is turned on. Induction occurs within a few minutes, and the cells begin to recover from small amounts of DNA damage within half an hour. Many of the SOS genes play direct roles in DNA repair. Others, it is thought, aid cell survival in more indirect ways. For still others, no function is known, and they may play roles in cell survival under conditions different from those normally used to study *E. coli* in the laboratory.

The SOS response can be regarded as a signal transduction pathway, in which an ordered set of events occurs in response to a signal. In this particular system, the central part of the pathway is the best understood aspect. The nature of the signals that activate RecA and the functions of the SOS gene products are less clear. For this reason, the regulatory proteins are discussed first.

0.1. Regulatory Proteins

RecA is a complex protein that plays central roles in genetic recombination and DNA repair in addition to its regulatory role. From *in vitro* studies it is believed that the activated form of RecA is a helical filament containing many RecA molecules polymerized on single-stranded DNA and containing ATP or dATP. This filament also plays crucial roles in recombination and repair.

LexA is a repressor similar to phage l repressor. It contains an N- terminal DNA-binding domain and a C-terminal domain involved in forming dimers. The protein binds to sites on DNA with dyad symmetry, and the bound form is a dimer. The specific proteolytic cleavage site lies between the two domains of the protein. Therefore, cleavage separates the DNA-binding function from the dimerization function, and DNA binding is inhibited because the protein cannot dimerize. The proteolytic reaction is unusual biochemically in that cleavage is a self-processing reaction carried out by groups in LexA, not in RecA. Activated RecA serves as a "co-protease" to stimulate this reaction (see LExA Repressor).

If the cell contains a **prophage** for phage l or a related bacterial virus (see Lambda Phage), the CI repressor of the prophage can undergo the same type of cleavage reaction, again stimulated by activated RecA. The result of this reaction is termed prophage induction . The viral lytic genes, normally controlled by CI, are then derepressed, and the virus proceeds to grow lytically, releasing a burst of progeny virus. It is believed that the responsiveness of the CI repressor to activated RecA is an adaptation of the virus to a signal that the cell is in trouble and may not survive. In this view, the cell has not developed a regulatory mechanism for the benefit of the virus. Rather, the virus puts an existing cellular mechanism to its own uses. Cleavage of the l repressor occurs at a much slower rate than that of LexA. Accordingly, if the DNA damage is not severe, cleavage of CI does not proceed to completion before the DNA damage is repaired (see Fig. 1), and prophage induction does not occur. This differential sensitivity of LexA and phage repressors reflects their differing regulatory niches. LexA has evolved to respond rapidly even to small inducing treatments, whereas l has evolved to respond slowly and only to levels of damage that threaten cell survival. Indeed, prophage induction becomes efficient only at doses of DNA damage that begin killing the cells. Another difference between the two systems is that SOS induction is reversible, in that the cells return to the normal growth state. By contrast, prophage induction is irreversible because the complicated regulatory circuitry of the l genetic switch prevents further CI expression, even if cleavage ceases.

0.2. Inducing Treatments and Inducing Signals

A variety of treatments induce the SOS response. DNA-damaging treatments include irradiation with ultraviolet light and treatment with reactive chemicals, such as mitomycin C and methyl methane sulfonate. These agents have in common their ability to modify the DNA bases so that they cannot form **Watson–Crick base pairs**. Other treatments that interfere with DNA replication are also effective inducing treatments. Examples are **nalidixic acid**, which inhibits DNA gyrase (see DNA Topology), starvation of a thymine auxotroph for thymine, and exposure of many conditional replication mutants to restrictive conditions. All of these inducing treatments converge on RecA protein, which can be regarded as a sensor of the state of the DNA.

It is believed that one important (but perhaps not the only) way that RecA is activated *in vivo* is a consequence of the mechanism of DNA replication. When a replication fork encounters an abnormal, noncoding base in the template strand, further extension of the growing strand is blocked. A new Okazaki fragment begins at a distance, typically thought to be a few hundred nucleotides, downstream of the damage, leaving a gap of single-stranded DNA, termed a daughter-strand gap . One likely way that RecA is activated then is by binding to this gap. One prediction of this model is that if replication were inhibited in a way that does not produce gaps, DNA damage would not induce the SOS response. Various lines of *in vivo* evidence are consistent with this prediction (1). Moreover, it is thought that inducing treatments that do not damage DNA directly (such as nalidixic acid treatment) also generate single-stranded DNA. However, it remains possible that other types of inducing signals also activate RecA.

0.3. Functions of SOS Gene Products
Many SOS gene products are directly involved in DNA repair . These include the excision repair proteins UvrA and UvrB and proteins involved in daughter-strand gap repair, including RuvA, RuvB, and RecA itself. Other SOS gene products play less direct roles in DNA repair. The SulA protein is a cell division inhibitor. While the SOS response is activated, cells cannot divide. It is likely that this helps daughter-strand gap repair by keeping several copies of the chromosome in the same cell, thereby providing templates for damaged molecules.

The SOS gene products UmuD and UmuC play central roles in the process of SOS mutagenesis. This process is believed to be a "court of last resort," in which irreparable damage is converted to a readable sequence, usually producing errors. UmuD protein is processed after synthesis to its active form, termed UmuD′. Once again, this processing reaction is a specific proteolytic cleavage reaction entirely parallel to those that inactivate LexA and l repressor. It differs, however, in that the cleavage product is activated, rather than inactivated, by the cleavage. UmuD′ and UmuC work together with RecA, acting in still another role in DNA metabolism. It is postulated that these proteins act to reduce the proofreading activity of **DNA polymerase** III.

Still other SOS genes code for functions that are not understood. This may be a consequence of the fact that *E. coli* is not typically studied in its natural environment. Laboratory conditions (exponential growth in rich media) are chosen for their reproducibility and convenience, but in nature the organism is generally found in the gut or in dilute aqueous environments, such as streams. It is likely that some functions that promote cell survival after DNA damage in these environments differ from each other and from laboratory conditions.

Southern Blots (DNA Blots)

In 1975, Edwin Southern published the method for transferring electrophoretically resolved DNA restriction fragments from agarose gels to nitrocellulose membrane filters to be subsequently **hybridized** with **DNA** probes (1). This procedure has since been termed Southern blotting (or DNA blotting) and is a milestone in molecular biology (2). Southern blotting provides the connection between a specific nucleotide sequence (in a known or synthesized DNA fragment) and a resolved DNA molecule, a possibility that has been central to the discovery and molecular analysis of genes and their **transcripts** and the structural elements that regulate them (cross reference).

Typically, DNA fragments are resolved in agarose gels, which are then treated with alkaline buffers to **denature** the DNA prior to transfer to the blotting matrix. Then the gel is neutralized in mildly acidic buffers and is prepared for blotting. Traditionally the transfer is accomplished via convection (see Blotting), where the gel is placed on a paper wick that draws buffer from a reservoir (3, 4). A

blotting matrix (originally a nitrocellulose membrane filter, although nylon membranes are often a preferred alternative, see Blotting Matrices) is applied to the surface of the gel and a stack of absorbent paper (paper towels) is placed on top of the matrix. A weight is added to ensure uniform pressure over the surface of the blot. Upon completion of transfer (commonly performed overnight), the DNA is fixed to the nitrocellulose membrane by baking at 80°C, which should be conducted in a vacuum oven to prevent igniting the matrix (with nylon, UV cross-linking is often employed). Then the blot is blocked, ie, prehybridized, originally with a solution containing a mixture of irrelevant DNA (eg, fragmented salmon sperm), polyvinylpyrrolidone, bovine serum albumin, Ficoll and a detergent, although other mixtures have since been found equally effective, especially with nylon matrices. The purpose of this step is blocking all unoccupied areas of the matrix to minimize nonspecific interactions with the probe. Probing the blot is achieved by incubating it in a solution containing the radioactively labeled single-stranded DNA or RNA of interest, typically at 65°C for 6 to 12 h. After incubation, the blot is washed extensively and ultimately autoradiographed.

Numerous modifications and improvements to the traditional procedure described have been introduced over the years (5). The time and temperature of probing, the salt conditions, and the presence of various reagents, such as **formamide**, all affect the stability of the hybrid formed on the surface of the blot. Thus the stringency of the assay can be varied, from which the degree of homology between the probe and bound DNA is inferred. The blotting matrices used and the methods of transfer have also been modified, for example, electrotransfer of DNA from **polyacrylamide gels** to nylon membrane filters in low salt buffers, to be cross-linked to the matrix with UV light (as opposed to baking at 80°C) is still considered Southern blotting.

Characteristically, the blot can be erased after having been analyzed by boiling the filter in an appropriate solution to remove the bound probe and thus enable a second round of reaction with a different probe. This can be repeated a number of times, which conserves DNA samples and allows efficient comparisons of probes and repeated examination of rare samples.

Soybean Trypsin Inhibitor (Kunitz), STI

Soybean trypsin inhibitor (Kunitz) (see **Serine proteinase inhibitors** and **Proteinase inhibitor, protein**) is a storage protein in soybeans. It is a polypeptide of 181 residues crosslinked by two disulfide bridges. The Arg^{63}-Ile bond serves as the reactive site for this powerful ($K_1 = 1 \times 10^{-11}$ M) inhibitor of trypsin. Chymotrypsin is also inhibited at this reactive site, albeit more weakly ($K_I = 1 \times 10^{-5}$ M). Soybean trypsin inhibitor (Kunitz) gave its name to a large family of proteins. Many, but not all, of these are proteinase inhibitors. The use of the word *Kunitz* for a family of predominantly plant inhibitors, as well as its use for the important family of predominantly animal

inhibitors [see **BPTI (bovine pancreatic trypsin inhibitor) (Kunitz)**], attests to Moses Kunitz's great achievement. However, it also causes massive confusion. Plant scientists think of STI, but medical and animal scientists of BPTI. Omitting (Kunitz) from STI was suggested, but that would also lead to confusion as soybeans contain many other trypsin inhibitors, among them several members of the Bowman–Birk family (see **Bowman–Birk proteinase inhibitors**).

Space Group

Crystallography is very important in molecular biology because X-ray crystallography can determine detailed and accurate structures of macromolecules. The molecules in a crystal are packed regularly throughout the crystal. This often leads to a symmetrical relationship among the molecules. Several types of symmetry elements occur: rotation axes, mirror planes, and centers of symmetry. In addition, the axes and mirror planes can be combined with a translation. The symmetry elements can be grouped in 230, and not more than 230, different ways, called space groups. The 230 space groups and their properties are tabulated in Ref. 1. As an example, one projection of the unit cell in space group $P2_12_12_1$ is given in Fig. 1.

Figure 1. One projection of the unit cell in space group $P2_12_12_1$. The graphic symbols indicate twofold screw axes. Molecules are related to each other by a 180° rotation around the axis plus a translation along the axis over half of the unit cell. The horizontal screw axes are above the plane of the drawing at one-quarter of the unit cell.

Spectrin

Spectrin is a flexible and elongated intracellular structural protein, originally isolated from **erythrocytes**, but now known to be a characteristic of many other cell types too. It is a major component of a supportive meshwork lying in the cytoplasmic face of the plasma membrane and in all cases plays an important mechanical role in helping to specify cell shape and in providing membrane stability. Spectrin associates indirectly with the membrane through the interaction of ankyrin with Band 3 protein (the **anion exchange protein**); it also interacts with a variety of other proteins, including actin. There are two types of spectrin molecule: (i) a-spectrin, which consists of a single a-chain of molecular weight about 240 kDa, and (ii) b-spectrin, which consists of a single b-chain of molecular weight about 230 kDa. Each has a length of about 100 nm and each can be conveniently divided into *N*-terminal, rod, and *C*-terminal **domains**. The *N*-terminal domain of b-spectrin (but not a-spectrin) contains an actin-binding site; the *C*-terminal domain in a-spectrin contains putative **calcium-binding** sites, and that in b-spectrin has an ankyrin-binding site. In between these end domains, the amino acid sequence has about 18 to 20 tandem repeats, each of length 106 residues. The repeat is predicted to be highly a-**helical**, an observation consistent with the overall observed a-helicity of the spectrin molecule (65% to 70%). It is these repeats that form the rod structure and account for the bulk of the observed molecular length. Approximately at the center of the rod domain is a region of sequence corresponding to part of the tenth repeat that is homologous to the ***src***-family of **protein kinases** and to phospholipase C. a- and b-spectrin form an antiparallel dimer *in vivo* in which the molecules are almost perfectly overlapped. These in turn aggregate via their end domains (the *N*-terminal domains of two a-spectrin molecules and two *C*-terminal domains of b-spectrin molecules) to generate a structure with actin-binding sites at each end separated by about 200 nm. The rod domain acts as a spacer between functionally important parts of the molecule (actin-binding site, Ca^{2+} binding site) and appears to have much potential for flexing and kinking.

If the entire sequence of the rod domain were a-helical, the predicted length would be close to three times that observed. Furthermore, there is evidence to suggest that a structure comprising a long single a-helix would be unlikely to be stable in an aqueous environment. Consequently it was proposed that short non-a-helical regions (perhaps b- turns) occurred in each repeat and that these would allow the a-helices to form an antiparallel bundle from a single spectrin chain, thus giving the structure its stability (1, 2). In such a bundle, two of the a-helical segments would lie parallel to one another but antiparallel to the third. This structure is known as the *three-a-helix motif* (3). An important development occurred when Winograd et al. (4) expressed appropriately phased fragments of *Drosophila* a-spectrin from which they were able to isolate a highly a-helical segment of length 109 residues. This folded into a stable structure, with properties very similar to those of native a-spectrin, and was proposed to correspond to the structural repeat. Its structure determined by X-ray crystallography (5) and nmr solution studies (6) confirmed the model of Parry et al. (3) in which the three a-helices were arranged in a left-handed bundle with left-handed chain connectivity (Fig. 1). The axial repeat was close to 5.0 nm as predicted, and the motif was stabilized by both nonpolar and interchain electrostatic interactions, again as proposed. Perfect coiled-coil packing, however, was not

maintained between two of the constituent a-helices, even though the sequences of all three a-helices exhibited the heptad repeat characteristic of such a conformation (5). Although there are elements of three antiparallel a-helices within an axial distance of about 5 nm along the rod domain, the structural unit can be considered as one long a-helix followed by a b-turn, followed by a short antiparallel a-helix of about half the length and another b-turn (Fig. 2). A very similar conformation is shared by both dystrophin and a-**actinin**.

Figure 1. Schematic diagram of a three-a-helix motif, showing the A, B, and C a-helices forming part of a left-handed coiled-coil structure. The connectivity was deduced as being left-handed on the basis of the number of potential interhelix interactions. The subsequent structure of a dimer determined by X-ray crystallography and nmr solution studies confirmed all the main points of this model. (From Ref. 3, with permission.)

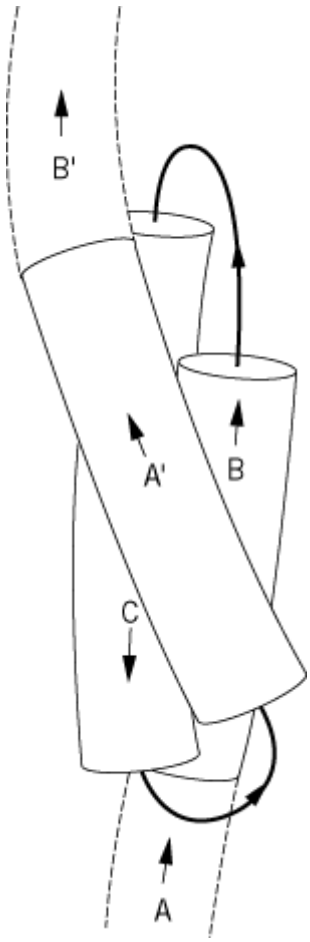

Figure 2. Schematic diagram of a portion of the rod domain of the spectrin superfamily of proteins. The repeat can be considered either as one a-helix about 9 nm in length (A and B) followed by a turn and then a second shorter a-helix about 5 nm long (C) followed by another turn, or as the three-a-helix motif illustrated in Fig. 1. It is predicted that the axial repeats will be different in spectrin and a-actinin. (From Ref. 3, with permission.)

Spectroscopy

Spectroscopy is the collective name for a diverse group of experimental techniques in which the interactions of electromagnetic radiation with a sample of interest are studied. Spectroscopies are grouped into different categories depending on:

1. the energies that are involved,
2. which type of transitions between energy levels are triggered in a molecule by the incident radiation, and

3. whether the molecules of interest absorb the energy or emit it (usually after prior excitation).

The energy E of an electromagnetic wave is proportional to its frequency and thus inversely proportional to its wavelength:

$$E = h\nu = hc/\lambda \quad (1)$$

where h is Planck's constant and c the velocity of light.

Most widely used are spectroscopic techniques in which the interaction of molecules with ultraviolet (UV) or visible (vis) light is studied. In this range, the energy of the incident radiation is equivalent to 150 to 400 kJ/mol, which is sufficient to promote electrons from the ground state to the first excited state. The absorbance of energy from the incident light as a function of its wavelength is measured in absorption spectroscopy. In fluorescence and phosphorescence spectroscopy (see Fluorescence Spectroscopy), the return from the activated to the ground state is studied. This deactivation is not always accompanied by the emission of light. Other pathways for deactivation can exist in which energy can be exchanged with the surrounding solvent, in a radiationless process.

Optically active substances can absorb left- and right-handed circularly polarized light to different extents. This phenomenon is called circular dichroism (CD). CD spectroscopy is especially well suited to study the conformations and conformational transitions of proteins and nucleic acids.

Transitions between different vibrational states of a molecule require energies in the range of about 50 kJ/mol (see Vibrational Spectroscopy). They lead to absorption of radiation in the infrared (IR) region of the spectrum, which is measured in infrared (IR) spectroscopy . Information about vibrations in molecules can also be obtained by Raman spectroscopy. The analysis of Raman spectra can complement that from IR spectra. To produce a Raman band, the polarizability of the molecule must change, rather than the dipole moment in IR spectroscopy, so the magnitudes of the IR and Raman signals differ.

Sperm

The spermatozoa in a male ejaculate are called sperm . A spermatozoon is the haploid, motile **gamete** of the male that is specialized in the transfer of genetic information and induction of the egg at fertilization. Spermatozoa are the smallest cells in the animal kingdom. They are produced in the testis from precursor **diploid** spermatogonia . These cells are located close to the basal lamina and are supported by sertoli cells. During proliferation and growth of spermatogonia, they undergo meiosis, develop to spermatocytes, and migrate from the basal lamina to the inner lumen of the testis. Differentiated haploid spermatozoa are transported to the epididymis, where they undergo further maturation to gain full motility and fertilization capacity.

The mature sperm cell consists of three distinct parts: a head, a midpiece, and a tail. The head consists of **acrosomal** and postacrosomal regions. The acrosomal cap covers the acrosomal vesicle. The head has dimensions 10×3 μm in mammals and contains mostly DNA, which is heavily condensed. This is due to the replacement of histones by protamines during spermatogenesis (1). **Gene expression** from the haploid genome in the fully differentiated sperm head has not been reported. The DNA in the sperm head is present solely for the transport of genetic information, along with a minimum of other material.

The midpiece of the sperm contains numerous mitochondria, which are closely attached to the dense fibers to provide energy for the movement of the **flagella**. These mitochondria do not become part of the new zygote and, consequently, mitochondria are inherited maternally exclusively. No ribosomes, endoplasmic reticulum, or Golgi apparatus are present in the midpiece or in the head. The proteins involved in sperm metabolism are the diazepam-binding **receptor** (2) and dynein (3). The sperm metabolism is also affected when deletions of the mitochondrial DNA are present, which appear to be associated with dead sperm in subfertile man.

The tail is important for the motility of the sperm. The flagella contain 9+9+2 dense fibers, of which the outer dense fibers are coded by *odf* genes (4-7)–. The *Fsc1* gene codes for a major **cytoskeletal** structure of the mammalian sperm flagellum (8). The ATP for motility is provided by the mitochondria in the midpiece.

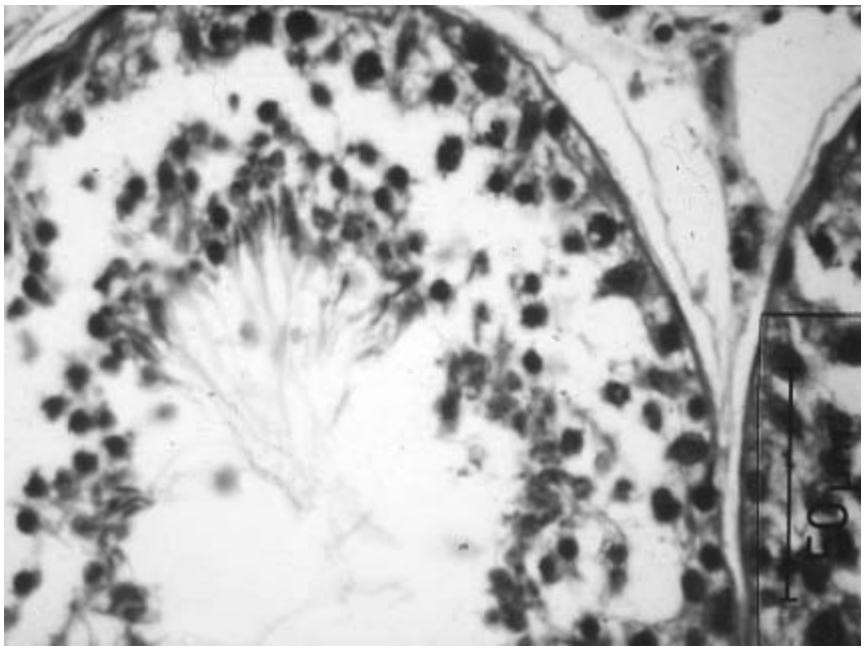
As spermatozoa are specialized to transfer genetic information and to induce the egg to promote the development of the new individual, they must have the ability to recognize specifically the **oocytes** to be fertilized. Adhesion molecules located on the surface of the acrosomal cap are called ligands and are responsible for species-specific interactions (see Acrosome and Fertilization). A plethora of adhesive proteins were found to interact with the zona pellucida of the oocyte. For instance, AQN and AWN, the so-called sperm adhesins (9), **beta-galactosidase**, a **trypsin**-sensitive site, and a number of proteins characterized immunochemically by their interaction with monoclonal antibodies were identified to be involved in binding to the egg. These are primary ligands (see Acrosome), most of which are expressed in the epididymis and then are associated with the acrosomal cap or the sperm head.

On contact with the zona pellucida of the egg, spermatozoa undergo an exocytosis, which is called the acrosome reaction. This essential reaction during fertilization leads to the exposure of those proteins that are otherwise protected by the acrosomal cap. The main component of the acrosome is *proacrosin*, which exhibits high affinity for zona pellucida **glycoproteins** and, after activation to *acrosin*, acts as a proteinase to digest zona pellucida glycoproteins locally (see Acrosome).

1. Spermatogenesis

During embryogenesis, primordial gonads develop that harbor the **germ cells**. The primordial urogenital tract develops either to a testis or an ovum. The primordial germ cells, the ancestors of which are the cells located in the polar plasma, increase in number by mitosis but, shortly after birth, mitosis comes to a standstill. From puberty on, because of an increase in testosterone levels, the type A stem spermatogonia start to divide again (Fig. 1). Diploid type A1 spermatogonia are produced, which undergo further rounds of mitotic divisions. After several rounds of mitosis, primary spermatocytes are formed, which enter a **tetraploid** phase. Subsequently, two cycles of meiotic division take place that are directed by the dose-dependent gene *roughex* (10) to form secondary spermatocytes and, subsequently, spermatids with a haploid genome. At the beginning of cell differentiation, the spermatids still have the shape of diploid cells. The process of histogenesis reshapes the spermatids. The change in morphology serves to produce cells that are specifically adapted to gene transfer. One feature of this specialization is the compaction and condensation of the nucleus, which is directed by transition proteins and protamines (11).

Figure 1. Development of sperm cells. Type A spermatogonia are located adjacent to the interstitial cells. They divide mitotically until primary spermatocysts are formed. The subsequent reduction of the genome occurs by two divisions during meiosis. Spermatids are formed, which then differentiate to spermatozoa. During this process, developing sperm cells migrate to the lumen. In the center of the tubuli, spermatozoa are visible. Further maturation of spermatozoa occurs in the epididymis. (Slide, with friendly permission from A. Bielefeld.)



Gene expression during the entire process of spermatogenesis can be divided into those genes that are expressed at the diploid stage (eg, *proacrosin*) or at the haploid stage (transition protein 2 gene) (12). Cytoplasmic bridges connect cells with each other so that an interchange of all necessary RNA, proteins, and so forth, is possible. During histogenesis, a tail is formed from a distal **centriole**, and the Golgi apparatus converts to the acrosomal vesicle and to the acrosomal cap. Mitochondria of the cell are arranged close to the distal centriole to form the midpiece later. The amount of **cytoplasma** is constantly reduced, and fully differentiated spermatozoa do not have any cytoplasm at all. Sometimes a droplet of cytoplasm that migrated to the distal end of the sperm tail is visible in ejaculated spermatozoa that have not matured completely.

Spermine, Spermidine

Spermine and spermidine are polyamines bound to **DNA** in semen and in other body tissues. Spermine is a tetramine, $H_2N\text{-}[(CH_2)_3\text{-}NH]_3\text{-}H$, and spermidine is a triamine, $H_2N\text{-}[(CH_2)_3\text{-}NH]_2\text{-}H$. The concentration of polyamines in the nucleus may modulate the binding of other proteins, such as histones, to DNA and facilitates the progression of enzymes like **RNA polymerase** along the DNA **double-helix** in a chromatin environment.

Sphingomyelinases

Sphingolipids constitute a large family of molecules based on a sphingoid backbone (such as sphingosine). Sphingolipids include sphingomyelin, ceramide, glycolipids, sulfatides, gangliosides, and other derivatives of sphingosine and ceramide.

1. Sphingolipid Structure and Function

The typical sphingolipid is composed of a sphingoid base, an acyl chain in amide linkage, and a substituent at the 1-hydroxyl position (see Fig. 1 for some representative structures). Sphingolipids are known to participate in several functions of the cell. For example, certain glycolipids can function as **receptors** or components of receptors. Gangliosides and glycolipids play a role in cell recognition and cell–cell contact response. Many cell types display specific patterns of glycolipids and gangliosides, and these have been associated with specific stages of development, differentiation, or tumor progression (1, 2). More recent studies have identified emerging roles for sphingolipids in signal transduction in a manner analogous to the role of glycerolipids in the phosphatidylinositol (PI) cycle (see Phospholipases C) and other pathways of signal transduction (3-5).

2. Sphingomyelinases and Regulation of Ceramide Formation

Many extracellular agents and stimuli cause activation of sphingomyelinases and/or accumulation of endogenous levels of ceramide. These include cytokines (such as **tumor necrosis factor**-a, the Fas ligands, and **nerve growth factor**), agents of differentiation or growth suppression (such as glucocorticoids and 1-25-dihydroxyvitamin D_3), chemotherapeutic agents (such as cytosine arabinoside, vincristine, and daunorubicin), and other agents of stress or injury (such as heat and irradiation) (3).

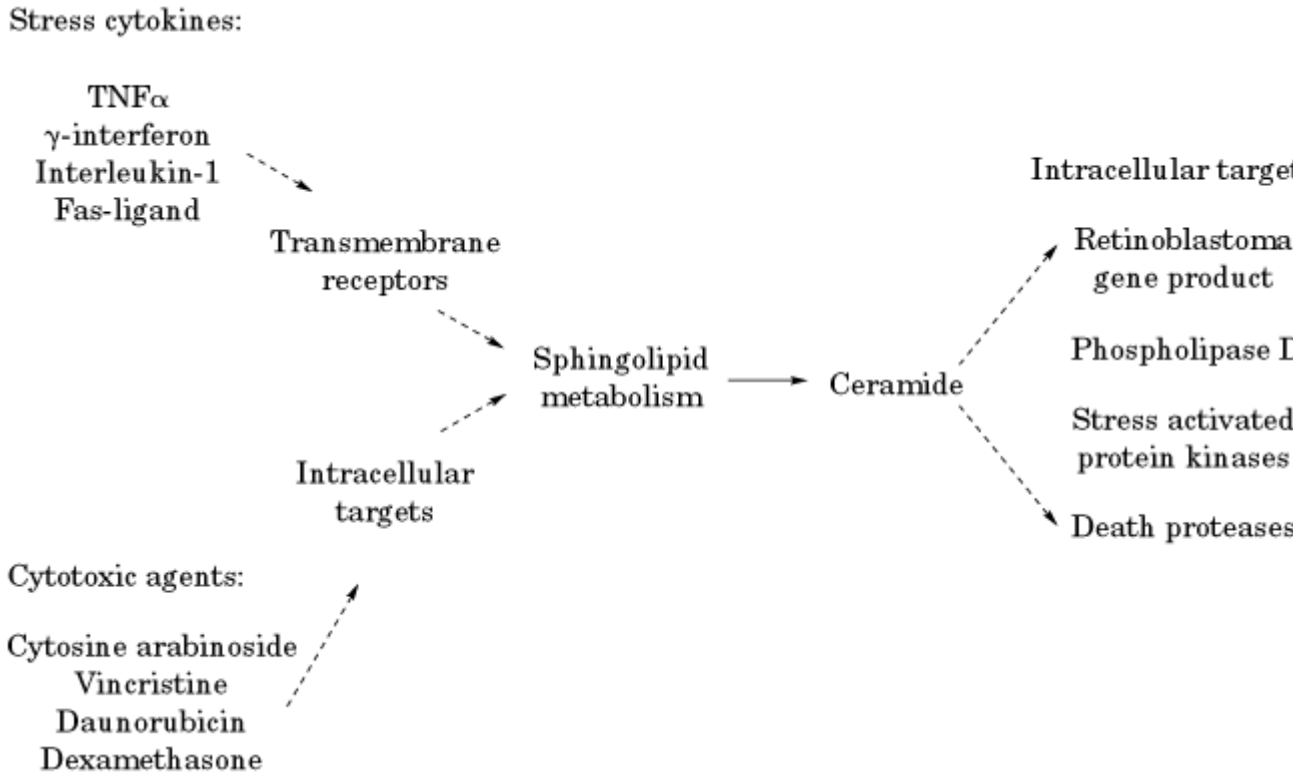
At least two distinct sphingomyelinases have been implicated in response to one or more of the above agents. Acid sphingomyelinase (with a pH optimum in the acidic range) has been cloned and is known to be deficient in the sphingolipid storage disorder, Niemann–Pick disease (6, 7). A secreted form of the enzyme is zinc-dependent and has been suggested to play a role in atherosclerosis. A neutral and magnesium-dependent sphingomyelinase has been implicated in the response to most of the above inducers of sphingomyelin hydrolysis and ceramide formation (3).

3. Ceramide and Sphingolipids in the Eukaryotic Stress Response

Ceramide formed in response to these agents participates in the **stress response** of cells (Fig. 2). The addition of cell-permeable analogs of ceramide or the modulation of endogenous ceramide

metabolism has been shown to regulate programmed cell death (apoptosis), cell cycle arrest, terminal cell differentiation, cell senescence, and inflammatory responses (8-11). In the cell, ceramide can regulate protein **phosphatases** and kinases, cell death proteinases, the **retinoblastoma** gene product, phospholipase D, and other elements critical in the response of cells to **mitogenic** or growth suppressor stimuli (12).

Figure 2. Scheme of the involvement of sphingolipids in stress responses. Various cytokines and cytotoxic agents modul and cause the accumulation of ceramide, which in turn serves to regulate a number of cellular processes related to growtl responses.



Sphingolipids are essential for the viability of **yeast**, as determined by the deletion of the first and rate-limiting enzyme of yeast sphingolipid biosynthesis, serine–palmitoyl transferase. Suppressors of this mutation result in viable cells that are defective in their response to environmental stresses such as heat, osmolarity, and acid pH (13). This can be overcome by the addition of specific sphingolipids. These result have been taken to suggest an important role for yeast sphingolipids in the response of yeast to various stress stimuli.

These studies demonstrate the significance of sphingolipids in stress responses of both “lower” and “higher” eukaryotic cells.

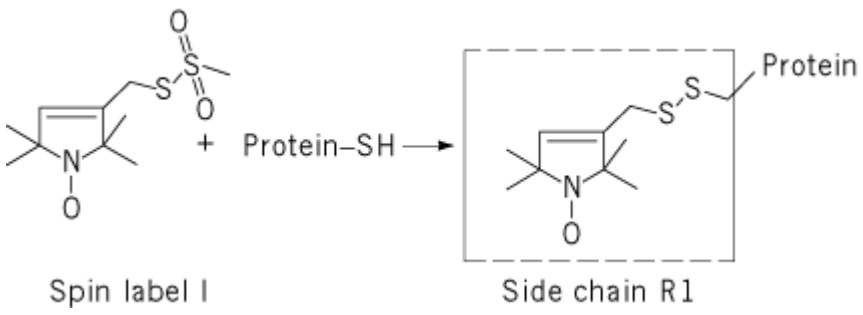
Spin Labeling

1. Spin Labeling

Unpaired electrons in molecules can be probed using **electron paramagnetic resonance** (EPR) techniques, but nature does not always provide the necessary free-radical at a site of interest. (1) Spin labels are stable, paramagnetic molecules that can be easily tailor-made by organic synthesis to provide selective structural and dynamic information via EPR spectroscopy (2, 3). An advantage of spin-label EPR studies is that they can be carried out at physiologically relevant temperatures. Nitroxide-labeled **nucleic acids** (4), lipids (5) and enzyme substrates (6) are among the varieties of spin label analogs that have been made. A molecular biology-based approach, called site-directed spin labeling (SDSL), for studying the dynamics, folding, and structure of proteins, has been developed (2, 3). In SDSL, a reactive nitroxide (for example, a methanethiosulfonate) reacts with a cysteine side chain that has been placed at one or more selected sites in a protein by site-directed mutagenesis. Figure 1 shows the reaction scheme most often used in the SDSL approach. Spin labels are also used in nuclear magnetic resonance (NMR) studies for drug discovery (7).

Figure 1. Introduction of a site-directed spin label. A methanethiosulfonate spin label reacts with the natural, or genetically engineered, sulfhydryl side chain of a protein to give a site-directed, spin-labeled protein. (Redrawn with permission from reference 2, Fig. 1.)



2. Dynamics of Proteins, DNA, and Membranes

The effects of motion of a spin labeled macromolecule can be observed indirectly as averaging of features in the EPR spectrum or directly by time domain EPR experiments. The effects of motion on a spin label EPR spectrum arise because the unpaired electron in the nitroxide molecule is in an asymmetric environment that renders its interaction with an external magnetic field sensitive to their relative orientations. When the spin label is rigidly attached to a larger molecule, the EPR spectra will reflect the motion of the macromolecule. The time-scale of motions that can be detected using spin-label EPR is determined by the frequency of the particular spectrometer used and the details of the detection scheme. Motions from milliseconds to fractions of a nanosecond have been measured. Applications include resolving spectra from distinct structural states of myosin in muscle (8), detecting time-dependent structural changes in bacteriorhodopsin (9), studies of the persistence length for DNA bending (4), and measurements of dynamics of lipids in membranes (5).

3. SDSL

This topic has been touched on in the preceding paragraphs (2, 3). The varied applications include determination of protein **secondary structure**, in which stepwise substitution of nitroxides on a protein structural element and magnetic effects of oxygen or paramagnetic ions in solution are used to determine surface exposure, and measurement of distances between two amino acid residues, in which two spin label sites are probed by EPR for magnetic interactions between them. Several experimental approaches can be taken to determine distances between spin labels on a macromolecule (2, 10). A measurement of inter-residue distance is illustrated in Figure 2. The inset (b) shows EPR spectra of folded, di-spin-labeled T4 lysozyme (bottom) and of the same protein unfolded in urea (top). The overall structure of the protein shown in (a) indicates the close proximity of the two spin label side chains. Spin labels separated by 7 to 24Å give broadened spectra from which the inter-residue distance can be determined. Once a protein derivative has been prepared with two interacting spin labels, spectral changes may be employed to measure the kinetics of refolding, as illustrated in (c). Inter-residue distances in membrane proteins, such as the lactose **permease** (11), can be estimated by the complementary techniques of **cysteine**-scanning mutagenesis and paired site-directed spin labeling.

Figure 2. Spin labeling of phage T4 lysozyme. The structure of a mutant form of T4 lysozyme in which two free cysteine residues were introduced (Ile3Cys and Val71Cys) and allowed to react with spin labels after reaction with spin labels is shown Figure 2a. The proximity of the spin labels leads to the broad electron paramagnetic resonance (EPR) spectrum shown in the inset (b, bottom). The EPR spectrum of the same sample unfolded in urea is sharp and shows little interaction between spin labels (b, top). The time-resolved rate of refolding can be followed by EPR (c). (Reproduced with permission from reference 2, Fig. 5.)

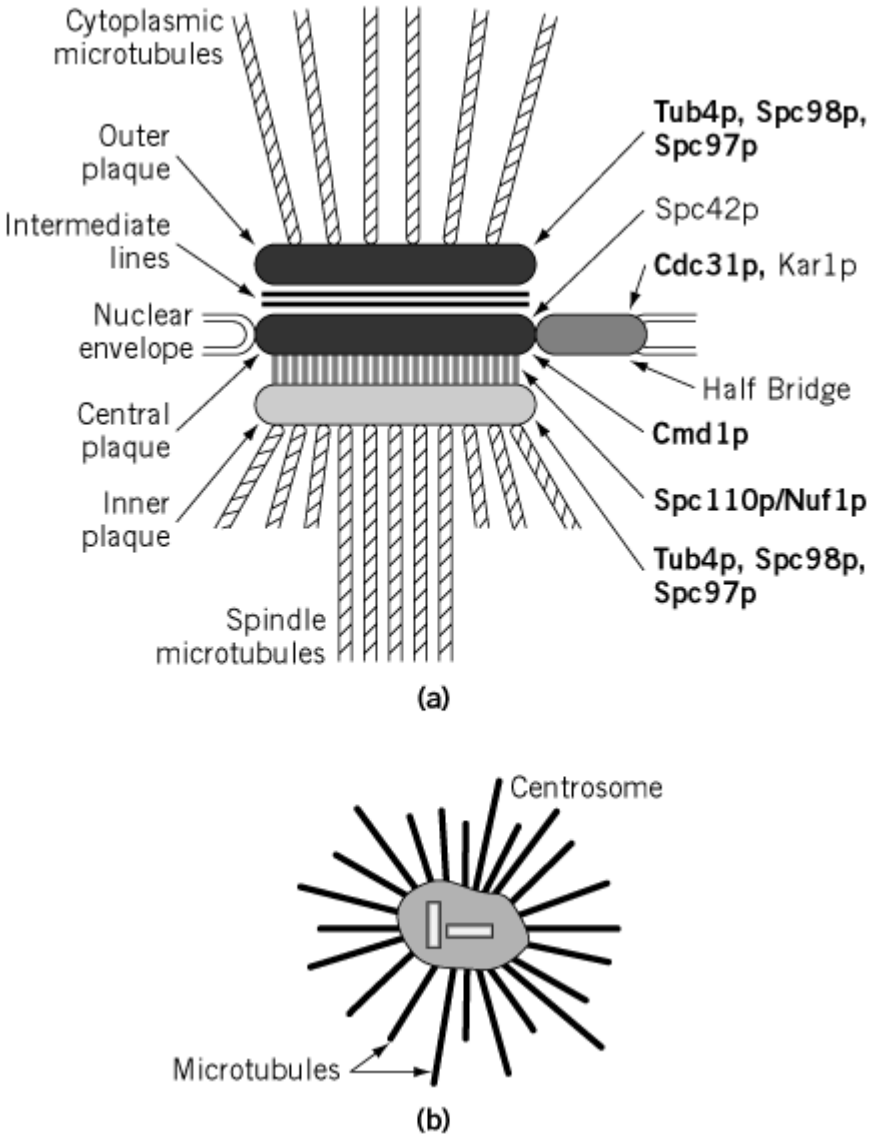
Spindle Pole Body

In yeast, microtubules are organized by the spindle pole body (SPB). The SPB is the fungal equivalent of the **centrosome**, and both are microtubule organizing centers (MTOC). Microtubules provide the physical means by which chromosomes are segregated during mitosis, and by which nuclei fuse during mating. SPBs organize the nuclear microtubules of the **mitotic spindle** and the cytoplasmic microtubules.

Since the baker's yeast *Saccharomyces cerevisiae* has been developed into a model genetic system, much has been learned about the SPB. The SPB is physically quite distinct from the animal centrosome, but the functional conservation is intriguing (Fig. 1). The centrosome consists of two centrioles surrounded by pericentriolar material, whereas the SPB is a multilayered cylindrical structure. Nevertheless, as more is learned about both MTOCs, some general themes emerge; there may be many more similarities than might be inferred from electron micrographs of these structures. Because *S. cerevisiae* is the model system in which the SPB has been most extensively studied, this article will emphasize what is known about the SPB in this yeast.

Figure 1. A diagram of the SPB of *S. cerevisiae* (**a**) with an inset diagram of the centrosome for comparison (**b**). For simplicity, the only proteins included are those both shown to localize specifically to the SPB (and not to the spindle microtubules near the SPB) and mentioned in the text. SPB proteins for which there exists a homologue in the centrosome are in **bold** (reviewed in (3, 17, 18)). Although the SPB has been studied by electron microscopy for many years, recent work has clarified some elements of SPB structure (the intermediate lines) (19). In the centrosome diagram (**b**), the gray represents the pericentriolar material; the inner rectangles are centrioles.



1. Structure of the Spindle Pole Body

The *S. cerevisiae* SPB is an electron-dense, short, cylindrical structure composed of several layers (Fig. 1). It is a permanent structure: it is always embedded in the nuclear envelope, and no nuclear envelope occurs breakdown occurs during mitosis in *S. cerevisiae*. This is in contrast with most other eukaryotes, where nuclear breakdown is concomitant with mitosis. Although permanence of the nuclear envelope is a common feature of yeast mitosis, a permanent association of the SPB with the nuclear envelope is not. In *Schizosaccharomyces pombe*, for example, the SPB is not permanently associated with the nuclear envelope.

The central plaque of the SPB is co-planar with the nuclear envelope and is interposed between the inner and outer plaques, from which the nuclear and cytoplasmic microtubules, respectively, emanate throughout the cell cycle (see Fig. 1). Separated by the nuclear envelope, the cytoplasmic and nuclear arrays are always separated compartmentally. Early in the cell cycle, a single SPB exists within the nuclear envelope.

Components of the SPB have been identified through biochemical, genetic, and direct cytologic approaches. Through biochemical approaches, some of the proteins that comprise the layers of the SPB have been identified (for example, Spc98p, Spc42p, and Spc110p/Nuf1p) (1-3). Some proteins

are thought to play a structural role, whereas others are more actively involved in association with microtubules. The essential phosphoprotein Spc42p, for example, is present at the central plaque. In conditional-lethal mutant strains containing a defective Spc42p, loss of viability occurs at the restrictive temperature as SPB duplication is attempted. SPB duplication is unsuccessful, and dense material collects above the half-bridge, suggesting that Spc42p is essential during SPB duplication, possibly for attachment of the SPB to the nuclear envelope. Overexpression of Spc42p results in a greatly lengthened central plaque, due to formation of a polymer of Spc42p (4).

Fibers connecting the inner and central plaques are composed of homodimers of Spc110p/Nuf1p, a coiled-coil protein. The coiled-coil encoding region of the SPC110/NUF1 gene is largely dispensable, and deletions of it lessen the distance between the central and inner plaques in a manner proportional to the length of the deletion. This distance between the inner and central plaques, although not essential for cell growth, was suggested to lend flexibility to the SPB, which might be important for microtubule array orientation after SPB duplication (5). Alternatively, such an element could allow regulatory molecules to access the dense SPB during SPB duplication or microtubule nucleation.

2. g-Tubulin and Microtubule Nucleation and Organization at the Spindle Pole Body

The major function of an MTOC is the nucleation and organization of microtubules. Microtubules do not polymerize spontaneously in vivo: The levels of tubulin within the cell are below the critical concentration necessary for spontaneous microtubule nucleation and assembly. Microtubules are nucleated in vivo at MTOCs, which obviate this requirement for a critical tubulin concentration. g-Tubulin, termed Tub4p in *S. cerevisiae*, functions specifically in microtubule nucleation. First discovered in *Aspergillus nidulans* (6), g-tubulin has been shown to localize to the MTOC and to be central to microtubule assembly. g-Tubulin is **homologous** to both a- and b-tubulin, but it is not incorporated into the length of the microtubule. Instead, it is a specialized tubulin that binds to the minus end of microtubules and is important for microtubule nucleation. In *S. cerevisiae*, Tub4p interacts with Spc98p and Spc97p, proteins that have homologues in higher eukaryotes (7-9). Together, these proteins form a complex in the cytoplasm, which then assembles at the inner and outer plaques (10, 11).

The organization of microtubules at the SPB is highly regulated. Because tubulin exchange occurs at both ends of the microtubule, the SPB presumably controls the activity at the minus end (the end proximal to the SPB). It has been suggested that g-tubulin has a role in depolymerization at the minus end of the microtubule, as a mutant g-tubulin gene in *A. nidulans* was able to suppress a microtubule hyperstability phenotype conferred by certain b-tubulin mutations. These g-tubulin mutants were proposed to do this by increasing the rate of depolymerization at the minus end of microtubules as a consequence of tubulin heterodimer removal (12).

3. SPB Duplication

Because SPB duplication marks the beginning of mitotic spindle formation, the timing of mitosis depends on the timing of this duplication. Although several events in SPB duplication have been identified by **electron microscopic** analysis (13, 14), and proteins that function in this process have been determined, the mechanism of this duplication is still unclear. It is known that early in the G1 stage of mitosis the SPB is not duplicated and is flanked by a “satellite” that is thought to be the precursor of the new SPB. This satellite abuts the cytoplasmic side of the half-bridge, a thick portion of the nuclear envelope next to the SPB (Fig. 1). After passage through Start (see Cell Cycle), two SPBs appear, separated by a full bridge. How this occurs is an active area of research. Several proteins that localize by **immunofluorescence microscopy** to the half-bridge cause a block in SPB duplication when defective, supporting the hypothesis that the half-bridge is important for duplication (reviewed in (14)).

SPB duplication is known to be a highly regulated process. SPB duplication must occur exactly once

per cell division cycle. Although many SPB proteins appear to be regulated by **phosphorylation**, the exact functions of these phosphorylations are a continuing area of study. Mps1p is a kinase essential for SPB duplication (15). There are other likely means of regulation of SPB duplication. For example, Pcs1p, a proteasome component, is thought to be important for degrading some component prior to SPB duplication (16).

4. The SPB and the Centrosome

Despite the morphologic differences between the SPB and centrosome, research reveals an increasing number of protein homologues that are shared between these two organelles (Fig. 1). It appears that elements of the SPB that are closest to the minus ends of the microtubules are those most likely to have animal cell counterparts. Tub4p, Spc97p, Spc98p, and Spc110p/Nuf1p, among other proteins, all have homologues in centrosomes. In addition, regulatory proteins such as centrin and calmodulin exist in both the yeast SPB and the centrosome. It is unknown how extensive the analogy between SPBs and centrosomes will be, but it is remarkable that so many elements of the MTOC are so highly conserved in organisms as disparate as fungi and animals.

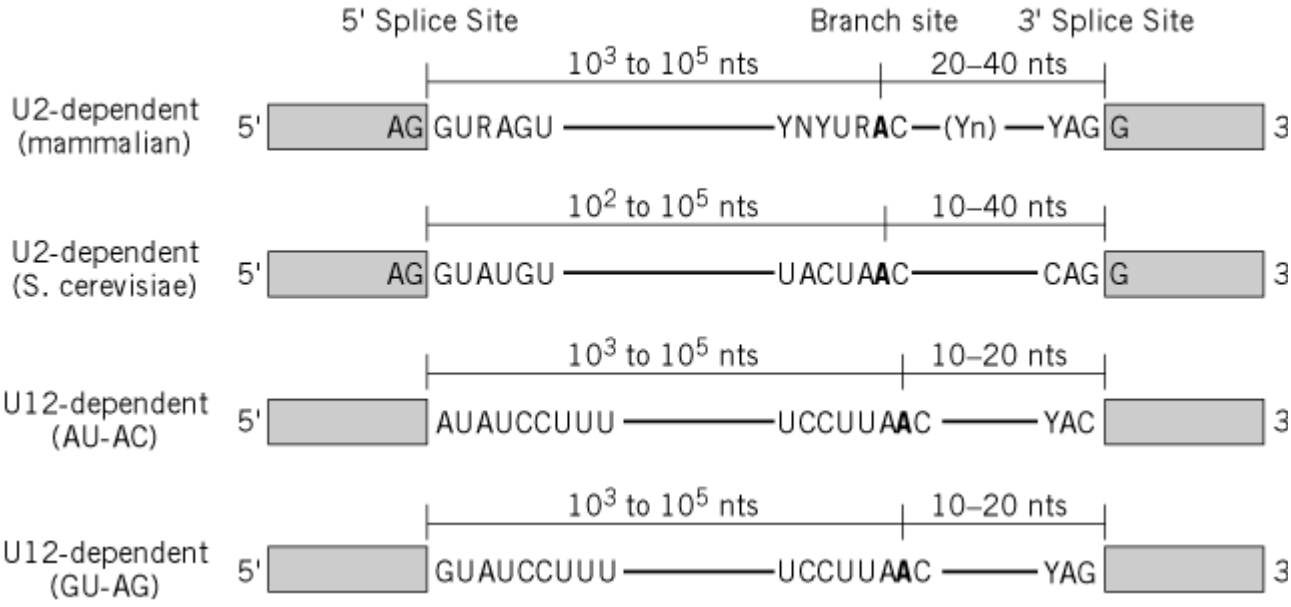
Splice Sites

Most eukaryotic **genes** are **transcribed** as messenger RNA precursors that contain noncoding regions called **introns**. Nuclear pre-mRNA introns are excised and the coding regions (exons) are ligated together by a process called RNA splicing. The exact phosphodiester bonds to be cleaved and ligated (ie, the so-called 5′ and 3′ splice sites, which are also referred to as the 5′ donor or 3′ acceptor sites, or left and right splicing junctions, respectively) are determined primarily by short conserved sequences at the exon–intron junctions (1). By comparing the sequences of nuclear pre-mRNA introns, **consensus sequences** surrounding the 5′ and 3′ splice sites have been identified. Based on the nature of these consensus sequences and the type of spliceosome that assembles on them, nuclear pre-mRNA introns have been divided into two classes: U2-dependent, which represent the vast majority of introns and are found in all eukaryotes, and U12-dependent, which are less abundant and absent from some eukaryotes (eg, the yeast *Saccharomyces cerevisiae*) (2). In the case of U2-dependent introns, mammalian 5′ splice sites are marked by the consensus sequence AG/GURAGU while those in the yeast *S. cerevisiae* are marked by AG/GUAUGU (where/indicates the splice site, R = purine, Y = pyrimidine, and N = any nucleotide) (see Fig. 1). The 3′ splice site can be divided into three distinct sequence elements that are typically found within the first 40 nucleotides upstream of the actual exon–intron junction (see Fig. 1). These include the so-called branch site, which is characterized by the consensus sequence YNYUAC in mammals and UACUAAC in yeast (where A represents the site of branch formation during pre-mRNA splicing), and the actual 3′ splice junction, which conforms to the consensus sequences YAG/G and CAG/G in mammals and yeast, respectively. In addition, many vertebrate U2-dependent introns contain a 10- to 20-nucleotide stretch of pyrimidines (designated the polypyrimidine tract) that is found just upstream of the 3′ splice junction. These splice-site consensus sequences are highly conserved in yeast, whereas in mammals the consensus represents the most prevalent sequence, but it often fluctuates considerably from one intron to the next. However, the terminal intron dinucleotides (GU and AG) are almost absolutely conserved in both higher and lower eukaryotes; greater than 99.9% of U2-dependent introns follow this so-called GU–AG rule. Mutations in these and other highly conserved nucleotides of both splice site sequences often lead to the activation of nearby sites (so-called cryptic splice sites) that are only used in the absence of the authentic site. Furthermore, splice site mutations account for a significant portion (up to 15%) of human genetic diseases that result from single point mutations (3).

Figure 1. Consensus sequences of nuclear pre-mRNA introns. 5′ and 3′ splice-site and branch-site consensus sequences are shown for U2-dependent introns in mammals and in the yeast *S. cerevisiae* and for U12-dependent introns, which are divided into (AU-AC) and (GU-AG) subtypes. R indicates a purine, Y a pyrimidine, and N any nucleotide. The branch point adenosine is indicated by bold lettering. In mammalian U2-dependent introns, a weakly conserved, 10 to 20-nucleotide-long pyrimidine tract (Yn) is found between the branch site and 3′ splice site. Exons are represented by shaded boxes and introns by lettering or a solid line. The intron lengths and distances from the branch point to the 3′ splice site, in nucleotides (nts), represent typical values for the majority of the specified introns. Due to limited information, the indicated length of U12-dependent introns is at present only an estimated value.



The recently identified minor class of nuclear pre-mRNA introns (ie, U12-dependent introns) contain distinct 5′ and 3′ splice-site consensus sequences, which are also summarized in Fig. 1. U12-dependent introns consist of two subtypes, AU-AC and GU-AG, which differ from one another solely in their terminal dinucleotides (4, 5). Both subtypes, which are estimated to comprise less than 0.2% of all nuclear pre-mRNA introns, possess strongly conserved consensus sequences at their 5′ splice site, branch site, and 3′ splice site and appear to lack a polypyrimidine tract (2, 6). The fact that these sequences are more highly conserved than the consensus sequences present in mammalian U2-dependent introns suggests that they play a greater role in directing the sites of spliceosome formation and thus ultimately the precise sites of cleavage and ligation during splicing.

The conserved sequences that define the 5′ and 3′ splice sites are recognized in a highly ordered manner by multiple factors during spliceosome assembly and the catalytic steps of splicing. For example, the 5′ splice-site consensus is bound initially by the U1 snRNP and subsequently by the U5 and U6 snRNPs, whereas the branch site is initially recognized by the splicing factor SF1/BBP and then interacts with the U2 snRNP. These and subsequent interactions ultimately lead to the formation of a catalytically active spliceosome that is responsible for the cleavage/ligation reactions of splicing. Due to their limited length and high degree of degeneracy in higher eukaryotes, however, the 5′ and 3′ consensus sequences do not contain enough information to distinguish authentic splice sites from other pre-mRNA sequences that mimic them. This is particularly a problem in higher eukaryotes where intron lengths can exceed 10^5 nucleotides and most pre-mRNAs contain multiple introns; yeast pre-mRNAs, on the other hand, contain at most a single intron whose length is typically much less than 10^3 nucleotides (7). How the correct 5′ and 3′ splice sites are first selected from a large number of potential candidates and then correctly paired is currently poorly understood (see also Alternative Splicing). In single-intron pre-mRNAs where the intron length is relatively short (ie, the

majority of pre-mRNAs used in *in vitro* splicing systems), splice-site recognition and pairing are thought to be mediated by interactions occurring at the early stages of spliceosome assembly between factors bound at the 5′ splice site and the downstream 3′ splice site (ie, across an intron) (see Spliceosome). In pre-mRNAs that possess multiple and relatively long introns, 5′ and 3′ splice-site recognition has been proposed initially to involve interactions that occur across an exon (reviewed in Ref. 8). This so-called exon definition model stems from the observation that the vast majority of exons in vertebrates are fewer than 300 nucleotides long. This would limit the number of competing nonauthentic splice sites located between the 3′ splice site and 5′ splice site flanking the exon and would ensure a relatively constant, short distance between them. Furthermore, this model is consistent with the observation that factors bound at a 5′ splice site can enhance the interaction of those binding to an upstream 3′ splice site (ie, across an exon). Because the splice sites within the same intron are not initially paired in this model, interactions between the proper pair of 5′ and 3′ splice sites have been proposed to occur at a later stage of spliceosome assembly, for example during B complex formation when the U6 snRNA interacts both with the 5′ splice site and with factors bound at the branch site (ie, the U2 snRNA) (see Spliceosome). While the exon definition model provides a general mechanism for this process, many aspects of splice-site recognition and pairing remain unclear and are thus the focus of much discussion and investigation in the nuclear pre-mRNA splicing field.

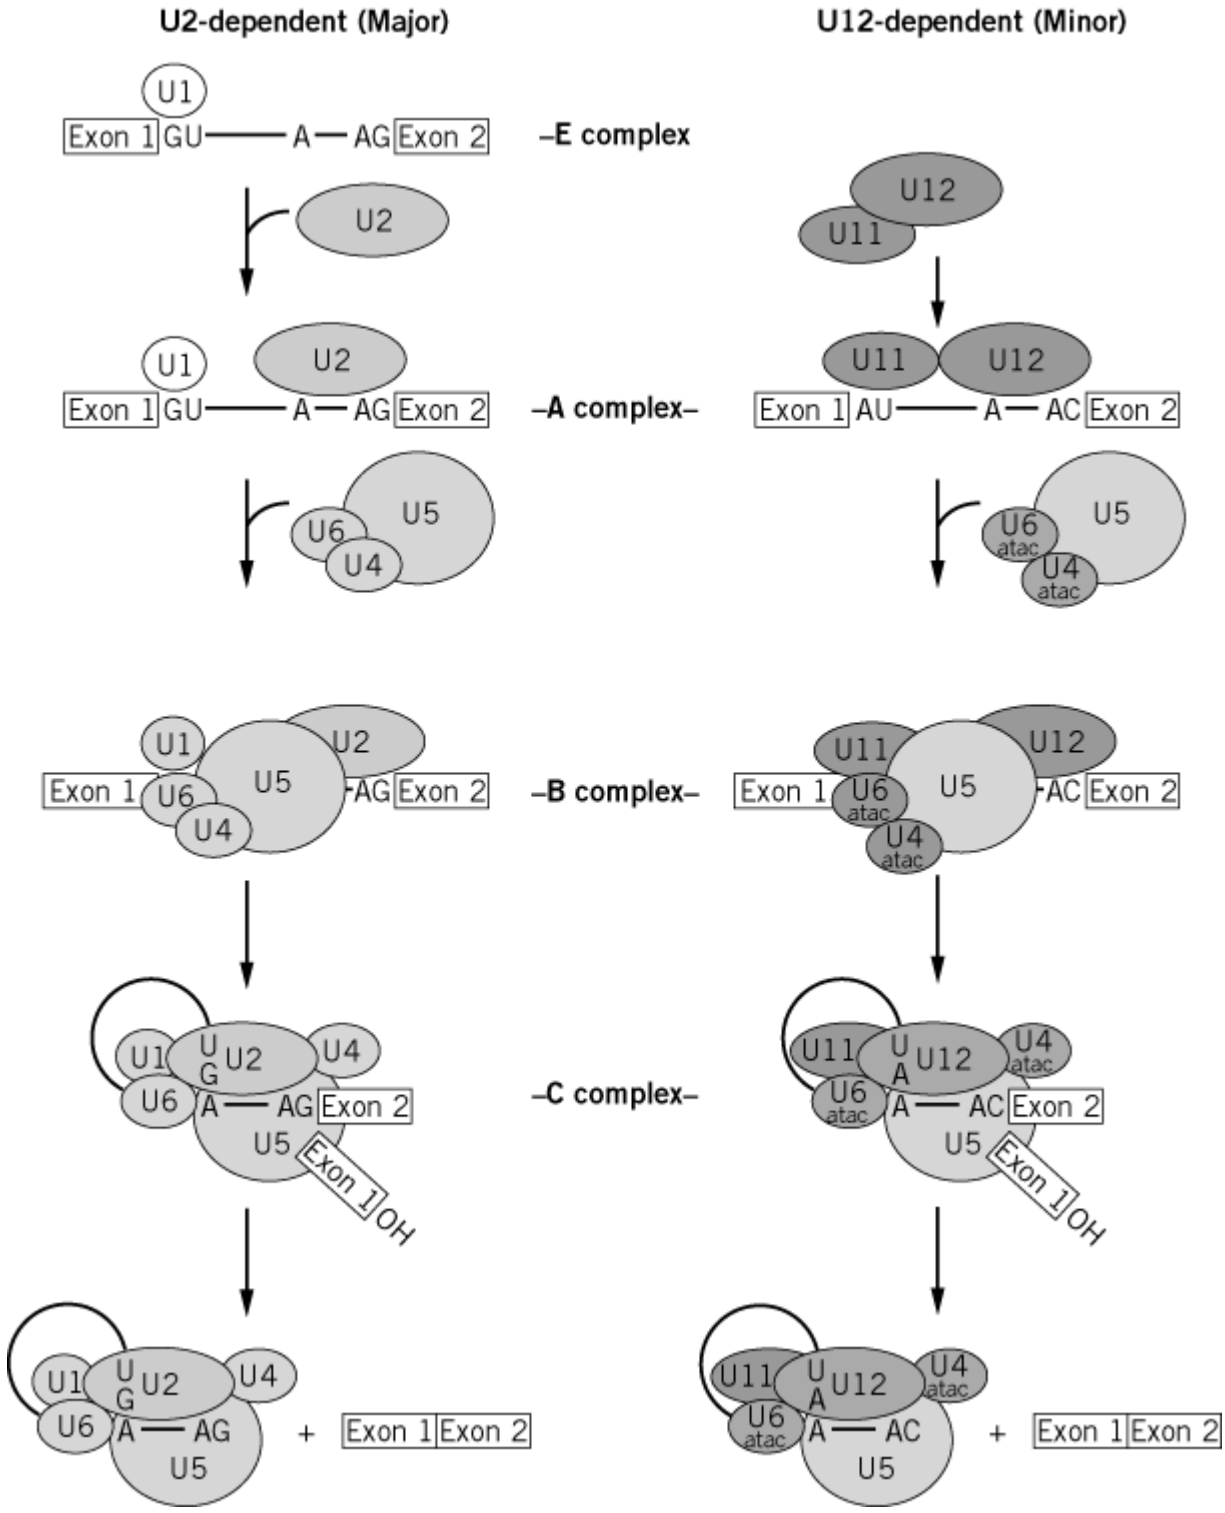
Spliceosome

RNA splicing of nuclear pre-mRNA is catalyzed by a large (50 S to 60 S) multicomponent ribonucleoprotein (RNP) complex termed the *spliceosome*. Spliceosomes are assembled stepwise on the pre-mRNA and consist of the UsnRNPs [see Small Nuclear Rnps (Snrnps)] and numerous non-snRNP proteins. During spliceosome assembly, the pre-mRNA is folded so that its reactive groups (eg, the 5′ splice site and branch site adenosine) are brought into close proximity. In this way, the

active site(s) responsible for the catalysis of splicing are formed. The majority of nuclear pre-mRNA introns are removed by the so-called major or U2-dependent spliceosome, which is comprised of the U1, U2, U5, and U4/U6 snRNPs. U12-dependent introns, which represent less than 0.2% of all nuclear pre-mRNA introns and have to date been identified in only a limited number of eukaryotes, are excised by the minor or U12-dependent spliceosome (1-3). The latter contains the U11, U12, U5, and U4atac/U6atac snRNPs. Spliceosome formation is a highly ordered process that requires ATP at all but the earliest stages of assembly. The assembly pathways of the major and minor spliceosomes are shown in Figure 1. The general assembly pathway of the U2-dependent spliceosome is identical in metazoans and yeast; due to the apparent lack of U12-dependent introns in the budding yeast *S. cerevisiae*, however, the latter does not possess a U12-dependent spliceosome (3). Because little is currently known about the U12-dependent spliceosome, we focus primarily on the mammalian U2-dependent spliceosome and refer to yeast only on those occasions where the two systems differ significantly.

Figure 1. Stepwise assembly of the U2- and U12-dependent spliceosomes. Only those steps that can be resolved by biochemical methods (eg, native gel electrophoresis or gel filtration) under normal conditions with mammalian splicing extracts are shown. For the sake of simplicity, the ordered interactions of the snRNPs (indicated by ellipses), but not those of non-snRNP proteins, are shown. The various spliceosomal complexes are named according to the metazoan nomenclature. Although not yet identified, a post-splicing complex (containing only the excised intron) similar to that formed upon dissociation of the U2-dependent spliceosome is depicted for the U12-dependent spliceosome. Exon and intron sequences are indicated by boxes and lines, respectively. The first two and last two intron nucleotides, as well as the branch site adenosine, are also shown.



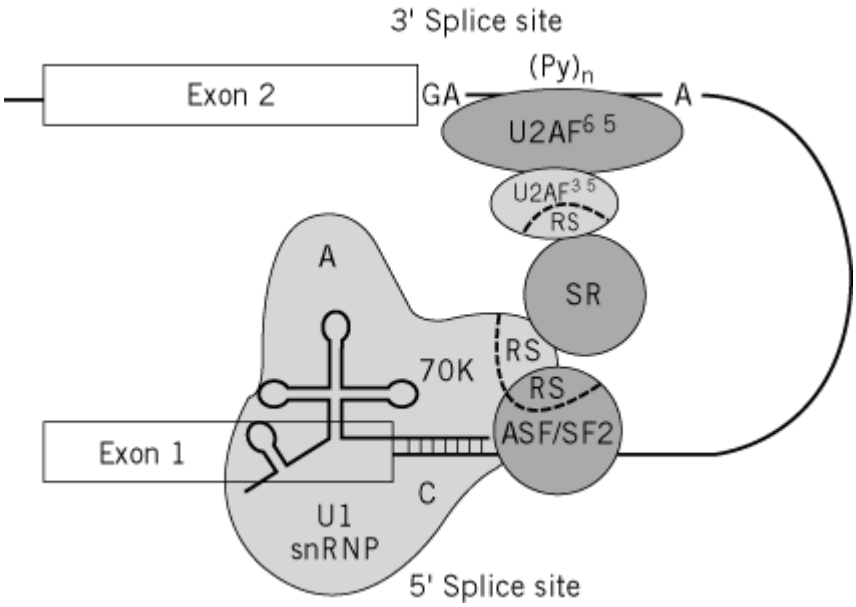
Although intermediate complexes exist (as evidenced, for example, by genetic techniques in yeast), under normal splicing conditions four distinct spliceosomal complexes can be readily detected by native gel electrophoresis and/or gel filtration. Assembly of the major spliceosome is initiated by the interaction of the U1 snRNP with the 5′ splice site of the pre-mRNA, which leads to the formation of spliceosomal complex E. The U2 snRNP then binds to the branch site, giving rise to the so-called pre-spliceosome or A complex. U5 and U4/U6 snRNPs, in the form of a preassembled [U4/U6.U5] tri-snRNP complex, subsequently interact to generate the spliceosome (B complex). After a conformational rearrangement, a catalytically active spliceosome (C complex) is ultimately formed.

Numerous non-snRNP splicing factors also interact at defined steps of the spliceosome assembly pathway and during catalysis (reviewed in Refs. 4 and 5). A similar assembly pathway has also been deduced recently for the U12-dependent spliceosome. In this case, initially the U11 and U12 snRNPs interact with the 5′ splice site and branch site, respectively (1, 2, 6, 7). Because the U11 and U12 snRNP form a stable 18 S di-snRNP particle, they, unlike U1 and U2, are thought to interact with the pre-mRNA together as a preformed complex (8). In the subsequent step, the U5 and U4atac/U6atac snRNPs also appear to interact as a preassembled [U4atac/U6atac.U5] tri-snRNP complex to form mature spliceosomes (9). Non-snRNP splicing factors present in the U12-dependent spliceosome have not yet been identified, but are also thought to associate at various stages of the assembly process. Although its characterization has just begun, initial studies indicate that an RNA–RNA network similar to that present in the U2-dependent spliceosome (see below) is also formed in the U12-dependent spliceosome. Based on these observations, it has been suggested that similar active sites are formed in both types of spliceosome.

1. E Complex

Spliceosome assembly is initiated by the formation of the commitment complex (yeast designation) or the early (E) complex (metazoan designation), in which the 5′ and 3′ splice sites are initially recognized by the U1 snRNP and the splicing factor U2AF (U2 snRNP auxiliary factor; Mud2 in yeast), respectively. E complex formation does not require ATP and may be considered a nucleation event for spliceosome assembly. That is, the pre-mRNA in these complexes is “committed” to spliceosome assembly, as evidenced by the inability of an excess of noncomplexed competitor pre-mRNA to inhibit the subsequent conversion of E complexes to active spliceosomes. In higher eukaryotes, E complex formation is dependent upon a complex set of molecular interactions involving primarily members of the SR protein superfamily. The latter proteins, which are not found in the yeast *S. cerevisiae*, are characterized by a domain rich in Arg–Ser dipeptide sequences (RS domain) and often one or more **RNA-binding** domains (RBDs) (reviewed in Refs. 10 and 11). Due to their modular organization, SR proteins can simultaneously bind RNA (eg, the pre-mRNA) via their RBD and other factors through **protein-protein interactions** involving their RS domain. Association of the U1 snRNP with the pre-mRNA involves base pairing between the 5′ end of the U1 snRNA and the 5′ splice site (Fig. 2) and is facilitated by several proteins, including the SR protein ASF/SF2 and the U1 snRNP 70K and C proteins (see Small Nuclear Rnps (Snrnps)). U2AF consists of a 35- and a 65-kDa subunit and interacts, via an RNA-binding domain in the latter subunit, directly with the pre-mRNA's polypyrimidine tract just upstream of the 3′ splice site (see Splice Sites). During E complex formation, a network of protein–protein interactions involving SR proteins is formed between the U1-70K protein and U2AF, both of which also contain an RS domain (Fig. 2). In this way, the 5′ and 3′ splice sites are apparently brought into close proximity with one another at the earliest stages of spliceosome assembly. In yeast, this bridging of the 5′ and 3′ splice sites may be carried out by proteins that are uniquely associated with the yeast U1 snRNP (12) (see Small Nuclear Rnps (Snrnps)).

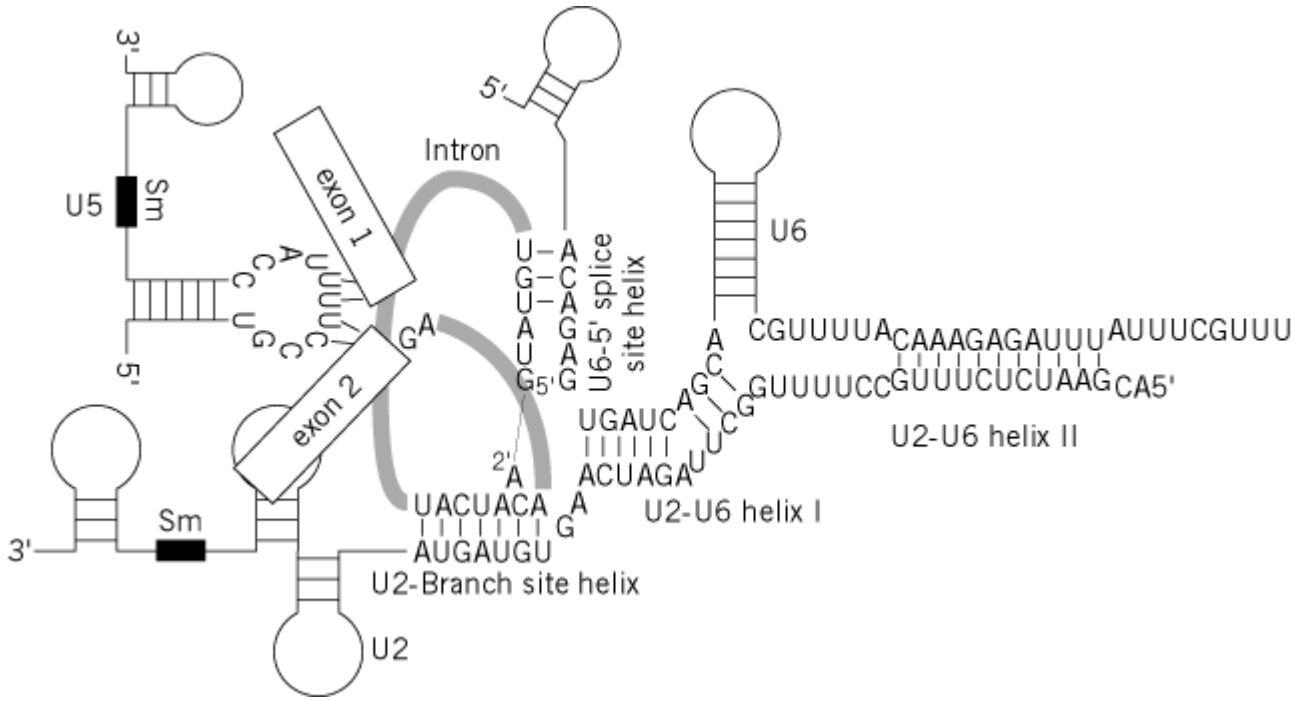
Figure 2. Network of protein–protein and protein–RNA interactions that occur during spliceosomal E complex formation. The U1 snRNP consists of the U1 snRNA (thick solid line), whose 5′ end base-pairs with the pre-mRNA's 5′ splice site, the snRNP core proteins (not indicated), and the U1-specific 70K, A, and C proteins. The U1 snRNA/5′ splice site interaction is facilitated by the interaction of the RS domain of the SR protein ASF/SF2 with that of the U1-70K protein. SR proteins are thought to bridge the 5′ and 3′ splice sites by interacting simultaneously with U1-70K and the 35 kDa subunit of U2AF, which also contains an RS domain. Exon and intron sequences are indicated by boxes and thin solid lines, respectively. RS domains are delineated by a dotted line. The branch point adenosine (A), the polypyrimidine tract (Py)n, and the conserved dinucleotide at the 3′ splice site (GA) are indicated.



2. A Complex

E complexes are converted to the pre-spliceosome or A complex by the ATP-dependent interaction of the U2 snRNP with the branch site. U2 snRNP binding involves base pairing between nucleotides near the 5′ end of the U2 snRNA and the conserved branch site sequence (see Fig. 3). This results in the bulging out of the branch site adenosine, which is thought to position it favorably for its nucleophilic attack at the 5′ splice site (see RNA Splicing). The interaction of U2 with the branch site is dependent on the presence of U2AF, as well as the splicing factor SF1/mBBP (BBP in yeast), which interacts with the branch site prior to A complex formation (13, 14). A subset of U2 snRNP proteins also plays a critical role in stabilizing the U2 snRNP interaction with the pre-mRNA. These proteins include the heteromeric splicing factors SF3a and SF3b, which are essential for A complex assembly and are part of the functional 17 S form of the U2 snRNP (see Small Nuclear Rnps (Snrnps)). SF3a and SF3b components interact with the pre-mRNA near the branch site and are thus thought to stabilize the U2 snRNP/pre-mRNA interaction (15). Most aspects of A complex formation appear to be conserved in yeast, including an essential role for the yeast **homologues** of most of the proteins comprising SF3a and SF3b (16, 17).

Figure 3. Network of RNA interactions occurring among the U2, U5, and U6 snRNAs and the pre-mRNA within the ma spliceosome. In this model, the pre-mRNA has undergone the first transesterification reaction. The cleaved exon 1 is hel place by interactions with nucleotides of the U5 loop 1 sequence. Exon sequences are indicated by open boxes; and intro sequences, other than conserved nucleotides at the 5′ splice site (GUAUGU), branch site (UACUAACA), and the 3′ spli site (AG), are depicted by a thick shaded line. The 2′, 5′ phosphodiester bond between the first intron nucleotide (G) and branch point adenosine is depicted by a thin dark line. Cartoon structural models of U2, U5, and U6 snRNAs are accordi to the metazoan consensus structure, whereas all nucleotide sequences are from the yeast *S. cerevisiae*. Courtesy of Patrizia Fabrizio.



3. B and C Complexes

Pre-spliceosomes are converted to spliceosomes by the association of a preassembled tri-snRNP complex that contains the U4/U6 and U5 snRNPs. B complex assembly is an ATP-dependent process that results in the formation of a complex pre-mRNA–snRNA network. In this network, the pre-mRNA is folded so that its chemically reactive groups (eg, the 5′ and 3′ splice sites and the branch site) are juxaposed (Fig. 3) (reviewed in Ref. 18). Subsequent to tri-snRNP association, the U6 snRNA dissociates from the U4 snRNA and forms new RNA duplexes with the U2 snRNA and intron nucleotides of the 5′ splice site (Fig. 3). These interactions appear to juxapose the 5′ splice site with the branch site adenosine, thereby facilitating the first transesterification reaction. Furthermore, the U6 snRNA/5′ splice site interaction appears to specify the precise site of nucleophilic attack at the 5′ splice junction. During B complex formation, the U1 / 5′ splice-site base-pairing interaction is disrupted, and the U5 snRNA, via its highly conserved loop 1, interacts with a small number of nonconserved exon nucleotides at the 5′ splice site (Fig. 3). This interaction is thought to be one of the factors responsible for retaining the cleaved 5′ exon in the spliceosome after the first transesterification reaction. Subsequent to this reaction, U5 loop 1 nucleotides also interact with exon nucleotides at the 3′ splice site, consistent with the idea that U5 also aligns the 3′ OH of the 5′ exon and the 3′ splice site for the second catalytic step of splicing. Although poorly understood when compared with the E and A complexes, B complex formation also undoubtedly involves the formation of multiple protein–protein and protein–RNA interactions. One well-established interaction is that between the U5 snRNP 220 kDa protein (Prp8p in yeast) and the pre-mRNA. This protein interacts with sequences surrounding both the 5′ and 3′ splice sites and is thus thought to stabilize U5 snRNA interactions with the pre-mRNA (19). In mammals, SR proteins have also been implicated in this step of spliceosome assembly, although the exact nature of their presumed interactions remains to be established (20). Recently, two proteins containing an RS domain, and therefore potential SR protein interaction partners, have been identified in the tri-snRNP complex (the U5-100 kDa protein and tri-snRNP associated 27 kDa protein) (21, 22). Thus, a network of SR protein interactions has also been proposed to help stabilize the interaction of the tri-snRNP complex with the pre-mRNA during B complex formation.

Just prior to or concomitant with the first transesterification reaction, major structural changes occur

in the spliceosome, generating complex C. This complex represents a catalytically active spliceosome that has undergone the first step of splicing and thus contains the pre-mRNA splicing intermediates (cleaved 5′ exon and the intron-3′ exon lariat; see RNA Splicing). The U1 and U4 snRNPs appear to be only loosely associated with the spliceosome at these later stages of the splicing reaction. Upon completion of both catalytic steps, the mRNA is released from the spliceosome in an ATP-dependent process, and the excised intron remains in a complex that is poorly characterized but contains at least the U2, U5, and U6 snRNPs. Ultimately, this post-splicing complex dissociates, and the intron lariat is debranched and degraded. The released snRNPs are believed to reassemble and participate repeatedly in new rounds of spliceosome assembly.

4. Dynamic Nature of the Spliceosome

Understanding the dynamics of RNA and protein interactions during spliceosome assembly and the catalytic steps of splicing is currently one of the major focuses of the nuclear pre-mRNA splicing field. Spliceosome assembly, as well as disassembly, is accompanied by changes in many of the interactions formed between the pre-mRNA and other spliceosomal components (snRNPs and non-snRNP proteins) and among the latter spliceosomal components themselves. The formation of some of these interactions is dependent on the disruption of others (ie, they are mutually exclusive), a phenomenon that appears to contribute to the highly ordered nature of spliceosome assembly. The best, albeit still poorly, understood conformational changes occur in the spliceosomal RNA–RNA network. For example, as eluded to above, major rearrangements occur at the 5′ splice site, which first interacts with the U1 snRNA and then, after U1 dissociation, with the U5 and U6 snRNAs. These multiple recognition events have been proposed to act as a proofreading mechanism that decreases aberrant cleavage at the 5′ splice site. Furthermore, the U6 snRNA exchanges its interaction partners, first base-pairing with the U4 snRNA in the tri-snRNP complex and later during spliceosome assembly with the U2 snRNA and the 5′ splice site. These and other RNA rearrangements appear to be catalysed by spliceosomal proteins belonging to the **DEAD**/H-box superfamily of ATPases and RNA Helicases. Members of this protein family share eight highly conserved sequence motifs, among them ATP-binding and hydrolysis motifs. At present, seven putative ATP-dependent RNA helicases have been detected in yeast and four in mammals (reviewed in Ref. 24). Some of these proteins (eg, Prp5p, UAP56,and Prp28p/U5-100 kD) perform essential functions during spliceosome assembly, facilitating U2 snRNP or [U4/U6.U5] tri-snRNP association. Others are required for the first or second catalytic steps of splicing (eg, Prp2p, Snu246/U5-200 kD, and Prp16p) or for the release of the splicing products from the spliceosome (eg, Prp22/HRH1 and Prp43p). Most of these proteins are known to exhibit RNA-stimulated ATPase activity. Thus, the requirement for ATP at various steps of the splicing process is due, at least in part, to the activity of these proteins. Only very recently has it been possible to demonstrate *in vitro* RNA duplex-unwinding activity for three of these spliceosomal proteins, namely Prp16p (25), Snu246/U5-200 kD (26, 27), and Prp22p (28, 29). Potential RNA substrates for each of these proteins have been proposed based on results obtained from *in vitro* studies and what is known about the step at which each of them is required for splicing. However, their exact substrates and functions within the spliceosome remain to be established. Spliceosomal rearrangements could also be facilitated by the U5 snRNP 116 kDa protein (Snu114 in yeast), which shares significant homology with the ribosomal GTPase EF2 (30). The latter protein facilitates translocation of the ribosome during translation, and the U5-116 kD protein has thus been proposed to function in an analogous manner in the spliceosome.

Although currently not well understood, changes in spliceosome structure also appear to involve the ordered formation and disruption of both protein–protein and protein–RNA interactions. For example, several spliceosomal proteins are known to interact transiently with the pre-mRNA and/or the spliceosome (5, 31). Changes in those interactions involving proteins may arise indirectly through the activity of RNA helicases or may be directly regulated by the activity of protein isomerases or **molecular chaperones**. Interestingly, a component of the [U4/U6.U5] tri-snRNP complex, the 20 kDa protein, shares extensive homology with known peptidyl-prolyl cis/trans

isomerases of the cyclophilin family, suggesting that it may promote protein conformational changes during splicing and thereby contribute to the dynamics of the spliceosome (32, 33). Protein–protein and protein-RNA interactions within the spliceosome also appear to be regulated by protein kinases and phosphatases. For example, SR proteins are known to undergo phosphorylation/dephosphorylation cycles during splicing, and their **phosphorylation** state has been shown to affect both spliceosome assembly and splicing catalysis (reviewed in Refs. 10 and 11). Several SR protein kinases (eg, SRPK1 and Clk/Sty) have been identified, and recently it has become clear that RS-domain phosphorylation can enhance the interaction of an SR protein with other RS domain-containing proteins (34). This suggests that SR protein interactions within the spliceosome are dynamic in nature. Moreover, at least two serine/threonine protein phosphatases, namely PP1 and PP2a, are required for both catalytic steps of splicing, and the former appears to be responsible for the dephosphorylation of one or more SR proteins (35). Despite recent advances, however, the regulation of nuclear pre-mRNA splicing by protein kinases and phosphatases remains a relatively poorly understood area of the splicing field.

Spore, Sporulation

Two of the major challenges facing all life forms are propagation of the species and survival under adverse conditions. One mechanism used by many organisms to meet these challenges is to encapsulate their genome in a specialized cell structure, known as a spore, that is metabolically inactive and often highly resistant to environmental assault. The spore protects the organism's genome until an appropriate time when the instructions encoded on the **DNA** can be used to produce a new individual. Because the morphogenic process of spore formation (sporulation) is often associated with extracellular production in many prokaryotic species of commercially valuable commodities (**antibiotics**, enzymes, bioinsecticides, and more) and is related to pathogenicity and toxicity of others, spore research remains an active and important scientific area. Additionally, sporulation cycles in some organisms serve as relatively simple examples of cellular differentiation events that can be analyzed at the molecular level.

Spores can be grouped into two broad types that are not necessarily mutually exclusive: reproductive spores and resting spores. The former, made by various **plant** species and some **fungi**, can be either single-celled or multicellular. Produced in enormous amounts and passively disseminated by wind, water, or animals after detachment from the parental organism, reproductive spores can each give rise to a new individual and thus serve for rapid increases in the population of the species. Resting, or dormant, spores are produced by many prokaryotic species (notably in the genera ***Bacillus***,

Clostridium, ***Streptomyces***, *Myxococcus*) and some lower eukaryotes (eg, ***Dictyostelium***) as a survival mechanism when the organism encounters an unfavorable environment. These spores can remain in a quiescent state until favorable growth conditions return, at which time they undergo a differentiation process, known as germination and outgrowth, to regenerate actively growing and dividing cells (vegetative cells). There is good evidence that dormant bacterial spores can remain viable for up to a century (1), and some recent observations suggest that survival for millions of years may also be possible (2). Although considerable progress continues to be made in unraveling the details of spore formation in *Myxococcus*, *Streptomyces* and *Dictyostelium* (for reviews see Refs. 3-5), the molecular biology of sporulation has been best characterized for *Bacillus subtilis*.

Extensive research on the structure and properties of *Bacillus* spores has served as a paradigm in the field. The two most important factors responsible for the longevity of these bacterial spores are:

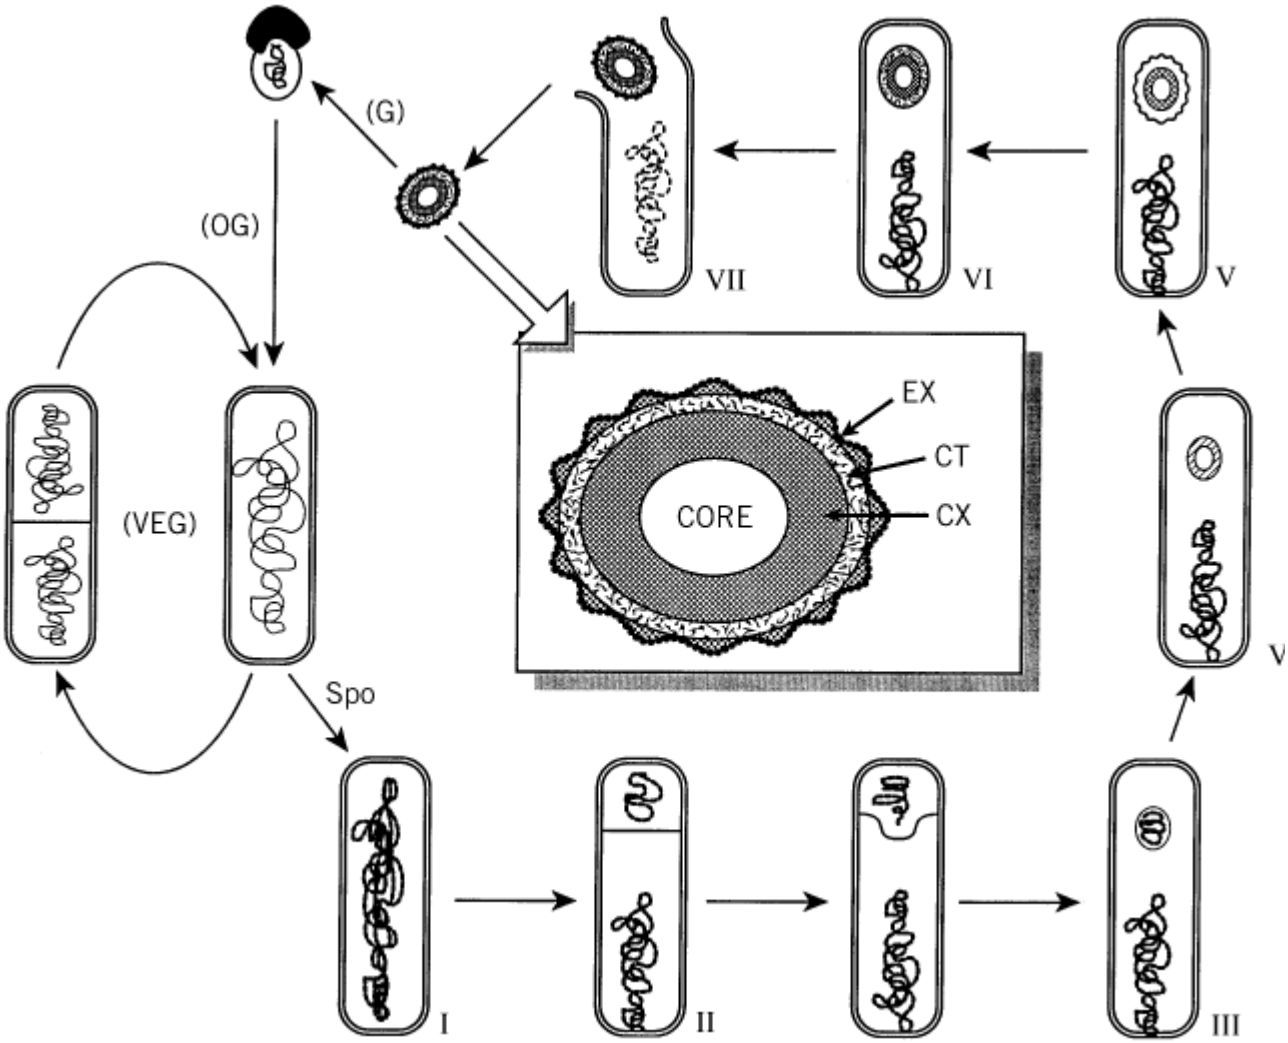
1. encasement of inactivated enzymes, ribosomes, and DNA in a dehydrated central core surrounded by a multilayered protective shell; and
2. protection of the DNA present in the core from environmental damage.

The factors responsible for the inactivity of spore enzymes are not entirely understood, but the lowered water content of the core (about 5- to 10-fold less than that present in the cytoplasm of growing cells) is undoubtedly a major contributor to both this property and to overall heat resistance (6). In spores of *Bacillus* and related genera, a class of fascinating proteins, known as a/b SASP (small acid- soluble proteins), coat the spore DNA and protect it from damaging assaults caused by desiccation, heat, oxidation and ultraviolet radiation (7). The multilayered integument (8) surrounding the core provides a permeability barrier preventing access of some damaging agents and functions to maintain physicochemical integrity of the core itself. From the inside out, the protective layers of a mature *Bacillus* spore generally include:

1. a cytoplasmic membrane enveloping the core;
2. a thin layer of peptidoglycan known as the germ cell wall that is very similar, or identical, to vegetative cell peptidoglycan;
3. a thick layer called the cortex that is comprised of a different form of peptidoglycan;
4. a second membrane;
5. a thick layer of proteinaceous coat that itself can be subdivided into layers of distinct appearance; and
6. an outer membranous layer known as the exosporium.

The morphological landmarks of *B. subtilis* sporulation are illustrated schematically in Figure 1. Mutation analysis has identified over 100 **genes** required for normal spore formation. Many of these genes are designated by a specialized nomenclature indicating at which morphological stage mutations in the gene halt development. For example, *spoII* mutants arrest at stage II (asymmetric septum formation) and do not proceed to stage III (forespore engulfment). Different operons are distinguished by a single capital letter (*spoIIA*, *spoIIB*, etc.), and different cistrons within the same operon are denoted by additional letters (*spoIIAA*, *spoIIAB*, etc.). Not all sporulation-associated genes use this nomenclature and, in many instances, elucidation of the biochemical function of the gene product has led to renaming of the gene (eg, *spoIIAC* was discovered to encode a s factor of **RNA polymerase**, and the gene is now called *sig*F).

Figure 1. Sporulation of *Bacillus subtilis*. Landmark morphological stages are: I, axial filament of chromosome; II, pola septation dividing the sporangium into smaller forespore and larger mother cell compartments; III, engulfment; IV, corte formation; V, coat formation; VI, maturation; VII, lysis of mother cell and release of spore. Under laboratory conditions 37%, the process takes about 8 h. Germination (G), outgrowth (OG), and vegetative growth (VEG) complete the life cyc The center inset is a diagram illustrating major features of a mature spore. The layers are not drawn to strict scale; spore membranes and distinctions in the coat layer are not shown. CX, cortex; CT, protein coat; EX, exosporium.



Sporulation is but one of the developmental options available to *B. subtilis* cells when they are deprived of nutrients and enter a stationary phase of growth. Numerous interconnected regulatory circuits sense the exact environmental and metabolic conditions and dictate which option is chosen. Initiation of the sporulation pathway is absolutely dependent upon the level of phosphate flux through a signal transduction system known as the phosphorelay (9). The phosphorelay is a complex assemblage of protein kinases, protein **phosphatases** and phosphorylatable proteins, with each component apparently being a focal point for input of signals indicative of nutritional and physiological status. There is only sketchy evidence suggesting how the activities of the kinases are regulated (10, 11) and how intracellular GTP levels might affect the phosphoprotein phosphotransferase encoded by *spo0B* (12). Most current excitement concerns the signaling roles played by small peptides that affect the activity of the phosphatases (13-15). The signals, whatever their exact nature, regulate the level of the ultimate output of the phosphorelay: Spo0A protein in its phosphorylated form (Spo0A~$P0_4$). Spo0A~$P0_4$ is a transcriptional regulatory factor that is responsible for activating expression of three operons (*spoIIA*, *spoIIG*, *spoIIE*) required for transition from stage II to stage III of sporulation. Additionally, Spo0A~$P0_4$ represses transcription of the *abrB* gene, and this leads to expression of many functions that had been kept silent during vegetative growth due to the regulatory actions of AbrB protein (16). Spo0A~$P0_4$ is also required for the hallmark of stage II: formation of an asymmetrically-positioned division septum. Although the exact mechanistic role of Spo0A~$P0_4$ in this event is unclear, it is clear that commitment to sporulate occurs soon after formation of this septum (17). Up until this point, the sporulation pathway could

have been aborted and the cell channeled either back into vegetative growth or else into an alternative developmental state of stationary phase.

Completion of the sporulation septum divides the cell (now termed the sporangium) into two compartments: the forespore (prespore) and the mother cell. [Because the mother cell subsequently engulfs the forespore compartment (stage III) and further development and maturation occurs in this configuration, the spore produced is more properly called an endospore.] Each compartment proceeds to express different sets of genes necessary for endospore formation. This compartmentalization is primarily due to differential activity of alternative RNA polymerase sigma factors (18), but it is likely that the differences in chromosome condensation in each compartment also play an important role (19). A fascinating aspect of sigma factor compartmentalization is that intercompartmental communication mechanisms temporally link the activity occurring in one compartment to the differential activity that occurs within the other. The general scheme of this crisscross regulation (20) is that σ^F activity in the forespore leads to activation of σ^E in the mother cell; σ^E activity in the mother cell is necessary for σ^G activation in the forespore; σ^G-directed transcription in the forespore is required for σ^K activity to follow σ^E activity in the mother cell. Much remains to be elucidated concerning how these complex interplays occur, but many of the details now known provide illustrative examples as to how cellular morphology can affect **gene expression**, and *vice versa*.

Spo0A~$P0_4$-activated expression of the operon (*spoIIA*) encoding σ^F occurs prior to completion of the sporulation septum, and so all three protein products of the operon (SpoIIAA, SpoIIAB, σ^F) are present in both compartments of the sporangium. However, σ^F activity occurs only in the forespore due to a regulatory mechanism termed “partner switching” (21). The SpoIIAB protein is an anti-sigma factor that can bind σ^F and sequester it in an inactive form. SpoIIAB can also bind SpoIIAA (an anti-anti-s factor), and its relative affinity for each mutually exclusive partner is influenced by the intracompartmental ATP/ADP ratio (see Adenylate Charge). Additionally, SpoIIAB is a kinase able to phosphorylate SpoIIAA, and SpoIIAA~$P0_4$ cannot bind SpoIIAB (22). Although many questions remain unanswered, the current model is that in the forespore the ATP/ADP ratio is low; this condition favors binding of SpoIIAB–SpoIIAA and release of free, active σ^F. Furthermore, a membrane-associated phosphatase encoded by *spoIIE* (whose transcription is activated by Spo0A~$P0_4$) becomes localized to the septum but becomes active only on the forespore side, thus counteracting SpoIIAB kinase action upon SpoIIAA in that compartment. In the mother cell, SpoIIAB-σ^F binding predominates, due apparently due to a higher ATP/ADP ratio, SpoIIAB phosphorylation of SpoIIAA, and absence of SpoIIE phosphatase activity (23).

Two genes expressed in the forespore due to σ^F-directed transcription are *sigG* and *spoIIR*. Gene *sigG* encodes the s factor responsible for late forespore gene expression, and *spoIIR* encodes a protein necessary for σ^E activation in the mother cell. As in the case of *spoIIA*, the operon (*spoIIG*) encoding σ^E is expressed prior to septum completion as a result of Spo0A~$P0_4$-mediated transcriptional activation. The initial proteins produced are a membrane-bound putative proteinase (SpoIIGA) and an inactive precursor of σ^E (pro-σ^E). The production of SpoIIR in the forespore compartment is the signal responsible for initial processing of pro-σ^E to σ^E in the mother cell (24). SpoIIR is secreted out of the forespore, and this process somehow activates SpoIIGA-dependent proteinase activity on the mother cell side of the septal membrane (25). It is not clear whether SpoIIR provides an absolute directionality that prevents pro-σ^E to σ^E processing from occurring in the forespore or if additional mechanisms that selectively inactivate σ^E in that compartment also exist (26).

Relatively little is currently understood concerning regulation of σ^G activation in the forespore, but it

is apparent that s^E-controlled transcription of the eight-**cistron** *spoIIIA* operon in the mother cell is a crucial event (27). It also is clear that s^G activity in the forespore is required for s^K activity to appear in the mother cell. Synthesis and activation of s^K involves a number of mechanisms, including one that could occur only in a terminally differentiated cell destined to lyse. An intact, contiguous gene (*sigK*) encoding s^K is not normally present on the chromosome: The *sigK* **open reading frame** is interrupted by a 48-kb element referred to as *skin*. During sporulation, s^E and a transcriptional regulatory protein, SpoIIID, activate transcription of a gene (*spoIVCA*) in the *skin* element. The SpoIVCA protein is a site-specific recombinase that catalyzes excision of a circular DNA molecule in which the truncated portions of *sigK* become fused in-frame (see Translation). The resultant intact copy of *sigK* is transcribed by s^E/SpoIIID, and the messenger RNA is translated to produce an inactive pro-s^K protein. This precursor is then processed to active s^K by a proteinase whose activity is dependent upon s^G-directed expression of genes in the forespore (28). Once activated in their respective compartments, both s^K and s^G direct further transcription of their own genes via positive autoregulatory feedback loops and are responsible for expression of gene products necessary for the final steps of endospore development and maturation.

The cascade of s factors during *B. subtilis* sporulation is obviously a primary means of achieving temporally regulated expression of genes required for the ordered assembly of the morphological structure of the endospore. Yet many details concerning this process remain to be elucidated, and it seems highly probable that other, perhaps novel, mechanisms await discovery. Although many genes responsible for the physical components and assembly of the spore structures (eg, the peptidoglycan cortex, protein coat) have been identified, very little is actually known about the biochemistry and enzymology underlying these assemblages. Additionally, much work remains to be done in order to understand the process of spore germination and outgrowth, an area that has received far too little attention in the past. Nevertheless, the continuing rapid pace of discovery has shown that sporulation is an excellent experimental system for examining fundamental aspects of cellular differentiation.

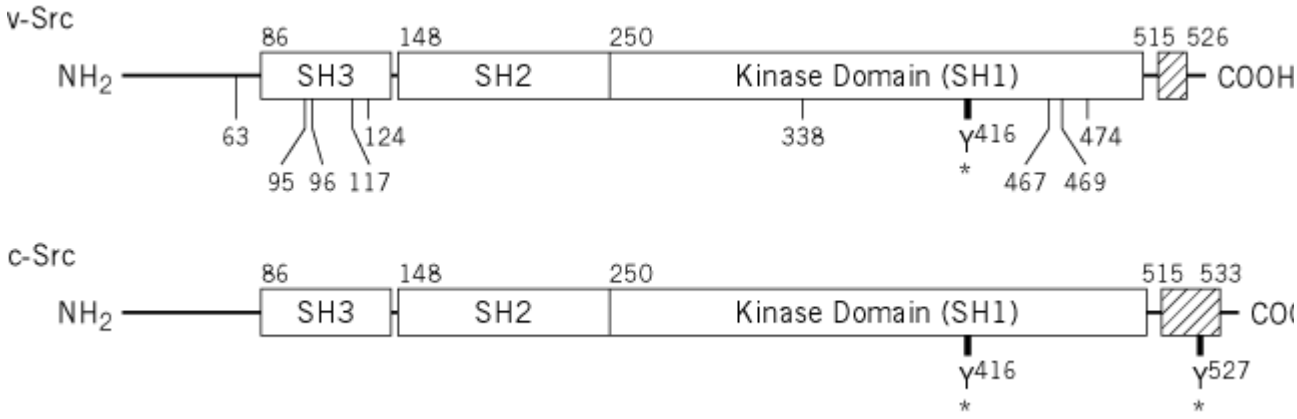
SRC Genes

Viral (v-) and cellular (c-) *src* genes were the first identified oncogene and proto-oncogene, respectively. The v-*src* gene was identified as the transforming gene of Rous sarcoma virus (RSV), a typical RNA tumor virus that causes neoplastic transformation of chicken cells (1). Hence, the gene name *src* (*sarc*oma). The translational product of v-*src* is a phosphoprotein of 60 kDa, designated as v-Src or $pp60^{v-src}$, which was shown to be the first example of tyrosine kinase, a novel family of protein kinases (2). The transforming ability of v-*src* is dependent on the tyrosine kinase activity of the gene product. On the other hand, the c-*src* gene was originally found as a cellular homologue of v-*src* in normal chicken cells and is now known to be widespread in higher eukaryotes. There are 12 exons in the chicken c-*src* (3), whereas v-*src* has no introns. It is believed that v-*src* has been derived from a spliced messenger RNA of c-*src*, and, thus, the c-*src* gene is called a proto-oncogene. The product of c-*src*, termed c-Src or $pp60^{c-src}$, is also a 60-kDa phosphoprotein and has an intrinsic tyrosine kinase activity. The gene expression of c-*src* is essentially ubiquitous. However, the expression level of c-Src is usually very low, in contrast to v-Src, which is highly expressed from the viral genome. In addition, the activity of c-Src is strictly regulated and much lower than that of v-Src. The c-*src* gene has been shown not to be oncogenic, even if it is artificially overexpressed.

The major structural difference between the v-Src and c-Src proteins resides at their carboxy termini (Fig. 1). The 19-amino acid residue tail of c-Src is replaced by an unrelated sequence of 12 amino acids in v-Src. Biochemical and molecular biological analyses have revealed that this difference is responsible for the elevated tyrosine kinase activity of v-Src and its transforming ability. Some other point mutations are also present in v-Src. These amino acid replacements may also contribute to the kinase activation. Several artificial mutations have been shown to activate c-Src. For example, the single amino acid change of Tyr527 to Phe can cause activation of the kinase and elevation of the oncogenic potential of the mutant gene product, although the product is still less potent as a transforming protein than v-Src.

Figure 1. Schematic structures of v-Src and c-Src. Both v-Src (from Rous sarcoma virus SR-A strain) and chicken c-Src are shown. The kinase domain (SH1) and two domains (SH2 and SH3) that are conserved among the Src family kinases shown by **open bars**. The carboxyl terminal sequences (shown by **hatched bars**) differ from each other in both sequenc and length. Nine single-amino acid substitutions are also known and indicated by **vertical lines** below v-Src with their residue numbers. v-Src or activated c-Src undergoes autophosphorylation on Tyr416 (Y^{416}), and inactive c-Src is phosphorylated on Tyr527 (Y^{527}). These sites are shown by **asterisks**.



After the discovery of *src* genes, several closely related genes have been identified as oncogenes of viral origin or proto-oncogenes, and these are now included in the Src family. The Src family members identified thus far are Src, Fyn, Yes, Fgr, Lck, Lyn, Hck, Blk, and Yrk (1-6). The Src family genes are evolutionary conserved in higher eukaryotes, and all encode nonreceptor tyrosine kinases of around 60 kDa. Structural comparison of the Src family kinases has revealed a common feature, designated as the Src homology domain, which consists of three conserved domains: Src homology 1 (SH1), Src homology 2 (SH2), and Src homology 3 (SH3). The SH1 domain corresponds to the carboxy-terminal kinase (catalytic) domain itself. The SH2 and SH3 domains reside in the amino-terminal noncatalytic region (Fig. 1). The amino-terminal sequence is divergent among the family members, except for the several N-terminal residues that contain the invariant Gly2. This glycine residue is shown to be necessary for the attachment of myristoyl group by which Src family kinases bind to the plasma membrane.

The inactive forms of Src family kinases have been shown to be phosphorylated on the carboxy-terminal tyrosine residue (Fig. 1). by another tyrosine kinase, named Csk (7). The SH2 domain binds to this terminal phosphotyrosine residue through an intramolecular interaction, while the SH3 domain reinforces this interaction by binding to a proline-rich motif in the same molecule. Therefore, one of the functions of SH2 and SH3 domains in the Src family proteins is to maintain the structure of the proto-oncogene product in an inactive state. This fact was demonstrated by crystallographic analysis of c-Src and Hck (8, 9). Because the carboxy-terminal tyrosine is absent from the v-Src sequence (Fig. 1), the SH2 domain in v-Src cannot form the intramolecular interaction. This is

thought to be the why v-Src kinase is deregulated and constitutively activated. The activation mechanism under physiological conditions of the normal Src family kinases is not well understood. However, it is conceivable that any kind of signal that leads to the dissociation of either SH2- or SH3-mediated interaction will activate the Src family kinases.

As to their physiological function, the Src family kinases are shown to be physically and functionally coupled with various surface receptors of hematopoietic cells. For example, Fyn is associated with the T cell receptor, Lyn with the B cell receptor, and Lck with CD antigens of T cells. Some receptor tyrosine kinases, such as platelet-derived growth factor receptor, epidermal growth factor receptor, and CSF-1 receptor are also known to be coupled with the Src family members (10).

Src Homology Domain

The Src homology (SH) domain is a general term for the three conserved domains (SH1, SH2, and SH3) originally identified by amino acid sequence analysis of protein products of *src* genes and related genes. The SH1 domain represents the catalytic tyrosine kinase domain. The SH2 and SH3 domains are modules that bind to phosphotyrosine-containing and proline-rich sequence motifs, respectively. Both SH2 and SH3 domains are now found in a wide variety of biosignaling molecules and have been shown to play important roles in the mechanism of signal transduction through protein-protein interactions.

Stabilization And Destabilization By Co-Solvents

The effect of a co-solvent on the stability of a protein (or other macromolecule) is determined strictly by the difference between the interactions of the co-solvent with the protein in the unfolded and native states (see Protein Stability). The essential interactions that must be known are preferential binding (or **preferential hydation**) and the transfer free energy, ie, **free energy** of interaction with (binding to) the protein of the structure stabilizer or destabilizer (1).

Let the unfolding (stability) process be represented by a simple equilibrium between the native *N* and denatured *D* states, and let this equilibrium be affected by a ligand (stabilizing or destabilizing co-solvent):

$$N \overset{K_L}{\rightleftharpoons} D \qquad (1)$$

The effect of the co-solvent can be expressed then relative to either of two reference states:

1. In the first reference state the given co-solvent concentration is given. The question is: Does the co-solvent at this concentration stabilize the protein relative to an infinitesimally smaller concentration? The effect the co-solvent has then is expressed by the *Wyman linkage relation*:

$$\frac{d\log K}{d\log a_L} = \nu^D - \nu^N = \Delta\left(\frac{\partial m_L}{\partial m_{pr}}\right)_{T,P,\mu_L} \qquad (2)$$

where n^D and n^N stand for the preferential binding of the co-solvent to the unfolded and native protein (a_L is the thermodynamic activity of the co-solvent, which frequently may be approximated by the concentration). Therefore, the slope of a log-log plot of the equilibrium constant versus the ligand concentration gives the difference in preferential binding between the two end states. Conversely, knowledge of n^D and n^N indicates whether a ligand (co-solvent) will be a stabilizer or destabilizer of the structure: Greater equilibrium dialysis binding to the unfolded form enhances the unfolding reaction; greater binding to the native form results in stabilization of the native structure.

(2) In the second reference state, the effect is measured relative to water as solvent. It is expressed by the difference between the binding free energies to the two end states:

$$\delta\Delta G^{0(N\to D)} = \Delta G^0_L - \Delta G^0_w = \Delta\mu^D_{pr,tr} - \Delta^N_{pr,tr} = \delta\Delta\mu^{N\to D}_{pr,tr} \qquad (3)$$

where ΔG^0_L is the standard free energy of the unfolding equilibrium at ligand concentration *L* and ΔG^0_w is that in water (this is related to the equilibrium constant by $\Delta G^0 = -2.303RT \log K$). $\Delta m_{pr,tr}$ is the transfer free energy of the protein from water (dilute buffer) to the solvent of the given composition in the denatured *D* and native *N* states; it, in fact, is the free energy of binding of the ligand (co-solvent) to the protein ($\Delta G_b = \Delta m_{pr,tr}$) in its two states.

Staggered Cut

Restriction Enzymes are bacterial endonucleases that recognize defined sequences of double-stranded DNA and catalyze phosphodiester bond hydrolysis of both strands at positions within or adjacent to the recognition sequence (see Restriction Enzymes). This article focuses on the type II restriction endonucleases, which represent greater than 90% of the known restriction enzymes and are those most used in recombinant DNA manipulations (see Cloning). For more information on types I, II, and III restriction enzymes, see the article on Restriction–Modification Systems.

The sequences recognized by restriction enzymes are 4–8 base pairs in length and are called *restriction sites*. The hydrolytic scission occurs 5′ to the phosphate in the phosphodiester bond of each strand, so that 5′ phosphoryl and 3′ hydroxyl termini are produced. The hydrolytic cuts can be made either directly opposite one another or offset from one another along the helix, generating either blunt or cohesive ends, respectively, in the resultant DNA fragments (see Restriction Fragment) (Fig. 1). Within the type II family of enzymes, there are several classes (types IIp, IIw, IIn, and IIt), which are distinguished by the nature of the sequence recognized and by the position of cleavage within or outside of the site (1). Representative examples are given in Table 1.

Figure 1. Types of cleavage by restriction endonucleases and resulting DNA termini: (**a**) staggered cut resulting in cohesive ends; (**b**) blunt cut resulting in blunt ends. Arrows indicate position of cleavage, and boldface **p** indicates phosphodiester bond cleaved.

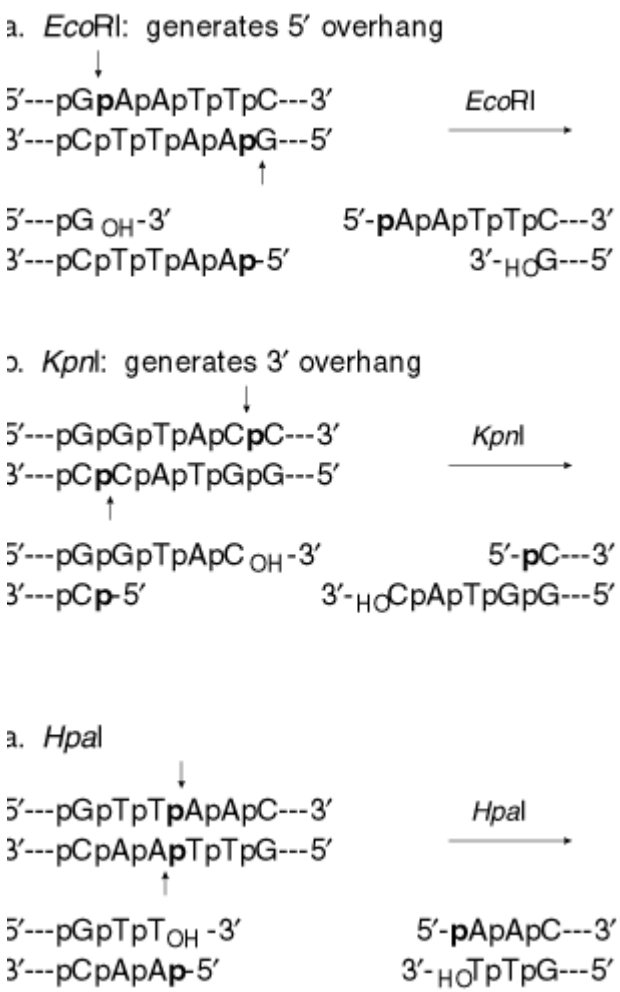

Table 1. Classes of Type II Restriction Enzymes

Type II Recognition			
Class	Specificity	Position of Cleavage	Example(s)
IIp	Palindromic sequence, with or without degeneracy[a] with even number of base pairs	Within recognition sequence	*Bam*HI: G ^ GATCC *Ban*I: G ^ G PyPu CC[b] *Sma*I: CCC ^ GGG *Pst*I: CTGCA ^G
IIs	Asymmetric	Outside recognition sequence (up to 20base pairs away)	*Hga*I: GACGC (5/10)[c] *Fok*I: GGATG (9 / 13)

IIw	Palindromic with degeneracy and odd number of base pairs	Within recognition sequence	*Hin*FI: G ^ ANTC[d] *Sau*96I: G ^ GNCC
IIn	Degenerate spacer segment interrupting palindromic sequence	Within spacer region	*Psh*AI: GACNN ^NNGTC *Pfl*MI: CCANNNN ^NTGG
IIt	Asymmetric	Similar to IIs with one cut inside recognition sequence	*Bsr*I: 5′-ACTGGN^ N-3′ 3′-TGAC ^ CNN-5′

[a] The allowance of one or more nucleotide substitutions at a specific position in the restriction site.

[b] Py is Pyrimidine containing nucleotide residue (C,T), and Pu is purine containing nucleotide residue (A,G).

[c] Indicates the position of the site of cleavage of the "top" and "bottom" strands 3′ to the recognition site.

[d] N is G,A,T, or C.

The cuts produced by restriction enzymes yield defined fragments of DNA that can be exploited in several recombinant DNA procedures. Appropriately cleaved fragments of duplex DNA produced from restriction digestion can be ligated (joined) to other fragments using a variety of methods (Table 2) (see also Ligation). For fragments containing compatible cohesive ends (3′ or 5′ overhangs) resulting from digests with the same enzyme, such as *Eco*RI or *Pst* I, ligation of both fragments with DNA Ligase regenerate the same restriction site. Fragments produced by different enzymes but having compatible termini can generate novel cleavage specificities on ligation. For example, *Sal*I (G ^ TCGAC)-digested and *Ava*I (C ^ TCGAG)-digested DNA fragments contain 5′ overhangs that are compatible with one another. On ligation of the fragments, both the *Sal*I and *Ava*I sites are destroyed, and only a *Taq*I (^ TCGA) restriction site remains in the product DNA.

Table 2. Manipulations of DNA Fragment Ends by DNA Ligation

DNA fragments containing:	DNA restriction fragment 1, with a given Terminus:	DNA restriction fragment 2, with a given Terminus:	Resultant, new restriction site upon ligation of fragments 1 & 2:

Compatible cohesive ends—same restriction enzyme	5′-G_{OH} 3′-$CTTAA_P$ *Eco*RI (G ^ AATTC)	$_PAATTC$-3′ $_{OH}G$-5′ *Eco*RI (G ^ AATTC)	5′-GAATTC-3′ 3′-CTTAAG-5′ *Eco*RI (G ^ AATTC)
Compatible cohesive ends—restriction enzymes with different specificities	5′-G_{OH} 3′-$CAGCT_P$ *Sal*I (G TCAGC)	$_PTCGAG$-3′ $_{OH}C$-5′ *Ava*I (C TCGAG)	5′-GTCGAG-3′ 3′-CAGCTG-5′ *Taq*I (5- ^ TCGA-3′)
Different blunt-ended termini	5′-GAT_{OH} 3′-CTA_P *Eco*RV (GAT ^ ATC)	$_PCCT$-3′ $_{OH}GGA$-5′ *Stu*I (AGG ^ CCT)	5′-GATCCT-3′ 3′-CTAGGA-5′ *Mbo*I (^ GATC)
Incompatible ends	5′-G*AATT*$_{OH}$[a] 3′-$CTTAA_P$ *Eco*RI treated with Klenow fragment of DNA polymerase I	$_PCC$-3′ $_{OH}GG$-5′ *Hae*III (GG ^ CC)	5′-G*AATT*CC-3′ 3′-CTTAAGG-5′ 5′-G*AATT*CC-3′

[a] Italics represent nucleotides added by Klenow fragment of DNA polymerase I.

New cleavage sites can also be generated by ligating blunt-ended termini together (see Blunt-End Ligation). For example, a *Mbo*I site (^ GATC) can be generated by ligating two blunt-ended fragments: one generated by the blunt-end producer *Eco*RV (GAT ^ ATC) and the other by *Stu*I (AGG ^ CCT). Fragments with incompatible cohesive 5′ ends can be converted to blunt-ended, double-strand molecules with the **Klenow fragment** of **DNA polymerase** I. For example, fragments containing the 5′ overhang of an *Eco*RI site (G ^ AATTC) can be filled in with Klenow fragment to form blunt-ended molecules with the 5′ sequence AATT and ligated to blunt-ended fragments produced by *Hae*III (GG ^ CC); the product DNA then contains a regenerated *Eco*RI site (G*AATTC*). Fragments containing either 5′ or 3′ overhanging ends can also be made blunt-ended by removing the single-stranded segment with either S1 nuclease or mung bean nuclease and ligated to other blunt-ended termini. Fragments produced by digestion with two different restriction enzymes, for example, with single *Pst*I and *Bam*HI sites, will have different termini (*Pst*I or *Bam*HI) on each end that can be ligated into cut DNA with similar, compatible termini.

Orientation problems are usually found with blunt-end ligations. For example, a gene borne on a blunt-ended DNA fragment ligated into a vector downstream of a promoter has only a 50% chance of being ligated in the proper orientation for expression, because blunt-end fragments can be joined in either orientation. This can be overcome with ligations using cohesive-end or double-digested fragments, which assure correct orientation of the gene on ligation, using restriction enzymes of the type IIp, IIw, IIn, and IIt classes (Table 1) (1).

The type IIs restriction enzymes (see Restriction–Modification Systems) offer unique opportunities for molecular cloning experiments because they cleave outside, but 3′ adjacent to, the sequence recognized, producing long staggered ends (2). One application involves the design of an adapter with a type IIs site within an engineered single-stranded region that anneals to a complementary single-stranded DNA template. This adapter can first be utilized as a primer for DNA polymerase to synthesize a double-stranded template, and this product can subsequently be hydrolyzed with the type IIs restriction enzyme to achieve the desired cut. Another application is for the precise excision of DNA fragments and for gene assembly using a DNA vector containing a unique restriction site immediately between two inward-facing type IIs sequences (2, 3). These applications illustrate why type IIs enzymes have been referred to as "universal" restriction enzymes.

Restriction enzymes can be used in combination with methyltransferases to generate new or rare cleavage specificities (see Methylation, DNA and Methyltransferase). For example, premethylation of (GGATCCCGG) sequences with the methylase M•*Msp*I to form mCCGG inhibits methylation by M• *Bam*HI (GGATmCC), but not cleavage by the restriction enzyme R•*Bam*HI. Therefore, all *Bam*HI sequences not adjacent to methylated *Msp*I sites will be rendered insensitive to *Bam*HI cleavage after methylation by M•*Bam*HI (4). Another application, methylase-limited partial digestion, involves incubation of DNA for limited times with methyltransferases in order to methylate some but not all canonical sequences. Therefore, some of the canonical sequences remain susceptible to cleavage by the partner endonuclease, while others do not. This method is convenient when large restriction fragments are desired (5).

Given the variety of sequence specificities, cleavage and methylation properties of available restriction and methylation enzymes, and the numerous ways in which they can be used in DNA manipulation and analysis, it is clear why the discovery of these enzymes revolutionized molecular cloning. Other applications of these enzymes are discussed in the articles on restriction map and Restriction Fragment.

Star Activity

Star activity refers to the aberrant DNA cleavage by type II restriction endonucleases at sites other than their canonical recognition sequences (see Restriction–Modification Systems and Restriction Enzymes). The star activity of an enzyme is usually denoted with an asterisk following the name of the enzyme, such as *Eco*RI*. Ordinarily, the recognition specificity of restriction endonucleases for the canonical sequence is very high. The canonical site is generally cleaved 10^6 times more frequently than other DNA sequences under optimal conditions (1). With high enzyme concentration or with long incubation periods, however, cleavage can also occur at sites differing by one or more base pairs (referred to as *star sites*), although the canonical site continues to be selected preferentially. Presumably star sites are cleaved much more slowly because of the absence of critical interactions of the enzyme with the bases or the phosphate backbone that are needed for optimal binding or catalysis (2).

Specificity can also be altered as a result of suboptimal reaction conditions: high pH, low ionic strength, Mn^{2+} instead of Mg^{2+}, or the presence of cosolvents (glycerol, DMSO, or ethanol). Under these conditions, selectivity for the canonical restriction site is reduced as the enzyme relaxes its sequence specificity, and cleavage at degenerate or shortened versions of the canonical sequence occurs more often. The allowable degeneracy may range from (*1*) a single-base-pair change, (*2*) loss of recognition of distal base pairs in the canonical segment, to (*3*) several possible base pair substitutions in the primary recognition site. In the presence of organic solvents, *Eco*RI, which normally cleaves at the sequence GAATTC, has a star activity, *Eco*RI*, toward sequences containing the core tetranucleotide sequence AATT (1). *Xba*I, which cleaves at the canonical sequence TCTAGA, is an example of an extreme star activity; it becomes a nonspecific nuclease under conditions of elevated pH and in the presence of glycerol and DMSO (1). Isoschizomeric enzymes (see Isoschizomer) have been shown to have different cleavage specificities under star reaction conditions (3), so they respond differently to conditions. Star activity can be a problem when restriction enzymes are used as tools for precisely fragmenting DNA. On the other hand, the characteristic changes in specificity patterns of restriction enzymes under conditions inducing star activity has been useful in mechanistic studies (4).

Start Codons

In *Escherichia coli*, the **codon** AUG of the genetic code is an efficient initiator of translation in **protein biosynthesis** and is by far the most common one. GUG and UUG are also efficient initiation

codons and are not uncommon. AUU is only rarely used, most notably in the gene for translation initiation factor 3.

At initiation of translation, the anticodon of a special initiator transfer RNA, $tRNA^{Met}_{f}$, pairs with the initiation codon bound at the P site of a ribosome. In **eubacteria**, chloroplasts and mitochondria, the initiating amino acid is formylmethionine (1). The formyl group permits binding by initiation factor 2. This, together with special features of $tRNA^{Met}_{f}$, ensures that formylmethionine is delivered to the ribosomal P site and becomes the first amino–terminal amino acid to be incorporated into a polypeptide chain. The formyl group is removed subsequently, however, so that methionine is the first encoded amino acid. Formylmethionine $tRNA^{Met}_{f}$ is not recognized by the elongation factor EF-Tu, which delivers aminoacyl tRNA to the ribosomal A site for incorporation at internal positions in polypeptide proteins. Instead, the "elongator" that decode AUG, GUG, UUG, and AUU at internal positions in coding regions are not acylated with formylmethionine, but rather with methionine, valine, leucine, and isoleucine, respectively, as in the normal genetic code.

There is a special context for initiator codons that gives them their distinctive function and meaning. In the overwhelming majority of cases in eubacteria, this special context is a short sequence of bases in the messenger RNA known as a **Shine–Dalgarno** sequence after its discoverers. It is located approximately 5 or more nucleotides 5′ of the initiator codon. The Shine–Dalgarno sequence of the messenger RNA pairs with a complementary sequence very close to the 3′ end of 16 S rRNA in the small (30 S) ribosomal subunit. The interaction serves to position the initiation codon for interaction with initiator tRNA at the ribosomal P site. In a small number of mRNAs from eubacterial bacteriophage or extreme thermophilic **archae**, there is no Shine–Dalgarno sequence, and occasionally no 5′ sequence at all. In these cases, some sequence 3′ to the start codon that is only partially defined serves to facilitate initiation.

In **eukaryotes**, AUG is again by far the most common initiator codon, but CUG, ACG, and GUG are also found. The special initiator tRNA, $tRNA^{Met}_{i}$, inserts methionine and not formylmethionine. The discriminatory features used to specify when these codons are to function as initiators are different from that utilized in eubacteria. With the aid of initiation factors, the small, 40 S subunit of eukaryotic ribosomes generally associates with mRNA via a -cap structure and, at least in yeast, the poly A tail at the 3′ end of the mRNA also plays a role (2, 3). The recruited subunit then scans until a potential initiator codon flanked by a consensus sequence is encountered (4). The large, 60 S ribosomal subunit subsequently joins to complete assembly of the intact, 80 S ribosome. The great majority of eukaryotic start codons are recognized by ribosomes recruited in this manner, but there are two interesting exceptions.

1. The mRNA for a number of **proto-oncogenes** and transcription factors have one or more short open reading frames (ORF) preceding the main protein coding sequence. Ribosomes that have translated a particular short ORF may have the potential to reinitiate translation at the main ORF start codon location some distance in the 3′ direction. This mode of initiation has been studied in great depth in yeast GCN4 (5).
2. 2. Special structures known as IRES (internal ribosome entry segments) permit ribosomes to make initial contact with internal regions in mRNA and initiate translation at appropriately positioned start codons (6). IRES-mediated internal initiation was initially discovered in translation of the picornaviruses, polio virus and encephalomyocarditis, where it enables viral protein synthesis to escape the consequences of viral-induced inhibition of cap-mediated initiation (7, 8). This inhibition serves to inactivate host translation. However, the start codons of a small number of chromosomally encoded genes are also recognized by IRES-mediated initiation.

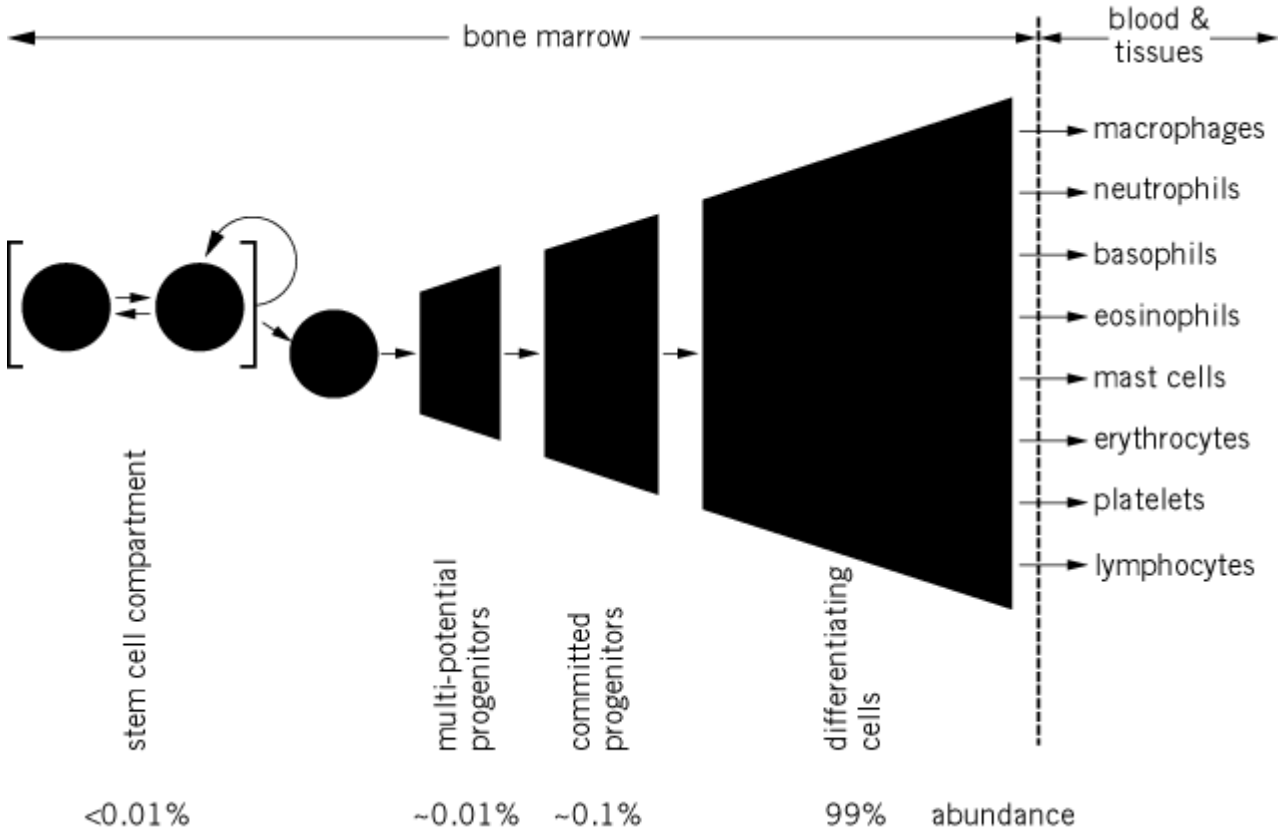
Stem Cells

In multicellular organisms, certain tissues, such as those of the **hematopoietic** system and epithelia, are characterized by high cell turnover. Throughout life, **senescent** mature cells are shed or removed by phagocytosis or apoptosis. These cells are continuously replaced by the proliferation and differentiation of immature cells that, in turn, arise continuously from small numbers of "stem cells" in the tissue. For example, it has been calculated that in steady-state hematopoiesis in the mouse, 2.6×10^8 cells must be replaced each day. Transplantation experiments with purified stem cells in lethally irradiated mice have indicated that engraftment of as few as three such cells can bring about long-term hematopoietic reconstitution (1), illustrating their enormous potential for giving rise to differentiated progeny. Experiments in mice with cytotoxic agents (such as 5-fluorouracil) that selectively kill actively dividing cells have shown that, during steady-state hematopoiesis, the majority of primitive hematopoietic stem cells (HSCs) are quiescent, but are rapidly recruited into the cell cycle following depletion of more mature cells (2). More recent observations on *in vivo*-labeled stem cells purified by procedures based on their small size, lack of lineage markers, and low staining with vital dyes such as rhodamine 123 or Hoechst 33342 indicate that the earliest identifiable murine HSCs actually cycle at a low rate (3). The relative quiescence of early HSC accounts, at least in part, for the selectivity of chemotherapeutic regiments used in the treatment of hematological malignancies.

As stated above, stem cells have great proliferative capacity that is used to maintain differentiated cell populations throughout the life of the animal. Intrinsic to this process is the maintenance of the stem-cell pool, a process termed "self-renewal." That is, primitive stem cells are believed to undergo asymmetric divisions, giving rise to a proportion of progeny with stem-cell characteristics and a proportion with the capacity to differentiate. Furthermore, the hematopoietic stem cell, and probably other stem cells, has the capacity to give rise to multiple lineages of differentiated cells (Fig. 1); that is, it is "multipotential." True "stem" cells are rare; in the case of human bone marrow, they

represent fewer than $1/10^4$ of the total cells. More abundant are their immediate progeny, the hematopoietic progenitor cells, which display active cell cycling, although lower proliferative potential, little or no self-renewal capacity, and greater lineage restriction; they account for approximately $1/10^3$ of normal bone marrow cells. The bulk of the cell population in normal bone marrow consists of postproliferative maturing cells, especially those of the neutrophil lineage.

Figure 1. Hierarchy of the hematopoietic system.



The following discussion will mostly use the hematopoietic system to illustrate the principles of stem cell behavior. An attempt will be made to illustrate the generality of the concepts by reference to keratinocyte differentiation. For more comprehensive treatment of a variety of other stem cell systems, including plants and invertebrates, see "Suggestions for Further Reading."

1. Assays for Stem Cells

Because of their rarity, stem cells have generally been studied indirectly by their ability to give rise to colonies and/or differentiated progeny *in vivo* or *in vitro*. The "gold standard" for assay of HSCs is their ability, at limiting numbers, to give rise to multilineage engraftment of lethally irradiated animals, usually syngeneic mice. When highly purified primitive stem cells are used for marrow repopulation, co-infusion of more mature cells is necessary to ensure survival until long-term reconstitution occurs (4). Congenic markers, such as Ly5 **allotypes**, or sex-mismatched donors are used to distinguish between reconstitution by donor stem cells and that due to short-term repopulating cells or autologous recovery. Self-renewal capability is assessed by the ability of donor-derived cells to engraft in multiple serial transplants (5, 6). Indefinite self-renewal may not occur, due to telomere shortening (1, 7). The fate of individual stem cells and their progeny, including the ability to contribute to multiple hematopoietic lineages, has been monitored by following retrovirus-

marked stem cells that have unique insertion sites detectable by restriction fragment length polymorphism (RFLP) analysis (8). Another *in vivo* clonal assay, the colony-forming unit–spleen (CFU–S) assay, which depends on the ability of infused bone marrow cells to give rise to clones of maturing hematopoietic cells in the spleens of irradiated mice after 8 to 12 days, was used extensively in early studies, but is now considered to measure more mature progenitor or "transit" cells (9, 10).

In vivo assays with limiting numbers of cells are clearly not applicable in studies on human HSCs, which have generally been dependent on *in vitro* assays where cells are seeded onto supportive stroma (11), in semisolid medium (eg, Ref 12), or, more recently, in liquid culture supplemented with defined **cytokine** combinations (13). The nature of the cells that proliferate and differentiate in these assays has been reviewed (10). It is unclear to what extent they measure HSCs capable of long-term marrow repopulation, although quiescence, high proliferative potential, and the ability to give rise to large numbers of committed progenitors and/or differentiated cells of multiple lineages are taken as indicators of "stemness." Recently, human stem and progenitor cell populations have been shown to be capable of giving multilineage engraftment of irradiated, immunocompromized mice (14). This may provide a useful model for studying early human HSCs *in vivo*.

2. Purification of HSCs

As described above, HSCs and progenitor cells are rare in hematopoietic tissues. Resistance to drugs that are selectively cytotoxic for cycling cells has long been used for enrichment of HSCs and very early progenitor cells (2). With the advent of fast and accurate multiparameter fluorescence-activated cell sorting (FACS; see Flow Cytometry), methods based on light-scattering characteristics, stains that correlate with quiescence/cycling, and multiple cell surface "differentiation" markers, detected by monoclonal antibodies, have been developed (15, 16). This is an area of great interest and potential clinical application in separation of normal and malignant cells for autografting in cancer therapy, as well as for identification of appropriate targets for gene therapy, and a number of procedures for large-scale antibody-based cell selection have been developed (17). In the mouse, the HSC is generally considered to have the phenotype lineage marker $(lin)^{-}$, thy-1^{low}, Ly6A/E $(Sca{-}1)^{+}$, c–kit^{+} (15, 16), although recent data suggest that the earliest HSCs lack a detectable cell-surface c-kit (6). In humans, the most definitive phenotype for the HSC at this time appears to be $CD34^{+}$, $CD38^{-}$, $rhodamine^{DULL}$, c–KIT^{+} (14, 18, 19).

3. Regulation of Stem Cell Growth and Differentiation

The process of production of mature hematopoietic cells requires at least three sets of decisions regulating (a) entry of quiescent stem cells into the cell cycle, (b) whether a daughter cell resulting from stem cell division retains stem cell characteristics or differentiates, and (c) lineage commitment of differentiating cells. These processes clearly involve the actions of both positive and negative regulators produced by the hematopoietic microenvironment, but the basis of the action of such factors remains controversial. Two schools of thought exist. The first of these, the "stochastic" model (20), proposes that decisions relating to self-renewal versus differentiation and to lineage commitment are probabilistic and intrinsic to the stem cell. The hematopoietic microenvironment is proposed to provide a permissive milieu that enables cells to survive and fulfill their intrinsic potential (21). In contrast, the "deterministic" model proposes that external influences, such as cytokines, instruct the differentiation of hematopoietic stem cells (22, 23). The lack of specificity of the intracellular signal transduction pathways induced by receptors for different "lineage specific" cytokines, along with a lack of evidence for "deterministic" effects of cytokines on primary cells, has been taken as supporting the stochastic model (24). Furthermore, some evidence suggests that the developmental program of hemopoietic cells may be intrinsically driven by **homeobox** genes (7). Thus, the function of external regulators such as cytokines is proposed to be to ensure the survival of cells so that they can fulfill their intrinsic developmental potential. On the other hand, there is direct evidence for the influence of the nature and level of the cytokine on differentiation of individual

daughter cells from divisions of granulocyte-macrophage progenitor cells (25, 26). It is not possible at the present time to resolve this issue.

The process of induction of quiescent stem cells into cell cycle is also largely unknown and is of importance for stem cell expansion and gene therapy (1). Positive and negative regulators may be involved. For example, **transforming growth** factor b (TGFb), produced constitutively by bone marrow stroma and in an autocrine fashion by hematopoietic stem and/or progenitor cells, can inhibit proliferation *in vitro*. The levels of this cytokine are, however, unaltered in mice undergoing hematopoietic regeneration following irradiation (27). Recently, Haylock et al. (28), using a limiting dilution serum-free culture system, demonstrated that Flt3 ligand was capable of recruiting quiescent primitive human HSC into cycle. Similarly, regulation of self-renewal versus differentiation on HSC division is not understood, and argument continues as to whether it is a stochastic process or regulated by environmental factors (eg, see Ref. 7). So far, factors capable of supporting self-renewal of HSCs *in vitro* have not been identified.

Cytokines clearly play a crucial role in hematopoiesis, although, as described above, the precise mechanism is unknown. Positive regulators include (a) **interleukins**-3 and -6, granulocyte-macrophage colony-stimulating factor, granulocyte colony-stimulating factor, and erythropoietin, which are ligands for members of the cytokine receptor family, and (b) stem cell factor (SCF), macrophage colony-stimulating factor (M-CSF), and Flt3 ligand, which activate members of the **receptor tyrosine kinase** family. Originally it was thought that distinct growth factors acted at different stages of hematopoiesis, but it is now known that individual factors act at multiple levels. For example, thrombopoietin and c-mpl ligand, which were thought to be specific megakaryocyte differentiation factors, are now known also to promote the growth of multipotential progenitor cells (29). Furthermore, cytokines act in a combinatorial fashion (30). A characteristic of primitive HSC is their requirement for multiple cytokines to promote their proliferation and differentiation *in vitro*, whereas committed progenitor cells require fewer factors (10). The actions of growth factors are antagonized by negative regulators, such as macrophage inflammatory protein (MIP)-1a and TGF-b; the latter may act in part by down-regulating the expression of cytokine receptors and/or by inducing apoptosis (27).

4. Role of the Hematopoietic Microenvironment

In humans, hematopoiesis occurs exclusively in the supportive environment of the bone marrow, and HSCs infused intravenously home selectively to the marrow. The bone marrow is architecturally complex, with different microenvironments apparently supporting the development of different lineages. At least two classes of molecules produced by the marrow stroma are involved: (a) growth regulatory factors as described above and (b) molecules mediating the adhesion between stroma and hematopoietic stem and progenitor cells (31). These sets of molecules are interactive and, in some cases, multifunctional. For example, certain growth factors, such as (SCF) and Flt-3 ligand, exist as **transmembrane** proteins, as well as in soluble form, and may directly mediate adhesion by binding to their receptors on HSCs. Furthermore, binding of SCF to its receptor c-KIT was shown to up-regulate **integrin**-mediated adhesion of HSCs to the extracellular matrix protein, fibronectin (32). Indirect evidence that c-KIT may be involved in retaining stem and progenitor cells in the bone marrow comes from the observations that SCF administered systemically is a potent agent for mobilizing HSCs from the marrow to the peripheral blood, and, irrespective of the mobilizing agent, peripheral blood HSCs show apparent down-regulation of c-KIT (33). It is clear that both positive and negative regulatory influences on HSC development are mediated by contact with the stroma. Output of both total cells and committed progenitor cells in cytokine-supplemented stroma-free long-term HSC cultures far exceeds that observed in the presence of stroma (19). This may in part be due to the production of negative regulatory factors by the stroma, but it almost certainly also involves contact-mediated interactions. Novel molecules implicated in this process are the mucins expressed by the HSCs. Interaction of these molecules with their stromal ligands may negatively regulate HSC proliferation and/or differentiation and, under some circumstances, appears to trigger apoptosis (34, 35).

5. Generalization to Other Stem Cell Systems

Hematopoiesis is arguably the best understood system of somatic cell differentiation in mammals. Another system that has been extensively studied, probably because of the relative ease of culturing nontransformed cells, is keratinocyte differentiation. Like hematopoietic cells, epidermal cells are characterized by rapid turnover throughout the life of the animal, with replenishment from a small population of stem cells. These cells, which are located in the basal layer of the epidermis, have been identified *in vivo* based on their relative quiescence, in that they display long-term retention of radiolabeled DNA after infusion of ^{3}H-thymidine, and on their great proliferative potential *in vivo* and *in vitro*. They comprise between 1% and 10% of the basal keratinocyte population in normal skin (36, 37). Intermediate between stem cells and their differentiating progeny are "transit amplifying" cells, which are actively cycling, have more limited proliferative potential, and may be the equivalent of the committed progenitor cells of the hematopoietic system. Until recently, characterization of epidermal stem cells has been hampered by the lack of markers to enable their isolation. Limited purification was accomplished based on their high expression of b1 integrins and rapid adhesion to type IV collagen (38), but the frequency of the cells isolated on the basis of these criteria suggested that the population also contained transit amplifying cells. More recently, a population of putative keratinocyte stem cells was isolated based on a high level of a6 integrin expression, combined with low expression of a cell-surface proliferation-associated marker (39). These cells, which represented approximately 10% of the a6 integrin-positive basal keratinocyte population, were quiescent based on cell cycle analysis, and they displayed extensive proliferative capacity *in vitro*, resulting in 10^{6}-fold or more expansion on long-term culture. While cells with characteristics of quiescence and capacity for extensive proliferation, both *in vitro* and *in vivo*, have been demonstrated in interfollicular epidermis, other stem-cell attributes of multipotentiality and self-renewal capacity (based on serial transplantation) have not been demonstrated thus far. Cells with the capacity to give rise to keratinocytes of epidermal phenotype in raft cultures have been identified in the sheath of the hair follicle and are probably derived from the bulge region, but it is not known whether they are precursors of epidermal stem cells in normal skin. These cells may also serve as stem cells for sebaceous glands (36).

6. Embryonic Stem Cells

This article has focused on stem cells that persist throughout the life of mammals. The most primitive stem cell in these animals is the embryonic stem (ES) cell, which has unlimited proliferative potential under appropriate culture conditions *in vitro*, but retains the ability to give rise to all tissues *in vivo* and multiple cell types *in vitro* (eg, Ref. 40). Because they can be genetically manipulated *in vitro*, then introduced into blastocysts and implanted into surrogate mothers, ES cells have provided the means for generating "gene-knockout" mice that are playing a vital role understanding the function of genes and proteins *in vivo*. Furthermore, their ability to undergo multilineage differentiation *in vitro* provides an important system for molecular analysis of early events in development.

Stereoisomers

Two molecules are stereoisomers if they differ in the spatial orientation of those atoms that cannot be rapidly interconverted by rotation about single bonds. The ability of two molecules to assume a common geometry “rapidly” differentiates conformers (see Conformation) from stereoisomers. Stereoisomers contain the same number and type of bonds and have the same chemical name, except for a prefix that is sometimes used to discriminate between the different stereoisomers. Stereoisomers are divided into enantiomers and diastereomers. Enantiomers are molecules with nonsuperimposable mirror images, whereas diastereomers comprise all other stereoisomers (1).

Steroid Hormone Receptors

The gonads and adrenal gland produce five major groups of steroid hormones: estrogens, progestins, androgens, glucocorticoids, and mineralocorticoids. Clinical symptoms associated with a reduced level of these hormones were known long before a concept of hormones was developed. Aristotle, for example, identified the effects of castration in humans and birds, and in 1855 Addison described the symptoms of chronic adrenal insufficiency. In 1896, Beatson observed, that female sex steroid hormones play a pivotal role in promoting mammary tumor growth. The same was found by Huggins and Hodges in 1941 for androgens and the growth of prostatic neoplasms. In the first half of the twentieth century, it became possible to isolate individual steroids from extracts derived from source tissues by employing biological complementation assays. In 1929 Butenandt was able to crystallize estrone from the urine of pregnant women, and in the 1930s Reichstein identified corticosteroids,

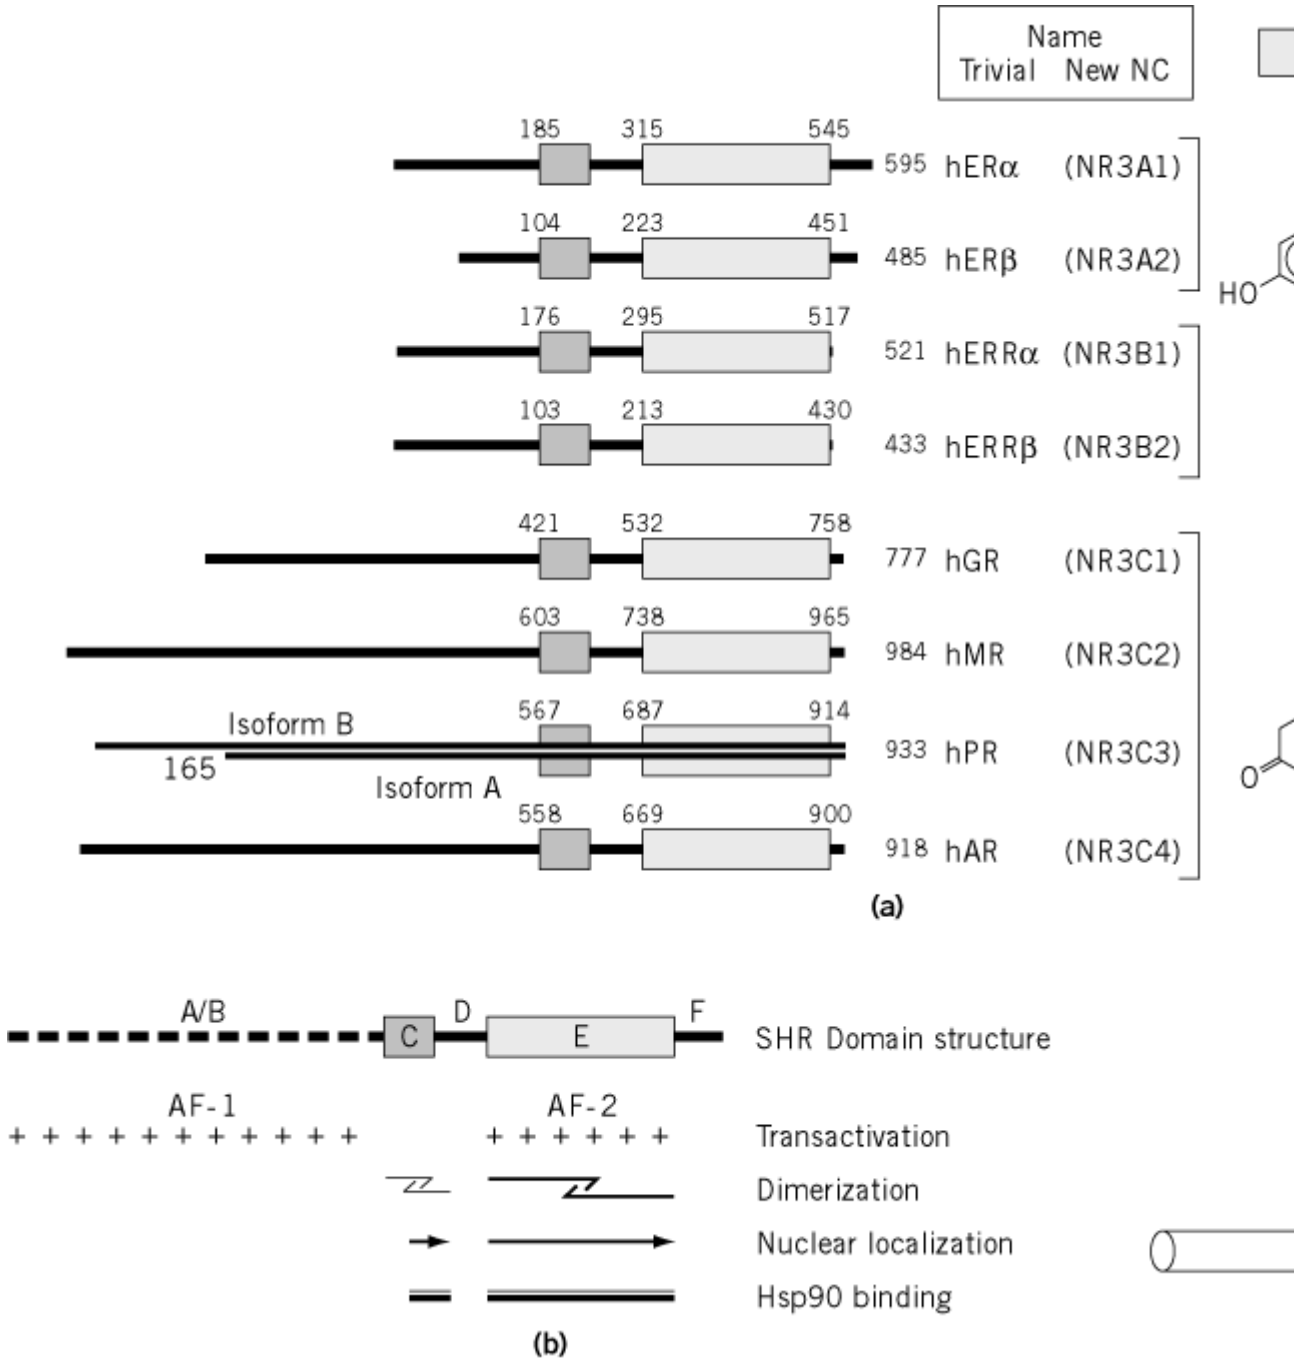
which gained popularity as anti-inflammatory and immunosuppressive therapeutic agents soon after (see Dexamethasone). The end of this period was marked by the isolation of aldosterone by Simpson and Tait in 1953. When ^{3}H- and ^{14}C-labeled hormone compounds became available in the late 1950s, it was possible to follow the fate of the steroid hormones up to their target tissues. Thus it could be shown that the hormone itself, not a metabolite, produced the response via the activation of **gene expression** mechanisms. The concept that steroid hormones are involved in control of gene transcription was also triggered by the observation of **ecdysone**-induced giant chromosome **puffs** by Clever and Karlson in 1960. About 10 years later, the groups of Jensen and Gorski (1) had established a two-step model that involved specific high-affinity steroid hormone receptors (SHRs) within the target cells that had to be activated by hormone in order to induce expression of hormone responsive genes (see Glucocorticoid Response Element Fig. 1). A further 10 years later, the **genes** for the hormone receptors for glucocorticoid and estrogen were **cloned**, and these receptors became the first known cellular transcription factors for **RNA polymerase** II. At around the same time, cloning of some SHR targets, such as the human metallothionein gene and the mouse mammary tumor virus genome, led to the identification of specific binding sites for SHRs termed hormone response elements (**HREs**; see also Glucocorticoid Response Element) serving as inducible enhancers. Within the past decade, many more facets of steroid receptors as hormone-activated transcriptional regulators have emerged and will be discussed briefly.

1. Nuclear Receptor Superfamily

The homology of the SHRs to the v-*erbA* **oncogene** led to the discovery of the c- *erbA* locus as the receptor for thyroid hormones. The identification of another structurally related receptor for the vitamin A metabolite retinoic acid solidified the concept of a nuclear receptor superfamily. All nuclear receptors are characterized by a central DNA-binding **domain** (see text below), which targets the receptor to the HRE. Among other approaches, use of this conserved DNA-binding domain as a screening probe under low stringency conditions proved very successful in the discovery of related receptors. Today, more than 60 different nuclear receptors have been described, including receptors for the known nuclear hormones and a vast number of so-called orphan receptors, with no, or unknown, and possibly novel ligands. With so many different receptors, nomenclature has become a real problem. Therefore, the majority of leading researchers in the field have now agreed to use a **unified nomenclature** (see text below) based on the system developed for the cytochrome P450 gene superfamily (2). Most nuclear receptors bind as homo- or heterodimers to an HRE that is often present in two copies (half-sites), which can be arranged as direct, inverted (**palindromic**), or everted repeats; the half-sites are separated by one to eight nucleotides. On the basis of their dimerization behavior, the nuclear receptors can be operationally placed into four subgroups: (1) the homodimerizing steroid receptors, (2) the receptors forming heterodimers with the retinoid-X receptor (RXR), and the (3) dimeric and (4) monomeric orphan receptors. This grouping is also supported by **phylogenetic** analyses (2) showing that the ligand-binding ability appears to be acquired by orphan receptors during the course of evolution, just as the ability to heterodimerize appears to be acquired by homodimerizing receptors. Nuclear receptor diversification probably occurred in two steps: one that took place very early, during the multicellularization event leading to the metazoan phyla, and resulting in the receptor subgroups we know today, and a second step occurring later on, corresponding to the advent of vertebrates and leading to the formation of multiple **paralogous** receptors within the existing subgroups. Therefore, the steroid and steroid-like receptors (nuclear receptor subfamily 3, NR3, with its three groups A, B, and C according to the new nomenclature system) depicted in Figure 1**a** must be viewed as a late “invention” of evolution. They include two receptors for estrogens (hERa and hERb or NR3A1 and NR3A2), two estrogen-related orphan receptors (hERRa and hERRb, or NR3B1 and NR3B2), and one receptor each for the other major steroid hormone classes: glucocorticoids (hGR or NR3C1), mineralocorticoids (hMR or NR3C2), progestins (hPR or NR3C3), and androgens (hAR or NR3C4). hERRa and b are the only receptors of the subfamily that bind to DNA as monomers rather than as homodimers. Notably, the receptors for secosteroids (vitamin D) and ecdysteroids (see Ecdysone) do not belong to this group. They form heterodimers with RXR or RXR-like proteins, such as the very recently identified

pregnane X receptor (PXR), which binds synthetic glucocorticoids and pregnenolone derivatives.

Figure 1. The human steroid hormone receptor family. (**a**) Illustrated primary structures of all family members, cognate numbers refer to amino acid residue positions. Highlighted are the DNA-binding domain (DBD) and the ligand-binding extensions are drawn to scale. The name of each receptor is indicated (trivial name and the abbreviation according to the human; ER, estrogen receptor; ERR, estrogen-related receptor; GR, glucocorticoid receptor; MR, mineralocorticoid rece androgen receptor. (**b**) SHR domain structure and structure–function relationships. The A/B, C, D, E, and F segments w sequence conservation amongst different SHRs. AF-1 and -2 are the transcription activation functions 1 and 2. (**c**) Illustr cognate hormone response element (HRE). The HRE is of an inverted repeat (IR) type (palindrome), and the half sites (a (N) nucleotides (IR3-HRE). The hormone ligand is indicated with a sterane formula.



2. Domain Structure

All steroid hormone receptors are modular proteins composed of distinct regions, as shown in Figure 1**b**, top panel (3). When the chicken estrogen receptor cDNA became available, comparison with the human estrogen and glucocorticoid receptor sequences led to the nomenclature based on regions A–F, which is used for all members of the nuclear receptor superfamily. From numerous functional and structural analyses, it became clear that these distinct regions correspond to functional and structural units called **domains**. Region C, the **DNA-binding** domain, and region E, the **ligand-binding** domain, display a high degree of sequence conservation, whereas no significant conservation is detected between the paralogous SHRs for the regions A/B, D, and F. Region D is considered as a flexible hinge region between the DNA- and ligand-binding domains. Its amino terminus is an integral part of the DNA-binding domain and is involved in its dimerization. The F region, now defined as the *C*-terminus beyond alpha-helix 12 of the ligand-binding domain (see text below), is essential for hormone binding in the receptors for progestins (PR), glucocorticoids (GR), and androgens (AR), but not in ERa. Recent work indicates that this domain is also important for the discrimination between agonistic and antagonistic hormone ligands. Region A is highly conserved only between chicken and human estrogen receptors, but this distinction is much less clear in the other steroid receptors. Therefore, regions A and B are combined to an A/B region in most cases.

Regions C and E are not only responsible for DNA and ligand binding, respectively, and they encode other functions as well (see Fig. 1b, lower panel). The intracellular distribution of steroid receptors is the result of nuclear–cytoplasmic diffusion and cytoplasmic–nuclear shuttling. At equilibrium, the majority of steroid receptors is in the nucleus due to the presence of so-called nuclear localization signals (NLSs) that are believed to be required for nuclear pore recognition (see Nuclear Import, Export). A constitutive NLS is located at the border of region C/D, whereas a second NLS in the ligand-binding domain is ligand-dependent. Intracellular localization is less clear for the glucocorticoid and mineralocorticoid receptors because hormone-induced nuclear translocation has been reported in these cases.

All unliganded SHRs are associated with a large multiprotein complex of **molecular chaperones**, including Hsp90, which maintains the receptor in an inactive state but keeps it well prepared for hormone binding. Again, the region at the C/D border together with the ligand-binding domain are required for an SHR–Hsp90 interaction to take place. Most likely these chaperones play an active role in keeping the SHRs functional.

Initially all SHRs were thought to bind as homodimers to their cognate response elements within the **promoters** of target genes, which is still a specific characteristic of this subfamily within the nuclear receptor superfamily. But with the identification of the estrogen-related receptors a and b, the family has now two orphan members that do bind to DNA as monomers. Moreover, it is well known that the predominant form of the glucocorticoid receptor is monomeric in solution and that dimerization occurs only after binding to an HRE, accounting for the **cooperativity** observed during DNA-binding. There are also reports showing that the glucocorticoid receptor can bind to an HRE half-site as a monomer, although with lower affinity. A weak dimerization domain encoded within the DNA binding domain and a strong dimerization interface provided by the ligand-binding domain are responsible for dimerization. It is generally believed that the glucocorticoid receptor only contains the weak dimerization interface within the DNA-binding domain.

Ligand binding confers transcriptional competence onto SHRs, which is exerted in most receptors by two independent **transactivation** functions: (*1*) a constitutively active one in the A/B region located close to the DNA-binding domain, referred to as *activation function 1* (AF-1; also known as q-1 or enh-1) and (*2*) a ligand-inducible activation function in the ligand-binding domain: AF-2. The long progesterone receptor isoform, PR-B (see text below), harbors a third activation function at its amino terminus, AF-3, which is specific for the promoter and the cell. The AFs connect the receptor to the transcription apparatus via direct interactions with basal transcription factors, sequence-specific transcription factors, and/or transcription intermediary factors (see text below).

3. Family Members

The human estrogen and glucocorticoid receptors were the first steroid hormone receptors which genes were cloned. The estrogen receptor (now called *hERa*; Fig. 1**a**) was cloned from a cDNA library produced from the breast cancer cell line MCF-7. Recently, a second estrogen receptor, ERb, was cloned which is very similar to ERa in terms of structure and function but also shows subtle and important functional differences (see Estrogen Receptors). Both receptors bind the ligands estradiol, diethylstilbestrol, estriol, and estrone with high affinity. cDNA clones for the estrogen-related receptors a and b (hERRa and b) were isolated from a human testis cDNA library, using the hERa DNA-binding domain as a probe.

For the glucocorticoid receptor, two different classes of cDNA have been described, hGRa and b, which are the result of alternative splicing from a single gene transcript. Both **isoforms** are identical up to amino acid residue 727 and then diverge; hGRa is slightly larger (777 amino acids) than hGRb (742 amino acids). In contrast to hGRa, which is commonly considered as the bona fide hGR, hGRb was long dismissed as a cloning artifact, but it is now shown to be expressed at modest but varying levels in a range of tissues. hGRb does not bind hormone, is transcriptionally inactive, and, therefore, acts as a ligand-independent negative regulator of glucocorticoid action in transfection experiments. However, the b-isoform is not conserved across species, and the relative expression of both isoforms is not known. hGRa shows high affinity for the artificial glucocorticoid dexamethasone, moderate affinity for the physiologic steroids cortisol and corticosterone, and low affinity for mineralocorticoids and progesterone.

The progesterone receptor was the first SHR shown to exist in two common isoforms generated by differential use of alternative promoters. One promoter initiates transcription at positions +1 and +15 of the gene, which gives rise to the longer isoform B (see Fig. 1**a**). The second promoter initiates hPR transcripts between nucleotides +737 and +842, to encode the 164-residue shorter hPR form A. Both isoforms display different target gene specificities because they differ in their A/B domains and, hence, in their transactivation functions (see text above). First regarded as an exception in the family, differential promoter usage and alternative splicing are now the rule for all members. Both progesterone receptor isoforms show high affinity for the natural ligand progesterone and the synthetic agonist R5020.

The human mineralocorticoid (hMR) and androgen receptors (hAR) were cloned 2–3 years after the glucocorticoid receptor had been described. The androgen receptor exists in two isoforms, hAR-A and hAR-B, which are structurally analogous to the two hPR isoforms. In contrast to hPR-A/B, however, hAR-A is expressed at substantially lower levels than the B form, and its contribution to androgen action is not known. The androgen receptor binds the two naturally occurring ligands dihydrotestosterone and testosterone with high affinity, whereas the mineralocorticoid receptor shows high and equivalent affinity for aldosterone, physiologic corticosteroids, and progesterone.

4. Genomic Organization

All the genes encoding SHRs have multiple **introns** and exons and range in length from at least 40 kbp for the human ERb gene to more than 140 kbp for the human ERa gene. Most genes contain 8 exons, with the positions of the introns being strictly conserved, and are scattered over the human genome (see Table 1). Only ERRa and progesterone receptor, and ERb and ERRb, colocalize to overlapping regions of chromosomes 11 and 14, respectively. Compared to the wealth of information on SHR structure–function relationships, relatively little is known about the regulation of the SHR genes themselves. Of the hERa gene, it is known that it is regulated by three tissue-specific promoters. As a result, hERa transcripts from various tissues can differ in the proximal part of their 5′-untranslated regions, depending on which promoter is used.

Table 1. Chromosomal Location of Human Steroid Hormone Receptor Genes

Gene[a]	New Nomenclature	Chromosome Location
ERa	(NR3A1)	6q25.1
ERb	(NR3A2)	14q22-q24
ERRa	(NR3B1)	11q12-q13
		13q12.1 (processed pseudogene)
ERRb	(NR3B2)	14q24.3
GR	(NR3C1)	5q31-q32
MR	(NR3C2)	4q31.1
PR	(NR3C3)	11q13-q22
AR	(NR3C4)	Xq11.2-q12

[a] ER, estrogen receptor; ERR, estrogen-related receptor; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; PR, progesterone receptor; AR, androgen receptor.

5. DNA Binding

The receptors for progestins, glucocorticoids, mineralocorticoids, and androgens recognize the same DNA sequence (half-site: AGAACA). This sequence deviates in two nucleotides from the DNA-sequence bound by both estrogen receptors (AGGTCA). The nonestrogen receptors recognize their half-site mainly by a **hydrophobic** interaction with the methyl group of the thymine in position 4 of the complementary strand (AGAACA) that is not present in the DNA-sequence recognized by the estrogen receptor (4). The half-site spacing of 3 base pairs is such that an SHR homodimer binds both half-sites on the same face of the DNA (see Fig. 1**c**). The DNA-binding domains of SHRs comprise approximately 80 residues encoded by region C, plus some 14 *N*-terminal residues of region D. The domain contains two patterns that are reminiscent of, but clearly distinguishable from, the **zinc finger** motifs first observed in the *Xenopus laevis* transcription factor IIIA. The SHR zinc fingers are also able to coordinate a zinc atom tetrahedrally, but are of the type (C_2–C_2), with four **cysteine residues** as ligands (5). Only very few amino acid residues within the SHR zinc fingers are responsible for specific recognition of the cognate HRE (see Estrogen Receptors for details).

6. Ligand Binding

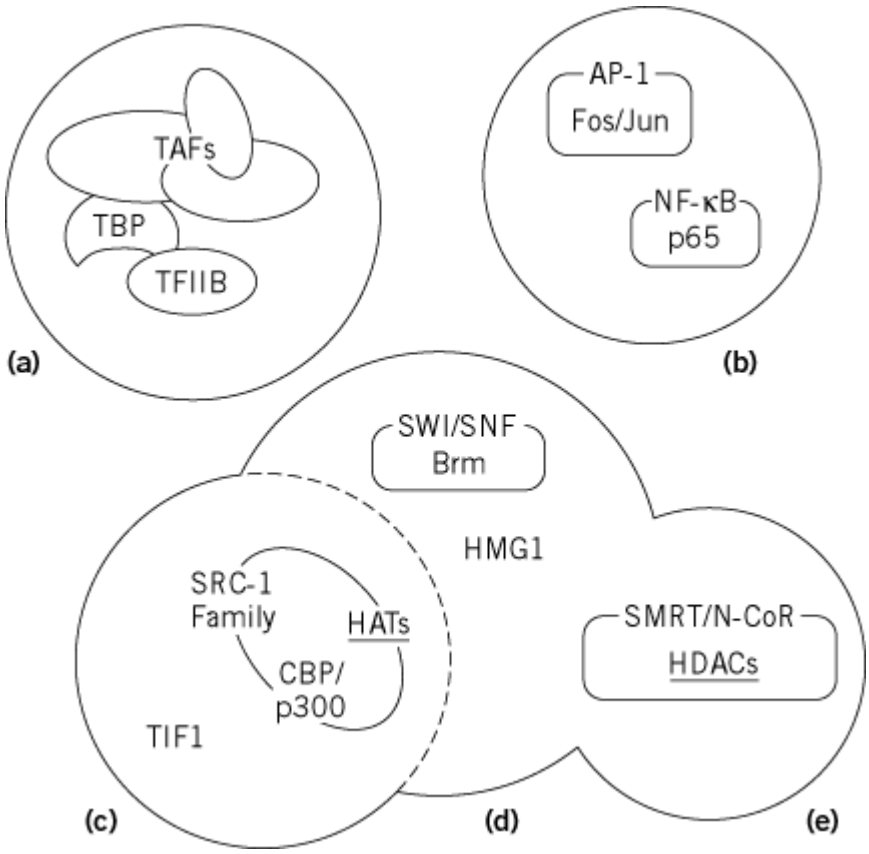
Although not proved, it is believed that the lipophilic steroid hormones, as well as synthetic antihormones, enter the target cell by simple diffusion and bind, within the cytoplasm, to a multiprotein complex of chaperones and SHR. Hormone binding induces a transformation of the SHR complexes that is associated with an increase in their affinity for DNA and a decrease in size of the complex. For example, it is well known that the unliganded hERa receptor sediments as an 8*S* complex on low salt sucrose density gradient centrifugation, but it can be activated with high salt, temperature, or hormone ligand, to yield a more compact and **proteinase**-resistant 4*S* form. Hormone-induced transformation of the 8*S* receptor complex appears to reflect loss of the associated chaperone Hsp90, followed by a tight association with the nuclear compartment. For hERa (PDB accession nos. 1ERE and 1ERR; see Structure Databases) and hPR (PDB accession no. 1a28), the three-dimensional structures of their ligand binding domains complexed with 17b-estradiol and the antihormone raloxifene or with progesterone, respectively, have been determined. Like other known ligand-binding domains of nuclear receptors, those of SHRs are folded into a three-layered, antiparallel a-helical sandwich that creates a wedge-shaped molecular scaffold, with the ligand-binding cavity at the narrower end of the domain. This cavity is completely partitioned from the

external environment and is closed by a-helix 12, operating as a “lid” after hormone has entered the binding pocket. The relocation of this amphipathic helix over the hormone binding site generates a new surface that allows coactivators to bind to the ligand-binding domain, thereby mediating the activity of activation function 2, which forms the core of helix 12. The ligand-binding domain dimerization interfaces are formed by a-helices that line up and/or intertwine and differ slightly between ERa and progesterone receptor.

7. Activation of Transcription by Steroid Hormone Receptors

To regulate transcription, agonist-liganded SHRs must communicate with the general transcription machinery (6). This can be achieved either by a direct contact between SHRs and the general transcription factors (GTFs; see Transcription), which are building up the transcription preinitation complex at the transcription starting point, or by means of transcriptional intermediary factors (TIFs; also called *coactivators*, *mediators*, or *bridging factors*), other sequence-specific transcription factors Transcription Factors) or **chromatin factors** that function as interpreters between SHRs and the general transcription machinery (Fig. 2).

Figure 2. Nuclear partners of steroid hormone receptors. Typical examples are shown for each class. In the case of the general transcription factors (**a**), the TATA-box-binding protein (TBP), the general transcription factor IIB (TFIIB), and some of the TBP-associated factors (TAFs), all parts of the transcription preinitiation complex, were shown to interact with SHRs. Of the interacting sequence-specific transcription factors (**b**), listed are the activator protein-1 (AP1) with its main subunits Fos (named after the oncogene identified in the FBJ murine osteogenic sarcoma virus) and Jun (named after the avian sarcoma virus 17; *jun* is the Japanese word for 17), and the nuclear factor kB (NF-kB) with its p65 subunit. Both factors are key mediators of inflammatory and immune responses. Important coactivators (**c**) are the transcription intermediary factor 1 (TIF1), the steroid receptor coactivator (SRC-1) family of proteins, and the general coactivators cAMP response element binding protein–binding protein (CBP), and a closely related factor, p300. Of the chromatin factors (**d**), brahma (Brm), a component of the very large SWI/SNF-complex (SWI stands for mating-type switching and SNF for sucrose nonfermenting) and the **HMG** (high-mobility group) protein 1 (HMG1) are mentioned. The silencing mediator for retinoid and thyroid hormone receptors (SMRT) and the nuclear receptor corepressor (N-CoR), (**e**) as well as the listed coactivators, are all involved in chromatin remodeling, through either histone acetyltransferase (HAT, underlined) or histone deacetylase (HDAC, underlined) activities, or direct contacts to structural chromatin components (TIF1). Therefore, chromatin remodeling seems to be a key process during steroid hormone receptor action.



For example, hERa has been shown to interact with the **TATA-box**-binding protein (TBP), the TBP-associated factor $hTAF_{II}30$, and the general transcription factor TFIIB. Likewise, the human progesterone receptor was shown to interact with *Drosophila* $TAF_{II}110$ and TFIIB. Because an interaction with the same GTFs has also been documented for many other sequence-specific transcription factors, the specificity of an individual interaction remains to be determined.

7.1. Transcription Intermediary Factors (TIFs)
TIFs are thought to bridge between DNA-bound sequence-specific transcription factors and GTFs. The suspicion that SHRs may require such TIFs for activation was derived from the squelching, phenomenon. “Squelching” refers to the observation that excess receptor can inhibit its own transactivation, as well as transcription by other transactivators. One possible explanation for this behavior is that additional factors, present in limited amounts and required for transactivation, are trapped by excess SHRs in unproductive complexes.

Today many of these transcription intermediary factors are known (see Fig. 2). One of the best characterized examples is the steroid receptor coactivator-1 (SRC-1) (7). SRC1 interacts with the human progesterone, glucocorticoid, and estrogen-a receptors and enhances their hormone-dependent transcriptional activities, without altering the basal activity of a target promoter. Moreover, by coexpressing SRC-1, it is possible to reactivate a target promoter that is squelched by excess SHR. Another important and general coactivator shown to interact with SHRs and SRC-1 is the cAMP response-element-binding protein, (CREB)–binding protein (CBP), and the related protein p300 (see text below).

For the binding of at least a subset of these TIFs to agonist liganded SHRs, the presence of one or more TIF signature motifs, Leu–X–X–Leu–Leu, are necessary and sufficient; in all known TIFs, at least one of these signature motifs is present in those parts of the proteins that were shown to interact with the SHRs. **Secondary structure prediction** analysis shows that the Leu–X–X–Leu–Leu

signature motif is part of an a-helix. After binding of an agonistic ligand to the SHR, helix 12, containing the AF-2 core of the receptor, is relocated (see text above), thus creating a new interface that is poised for interaction with the signature motif of a TIF.

7.2. Corepressors

For some members of the nuclear receptor family, such as the thyroid hormone receptor (TR) and the retinoid acid receptors (RARs), which form heterodimers with the retinoid X receptor (RXR), it is well known that they repress basal transcription in the unliganded state. Recently, it could be shown that this silencing effect is mediated by corepressors that were called nuclear receptor corepressor (N-CoR) and silencing mediator for retinoid and thyroid hormone receptors (SMRT). N-CoR and SMRT associate with DNA-bound TR/RXR or RAR/RXR heterodimers in the absence of hormone, but not in its presence. SMRT and N-CoR are multiprotein complexes that exhibit histone deacetylase activity. The same proteins are also implicated in steroid hormone action, as it was demonstrated that overexpression of N-CoR and SMRT represses the partial agonistic activity of ERa bound to the antihormone tamoxifen and of progesterone receptor bound to the antagonist RU486. Because all previous investigations in this field have been done by using artificial assays, including yeast two-hybrid systems and transfection experiments, these results must be considered with caution in terms of their *in vivo* relevance.

In summary, SHRs can exist in a multitude of conformations depending on the nature of their bound ligand. The various interaction surfaces are determined by a-helix 12, and most probably also the following *C*-terminal residues, the F region. Transactivation by SHRs appears not to be a simple net activation, but the sum of the relief from repression by corepressors and activation by coactivators. The switch from the repressed to the activated state is promoted by the hormone ligand through an **allosteric** change in the SHR structure.

7.3. Interactions with Sequence-Specific Transcription Factors

SHRs also control the activities of natural promoters through positive and negative interactions with sequence-specific transcription factors. Particularly interesting is an interaction that represses the activity of both partners, as exemplified in the case of human glucocorticoid receptor and the heterodimeric transcription factor AP-1. Typically, this mutually inhibitory interaction occurs with composite binding sites, specifically, overlapping or closely spaced hormone response elements and AP1 sites, or on separate HRE or AP1 sites, and depends on the precise composition of the AP1 dimer. Similar interactions have been described between glucocorticoid receptor, the p65 subunit of the transcription factor NF-kB, and the transcription factor GATA-1. From experiments with numerous SHR mutants, it can be concluded that repression is most probably mediated by a protein–protein interaction with an SHR monomer that requires the N-terminal portion of the receptor at least (the N-terminal portion of an SHR monomer). Because most immunoregulatory genes, as well as genes involved in inflammation, are positively regulated by the transcription factors AP1 and NF-kB, it is conceivable that the immunosuppressive and anti-inflammatory activities of glucocorticoids are mediated through inhibition of AP1- and NF-kB-mediated transactivation by glucocorticoid receptor.

8. Crosstalk with Other Signal Transduction Pathways

Steroid hormone receptors are phosphoproteins, and their functions are modified not only by hormone, but also by **phosphorylation** . Most of the identified phosphorylation sites are serine and threonine residues, but some of the family members are also phosphorylated on tyrosine. In case of the chicken progesterone receptor, for example, four phosphorylated serine residues have been identified that are common to both isoforms PR-A and PR-B. The two *N*-terminal sites are only moderately phosphorylated in the absence of hormone, whereas an increase in phosphorylation of these sites, and the appearance of two new phosphorylation sites, are observed after hormone treatment. Mutation of these serine residues results in a cell- and promoter-specific variation of receptor activity when tested in transfection experiments.

Modulation of kinase activity can also cause activation of some SHRs, even in the absence of hormone. Epidermal growth factor (EGF) treatment of ovariectomized mice, for example, results in nuclear translocation and an altered phosphorylation state of the estrogen receptor ERa. In transient transfection studies, EGF can activate the ERa. In contrast, it was found in ER-containing MCF-7 mammary tumor cells that estradiol stimulates within minutes the c-Src kinase and mitogen-activated protein (MAP) kinase signal transduction pathways. Here, ERa was shown to interact directly with c-Src. Likewise, in the progesterone receptor-positive T47D mammary tumor cell line, progestins rapidly and reversibly stimulate the c-Src/p21ras/Erk-2 pathway. This activation requires not only PR-B but also ligand-free ERa (8). In contrast to ERa, PR-B does not interact with c-Src, but with ERa via its amino terminal part, which is not present in PR-A. The transactivation function of PR-B is not required to activate this signal transduction pathway. Therefore, extensive crosstalk takes place between peptide growth factors and SHRs, which could explain the mitogenic effects of steroid hormones and the steroidlike effects of growth factors.

9. Interaction with Chromatin

The interaction of SHRs with DNA, the general transcription machinery, corepressors and coactivators, as well as sequence-specific transcription factors, takes place in the nucleus with its DNA compacted into chromatin (see Nucleosome). Genetic analyses have demonstrated a widespread involvement of chromatin structure in gene regulation in general. For the glucocorticoid receptor, it was shown that components of the so-called SWI/SNF complex, a set of pleiotropic transactivators that counteract repressive functions of chromatin, are required for transactivation in yeast. In human cells lacking brahma (hBrm), the homologue of yeast SWI2, transactivation by glucocorticoid receptor is weak and can be selectively enhanced by ectopic expression of hBrm. Similar to SWI2 in yeast, hBrm is part of a large multiprotein complex that mediates ATP-dependent disruption of a nucleosome. These results document the link between SHRs and the cellular machinery involved in chromatin dynamics.

One well-documented example for SHR-chromatin interactions is the mouse mammary tumor virus (MMTV) promoter. The MMTV promoter is transcriptionally controlled by steroid hormones, in particular glucocorticoids and progestins. The cognate hormone receptors bind to a cluster of hormone response elements (HREs) and facilitate the binding of other transcription factors, including nuclear factor 1 (NF1). Many investigators find nucleosomes in defined positions over the MMTV promoter. One dominant nucleosome phase found both in mammalian and yeast cells carrying the MMTV promoter permits SHR binding to the HREs, while precluding binding of NF1. This difference between SHRs and NF1 seems to reflect the way in which a DNA-binding protein recognizes the major groove of its cognate DNA site. Whereas SHR–DNA interactions take place largely on one face of the DNA double helix, and within a small sector of the helix circumference, many sequence-specific transcription factors, including NF1, exhibit more contacts around the helix circumference and almost completely embrace the double helix. This means that an HRE positioned on the surface of a nucleosome is still accessible to SHRs, so long as the major groove recognized by the receptor is pointing away from the nucleosome. But in the case of NF1, no matter what the rotational orientation of its binding site on the nucleosome surface might be, a fraction of the required protein–DNA contacts is always occluded by the histones, and binding is not possible. Therefore, the SHRs might represent a class of transcription factors whose cognate binding sites are still accessible within chromatin, if the rotational HRE orientation is favorable, and thus can act as initiators of chromatin remodeling so that other transcription factors, exemplified by NF1, can bind in a second step.

Apart from the SWI/SNF complex and related ATP-dependent chromatin remodeling machines, increasing evidence has accumulated in recent years implicating the modification of histones in the regulation of gene transcription. Histones are composed of a histone-fold domain, involved in wrapping the DNA in nucleosomes, and an *N*-terminal tail rich in lysine residues that is protruding out of the nucleosome. **Acetylation** of the tail lysine residues greatly reduces the affinity of the histone tails for DNA, and it is believed to render DNA more accessible to transcription factors,

while still maintaining a nucleosomal architecture. Moreover, some of the identified coactivators for the SHRs such as CBP/p300 and SRC-1 (see Fig. 2), as well as the largest subunit of the pivotal general transcription factor TFIID, TAF $_{II}$230 / 250, turned out to be histone acetyl transferases. All these observations lead to the **current two-step model** for transcriptional activation by SHRs that is built on the recruitment of coactivators and other transcription factors with histone acetyl transferase activity, resulting in the local destabilization of repressive histone–DNA interactions, followed by direct or indirect interactions with the basal transcription machinery.

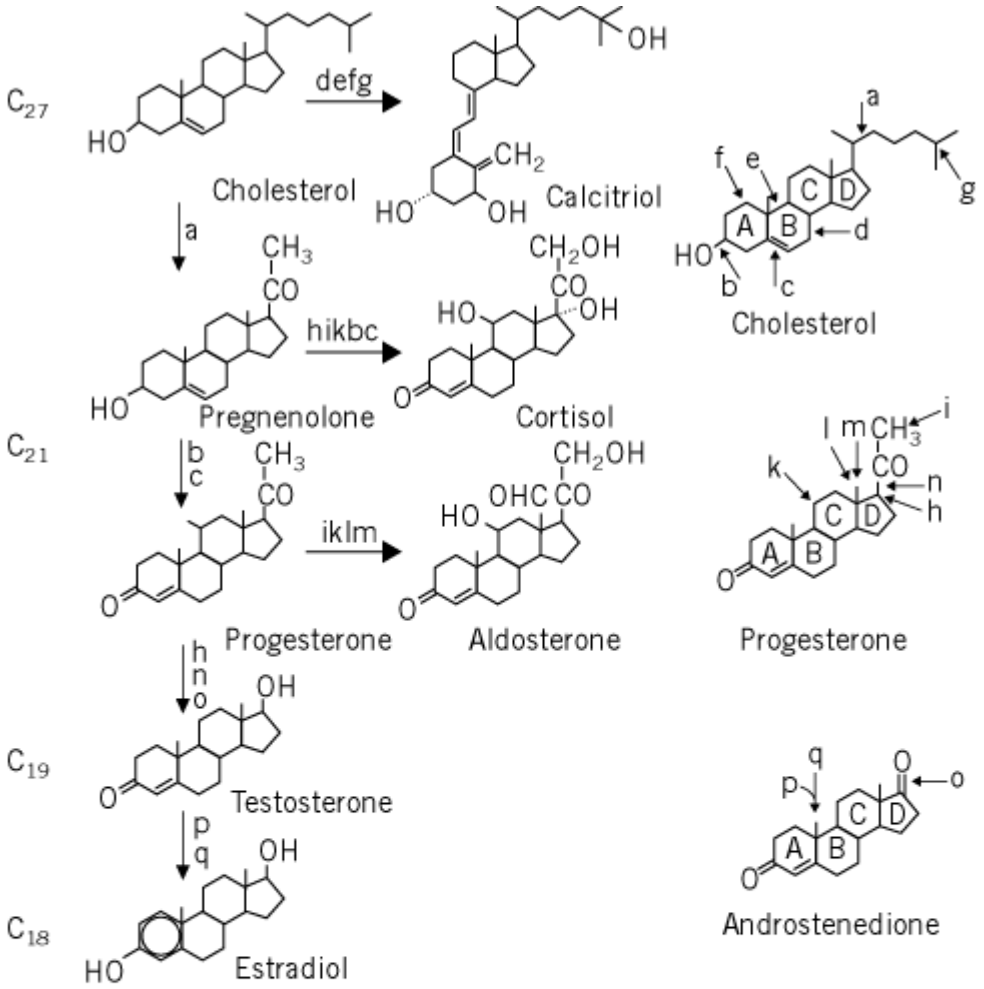
Steroid Hormones

Steroid hormones comprise a major group of hormones that is characterized by the presence of the cyclopentanperhydrophenanthrene ring. The main steroid hormones and their major biosynthetic pathways are shown in Fig. 1 **a**. Steroid hormones are derived from blood cholesterol or from cholesterol synthesized in the gland cell. The first step of the biosynthetic pathway is cleavage of the cholesterol side chain; the only steroid hormones that retain the side chain are the ecdysteroids. Further enzymatic steps (eg, cleavages, isomerization, and aromatization) lead to the various steroid hormones.

Figure 1. Biosynthesis and inactivation of steroid hormones. (**a**) Biosynthesis. The enzymes involved catalyze the

following reactions: hydroxylations (a, f, g, h, i, k, l, p), dehydrogenations b, d, m), isomerization (c), hydrogenation (o), cleavages (a, e, n), aromatization (q). To illustrate the sites of action of each type of enzyme, the three steroids cholesterol, progesterone, and androstendione (an intermediate in testosterone biosynthesis) are shown. (**b**) Inactivation. (From Ref. 11, with permission.)



Steroids released in the blood circulation are bound to albumin. Glucocorticoids and the sex hormones are also bound specifically to corticosteroid-binding globulin and sex-hormone-binding globulin, respectively. Inactivation of steroid hormones (Fig. 1**b**) takes place primarily in the liver, but also in other organs and cells.

Steroid hormones act in target cells by regulating gene transcription (see Hormone Receptors). They

bind to intracellular **receptors** (see Estrogen Receptors) in a highly specific manner (1, 2). Interaction of the ligand with the receptor leads to dimerization of the protein and binding to specific nucleotide sequences, the hormone response elements. These are enhancer elements, placed at various distances from the **promoter** of the hormonally regulated gene. Binding of the receptor dimer to these sequences, and its interaction with other transcription factors and regulatory proteins, results in modulation of gene transcription. In addition, some steroid hormones also exert rapid, nongenomic effects on intracellular Ca^{2+} and other ion concentrations, acting at the level of the cell membrane.

1. Glucocorticoids

The main representative glucocorticoids are cortisol (in man) and corticosterone (in rodents). They are synthesized in the zona fasciculata of the adrenal cortex, and they regulate carbohydrate, lipid, and protein metabolism. In the liver, glucocorticoids stimulate protein synthesis, whereas they stimulate **protein degradation** in muscle, bone, and lymph organs. Some of the amino acids released by protein degradation are metabolized in the liver to glucose precursors and subsequently to glucose and glycogen (gluconeogenesis). Glucocorticoids induce the biosynthesis of the crucial enzymes that are involved in gluconeogenesis (3).

2. Mineralocorticoids

The main representative of this class is aldosterone (11b,21-dihydroxy-3,20-dioxopregn-4-en-18-al), which is synthesized in the zona glomerulosa of the adrenal cortex. Aldosterone regulates Na^+ reabsorption and K^+ excretion, by inducing the biosynthesis of the Na^+/K^+-ATPase in the epithelial cells of the kidney involuted tubules. Together with Na^+, Cl^- ions are also reabsorbed, as well as water, which then returns to the blood circulation (4).

3. Androgens

Androgens are the male sex hormones. The effects of castration were recognized very early, and the amelioration of these effects by transplantation of testis can be regarded as one of the first experiments in the field of Endocrinology. The major representatives of this group of hormones are testosterone (D4-androsten-(7b-ol-3-on) and its D4-reduced derivative, 5a-dihydrotestosterone (DHT). Testosterone is synthesized in the Leydig cells of the testis, whereas 5-DHT is produced within the target cells, by the action of 5a-reductase, an enzyme whose synthesis is induced by testosterone. Steroids with androgen activity are also synthesized in the adrenals (androstenedione and 11-hydroxyandrostenedione) (5). In adrenal tumors, the concentrations of these steroids rise, causing virilism in women.

Testosterone acts during embryogenesis, causing the sexual differentiation of the male (differentiation of the Wolffian ducts to epididymis, sperm duct, and sperm cyst), whereas 5-DHT, which is formed in a later period, is responsible for the development of the prostate, the external genitals (penis and scrotum), and growth of male hair (6). In adults, the continuous production of androgens is necessary for sperm maturation and for the activity of the accessory glands of the genital tract. The action of androgens on spermatogenesis is a paracrine effect, as testosterone synthesized in the Leydig cells diffuses directly to the seminiferous tubule and acts there. Androgens also stimulate **erythropoiesis**, affect the immune system, and increase muscle mass. This last effect is due to increased protein synthesis and increased nitrogen retention (“anabolic action”). Androgen derivatives lacking significant androgen action but exerting the anabolic effects (anabolic steroids) are used in therapy, but are also misused by athletes. Steroids with antiandrogen effects have been synthesized, acting through competitive inhibition of the androgen at the level of the androgen receptor (cyproterone).

4. Estrogens

The main representative of estrogens is 17b-estradiol (1,3,5-estratriene-3,17b-diol). It is synthesized in the ovary and in the placenta. Estrogens are responsible for the development of the secondary female sex characteristics (breast, hair, skin, and fat distribution) (7). They have proliferative effects on the endometrial mucosa, acting during the first half of the menstrual cycle. Estrogens induce the biosynthesis of a series of proteins involved in cell proliferation and the cell cycle, such as growth factors, transcription factors, and cyclins .

5. Progesterone

Progesterone (pregn-4-ene-3,20-dione) is synthesized in the ovary (corpus luteum). It acts during the second half of the menstrual cycle, inducing the secretory phase of the endometrial mucosa and thereby preparing the endometrium for possible embryo implantation (8). Progesterone acts antagonistically to estrogens with regard to cell proliferation, inhibiting transcription of genes encoding growth factors. Furthermore, progesterone induces the biosynthesis of a series of uterus-specific proteins. One important effect of progesterone is the triggering of the acrosome reaction in human sperm cells, which is accomplished by a nongenomic, direct membrane effect of the hormone, activating a signal transduction pathway.

6. Ecdysteroids

Ecdysone((22R)-2 b, 3 b, 14, 22, 25-pentahydroxycholest-7en-6-one) and its 20-hydroxylated derivative, ecdysterone, are the major members of this class and the steroid hormones of insects and crustaceans (Fig. 2). Ecdysone is produced in the prothoracic glands, transported by the hemolymph to target cells, and there it is hydroxylated to the hormonally active ecdysterone. One other hormonally active ecdysone derivative is ponasterone (25-deoxy-ecdysterone). A major function of ecdysteroids is the regulation of ecdysis and metamorphosis. In addition, ecdysteroids affect many other processes, namely, embryogenesis, ovarian maturation, vitellogenesis, ovulation, spermiogenesis, and behavior. In these processes, cell proliferation and apoptosis are involved and are modulated by ecdysteroids. Ecdysteroids act by regulating gene transcription. This was first shown by Clever and Karlson (9) in the midge Chironomus tentans by injecting ecdysone into larvae and observing rapid puff induction in salivary gland polytene chromosomes . On the basis of this observation, the hormone-gene activation hypothesis was formulated; it has subsequently been corroborated in several vertebrate systems and is still acquiring general validity. The receptor for ecdysteroids has been characterized in several insect species, and three isoforms have been detected in *Drosophila melanogaster*. The isoforms bind to DNA as heterodimers with the **orphan receptor** Ultraspiracle (see Hormone Receptors), a homologue of the vertebrate **retinoid** X-receptor (10).

Sterol Response Element

The sterol response element is a 10-bp response element that controls the activation of specific **genes** in response to a fall in the levels of cholesterol (1). The regulation of specific genes in response to the levels of cholesterol is necessary because cholesterol can be obtained by mammalian cells either by uptake of cholesterol-containing **lipoprotein** particles or by *de novo* biosynthesis. Mammalian cells control these two pathways so as to ensure an appropriate supply of cholesterol by feedback **repression** of several key genes involved in cholesterol metabolism.

In response to lowered levels of cholesterol, the supply is increased both by activating the expression of the gene encoding the **low-density lipoprotein** (LDL) receptor, which plays a central role in cellular uptake of cholesterol, and by activating the genes encoding various enzymes involved in the *de novo* biosynthesis of cholesterol, such as HMG-CoA reductase and HMG-CoA synthase. The genes encoding these proteins contain a sterol response element (SRE) that is able to bind two SRE-binding proteins (SREBP-1 and SREBP-2). These two proteins are synthesized as high-molecular-weight molecules that are bound to cellular membranes; hence, they cannot enter the nucleus and activate transcription by binding to the SRE. Following a decrease in cholesterol levels, SREBP-1 and SREBP-2 are cleaved **proteolytically**, so that a smaller active fragment of each is released from the membrane; it enters the nucleus, where it binds to the SRE and activates transcription (2, 3).

In this manner, these transcription factors are able to activate specific genes in response to decreased

levels of cholesterol by binding to the SRE and activating the transcription of genes involved in the uptake or synthesis of cholesterol. This simple homeostatic mechanism thus ensures the precise regulation of cholesterol levels within these cells.

Stokes Radius

In examining the function of biological macromolecules, it is useful to have information about the size and shape of each relevant macromolecule. In the absence of high resolution structural information, like that obtained from X-ray crystallography or NMR spectroscopic methods, transport studies can provide low resolution information about these structural parameters and the hydrodynamic volume. Examples of transport techniques include size exclusion chromatography, sedimentation velocity centrifugation, and electrophoresis. The rate of transport of any molecule through a medium using any of these techniques is dictated in part by the frictional resistance of the molecule to motion. This frictional resistance, which is expressed as a **frictional coefficient**, is, in turn, determined in part by the size and shape of the macromolecule. Here the size of a macromolecule will be discussed in terms of the Stokes radius. Use of the Stokes radius to estimate the **molecular weight** will also be presented, as well as the complications arising from the effects of hydration and molecular shape.

For a spherical molecule, the frictional coefficient is related to its size by

$$f = 6\pi\eta R \tag{1}$$

where h is the viscosity of the fluid through which the molecule is transported and ***R*** is the radius of the sphere (1-3). ***R*** is referred to as the Stokes radius, and Equation (1) is known as Stokes' law. This law was originally proposed in 1851 by the British scientist Sir George Stokes from consideration of the forces acting on a particle as it sinks through a liquid column under the influence of gravity (4). For a given total particle volume, a sphere has the minimum possible frictional coefficient, which is referred to as f_0.

In using the Stokes radius to obtain information about the size and shape of a biological macromolecule, it is important to consider two factors: (*1*) biological macromolecules are highly solvated and, (*2*) many are nonspherical. The solvation factor can be readily taken into account. The radius of a sphere is related to its volume by $r = (3\text{volume}/4\text{p})^{1/3}$. For a solvated sphere, however,

the volume is expressed as follows:

$$V_h = \frac{M}{N_0(\overline{V}_2 + \delta_1 \overline{V}_1)} \tag{2}$$

where M is the molecular weight of the unsolvated macromolecule, N_0 is Avogadro's number, V_2 is the **partial specific volume** of the macromolecule in cm^3/g, $\mathbf{d_1}$ is the hydration defined as the grams of water per gram of protein, and V_1 is the partial specific volume of the aqueous solvent or water in cm^3/g. This last term is simply the inverse of the solvent density. For a more detailed discussion of macromolecular hydration and the measurement or estimates of these terms, refer to the Hydrodynamic Volume article. Using Equation (2), the radius of a solvated spherical molecule is related to the molecular weight of the molecule by the following equation:

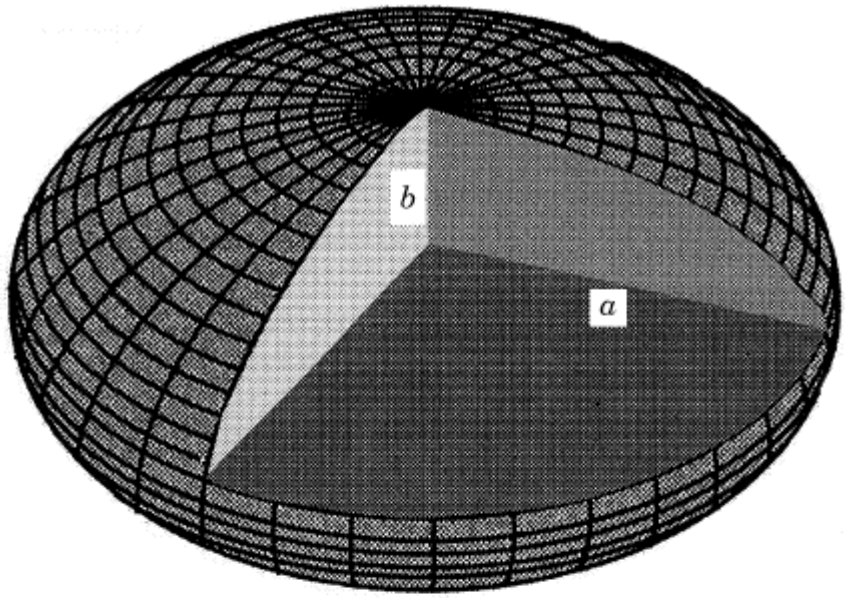
$$R = \left[\frac{3M_w\overline{V}_2}{4\pi N_0}\left(1 + \frac{\delta_1\overline{V}_1}{\overline{V}_2}\right)\right]^{1/3} \tag{3}$$

As indicated above, this equation will apply only to spherical molecules. For those that are nonspherical, use of a Stokes radius determined by, for example, size exclusion chromatography to calculate the molecular weight will lead to an erroneously high value. Nonspherical molecules can, however, be modeled using different assumed shapes, such as ellipsoids or rods, on the basis of information obtained from transport measurements. For such molecules, a term R_e is defined as the radius of a sphere that is equivalent in volume to that of the nonspherical particle and

$$f_0 = 6\pi\eta R_e \tag{4}$$

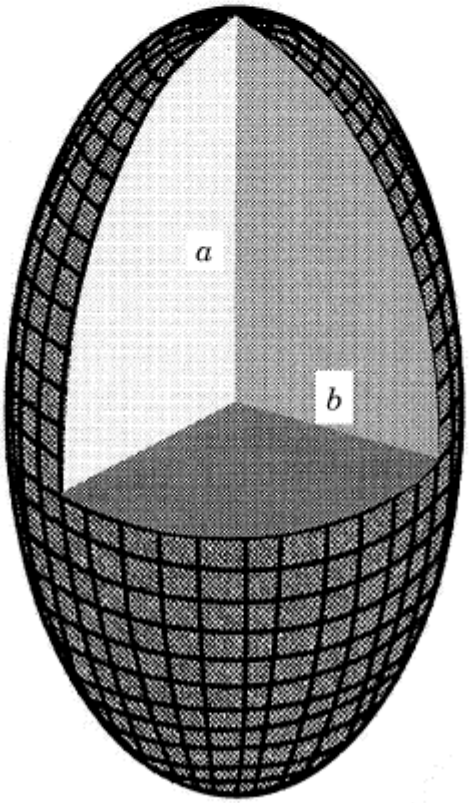
R_e is referred to as the equivalent radius; it can be calculated using Equation (3), provided that the molecular weight of the macromolecule is known. In Equation (4), f_0 is the frictional coefficient that would be measured for a sphere of volume equivalent to that of the nonspherical particle. It is a "minimal" frictional coefficient. The ratio of the true frictional coefficient of the nonspherical particle, f, to this minimal frictional coefficient of a hypothetical sphere of equivalent volume is useful in obtaining information about the shape of a macromolecule. Mathematical relationships have been derived for prolate and oblate ellipsoids (Fig. 1), as well as for macromolecules that are best described as rods (5). The equations pertaining to ellipsoids are shown in Table 1. From the known frictional coefficient ratio, f/f_0, one can estimate the shape of the molecule and its asymmetry as expressed by the axial ratio. These relationships are shown graphically in Figure 2.

Figure 1. Diagrams of perfect ellipsoidal shapes: (**a**). Obláte ellipsoids; (**b**) Prolate ellipsoids. A prolate ellipsoid can be considered to be an elongated sphere, and an oblate ellipsoid is generated by flattening a sphere. For both shapes, *a* is the semimajor axis length and *b* is the semiminor axis length. The frictional ratios, f/f_0, for each shape were calculated using the equations shown in Table 1.



$a/b = 3.0\ f/f_o = 1.105$

(a)



$a/b = 2.0\ f/f_o = 1.044$

(b)

Figure 2. Graphical representations of the relationship between the fictional ratio (f/f_0) and the axial ratio (a/b) for oblate and prolate ellipsoids. The equations relating these two quantities are shown in Table 1.

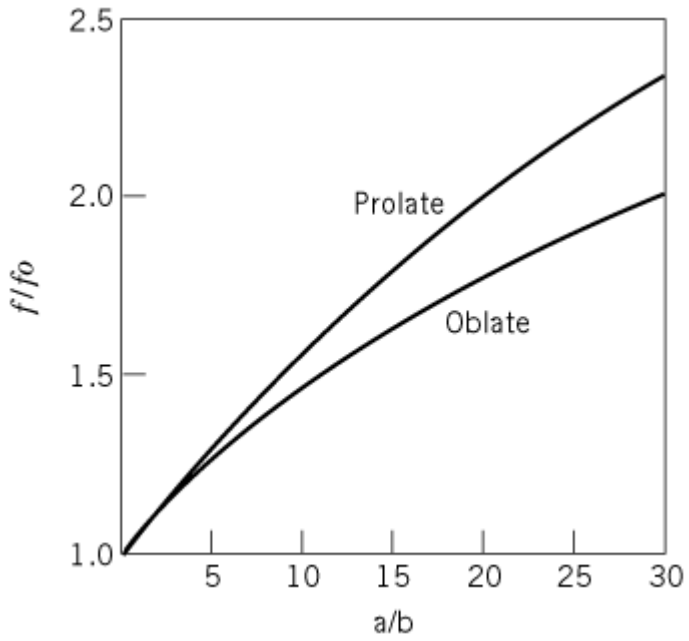


Table 1. Relationships between Frictional and Axial Ratios for Ellipsoidal Shapes

Shape	f/f_0 [a]	R_e [b]
Prolate ellipsoid	$\frac{(\frac{a}{b})^{-1/3}((\frac{a}{b})^2-1)^{1/2}}{\ln[(\frac{a}{b})+((\frac{a}{b})^2-1)^{1/2}]}$	$(ab^2)^{1/3}$
Oblate ellipsoid	$\frac{((\frac{a}{b})^2-1)^{1/2}}{(\frac{a}{b})^{2/3}\tan^{-1}[((\frac{a}{b})^2-1)^{1/2}]}$	$(a^2b)^{1/3}$

[a] The axial ratio, a/b, is the ratio of the semimajor axis length, a, to the minor axis length, b. These terms are shown pictorially in Figure 1. Remember that the inverse tangent should be taken for a number expressed in radians.

[b] The parameter R_e is the equivalent radius or the radius of the sphere that is equivalent in volume to that of the nonspherical particle.

Stop Codons

In the standard genetic code, three **codons**, UAG, UAA, and UGA, are assigned as *stop codons* to terminate translation of the messenger RNA in **protein biosynthesis**. For historical genetic reasons, they are often referred to as the *amber, ochre*, and *opal* codons, respectively. To some extent, however, the termination signals are effectively quadruplet since the identity of the 3′ base immediately following substantially influences the efficiency of termination (1). The triplets themselves do not have the same efficiency; UGA is somewhat less efficient than the other two but still functions with at least 97% efficiency (ribosomes that do not terminate readthrough by inserting an amino acid, often Trp, when the stop codon is UGA). In **eubacteria**, the relative frequency of use of the termination triplets is UAA > UGA >> UAG. Healthy mutants, especially of eubacteria and **yeast**, have been isolated with the anticodon of a transfer RNA species altered so that it can decode a stop codon. Such **"suppressor" mutants**, especially those for UAG, have been very useful for genetic analyses. Normally, no tRNA corresponds to the termination codons. Instead, protein termination factors mediate release of the polypeptide chain from the ribosome. In *Escherichia coli*, there are two codon-specific release factors, whereas **eukaryotes** have only one (2). In both cases, there is an additional codon-independent protein factor involved.

In eubacteria, there is not always independent ribosome entry to different coding regions contained on the same mRNA. In several cases, the stop codon for one **cistron** overlaps with, or is very close to, the start codon for the next coding region. Although the polypeptide chain is released at the end of the first coding region, the 30S ribosomal subunit, or perhaps the entire 70S ribosome, need not dissociate from the mRNA but immediately initiates decoding of the next sequence. In the absence of such translational coupling, the ribosome recycling factor functions to generate separate ribosomal subunits for independent initiation elsewhere (3).

Stop codons are essential for release of the nascent polypeptide from ribosomes and, consequently, release of ribosomes from mRNA. On occasion, transcription to synthesize mRNA stops prematurely, or an mRNA is cleaved internally by a **ribonuclease**, so that a coding region without an in-frame stop codon results. When a ribosome comes to the 3′ end of such a terminatorless mRNA, it, along with the incomplete nascent peptide, gets stuck. Recently, it has been found that eubacteria have a remarkable rescue mechanism involving an RNA, known as tmRNA, which has both tRNA and mRNA-like features. The *E. coli* tmRNA consists of 363 nucleotides. Its 5′ and 3′ ends base-pair to form a partial tRNA-like structure that is aminoacylated. The current model indicated by the experimental observations is that tmRNA enters the A site of ribosomes stalled at the end of terminatorless mRNA, donates its amino acid to the carboxy terminus of the stalled nascent peptide, and then functions as an mRNA. The mRNA portion is internal to the molecule and encodes 10 amino acid residues before the ribosome encounters a stop codon and terminates normally, with recycling of ribosomes (4-6). The carboxy-terminal extension of the nascent polypeptide encoded by tmRNA constitutes a recognition site for a proteinase, which destroys the aberrant protein (5).

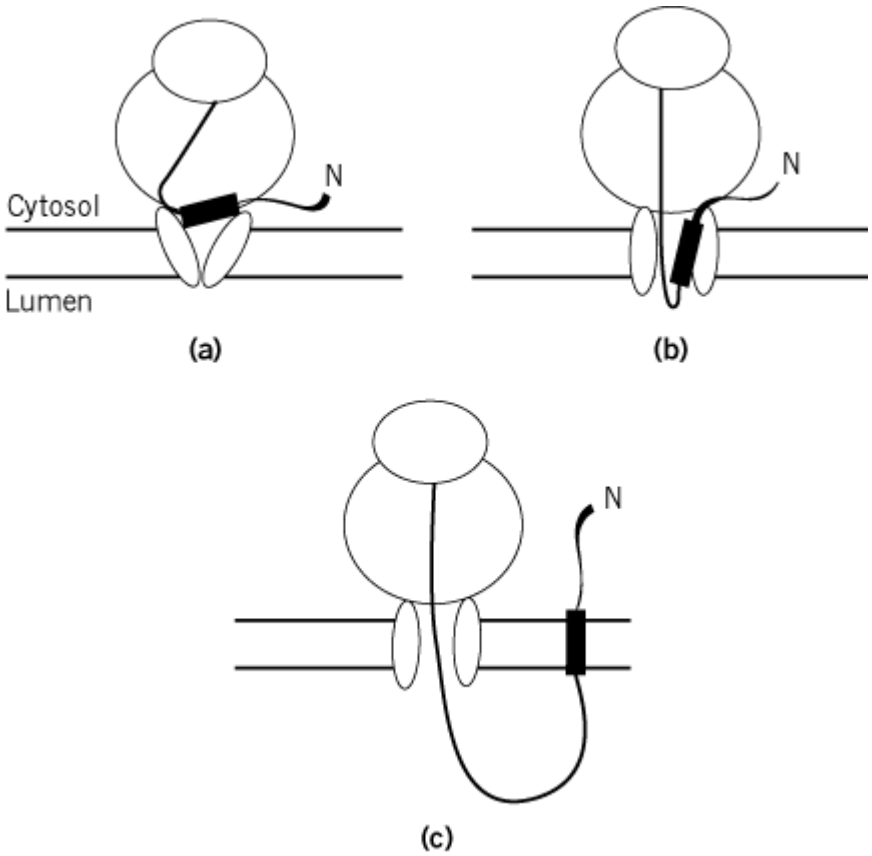
Stop-Transfer Sequence

During the biosynthesis of an integral membrane protein, the nascent polypeptide chain passes through a transmembrane channel system known as the translocon. When a peptide containing a stop-transfer sequence [a concept originally suggested by Blobel (1)] inserts into the channel, the translocation process is interrupted. Subsequently, the translocation channel releases the polypeptide chain carrying the stop-transfer sequence laterally to the lipid bilayer. The stop-transfer sequence thus becomes a **transmembrane** segment (2).

Especially in higher eukaryotes, the translocation of most integral membrane proteins across the endoplasmic reticulum (ER) membrane occurs cotranslationally and with the help of metabolic energy via the same route as the translocation of secreted soluble proteins—that is, through the Sec61p-complex (2, 3) (see Protein Secretion). The latter is a heterotrimeric transmembrane protein complex that forms an aqueous channel across the ER membrane and interacts with a number of other components of the protein translocation machinery. In yeast and bacteria, most membrane proteins seem to be inserted to the membrane posttranslationally rather than cotranslationally. Despite this, the majority of them use the Sec-complex for integration into the membrane. However, a Sec-independent route may also exist.

The translocation process is initiated when one of the **Sec proteins** recognizes the complex formed by the **signal sequence**, the signal recognition particle (SRP), and the SRP receptor. This causes the ribosome from which the signal sequence is emerging to bind to the translocation channel, sealing its entrance to the cytoplasm (Fig. 1). It is thought that the signal sequence then interacts with the channel, which opens, allowing the nascent polypeptide to insert into it. The polypeptide is translocated across the membrane until the process is halted by a stop-transfer sequence, which interacts with the channel. Although the *N*-terminus of the stop-transfer sequence enters the channel first, the orientation of the sequence relative to the membrane can change during its stay in the channel. Finally, the translocation channel releases the transmembrane segment with the desired orientation laterally to the lipid bilayer. The ribosome remains bound to the Sec61p complex, and the synthesis and translocation of the polypeptide proceeds.

Figure 1. Cotranslational integration of a membrane protein into the ER membrane. (**a**) A ribosome that is synthesizing a single-span membrane protein binds to the translocation channel. The stop-transfer sequence (which in this case is also an *N*-terminal signal-anchor sequence) interacts with the channel and opens it. (**b**) The stop-transfer sequence adopts the orientation in which the *N*-terminus is in the cytosol and the *C*-terminus is in the ER lumen. (**c**) The stop-transfer sequence has been released to the membrane, and the synthesis and translocation of the lumenal domain of the protein continue. For details and more complex situations, see Ref. 2.



During synthesis of polytopic membrane proteins, with multiple transmembrane segments, the translocation channel may store more than one transmembrane segment at a time until these reach the correct topology in the bilayer and are released simultaneously. Such a cooperativity could allow utilization of the favorable **free energy** of membrane insertion of one transmembrane helix to be coupled to the insertion of another helix with less favorable insertion energetics, perhaps due to the presence of charged residues.

The general features of a stop-transfer sequence include hydrophobicity and positively charged residues in the nontranslocated flanking sequence (the "positive-inside rule"; see Hydropathy). A stop-transfer sequence typically comprises about 20 hydrophobic residues, as expected for a transmembrane a-helix. However, a systematic analysis of the requirements for the stop-transfer function has shown that a stretch of only nine leucine residues is enough for stable insertion into the membrane. In contrast, more than 19 alanine residues are required for the same function.

A concept related to the stop-transfer sequence is the stop-transfer effector. In the prion protein, it is the hydrophilic sequence that precedes a sequence with a conditional stop-transfer function (4). Mutations in both stop-transfer sequence and effector lead to a change in the transmembrane orientation in a population of the prion protein. It appears that the Gerstmann–Straussler–Scheinker-type prion disease, caused by an Ala117Val mutation in the stop-transfer sequence, is linked to the generation of a misoriented transmembrane form of the protein. In general, not many examples of membrane proteins with more than one topology are known. However, ductin and the proteolipid of a V-type ATPase appear represent a case in which the same polypeptide is inserted in the membrane in two different topologies (5).

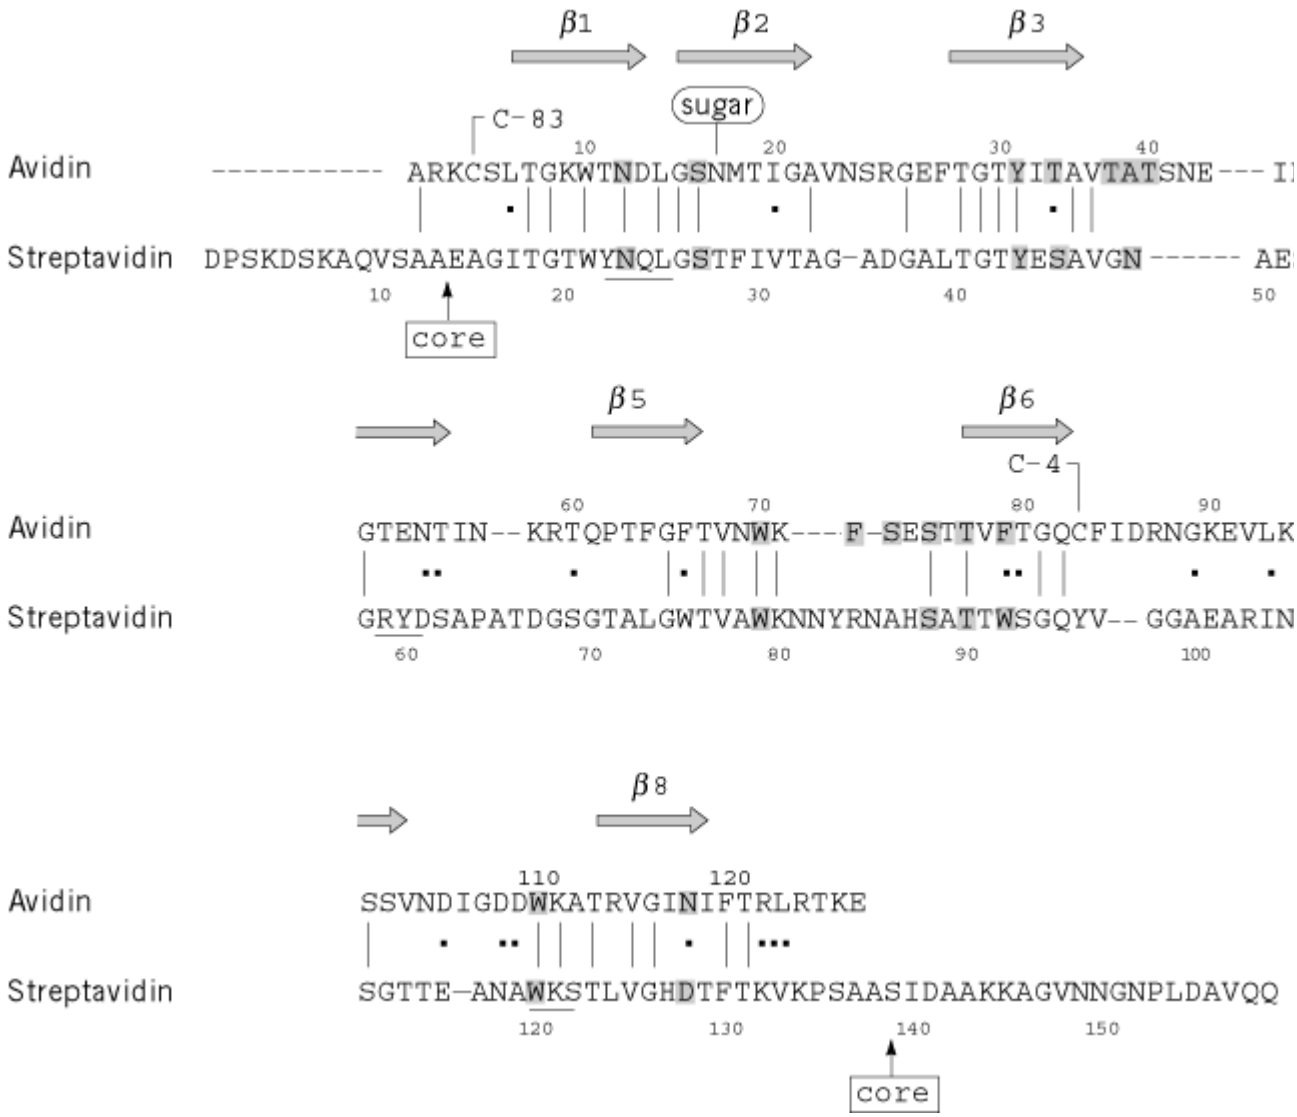
Streptavidin

Streptavidin, a bacterial protein produced by various strains of the genus *Streptomyces* (1, 2), is a distant relative of egg-white avidin. Similar to avidin, the streptavidin monomer associates into a tetramer and binds the vitamin biotin with a similarly high **association constant** [K_a (streptavidin) = 2.5×10^{13} M^{-1}versus K_a(avidin) = 1.7×10^{15} M^{-1}]. Twelve of the 16 biotin-binding residues that make up the binding site of avidin are conserved in streptavidin (Fig. 1). Unlike avidin, which is a positively charged **glycoprotein**, streptavidin is unglycosylated in the native state and bears an overall charge close to neutral.

Figure 1. Structure-based sequence alignment of avidin and streptavidin. Identical residues are indicated by vertical line similar residues by dots. The positions of the b-strands are shown by arrows. Residues that participate in binding biotin a The glycosylation site of avidin is shown, as are the N- and C-terminal cleavage sites of streptavidin that are sensitive to digestion. Cellular recognition motifs on streptavidin that cause erratic targeting are underscored.



Streptavidin is the protein component of a two-component antibiotic complex that acts mainly on **gram-negative** bacteria (3). It binds to a group of low molecular weight peptides (termed "stravidins"), each of which contains an unusual amino acid called amiclenomycin (Acm) (4). Acm is a biotin antimetabolite that inhibits one of the enzymes of the biotin biosynthetic pathway. It is interesting to note that avidin can replace streptavidin as the protein component of the antibiotic, even though such a function has not been described in the egg.

Like avidin, streptavidin binds to the dye 4′-hydroxyazobenzene-2-carboxylic acid (HABA) but with a significantly lower association constant. Streptavidin also binds peptides that contain the consensus sequence His-Pro-Gln (HPQ), which has been termed *Strep*-tag when used for affinity-based separations. Egg-white avidin fails to recognize this peptide but binds to a different consensus sequence, His-Pro-Tyr-Pro (HPYP), with a much lower affinity.

Streptavidin gained prominence due to its suitability for use in avidin-biotin technology (see Avidin-Biotin System). Because of its nearly neutral charge and lack of oligosaccharide moiety, streptavidin is often preferred over egg-white avidin in many applications. Nevertheless, a certain level of familiarity with its molecular properties is advised, because, like avidin, the molecule contains a variety of undesirable characteristics that may cause "nonspecific" or "unwanted" binding with extraneous substances in the experimental system under study.

Streptavidin is secreted as a tetramer in the native state, has a molecular weight of about 66,500 and a subunit molecular weight of about 16,600. The protein undergoes postsecretory **proteolysis** to a molecular weight of 52,800 (13,200 for the subunit). The cleavage site occurs near a Ser-Ala-Ala sequence that is located at both the *N*- and *C*-termini of the protein (5). This truncated protein was termed "core" streptavidin (6) and is the commercially available form generally used in the various applications of the avidin-biotin system.

Core streptavidin has been crystallized (7, 8), and the structure of the binding site is very similar to that of avidin (9), which suggests that nature likes to conserve the prime binding sites. In contrast, despite the identical fold (see Avidin) and remarkable superimposition of the two proteins, there is only about 30% similarity in the residues that are not part of the binding site (Fig. 1). The dissimilarity is strongest in the loops that interconnect the b-strands, and this dissimilarity is so strong that antibodies raised against one protein fail to interact with the other.

Streptavidin contains several intracellular and extracellular motifs that avidin lacks. This includes the Arg-Tyr-Asp (RYD) sequence, which mimics the Arg-Gly-Asp (RGD) motif—the universal cell recognition domain present in a series of **cell-adhesion**-related proteins (10). In fact, streptavidin interacts specifically with cell-surface integrins in an RGD-dependent manner, similar to that of fibronectin, vitronectin, and other adhesion molecules (11).

Streptavidin also contains a Trp-Lys-Ser (WKS) sequence. This motif is very rare among known proteins and it was postulated that it has a significant role in the high-affinity interaction of human tissue factor with its ligand. The protein also contains another consensus sequence, Tyr-Xaa-Xaa-Leu (YXXL), known as the immunoreceptor tyrosine-based inhibitory motif (ITIM), which is present in many cytoplasmic protein **domains** from **B** and T cells.

Finally, it seems that the "alanine-scanning information principle" (12), which is currently popular in the development of second-generation drugs, was used by nature in the case of streptavidin. Streptavidin contains 25 alanine residues (!) whereas avidin contains only five. Different kinds of amino acids were apparently replaced by alanine. Perhaps streptavidin is a later version of avidin in evolution?

Streptavidin may be a "second-generation" protein, but it is certainly the preferred choice, at least currently, for use in the avidin-biotin system. Nevertheless, because of the different intrinsic binding motifs that characterize the streptavidin molecule, it should be used with care in avidin-biotin technology.

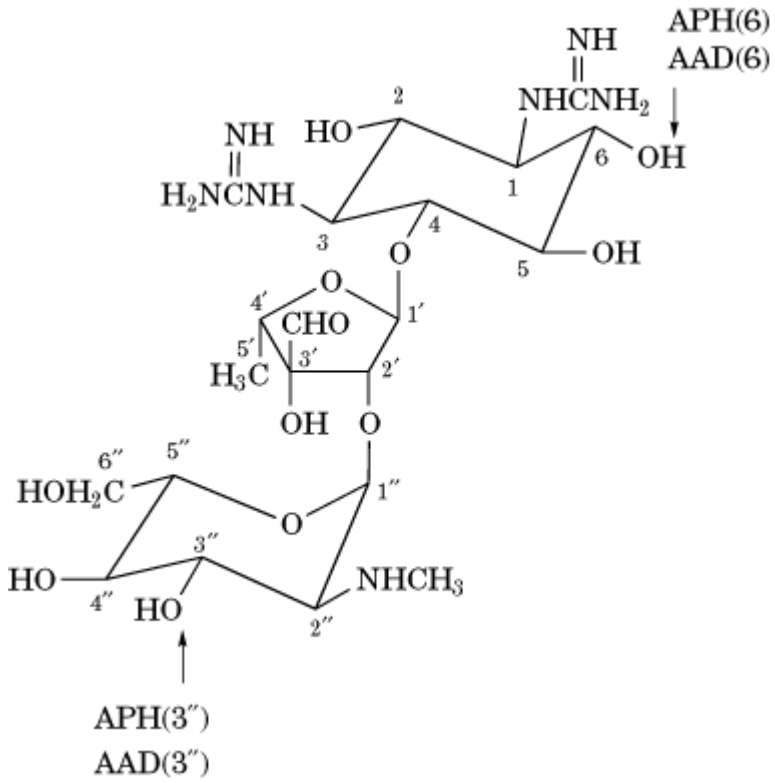
Streptomycin

Streptomycin (SM) was the first aminoglycoside antibiotic agent, introduced in 1944 by Schatz, Bugie, and Waksman (1). It has been used as an effective antimicrobial substance for the treatment of infectious diseases caused by aerobic **Gram-negative** and **Gram-positive** organisms, especially as a first-line drug for the therapy for tuberculosis. However, the appearance of resistant microorganisms (2), SM's ototoxicity, and the introduction of the less toxic broad-spectrum b-lactam antibiotics decreased SM's clinical usefulness in recent years. It has also been used as a tool for analysis of the mechanism of translation during **protein biosynthesis**, because it binds to the 30 S subunit of ribosomes and causes misreading of the messenger RNA.

SM was discovered from culture supernatants of *Streptomyces griseus*, although it is now known also to be produced by *S. bikiniensis*, *S. olivaceus*, *S. mashuensis*, *S. galbus*, *S. rameus*, and *S. glovisporus streptomicine*. SM is one of the aminoglycosidic aminocyclitols and belongs to the oligosaccharide group of basic water-soluble antibiotics (Fig. 1). It consists of streptidine, L-streptose, and *N*-methyl-L-glucosamine ($C_{21}H_{39}N_7O_{12}$, molecular weight 581.58) (3).

Figure 1. The structure of streptomycin. The sites that are modified by inactivating enzymes are indicated. Key: APH, *O*-phosphotransferase; AAD, *O*-adenyltransferase.



1. Mechanism of Action

SM exhibits bactericidal activity (killing bacteria) by inhibiting prokaryotic protein biosynthesis, although most such inhibitors have only bacteriostatic activity, ie, inhibiting bacteria's growth but not killing them. Its bactericidal activity can be explained by four processes: (*i*) SM associates with the cell surface by ionic binding and diffuses through the outer membrane into the periplasmic space, in an energy-independent process (4, 5). This diffusion process may be owing to a "self-promoted uptake" mechanism, in which SM displaces divalent cations that cross-bridge adjacent lipopolysaccharide molecules, permeabilizing the outer membrane (6);

(*ii*) SM enters the cytoplasm, using the electron transport system to cross the inner membrane (energy-dependent phase I) (6);

(*iii*) SM binds to the 30 S ribosomal subunit at nucleotides 911–915 of the 16 S ribosomal RNA in *Escherichia coli* (7, 8). The 900 stem and the 530 stem/loop regions of the 16 S rRNA interact with ribosomal proteins S4 and S12 (9-12). Proteins S4, S5, and S12 have been reported to be close neighbors in the protein map of the 30 S ribosomal subunit (13), and these proteins and their associated RNA segments constitute an area of the 30 S ribosomal subunit known as the accuracy region (13). SM binds irreversibly to the 30 S ribosomal subunit and subsequently forms abnormal initiation complexes, so-called streptomycin monosomes, by fixing the 30 S/50 S ribosomal complex at the start codon of the mRNA (14). Accumulation of the abnormal initiation complex blocks further translation of the mRNA, elicits premature termination, and incorporates incorrect amino acids, producing abnormal proteins; and

(*iv*) The abnormal proteins are incorporated into the cell membrane, and this alters its permeability. The alteration of the cell membrane stimulates the further entry of SM through the energy-dependent phase II process (15) and causes its bactericidal activity (16).

The energy-dependent transport across the inner membrane is inhibited by divalent cations (eg, Ca^{2+}

and Mg^{2+}) and by acidic and anaerobic conditions (6). Therefore, SM shows a reduced level of bactericidal activity in the presence of Ca^{2+} and Mg^{2+}, or in acidic conditions, and does not have bactericidal activity against anaerobic organisms and facultative bacteria cultured anaerobically (17). The bactericidal activity of SM competes with other inhibitors of protein bio-synthesis, such as chloramphenicol, **erythromycin**, and **tetracycline**, but not with puromycin (18).

It has been reported that organisms with mutations at the *rps*L gene, encoding the S12 protein, exhibit SM-resistant or SM-dependent phenotypes. Furthermore, mutations in the genes encoding the S4 or S5 protein—*ram* (ribosomal ambiguity) mutations—of an SM-dependent mutant that cannot grow in the absence of SM cause it to revert to SM independence and to grow in the absence of SM (19).

2. Resistance

Two resistance mechanisms to SM have been reported. One is the modification of SM by modifying enzymes, and the other is mutation of the genes encoding the target sites (20, 21).

The modifying enzymes are usually encoded by resistance **plasmids**, but in *Serratia marcescens* and *Providencia sturartii*, they are encoded by chromosomal genes (22). Two modifying enzymes have been elucidated: *O*-phophotransferase, encoded by the *aph* gene, which phosphorylates at the 3″-OH or 6-OH groups of SM, and *O*-adenyltransferase, encoded by the *aad* gene, which adenylates at the 3″-OH or 6-OH groups (Figure 1). Cross resistance between SM and kanamycin has been reported. However, because kanamycin, neomycin, paromomycin, and gentamicin are not affected by these modifying enzymes, SM-resistant strains possessing the modifying enzymes are sensitive to these aminoglycosides. Resistance plasmids encoding the modifying enzymes have been found in *Enterobacteriaceae*, *Pseudomonas aeruginosae*, and *Staphylococcus*, but not in mycobacteria.

The other resistance mechanism is the alteration of target sites. This occurs in the S12 protein (the *rps*L gene) and in the region of the 16 S rRNA (the *rrs* gene) that interacts with the S12 protein. In *E. coli*, substitution mutations on the *rps*L gene are replacement of Lys43 by arginine, isoleucine, or asparagine and replacement of Lys88 by arginine (23). Similar mutations of the *rpsL* gene are found in mycobacteria (24-30), with Lys43 replacement by arginine or threonine and Lys88 replacement by arginine or glutamine. In addition, Arg9 replacement by histidine and Val93 replacement by methionine have been reported. Resistance mutations in the *rrs* gene have occurred in the regions of the 900 stem and the 530 stem/loop, which interact with the S12 protein as described in the text above: C→T transition mutations at positions 491, 512, or 516, A→C or T transversion mutations at position 513, C→A or G transversions at position 903, or A→G transition at position 904. Meyer et al (26) have shown that approximately 30% of resistant *M. tuberculosis* strains have missense mutations at Lys43 or Lys88 of the S12 protein. They have also reported that the resistance level to SM is dependent on the mutation site; mutations at Lys43 or Lys88 of the S12 protein confer high-level resistance, whereas mutations at the 530 stem/loop of 16 S rRNA give intermediate-level resistance. In mycobacteria, approximately 80% of SM-resistant strains carry mutations in either the *rps*L or the *rrs* gene (28-30), but low-level resistant strains possess no such mutations (25, 26). It has been suggested that alteration of the permeability of the cell wall is a third resistance mechanism, because the addition of the membrane-active detergent Tween 80 lowered the resistance level (26). Resistance mutations in S12 protein and 16 S rRNA are phenotypically recessive. Therefore, mutation of a single gene cannot generate the resistant **phenotype** in organisms that have multiple copies of the *rrs* gene, such as *E. coli* (with seven copies) and *M. smegmatis* (with two). Because the slowly growing mycobacteria, eg, *M. tuberculosis* and *M. leprae*, have a single rRNA gene copy (31, 32), mutation of the *rrs* gene can confer resistant-phenotype organisms.

SM-dependent mutant strains that require SM for growth possess mutations of the S12 protein: Pro42 altered to leucine, Lys43 altered to glutamic acid, deletion of Lys88, Pro91 altered to leucine or arginine, Gly92 altered to aspartic acid, and deletion of Arg94 (23); plus a mutation of the S4

protein (the *rps*D gene). Furthermore, a revertant mutation from SM dependence to SM independence has been reported for Gln73 (to proline) in S4 protein (33).

3. Clinical Uses

SM is active against mycobacteria and a number of aerobic Gram-negative rods (*Enterobacteriaceae*) and Gram-positive cocci (*Enterococcuceae* and *Staphylococcus*) (2). It is not active, however, against *Streptococcus pyogenes*, *S. pneumoniae*, fungi, and anaerobic bacteria. SM is now used rarely except for the treatment of tuberculosis and some unusual infections, for example, tularemia (*Francisella tularensis*), plague (*Yersinia pestis*), and Weil's disease (*Leptospira interrogans* serovar. *icterohaemorrhagiae*). With the emergence of multiple **drug-resistant** (MDR) strains of *M. tuberculosis*, SM has been renewed as the first-choice drug for tuberculosis. However, SM cannot enter into living cells, so it cannot kill and eradicate intracellular microbes such as mycobacteria.

As SM is a polar cation, it is poorly absorbed from the gastrointestinal tract. It is primarily excreted via the kidneys, essentially unchanged. Therefore, oral administration cannot be expected to be effective against systemic infection.

Considerable intrinsic toxicity, mainly in the form of nephrotoxicity and vestibular or auditory toxicity, is a characteristic of all the aminoglycosides. The toxicities are caused by damage to the eighth cranial nerve and to hair cells in the cochlea. This side effect is irreversible, even after discontinuance of the drug. The nephrotoxic potential varies among the aminoglycosides and is usually reversible when the drug is discontinued.

Stringency

The results of **hybridization** reactions of nucleic acids depend on the solution conditions under which they are performed. Some conditions will favor hybridization of the probe nucleic acid to the target nucleic acid. Low stringency conditions favor duplex formation. High stringency conditions destabilize the duplex, thereby selecting only the most stable duplexes. Under high stringency solution conditions, probes will bind only to regions of high sequence homology. Under low stringency conditions, the requirement for sequence specificity is relaxed, and significant numbers of mismatches, bulges, or hairpins may be tolerated. Regions of the target nucleic acid can be discriminated as a function of sequence homology by adjusting the stringency of the hybridization reaction.

Typically temperature, salt concentration, and chemical **denaturant** concentration are adjusted to optimize the stability of probe–target nucleic acid duplexes. Duplex stability decreases with decreasing salt concentration, with increasing temperature, and with increasing denaturant concentration. Selection of the appropriate level of stringency requires consideration of the influence of the various adjustable conditions on duplex stability.

Several factors, in addition to the base composition, sequence, and length, affect the stability of nucleic acid complexes. These factors include environmental variables such as temperature, the nature and concentration of salts, concentration of added denaturant, and in some cases pH. The concentration of nucleic acid strands is a significant determinant of thermal stability when oligonucleotides are involved in the equilibrium.

The influence of cations on nucleic acid complex stability may be due to specific interactions or to nonspecific binding. Nonspecific, or “territorial”, binding is characterized by an elevated cation concentration over that in the bulk solution in the vicinity of the nucleic acid. This type of binding, which is also called “counterion condensation,” occurs when the linear charge density of a polymer exceeds a critical value.

Both single-stranded and higher order complexes of nucleic acids possess condensed counterions. The linear charge density of the isolated strands is less than $1/n$ (where n is the molecularity) of the linear charge density of the complex, due to elongation of the single strands. Therefore, the complex binds more cations than do the isolated strands. When the strands separate, the excess cations are released into solution. As the bulk cation concentration increases, this cation release is increasingly unfavorable. Thus, more energy is required to effect the transition, and the complex is stabilized. This effect depends on the counterion valence, with higher valence counterions promoting greater stabilization than monovalent ions at the same concentration.

Because of the large negative charge of nucleic acid duplexes, anions seldom bind strongly to these molecules. The influence of anions is exerted via effects on cations and on water structure. Anion effects are usually small; at very high concentration, however, chaotropic anions can reduce the thermal stability of DNA.

Chemical denaturants are used in hybridization reactions to reduce the T_m into an experimentally convenient range. This is particularly important for experiments using RNA, which is degraded readily at high temperature. Formamide is used frequently as a chemical denaturant because it does not react with the DNA to make or break chemical bonds, it reduces the T_m of duplexes significantly at reasonable concentrations, it is readily miscible in water, and it has desirable optical properties (low absorbance in the UV region relative to alternatives).

Because neither the nucleic bases nor the sugar–phosphate backbone have titratable groups near neutral pH, the stabilities of nucleic acid complexes are typically insensitive to pH over a wide range. The primary exception is the pyrimidine–purine–pyrimidine **triple helix** . Formation of this complex is accompanied by protonation of the third-strand cytosine residues. This protonation equilibrium is coupled to triplex formation and therefore influences the stability of the complex; it can increase the apparent pK_a of the cytosine by more than 2 pH units.

Optimization of the hybridization conditions requires consideration of the thermal stability and the rate of formation of the hybrid duplex. The rate depends on temperature and usually reaches a maximum at about T_m–25°C (1). Selection of the solution conditions typically is made with the aid of empirical equations that predict the T_m of the fully formed duplexes (p. 31 of Ref. 1). The estimates of T_m are rather crude, but high precision is usually not required. Different equations are used for DNA–DNA, RNA–RNA, and DNA–RNA duplexes. These equations contain terms for sodium ion concentration, %GC, length (L), and % formamide, but are valid only for duplexes of length $L \geq 50$ base pairs. DNA–DNA duplexes:

$$T_m(^\circ\mathrm{C}) \approx 81.5 + 16.6\log([\mathrm{Na}^+]/1 + 0.7[\mathrm{Na}^+]) + 0.41(\%\mathrm{GC}) - 500/L - 0.63(\%\mathrm{formamide})$$

RNA–RNA duplexes:

$$T_m(^\circ\mathrm{C}) \approx 78 + 16.6\log([\mathrm{Na}^+]/1 + 0.7[\mathrm{Na}^+]) + 0.7(\%\mathrm{GC}) - 500/L - 0.35(\%\mathrm{formamide})$$

DNA–RNA duplexes:

$$T_m(^\circ C) \approx 67 + 16.6\log([Na^+]/1 + 0.7[Na^+]) + 0.8(\%GC) - 500/L - 1.0(\%\text{formamide} : 0\text{–}20\%) - 0.3(\%\text{additional formamide})$$

If additional components are included in the solutions, the equations may fail to provide useful estimates. A pH value near neutrality is normally used, so a pH term is not included in the empirical equations, but significant deviation from neutral pH will compromise use of these empirical equations. Examination of the equations shows that the %GC and *L*-dependent terms are determined by the construction of the molecule. The T_m can be adjusted by manipulating the concentrations of Na^+ and formamide. A given T_m can be obtained by infinitely many different combinations of Na^+ and formamide concentration. This gives the experimenter flexibility in the design of hybridization conditions.

The T_m of nucleic acid polymers depends linearly on the GC content, a property that is exploited in the empirical equations shown above. This linearity is due to the sequence effects averaging out over a polymer. For oligonucleotides, the sequence effects become important in determining the thermal stability. Therefore, explicit account of sequence must be made when estimating the T_m of oligonucleotides. Another feature that differs from the polymer case is the dependence of T_m on $[Na^+]$, which depends on the length for oligonucleotides. Reliable estimates for the enthapy, D*H*°, and free-energy, D*G*°, changes associated with formation of DNA (2) and RNA (3) duplexes and for T_m can be computed with knowledge of the base sequence and solution conditions. Thermodynamic data for RNA–DNA duplexes and for higher molecular structures, such as **triple helices**, are sparse relative to the databases for DNA–DNA and RNA–RNA duplexes. Data for these systems are being accumulated, and reliable predictive models should be forthcoming.

Adjustments in stringency can be used to discriminate among nucleic acids with different backbones, thereby favoring binding of a desired hybridization probe. Use of high formamide concentration (80%) selects for RNA–DNA hybrids over DNA–DNA duplexes, so it is useful when RNA probes are employed. The physiochemical properties of the various backbone-modified nonnatural nucleic acid analogues can be exploited by adjustment of the conditions of the binding reaction. Discrimination also can be made between nucleic acid complexes of different numbers of strands. When specific base composition requirements are met, three-stranded nucleic acid complexes can form. Cytosine protonation is required for the formation of the pyrimidine –purine–pyrimidine triple helix, thereby making its formation strongly dependent on pH. Triple helices also exhibit different salt concentration dependencies than do duplexes. Thus, solution conditions can be adjusted to favor or disfavor formation of three-stranded complexes relative to duplexes.

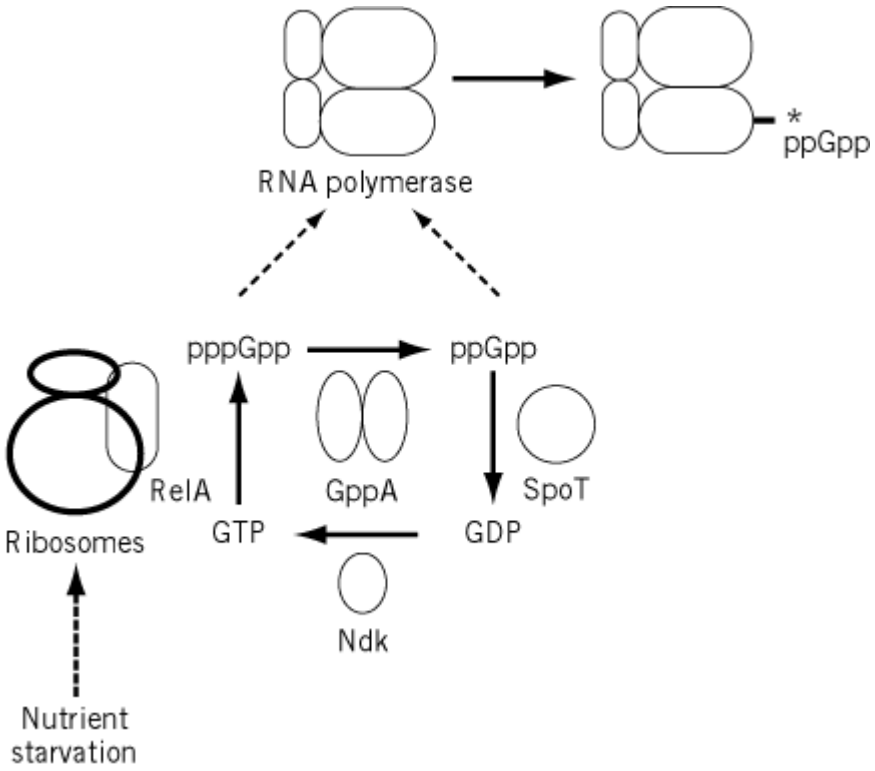
Stringent Control

On amino acid starvation, bacterial cells exhibit an adaptive response, known as the stringent response, for repression of production of the machinery for cell growth, such as the translation and transcription apparatus (1, 2). The requirement for amino acids is, however, relaxed by mutations in a single RNA control locus called *relA* (3). The search for a regulatory molecule under the control of *relA* led to the discovery of accumulation under starved conditions of unusual guanine **nucleotides**, called magic spots I and II (4), which were later identified as ppGpp and pppGpp, respectively (5, 6).

1. Synthesis and Degradation of ppGpp

The *relA1* gene encodes the RelA enzyme (p)ppGpp synthetase I, originally called stringent factor, that catalyzes the synthesis of pppGpp and ppGpp (7-9) [Fig. 1]. This RelA protein is associated with ribosomes, but it can be released by high-salt washes. The (p)ppGpp synthesis reaction requires that the ribosomes have bound messenger RNA and codon-specified uncharged transfer RNA bound at the acceptor (A) site (10, 11). Thus, the synthesis of (p)ppGpp takes place at an elongation step in protein biosynthesis without ribosomal movement (10). The purified RelA enzyme, free of ribosomes, is virtually inactive, but it can be activated by inducing conformational changes with methanol and detergents.

Figure 1. Regulatory circuit of the stringent response. Ribosome-associated RelA catalyzes the synthesis of both pppGpp and ppGpp from GTP and GDP, respectively, but, from the high K_m value, GTP is considered to be the natural substrate. The conversion of pppGpp to ppGpp is catalyzed by several different enzymes but, from its low K_m value, the *gppG* gene product is considered to play a major role *in vivo*. SpoT catalyzes the breakdown of (p)ppGpp to GTP or GDP; in the presence of high concentrations of GTP or GDP, however, it acts as (p)ppGpp synthetase II. The most probable target of (p)ppGpp action is the b subunit of RNA polymerase.



The synthetic reaction of (p)ppGpp is a pyrophosphoryl group transfer from ATP to the 3′ hydroxyl of GDP or GTP acceptor nucleotides (7, 12). The high K_m (Michaelis constant) values for GTP and GDP (0.5 mM) are within the physiological concentration range for GTP but not for GDP, suggesting that pppGpp is the most likely primary product *in vivo* (7, 9). Conversion of pppGpp to ppGpp can be catalyzed by a variety of enzymes *in vitro*, including two exopolyphosphatases, products of the *gppG* and *ppx* genes (13-15) [Fig. 1].

The *spoT* gene encodes an enzyme for ppGpp degradation, ie, removal of the 3′-pyrophosphate residue from either ppGpp or pppGpp (16) [Fig. 1]. The protein SpoT is also associated with ribosomes but is active even after release by high-salt treatment (17, 18). The *spoT* operon includes five *genes* in the order: *gmk* (guanylate kinase), *rpoZ* (**RNA polymerase** w subunit), *spoT* (ppGpp 3′-pyrophosphatase), *spoU* (RNA 2′-O-methyltransferase) and *recG* (junction-specific RNA helicase) (19). At least three gene products are involved in guanine nucleotide metabolism. RNA polymerase-associated w protein was suggested to control the ppGpp sensitivity of RNA polymerase (20), but this concept has been challenged (21). SpoT catalyzes the *relA*-independent synthesis of (p) ppGpp, the reverse reaction of (p)ppGpp degradation and, therefore, SpoT is now recognized as (p) ppGpp synthetase II (22, 23).

2. Target of ppGpp Action

The concept that the target of ppGpp action is **RNA polymerase** is proposed on the basis of observations that *in vitro* transcription of stringently controlled genes by purified RNA polymerase is inhibited by ppGpp in the absence of additional factors, even though the step of transcription affected by ppGpp seems to vary, depending on which template is used (24-28). Early *in vitro* studies, however, gave conflicting results regarding the effect of ppGpp on transcription of the stringently controlled genes. This disagreement has now been attributed to various factors, including the heterogeneity in RNA polymerase preparations used in early studies, the involvement of several additional factors for maximum transcription of the stringent **promoters**, the presence of multiple promoters with different specificities in the same and different genes, nonlinear DNA dependency of

the stringent promoters, and inhibition by ppGpp of not only initiation but also transcription elongation.

In parallel with in vitro transcription studies, genetic studies have reached the same conclusion. Some **rifampicin** -resistant *rpoB* mutants of an *Escherichia coli* B *relA* parental strain were found to be hypersensitive to ppGpp levels (29). Among point mutations of the b subunit of RNA polymerase generated by the **suppression** of amber mutations in the *rpoB* gene, three amino acid substitutions were found to result in a relaxed RNA-control **phenotype** (30). This result has been confirmed by in vitro transcription studies using RNA polymerase purified from these *rpoB* mutants with relaxed phenotype (31).

The outcome of these biochemical and genetic observations supported the simple model that ppGpp is one of the transcription factors that interacts with RNA polymerase and modulates its promoter selectivity (32-34). Evidence for direct contact between ppGpp and the RNA polymerase b subunit has accumulated [Fig. 1]. Owens et al. (35) demonstrated crosslinking of azido-ppGp to RNA polymerase. Reddy et al (36) showed stoichiometric binding of a fluorescence-labeled ppGpp to RNA polymerase and estimated its distance from the rifampicin-binding domain of RNA polymerase. Chatterji et al (37) synthesized azido-ppGpp and, using a **radiolabeled** derivative, identified the sites of ppGpp crosslinking on the b subunit of RNA polymerase, which are close to those of *rpoB* mutations conferring relaxed phenotype (31). Spontaneous **missense** suppressor alleles, which are able to confer complete **prototrophy** to *E. coli* mutants lacking both of the (p) ppGpp synthases, RelA and SpoT, were localized in RNA polymerase subunit genes, 97% in *rpoB* and *rpoC* and 3% in *rpoD*. Mutations in conserved region 3 of sigma factor s^{70} increases the ppGpp sensitivity of RNA polymerase (38). One possibility is that these mutant s^{70} induce conformational changes of the b subunit, leading to alteration in its affinity for ppGpp.

3. Inhibition of RNA Synthesis by ppGpp

Escherichia coli possesses seven ribosomal RNA (rRNA), *rrn* operons, which all contain a *tRNA* gene in the spacer region between the *16S* and *23S rRNA* genes and the *5S rRNA* gene, in the region distal to the *23S* gene. The promoter region of these long transcripts is sufficient to determine their regulation during the stringent response, as well as during growth-rate control. Two promoters have been identified, upstream P1 and downstream P2, which together display complex transcriptional regulation. Upstream of the P1 promoter are regions implicated in transcript activation, ie, the UP element (or prokaryotic enhancer) and the Fis protein-binding site (39). Activity of the *rrn* promoters *in vitro* is strongly dependent on DNA **supercoiling** in purified assays (40). The C-terminal domain of RNA polymerase alpha-subunit is involved in recognition of both the DNA UP element and the Fis protein (33, 34). From the three-dimensional structure of this domain (41), the same protein surface seems to be involved in contact with both the DNA and protein factors, each leading to modulation of the promoter-recognition properties of RNA polymerase. Direct measurement of P1 and P2 activities *in vivo* indicated that the strong promoter P1 plays a major role in rRNA synthesis in rapidly growing cells and is subject to inhibition during the stringent response, but that P2, a weaker constitutive promoter, is insensitive to amino acid starvation (42, 43). Using an *in vitro* mixed transcription system, Kajitani and Ishihama (25) revealed that the upstream P1 promoter was specifically repressed by ppGpp, whereas the downstream P2 promoter was virtually unaffected.

Several lines of evidence indicate that transcription of stringently controlled genes, including *tRNA* genes and some ribosomal protein genes, by purified RNA polymerase holoenzyme Es^{70} is also inhibited in the presence of ppGpp (25, 44). Taken together, these observations indicate that these stringently controlled genes share a common regulatory DNA sequence that is specifically recognized by ppGpp-associated RNA polymerase.

4. Stringent Signal

Sequence comparisons suggested the presence between the –10 Pribnow Box and the +1 RNA transcription start site of a GC-rich region that has been called a "discriminator" and has been proposed as a common feature of all promoters negatively regulated during the stringent response (32, 45). When the GC-rich discriminator of the *tyrT* gene was replaced with an AT-rich sequence, the promoter became more active than the wild-type one. The mutant promoter also became resistant to negative stringent control *in vivo* (44).

Transcripts of the *tufB* operon contain four *tRNA* genes upstream of the *tufB* gene and display negative stringent control *in vivo* and ppGpp inhibition *in vitro* (46). Studies of ppGpp inhibition of promoter mutants implicated the critical role of base-pair positions –7 to –4, which normally have the sequence GCGC (47). Changing each of the GC pairs at the –7 to –4 positions individually to AT pairs led to a reduction in the degree of ppGpp inhibition *in vitro*. The upstream and strong *rrn* promoter P1 is responsible for both stringent control and growth-rate–dependent control, whereas the activity of P2 is weak and is involved in a low level of constitutive expression of the *rrn* genes. At slow growth rates, the P2 activity predominates and is responsible for the persistence of rRNA synthesis, because it is resistant to ppGpp inhibition. The core promoter region of P1, from nucleotides –41 to +1, is sufficient for growth-rate–dependent control (48), which overlaps the discriminator signal for stringent control.

5. Transcription Activation by ppGpp

Venetianer (49, 50) observed that the his operon *mRNA* was abundant during the stringent response. This finding suggested that the expression of certain genes, including those of amino acid biosynthetic operons, is activated during the stringent response. It is currently thought that many genes are subject to positive ppGpp control. Two-Dimensional Gel Electrophoresis analysis of proteins synthesized during the stringent response reveals that the fraction of proteins showing positive control is approximately equal to those showing inhibited synthesis (51, 52).

As with negative control, ppGpp has been implicated as the regulatory signal mediating positive control. The *relA* gene product is required for maximal expression *in vivo* of the *his* operon (53, 54). Again, these effects are promoter-specific, for they occur even when the *his* **attenuator** is deleted (54). Positive regulation of *his* operon expression has been verified as occurring at the promoter (55, 56). Enhancement of transcription of the *arg* and trp operons *in vitro* was also found in the presence of ppGpp (25, 57).

6. Role of ppGpp in Growth Control

Early studies suggested that, during steady-state growth, both relaxed and stringent strains displayed an inverse correlation between basal ppGpp levels and both growth rate and RNA accumulation levels (58, 59). The relationship between ppGpp levels and rRNA accumulation during very slow steady-state growth is, however, complicated by a number of features: (1) rRNA is synthesized but is not assembled into ribosomes, as a result of unbalanced synthesis of ribosomal proteins and/or rapid degradation of newly synthesized rRNA (59-61) and (2) ppGpp affects the expression of many genes in different ways, either repression or activation, and to various extents. Thus, the hierarchy of **gene expression** is markedly influenced, affecting directly or indirectly the rate of rRNA synthesis.

Growth-rate control is observed both in the presence and in the absence of ppGpp (39) suggesting that ppGpp does not play a major role in growth-rate control. Instead, Gaal et al. (62) provided conclusive evidence that the concentration of substrate nucleoside triphosphates determines the growth-rate–dependent control of rRNA transcription. Thus, the core promoter sequence may specify the concentration of nucleoside triphosphates required for efficient initiation of transcription.

Although ppGpp is not directly involved in growth-rate–dependent control, it is involved in growth-phase control by inducing the synthesis of RNA polymerase s^S subunit for transcription of stationary

phase-specific or **stress response**–specific genes (63). In the stationary phase of *E. coli* growth, ppGpp also induces the production of polyphosphate (64), which ultimately leads to alteration in the gene expression pattern by binding to the RNA polymerase and modulating its promoter selectivity (65).

Structure Databases

Structure databases contain the three-dimensional structures of biological macromolecules determined by X-ray crystallography and by NMR. The primary structure database is Protein Data Bank (PDB), which is an archive of all publicly available three-dimensional structures of proteins, **nucleic acids**, carbohydrates, **viruses**, and biomolecular complexes. Unlike the sequence databases, which are organized by using database management systems, PDB is basically a collection of text files, each of which contains a structure entry deposited by the authors. An entry file consists of the textual information of definition, source, references, and comments, the sequence information, the **secondary structure** information, the three-dimensional information of atomic coordinates, crystallographic structure factors, and NMR experimental data. Other useful structure databases include Nucleic Acid DataBase (NDB) for nucleic acids and Cambridge Structural Database (CSD) for organic and metal-organic compounds. The WWW addresses for these databases are given in Table 1.

Table 1. WWW Addresses for the Structure Databases

Database	Address
PDB	www.pdb.bnl.gov
NDB	ndbserver.rutgers.edu
CSD	(site currently unavailable)

The first three-dimensional protein structure was elucidated for myoglobin in 1960 by John C. Kendrew (1). The need to computerize X-ray crystallographic data was immediately apparent, and the PDB was established in 1971 (2). Compared to one-dimensional sequence information, the three-dimensional structure information is far more difficult to analyze and comprehend. The PDB has stimulated computational research in this area, especially of the **protein folding** problem of predicting the three-dimensional structure from the amino acid sequence (see Protein Structure Prediction). PDB is the basis of our current knowledge of macromolecular structures, which is used, for example, in threading protein sequences, where an amino acid sequence is matched against a library of representative three-dimensional folds of the polypeptide backbone. The information in PDB has been used to develop a number of value-added databases. For example, SCOP (3) provides a hierarchical classification of protein folds. Individual entries of the PDB also comprise a useful resource that can be examined in more detail, perhaps by using computer graphics and **computer simulation**, for basic understanding of structure–function relationships and applied research in drug

design and other areas. Although the majority of the databases in molecular biology are publicly available and freely accessible in the WWW (see Databases), some structure databases that inherited the tradition of chemical information are not in the public domain.

Structure Factor

In X-ray crystallography, the structure factor **F**(h k *l*) for a reflection (*h k l*) is related to the electron density distribution in the unit cell.

$$\mathbf{F}(hk\ell) = V \int_{x=0}^{1} \int_{y=0}^{1} \int_{z=0}^{1} \rho(xyz) \times \exp[2\pi i(hx + ky + \ell z)]dxdydz \qquad (1)$$

where *x*, *y*, and *z* are fractional coordinates along the unit cell axes **a**, **b**, and **c**; *V* is the volume of the unit cell, and r the electron density distribution in the unit cell. **F** can be regarded as a vector whose amplitude is |*F*| and whose phase angle is a: $F = |F| \exp(ia)$. The crystal scatters (reflects) only in specific directions given by the indices *h*, *k*, and ℓ. The reason is that the beams originating from the individual unit cells positively interfere only in these directions. In other directions they extinguish each other. The crystal "amplifies" the scattering by one unit cell and the scattered beam, or reflection (*h k* ℓ), is characterized by the structure factor **F**(h k ℓ) as calculated for one unit cell. Its amplitude |*F*(*h k* ℓ| is, apart from correction factors, equal to $\sqrt{I(hk\ell)}$, where *I* (*h k* ℓ) is the intensity of the scattered beam. The phase angles cannot be derived straightforwardly from the X-ray diffraction pattern (see Phase Problem).

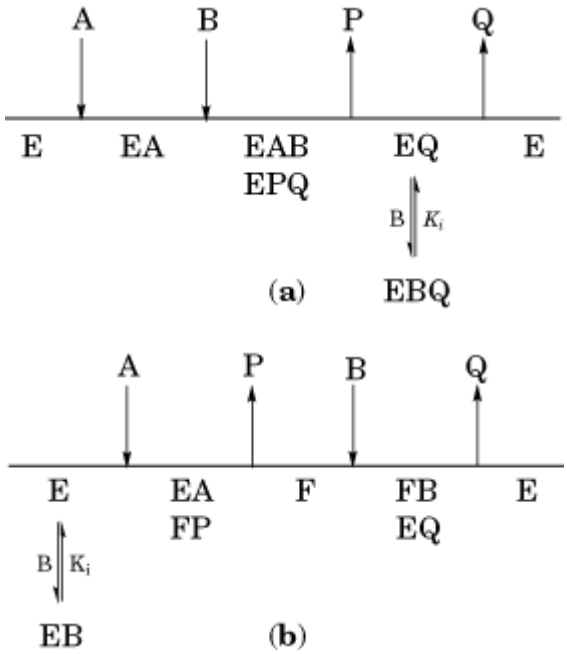
Substrate Inhibition

Inhibition of an enzyme by its substrate occurs whenever a **dead-end** enzyme-substrate complex forms. Such a reaction usually occurs at high substrate concentrations and is due to that substrate binding to a form of enzyme with which the product of the substrate normally combines. Two common **kinetic mechanisms** for substrate inhibition are illustrated in Figure 1. For the ordered mechanism of Figure 1**a**, substrate B combines with EQ to form a dead-end EBQ complex. B is behaving like P in combining with the EQ complex. The substrate inhibition by B with respect to A

would be uncompetitive inhibition. Pyruvate behaves in this way for the lactate dehydrogenase reaction, which conforms to an ordered mechanism, with NADH being the first substrate to add and NAD the last substrate to leave the enzyme (1). The dead-end complex is E-NAD-pyruvate.

Figure 1. The two most common mechanisms of substrate inhibition: (**a**) Uncompetitive inhibition by substrate B with respect to the variable substrate A for an ordered Bi-Bi kinetic mechanism; (**b**) Competitive inhibition by substrate B with respect to the variable substrate A for a Ping-Pong kinetic mechanism.



Ping-Pong mechanisms are subject to substrate inhibition because of the structural similarity of the free enzyme (E) and the covalently modified enzyme (F). In Figure 1**b**, substrate B, which normally combines with F, reacts with E also. Since B, as an inhibitor, and A, as a varied substrate, combine with the same form of enzyme, the inhibition by B would be linear competitive with respect to A (see Competitive Inhibition). Double substrate inhibition can occur with Ping-Pong mechanisms because of the formation of both EB and FA complexes. When such inhibition occurs, the double-reciprocal Lineweaver-Burk plot looks quite complex. At high concentrations of the variable substrate, there is upward curvature of the plot, and the slope of the line increases as the concentration of the other, fixed substrate moves into the inhibitory range (see below).

The general equation for substrate inhibition is shown in equation 1.

$$v = \frac{VA}{K_a + A + A^2/K_i} \tag{1}$$

where V is the maximum velocity of the enzyme-catalyzed reaction, A the concentration of the substrate, K_a its $\boldsymbol{K_m}$ (Michaelis constant), and K_i its inhibition constant. This equation indicates that the reaction velocity would increase initially with the concentration of A and then decrease with further increases in substrate concentration (Fig. 2**a**). Equation 1 can be rearranged in reciprocal form as equation 2:

$$\frac{1}{v} = \frac{K_a}{V}\frac{1}{A} + \frac{1}{V} + \frac{A}{VK_i} \tag{2}$$

It should be noted that *A* appears in the denominator of the equation as a substrate and in the numerator as an inhibitor. The result is that an upward curvature is observed in double-reciprocal plots at higher concentrations of substrate (Fig. 2**b**). Over the high range of substrate concentrations, equation 2 reduces to equation 3:

$$\frac{1}{v} = \frac{1}{VK_i}A + \frac{1}{V} \tag{3}$$

A plot of data from the curved portion of Figure 2**b** would yield a straight line that intersects the abscissa at the point where $-A = K_i$.

Figure 2. Kinetic plots for substrate inhibition: (**a**) variation of initial velocity as a function of substrate concentration, and (**b**) double-reciprocal plot of the variation of initial velocity with substrate concentration.

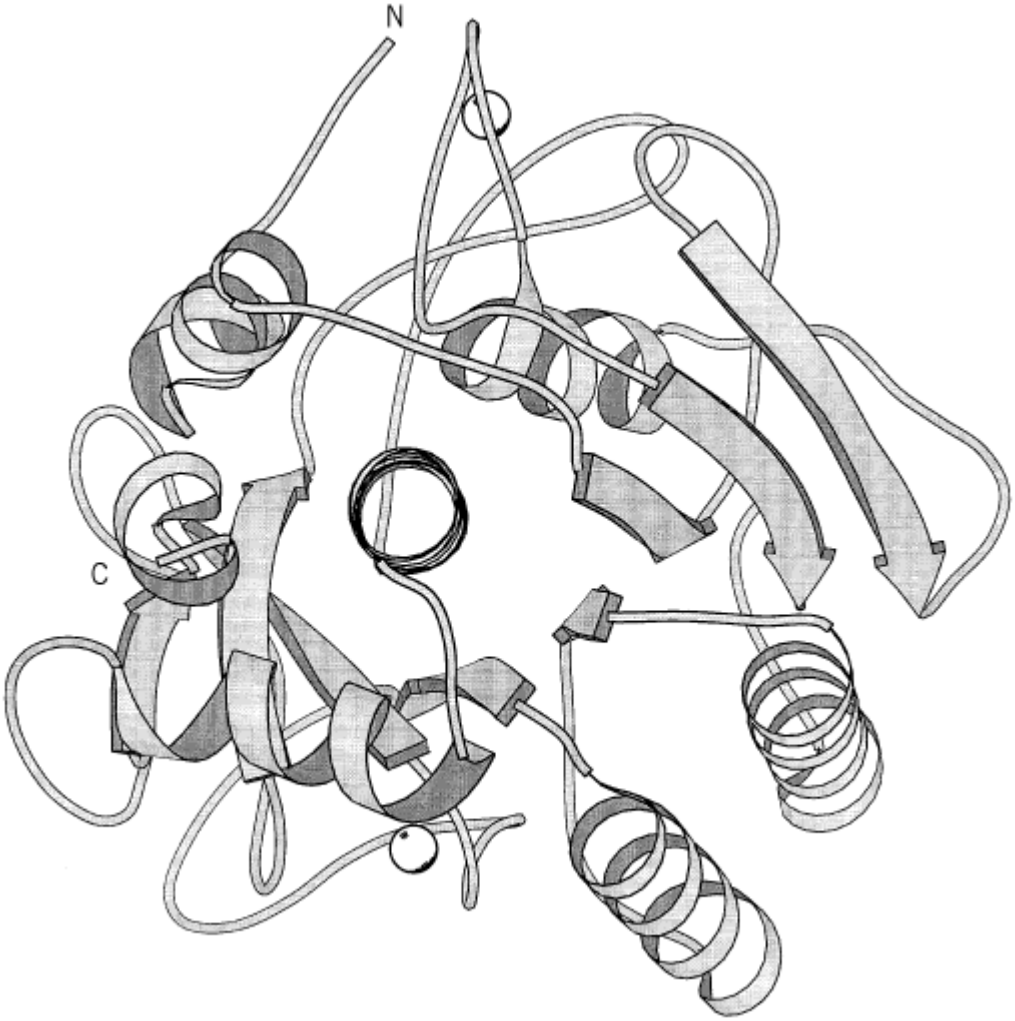
Subtilisin

Subtilisin is a member of the subtilase family of serine proteinases, of which more than 50 have been identified (1) (Fig. 1). Family members are recognized on the basis of amino acid sequence homology. The name subtilisin was originally given to an enzyme isolated from a culture of *Bacillus subtilis*. Later this culture was reclassified as *B. amyloliquefaciens*, and the enzyme is now known as subtilisin BPN′ (2). A second subtilisin has been obtained from *B. licheniformis* and is known as subtilisin Carlsberg. In an attempt to avoid confusion, an alternative nomenclature has been introduced. Subtilisin Carlsberg is called subtilopeptidase A or subtilisin A, and BPN′ is subtilopeptidase B or subtilisin B. The latter has also been referred to as Nagarse in earlier literature. The Enzyme Commission of the International Union of Biochemistry and Molecular Biology has assigned them to subsection E.C. 3.4.21.62 (serine proteinases are E.C. 3.4.21.). It should be noted that some suppliers refer to subtilisins as bacterial proteinases. Other members of the family have been given quite different trivial names such as thermitase and proteinase K.

Figure 1. The three-dimensional structure of subtilisin. Only the polypeptide chain is depicted as a ribbon, with arrows for b-strands and coils for a-helices.



The active site of each subtilisin contains a catalytic triad typical of serine proteinases, and the catalytic mechanism similarly involves an acylenzyme intermediate. These enzymes have broad substrate specificity, although there is some preference for cleavage adjacent to neutral and acidic

amino acid residues. They can bring about extensive degradation of denatured proteins and can even degrade some native proteins. This ability to act on native proteins has been used to advantage to explore structure–function relationships of various proteins (3).

Subtilisin BPN′ is such an effective proteinase that it has acquired commercial applications as a component of cleaning solutions. It is stable as a dry powder but undergoes autolytic degradation in solution. Stock solutions prepared in glycerol are stable for many months in the frozen state. Subtilisins are inactivated by **DIPF** and PMSF, as well as by oxidants. An enormous number of mutants have been prepared in efforts to alter virtually all aspects of the activity and stability of the enzyme (4).

Subtractive Hybridization

Subtractive hybridization is a technique for identifying and characterizing differences between two populations of **nucleic acids**. It detects differences between the **RNA** in different cells, tissues, organisms, or sexes under normal conditions, or during different growth phases, after various treatments (ie, hormone application, **heat shock**) or in diseased (or mutant) versus healthy (or wild-type) cells. Subtractive hybridization also detects **DNA** differences between different genomes or between cell types where deletions or certain types of genomic rearrangements have occurred. Subtractive hybridization techniques have identified many differentially expressed sequences from a wide variety of organisms. For example, recent studies using subtractive hybridization have identified mouse complementary DNA (cDNA) associated with retinoic acid-induced growth arrest (1), bacterial DNA differentiating clinical from nonclinical populations of *Staphylococcus aureus* (2), and plant senescence-associated genes from *Brassica napus* (3).

Subtractive hybridization requires two populations of nucleic acids; the tester (or tracer) contains the target nucleic acid (the DNA or RNA differences that one wants to identify), and the driver lacks the target sequences. The two populations are **hybridized** with a driver to tester ratio of at least 10:1. Because of the large excess of driver molecules, tester sequences are more likely to form driver–tester hybrids than double-stranded tester. Only the sequences in common between the tester and the driver hybridize, however, leaving the remaining tester sequences either single-stranded or forming tester–tester pairs. The driver–tester, double-stranded driver and any single-stranded driver molecules are subsequently removed (the “subtractive” step), leaving only tester molecules enriched for sequences not found in the driver. Usually multiple rounds of subtractive hybridization are necessary to identify truly tester-specific nucleic acid sequences.

There are five basic steps to subtractive hybridization: (*1*) choosing material for isolating tester and driver nucleic acids; (*2*) producing tester and driver; (*3*) hybridizing; (*4*) removing driver–tester hybrids and excess driver (subtraction); and (*5*) isolating of the complete sequence of the remaining target nucleic acid. Variations are possible at each step, and the materials used and methods chosen

depend on the desired results.

When choosing appropriate sources for driver and tester, it must be kept in mind that the less complex the source of tester and driver and the more sequences they have in common, the easier it is to isolate specific target sequence differences. For example, it is easier to identify RNA differences between cell types than it is to identify differences between tissues because fewer genes are expressed in single cells.

1. Preparation of Driver and Tester

In principle, both tester and driver samples can be either DNA or RNA, but it is often most practical for the tester to be DNA (because the tester is present in a low concentration, and DNA is more stable than RNA), and for the driver to be RNA (after hybridization, excess driver RNA can be eliminated enzymatically or by alkali degradation). In the basic subtractive hybridization protocol, RNA from the tester source is **reverse transcribed** into complementary DNA (cDNA) and hybridized to poly A^+ driver RNA. The tester–driver hybrids are removed, excess fresh driver is added, and the hybridization is repeated once. The remaining "target" cDNA is either **cloned** or used to make a probe. This basic procedure is useful if the starting material is not very complex and is easy to isolate.

If little starting tissue is available or if the starting material is complex, multiple rounds of hybridization-subtraction are needed, and it is necessary to use a **library**- or a **PCR**-based technique. Tester and driver are prepared from cDNA libraries as **phagemids** or as library inserts amplified by PCR or *in vitro* transcription. Alternatively, cDNA from tester and driver sources is ligated to different primers, amplified by PCR, and hybridized. The steps are repeated as needed.

2. Hybridization

When single-stranded nucleic acids are hybridized to each other, more abundant sequences anneal more rapidly because they encounter each other more frequently (see **C_0t curve**). During subtractive hybridization, the hybridization step is driven by the excess driver sequences, so tester sequences that have complementary sequences in the driver population rapidly form driver–tester hybrids, whereas sequences unique to the tester population remain single-stranded or form tester–tester pairs more slowly. Rare sequences from either population take longer to pair up than abundant sequences. The ratio of driver to tester, the overall concentration of driver, the temperature, and the length of hybridization should be chosen based on the complexity of the driver and tester, the abundance class of the target nucleic acids, and the length of the driver and tester sequences used.

2.1. Subtraction

The purpose of the subtraction step is to remove driver–tester hybrids formed during the hybridization step, leaving behind tester enriched for the target sequences. Many different methods are used for subtraction, depending on the nature of the driver and the tester. A few possibilities are mentioned.

Hydroxyapatite chromatography is used to bind double-stranded driver and driver–tester hybrids, leaving single-stranded nucleic acids behind. This is a good choice if the driver is RNA because single-stranded RNA can be removed chemically or enzymatically, leaving only single-stranded cDNA tester after the subtraction.

If the tester is a single-stranded phagemid library and the driver is first-strand cDNA, after hybridization the double-stranded driver-tester hybrids can be digested with a frequent-cutting restriction enzyme, and the hybridization mixture used to infect **bacteria**. Only the single-stranded tester phagemids infect, and they can thus be isolated.

A common procedure is to use biotin–streptavidin binding to separate nucleic acids. Streptavidin binds to biotinylated driver sequences, and phenol extraction is used to remove the streptavidin protein and the bound driver and driver–tester hybrids. Streptavidin can also be attached to beads or to a column and used to remove excess driver and driver–tester hybrids.

The effectiveness of the subtraction is monitored by using **radiolabeled** tester and determining whether the levels of single-stranded tester decrease after subtraction. Alternatively, enrichment for target sequences is monitored. If there are known genes common to the driver and tester and one or more specific to the tester, it can be determined, after each round of hybridization and subtraction, whether the tester-specific gene is becoming more abundant compared with the common genes.

2.2. Isolation of Target Sequences

After one or more hybridization and subtraction steps, the resulting tester nucleic acids should be greatly enriched for target sequences. However, it is still possible that rare sequences common to both the driver and the tester remain, and in many cases the sequences isolated are only partial gene sequences. The remaining tester sequences are isolated and analyzed in a variety of ways. Tester can be made into an enriched library and probed with driver and tester sequences to look for tester-specific clones, or the tester is labeled and used to probe tester and driver libraries and to isolate full-length clones. It is necessary to further analyze isolated tester sequences by **Northern blotting**, in situ hybridization or **PCR** methods to determine whether the sequences are truly tester-specific.

2.3. Alternatives to Standard Subtractive Hybridization Techniques

2.3.1. Positive Selection

An important alternative to subtractive hybridization is positive selection. Hybridization of tester and driver are still carried out but, rather than removing unwanted driver–tester and driver sequences by subtraction during step 4, double-stranded tester sequences are positively selected for selective cloning or selective amplification. Again, various methods are employed to carry out positive selection. A simple method is to digest tester with a restriction enzyme producing **cohesive ends**, while using sonication to shear the driver DNA randomly. After hybridization, DNA Ligase and **vector** DNA are added. Only double-stranded tester is cloned into the vector, and then it can be used to **transform** bacteria.

2.3.2. Representational Difference Analysis (RDA)

RDA is a positive selection technique employing PCR. RDA was originally used to identify differences between complex genomes, such as those caused by chromosomal rearrangements or losses due to cancer, infections with pathogens, and polymorphisms between individuals (4), and it was later adapted to analyze differences in gene expression (5). In both cases, tester and driver are ligated to adapters, amplified by PCR, the original adapters are removed, and new adapters (T2) are ligated only to the tester. After hybridization, only tester–tester DNA is amplified by using primers specific for the T2 adapter. The amplified tester is used again in further rounds of hybridization.

2.3.3. Suppression Subtractive Hybridization (6)

In this positive selection technique, both driver and tester are digested with a frequent-cutting restriction enzyme to give **blunt ends**. Tester is divided into two samples, which are ligated to different adapters, P1 and P2, and then hybridized to excess driver. Then the two tester populations are mixed, and additional driver is added. Hybrids formed between members of the two subtracted tester populations are selectively amplified by PCR using primers specific to P1 and P2. Molecules that have either P1 or P2 adapters at both ends form “panhandles” as the adapters hybridize to each other. and these molecules are not amplified by PCR (this results in the “suppression”).

2.3.4. Differential Display (7)

Differential display is a PCR-based technique that uses random amplification of cDNAs in different populations to identify differences between the populations. For each reaction, one primer is 5′-T_{11}NN, where NN are any two specific nucleotides. This primer binds to a subset of cDNAs containing the two nucleotides complementary to NN immediately adjacent to the poly A tail. The

second primer is an arbitrary 10-mer. PCR using these two primers amplifies the same subset of expressed messenger RNA in each sample. Differences in amplification products between different samples are visualized by running the products on a sequencing gel. Band differences on the gel are cut out, and the DNA is eluted and cloned for further analysis. Differential display has the advantage that, for each primer set, a large number of different populations are comparable side by side on one sequencing gel. However, one disadvantage is that a large number of primers and reactions are needed to survey all of the expressed genes in a population.

2.3.5. Serial Analysis of Gene Expression (SAGE) (8)

SAGE is based on the fact that nine bp of sequence located at its 3′-end is all the sequence information needed to identify a gene unambiguously. The first step in SAGE involves generating a 9-bp cDNA tag for each of the mRNAs in a population. Then many unrelated tags are concatenated, the concatenated tags are cloned, and random clones are sequenced. These sequences give a spectrum of the genes expressed in the tissue and indicate their relative abundance. Many genes can be analyzed at once, because only nine bp of each gene are sequenced and many tags are sequenced in a single reaction. To be useful for most purposes, however, full-length genes corresponding to the tags must be subsequently identified and isolated.

2.3.6. Microarrays

cDNAs representing either known or unknown genes can be spotted onto glass and probed with different sources of fluorescently-labeled mRNA (9). Alternatively, 20-mer oligonucleotides (oligos) can be synthesized *in situ* in high-density arrays (10). Oligo sequences are derived from known gene sequences, and a number of oligos are prepared for each gene, so that there are many internal controls. Arrays can be synthesized that contain hundreds of thousands of oligos and can thus simultaneously monitor differences in the expression of tens of thousands of different genes corresponding to the cDNAs. A number of different probes can be analyzed at once because differently colored fluorescent labels are available. As the full repertoire of expressed sequences becomes available for different organisms, this technique will be extremely useful in monitoring genomewide changes in gene expression in different tissues, developmental states, and mutant backgrounds.

3. Conclusion

Many different methods have been used to analyze DNA differences between genomes and differences in gene expression (RNA differences). The use of subtractive hybridization has resulted in the isolation of many useful tissue-specific markers and interesting genes, but it is quite labor-intensive. Various positive selection techniques are more rapid, but they may not result in identifying all differentially expressed genes. Both subtractive hybridization and positive selection only compare two nucleic acid populations at once. The final products are used to make a subtracted probe or to produce a subtracted library, which then are used to identify and isolate full-length target sequences. If full-length cDNA libraries are used, it is not necessary to include this final step. Techniques, such as differential display, SAGE, and the analysis of microarrays, allow comparing a number of different mRNA populations, but differentially expressed genes are not specifically selected. Target genes are identified as a band on a gel (differential display), a very short sequence (SAGE), or a cDNA sequence (microarrays), so that a further step is needed to identify and/or clone full-length sequences. All of the techniques described are used with success, so the choice of technique for detecting DNA and RNA differences depends on the materials available to the investigator and the end results desired.

In the future, there will be so much sequence information available from genome sequencing and expressed sequence tag (see Expressed Sequence Tag) projects that, for investigators studying certain organisms, these types of differential cloning experiments will be superseded by sequence database searches. The potential for this type of database search has been demonstrated with the isolation of three prostate-specific genes identified by the comparison of human ESTs isolated from different tissue-specific libraries (11).

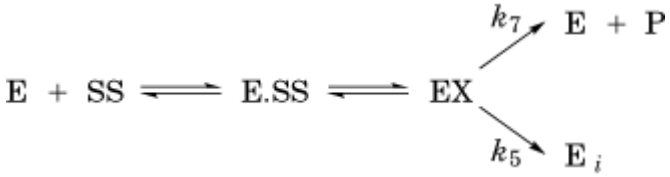
Suicide Inhibitor

A suicide inhibitor, also known as a *suicide substrate*, is a structural analogue of a substrate for an enzyme that contains a latent reactive group. Following reversible binding of the inhibitor at the enzyme's active site, this group is activated by the enzyme during the course of its catalysis of the normal reaction to release a chemically reactive group within the active site. This reactive group can react covalently with an appropriately located active-site residue, inactivating the enzyme. That is, the enzyme catalyzes its own suicide (1). A wide range of functional groups can be catalytically unmasked by their target enzymes to produce electrophiles that cause inactivation. These include acetylenes, olefins, and beta-substituted amino acids. The chemical mechanism of their action has been outlined (2).

Suicide substrates are characterized kinetically by the concomitant formation of product and inactivation of the enzyme. The reactions can be formulated as



After the reversible formation of the enzyme–suicide substrate complex (E.SS), the enzyme catalyzes the reversible formation of an EX complex, where X is an activated intermediate that can either (1) be released as product P or (2) modify the enzyme. The partition ratio that describes the relative rates of the two reactions, k_7/k_5, remains constant over the time course of the reaction and is,

in effect, a measure of enzyme turnover relative to enzyme inactivation.

With a suicide inhibitor, a plot of the concentration of P as a function of time would show a time-dependent decrease in the rate of product formation, long before the equilibrium of the reaction was reached. Further, at infinite time, the enzyme would be completely inactivated, and the kinetic plot would exhibit a horizontal asymptote. In this respect, the behavior of a suicide substrate is similar to that of a **slow-binding enzyme inhibitor** whose action is, essentially irreversible. At infinite time, with classical, non-**allosteric** enzymes, a stoichiometric amount of intermediate should be covalently bound to all the enzyme molecules so that P_∞/E_t, the ratio of the total amount of product formed, P_∞, to the total amount of enzyme present, E_t, equals k_7/k_5, the partition ratio (3). Partition ratios vary from one for the inactivation of GABA aminotransferase by gabaculine and L-aspartate aminotransferase by vinylglycine, to values in excess of 1000 (1). The lower the partition ratio, the greater is the effectiveness of a suicide inhibitor as an enzyme inactivator.

Sulfate Salts

Ammonium, sodium, and magnesium sulfate have been used as agents for precipitation and crystallization of proteins for more than half a century. Na_2SO_4 and $(NH_4)_2SO_4$, being on the **salting out** end of the Hofmeister series, are good protein precipitants; $MgSO_4$ is a weaker precipitant but is useful when Mg^{2+} ions interact with the protein. $(NH_4)_2SO_4$ is the most frequently used salt, due to its great solubility.

The usual procedure in the use of these salts in the purification of a protein is that of fractional precipitation by a step-wise increase in salt concentration (1). To a crude protein extract, one adds $(NH_4)_2SO_4$ up to a certain salt concentration. The precipitated material is centrifuged off, and more salt is added to the supernatant, precipitating more protein. In such manner, a step is reached that precipitates the protein of interest, usually detected by a specific bioassay. The fractionation is then refined. The active precipitate is dissolved in dilute buffer, and $(NH_4)_2SO_4$ is added in much narrower steps, with the isolation of the active fraction.

In protein fractionation, ammonium sulfate is used most frequently because of its high solubility in water (~4 *M*). It would be preferable to use Na_2SO_4 because of possible problems with subsequent nitrogen analysis and interference of the NH^+_4 ion with some biological assays. The drawback to Na_2SO_4 is its lower solubility (~2 *M*) that frequently is insufficient for the desired fractionation.

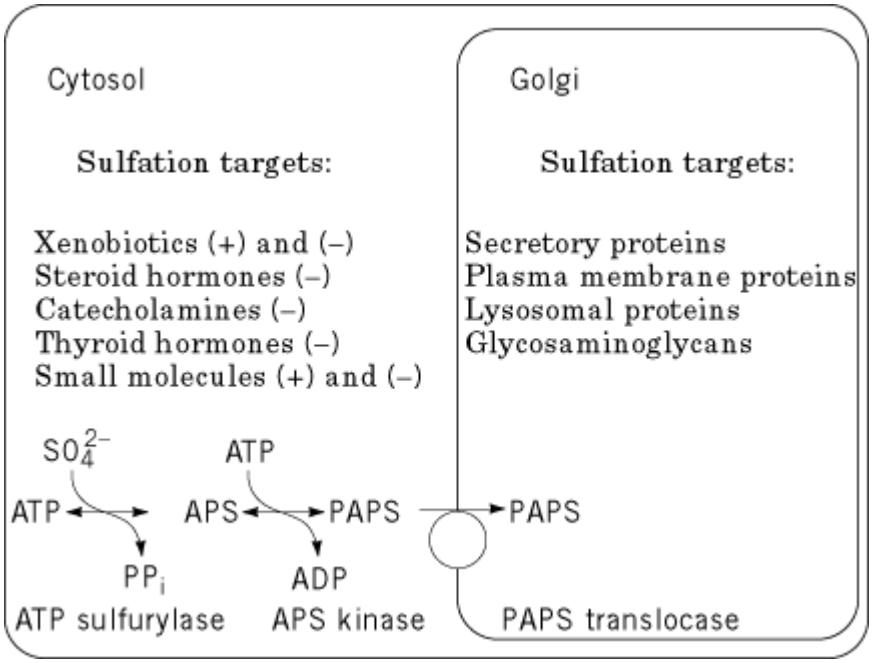
Sulfation

Biotransformations that involve sulfate conjugation were first described more than 120 years ago. Originally, sulfation was connected mainly with drug inactivation and metabolism, which is initiated by an oxidative reaction that inactivates the target (phase I), followed by subsequent conjugation of, for example, sulfate or glutathione (phase II). Such conjugation increases the drug's water solubility and thereby facilitates excretion of the end product. Since then, many additional targets and functions of sulfate conjugation has been revealed: (i) inactivation of hormones and catecholamines, (ii) activation and inactivation of xenobiotics, (iii) removal of endogenous products (eg, bile salts), and (iv) modulation of protein structure and function.

The sulfation reactions are catalyzed by members of a family of enzymes designated sulfotransferases (ST). They use 3′-phosphoadenosine 5′-phosphosulfate (PAPS) as a co-substrate and sulfate donor. Thus, sulfation denotes conjugation of a given substrate with a sulfuryl group ($-SO_3^-$); accordingly, the reaction should more correctly be designated as *sulfonation*. The functional groups of the affected substrates are typically either hydroxyl groups, resulting in formation of an ester, or unprotonated amines, leading to sulfamates.

Sulfation is widespread in nature, and sulfotransferases are found in both plants and animals. In mammals, sulfation appears to be ubiquitous in all tissues, but the type of sulfation and the target specificity may well be tissue-specific. The targets range from various xenobiotics, neurotransmitters, steroid hormones, and thyroid hormones, to proteins, **glycoproteins**, and glycosaminoglycans. The targets are localized both in the cytosol and in the protein secretion pathway (Fig. 1). These intracellular localizations define two subsets of sulfotransferases: (i) the soluble sulfotransferases in the cytosol and (ii) the membrane-associated sulfotransferases in the Golgi apparatus. Along with their differences in enzymatic properties and substrate specificities, each subset will be described according to their intracellular localization.

Figure 1. Schematic diagram of the intracellular localization of sulfation reactions and targets in a typical mammalian cell. In the cytosol, brackets indicate whether sulfation leads to activation (+) or inactivation (–). An overview of PAPS synthesis and localization is also shown at the bottom. Xenobiotics refer to exogenic products administered to the cell, such as drugs.



1. PAPS Biosynthesis

The co-substrate PAPS is produced in the cytosol in a two-step enzymatic reaction from ATP and inorganic sulfate (Fig. 1). For sulfation reactions in the Golgi, PAPS is translocated to the lumen of the Golgi by a specific translocase (1). The rate-limiting step in PAPS formation is the formation of APS, and its steady-state concentrations are relatively low and display tissue-specific variations. Even in the liver, where PAPS concentrations are highest, stores can be depleted within minutes during maximal sulfation rates. Under normal conditions, PAPS concentrations are independent of the availability of inorganic sulfate. In rat liver, however, challenge of the conjugation reaction with high doses of exogenous substrate decreases the PAPS concentrations and depletes sulfate in the serum. This is in contrast to mice, in which the sulfotransferase activity limits the sulfation rate under corresponding conditions (2). Thus, sulfate availability, which changes with age and during physiological changes and diseases, can be affected by drug intake. Such depletion of sulfate stores can introduce serious toxic effects. Hence, regulation of PAPS synthesis is equally important for sulfation, as is the regulation of expression of the sulfotransferases.

2. Sulfation in the Cytosol

Sulfation in the cytosol involves a number of different functions and targets. The reactions have been studied both by endocrinologists and pharmacologists, and enzymes have been named after the substrate used for investigation. The overlapping substrate specificities has led to a confusing nomenclature of the enzymes, which is being unraveled by the cloning of the genes for the sulfotransferases. At present, five cytosolic sulfotransferases have been characterized in humans, but more will probably be identified in coming years (see Table 1).

Table 1. Overview of the Best Characterized Human Cytosolic Sulfotransferases [a]

Enzyme	Endogenous Substrate	Xenobiotic Substrates

TS PST1 (P-PST)	Iodothyronine, estrogen	Hydroxyarylamines, simple phenols
TS PST2 (SULT1A2)	Unknown	Hydroxyarylamines, simple phenols
TL PST (M-PST)	Catecholamines, iodothyronine	1-Naphthol, minoxidil, salbutamol
EST	Estrogen	Ethinylastradiol, equilenin
DHEAST (HST)	Androgens, cholesterol, bile salts, estrogen	Aliphatic alcohols, benzylic alcohols

[a] The most common names of the enzymes are given in abbreviations: TS PST-1 (–2), thermostable phenol ST-1 (–2); P-PST, phenol-preferring phenol ST; SULT1A2, sulfotransferase 1A2; TL PST, thermolabile phenol sulfotransferase; M-PST, mono-amine preferring phenol ST; EST, estrogen ST; DHEAST, dehydroepiandrosterone ST; HST, hydroxysteroid ST.

Sulfation in the cytosol has a number of endogenous targets. For example, sulfation plays a role in the inactivation of thyroid hormones. The prohormone thyroxine (T4) is converted into T3, the active component, in peripheral tissue. Inactivation occurs by deiodination or by sulfation by thermostable phenol sulfotransferase 1 (TS PST1). Sulfated T3 does not bind to the thyroid receptor, and sulfated T3 and T4 are rapidly degraded. Similarly, sulfation of catecholamines such as dopamine by TL PST (thermolabile phenol sulfotransferase) renders dopamine inactive as a neurotransmitter. In fact, about 90% of the dopamine circulating in plasma is found as sulfate conjugates, but the exact role of this derivative is at present unclear.

In addition, sulfation plays a key role in homeostasis and metabolism of another class of important hormones: the steroids. Sulfation of steroids excludes binding of the steroids to their receptors and thereby eliminates their effect. However, steroid sulfation may also be a way of transporting more soluble steroids, and the biological activity can be regained by the aid of tissue-specific sulfatases leading to specific receptor binding with subsequent signaling. The most abundant steroid in plasma is sulfated dehydroepiandrosterone (DHEA). The sulfated form of DHEA is metabolized 100-fold more slowly than nonsulfated DHEA, but the biological significance of its high plasma concentrations, which decrease with age, is not yet understood. However, DHEA serves as a precursor of both estrogen and androgen. DHEA is the target of DHEA sulfotransferase, which is highly abundant in the liver. This enzyme is also responsible for the sulfation of cholesterol and secondary bile salts. Secondary bile salts are generated from salts that are secreted by the liver and by bacteria in the intestine. These salts have a toxic effect on hepatocytes, but sulfation facilitates the excretion of the bile salts through the urine.

Sulfation also plays an important role in the biochemistry of estrogen. Sulfated DHEA is the major precursor of estrogens and androgens. Also, sulfated estrone is the most abundant estrogen in the plasma. Like other steroid hormones, estrogens are inactivated by sulfation. Hence, sulfotransferases serve a regulatory role of estrogen activity. For example, estrogen sulfotransferase is expressed in a cyclic manner in the endometrium and is induced by progesterone. Thus, this sulfotransferase may regulate stimulation by estrogen during the menstrual cycle. However, three sulfotransferases are capable of sulfating estrogens, albeit with different affinities, and this makes characterization of the reactions difficult.

Besides inactivation, sulfation can activate a number of compounds. One example is minoxidil, an antihypertensive agent, which is active only after endogenous sulfation. However, sulfation is also engaged in a less fortunate type of bioactivation: generation of mutagens. Many carcinogens, including dietary procarcinogens such as safrole and estragole, only obtain their mutagenic

properties after metabolic modification, such as by sulfation. This effect of sulfation was first demonstrated for hydroxamic acids and hydroxylamines, but at present the list of affected compounds is long, and most cytosolic sulfotransferases are involved in the process.

In recent years, much has been learned about the cytosolic transferases and their activities. Recently, the first three-dimensional protein structure of estrogen sulfotransferase was presented (3), and new sulfotransferase variants will probably be identified. The availability of sulfotransferases as recombinant proteins will also facilitate future studies of the bioactivity of the sulfotransferases.

3. Sulfation in the Golgi

In the Golgi, two classes of molecules are sulfated: proteins, which are sulfated on tyrosine residues, and glycosaminoglycans. The types of sulfotransferases involved are different and do not overlap in substrate specificity.

Sulfation of tyrosine residues was first discovered as a modification of fibrinogen in the mid-1950s. In the 1960s, the modification was found in a few peptide hormones, but only in the beginning of the 1980s was the truly widespread nature of tyrosine sulfation recognized (4). Since then, sulfation of a number of proteins has been demonstrated. Tyrosine sulfation occurs in the *trans* Golgi network; as a consequence, the proteins affected are secretory proteins, membrane proteins, and presumably lysosomal proteins (5). The modification is the most common side-chain modification of tyrosine residues, and up to 1% of the tyrosine in a given cell may be sulfated. Tyrosine sulfation appears to be ubiquitous in all tissues and has been traced back to *Caenorhabditis elegans*.

Tyrosine sulfate appears to be involved in various types of protein–protein interactions. The following effects are well established: (i) Tyrosine sulfation of the peptide hormone cholecystokinin is a prerequisite for receptor binding; (ii) sulfation of the leech anticoagulant protein hirudin increases the affinity toward thrombin; (iii) sulfation increases the affinity between factor VIII and von Willebrand factor, (iv) sulfation is necessary for the binding of P-selectin to P-selectin glycoprotein ligand 1; (v) sulfation increases the intracellular processing of the peptide hormone gastrin; and (vi) sulfation alters the secretion kinetics of Drosophila yolk protein 2. For many of the proteins that are known to be sulfated (eg, the b-amyloid precursor protein), the function is unknown. This is in part due to the difficulties in prediction of tyrosine sulfation sites. Furthermore, the high frequency of tyrosine sulfation suggests that more proteins than those known today will be found to be sulfated. Based on the structures surrounding known tyrosine sulfation sites, and *in vitro* experiments using synthetic peptides, a **consensus sequence** for prediction of sulfation has been suggested. The main feature is the presence of an acidic residue on the amino-terminal side of the tyrosine and additional acidic residues neighboring the sulfation site. At least partial sulfation can be obtained, however, without an acidic residue on the amino-terminal side of the tyrosine residue, as found in the peptide hormone gastrin. It is at present unclear how common partial sulfation is and what are the precise structural requirements for sulfation. With the recent identification and cloning of two tyrosylprotein sulfotransferases [TPST-1 (6) and TPST-2 (7, 8)], new tools are available for precise definition of the requirements. It is also possible that additional TPST family members will be identified.

The two TPST complementary DNAs each encode a type II integral membrane protein that displays an overall identity of 64% in amino acid sequence. Both enzymes are **glycoproteins**, of 370 and 377 amino acid residues, respectively, and contain a short (7-residue) cytosolic tail that is probably involved in intracellular transport and localization of the enzymes. Little is known about the regulation of the enzymes, but, with the recent cloning, this will be a topic for further investigation.

Another class of molecules sulfated in the Golgi is the glycosaminoglycans (GAGs). These molecules are disaccharides and constituents of the proteoglycans, proteins that are also glycosylated to an extreme degree, ending up with molecular weights of up to several million. The proteoglycans consists of a complex protein core of varying composition conjugated with between 1 and 100 GAG

chains. There are seven classical GAGs, six of which are sulfated in at least one position: chondroitin-4-sulfate, chondroitin-6-sulfate, dermatan sulfate, keratan sulfate, heparin, and heparan sulfate. Accordingly, large proteoglycans can contain a high number of negatively charged groups. These charges are central for the physiological functions of glycosaminoglycans and proteoglycans in interacting with other proteins, similar to the biological role of tyrosine sulfation. Glycosaminoglycans were traditionally considered structural components of the extracellular matrix in connective tissue. However, recent years have disclosed much more active roles of glycosaminoglycans.

The best-characterized effect of sulfation is in the anticoagulant effect of heparin. Heparin binds antithrombin III in a reaction that is strictly dependent on sulfation of a specific position of heparin and alters the conformations of both molecules. Heparin also modulates the effect of basic fibroblast growth factor (FGF), and the receptor binding of this growth factor is affected by heparan sulfate. Recent studies suggest that selection between FGF-1 and FGF-2 by the activating proteoglycan during development is mediated by changes in heparan sulfate side chains, and possibly by a change in sulfation pattern during differentiation and growth arrest (9). Similarly, the chondroitin sulfates, which are involved in cell adhesion, cell migration, and possibly also neural development, show differences in sulfation pattern during development and tumor progression that are likely to influence the physiological function of the proteoglycans carrying these sulfates. Considering the increased interest in the functions of proteoglycans in signal transduction and other types of cell signaling, along with the developmental changes in compositions of glycosaminoglycans, additional examples of functional significance of sulfate in proteoglycans can be expected.

4. Homology of Sulfotransferases

The sulfotransferases with all the different targets described here have surprisingly little homology, suggesting that these enzymes may have evolved independently. This was disputed recently, when homology between two protein regions involved in PAPS binding from cytosolic transferases and from several glucosaminoglycan/heparan sulfotransferases was demonstrated (10). Following the cloning of the genes for the two TPSTs, a general comparison of all the types of sulfotransferases is possible. This shows that the TPSTs differ from the other membrane-associated sulfotransferases and from the cytosolic enzymes, even in the most conserved regions (Fig. 2). Hence, if the sulfotransferase have evolved from a common ancestor, they have diverged sufficiently to have very different primary structures.

Figure 2. Alignment of partial protein sequences of sulfotransferases. Two spatially separated regions that are important for PAPS binding are the primary homologous regions of sulfotransferases. They are denoted the PSB loop and the 3′-binding site. All sulfotransferases were aligned as described (8) except for the TPSTs. The abbreviations of the protein sequences are: mEST, mouse estrogen sulfotransferase; mPST, mouse phenol sulfotransferase; mHST, mouse hydroxysteroid sulfotransferase; FST, flavonol sulfotransferase (plants); hTPST, human tyrosylprotein sulfotransferase; GalCerST, human 3′-phosphoadenylsulfate galactosylceramide sulfotransferase; hHSNST, human heparan sulfate *N*-deacetylase/*N*-sulfotransferase; hHS2OST, human heparan sulfate 2-sulfotransferase.

Sulfur Isotopes

Sulfur (or sulphur) (1) is element number 16 in the periodic table. Thirteen isotopes of sulfur have been studied (2), ranging in atomic mass from ^{28}S (half–life = 0.12s) to ^{40}S (half–life = 9s) (see Radioactivity and Radioisotopes). Four stable isotopes are found in nature: ^{32}S at 95.02%, ^{33}S at 0.75%, ^{34}S at 4.21%, and ^{36}S at 0.02% abundance.

The most important radioactive isotope of sulfur is ^{35}S (half-life = 87.44days). It decays by beta-minus emission to chlorine-35, which is stable. Sulfur-35 yields one beta particle per decay, with an energy of 0.167 MeV maximum, 0.0488 MeV on average.

Sulfur-35 is prepared in an accelerator by bombarding a stable chlorine-37 target with deuterons according to the reaction ^{37}Cl(*d*,a)^{35} S. Carrier-free sulfur-35 may be prepared in a reactor according to the reaction ^{35}Cl(*n*,*p*)^{35}S. Sulfur-35 may also be prepared by activation of natural sulfur according to the reaction ^{34}S(*n*,g) ^{35}S.

Sulfur-35 was first used in biological studies in the 1930s to study sulfur metabolism. Penicillin was labeled with sulfur-35 in 1940. Plasma proteins were first labeled with ^{35}S-**cysteine** in 1943 using cyclotron-produced sulfur-35 (3). Ceccaldi and co-workers in 1953 used sulfur-35 to identify the origin of enterocytes and mucocytes and their migration along villi walls (4).

Sulfur-35-labeled cysteine and methionine are incorporated into proteins and used to monitor protein biosynthesis. One of the advantages of ^{35}S-labeling is that high specific activities can be achieved (eg, about 200 times greater than that possible with ^{14}C labels). Consequently, sulfur-35 is used in molecular biology whenever possible. Sulfur-35 is detected by beta-particle liquid scintillation counting and by autoradiography and fluorography.

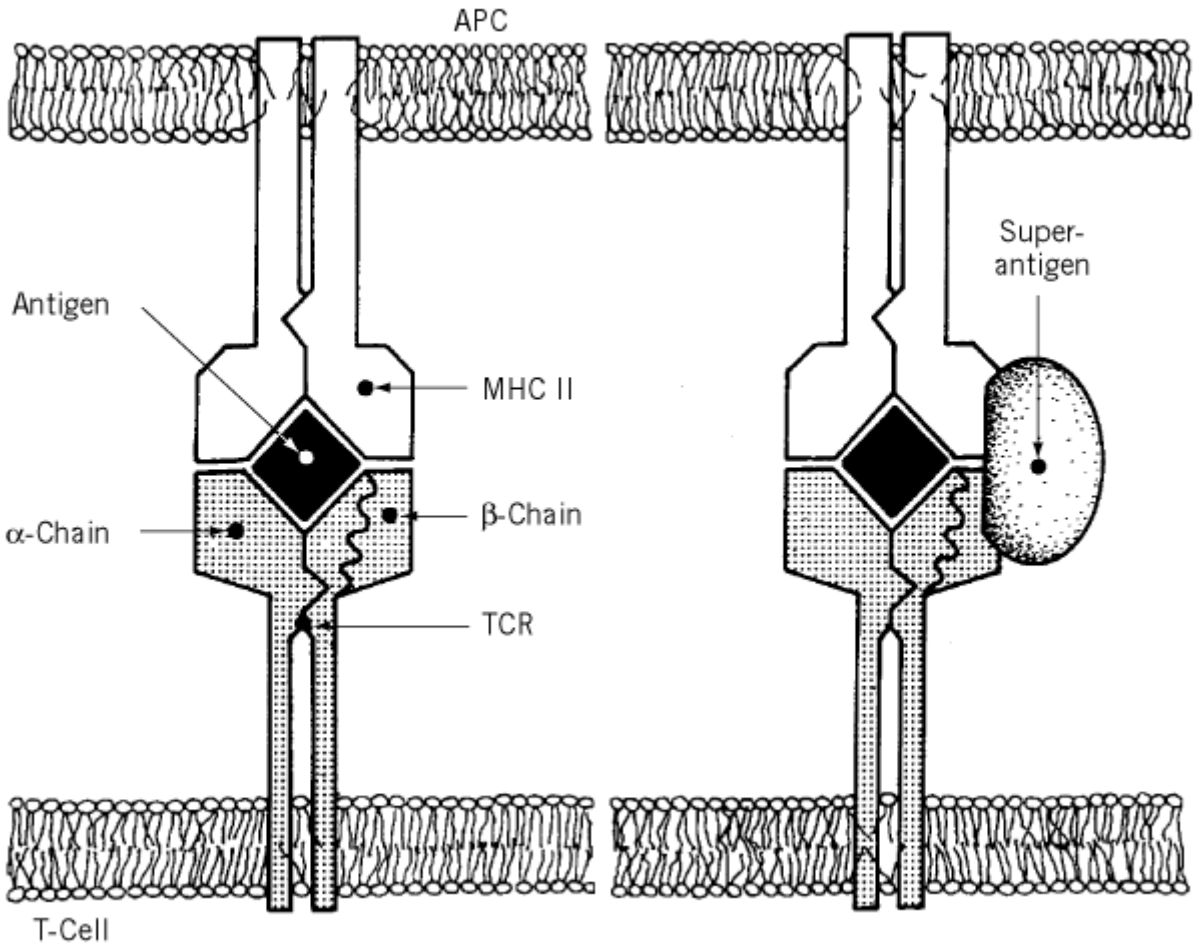
Superantigen Toxins

The vital importance of the immune and inflammatory responses against microbial infections is underlined by the many bacterial toxins active against cells involved in body defense. Several toxins, such as **mellitin and membrane-perturbing toxins** and pertussis toxin, manifest their effects primarily, but not uniquely, on inflammatory and immune cells. More specific are the 22- to 28-kDa protein superantigent toxins involved in staphylococcal food poisoning and toxic shock syndromes, which are produced by different species of *Streptococci* and *Staphylococci* (1, 2). It is likely that similar protein toxins are produced by several other bacteria. These toxins share various degrees of primary structure similarities, but are structurally and functionally very similar (3). The protein molecules have two lobes: One is organized as a beta-sheet and the other as a b-barrel, with hydrophobic residues lining the inner surface of the cylinder. a-Helices are concentrated in the region connecting the two **domains**, with a key role played by a central long a-helix. Two major grooves are present on the opposite sides of this helix, one of them appears to be involved in binding major histocompatibility complex (MHC) class II (MHC-II) and is adjacent to the T-cell receptor (TCR) binding site.

The most relevant aspect of their superantigen toxin action appears to be the stimulation of T-cell proliferation, which has led to their general classification as superantigens . This stimulation is quite different from that of most other mittens like lectins (eg, concanavalin A). Superantigen toxins are capable of a double interaction: with MHC-II molecules and with the TCR (Fig. 1). A ternary complex forms upon antigen presentation to T-cells by an **antigen-presenting** cell in the presence of a superantigen toxin, which stimulates T-cell proliferation and the release of **cytokines**. However, at variance from normal antigens, which are processed intracellularly and presented on a groove on the MHC-II surface, superantigen toxins bind to a different site of the MHC-II molecule, with **dissociation constants** in the 10^{-5} to 10^{-8} M range. One group of superantigen toxins binds MHC-II molecules via an atom of Zn^{2+}, which bridges three toxin histidine residues, one located on the ß chain of MHC-II; other superantigen toxins bind directly to different sites on the class II molecule.

Figure 1. Stimulation of T-cell proliferation by conventional antigens (left) and bacterial superantigens (right). Both antigens are recognized only when presented to the T-cell antigen receptor (TCR) by a class II molecule of the major histocompatibility complex (MHC-II). Antigens are processed intracellularly by antigen-presenting cells (APC) and presented to the T cells as small peptides on a groove on the surface of MHC-II. In contrast, superantigens bind a different site on MHC-II, leaving the groove for peptide presentation free and functional. The normal antigen–MHC-II complex interacts with TCR using multiple contacts involving both variable (V) and constant segments of the TCR a and b chains, and this ensures stimulation of the few T cells bearing the appropriate receptor. The superantigen–MHCII complex interacts with the Vß region of TCR, leading to an unspecific stimulation of a large proportion of the total T-cell population.



The MHC-II-complexed T-cell epitopes interact with the TCR via multiple contacts to both its a and ß chains (Fig. 1). In contrast, the superantigen toxin interacts merely with the Vß region of the TCR, whereas it interacts with the Vg region of gd-T-cell receptors. The Vß region is well conserved, and it might be involved in the crucial elimination of antiself T-cells. This reduces the possibility that the host mutates its T-cell receptor to delete the superantigen-binding region.

Superantigen toxins induce an unspecific stimulation of a large proportion of the total T-cell population of the host (from 8 to 40%, depending on the type of toxin) with a massive release of cytokines, which cause a variety of pathological consequences, including fever, malaise, nausea, vomiting, and diarrhea (common symptoms of food poisoning) and systemic shock reaction. Superantigen toxins can also potentiate the effect of lipopolysaccharide endotoxins, and they may activate other cells, such as mast cells. T-cell clones amplified by superantigens often disappear, or become inactive after being stimulated, and this might lead to immune depression.

Superantigens

Superantigens are a special type of antigen that bind to **multiple histocompatibility complex** (MHC) class II molecules and to polymorphic regions of the b chain of the ab **T-cell receptor** (TCR), without involving interacting structures that condition normal MHC–peptide complex recognition by the TCRab specific combining site. All **T cells** that express a TCR with a b chain bound by a superantigen will be activated, which may represent an important fraction of the T-cell population.

Extensive analysis of this phenomenon provided understanding of the nature of Mls (minor lymphocyte stimulating) antigens, described long ago by Festenstein. Mls antigens were detected *in vitro* using lymphocytes from strains of mice having identical MHC, but different Mls. When they were mixed, the lymphocytes proliferated, which was called *mixed-lymphocyte reaction* (MLR). It turned out that these Mls antigens were encoded by mouse mammary tumor viruses (MMTVs) that had been integrated into the mouse genome and genetically transmitted. An interesting phenomenon that is associated with these viral superantigens is that they induce selection against T cells that express the TCR b chain that interact with the endogeneously expressed MMTV. This is the result of clonal deletion that occurs at the double-positive (DP) stage, when thymocytes are about to leave the thymic cortex. Entire Vb families may thus be eliminated by one given Mls/MMTV antigen and are therefore absent from the corresponding mouse strains. It has been shown that MMTV viral antigen binds to the b chain of the MHC class II molecules, at the external side of the **a-helix**, in a region that is not involved in recognition by the TCR combining site.

Another well-studied example of superantigens is provided by bacterial toxins [such as staphylococcal enterotoxins (Se A-E)] that cause food poisoning in humans or toxic shock syndrome (TSST-1) (see Cholera Toxin and Enterotoxins). X-ray crystallography structures of complexes of MHC class II molecules with these enterotoxins indicate that the bacterial superantigen binds to the a chain.

B-cell superantigens have more recently been described as proteins that also bind to **variable regions** of **immunoglobulins**, leading to activation of naive B cells at a much greater frequency than when stimulated in the conventional way.

More and more examples of superantigens are being described and found to be responsible for the induction of immunopathological disorders; this is undoubtedly an expanding chapter of pathology, as recently illustrated by the observation of superantigen activity associated with human **herpes virus**, cytomegalovirus, and **Epstein–Barr virus**.

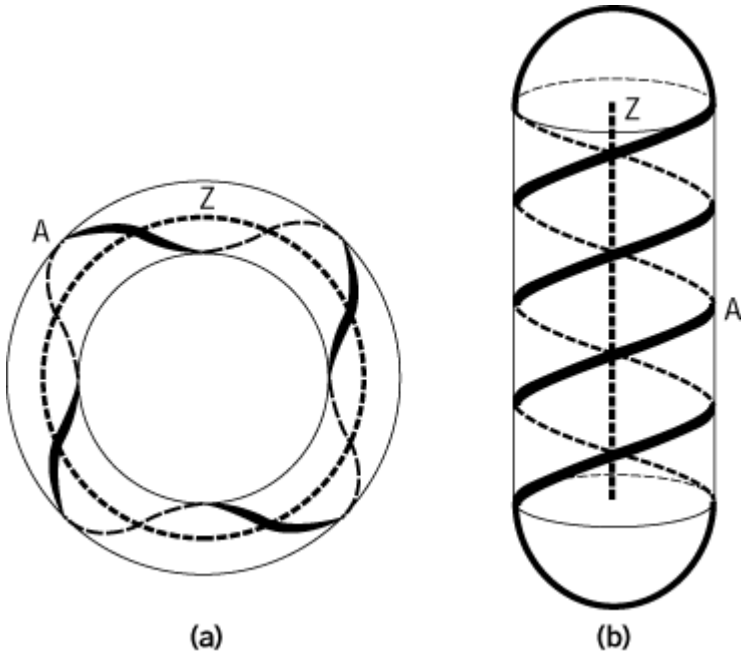
Supercoiling of DNA

The geometry of closed circular DNA (see DNA Topology) includes the trajectory of the axis and the twist of the duplex taken to be a continuous variable along the duplex axis. For this purpose, the DNA is usually modeled either as an elastic rod or as a full or half ribbon (1) (see DNA Structure). There are two classes of superhelical structure, which can be reversibly interconverted without strand scission. The class characteristic of purified, monomeric closed circular DNA is the plectonemic or interwound superhelix, in which the DNA axis winds solenoidally up and down a virtual cylinder, forming a double helix, with smoothly curved connection at the ends of the cylinder. The type often encountered in DNA either associated with other DNA molecules (catenated DNA) or wrapped on a protein surface is the toroidal superhelix. Here the DNA axis winds solenoidally around the surface of a torus or a segment of a torus, forming a single helix. The two types of superhelix are illustrated in Figure 1.

Figure 1. The two types of superhelix winding in superhelical DNA. (**a**) Model of a toroidal superhelix. The figure shows the DNA axis, A, winding four times in a right-handed sense about the superhelical axis, Z. The superhelical axis is circular, and the DNA axis appears to be wrapped on the surface of a circular torus. (**b**) Model of a plectonemic or interwound superhelix. The figure shows the DNA axis, A, winding two times up and two times down a linear superhelical axis, Z. The axis lies at the center of a cylinder, on the surface of which the DNA appears to be winding. The DNA axis is joined to itself at the cylinder caps along a great circle.



Concentration affects both factors; the stiffness (bending modulus) decreases with increasing ionic strength (2), but so do the intraduplex repulsions (3). The response of superhelical structure to changing ionic conditions, as well as to the temperature, is therefore expected to be complex.

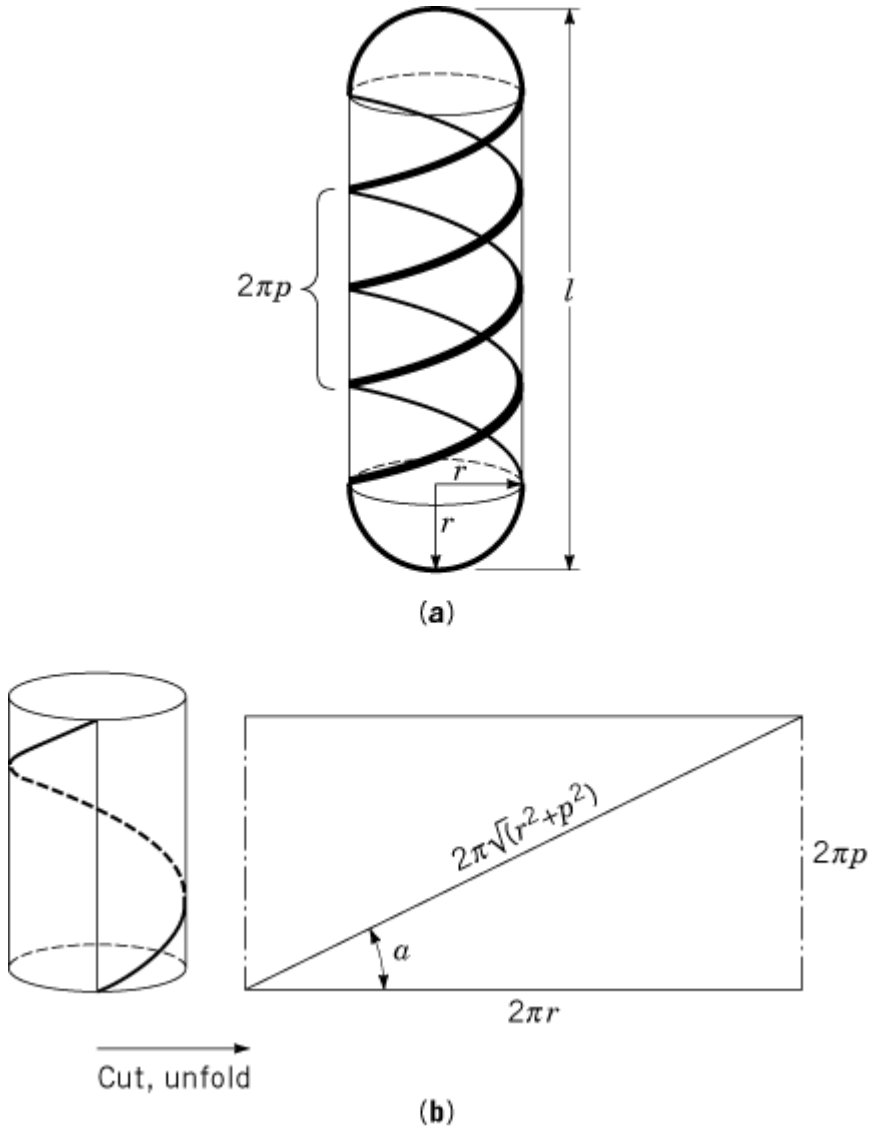
DNA behaves like a chain polymer in solution and is consequently flexible. This applies to superhelical DNA as well, leading to the expectation that the structure of the superhelix fluctuates significantly about some sort of average. The detailed structure will be determined by a balance among forces. One of the more important of these forces results from the tendency to minimize the bending distortion, which encourages the opposing duplex strands to approach nodal self-contact. Actual self-passage would, of course, nearly eliminate the bending distortion. This factor tends to reduce the superhelix radius, *r*. Polyanionic repulsion forces, on the other hand, tend to repel the opposing duplex strands and to increase *r*. Any change in the salt composition and

The geometry of plectonemic superhelical DNAs has been investigated experimentally within a fairly narrow range of conditions. The important tertiary structural properties are the number of supercoils (*n*); the superhelix pitch (2p*p*) and radius (*r*), the number of branches, and the average twist and writhe. These properties are illustrated schematically in Figure 2. The geometric quantities have been estimated for closed circular DNAs of 3.5 and 7.0 kbp by a combination of conventional electron microscopy and site-specific recombination (4). The results apply to a buffer containing 20 m*M* Tris-HCl, 50 m*M* NaCl, and 20 m*M* $MgCl_2$, although some experiments in the electron microscope used much lower salt (10 m*M* Tris-HCl); no major differences were observed between these two solvents by electron microscopy. Under these conditions, the superhelix pitch was found to be nearly constant, independent of s and *N*, at 54–56°. The superhelix radius depends on the superhelix density according to

$$\frac{1}{r} = 0.00153 - 0.268\sigma \qquad (1)$$

where *r* is measured in Å. The length of the superhelix axis is independent of s but proportional to the contour length of the DNA. The ratio of the superhelix axis length to the DNA length is 0.41. The number of branch points is independent of s but approximately proportional to the DNA length. The number of supercoils is proportional to D*Lk*, and *n* = 0.89*vbm*0D*Lk vbm*0;. The ratio between the twist increment and the writhe is constant, and D*Tw*/*Wr* ≈ 3. Individually, D*Tw* = 0.28D*Lk* and *Wr* = 0.72D*Lk*.

Figure 2. Geometry of an interwound (plectonemic) DNA superhelix. (**a**) In this schematic model the DNA axis winds up the surface of a virtual cylinder, crosses the top in a hemispheric circle, winds back down the cylinder with the same handedness, and finally completes the path as a second hemispheric circle at the bottom. The height of the capped cylinder is *l*, the radius is *r*, and the height of the cylindrical portion is 1–2*r*. In this model, the total number of superhelical turns, *n*, is 4, with 2 winding up and 2 winding down the surface of the cylinder. The pitch, 2p*p*, is shown for a representative superhelical turn. (**b**) Here the surface has been cut open and unfolded into a plane. The DNA axis forms a diagonal across the resulting rectangle. The height of the rectangle is the superhelical pitch 2p*p*, and the base of the rectangle is the circumference of the cylinder, 2p *r*. The superhelix winding angle, a, is given by $\sin(\alpha) = p/\sqrt{r^2 + p^2}$.



The salt dependence of the superhelix radius is uncertain and somewhat controversial. It has been reported, based upon experiments employing cryoelectron microscopy, that the superhelix radius is highly salt-dependent, with the opposing duplex segments approaching self-contact at moderate counterion concentrations (5, 6). On the other hand, the results of static and dynamic light scattering, time-resolved fluorescence polarization anisotropy of intercalated ethidium bromide, and circular dichroism indicate that the structure remains much more relaxed at high salt, with no evidence of lateral intraduplex contacts (7). Yet another study using atomic force microscopy found somewhat intermediate results (8). Superhelical DNA was found to form an increasingly tight plectonemic superhelix with increasing salt concentration, including regions of close DNA–DNA contacts. The structures observer were, however, relatively looser than those observed with cryoelectron microscopy.

Superfamily

A superfamily is a set of several that have similar amino acid sequences or **tertiary structures** of the they encode, even though each member of the family has a different function. For example, **immunoglobulins** and **T-cell receptors** are direct counterparts, each of which is produced by its own type of lymphocyte, **B cells** or **T cells**. Their **protein structures** are related to each other, and their gene organizations are also similar. Moreover, the mechanisms of generating their variability also share common features. By including the **major histocompatibility complex** (MHC) proteins, which also have common features in various aspects, the immunoglobulins, T-cell receptor, and MHC constitute a superfamily (1). Indeed, it is quite possible that this superfamily originated during from a common ancestor.

Superfamily is a classification of gene families on the basis of comparisons of the entire gene region as a unit. It has become apparent recently, however, that there are many kinds of **mosaic proteins**, which contain more than one different functional domain (see also). It follows that many genes may share only a part of their gene regions, and that their entire gene regions are not necessarily similar. This suggests that a superfamily, on the basis of the entire gene regions, may not be sufficient to reflect the variety of protein-coding genes (Fig. 1). Thus, a superfamily must be redefined on the basis of their common domains.

Figure 1. Superfamilies defined on the basis of their entire gene regions (**a**) or with only a common domain being shared among different mosaic proteins (**b**). The solid boxes and circles indicate the homologous regions.

Superhelical DNA Energetics

1. Topology-Dependent Energetics

The constancy of the **linking number** for a DNA topology domain places an additional constraint upon all chemical reactions and other changes of state of the DNA structure. This is reflected in significantly altered thermodynamic quantities, thermal **denaturation** patterns, transitions to non-**B DNA** duplex structures, and binding of various reagents. Generally speaking, two opposing tendencies must be balanced in analyzing superhelical DNA energetics. The first is minimization of the deviation of the **twist**, *Tw*, of closed duplex DNA (cdDNA) from that of the corresponding nicked duplex DNA. The second is minimization of the bending distortion that accompanies superhelix formation.DNA Ligase The net free-energy change due to a change in linking difference, D*Lk*, results from some combination of these two factors and is known as the free energy of superhelix formation. In terms of the superhelix density, s the free energy is

$$\Delta G(\sigma, T) = \frac{NRT}{h_0^2} q(T)\sigma^2 \qquad (1)$$

where N is the number of base pairs in the DNA, and h_0 is the helical repeat of nicked circular or linear duplex DNA, 10.5 bp/turn. The superhelix density is s = $(Lk–Lk_0)/Lk_0$, where Lk is the cdDNA linking number and $Lk_0 = N/h_0$.Gel Electrophoresis

1.1. Experimental Determination of Free Energy

The free energy that appears in Equation (1) has been determined by three independent methods. The first depends on the perturbation of the binding constant of intercalating drugs with changes in s (1). This method determines D *G* over the entire accessible range of ±s. The second method is based on the width of the distribution of topoisomers when a closed circular DNA is equilibrated in the presence of a **topoisomerase** (2-4). This method determines D*G* over a narrow range of ±s in the vicinity of s = 0. The third method relates the extent of the linking difference to the local denaturation (5). This method determines D*G* over a wide range of values of s<0. All methods give comparable results under similar environmental conditions.

The experimental results show that the free-energy coefficient $q(T)$ in Equation (1) is independent of superhelix density, s, and of the length of the DNA, N, for N>2400bp. For shorter DNAs, q increases as N decreases (6, 7) according to the relationship (8)

$$q(37^\circ, N) = 3939 - 1.1N \text{for} N < 2400\text{bp} \tag{2}$$

No data have been reported to date for the temperature dependence of q for DNAs in this size range. The value of $q(T)$ for N>2400bp is 1160 bp at 37°C and decreases with temperature (9, 10) according to the relationship

$$q(T) = \frac{0.968 \times 10^6}{T} - 1.92 \times 10^3 \text{bp for} N > 2400\text{bp} \tag{3}$$

Both the entropy and enthalpy of superhelix formation are quadratic functions of the superhelix density but are independent of temperature. Numerical values have been determined for pBR322 (4, 9), pSM1 (10), and ColE1 *amp* plasmid (11, 12). Experiments with pSM1 (N = 5804bp) and pBR322 (N = 4363bp) DNAs, indicate that the enthalpy change per mole base pair is $D H/N = 17.3 s^2$kcal/mol, and the entropy change per mole base pair is $D S/N$ = 35cal/mol/deg. At 37°C, the free-energy change per mole base pair is $D G/N = 6.4 s^2$kcal/mol.

1.2. Boltzmann Distribution of Topoisomers

Perhaps the clearest manifestation of the free energy of superhelix formation is in the appearance of the thermal distribution of topoisomers that results from equilibration in the presence of a DNA topoisomerase (2, 3). In this type of experiment, a cdDNA is incubated with topoisomerase (or the appropriate nicked circular DNA is incubated in the presence of Linking Number Of DNA), and thermal equilibrium established. The enzyme is then inactivated, and the resulting Boltzmann distribution of topoisomers is fractionated by gel electrophoresis, as shown in Figure 1. The Boltzmann distribution is determined by the free energy difference between topoisomer i and the hypothetical completely relaxed species at the center of the distribution, with $D Lk = \varepsilon$. The distribution is then

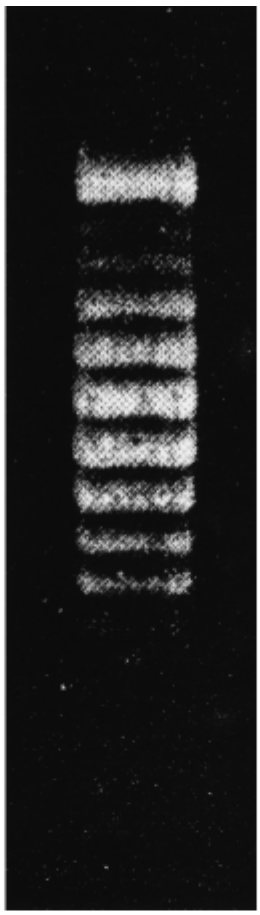
$$c_i = \left(\frac{1}{Q}\right) \exp\left[\frac{\Delta G(i+\varepsilon)}{RT}\right] \tag{4}$$

where the factor Q is the partition function, here simply a constant. Incorporating Equation (1), using the definition of s and simplifying, the Boltzmann distribution has the form

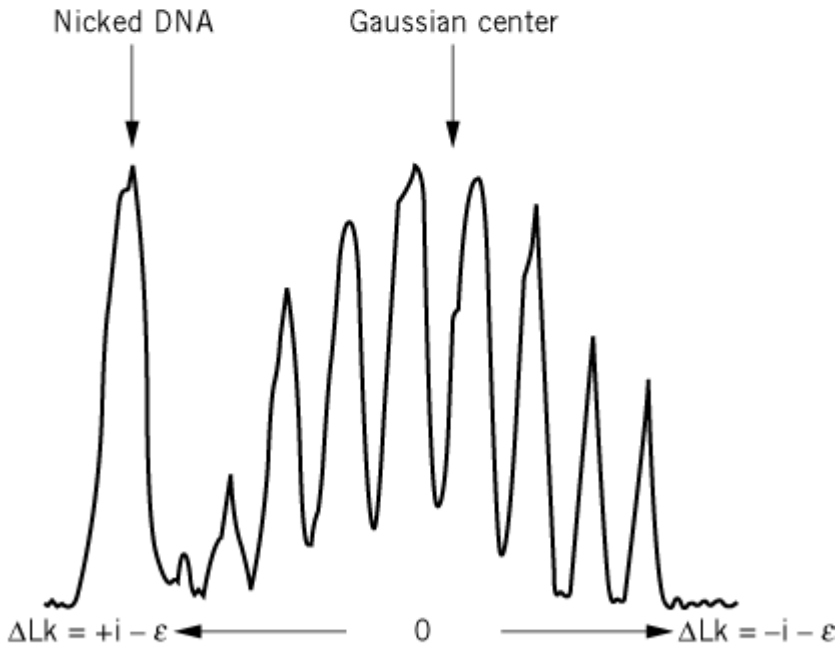
$$c_i = \left(\frac{1}{Q}\right) \exp\left[\left(\frac{q}{N}(i+\varepsilon)^2\right)\right] \tag{5}$$

Figure 1. Experimental measurement of DNA superhelical energetics. (**a**) Fractionation of a distribution of topoisomers by gel electrophoresis. The topoisomers are offset from the nicked circular DNA because of a difference

in temperature between the topoisomeric equilibration conditions and the gel electrophoresis conditions. (Modified with permission from Ref. 2; copyright 1975, National Academy of Sciences.) (**b**) (See next page) Densitometric tracing of the same gel, showing the intensity profile as a function of distance. The location of the nicked DNA is indicated, as is the approximate location of the Gaussian center of the distribution. (**c**) Analytical plot of the topoisomer distribution. The D *Lk* values of the topoisomers are $i+\varepsilon$, where $i = 0, \pm1, \pm2$, and so on.



(a)



(b)

For analytical purposes, it is convenient to recast the result in Equation (5) as a ratio of the concentration of topoisomer i relative to that of the most prominent topoisomer, taken to lie at $i = 0$. Writing Equation (5) for each and taking the ratio, we obtain

$$\frac{c_i}{c_{i=0}} = \exp\left[\left(\frac{q}{N}\right) i(i + 2\varepsilon)\right] \tag{6}$$

If the relative concentrations of the various topoisomers are plotted on a linear scale, the resulting distribution is the expected Gaussian distribution. The separation between the maximum of this distribution and the location of the nearest topoisomer is equal to e, the difference in winding between a nicked circular DNA and the nearest relaxed, closed DNA (see Linking Number Of DNA). Taking the logarithms of both sides of Equation (6) gives a straight line representation that can be applied to the data

$$\left(\frac{1}{i}\right) \ln\left(\frac{c_i}{c_{max}}\right) = \left(\frac{q}{N}\right) (i + 2\varepsilon) \tag{7}$$

This is the equation that is plotted in Figure 1(c), with the slope giving q/N and the intercept at $i = 0$ yielding ε.

2. Topology-Dependent Chemical Reactivity

The free energy of superhelix formation enters into all chemical reactions that involve a change in the average duplex rotation. The classical example of such a reaction is the intercalation of ethidium bromide, which unwinds the DNA duplex by 26°, or 0.072 duplex turn. In general, the free energy for the binding of n ligands per base pair to a closed circular DNA, DG(n,s), is the sum of two contributions: the intrinsic binding free energy, DG°(n), and the associated change in the free energy of superhelix formation, DDG(s). The binding constants are related to the intrinsic and total binding free energies by the usual relationship $RT \ln(K) = -\mathrm{D}G$ and $RT \ln(K°) = -\mathrm{D}G°$, where $K°$ is the intrinsic binding constant for a nicked circular or linear duplex DNA. The change in the superhelix free-energy term DG(s) is [dD G(s)/ds]Ds. If a bound ligand alters the duplex rotation by f turns, then Ds = $h_0 f/N$. Combining these terms, the binding constant is dependent on the superhelix density and temperature according to

$$K(\sigma, T) = K°(T) \exp\left[-\frac{2f}{h_0} q(T) \sigma^2\right] \tag{8}$$

The effect on K can be significant under biologically relevant conditions. For example, if a protein binds to a DNA of s = –0.07 and removes one duplex turn in the process, K(s = –0.07,37°C) = 3K°. This means that the avidity of such a closed circular DNA for the protein binding is approximately three times that of a comparable nicked circular or linear DNA under the same environmental conditions. This effect can be even more pronounced for a **supercoiled** DNA that has been prepared with a very high (negative) superhelix density. Thus, if s = –0.17, with one duplex turn removed in the binding process, K(s = –0.17,37°C) = 600K°. Consequently, if two DNAs of low and high (negative) superhelix density compete for binding of the same protein, the closed DNA of high |s| has a significant advantage. In the event that s > 0, of course, the effect is reversed and K(s > 0) < K°.

Supersecondary Structure

Supersecondary structure is an alternative term for protein motif. The term is used to describe preferred packing arrangements of combinations of **secondary structure** elements in **protein structures**.

[See Protein Structure.]

Suppressor Mutation

Suppressor mutations relieve the phenotypic effects of preexisting mutations. These “second-site” mutations have been extremely useful in genetic and biochemical analyses. The suppressor mutation identifies a new site affecting the phenotype of interest, and suppression is strong evidence that the two genetic sites functionally interact. Suppressor mutations can occur in the same gene as the initial mutation (intragenic suppression), or the two mutations may be in separate genes (intergenic suppression). Intragenic suppression may occur if the amino acids specified by the two sites must interact to give the normal function of the gene product. Intragenic suppression may also occur by the relief of a polar effect on expression. Intergenic suppression has been extensively used to characterize interactions between gene products. This analysis has been used to identify proteins that

interact in various biochemical, gene expression, and signal transduction pathways. A special kind of intergenic suppression occurs when mutations occur in transfer RNAs so that they translates stop (nonsense) codons as sense codons. These tRNAs (nonsense suppressors) can allow expression of genes that have suffered mutations that create stop codons within coding sequences. Another special kind of suppression occurs when mutants are "rescued" by normal genes expressed from high-copy plasmids. See Nonsense Suppression for more complete discussions and references.

Suppressor tRNA

Suppressor transfer RNAs (tRNAs) are mutant tRNAs that insert a suitable amino acid at a mutant site in protein encoding genes. The term "suppressor" is used because the mutant tRNA "suppresses" the phenotypic effect of the coding mutation. Most suppressor tRNAs contain a mutation in either the anticodon, changing codon specificity, or at some position that alters the aminoacylation identity of the tRNA. Suppressor tRNAs have been isolated that decode each of the three termination (nonsense) codons. Suppressors of missense and frameshift mutations are also known. Suppressor tRNAs have been used extensively to study tRNA functions. Suppressors have also been used to insert specific amino acids at particular positions within proteins to study effects of specific amino acid substitutions. For other discussions of suppressor tRNAs, see Nonsense Suppression.

Because suppressor tRNAs can potentially affect the production of a large fraction of the cellular protein, many suppressors have relatively low translational activities, so that normal translation predominates. Exceptions include the UAG termination codon suppressors (amber suppressors) in *Escherichia coli*. The UAG termination codon is rare in *E. coli* and, apparently, frequent translation as a sense does not severely affect this organism. Because the normal translational functions of tRNAs are essential, most suppressor tRNA mutations occur in one of a family of duplicate tRNA genes, and the nonmutated copies continue to perform normally. Suppressor alleles for single copy tRNA genes can be generated using cloned copies of the gene.

A great deal of information about tRNA function has been gained by measuring the efficiency with which suppressor tRNAs decode. Suppressor tRNA genes are easy to manipulate, and suppression efficiencies are readily quantified; together, these properties make suppression the assay of choice for probing translational mechanisms. Suppressor tRNAs must compete with normal molecules for decoding. Nonsense suppressors, for example, must compete with the peptide release factors that normally decode nonsense codons. Suppressors that are good competitors allow for efficient suppression of the nonsense mutation. To study tRNA structure and function, many workers have created additional mutations in nonsense suppressors to determine how those secondary mutations affect suppression efficiency. In an extensive mutational analysis of the anticodon arm, for example, Yarus et al. (1) showed that the native sequence was optimal for suppression, and that mutations reduce suppression efficiency by various degrees. It was concluded that tRNAs utilize an "extended anticodon" in which the nucleotides near the anticodon contribute to its ability to translate codons.

Murgola and co-workers have isolated a large number of missense suppressors in *E. coli* (2). These tRNAs insert suitable amino acids at missense mutations. Many of these mutant tRNAs have anticodon mutations that change codon specificity, changing a glycine tRNA so that it reads the tryptophan codon, for example. Other suppressors are aminoacylated with a different amino acid. These tRNAs may thus insert a suitable amino acid at missense sites that contain their cognate codons. Missense suppressors are generally inefficient, probably because efficient translation of codons with a different meaning is toxic.

Frameshift suppressor tRNAs are also known (3, 4). In the classic examples the tRNAs have an extra

base inserted into the anticodon loop such that they may decode with a four-base anticodon. Certain of these tRNAs may in fact decode this way. For example, tRNATrp derivatives that have four-base anticodons cognate to UAGU, UAGC, or UAGU sites decode those sites as four-base codons. Interestingly, they can also decode these sites as three-base codons. Together, these data have been used to argue that tRNA anticodon loop conformation determines the number of bases decoded (5). Not all frameshift suppressors may act in this way. There is strong evidence that some frameshift suppressor tRNAs that have an extra large anticodon loop probably do not decode at all. The insertion of the extra base into the "suppressor" tRNA may prevent it from functioning and thus "starve" its codon. Then, frameshifting may occur when the starved codon is read by a normal but noncognate tRNA such that the reading frame is somehow perturbed, thus linking misreading and frameshifting (6). There is at least one example in which a frameshift suppressor with a normal sized anticodon loop directly causes frameshifting by misreading (7). Frameshift suppression by mutations in tRNA nucleoside modification enzymes may function in a similar way. The undermodified tRNAs may act poorly in translation, thus starving their codons and allowing for misreading/frameshifting events (6). These studies have been instrumental in our understanding of both reading frame maintenance and translational accuracy.

McClain and co-workers (8) have used suppressor tRNAs to demonstrate changes in the aminoacylation specificities of several tRNAs and thus map the determinants for tRNA amino acid "identity." They engineered an amber termination site near the 5′ end of the gene for the easily isolable dihydrofolate reductase enzyme. They then mutagenized tRNA suppressors and determined which amino acids were inserted by the mutant tRNAs by sequencing the amino termini of isolated enzymes. They found that a small number of nucleotides are mostly responsible for defining tRNA identity. The use of suppressor tRNAs was critical to this work because there was no ambiguity about which tRNA actually decodes the amber site.

Studies of the roles of nucleoside modifications are greatly facilitated by the use of suppressor tRNAs. Modifications are ubiquitous in RNA, and work thus far shows that they are important for the functions of tRNAs (9, 10). Comparisons of the activities of suppressor tRNAs that either do or do not contain certain modifications have shown, for example, that modifications near the anticodon increase translational efficiency. Mechanisms are not always clear, but a common theme is that bulky modification 3′ to the anticodon increases translational efficiency, as if increased base stacking stabilizes anticodon:codon complexes.

Suppressor tRNAs are also used to show that codon translation is affected by neighboring nucleotides (codon context). Many studies show that nonsense codons are more readily suppressed if the 3′ neighbor nucleotide is a purine. This context effect is likely to have two sources, base stacking with the 3′ purine stabilizes the anticodon:codon complex (11, 12), and the release factors are highly dependent on the neighbor for termination and a 3′ U appears to be optimal (13, 14).

Transfer RNA Suppressors will also be useful for protein engineering. In one approach, Abelson and collaborators have constructed an extensive set of tRNA suppressors that can be used to insert a wide range of amino acids at amber mutations (15). These tRNAs may allow systematic tests of the effects of various amino acids on protein structure and function. Transfer RNA suppression systems for labeling proteins with novel amino acids at specific positions are also in development. Amber suppressor tRNAs are being aminoacylated with nonstandard amino acids. Then these tRNAs direct the incorporation of the novel amino acid into a nascent protein whose gene has been mutated to contain an amber codon at a specific site within its coding sequence. At this time, only a few nonstandard amino acids may be incorporated in this way, but it is anticipated that it will soon be possible to label proteins with a large variety of amino acids containing affinity tags, fluors, or reactive groups (16).

Surface Wrapping Of DNA

Closed duplex DNA (cdDNA) is often found wrapped on a protein surface, either entirely or partially. Such wrapping provides a frame of reference in which to analyze the topological and geometric properties of the DNA (see DNA Topology), thereby greatly simplifying many of the associated relationships. For this purpose, both the protein surface and the DNA are modeled as continuous (smooth) objects. The protein surface is defined by moving a **water**-sized spherical probe around the van der Waals surface of each external atom. The solvent-accessible surface is the continuous sheet defined by the locus of the center of the probe (1) (see Accessible Surface). The surface on which the DNA axis lies is then defined by extending outward by 1 nm from the protein surface in order to account for the thickness of the DNA structure.

Even more generally, a closed duplex DNA not actually wrapped on a protein often behaves in some respects as if it were bound to a surface of a particular shape. Some of the general properties of DNA

wrapped on a physical surface apply to wrapping on such a virtual surface as well. The relationships appropriate to surface wrapping begin with the fundamental relationship for a topological domain (see Linking Number Of DNA)

$$Lk = Tw + Wr \tag{1}$$

which relates the two geometric quantities: **twist**, *Tw*, and **writhe**, *Wr*, to the linking number, *Lk*. This equation applies to all closed duplex DNAs, regardless of whether they are wrapped on a surface. Unfortunately, except in a few special cases, neither *Tw* nor *Wr* is directly accessible experimentally or readily interpretable in structural terms. Equation (1) is analogous to the combined first and second laws of thermodynamics, in that *Lk* is a state function, while both *Tw* and *Wr* are dependent on the path of any deformation.

1. Surface Linking Number

The presence of a surface reference frame permits the reformulation of the above fundamental relationship into a much more tractable form. For DNA associated with a surface, the twist divides into two parts, one determined by the contour of the surface at the loci of attachment of the DNA axis (*STw*), and the other by the local winding of the DNA about its axis (F). The total twist is then the sum of two independent contributions (see Twist, DNA)

$$Tw = STw + \Phi \tag{2}$$

Both *STw* and F are experimentally accessible. This expression for the twist is combined with the fundamental relationship, Equation (1), to obtain

$$Lk = STw + Wr + \Phi \tag{3}$$

Equation (3) now contains two quantities that are determined by the shape of the surface/axis (*STw* and *Wr*) and one that is intrinsic to the DNA (F).

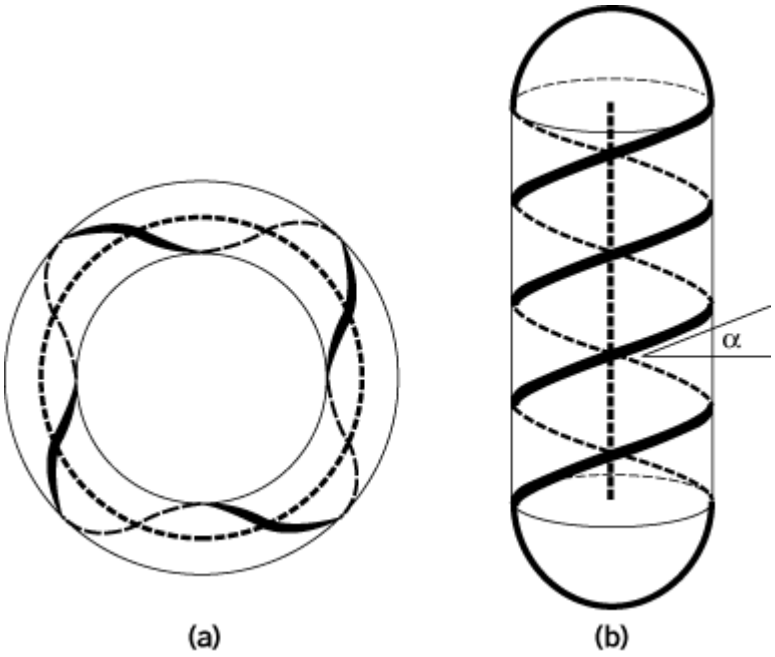
The surface-dependent quantities are combined into the surface linking number, *SLk* (2):

$$SLk = STw + Wr \tag{4}$$

This equation is another fundamental relationship, analogous to the more general Equation (1), which applies to surface-wrapped closed duplex DNA. The surface linking number, like the linking number, is an integer for a superhelical DNA. The surface linking number is a topological quantity and is therefore unaltered if the surface is distorted smoothly. In addition, for any surface distortion that does not break the surface near the DNA axis, any change in *STw* is offset by an equal and opposite change in *Wr*. For example, a plectonemic superhelix can undergo very large distortions, including the formation of one or more branches, without transformation to a toroidal superhelix. In all such distortions, *SLk* is unchanged; hence changes in surface twist are equal in magnitude and opposite in sign to changes in writhe. Since calculation of *STw* is usually much easier than direct calculation of *Wr*, the latter is usually unnecessary in this very common case (see Writhe, DNA).

The most important types of surfaces from the practical view are the spheroid and the circular torus. The spheroid applies to DNA wrapped entirely on the surface of a globular protein; it also applies, as a virtual surface, to all interwound cdDNAs (3). The circular torus applies to DNA wrapped on a cylinder, such as a nucleosome core. For all spheroidal surfaces, $SLk = 0$. For wrapping n times around a toroid, $SLk = +n$ if the wrapping is right-handed and $SLk = -n$ if the wrapping is left-handed. Examples of the two types of surface wrapping for DNA are illustrated in Figure 1.

Figure 1. Wrapping of a closed circular DNA onto two different types of surfaces. (**a**) The DNA is wrapped in a right-handed sense on the surface of a spherical torus, where the number of superhelical turns $n = +4$. (**b**) The DNA is wrapped on the surface of a capped cylinder. Here the wrapping is also right-handed, and $n = +2$ up the cylinder and +2 down, for a total of +4. The DNA axis is connected at the tops by a perfect half circle.



Combining Equations (3) and (4), an alternative expression for the linking number is obtained:

$$Lk = SLk + \Phi \tag{5}$$

The linking number of superhelical DNA wrapped on a protein surface or a well-defined virtual surface is thus the sum of two integers, each of which can be independently and experimentally determined. This expression for the linking number in Equation (5) is much more straightforward than that of Equation (1). Here the component expressing the axis trajectory, *SLk*, is rigorously separated from the winding of either strand about the axis, F. For the common case of a DNA wrapped entirely as plectonemic superhelix, Equation (5) simplifies even more to $Lk = f$. For a DNA wrapped entirely as a toroidal superhelix, $Lk = \pm n + f$. *Lk*, *SLk*, and F have been independently measured (4) and found to be in agreement with Equation (5).

2. DNA Helical Repeat

The second independent quantity in Equation (5) is F, the winding number of the DNA axis about the normal to the protein surface. F is $\pm\frac{1}{2}$the number of times the backbone curve *C* intersects the surface as measured by chemical or **nuclease** probes. The helical repeat (*h*) of surface wrapped DNA is directly calculated from F and the number of base pairs (*N*) by

$$h = \frac{N}{\Phi} \tag{6}$$

The related quantity, *N*/ *Tw*, differs from *h*, usually be a few percent, depending on the details of the surface geometry (3). Specifically

$$\frac{N}{Tw} = \frac{h}{1 + (STw/\Phi)} \tag{7}$$

For a regular, right-handed plectonemic superhelix, $STw = \pm n \sin(a)$, where a is the superhelix pitch angle. Then for a plectonemic superhelix, Equation (7)a simplifies to

$$\frac{N}{Tw} = \frac{h}{1 + (n/N)h\sin(\alpha)} \tag{8}$$

where n is the number of plectonemic superhelical turns. These geometric quantities are specified in Figure 1.

For the case of a nicked circular DNA, or of a closed DNA with DLk = 0, the helical repeat is that of DNA with a linear axis, $h_0 = N/f_0$, where $f_0 = Lk_0$, the pseudo–linking number of open circular DNA [see Linking Number Of DNA]. These considerations lead to a general expression for the helical repeat of a closed circular DNA. Equations (5) and (6) are combined, along with the definition of the superhelix density, $s = (Lk–Lk_0)/Lk_0$, to yield

$$h = \frac{h_0}{\sigma - (SLk/\Phi_0) + 1} = \frac{h_0}{(1 + \sigma) - (SLk/N)h_0} \tag{9}$$

2.1. Interwound Superhelix

The result here applies to purified, noncatenated DNA. Since $SLk = 0$ for any plectonemic superhelix, the helical repeat in this case is a simple function of the linking number or superhelix density. Equation (8) then simplifies to

$$h = \frac{N}{\Phi} = \frac{h_0}{1 + \sigma} \tag{10}$$

The relationship in this equation has been confirmed for several cdDNAs. For a typical naturally occurring cdDNA, with s = –0.06, the helical repeat is increased from the linear axis value of 10.5 bp/turn to the significantly higher value of 11.2 bp/turn. Superhelix densities as great as –0.17 have been reported, corresponding to h = 13.1bp/turn (5). Positively supercoiled DNA, having s>0, can be generated with the DNA reverse gyrase (6) (see **Topoisomerases**). For example, if s = +0.10, h = 9.55bp/turn.

2.2. Toroidal Superhelix

The result here applies to DNA wrapped on a protein surface and to the closed circular submolecules of catenated DNA. In the latter case, either submolecule of the catenated pair can be taken as defining a virtual toroidal surface about which the other winds. (The former must have a circular axis but need not contain its own topological domain.) Now $SLk = \pm n$ for any toroidal superhelix, with n>0 for right-handed winding and n<0 for left-handed winding. The helical repeat for a DNA topological domain wrapped on either type of surface is then

$$\frac{1}{h} = \frac{1}{h_0}(1 + \sigma) \pm \frac{n}{N} \tag{11}$$

For example, the variation of n with s has been determined for catenanes of DNAs of various lengths (7). In one such case, identical submolecules of length 3.5 kbp were wound right-handed n times, with the average value of n varying from 2.5 to 5.5. It was found experimentally that s = (0.32n–

0.30)Lk_0. Applying Equation (9), we see that the helical repeat in this catenane is increased from 10.50 bp/turn (n = 0) to 10.56 bp/turn (n = 2.5) to 10.63 bp/turn (n = 5.5). Another example is the **SV40** minichromosome (8). Here the DNA is wrapped left-handed 1.8 times about each of 26 **nucleosomes**, hence $n = SLk = -46.8$. (Since SLk must be an integer for the DNA as a whole, an extra contribution of –0.2 comes from the closure of the axis around a virtual connecting torus, giving $SLk = -47$ in total.) Applying Equation (9), we note that the helical repeat of DNA on the octamers is reduced from 10.50 to 10.17 bp/turn, a result consistent with nuclease digestion results (9).

SV40 (Simian Virus 40)

The virion of the simian **virus** (SV40) has a diameter of about 45 nm and a **sedimentation coefficient** of 240 S (see Papovavirus). SV40 grows permissively and produces thousands of progeny viruses in monkey cells, its natural host. Cells from rodent and other mammalian origins are abortively infected by SV40. Some, but not all, of such nonpermissive primary-culture cells are immortalized. Some immortalized cells are released from the tightly controlled cellular growth regulatory system and become transformed (see Neoplastic Transformation).

The genome of SV40 is double-stranded circular DNA, 5243 bp in length, and encodes both early and late genes. Two proteins with a molecular weight of 90 kDa and 17 kDa, named large and small **T antigens**, respectively, are **translated** from the early **messenger RNAs** that are transcribed primarily before the onset of viral DNA replication. The large T antigen is localized exclusively in the nucleus. The small T antigen exists in all fractions as a soluble form. Viral capsid proteins—VP1, VP2, and VP3—are encoded from the late gene.

By binding to many cellular proteins that can regulate the cell cycle at the G1 phase, such as **p53, retinoblastoma** protein, p107, and p130, the large T antigen inactivates them and makes the infected cells enter S phase. Moreover, the large T antigen participates directly in viral DNA replication. The large T antigen binds to the GGAGGC sequence at the replication origin and unwinds the adjacent region by its ATPase and DNA helicase activities (the preinitiation complex). By recruitment of **DNA polymerase** a-primase and RPA (replication protein A), the preinitiation complex is converted to the initiation complex. The large T antigen functions as a DNA helicase to unwind the two strands of preforked parental DNA. The replicative chains are elongated by the function of DNA polymerases d and e, replication factor C, and **proliferating cell nuclear antigen** (PCNA). **Phosphorylation** of residue Thr124 of the large T antigen by cyclin-dependent kinase is required for viral DNA replication. At the late stage of DNA replication, the large T antigen autoregulates its own mRNA synthesis and transactivates the late-gene transcription by bridging transcription factors TEF-1 (transcription enhancer factor 1) and TBP (TATA box-binding protein), which are associated with the late **promoter**. Newly synthesized SV40 DNA and capsid proteins are assembled in the nucleus to produce virus particles. Eventually, the infected cells die and lyse, to release progeny viruses.

The small T antigen forms a complex with protein **phosphatase** 2A and inhibits its enzymatic activity. Thereby, the enhanced mitogen-activated protein (MAP) kinase pathway stimulates cell proliferation. This function is dispensable for viral DNA replication, however, because the mutant lacking small T antigen still produces progeny viruses at the same efficiency as does wild type.

In SV40-infected nonpermissive cells, viral DNA replication is not induced due to the absence of a permissive factor, which is considered to be the nature of DNA polymerase a-primase complex, even though the large T antigen is fully expressed. Continuous expression of the large T antigen inactivates p53 and retinoblastoma family proteins and causes the infected cells to be immortalized and/or transformed by the deregulation of the cell growth control. Such transformed cells can grow in soft agarose media, but they hardly induce tumors in animals upon injection.

Human primary-culture cells expressing the large T antigen, prepared by DNA transfection, also become transformed, but not immortalized. In addition to the deregulation of the functions controlled by p53 and the retinoblastoma family proteins, inactivation of the putative senescence genes, which seem to act against immortalization, is also required for the immortalization of human cells. However, the efficiency of spontaneous immortalization of T-antigen-expressing human cells is increased about 10^5-fold over that of control cells not expressing T antigen. This is presumably caused by the increased **mutation** frequency in the senescence genes, due to the enhanced recombination and rearrangements of chromosomes induced by the large T antigen. Therefore, the large T antigen is often used to immortalize human primary-culture cells prepared from rare tissues or biopsy materials.

Svedberg Unit(S)

The *Svedberg unit* is the unit in which **sedimentation coefficients**, or *s*-values, are normally expressed. It is a unit of time defined as 1×10^{-13}s . Its symbol is S. Thus 1×10^{-13}sec is equal to 1 Svedberg unit or 1S. See Analytical Ultracentrifugation and Sedimentation Velocity Centrifugation.

Switch Region

Isotype or class switching occurs during the primary immune response upon stimulation with **T-cell**-dependent **antigens**. It happens only after the immunoglobulin (Ig) gene rearrangement has taken place for the heavy chain, so that the V–D–J encoded region of the heavy chain will be conserved after switching. Because the light chain remains unmodified, this implies that isotype switching does not change the antibody specificity. Switching may take place between m and any other H-chain isotype, to change from IgM to another isotype, although the most frequent event is m → g (IgM → *bIgGb*). The choice of the acceptor isotype is controlled by cytokines synthesized by T cells. The distinct T_H1 and T_H2 populations drive different switches, because they produce different cytokines. Thus in the mouse T_H1 will induce B cells to switch to IgG2a, whereas T_H2 will drive a change to IgG1 or IgE. In humans, where the T_H1/T_H2 dichotomy is not as clear, **interleukin**-4 (IL-4), a typical T_H2 cytokine in mice, also induces a m → ε switch.

Switch regions are located at the 5′ position of each set of heavy-chain constant genes, except for the d gene, which accounts for the simultaneous expression of IgM and IgD on mature B cells. They are designated as Sm, Sg1 to Sg4, Sa1, Sa2, and Sε, according to the flanking isotype. Their length varies between 2 and 10 kbp, depending upon the isotype. They contain highly repetitive sequences in which GAGCT and GGGT motifs are frequently present. In the mouse, for example, the Sg regions contain repeated sequences of 49 nucleotides. These regions provide the basis for the switch mechanism, because this mechanism occurs by nonhomologous recombination. The enzymatic process, which is not dependent on recombinase activating genes, has not been elucidated thus far. Class switching most usually involves deletion of the DNA section located between the two switch regions. This piece of DNA is circularized, and such DNA circles have indeed been isolated and sequenced. Switching may also occur by inversion, which leaves the possibility of having revertants, although this appears rather exceptional.

Switch regions are preceded 5′ by a **promoter**-like region that is involved in synthesis of I transcripts, which initiate just before the switch occurs. For example, Im → Ig1 transcripts will be produced before m → g1 switching. These transcripts contain the I region, plus the constant region of the 3′ isotype. Many speculations have been made regarding a possible role for these transcripts in switch control, including the possible formation of a transient triplex. To date, no convincing data have supported any hypothesis. These transcripts may simply be a passive witness of DNA accessibility that would condition binding of the still elusive enzymatic complex. Isotype switching is controlled by a regulatory gene located at the 3′ position of the entire IGCH locus.

Synaptonemal Complexes

Synaptonemal complexes (SCs) are proteinaceous, zipperlike structures that are formed between homologous chromosomes during the prophase of the first meiotic division (1). SCs were first described in 1956 (2, 3), and they have since been found in almost all sexually reproducing eukaryotes analyzed thus far (1). Their assembly and disassembly accompanies the successive chromosomal alterations of meiotic prophase, namely pairing, recombination, and condensation of homologous chromosomes. Originally, it was thought that SCs created the preconditions for meiotic **crossing over** by bringing corresponding parts of homologous chromosomes in close apposition (1). However, this view was gradually undermined during recent years, and SCs are now considered as structures that control both the number and distribution of reciprocal exchanges (crossovers) and convert crossovers into functional chiasmata (4). How SCs fulfill these roles remains to be elucidated.

1. Assembly and Disassembly of SCs

Meiosis consists of two successive divisions, meiosis I and meiosis II, which follow a single round of DNA replication. After the premeiotic S-phase, during the prophase of meiosis I, homologous chromosomes pair, non-sister chromatids of homologous chromosomes recombine with each other, the chromosomes condense while they are still paired, and then they disjoin at meiosis I. As a result, **diploid** nuclei produce haploid nuclei with novel assortments of genes. The assembly and disassembly of synaptonemal complexes accompany these chromosomal alterations. After premeiotic DNA replication, in the leptotene stage of meiotic prophase, the two sister chromatids of each chromosome develop a single proteinaceous axis, called axial element or axial core. Axial elements of SCs differ in several respects from the axes (also called scaffolds) of mitotic metaphase chromosomes: (i) Axial elements of SCs are much longer; (ii) they contain several meiosis-specific proteins (see below and Table 1), and (iii) they are shared by the two sister chromatids of a chromosome, whereas in a mitotic chromosome there is a separate axis (scaffold) for each sister chromatid. Usually, the assembly of axial elements starts at the nuclear envelope (1, 5). Subsequently, in the zygotene stage, the axial elements of homologous chromosomes are connected ("synapsed") along their length by numerous transverse filaments to form the structure of an SC (Fig. 1a); the connecting process is called synapsis. In most species, synapsis initiates preferentially, but not exclusively, in the (sub)**telomeric** regions (1, 5). In the pachytene stage of meiotic prophase, synapsis is complete, and the axial elements are connected along their length by transverse filaments. Axial elements within the SC structure are referred to as lateral elements. Between the two lateral elements of an SC, a third longitudinal structure, the central element, is formed on the transverse filaments. Both lateral elements, together with the central element, make up the tripartite structure of the SC (Fig. 1a). In some organisms, complete axial elements are assembled and aligned along their entire length before synapsis (6). This phenomenon of presynaptic alignment is probably a common feature of meiosis, although it may be difficult to observe in species in which the assembly and alignment of axial elements is rapidly followed by synapsis (6, 7). Aligned axial elements are further apart (≥300nm) than synapsed lateral elements (about 100 nm). Fibrous connections appear to pull aligned axial elements together at irregular intervals (6, 7), and synapsis starts where axial elements have approached each other within 300 nm, possibly because transverse filament components

protruding from opposite axial elements can then interact.

Figure 1. Structure, assembly, and disassembly of the SC. (**a**) Overview of the organization of the central region. RN, recombination nodule. This overview is mainly based on Refs. 8 and 9. (**b**) Assembly and disassembly of SCs. The successive stages of meiotic prophase are indicated from early (left) to late (right). RN, recombination nodule.

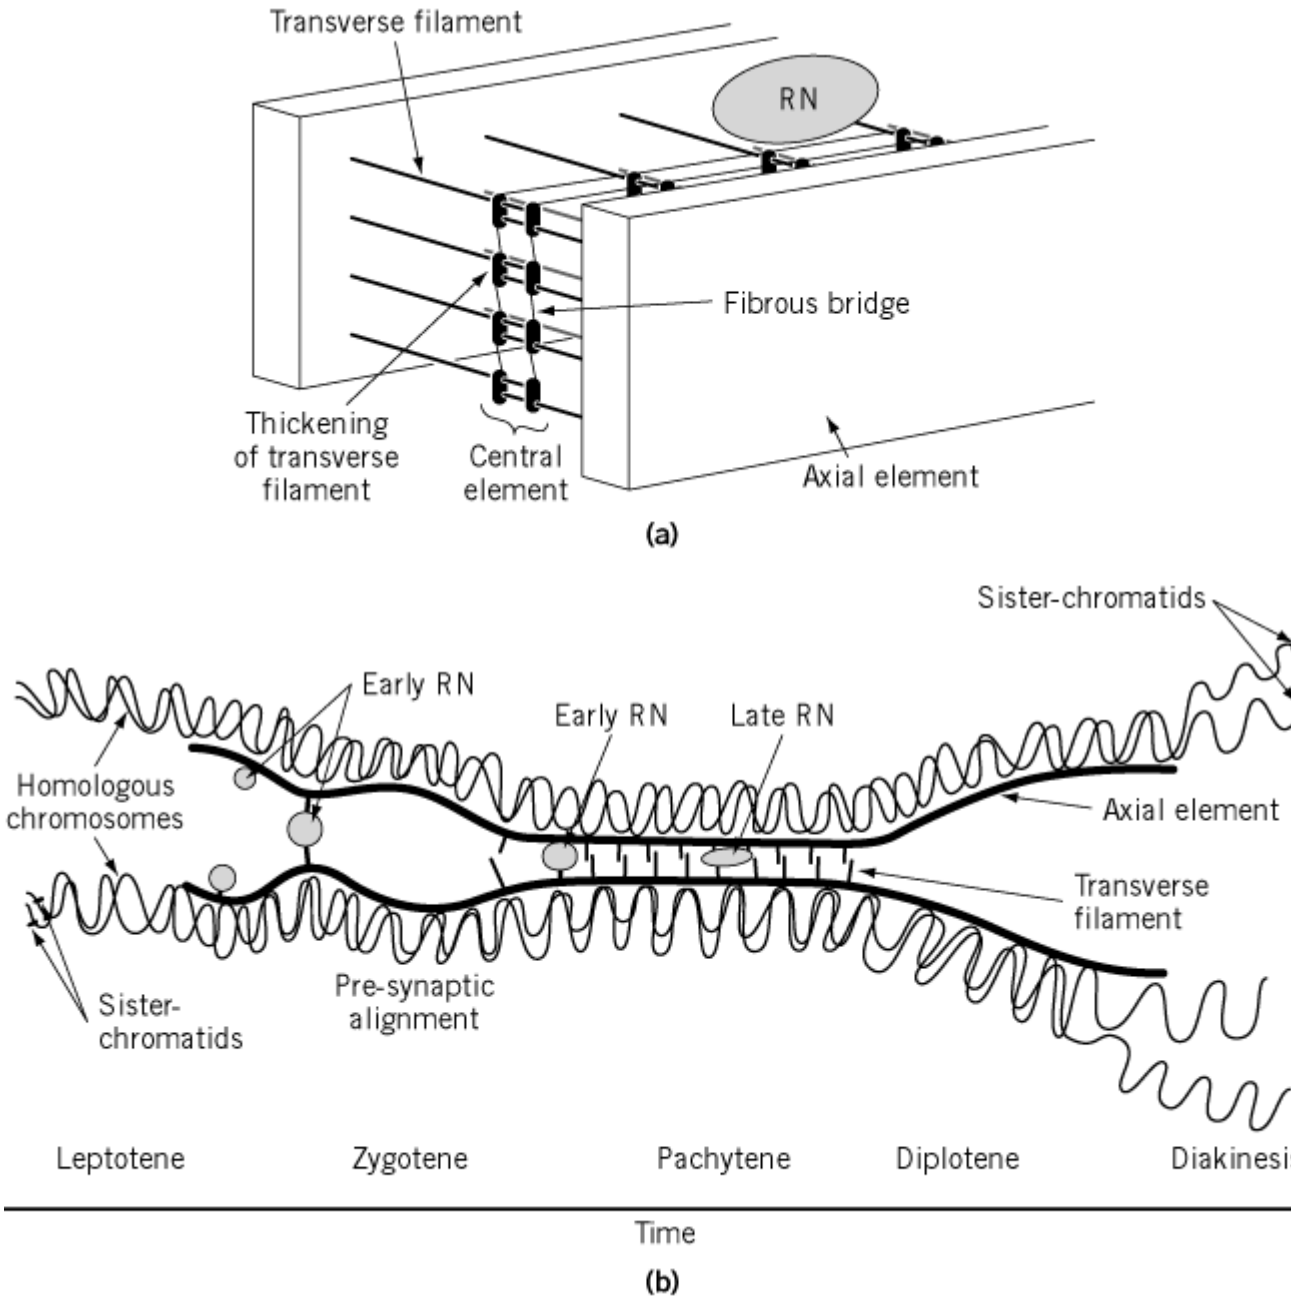

Table 1. Protein Components and Candidate Components of Synaptonemal Complexes

Component	First Identified in	Gene or cDNA	Molecular Weight[a]	Localization within SC	Remark[a] TF, transverse filament.	Reference

		Cloned				
SCP1	Rat	Yes	120,000 Da	Central region	TF component	(18)
SCP2	Rat	Yes	170,000 Da	Axial element	Synapsed+unsynapsed	(21)
SCP3	Rat	Yes	30,000 Da	Axial element	Synapsed+unsynapsed	(20)
SC65	Rat	Yes	50,000 Da	Central region	Not meiosis-specific	(22)
Unnamed	Rat	No	48,000 M_r	Central region		(19)
Unnamed	Lilium	No	52,000 M_r –70,000	Axial element	Synapsed+ unsynapsed	(23)
Zip1p	Yeast	Yes	110,000 Da	Central region	TF component	(7),(27)
Hop1p	Yeast	Yes	70,000 Da	Axial element	Unsynapsed	(24),(26)
Red1p	Yeast	Yes	90,000 Da	Axial element	Synapsed+unsynapsed	(25)

[a] Da, molecular weight predicted from nucleotide sequence of gene or cDNA; M_r, relative electrophoretic mobility.

At the ultrastructural level, the organization of the region between the lateral elements (the central region) is essentially the same in different species (8-10). The structural unit of the central region consists of a single transverse filament, which spans the distance between the axial elements, and carries two symmetrically placed thickenings, at fixed positions (Fig. 1b). Fibrous bridges connect the thickenings with each other in two longitudinal rows, which together constitute the central element. Three to five layers of transverse filaments occur on top of each other within the central region; these layers are also kept in register by fibrous bridges between the thickenings (9). In most species, this tripartite structure of SCs has been conserved. There is, however, much variation in the detailed structure, in particular with respect to the degree of order in the central region, the structure of the central element, and the appearance of the lateral elements (1, 10); in some fungi, the lateral elements display a regular, transverse striping (11). At least two species with an otherwise normal meiosis do not have detectable SCs, namely *Schizosaccharomyces pombe* (fission yeast) (12) and *Aspergillus nidulans* (a filamentous **fungus**) (13). Meiotic prophase cells of *S. pombe* contain so-called linear elements, which possibly correspond to the lateral elements of SCs (12, 14).

At the end of meiotic prophase, the SC structure is disassembled. In most species, the transverse filaments disappear first and then the axial elements (diplotene stage). Until their disassembly, the axial elements remain attached through their ends to the nuclear envelope; some species have special thickenings, called attachment plaques, by which the axial/lateral elements are attached to the nuclear envelope (1). The disassembly of SCs is in many species followed by the diffuse diplotene stage, in which no axial elements or chromosomal axes can be distinguished (15). In postdiffuse diplotene and diakinesis, the chromosomes recondense in preparation of the first meiotic division; the two sister chromatids then become clearly distinguishable, and each displays their own longitudinally supporting structure, the chromatid scaffold, instead of the single, common axial element of the SC.

2. Recombination Nodules

The assembly of SCs is accompanied by the appearance of spherical or ellipsoidal electron-dense structures called recombination nodules (RNs) (reviewed in Ref. 16). In several species, two types of RNs can be distinguished on the basis of their morphology and time of appearance: early and late RNs (16). Late RNs are found on top of the central region of pachytene SCs (Fig. 1a). Their frequency and distribution along the bivalents in mid-pachytene correlates with the frequency and distribution of chiasmata and crossovers (16). Late RNs are therefore probably protein complexes that are involved in crossover formation.

Early RNs are more numerous than late RNs; they occur throughout the nucleus in leptotene. During zygotene and early pachytene, they concentrate along unpaired axial elements and on (part of) the fibrous connections between the axial elements of aligned chromosomes. In late zygotene and early pachytene, they are also found on top of the central region of the SC, but their number decreases gradually, until in mid-pachytene all early RNs have disappeared (16, 17). The distribution of early RNs along the bivalents does not correlate with the distribution of crossovers. It has been suggested that early RNs are involved in homology search and that they leave **gene conversions** as footprints of their activity (16). It is possible that some of the early RNs develop into late RNs (reviewed in Ref. 17).

3. SC Components

Protein components can only be assigned with certainty to SCs by ultrastructural studies. Table 1lists the protein components that have thus been assigned to SCs, along with a number of strong candidate SC components. In rodents (18-22) and *Lilium* (23), SC proteins were identified in preparations of isolated SCs, and they were localized within the SC structure by immunolabeling. The Hop1 (24) and Red1 (25) proteins of budding yeast (*Saccharomyces cerevisiae*) were identified as candidate SC components on the basis of **immunofluorescence** or immunogold studies and cytological analyses of hop1 and red1 mutants (24, 26). Zip1p of yeast has been assigned to the central region on the basis of immunofluorescence studies and a systematic ultrastructural analysis of SCs in a series of mutants carrying deletions or insertions in the zip1 gene (27). No amino acid sequence similarity has been detected between the SC-proteins of yeast and mammals. However, mammalian SCP1 (18) and yeast Zip1 (7) have similar predicted **secondary structures** and are incorporated in a similar way into the SC (27, 28). Most probably, SCP1 and Zip1 are components of the transverse filaments.

In the mouse, an increasing number of proteins that are known or suspected to play a role in recombination and/or DNA repair (RAD51, RPA, MLH1, POLb), or in signaling pathways that link DNA-repair to progression of the cell cycle (ATM, ATR, BRCA), have been localized on or along SCs by immunofluorescence (reviewed in Ref. 17). In yeast, comparable studies have been performed (29, 30). Most probably, these recombination proteins are not part of SCs. They associate with SCs in a characteristic order and pattern (reviewed in Ref. 17 for the mouse), presumably to perform or monitor certain steps in meiotic recombination. Of these proteins, only RAD51 has been localized ultrastructurally (31, 32). It is part of early RNs and localizes along (not on) the axial elements of SCs in zygotene and early pachytene. The immunofluorescence pattern of MLH1 strongly suggests that it is localized in late RNs (17). Furthermore, in male but not female mice, Hsp70-2 (33) has been localized along the axial elements, whereas **topoisomerase** II gradually congregates onto the axial elements toward the end of meiotic prophase (34).

The axial elements/lateral elements of SCs are rich in DNA, whereas very little DNA occurs in the central region (35). At irregular intervals, threads of DNA or chromatin cross the central region; some of these threads are associated with RNs, which appear to be enriched in DNA (35).

4. Possible Functions of SCs

Originally, SCs were considered as structures that bring corresponding parts of homologous chromosomes in close apposition to enable correct meiotic genetic exchange (1). However, this view has been abandoned for various reasons (reviewed in Ref. 4). One obvious reason is provided by *S. pombe* and *A. nidulans*, which lack SCs but perform correct meiotic recombination (12, 13). In budding yeast (*Saccharomyces cerevisiae*), the assembly of SCs has been analyzed systematically in relation to meiotic chromosome pairing and recombination, by the determination of the order of events at the DNA and chromosomal levels and by the analysis of SC assembly and recombination in meiotic mutants (reviewed in Refs. 36 and 37). In yeast, SCs are not required for high levels of meiotic recombination (36); on the contrary, successive steps in SC assembly appear to depend on successive steps in recombination (36, 37). In other organisms, however, apparently normal SCs are assembled in the total absence of meiotic recombination (38, 39). The following possible roles of SCs have been proposed on the basis of the studies in yeast and in various other organisms: (i) SCs are required for crossover interference (36), which is the phenomenon that the presence of a crossover reduces the probability of another crossover nearby on the same chromosome pair (bivalent). Interference can be considered as a manifestation of a regulatory mechanism that ensures at least one crossover per bivalent, even if the average number of crossovers per bivalent is close to one. At least one crossover per bivalent is required for the proper segregation of chromosomes at meiosis I. The intact, tripartite SC structure is required for crossover interference (36), but it is not at all clear how the SC is involved. *S. pombe* and *A. nidulans*, which lack SCs, do not display crossover interference. The average number of crossovers per chromosome pair is so high in these organisms that a regulatory mechanism that ensures at least one crossover per bivalent is not required (12, 13). (ii) The axial elements of SCs may have a role in monitoring the recombination process, so that it can be related to progression of the meiotic cell cycle (40). (iii) The axial elements direct initiated recombination events to the homologous chromosome rather than to the sister chromatid (41). (iv) Axial element components are required to link recombination at the DNA level to crossing over at the level of chromosomal axes (36, 37); this is essential for the formation of functional chiasmata—that is, structures that can ensure proper segregation of homologous chromosomes at meiosis I.

To summarize, SCs appear to steer recombination in the right direction, and they also appear to link recombination events to the meiotic cell cycle and to the mechanisms of meiotic chromosome segregation (4, 42). It remains to be elucidated how SC components are involved in these possible functions.

Suggestions for Further Reading

43.

References 1, 6, 16, 36, and 42 of the above list are suitable for further reading. Reference 1 is a comprehensive review of the cytology of SCs. Reference 6 is more up-to-date than Ref. 1 and relates the cytology of SCs to *in situ* hybridization studies and analyses of meiotic recombination at the DNA level. Reference 16 is focused on recombination nodules. Reference 36 is the best start to get familiar with the complex literature on meiosis and synaptonemal complexes in yeast. Reference 42 is a good and up-to-date introductory text.

44. N. Kleckner (1996) Proc. Natl. Acad. Sci. USA **93**, 8167–8174. This review considers various possible roles of SCs in meiotic chromosome pairing and recombination.

Syncytium

A syncytium is a cell that contains multiple **nuclei** in the same cytoplasm. Some organisms are completely syncytial, such as the slime mold Physarum ***Physarum***. In other organisms, only some tissues are a syncytium. For example, human muscles are syncytia, formed by the fusions of individual cells called myoblasts. A syncytium may also be present at only some stages in development. Early *Drosophila* embryos (prior to blastoderm formation) are a syncytium (1). The first nuclear divisions after fertilization take place without any cellular division. After 13 divisions, the germ cells have formed separate cells, but the somatic nuclei remain in one cytoplasm. Most of the somatic nuclei are at the surface and form a stage called the syncytial blastoderm. Only after 13 divisions does cytoplasmic division follow the somatic nuclear divisions. Cellular membranes form around all of the somatic nuclei at the periphery of the blastoderm, to form the cellular blastoderm stage. A few nuclei remain in the interior of the blastoderm in a syncytium with the yolk.

Synonymous Substitution

Synonymous substitution is an **evolutionary** term meaning the fixation of a silent mutation in a population or subpopulation. Because the genetic code is redundant, particularly in the third position (see Degeneracy of the Genetic Code), silent mutations are frequent. If codons for the 20 amino acids were distributed equally in **genomes** and if all types of base substitutions were equally likely, 19% of all base-pair substitution mutations would be silent. The rate of synonymous substitution during evolution, however, is far higher than this. Indeed, synonymous substitutions can be 70 to 90% of all substitutions (1). The obvious reason is that most amino acid changes have deleterious effects, whereas silent mutations can be **neutral** or nearly so. Thus, they may not be **selected** against and come to fixation by genetic drift. But organisms can have preferred codons for certain amino acids (see Codon Usage and Bias), in which case particular silent mutations may be selected for or against, especially when they occur in highly expressed genes.

Reznikoff, M. Riley, M. Schaechter, and H. E. Umbarger, eds.), American Society for Microbiology Press, Washington, DC, pp. 2708–2720.

Syntenic Genes

Syntenic genes are **genes** situated on the same chromosome. Genes that are syntenic on one chromosome of a species are often also syntenic on a chromosome of another species. A few examples are given below. For example, syntenic relationships of genes for *galactokinase* and thymidine kinase are conserved between humans (chromosome 17) and chimpanzees (chromosome 19). Other syntenic relationships and gene assignments are consistent with proposed homologies between chimpanzee and human chromosomes (1). In the same vein, homologous genes for enolase, phosphogluconate dehydrogenase, phosphoglucomutase, and adenylate kinase are syntenic on mouse chromosome 4 and human chromosome 1 (2). Many syntenic groups have been found between the baboon *Papio papio* and *Homo sapiens* by cosegregation analysis of hybrid cells obtained between *Papio* fibroblasts and a mouse cell line deficient in thymidine kinase 3, 4. Mapping genes spanning the chromosomes in humans, cattle, and mice permits syntenic comparisons between prototypic genomes of three mammalian orders and provides insight into the evolutionary history of the ancestral mammalian genome (5).

Synthase/Lyase

Lyases are enzymes that catalyze the cleavage or formation of C—C , C—O and C—N bonds by means other than hydrolysis or oxidation. They have a single substrate in one direction and two substrates in the other. The carbon-carbon lyases include those that bring about carboxylation reactions, reverse aldol condensations, or the reversible cleavage of a 3-hydroxy acid. The action of carbon-oxygen lyases leads to the formation of unsaturated products, and the recommended names for specific enzymes belonging to this group are dehydratases, hydratases, and synthases. The carbon-nitrogen lyases catalyze the elimination of ammonia with the formation of a double bond and are either ammonia or amidine lyases. Carbon-sulfur lyases also belong to this group. It should be mentioned that, under conditions in which the synthesis of the single substrate is considered to be more important, the alternative name of synthase is used. A synthase differs from a **synthetase** in not having a requirement for ATP or another nucleoside triphosphate.

Synthetases/Ligases

Ligases are a group of enzymes that are involved with linking together two molecules covalently, with the concomitant hydrolysis of a phosphoryl or pyrophosphoryl group of a nucleoside triphosphate that is generally **ATP**. The bonds formed in the joining of two molecules are C—O,C—S, and C—C. Enzymes catalyzing reactions of this type were referred to originally as *synthetases*, but this term proved to be unsatisfactory because of the confusion with **synthase**. Nevertheless,

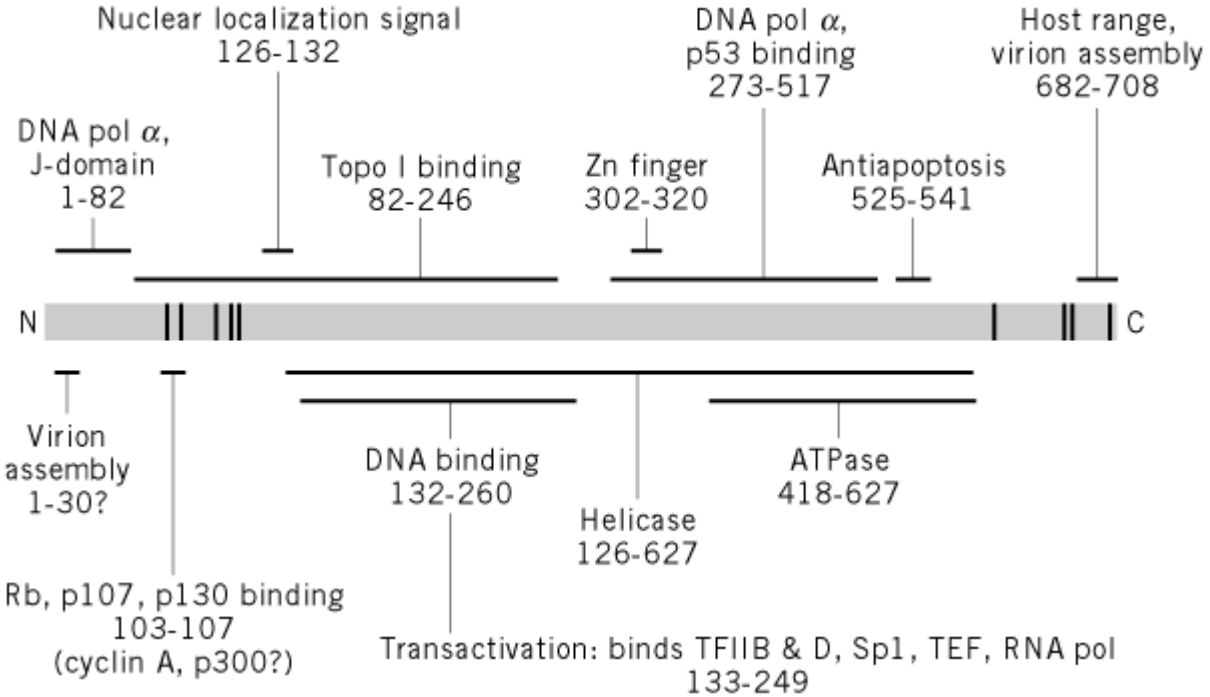
synthetase is still being used as a trivial name. It should also be noted that older names are being retained. For example, *pyruvate carboxylase* is the name given to the enzyme responsible for the conversion of pyruvate to oxaloacetate at the expense of ATP, and *synthase* is used for enzymes that restore phosphodiester bonds in nucleic acids.

T Antigen

T antigens are multifunctional proteins encoded by **papovaviruses**, such as simian virus 40 (SV40), mouse **polyoma virus**, and human BK and JC viruses. Under certain circumstances, animals infected with a papovavirus can develop tumors and will produce **antibodies** against the early gene products of the virus, which are called tumor or "T" antigens. T antigens regulate expression of both viral and host genes, modulate cellular proliferation, and participate in viral DNA synthesis and virion assembly.

The most intensively studied T antigen is that of SV40 virus. Although there are some differences, the T antigens of other papovaviruses function quite similarly to that of SV40. Pre- messenger RNA transcribed from the A gene of the SV40 virus is differentially spliced (see **Splicing, RNA**) to produce two mRNAs that yield the SV40 large T and small t antigens. The 708 amino acid-residue large T antigen has a molecular weight of about 82,500 (Fig. 1). The 17,000-Da small t antigen comprises the amino-terminal 82 amino acid residues of the large T antigen plus an additional 97 residues encoded by the **intron** of the A gene.

Figure 1. Distribution of functional domains on SV40 large T antigen. The polypeptide chain of T antigen is represented by the stippled bar with *N* at the amino terminus and *C* at the carboxy terminus. Vertical lines within the bar represent phosphorylation sites. Numbers indicate the residues that constitute each domain, which is indicated by horizontal lines. (Modified, with permission, from the *Annual Review of Biochemistry*, Vol. 61, © 1992 by Annual Reviews Inc.)

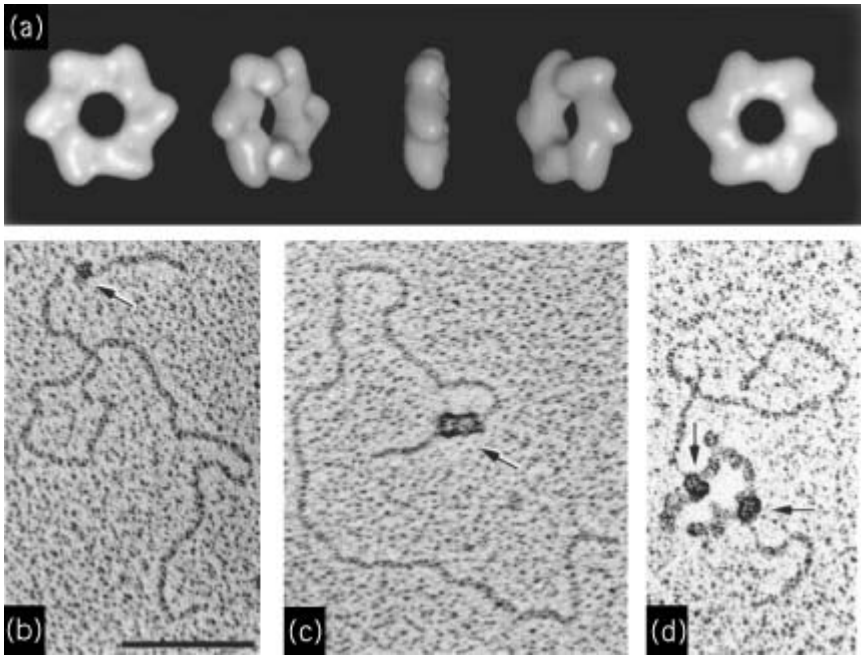


Large T antigen undergoes numerous types of post-translational modifications that include acylation, glycosylation, ribosylation, adenylation, and phosphorylation. These modifications modulate the activity and distribution of the protein within the cell. The phosphorylation sites are clustered near the amino and carboxy ends of the polypeptide chain (Fig. 1). Phosphorylation of the various sites within the clusters modulates both positive and negative control of viral DNA replication .

T antigen is composed of several functional **domains** that have a variety of functions (1-9) (Fig. 1). One of these domains binds DNA and consists structurally of a central five-stranded antiparallel **b-sheet** that is flanked by a pair of **a-helices** on one side and an a-helix and a 3_{10} helix on the other side (see Protein Structure). Residues 152–155 and 203–207 are juxtaposed to form a surface that contacts the recognition sequence of the DNA (10). This domain has a greater affinity for single-stranded DNA than for double-stranded, unless the duplex DNA contains the pentanucleotide sequence GAGGC, which is specifically recognized and bound. Clusters of this recognition sequence are located near and within the SV40 **origin of replication**, which separates the **promoters** for the early and the late genes. The spacing of these pentanucleotides within the clusters promotes protein–protein contacts that further strengthen the affinity of T antigen for duplex DNA. The binding of T antigen to these clusters governs the transcription of viral genes and the initiation of viral DNA replication.

Another domain possesses an ATPase activity that is strongly stimulated by the binding of single-stranded DNA. The binding of either ADP or ATP to T antigen induces its oligomerization into a hexamer, which is propeller-shaped with a central channel (11) (Fig. 2a). The hexameric form of T antigen functions as a DNA helicase, which translocates in a 3′–5′ direction along one strand of the duplex as it unwinds the DNA. The helicase domain spans the ATPase and DNA-binding domains and contains a **zinc finger**.

Figure 2. Reconstructed image and electron micrographs of T antigen. (**a**) Reconstructed three-dimensional images of hexameric T antigen assembled in the presence of ADP. (Image panel provided by M. C. San Martin and J. M Carazo; reprinted with permission from reference 11). (**b**) T antigen bound to a linearized **plasmid** containing the SV40 origin of replication near one end of the DNA molecule. Arrow points to the bound T antigen. (**c**) Double hexamer of T antigen bound to a linearized plasmid containing the SV40 origin near one end of the DNA molecule. Arrow points to the double hexamer. (**d**) Unwound structure formed by mixing linear plasmid DNA containing the SV40 origin with T antigen, single-stranded DNA binding protein, topoisomerase, and ATP. Arrows point to hexameric T antigen at the unwinding forks. (Bar = 0.1 μm) (Electron micrographs provided by Dr. F. B. Dean.)



At the amino terminus of T antigen is a domain that is functionally homologous with the J-domain of DnaJ/hsp40 **molecular chaperones** (see DnaK/DnaJ Proteins). This domain interacts with the host hsc70 protein (see **Hsc, hsp proteins**) and is also required for efficient synthesis of viral DNA. The extreme carboxy terminus determines the host range of the virus, and in conjunction with the J domain, also governs virion maturation. Other domains modulate host transcription, cell cycle progression, and defense responses by interacting with the cellular factors that regulate these processes.

T antigen regulates both viral and host transcription. After the initial synthesis of T antigen, transcription of early viral genes is down-regulated by the binding of monomeric or dimeric T antigen to one of the clusters of pentanucleotide recognition sites at the origin (Fig. 2**b**,**c**). Positive regulation of late viral transcripts by T antigen is partially achieved by binding to TEF-1, which is a cellular transcription factor that represses late transcription of viral genes (12).

T antigen transactivates simple host promoters that contain a TATA box and binding sites for the transcription factors SP-1, ATF, AP1, or TEF-1. T antigen binds SP1, TFIIB, TATA-binding protein, and other components of transcription factor TFIID, and the 140-kDa subunit of **RNA polymerase II** (3). T antigen also transactivates **ribosomal** RNA genes by binding to SL1 protein, which is required for efficient transcription of this class of genes (13). The mechanism by which the binding of T antigen to these factors transactivates host genes is not completely known. T antigen may simply function as a TATA-binding protein–associated factor in a complex with TFIID. Alternatively, the interaction of T antigen with host transcription factors may block the binding of repressors that inhibit the formation of preinitiation complexes.

T antigen can also repress the expression of certain host genes by sequestering transcriptional activators such as p300, which modulates the expression of genes controlled by cAMP-**response elements** (CRE). T antigen binds specific **isoforms** of p300, which results in repression of CRE promoters (8).

T antigen interacts with several cellular factors that govern cell growth, such as the **retinoblastoma** tumor suppressor (Rb) and p53. T antigen contains domains that bind to each of these cellular proteins (Fig. 1). Rb is a growth suppressor that normally sequesters the transcription factor E2F. By sequestering Rb, T antigen frees E2F, which then promotes the expression of factors that advance the

entry of the cell into the **S phase** of the cell cycle. The freed E2F also promotes the expression of factors required for nucleotide synthesis and for DNA replication. The Rb-related factors p107 and p130, which interact with E2F-like transcription factors, are also bound and inhibited by T antigen (14). p53 is a damage response factor that indirectly stimulates the activity of Rb and also participates in the induction of apoptosis. By sequestering p53, T antigen further inhibits the suppression of E2F by Rb and impedes the induction of apoptosis. T antigen also induces the expression of several factors that are required for progression of the cell cycle, including cyclin A, cyclin B, p33cdk2, and p34**cdc**2 (15). Two of these factors, cyclin A and p33cdk2, form a complex with T antigen at replication initiation sites on the viral DNA (16).

T antigen can induce the formation of tumors in rodents that have been inoculated with SV40. Rodents are not a natural host for SV40, and the virus is unable to complete its life cycle. However, the viral DNA may be integrated into the genome of the rodent cells, which leads to expression of T antigen. Because T antigen affects the progression of the cell cycle in rodents just as it does in simians, critical cell-cycle checkpoints are disabled (15). Karyotype instability eventually ensues, which may then lead to oncogenic transformation of the infected cells. SV40 may also induce tumors in its natural host if the virus contains a mutation that blocks completion of its life cycle but does not alter the overall structure or function of T antigen itself.

T antigen participates in viral DNA replication, where it functions as a DNA helicase and binds at the origin of replication. On binding ATP, T antigen assembles into two hexamers that encircle the DNA at the replication origin (17) (Figure 2**c**). The hexamers then recruit host-encoded replication factors to the origin via specific protein-protein interactions. The host replication factors that specifically interact with T antigen include single-stranded-DNA binding protein (SSB), topoisomerase I (see DNA Topology), and DNA polymerase a (2, 18). Upon association with the SSB and topoisomerase, each hexamer begins unwinding the origin DNA (Fig. 2 **d**). DNA replication is then initiated at each unwound fork by DNA polymerase a. Additional replication factors are then recruited so that the synthesis of viral DNA can be completed.

1. Small t Antigen

Although not required for viral growth, small t antigen stimulates viral DNA synthesis (19). Small t antigen is required for efficient transformation of growth-arrested cells, where it promotes the transition to the S phase of the cell cycle. The promotion of this transition is probably a consequence of small t antigen's ability to induce the expression of cyclin D1 and to bind and block the activity of protein **phosphatase** 2A, which dephosphorylates threonine residues (4, 20). Inhibition of this phosphatase may activate **mitogen**-activated protein kinases that induce signaling pathways that initiate the transition to S phase. Since phosphatase 2A can dephosphorylate large T antigen, small t may also facilitate the activation of large T antigen by sequestering this phosphatase. Small t antigen may also activate and repress the expression of various host genes (21).

T Cell

T lymphocytes represent an essential component of the immune system, because they are responsible for cell-mediated immunity, such as allograft rejection or delayed hypersensitivity. They are also necessary for most humoral responses—that is, production of circulating **antibodies** by B cells to the so-called **T-cell**-dependent **antigens**, which are mainly proteins. T cells that are involved in cell-mediated immunity are called *effector T cells*, such as cytotoxic T lymphocytes, whereas those that control B (and effector T) expression are designated as helper T cells, or Th.

T cells recognize antigens in a manner that is totally different from that of B cells, because they do not interact with native **epitopes** but with **peptides** derived from **antigen processing** and presented in association with major histocompatibility complex (MHC) molecules at the cell surface of antigen-presenting cells. T-cell recognition is mediated by the T-cell receptor (TCR), which is

expressed exclusively at the cell surface, as part of a membrane receptor complex that contains also a signaling module, termed CD3. TCR is a heterodimer composed either of a and b or g and d polypeptide chains, which are generated upon gene rearrangement of discrete mosaic genes organized in a fashion (ie, V–D–J and V–J) similar to that of immunoglobulin (Ig) genes. In addition to the TCR–CD3 complex, T cells express many other surface components, among which CD4 and CD8 are of prime importance, because they condition interactions with MHC class II and class I molecules, respectively.

Differentiation of T cells takes place in the thymus, which is first colonized by early progenitors that emigrate from the bone marrow. The discrete steps that lead to fully differentiated T cells have been dissected with a large collection of mice inactivated for most genes implicated in this complex cascade of events. Critical markers are the sequential rearrangements of the TCR a and b genes and expression of the CD4 and CD8 molecules. Early progenitors first migrate in the thymic cortex with a TCR^{-}, $CD8^{-}$ $CD4^{lo}$ phenotype. In the subcortical epithelium, progenitors start to divide and are designated as triple-negative (TN) because they express neither CD4, CD8, nor TCR molecules. The first gene rearrangements (V–D–J of the b locus) take place. The b chain associates with preTa and becomes expressed as a heterodimer at the cell surface. This molecule controls allelic exclusion of the b locus, thus ensuring monoclonal expression of the b chain. As thymocytes migrate deeper into the cortical epithelium, the a locus V–J gene rearranges, and the TCRab may now be expressed at the cell surface. Both the CD4 and CD8 molecules become expressed, so that the double-positive (DP) $CD4^{+}CD8^{+}$ stage is now reached. The following steps will be critical, because they will drive the expressed repertoire of circulating T cells. At the DP stage, when still in the cortical epithelium, cells will interact with MHC molecules that have bound a huge variety of endogenous peptides. T cells that bind with a high affinity will be eliminated, as dangerously autoreactive. T cells that do not encounter any MHC peptide complex will die by “neglect.” Those that interact with a moderate affinity will be positively selected and enter terminal maturation in the thymic medulla. The DP cells now interact with either MHC class I or MHC class II, resulting in the occurrence of single-positive (SP) cells that are CD8 or CD4, respectively. The “choice” of interacting with either MHC class is more or less predicted by the sequence of the TCR molecules, especially in some complementarity determining regions, CDR1 and CDR2 a regions (see Immunoglobulin Structure), that may have coevolved with monomorphic interacting regions of the MHC molecules. Recent **X-ray crystallographic** structures have suggested a structural basis for a better understanding of the positive selection.

Further functional specialization of T cells is dependent on antigenic stimulation and a complex interplay with a variety of cytokines. Helper T cells (Th) are generated from CD4 cell Th precursors (Thp) upon antigenic stimulation that takes place through interaction with an antigen-presenting cell. Thp will mature to Th0 cells that, depending on the nature of the antigenic stimulus and/or the cytokines present in the microenvironment (the two later being closely linked), will finally acquire the distinctive properties of Th1 or Th2 cells. Th1, stimulated by **interleukin**-12 (IL-12), are involved in cell-mediated immune responses and secrete IL-2, tumor necrosis factor, and interferon g (IFNg). In contrast, Th2 are reactive to IL-4 and are implicated in the control of T-dependent antibody responses, including immediate hypersensitivity mediated by IgE; they synthesize IL-4, IL-5, IL-6, IL-10, and IL-13. Th1 and Th2 down-regulate each other, mostly through IFNg that down-regulates Th2, and IL-4 that represses Th1. The distinction between Th1 and Th2, described mostly in mice, may not be so clear-cut, and it may be better to consider instead the cytokines of type I or type II that are organized as a complex interacting network.

T cells may also behave as direct effectors for cell-mediated responses. This is the case for CD4 T cells that are responsible for delayed-type hypersensitivity and of CD8 cytotoxic T lymphocytes. The latter are derived from cytotoxic T precursors (Tcp) that interact with helper T cells to become potent effectors of T cell cytotoxicity, which may target a large variety of cells that they are induced to kill by apoptosis after mobilization of the Fas system.

Finally, a word should be mentioned about suppressor T cells (Ts), once extremely popular but now less so. The existence of Ts cells was postulated when it was reported that certain **tolerance** states could be transferred from mouse to mouse, thus excluding the simple explanation of tolerance as merely due to clonal deletion. The suppression problem has not really been solved, especially with the realization of dominant tolerance, but it might also be understood as a complex regulatory network involving subsets of T cells.

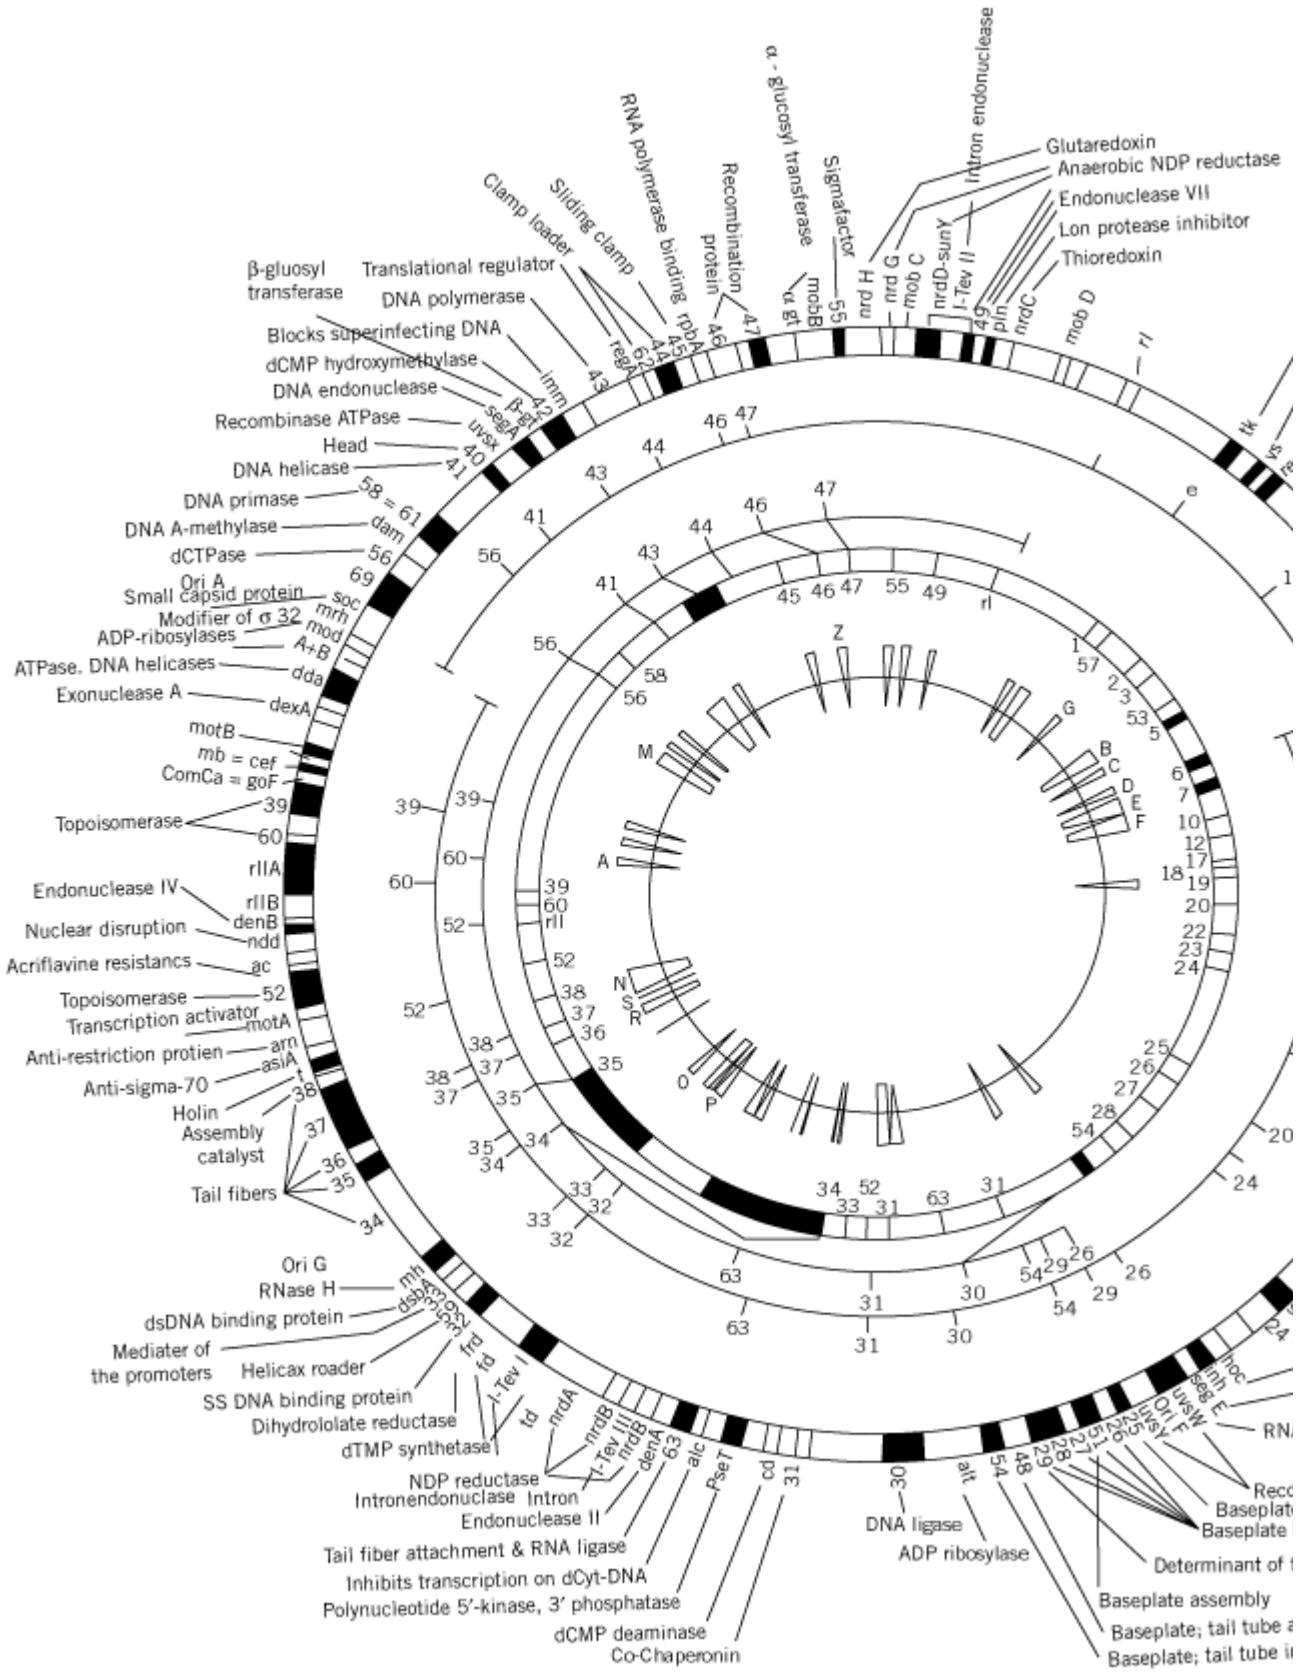
T4 and T-Even Bacteriophages

1. History and Overview

Bacteriophages T2, T4 and T6 were among seven *Escherichia coli* phages selected by Max Delbrück to study the fundamentals of viral replication. They are serologically and genetically related and are collectively called the "T-even" phages (1). Based on similar genomic organization, regulatory patterns, virion structure and sequence similarity of their "essential" genes, many other phages from different parts of the world belong to this family (2). More distantly related phages have been called pseudo T-even phages (3) and schizo T-even phages (4). The genomes of these phages are contained in large (≈ 174-kbp) linear, double-stranded DNA molecules, whose termini contain repetitions of 3 to 5% of the 168,903 base pair genome (5). The termini are randomly permuted over circular maps (Fig. 1). The DNA contains hydroxymethylcytosine (HMC) instead of cytosine. In most members of the family, the HMC residues are further glycosylated to different extents. These modifications allow escape from host restriction enzymes and are important for the developmental strategy of these phages.

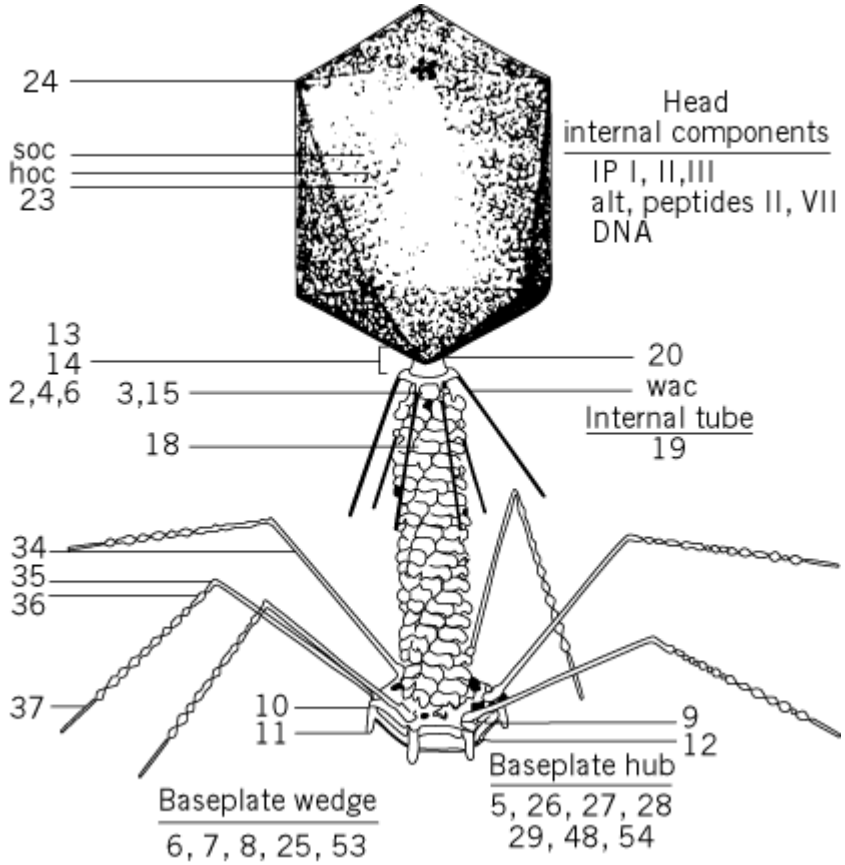
Figure 1. Comparison of several maps of T4 genes. The outermost circle shows the map of known genes and origins of r (5). The next three overlapping circular segments drawn as thin lines show the positions of the indicated genes based on packaging between these genes and reference markers in *r*I, *r*II, and *r*III (76). The next circle shows the position of these frequencies (107). The innermost circle represents the heteroduplex loops between T2 and T4 DNA (90). The substitutio gene *69* (40).



DNA is packaged in elongated "heads" of quasi-**icosahedral symmetry**. Heads are joined to tails whose baseplates and fibers (Fig. 2) are instrumental for recognition, adsorption, and injection of the DNA into host bacteria. Different phages of the T-even family recognize different receptors in different host strains. Apparently, illegitimate recombination with genomes of plasmids and other

phage genomes in the same host cell facilitates rapid evolution of T-even tail fiber genes and adaptation to different hosts (6).

Figure 2. Diagram of the T4 virion, based on electron microscopy at 2 to 3 nm resolution. Locations of proteins are indicated by the corresponding gene numbers (see (Fig. 1). The portal vertex (gp20) is attached to the upper rings of the neck structure inside the head itself. An internal tail tube lies inside the tail sheath. The short fibers of gp12 are shown in stored, folded conformation. (Reproduced from (Ref. 80).



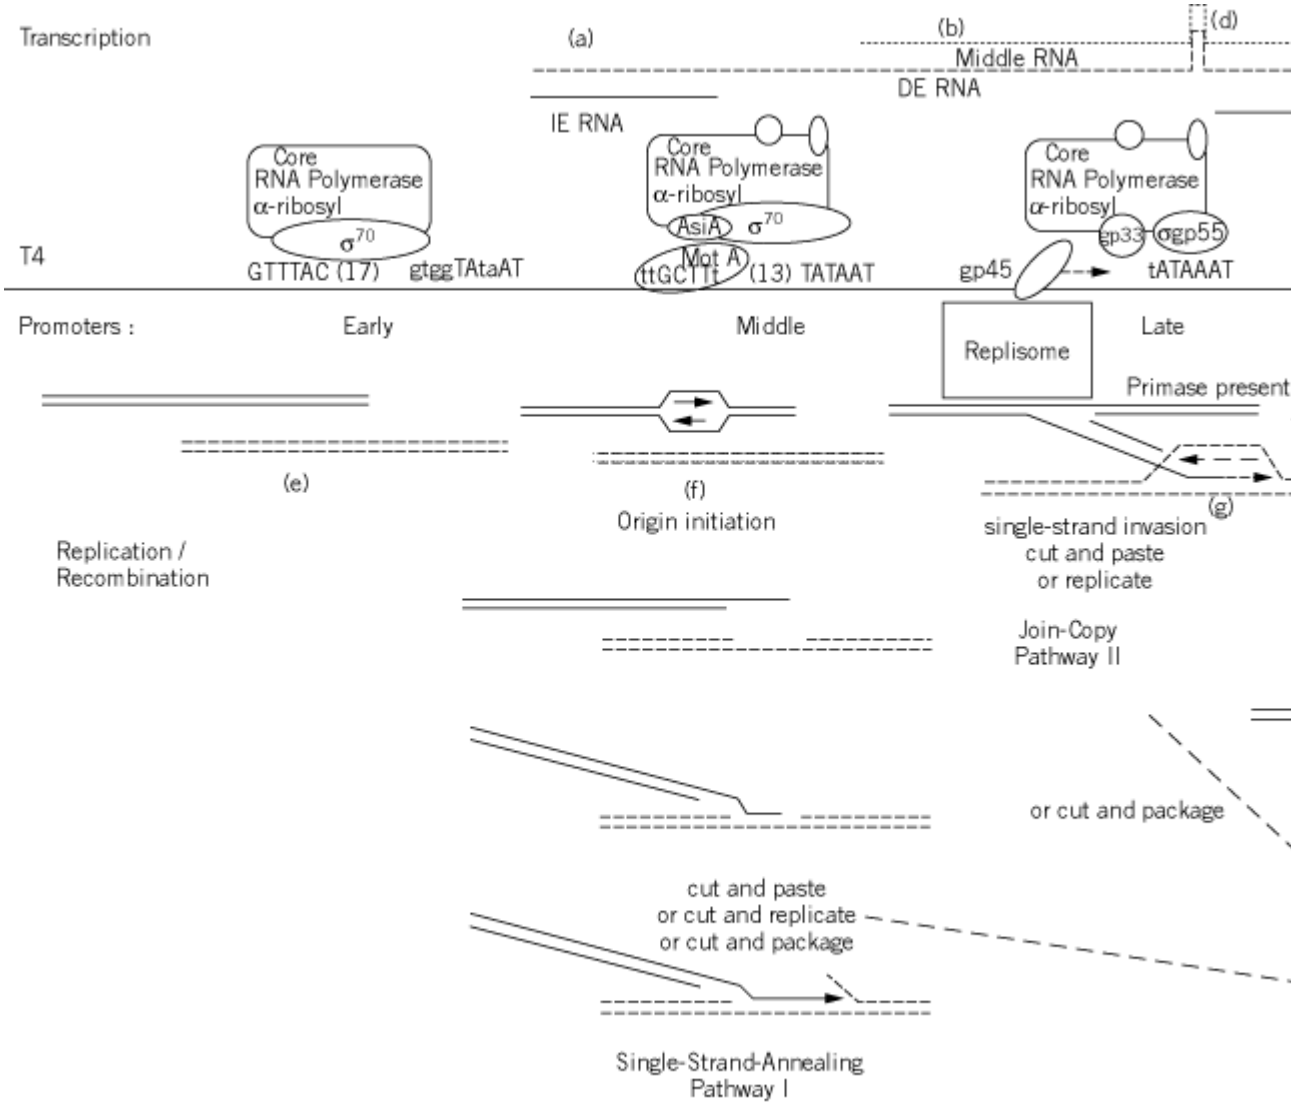
T-even phages are some of the most successful molecular parasites. Their genomes code for phage-specific DNA replication, recombination, and DNA repair functions and provide well-characterized genes and proteins for detailed analyses of these fundamental biological processes.

Nevertheless, like all viruses, T-even phages depend for their propagation on many vital structures and functions of their hosts, for example, membranes, energy metabolism, transcription, and translation. They manage to usurp host structures and functions in an exquisite choreography that allows adaptations to different environmental conditions including different physiological states of the host.

Most of the recent work on T-even phages has been done with T4, mainly because the isolation of a large collection of conditional lethal mutants provided a powerful impetus for molecular analyses by biochemical and biophysical methods. The results of the combined efforts of many research groups that worked on T4 and related phages are summarized in a monograph (1), and comparisons with other members of this phage family have been reviewed (2-4, 7). Because of space limitations, the references cited here are restricted mainly to chapters in Ref. 1 and subsequent summarizing publications. The recipe for the success of T4 as a molecular parasite is based on multiple redundant pathways for most, if not all, physiologically important DNA transactions, which are interconnected

at many levels (Fig. 3). These redundancies and cross-connections allow flexibilities during development and evolution.

Figure 3. A diagram of the relationships of different transcription modes and pathways of DNA replication, recombinati (progressing in time after infection from left to right). The upper panel (**a–d**) shows a stylized example of overlapping ea region of the T4 genome. Ribosome-binding sites for late proteins in prereplicative transcripts are sequestered in hairpins panel indicates modifications of host RNA polymerase after infection and the consensus sequences of early, middle, and different forms of RNA polymerase. The lower panel shows different stages of DNA replication and recombination. (**e**) (**f**) Bidirectional origin initiation in one of them. Leading-strand synthesis is primed by RNA polymerase-generated trans by short RNAs synthesized by primase. As soon as the first growing point reaches an end (only one is shown), the partia homologous region of another chromosome (**g**) or the terminal redundancy of the same chromosome (not shown). "Join- invading 3' DNA end. When an endonuclease cuts the invaded DNA at the backward recombinational junction at the bla recombination can be initiated from the cut 3' end to allow copying of single-stranded segments of an invading DNA. (A arrowheads does not allow direct initiation of DNA replication but breaks the DNA.) Together, both processes generate l increasingly more complex by reiteration. This DNA is processed into mature, unbranched chromosomes during packagi lines, filled with different patterns. Newly synthesized DNA is drawn as thin lines. Discontinuous synthesis of Okazaki p continuous synthesis by solid lines. Arrows indicate the directions of RNA or DNA synthesis.



The gradual subversion of host functions to support different aspects of phage propagation is

achieved in many small steps:

1. A cascade of phage-induced proteins modifies the host **RNA polymerase** and its accessory transcription factors covalently and noncovalently, allowing sequential recognition of different classes of **promoters** and modulating the processivity of RNA polymerase to transcribe HMC-containing DNA selectively. Thereby, all host transcription is inactivated, and timed functioning of different classes of phage promoters is achieved. At least one of these proteins, an enzyme that ADP ribosylates one a subunit of host RNA polymerase, is packaged into virions and injected with the phage DNA into the next host bacterium. 2. RNA processing by phage and host enzymes, translational repressors, and still poorly understood modifications of ribosomes, all modulate T4 gene expression. No transcriptional repressors are known, and it is surmised that posttranscriptional modulations can better adjust to rapid physiological changes during the short T-even development: One growth cycle is finished in less than 30 minutes at 37°C.
2. The host DNA and messenger RNA present at the time of infection are rapidly degraded, and the breakdown products are efficiently reused to synthesize phage DNA and RNA.
3. The onset of the first phage DNA replication from specific origins requires host RNA polymerase to generate primers and is thereby influenced by the physiological regulatory processes of the host. Most subsequent T4 replication depends on phage-encoded replication and recombination proteins and on DNA primers that are intermediates of homologous recombination. This subsequent replication is entirely phage controlled.
4. The requirement of late transcription for the sliding clamp protein of replisomes, couples DNA replication and transcription.
5. During the later stages of development, proteins involved in packaging DNA also become important for DNA replication and repair and thereby coordinate these processes.

2. Genome Structure and Genetic Map

The genome of T4 resides in 168,903 bp of double-stranded DNA containing glucosylated HMC residues. The complex **modification** and **restriction** of T4 DNA can best be rationalized as the result of an ongoing evolutionary process that includes exchanges between the phage, its host, and prophages resident in the host.

T-even phages destroy dCTP, synthesize dHMCTP, and use the latter for DNA synthesis. This modification protects the T4 DNA against T4-encoded restriction endonuclease II that together with endonuclease IV and the gene *46/47*-controlled **nuclease** degrades the host DNA as part of the parasitic strategy to usurp the host (8-10). It also makes phage DNA resistant to most type I, type II, and type III restriction enzymes. Although, HMC residues confer resistance to most I, type II, and type III restriction systems, they render DNA susceptible to the Mcr restriction systems of the host. These host functions were the first restriction systems (then called Rgl) discovered. They are now called McrA and McrBC, because they restrict DNA that contains methylcytosine or hydroxymethylcytosine. These enzymes are inactive, when the HMC residues are glycosylated. In T4 DNA, all HMC residues are modified; 70% with a- and 30% with b-glycosyl linkages. There are no a-glycosyltransferases, in T2 and T6 DNA and 25% of the HMC residues remain unglycosylated. T6 contains many diglycosylated residues. In addition, an early T4 antirestriction protein (Arn) protects nonglycosylated T4 DNA against McrA but not McrBC.

Phages T2 and T4, but not T6, encode a Dam **methylase** that methylates 0.5 to 1.5% of the adenine residues at the N^6 positions, mostly but not exclusively at GATC sequence. These enzymes exhibit patches of similarity at the protein level to the *E. coli* Dam methylase and the *Dpn*II methylase of *Diplococcus pneumoniae*. The only proven physiological role of adenine methylation is protection against the phage P1 restriction system, when there is no HMC glycosylation (8).

Using genetic tricks, T4 mutants that contain unmodified cytosines or adenines in their DNA have

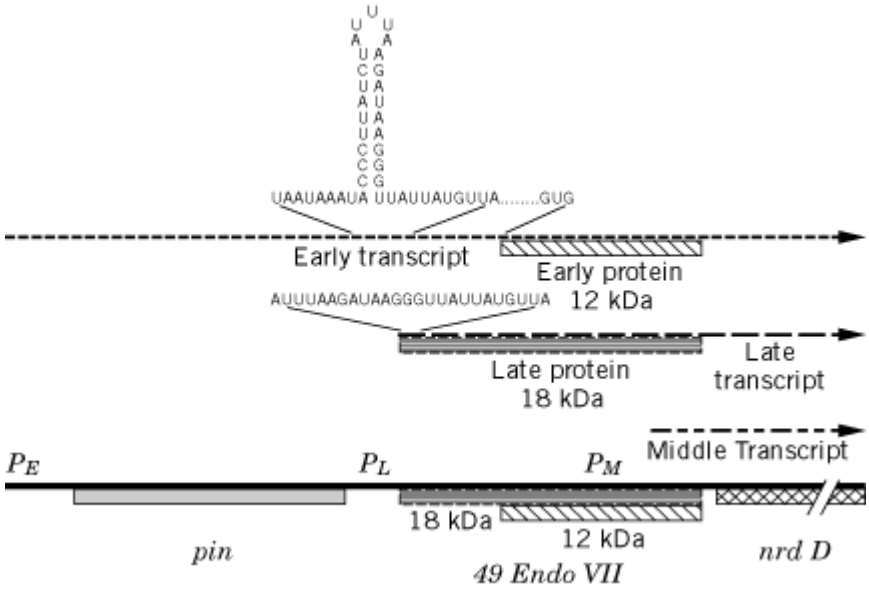
been isolated (8, 10). The cytosine-containing mutants have limited variability and host range. Their DNA has been instrumental in mapping and sequencing the T4 genome, but the lack of modification affects regulation of transcription termination (10, 11), and origin-dependent DNA replocation (12, 13), and initiation of packaging (14) appear to be different from wild-type T4.

Mature T4 DNA molecules (chromosomes) packaged into virions are linear. In contrast, intracellular replicating DNA contains multiple covalently linked copies of the genome, called "concatemers," that are highly branched as a result of recombination and replication. These are debranched and cut during packaging (see below) at nearly random (i.e., circularly permuted) map positions (1) and generate "terminal redundancies" at the ends so that 3 to 5% of the genome is diploid.

Numerous mutations and their assignments to complementation groups and open reading frames (ORFs) have defined 161 proteins (counting proteins initiated from gene-internal ribosome binding sites as separate proteins) that have known or deduced functions. Approximately 127 additional ORFs were revealed by DNA sequence analyses. Most, if not all of these are transcribed, and their protein products have been detected by acrylamide gel electrophoresis. However, the many functions of many of them are still unknown. There are many overlapping coding regions; several genes direct synthesis of more than one protein from in-frame internal start codons; many ORFs are very small; and in at least two regions, both complementary DNA strands encode proteins. In spite of the large genome size, only a few short regions have no coding capacity. These and other observations suggest that apparently redundant and "nonessential" genes confer no selective disadvantages.

In contrast to transcription units of many other (e. g., the **lambdoid phages** and **T7-related phages**, T-even early, middle and late transcription units are interdigitated. Most genes are transcribed from multiple promoters, gene for related or interacting proteins are not necessarily clustered, and in many cases early and late genes are cotranscribed (15) (see Figs. 1 and 4). In this and other respects, the T-even phages more closely resemble the **Herpes viruses** than certain other phages. Intriguingly, some T4 proteins (e.g., **DNA polymerase** and terminase) also resemble the corresponding proteins of Herpes viruses.

Figure 4. An example of interwoven transcriptional and posttranscriptional controls in the T4 gene *49* (Endo VII) region (see (Fig. 1). The locations of early (P_E), middle (P_M), and late (P_L) promoters and the protein-encoding segments of genes *pin, 49* and *nrdD* are marked. Overlapping transcripts are distinguished by differently patterned horizontal lines with arrows. The *nrdD* transcripts encode two proteins; one from spliced and the other (a truncated peptide) from unspliced RNA. The late gene *49* transcript is predominantly translated into the 18-kDa Endo VII. In the larger, early transcript, the Shine–Dalgarno sequence is sequestered in a hairpin. A shorter 12-kDa protein can be initiated in frame from an internal GUG. (Modified from Ref. 15.)



3. Temporally Controlled Gene Expression During T-Even Development

The classical Hershey–Chase experiment established unambiguously that T-even DNA is sufficient to establish viral growth (16). T4 adsorption and infection (17, 18) occur in steps, described below. Complete injection of phage DNA and a few packaged proteins through the membranes of host cells requires membrane potential. Inactivation of host functions and temporal regulation of expression of different classes of phage genes from the injected DNA and its copies are then exerted at several levels: **trascript** initiation, elongation, termination, and stability, **translational** controls, and combinations thereof (15). In contrast to T7-related phages, the T-evens use the host's core RNA polymerase throughout their life cycle. Differential transcription initiation from host or T4 early, middle, or late promoters is due, in part, to a cascade of RNA polymerase modifications: several accessory T4 proteins (1) associate noncovalently with the core RNA polymerase, and the a-subunits are covalently **ADP-ribosylated**.

Different classes of phage genes can be distinguished in terms of timing as early (also called immediate early, IE), middle (also called delayed early, DE), or late. Another classification criterion distinguishes all genes that are expressed before the onset of DNA replication as "prereplicative" or "early" from "postreplicative" or "late" genes, whose expression depends on DNA replication. However, the regulation of T4 gene expression resembles more a web of interacting regulatory networks than a cascade of linear timed pathways.

Operationally, early (IE) genes are defined as transcribed by host RNA polymerase when phage gene expression is prevented by inhibitors of protein synthesis (eg, chloramphenicol). Under these conditions, the host RNA polymerase uses unmodified s^{70} to recognize early T4 promoters, but the core RNA polymerase is altered by T4 Alt protein that is packaged and coinjected with the phage DNA. Alt protein ADP ribosylates one a-subunit at Arg 265, a position that is important for recognition of so-called UP elements in promoter DNA (19) and for the dimer configuration of the carboxy-terminal domains of RNA polymerase a-subunits (R. Ebright, personal communication). This ADP-ribosylation is beneficial, but not essential for T4 growth.

Expression of all other T-even genes requires phage-directed protein synthesis for several reasons discussed below. The distinction between different classes is, however, blurred because most T4 genes are under dual or multiple transcriptional controls and many late T4 genes are transcribed from late promoters, but are also cotranscribed with early genes from early or middle promoters. For these

late genes, posttranscriptional mechanisms (discussed below) prevent early expression.

Collectively, prereplicative genes encode i) **nucleases** that degrade the host DNA; ii) enzymes of the deoxyribonucleotide biosynthesis complex (see Ribonucleotide Reductase); iii) proteins of the DNA replication, recombination, and repair machines; iv) proteins that modify the T4 DNA to protect it from degradation by its own nuclease and from other restriction enzymes; v) several transfer RNAs that are processed from precursor RNAs and supplement host tRNAs during translation; vi) proteins that modify the structure and function of the host RNA polymerase; vii) at least one ribonuclease (RegB protein) that selectively destroys certain early transcripts; and viii) a translational repressor (RegA protein). In addition, some prereplicative transcripts serve as primers for leading strand DNA synthesis in **origins of replication** (see text below).

The late genes code for all virion components, for some DNA recombination and DNA repair proteins (defining a late T4 "join-cut-copy" DNA replication, recombination and repair pathway described below), and for proteins that cut and package the complex vegetative DNA into preformed heads. A soluble lysozyme (gp e) lyses the cell wall of host bacteria to release the progeny phage particles. It is paralogous to a baseplate lysozyme (gp5) that attacks the cell wall from the outside during infection (20). The gp e lysozyme gains access to its substrate in the outer cell wall through a protein channel that forms from the holin (T protein) that causes the membrane potential to break down. In T4, this process is regulated, in part, in response to superinfection sensed by the RI protein (17, 21, 22).

T4 early promoters are recognized by the *E. coli* RNA polymerase that contains the major sigma factor s^{70}, when the host DNA is still largely intact. These promoters resemble the **consensus sequence** of *E. coli* promoters, but most of them also have some differences and some additional information content (23) (Fig. 3a). Many of them have upstream poly A or poly T tracts that may enhance transcription as bendable sequences or as UP elements or both.

Several factors, none of them essential for T4 growth, have been proposed as contributors to the preferential transcription from T4's early promoters compared with *E. coli* promoters (24):

1. Most importantly, once the early T4 Alc protein is made, it inhibits all transcript elongation on (cytosine-containing) host DNA.
2. Transcription from various T4 or *E. coli* promoters is affected differentially by ADP ribosylation of Arg^{265} (in the C-terminal activation and dimerization domain) of one a-subunit of the host's RNA polymerase by the T4 Alt protein, as mentioned above, and subsequent ADP ribosylation of Arg^{265} of the other a-subunit by the early T4 ModA protein (25, 26)).
3. When infection occurs, the host DNA is associated with nonspecific (eg, HU, H-NS) or semispecific (eg, IHF, FIS) DNA binding proteins. In contrast, the infecting phage DNA is at first largely free of proteins and may be more readily accessible to the host's RNA polymerase (24).
4. The T4 Ndd protein, a DNA-binding protein, disrupts the *E. coli* nucleoid (27, 28).
5. The early T4 AsiA protein binds to the C-terminal segment of s^{70} (29) and interferes with transcription from host promoters that contain consensus –35 regions (30, 31).
6. The host DNA is relaxed and degraded by early T4 proteins.

Both early and middle promoters require host s^{70}. Binding of AsiA protein to s^{70} prevents transcription of early T4 promoters with "standard" –35 regions, but infection can proceed because most prereplicative genes are also transcribed from middle promoters (11) (Fig. 3**b**). At middle promoters, the RNA polymerase, whose s^{70}-subunit has acquired AsiA protein, recognizes consensus –10 regions and T4 MotA protein bound to consensus DNA sequences called *motA* boxes (11, 32, 33) (Fig. 3). Transcriptions from early and middle promoters can overlap in time, another

example why linear classification schemes are oversimplified.

RNA polymerase is directed to late promoters by a phage-encoded sigma factor, gp55. Initiation from late promoters (34) (Fig. 3), requires, in addition, the adapter protein gp33 and the **sliding clamp** of the replisome, gp45, which is loaded onto the DNA at single-strand interruptions by a gp44–gp62 complex (see DNA Replication). This sliding clamp tracks along DNA and allows RNA polymerase, bound at late promotes, to form open complexes. The requirement for the sliding clamp couples late T4 transcription to DNA replication. In certain recombination — and repair — defective mutants, late transcription can occur without DNA replication because single-strand interruptions in the DNA provide entry sites for the sliding clamp (34).

Even when some genes, are located downstream of a promoter, they may be poorly expressed because of i) premature transcriptional termination, ii) RNA processing or degradation, or iii) ribosome binding sites are sequestered by secondary structures (see Attenuation). Certain mutations that affect the transcriptional termination factor Rho (also called host defective, *hdF* or *nusD*) of *E. coli* prevent growth of wild-type T4 by causing premature termination of many T4 transcripts (11). Mutations that allow growth in these *rho* mutants have been found in three nonessential T4 genes. It was initially thought that these encode transcriptional **antiterminators**, but current evidence suggests that at least one of them, *goF*, allows T4 growth in the (*nusD*) *rho* mutants, because it stabilizes the few functional transcripts that have not been prematurely terminated. Plasmid-encoded Rop protein has similar stabilizing effects, and pBR322 plasmids allow T4 growth in these **rho** mutant hosts (35, 36).

Several additional nonessential T4 proteins also associate with or modify host RNA polymerase subunits (Table 1). Some of them affect the binding of minor host s factors to core RNA polymerase and prevent competition with s^{70} that is essential for T4 development. For example, the Mrh protein modulates phosphorylation of the host's s^{32}, which affects T4 growth at 42°C (37, 38).

Table 1. Phage T4-Encoded Proteins That Modify Structure or Function of the Host RNA Polymerase[a]

Modification	Product of Gene	Molecular Mass (kDa)	Time of Synthesis
ADP ribosylation of one a-subunit at Arg^{265}	*alt*	76.8–75.9	Late, packaged into heads, cleaved in the head, and injected with DNA
ADP ribosylation of second or both a subunits at Arg^{265}	*modA*	23.3	Early
ADP ribosylation of ribosomal protein S1 and yet undetermined proteins	*modB*	24.2	Early
Association with ternary transcribing complex, causing termination on C-containing DNA	*alc*	19.1	Early
Modulation of host s^{70}	*asiA*	10.6	Early
Activation of middle	*motA*	23.6	Early

promoters, binds to DNA and to host s^{70}			
Modulation of phosphorylation of host s^{32}	*mrh*	18.5	Early
Similarity to (decoy of?) host s^{32}	*srh*	8.1	Early
Similarity to host s^{70}	*srd*	29.0	Early
Binding to RNA polymerase	*rpbA*	15.5	Early and middle
s factor for late promoters	*55*	21.5	Middle
Bridge between σ^{gp55} and sliding clamp	*33*	12.8	Middle
Binding to some late promoters	*dsbA*	10.4	Middle
Activator of late promoters, sliding clamp of DNA polymerase	*45*	24.8	Early and middle
Clamp loader	*44*	35.8	Early and middle
Clamp loader	*62*	21.4	Early and middle

4. Posttranscriptional Controls

Due to the interspersion of early and late genes on the T4 map (Fig. 1), many early and middle transcripts are extended into late genes (Figs. 3 and 4). Nevertheless, few corresponding late proteins are synthesized early below 37°C. There is some early expression of these late genes *in vivo* at higher temperatures. It is remarkable that expression of at least ten such late genes investigated so far follows similar pattern: in the long early transcripts, a hairpin sequesters the translation initiation region, either the Shine–Dalgarno sequence or the start codon, or both. A late promoter, immediately upstream of these late genes, directs synthesis of transcripts that cannot from the hairpin; these late transcripts are efficiently translated (Figs. 3d and 4). As an example, expression of gene *49* coding for endonuclease VII is depicted in Figure 4. In this case, a shorter peptide, initiated from an internal GUG, plays a role in join-cut-copy replication/recombination (39), discussed below. The late T4 lysozyme gene *e* is similarly transcribed early and late, but mainly translated late. These late genes can be translated early *in vivo* at high temperatures, or *in vitro*, when RNA is partially degraded, because under these conditions the ribosome binding sites become accessible. I speculate that the corresponding position of late promoters provides some selective advantage because if RNA polymerase that enter at the early or middle promoters, pauses and terminates near the hairpins formed in early transcripts, it might facilitate acquisition of T4-encoded s^{gp55} and transcription initiation from the late promoters, which reside in each case in the corresponding palindromic DNA sequence.

Three additional regulatory systems of T4 depend on translational controls (40a). Two genes are autogenously regulated by translational repression: gene *32*, which codes for the major single stranded DNA binding protein (SSB) involved in DNA replication, recombination and repair, and gene *43*, encoding DNA polymerase. A more general, nonessential translational repressor (RegA protein), which binds to several specific transcripts, reduces translation of several T4 replication proteins and of some host proteins. This repression is most apparent under experimental conditions

that prolong early transcription.

Translation of certain early transcripts is prevented at later times by a T4 *regB*-encoded ribonuclease, which selectively cleaves these transcripts at the ribosome binding sites.

5. DNA Replication and Recombination

The combination of genetic experimentation and virtuoso biochemical and biophysical characterization of replicative proteins has led to an understanding of the functions and interactions of replicative proteins in the basic replisome, a biological machine that moves the replicative fork (or through which replicating DNA passes) (see DNA replication).

The proteins that assemble into basic replisomes in all organisms share sequence and structural similarities, and some of the T4 replication proteins can function partially in eukaryotic *in vitro* systems (41).

Seven T4 proteins, corresponding to genes *43* (DNA polymerase), *44* and *62* (sliding clamp loader), *45* (sliding clamp), *41* (DNA helicase), *61* (primase to synthesize primers for Okazaki fragments), and *32* (single-stranded DNA binding protein) together replicate model templates at *in vivo* speeds. In wild-type T4, leading and lagging strand synthesis are coupled (42), but they can be uncoupled *in vivo* or *in vivo* (43), for example, in primase- or **topoisomerase**-deficient mutants (39). T4 DNA polymerase has been well characterized by exquisite mutational, biochemical, and biophysical methods. Mutator and antimutator mutations have delineated domains that are important for polymerizing and for proofreading activities that contribute to the exceptionally high fidelity of this enzyme (44-46). Mutated sites in replisome components can now be correlated with the 3-D structure of the T4 and related RB69 DNA polymerase, the sliding clamp (gp45), and a large segment of the single-stranded DNA binding protein gp32 (47-50). Dynamic interactions between these proteins have been dissected in exquisite detail (see Refs. 42 and 51 for recent reviews).

Gene expression, DNA replication, and recombination are tightly interwoven. Replication and recombination follow several different redundant pathways, shown diagrammatically in Fig. 3 (39, 52-54). The functioning of each pathway in time depends in part on timed expression of the genes required for each pathway. Redundant alternative modes of replication and recombination ensure that both processes work under many different conditions and during different stages of development.

The first round of DNA replication is initiated from one of several potential origins. Because of the circular permutation of chromosomal ends (indicated in Fig. 3**e**), any origin in each individual chromosome is located at a different distance from the DNA termini. Only one origin is used, in most chromosomes perhaps because at first, there are limited supplies of replisome components. Each of the four origins that have been closely investigated has a different sequence. Three origins (*A, F*, and *G*) require transcription from middle promoters (13), whereas *ori E* uses an early promoter (55, 56). Figure 3**f** depicts initiation from an arbitrary generic origin. Transcripts initiated from these promoters serve as primers for leading-strand DNA synthesis. (They also encode proteins, but priming and directing protein synthesis are mutually exclusive.)

Primase then synthesizes primers for Okazaki fragments (57). Transition from RNA to DNA synthesis occurs at several sites within a region approximately 1 kb downstream of each origin promoter (55, 56, 58).

The transition from σ^{70}-dependent prereplicative transcription to T4 σ^{gp55}-dependent late transcription inhibits initiation from these replication origins, because the modified RNA polymerase no longer recognizes origin promoters (56, 59), and/or because the late UvsW protein, an RNA–DNA helicase, actively unwinds potential primers from the DNA template (54, 60).

Subsequent DNA replication is initiated from intermediates of homologous recombination, by a mechanism first compellingly demonstrated in phage T4 (59), (Fig. 3**g** and **i**). Therefore, the T4 recombination genes (Table 2) are also important for DNA replication in vivo, and recombination-deficient T4 mutants arrest DNA replication prematurely (13, 53). It is now apparent that there are several ways by which recombination intermediates can prime DNA synthesis (39, 52). Such intermediates can be formed by annealing complementary single strands or by invasion of a single-stranded terminus into the homologous region of another molecule (or at the other end of the same molecule). Both structures can initiate replication using the 3' end of the invading or annealing single strand (join-copy recombination) (Fig. 3**g**). In addition, invasion intermediates can initiate replication from a 3' end in the invaded strand after an endonuclease or a damaging agent has broken the invaded strand at the branch-migrating junction (join-cut-copy recombination) (Fig. 3**i**. The join-copy mode can start as soon as a growing point has reached an end. The join-cut-copy mode occurs usually with some delay, because in the absence of DNA nicks imposed by damaging agents, it depends on prior synthesis of late endonucleases. Because only the join-cut-copy mode can bypass the requirement for primase or topoisomerase in T4 DNA replication, mutants defective in these enzymes appear to have a delay in recombination-dependent DNA replication. Radiation and other agents that cause single-strand nicks or double-strand breaks can enhance recombination and reduce the delay in DNA synthesis of primase or topoisomerase mutants.

Table 2. T4 DNA Replication and Recombination Proteins

Protein	Gene	DNA phenotype of Mutants[a]	Time of Expression
DNA polymerase	*43*	D0	Early and middle
Sliding clamp	*45*	D0	Early and middle
Clamp loader	*44 & 62*	D0	Early and middle
Primase	*61*(= 58)	DD	Early and middle
DNA helicase	*41*	DA	Early and middle
DNA helicase	*dda*	DD	Early
Loader of gene 41 helicase	*59*	DA	Early and middle
Single-stranded DNA binding protein	*32*	DA	Early, middle, and late
dNMP kinase	1	DS	Middle and late
dCMP hydroxymethylase	*42*	DS	Early
dCTPase, dUTPase, dCDPase, dUDPase	*56*	DS	Early and middle
5' to 3'Exonuclease, RNase H	*rnh*	WT	Early
DNA topoisomerase	*39 & 52 & 60*	DD	Early and middle
DNA ligase	*30*	DA	Early
Recombination protein and nuclease[b]	*46 & 47*	DA	Early and middle
RecA-like recombination protein	*uvsX*	DA	Early and middle

Helper of UvsX protein	*uvsY*	DA	Middle and late
DNA and RNA-helicase	*uvsW*	WT[b]	Late
Endonuclease VII	*49*	WT[b]	Early (weak) and Late (strong)
Packaging terminase	*16 & 17*	WT[b]	Late
Membrane-associated proteins	*rIIA & rIIB*	WT[b]	Early and middle
Endonuclease II	*denA*	WT[b]	Early and middle
Exonuclease A	*dexA*	WT[b]	Early

[a] D0, no DNA synthesis; DA, DNA arrest; DD, recombination-dependent DNA arrest; DD, recombination-dependent DNA replication delayed; DS, slow DNA synthesis;WT, normal DNA synthesis, except under special conditions.

[b] DNA synthesis is altered in combination with other phage or host mutations.

Ultimately, reiteration of recombination-dependent DNA replication generates a highly branched concatemeric DNA network in which no individual chromosomes can be distinguished.

Of course, not all recombination junctions need to be converted to replication forks. T4 recombination can occur, albeit later than usual, when DNA replication is inhibited. Electron micrographs of such T4 DNA intermediates provided the first compelling evidence for the importance of branch migration in homologous recombination (61). Under these conditions, no viable progeny particles are produced, because no packageable concatemers are formed, there is little late transcription (which depends on DNA replication), and thus there are no heads that can be filled.

Recombination-dependent DNA replication *in vitro* has been achieved for some time (13, 62). Consistent with genetic analyses, reactions require several recombination proteins in addition to the seven basic replicative proteins just mentioned. T4 UvsX (a **RecA** homologue) and T4 UvsY (a mediator, that binds to single- and to double-stranded DNA and is needed only at low UvsX concentrations) promote strand invasion. Gp59 facilitates loading of the replicative gp41 helicase, which is also important in driving branch migration of recombining DNA. These proteins also interact with the major T4 ssDNA binding protein, gp32. *In vitro* recombination-dependent replicative reactions are primed by 3' ends of single-stranded DNA invading homologous duplex DNA. With an excess of UvsX protein, and in the absence of primase or topoisomerase, they result in conservative DNA replication called "bubble migration," in which the nascent DNA strand is extruded from the DNA template, much like nascent transcripts are extruded by RNA polymerase (62). This process has been postulated to provide the single-stranded DNA for homing of **introns** by a recombination model dubbed the synthesis-dependent strand-annealing model (63, 64). There is no direct evidence that bubble migration occurs *in vivo* at physiological concentrations of UvsX protein, primase, and topoisomerase (reviewed in 13). Moreover, these *in vitro* systems do not depend on gps 46 and 47, which are required *in vivo* for recombination-dependent DNA replication (59).

Recently, *in vitro* initiation has been accomplished from a plasmid-borne T4 *ori F* (*uvsY*) (58). A short transcript, hybridized to supercoiled plasmid DNA *in vitro*, primed leading-strand DNA synthesis in this system. This priming occurred at a position different from the RNA–DNA transition observed at this origin *in vivo* (55, 56).

Many of the T4-encoded DNA enzymes, most importantly DNA ligase, polynucleotide kinase, DNA polymerase, and ssDNA binding protein, are now standard components of cloning and sequencing

procedures and kits.

6. DNA Packaging

Branched, concatemeric, intracellular T4 DNA can be debranched by T4 endonuclease VII (gp49) and by a terminase, a heteromeric protein encoded by genes *16* and *17*. These proteins associate with DNA and with gp20 at the portal vertex of the head to form a "packasome" that drives DNA into performed heads (65, 66) by an ATP-dependent process. Gene *17* produces several proteins of different sizes by initiation from in-frame internal initiation codons (67). At least two of these have nuclease activities that can be abolished by mutations (68, 69); the largest also binds to folded single-stranded DNA segments (68). Packaging of nonmodified dC-containing DNA starts preferentially at apparent *pac* sequences located in the overlap of genes *16* and *17* and duplicated in gene *19* (66). Other evidence indicates that T4 initiates packaging of HMC-modified DNA at random positions of the genome at folded single-stranded DNA segments (68), suggesting that packaging, like DNA replication, is also initiated by redundant mechanisms. Processive packaging of 103 to 105% genome lengths to fill the preformed heads generates the random circular permutation of the ends in mature virion DNA. Endonuclease VII, which cuts **Holliday junctions**, Y-junctions, and mismatched base pairs *in vitro*, can trim the branches of vegetative DNA *in vivo* and *in vitro* (70). This enzyme binds *in vitro* to the portal protein gp20 (71). DNA ligase, endonuclease V, and topoisomerase are also required for packaging, presumably to ascertain that any lesions and single-stranded segments in DNA are repaired before the DNA is packaged (65).

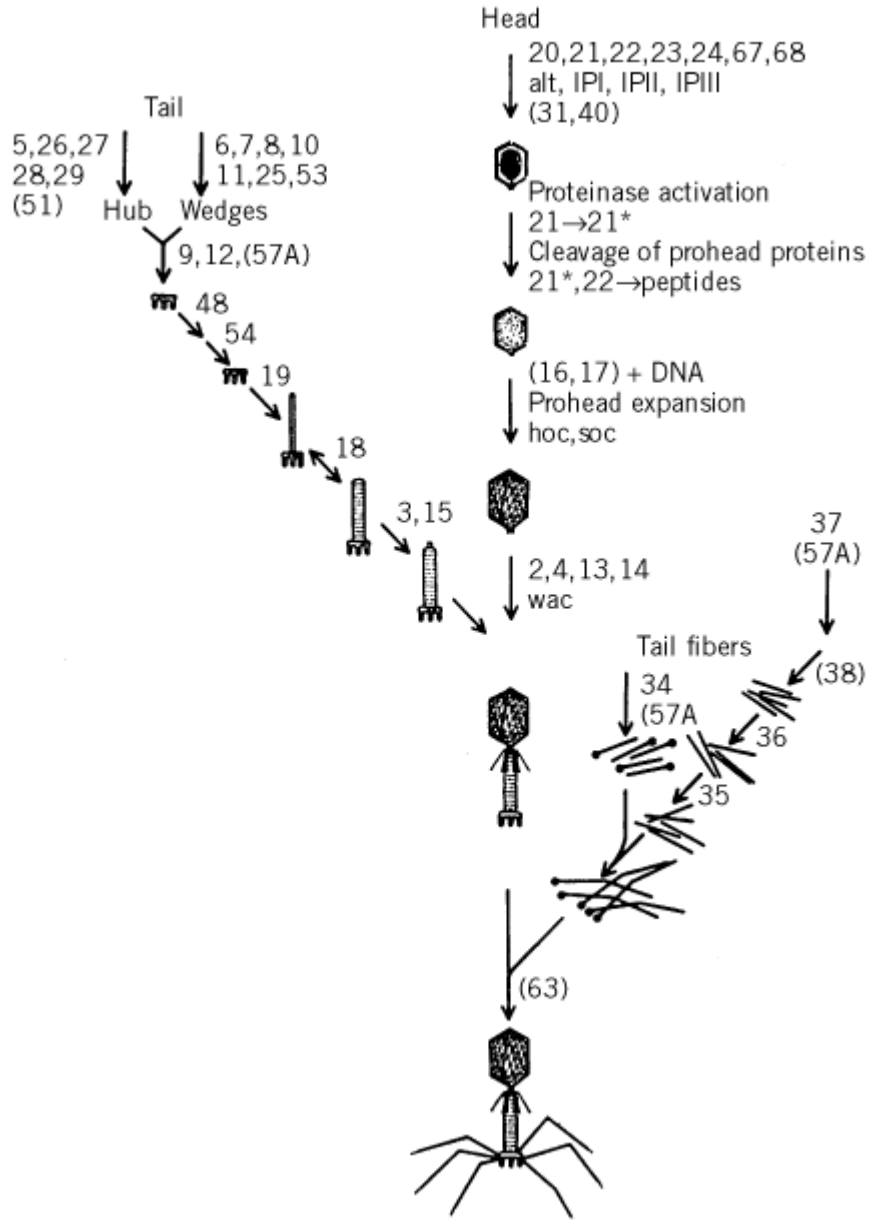
Both endonuclease VII and the nuclease activity of gene *17* products play important roles in the late, join-cut-copy, recombination-dependent DNA replication described above (39, 52). Thus, these activities can link DNA replication and packaging at a physiological level.

7. Virion Structure and Assembly

T-even phages build some of the most complex virus particles, which resemble lunar landing modules (Fig. 2). They devote more than 40% of their genetic information to synthesizing and assembling the protein components of these particles. The importance of host functions for assembly became apparent from "host defective" (*hd*) mutations and compensating phage mutations and led to the discovery of the first chaperonin, now called GroEL. The small subunit of this chaperonin in *E. coli*, GroES, is not necessary for T4 growth, because T4 gene *31* encodes a similar protein that is better adapted to interact with the major capsid protein (72).

Exquisite mutational and biochemical analyses revealed the complex assembly pathways (Fig. 5) that accommodate efficient packaging of DNA and efficient genome transmission (65). This system can also be used to package and deliver large pieces of foreign DNA (73).

Figure 5. Pathways of T4 virion assembly. Gene numbers in parentheses correspond to assembly factors that are not part of the final structure. The identities of gp26, gp28, and gp51 are uncertain. (Reproduced from Ref. 80 with permission.)



Twenty-four genes are involved in head morphogenesis, more than 25 encode structural components of the tail and tail fibers, and five more are needed as morphogenetic catalysts. Heads, tails, and tail fibers are assembled independently and put together after the heads are filled with DNA (Fig. 5).

Protein components of heads, tails, and baseplates and shapes of the protein subassemblies are similar among the T-even phages, except that one or two nonessential proteins (Hoc, Soc) that decorate and stabilize T4 heads are missing in some members of the T-even family.

In vivo assembly of heads is initiated on the bacterial membrane from the portal protein (gp20). The major head subunits (gp23) assemble around a scaffolding core, and gp 24, which is related to gp 23, forms pentamers at the vertices. Both gp23 and gp24 have to be converted into an assembly-competent state by the chaperonins mentioned above. Exquisite cooperative conformational changes lead to changes in the relative positions of proteins while the head precursors are being assembled. Subsequently, a phage-encoded **proteinase**, which is derived from gp21, one of the scaffolding proteins, cleaves each head subunit, the scaffolding proteins, and other packaged proteins, eg, the ADP-ribosylating Alt protein (see Gene Expression). Thus, head assembly is irreversible. Proteolysis is probably triggered *in vivo* by closure of the head vertices and perhaps by entry of some DNA into

the head; it can be achieved *in vitro* by other conditions. In any case, subsequent rearrangement of the subunits that lead to expansion of the head volume is triggered by the entry of DNA (74). The T4 heads are then stabilized by decoration with the Hoc and Soc proteins mentioned above. The complete assembly pathway has resisted *in vitro* reconstitution (65).

The normal, elongated T4 heads can be described by skewed **icosahedral symmetry**, in which the bottom and top triangles have a triangulation number T = 13, and the faces are elongated with a Q number Q = 21. These heads can accomodate full-length chromosomes with terminal redundancies. Anomalous heads of different sizes and shapes are made in low proportions (less than 5%) by wild-type T4, and in higher proportions by certain mutants or in the presence of an arginine analog, canavanine. Head lengths and shapes are determined at an early assembly stage, before formation of the unprocessed proheads.

Small heads (sometimes called "petites") contain incomplete genomes, which represent nearly random permutations of the genetic map. Most of these can be depicted as isometric (not elongated as the normal head) icosahedra and have a predicted volume that matches the measured DNA content (two-thirds of normal length). After infection with two such incomplete genomes, recombination reconstitutes complete genomes in one third of the doubly infected bacteria at, the frequency expected if they represent random circular permutations of the map (75, 76). Heads intermediate in size between the isometrics and normal elongated ones contain intermediate sized DNA molecules (77, 78). Larger heads, called "giants," contain oversized chromosomes that represent linear concatemers (79). A small proportion of all heads contains more than one DNA molecule; some heads are asymmetrical and contain more than one portal (80). The anomalous head sizes and shapes occur because assembly depends on numerous interactions of several proteins, each of which can exist in multiple conformational states and in different concentrations.

The base plates are built like exquisite cocked mechanical devices that lock the DNA into the virion and serve as valves that allow DNA to exit during infection. They consist of a central hub, six outer wedges, and six tail spikes; each of these substructures is assembled in independent pathways. The tails have a remarkably uniform length, determined by a subunit of the base plate that acts like a tape measure. Tails have a tubular inner core, through which DNA passes from the head to the base plate, and an outer sheath that contracts during infection by concerted conformational changes of individual subunits. Six bent tail fibers are attached to each tail. Each fiber consists of two half-fibers whose proteins are joined at an angle. The inner (proximal) half-fibers are attached to the base plate. In many newly formed phage particles, the other end is attached to short fibers that emanate from the junctions of heads and tails.

These complex assembly pathways, it is thought, facilitate the stability of the free virion while allowing subsequent conformational changes in response to contacts with the next host bacterium, as a prelude to DNA injection. The outer (distal) half-fibers contact phage-specific receptors on the surface of the bacterial cell wall during the first reversible step of adsorption. These contacts facilitate a second irreversible step in which the base plate contacts different receptors. Then, a concerted conformational change of all base plate components from a hexagon to a star configuration opens a hole in the tail to allow DNA to exit from the particles. This transition also activates contraction of the tail sheath and cleavage of gp5, a base plate protein, to release a lysozyme that actively digests host cell wall components from the outside.

Heads, tails, and tail fibers, made in different bacteria after infection with appropriate mutants, can be assembled *in vitro* to infectious particles, into which DNA can be packaged *in vitro*, allowing packaging of foreign DNA.

8. Restriction and Modification

In the following discussion, the term "restriction" is used in its broadest meaning and is not limited to type II restriction enzymes. The complex modifications and restrictions of T4 DNA and restriction

of other DNA by T4 can be best rationalized as a result of an ongoing evolution that is accelerated by strong selective forces and exchanges between the genomes of T4 and its host, especially plasmid and prophage genomes that reside in the host.

As mentioned before, HMC-containing DNA is protected from the T4-encoded nucleases that degrade host DNA. However, it is susceptible to McrA and McrBC restriction systems, unless it is glycosylated (81). McrBC is a GTP-dependent enzyme that moves along DNA (82), and assembles as rings (83). McrA of *E. coli* K12 resides in a cryptic prophage-like element, *e14*, that is not present in all *E. coli* strains (84). It is counteracted by the T4 protein Arn. Such restriction systems provide powerful selective advantages for the different DNA glycosylating enzymes of various T-even phages.

Lit, another protein also found in bacteria containing *e14*, cleaves the host's elongation factor EF Tu, if and only if it is directed to its target by a short internal peptide (*gol*) of the major T4 head protein, gp23. Thus, in *e14*-containing bacteria, all late T4 protein synthesis is inhibited (85, 86).

The classical example of phage exclusions by genes of resident prophages is that of T4 *rII* mutants by the *rexA* and *rexB* genes that are expressed in lambda phage lysogens. This exclusion was elegantly used in Benzer's classical analyses of structure and function of a gene. It occurs at the time of transition from join-copy to join-cut-copy recombination discussed under DNA replication and recombination, and it involves the late T4 endo VII that is important in the join-cut-copy pathway (52). The molecular mechanism of this exclusion is still unknown. It has been proposed, without direct experimental evidence, that the RexB proteins form an ion channel that, when opened after infection with T4 *rII* mutants, leads to cessation of host metabolism (87).

Another cryptic DNA element of certain *E. coli* strains, *prr*, encodes a PrrC protein that excludes mutants deficient in T4 RNA ligase or **polynucleotide kinase**. PrrC protein is a cryptic RNA endonuclease that is activated by the small (26 residue) T4 Stp protein to cleave the anticodon loop of an essential host $tRNA^{Lys}$. The T4 RNA ligase can repair this damage, but in the absence of RNA ligase, the cleavage of this tRNA is lethal to T4 protein synthesis. Intriguingly, the *E. coli prrC* gene is located between three genes of a type IC restriction cassette. The corresponding proteins are thought to inhibit PrrC RNase activity in uninfected cells.

Phage P2 lysogens exclude T4 by two mechanisms: the Tin protein poisons the single-stranded DNA binding protein gp32 (except in certain T4 gene 32 mutants) that is essential for all T4 DNA replication and recombination (88), and the P2 Old protein can degrade T4 and lambda DNA from ends, nicks, and gaps (89), unless they are protected by certain proteins.

9. Evolution

The sequences and map positions of homologous "essential" genes of most T-even phages are similar. In contrast, different members of the family have different "nonessential" genes interspersed between the homologous essential genes (Fig. 1). The differences contribute to apparent exclusions of alleles of one phage by another, and to the species barriers between different members of the family. The different "nonessential" genes became evident first as insertion or substitution loops in electron micrographs of heteroduplex DNA prepared *in vitro* by annealing single strands of T2, T4, and T6 DNA (90) and have been confirmed by sequence comparisons in many cases (2, 3, 39, 91). Although inactivating these nonessential genes has little or no consequence for phage growth in the laboratory, these genes are known or suspected to be important under different physiological conditions, in different hosts, and in the face of various restrictive systems imposed by different hosts.

In some cases, the sequence divergence reflects gene amplifications, inversions, and/or permutations of duplicated sequences (7, 92). In other cases, illegitimate pairing of partially homologous

sequences, join-copy and join-cut-copy recombination, and partial repair of mismatched heteroduplexes (discussed above) are proposed to lead to horizontal gene transfer. For example, in different T-even phages, different nonessential genes were acquired adjacent to the essential dCTPase gene, generating different apparent mutations in the corresponding dCTPase genes (39, 91). This mechanism can explain variabilities of other phage genes as well, for example, differences in the DNA polymerase genes of T4 and RB69, differences in the *e* lysozyme and the base plate lysozyme genes of phage T4, and similarities of base plate gene of T4 to phage P2 (93). Moreover, substitutions of sequence blocks of individual tail fiber genes by foreign sequences can account for the differences in tail fibers and host range of different members of the family and for the remarkably rapid coevolution of viral and host genomes (6).

10. Perspectives

The T-even phages have been instrumental in the initial formulations of many fundamental biological concepts: the unambiguous recognition of nucleic acids as genetic material; the operational distinctions in defining the gene by mutational, recombinational, or functional analyses; the demonstration of messenger RNA; the nature of the genetic code; light-dependent and light-independent DNA repair mechanisms; restriction and modification of DNA; the presence of **introns** in prokaryotes, and the facility for self-splicing or skipping of introns during translation; and the importance of an rules governing macromolecular assemblies during morphogenesis and DNA metabolism.

The essential role of homologous recombination in initiating DNA replication was first demonstrated in T4. Recombination-dependent DNA replication has also been observed in other phages, bacteria, chloroplasts, mitochondria, and yeast. It is a most important component of DNA repair (53, 94-99). It is important for survival of the T-even phages under all conditions because origin-dependent DNA replication is inactivated as a consequence of the developmental program. RNA-polymerase-generated transcripts are also used in other systems to initiate leading-strand DNA synthesis at origins (99, 100). A bypass of primase deficiencies by recombination enzymes has so far only been demonstrated in T4, but is also likely to operate in ColE1-like plasmids.

Other phages in which recombination deficiencies appear to result in premature arrest of DNA replication, include T1 (101, 102), in which a similar reason as in T4 is suspected, P22 (103), and a family of *Bacillus subtilis* phages (104, 105).

One of the more general aspects of T4 biology is the remarkable redundancy of pathways and proteins to initiate fundamental processes, such as DNA replication and recombination. The importance of redundant pathways for global evolution of novel development circuits has been discussed (106). To maintain redundant pathways during evolution, it is important that they are based on different principles and subject to different pressures. The persistence of mechanically different redundant pathways in T4 can be readily rationalized because they are best adapted to different stages of transcription, gene expression in general, and DNA packaging during phage development (39, 52, 55) (Fig. 3). Therefore, these redundancies are ready to bypass certain lesions in other important genes, (eg, the T4 primase gene), they facilitate cross-talk, coordination and optimization of transcription, translation, DNA replication, recombination, repair, and packaging, and they confer tolerance to changes that facilitate evolution.

1. General Properties

One of the original Type phages isolated by Demerec and Fano, T7 is now considered the prototype of a group of virulent phages that have an icosahedral head and a short, stubby tail, to which are attached six tail fibers (1). A major feature distinguishing it from other members of the *Podoviridae* is the synthesis, early after infection, of a new **RNA polymerase** that is resistant to the antibiotic rifampicin and highly specific for **promoters** on the phage genome. T7 was isolated as a phage that grows on *Escherichia coli* B, but T7 and its close relatives grow equally well on *E. coli* K-12 and C strains and on some of the Shigellae. It does not form plaques on fresh natural isolates of *E. coli* because it does not adsorb well (if at all) to smooth or capsule-containing bacteria, and it can be propagated on *Salmonella typhimurium* strains only if the latter are rough (and lack the *hsdLT* restriction system).

The T7 group of phages has been subdivided into three on the basis of the promoter specificity of the phage RNA polymerase: (i) Of the more than 60 coliphage isolates, T3 appears unique and is more closely related to the *Yersinia enterocolitica* phage YeO3-12 than other coliphages. (ii) There are three members of a second group (BA14, BA127, and BA156). (iii) The remainder are like T7 (2). Members of a given subdivision undergo recombination efficiently with each other, but recombinants between phages in different subdivisions are rare. In part this is due to divergence of the terminal repeat sequences that are essential for growth, and in part to the specificity of the phage RNA polymerase for its cognate promoters. In addition, T3 and T7 (the BA phages have not been tested) also exhibit mutual exclusion in coinfections, with most such coinfected cells producing either T3 only or T7 only. Nevertheless, the ancestors of T7 and T3 did recombine, because the gene *17* promoter in T3 is actually of T7 specificity and is not used during a normal T3 infection.

Heteroduplex analyses of a few T7-like genomes have shown that they exhibit varying degrees of homology, containing regions of >90% sequence identity and others with no apparent similarity, this has been confirmed by DNA sequence data for T7 and T3. T7-like phages that infect enteric bacteria other than *E. coli* are significantly less closely related than the coliphages; for example, the *S. typhimurium* phage SP6 has not even maintained the same gene order as T7. As may then be expected, phages growing in nonenteric bacteria have diverged even further.

2. Genetic Structure

The genetic map of T7 is based on the DNA sequence of 39,937 bp (3; Genbank Accession V01146) and contains 56 known or potential genes (Table 1). The genes are all **transcribed** from the same strand of DNA and are ordered by number sequentially from the genetic left end, which is the first end of the genome to enter the infected cell. Thus gene *0.3* is the first gene to be expressed, and *19.5* is the last. Integral numbered genes are unconditionally essential (except that gene *2* amber mutants grow on *E. coli* C), whereas most noninteger genes are nonessential or conditionally essential, exceptions being *2.5*, *6.7*, and *7.3*. Coding sequences occupy almost 92% of the genome; most of the remainder contains the terminal repeats, **origins of replication**, **promoters**, and ribonuclease III processing sites, or other recognizable genetic signals. The T7 genes are described as close-packed, but there are five instances of potential overlapping genes that are read in a different reading frame: genes *4.1* and *4.2* are almost entirely within gene *4* coding sequences, gene *18.7* lies within gene *18.5*, and both genes *19.2* and *19.3* overlap the gene *19* sequence. In addition, gene *4* codes for two proteins, gp4A and gp4B, due to the use of an in-frame internal initiation codon. Furthermore, programmed frameshifting of the ribosome to the +1 frame during translation of gene *0.6* and to the –1 frame during translation of genes *5.5* and *10* affords, respectively, gp0.6B, a 168-residue *5.5–5.7* fusion protein, and gp10B (3, 4). No biological function for these frame-shifted products is known, but T3 contains a different, yet comparable, shift sequence at the same relative position in gene *10* that also leads to a gp10B product (5). The gene *10* homologues of other T7-like phages are also thought to make two products; gp10B may therefore be important under some conditions of

infection.

Table 1. Genetic Map of T7

T7 Gene	M_r product	Function or Comment
Class-I		
0.3	13,678	Nonessential; inactivates Type I restriction enzymes
0.4	5,621	Nonessential
0.5	4,744	Nonessential
0.6A	6,201	Nonessential
0.6B	13,250[a]	Nonessential
0.7	41,124	Nonessential; protein kinase, inactivates host transcription. Col Ib exclusion
1	98,092	RNA polymerase
1.1	5,180	Nonessential
1.2	10,059	Nonessential; inhibits *E.coli* deoxyguanosine triphosphohydrolase, F exclusion
1.3	41,133	DNA ligase; exclusion by *Shigella sonnei* D_2 371-48
Class II		
1.4	5,446	Nonessential
1.5	3,174	Nonessential
1.6	9,946	Nonessential
1.7	22,053	Nonessential
1.8	5,781	Nonessential
2	7,043	Inactivates *E. coli*RNA polymerase
2.5	25,562	Single-stranded DNA-binding protein
2.8	15,617	Nonessential; derived from group I intron? Absentin T3 genome
3	17,040	Endonuclease, Holliday junction resolvase
3.5	16,806	Amidase (lysozyme), regulates T7 RNA polymeraseactivity
3.8	14,329	Nonessential; derived from group I intron? Absentin T3 genome
4A	62,656	Primase/helicase
4B	55,743	Helicase
4.1	4265	Overlapping gene, expression not determined
4.2	12,653	Overlapping gene, expression not determined
4.3	7,927	Nonessential
4.5	9,960	Nonessential
4.7	15,208	Nonessential. Absent in T3 genome
5	79,692	DNA polymerase
5.3	13,067	Nonessential; derived from group I intron?

5.5	7,280	Nonessential; binds to H-NS, l *rex* exclusion. *5.5–5.7* fusion proteinalso made
5.7	7,280	Nonessential
5.9	5,913	Nonessential, inactivates RecBCD
6	34,371	5′ → 3′ double-stranded exonuclease
6.3	4,088	Nonessential
Class III		
6.5	9,474	Nonessential
6.7	9,207	Adsorption
7	15,303	Nonessential; host range. Absent in T3 genome
7.3	9,937	Initiation of infection
7.7	14,737	Nonessential; derived from group I intron? Absentin T3 genome
8	58,989	Head–tail connector
9	33,766	Scaffolding protein
10A	36,414	Major capsid protein, *Shigellasonnei* D_2 371-48 and F exclusion
10B	41,700	Minor capsid protein, *Shigellasonnei* D_2 371-48 and F exclusion
11	22,289	Tail protein
12	89,265	Tail protein
13	15,852	Internal head protein; initiation of infection
14	20,836	Internal core protein ejected from particle atinitiation of infection
15	84,210	Internal core protein ejected from particle atinitiation of infection
16	143,840	Internal core protein ejected from particle atinitiation of infection
17	61,411	Adsorption, tail fiber protein
17.5	7,391	Holin for cell lysis
18	10,145	DNA packaging, small subunit
18.5	16,243	Cell lysis; l *Rz* homologue
18.7	9,195	Overlapping gene; cell lysis; l *Rz1* homologue
19	66,130	DNA packaging, large subunit
19.2	9,264	Overlapping gene, expression not determined
19.3	6,429	Overlapping gene, expression not determined
19.5	5,434	Nonessential

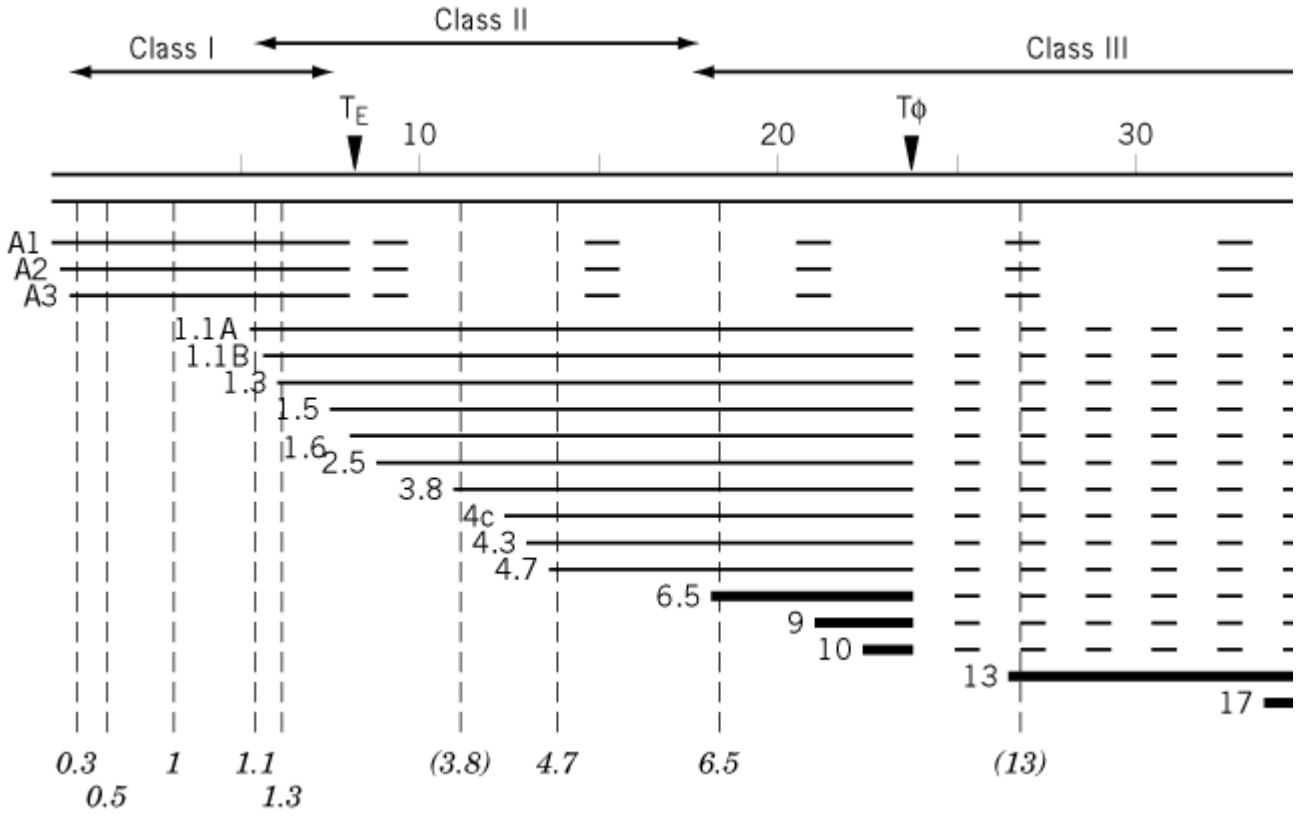
[a] Predicted only, site of frameshift not determined experimentally.

T7 DNA contains only the four normal bases; a limited amount of adenine **methylation** occurs from the Type I **restriction–modification** enzyme and from Dam methylase, but not all potential sites are fully methylated, because the rate of T7 DNA replication and packaging is so high. Some of the

other T7-like phage DNAs, including that of T3, are completely unmethylated, because they code for an S-adenosylmethionine hydrolase, which removes the donor of the methyl groups. The sequence GATC, as well as sequences corresponding to several common restriction enzymes, is grossly underrepresented in T7 DNA. For example, although expected 156 times on statistical grounds, the sequence GATC is present only six times in T7 DNA, ten times in T3 DNA, and not once in BA14 DNA.

Three classes of T7 genes have been recognized (Fig. 1): class I genes are those expressed from about 2 min to 8 min after infection at 30°C; class II genes from about 6 min to 15 min; and class III genes from 8 min until lysis, which occurs after ~25min (6). The ten class I genes are transcribed by *E. coli* RNA polymerase; their functions are mainly to subvert the bacterium into a phage-producing factory. The only essential class I gene is gene *1*, coding for the T7 RNA polymerase. The latter enzyme transcribes the class II genes, which are involved mainly in phage DNA metabolism, and the class III genes, whose functions are predominantly morphogenetic.

Figure 1. Schematic depicting the RNAs of phage T7. The three classes of genes are shown above the T7 genome, and tl terminators are indicated. T_E only affects *E. coli* RNA polymerase. Tø is the major T7 RNA polymerase terminator; on r dependent terminator, designated T_{pac}, is important for DNA packaging. The promoter for each transcript is indicated at first gene transcribed; dashed lines indicate that readthrough of the terminators occurs. Vertical dashed lines indicate site by the first gene following the site of cleavage; sites where cleavage is inefficient are in parentheses.



All but five T7 proteins are initiated with an AUG codon; the remaining five use GUG. All coding sequences are preceded by a recognizable Shine–Dalgarno sequence that can potentially form at least four base pairs with the T7 mRNA. Some of the messenger RNAs are more efficiently translated than others, suggestive of some level of translational control. The Class III gene *10* mRNA is one of the most actively translated RNAs known. More than 10^5 copies of gp10 are made in about 20 min at 30°C. In addition to the abundance of the gene *10* mRNA, its leader sequence and the initial codons

appear designed to maximize ribosome binding and translation initiation.

3. The T7 Particle

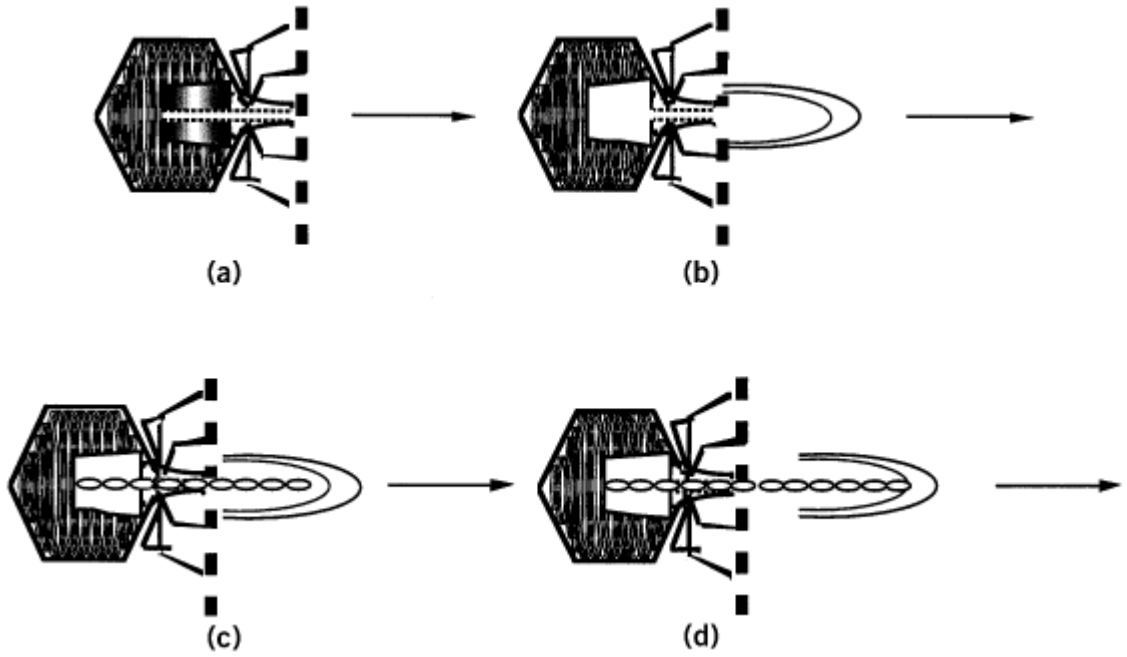
The phage capsid (**icosahedral symmetry**, $T = 7$) contains 415 molecules of either gp10A or gp10B (7). About 10% of the capsid is normally gp10B, but phages making only gp10A or gp10B are viable; gp10A-only phages grow like the wild type, but gp10B-only phages produce distinctly smaller plaques. At one vertex of the icosahedron, 12 molecules of gp8 act as the head–tail connector, whose structure is known from cryoelectron microscopy (8, 9). A central hole extends the length of the connector and is collinear with the internal channel of the ~20–nm tail; the latter consists of 6 molecules of gp12 and 12 copies of gp11. Six tail fibers, each containing trimers of gp17, are attached to the tail just below its junction with the connector protein. The 87-residue gp6.7 should also be part of the tail or tail fiber, because *6.7* null mutants fail to adsorb to cells. In addition to DNA, the head also contains a number of internal proteins, most prominent of which are gp14 (18 copies), gp15 (12 copies), and gp16 (3 copies), which form a hollow cylindrical structure, coaxial with the tail; this internal core is attached to the inner surface of the capsid and the connector (7, 10). The core is essential both for DNA ejection and for morphogenesis of new phage particles. The double-stranded DNA is spooled in about six layers around the axis of the core–connector–tail structure (11).

4. Infection Cycle

4.1. Adsorption, DNA Penetration, and Transcription

The tail fibers attach to the lipopolysaccharide of the *E. coli* outer membrane to initiate adsorption. A second receptor probably exists, and probably interacts with a tail component, but it has not yet been identified. Following adsorption, the infection is made irreversible by the degradation of the internal head proteins gp7.3 and gp13; the core then disaggregates, and its components (gp14, gp15, and gp16) pass through the connector and tail and enter the cell (Fig. 2). Both gp15 and gp16 are large proteins (84.2 and 143.8 kDa, respectively), and they may have to unfold to pass through the connector–tail channel, whose diameter is only ~3.7nm.

Figure 2. Conceptual model for entry of the T7 genome into the cell. (**a**) Proteolysis allows disaggregation and ejection of the internal core structure into the cell. Gp14 localizes to the outer membrane, possibly forming a channel. Gp16 inserts into the inner membrane; gp15 is also in the cell. (**b**) Probably with the help of gp15, gp16 establishes a DNA translocase. (**c**) About 850 bp of the genome is ratcheted into the cell, causing separation of the translocase from its energy source; DNA translocation stops. (**d**) Transcription, initially by *E. coli* RNA polymerase and then by T7 RNA polymerase, brings the remainder of the 40-kbp genome into the cell.



Gp14 localizes to the outer membrane, presumably forming a channel. The 143-kDa gp16 can then enter the **periplasm**, from where it inserts into the cytoplasmic membrane, thereby completing a protein channel across the cell envelope for DNA translocation. Gp15 is thought to pass through this channel into the cell cytoplasm, although it cannot yet be excluded that the protein has localized to an osmotic shock-resistant part of the periplasm. The natural cross-linking of peptidoglycan in the outer membrane provides a barrier to molecules greater than ~50kDa (12), but the *N*-terminal portion of gp16 is homologous to the active site region of *E. coli sltY*, the soluble lytic transglycosylase Slt70, and this part of the protein may enlarge a hole through the peptidoglycan layer. This presumed activity of gp16 is important only when the conditions of infection favor increased peptidoglycan cross-linking (low temperature, high cell density).

Only when the transmembrane channel has been formed does DNA leave the phage head, but even then only ~850bp of the 40-kb genome enter the cell immediately (13). Thus the often espoused idea that phages are like syringes with their contents under pressure does not apply to T7 (and probably not to any phage). The remainder of the genome is normally translocated into the cell as a result of transcription (see text below). The proton motive force is necessary for the leading part of the genome to enter the cell, energy seemingly being required both for the insertion of gp16 into the cytoplasmic membrane and to power the motor that ratchets T7 DNA into the cell. The motor is currently thought to consist of gp16 and gp15: certain gene *16* missense mutants uncouple genome entry from transcription and cause the entire 40-kb genome to enter the cell at a constant ~70bp/s at 30°C (14); gene *15* mutants have also been shown to affect the kinetics of genome entry.

The leading 850 bp of T7 DNA that enter the cell contain three strong *E. coli* promoters and a T7 promoter. Transcription from any of the *E. coli* promoters not only makes RNAs for class I gene expression, but it also pulls the first 19% of the genome (to the Rho-independent terminator TE) into the cell. The rate of genome entry at this stage is ~40bp/s at 30°C, the same rate that *E. coli* RNA polymerase transcribes DNA *in vitro* under optimal conditions (13). Again via transcription, T7 RNA polymerase pulls the remainder of the phage genome into the cell at ~250bp/s, simultaneously making mRNAs for class II and class III gene expression. About 10 min, one-third of the latent period, is occupied with the complete internalization of the T7 genome. The slow entry may play a role in control of gene expression, but the most compelling explanation for the coupling of genome entry to transcription is that the first gene transcribed is *0.3*, whose product binds and inactivates Type I restriction enzymes before most of the genome enters the cell. T7 normally is fully resistant

to Type I restriction, but its genome is rapidly degraded if introduced into the cell from a lambda phage particle (13).

T7 has no defense, other than lacking the pertinent sequences, against Type II restriction enzymes, although some members of the T7 family do grow on hosts that contain Type II enzymes, even though their genomes do contain cognate recognition sites. T7 is also sensitive to the **P1 phage**-encoded Type III enzyme, but not to that of *Eco*P15, whose methylase recognition sequence is 5′-CAGCAG/5′-CTGCTG. The *Eco*P15 restriction enzyme requires two copies of this sequence in opposite orientations, but the 36 copies of this hexamer are all oriented the same way in the T7 genome (15). T3 is restricted by *Eco*P15, because its genome contains the recognition sequence in both orientations.

In vitro, the linear T7 genome is susceptible to degradation by the **RecBCD** nuclease. Gp5.9 protein binds stoichiometrically to RecBCD holoenzyme, but not to its isolated subunits, and inhibits all its **nuclease** and ATPase activities. Gp5.9 is a class II protein and is not found in the phage particle, so how the entering T7 genome is protected from RecBCD at the beginning of the infection is unknown. Furthermore, gene *5.9* appears to be nonessential for growth in RecBCD-containing cells (16); either the ends of T7 DNA are protected from the RecBCD, or a second but unknown T7 gene may have an activity comparable to that of gp5.9.

T7 primary transcripts are processed by RNase III at ten sites, although the enzyme is not essential for phage development (3). Except for the gene *1* RNA, the processed RNAs have multiple **cistrons**, but there is no evidence for polarity effects due to amber mutations. In the late region of the genome, this can be easily explained by the fast rate of transcription by T7 RNA polymerase. T7 RNAs are stable throughout the infection, possibly due to the formation of base-paired structures at the 3′ ends of the processed primary transcripts. The *0.3* mRNA, which is used *in vivo* for only about 8 min of infection, is said to be competent for *in vitro* translation experiments even when isolated late after infection. How the translational shut-off of class I and class II proteins is achieved is unknown.

In addition to gp0.3 and gp1, the phage RNA polymerase, other early gene products include gp0.7, a **serine/threonine kinase** that **phosphorylates** several host proteins involved in translation and RNA metabolism, including RNase III (17). Distinct from its kinase activity, gp0.7 also causes the abrupt shut-off of host-catalyzed transcription (18). Despite its multiple functions, mutants lacking *0.7* grow better than wild-type in rich medium in most laboratory strains. However, *0.7* is necessary for phage growth under nutrient-poor conditions. Gp1.2 inhibits *E. coli* dGTPase (*dgt*), and gp1.3 is a DNA Ligase; these proteins are essential only if the host overexpresses *dgt* or is ligase-defective, respectively.

The X-ray crystallography structure of the 883-residue T7 RNA polymerase has been determined at 3.3 Å resolution (19). About 45% of the molecule shows extensive structural homology to the **Klenow fragment** of *E. coli* **DNA polymerase** I and resembles a cupped right hand, with finger, palm, and thumb domains that form a cleft. Amino acid residues in the cleft can be **cross-linked** to the promoter. The thumb subdomain wraps around the template strand and probably confers processive synthesis of RNA. A loop of residues 743 to 773 project out from the fingers domain of the cleft and contain promoter-specificity determinants.

T7 promoters consist of a highly conserved 23-bp sequence that runs from nucleotides –17 to +6 relative to the transcription start site. Two functional domains have been recognized, an initiation domain that spans positions –5 to +6, and a binding domain between –17 and –6 (20). The Asn748Asp mutant form of the T7 enzyme recognizes T3 (and not T7) promoters; conversely, changing positions –10 and –11 of a T7 promoter to those found in T3 promoters abolishes T7 promoter activity, but allows full recognition by T3 polymerase (21, 22). Similarly, positions –8 and –9 are the primary determinants of SP6 versus T7 promoters (23). A second specificity determinant that has been recognized is residue 758 of the T7 enzyme, which interacts with the promoter at

position –8 (24).

There are 17 T7 promoters in the phage genome, ten upstream of class II genes, five upstream of class III genes, and two, ø *OL* and ø*OR*, near the genome ends. ø*OL* is used only weakly, while ø*OR* is a strong, consensus promoter that can provide an mRNA only for gene *19.5*; it has been proposed that ø*OL* and ø*OR* are replication promoters, but neither one is essential for viability. There is a major terminator Tø for T7 RNA polymerase just downstream of gene *10*. All transcripts from class II promoters and those from the class III promoters ø*6.5*, ø*9*, and ø*10* terminate at Tø with about 85% efficiency (25). This results in a nested set of mRNAs, all of which contain gene *10* near their 3′ end, thereby providing the necessary high dosage of the major capsid protein mRNA. Readthrough of the terminator Tø is programmed into the T7 developmental cycle; the approximately 15% of transcripts that fail to terminate at Tø include RNA for the essential genes *11* and *12*, which are not expressed at high levels (3).

Class III promoters all have the consensus sequence, whereas class II promoters vary at one to three positions. Class II promoters produce less mRNA, mainly because of an increased frequency of abortive initiation, which is further enhanced by formation of a complex of T7 RNA polymerase (gp1) with lysozyme (gp3.5). Gp3.5 exerts its effects on T7 RNA polymerase by preventing its isomerization from the initiation to elongation complex (26). Abortive initiation is the main reason why class II promoters appear to be weaker than class III promoters, and why class II gene expression is selectively shut off during infection. The inhibitory gp1:gp3.5 interaction constitutes a feedback loop because gene *3.5* is a class II gene that is expressed by gp1. This interaction is important, although not essential, in the T7 life cycle: Its absence reduces RNA polymerase function in both initiating DNA replication and in the maturation/packaging steps of replicated DNA.

The crystal structure of gp3.5 has been determined to 2.7 Å and that of a mutant protein lacking residues 2 to 5 to 2.2 Å (27). The *N*-terminal eight amino acid residues, together with a region containing residues 30 to 42, form a surface that interacts with T7 RNA polymerase. Gp3.5 is a single-domain globular protein first characterized as possessing a **lysozyme** -like activity, shown later to be a zinc-containing amidase. Zinc is necessary for catalytic activity, but not for polymerase binding. Amidase activity is important, but not essential, for cell lysis by T7; amidase mutants only delay lysis, and the major role of the amidase activity of gp3.5 is to release phage from cell debris. The lysis defect observed with gene *3.5* mutants that fail to interact with gene *1* is due to defects in DNA replication and maturation; a comparable lysis defect is also observed with mutants defective in other replication functions.

4.2. DNA Replication

DNA replication *in vivo* requires T7 RNA polymerase, DNA polymerase, primase/helicase, single-stranded DNA binding protein, endonuclease, and exonuclease. Two other phage gene products are less directly required: The importance of the gp1:gp3.5 interaction mentioned above may be to stall RNA polymerase near the promoter(s) in an origin, causing the origin DNA to remain strand-separated and to allow assembly of the replication machinery. The gene *2* protein is also normally required in DNA replication to inhibit *E. coli* RNA polymerase, which, although transcriptionally inactive by the time DNA synthesis begins, can interfere with the late steps of replication. Phage replication is independent of all *E. coli* DNA replication genes, including topoisomerases; the latter is due to the T7 genome not being circularized. However, *E. coli* thioredoxin is absolutely required for T7 replication; the protein makes a 1:1 complex with T7 gp5 to form a highly processive DNA polymerase. Purified gp5 has extremely limited DNA polymerase and 3′ → 5′ exonuclease activities. The presence of thioredoxin increases the processivity of the polymerase 1000-fold (to a level equivalent to more complicated DNA polymerases that require a **sliding clamp** for processive synthesis), thereby also increasing the overall rate of synthesis (28). Stimulation by thioredoxin is independent of its **redox** capacity, although oxidized thioredoxin does not bind to gp5. Replacing either active-site cysteine residue in thioredoxin with Ser or Ala reduces its affinity for gp5 but does not reduce the maximum level of processivity increase (29). Addition of gp2.5 to T7 DNA polymerase further increases the processivity and also increases the specific rate of DNA synthesis *in*

vitro (30). A remarkable crystal structure of T7 DNA polymerase, complexed with a primer-template and nucleoside triphosphate in the polymerase active site, has recently been generated at 2.2 Å resolution (31). Like the RNA polymerase, T7 DNA polymerase shares extensive sequence homology with *E. coli* DNA polymerase I, and both are members of the Pol I structural family. The addition of the l76 residue thioredoxin-binding domain of gp5 to the comparable region of Pol I makes a protein that forms a 1:1 complex with thioredoxin. Interestingly, and consistent with the function of thioredoxin in T7 DNA polymerase, both Pol I and the modified enzyme synthesize DNA distributively, but addition of thioredoxin results in a large increase in processivity by the modified enzyme (32).

The primary origin of replication is an A + T-rich region about 15% from the genetic left end, upstream of and overlapping the 5′ end of gene *1.1*. This origin is not essential, because deletion mutants lacking this region grow well. Several secondary origins have been identified using electron microscopy of replicating molecules and by both *in vivo* and *in vitro* plasmid replication assays (33, 34). The *øOR* secondary origin can also be deleted from a primary origin mutant; it is likely that several sequences can be used to initiate replication under normal laboratory conditions, and perhaps all potential origins can be active under different growth conditions. Replication from the primary origin is bidirectional on the linear T7 genome, although the leftward moving fork is assembled later than the rightward fork. Electron microscopy has revealed replication bubbles and Y-shaped molecules (the origin is closer to the left end), and multiple initiation events on the same molecule have been observed.

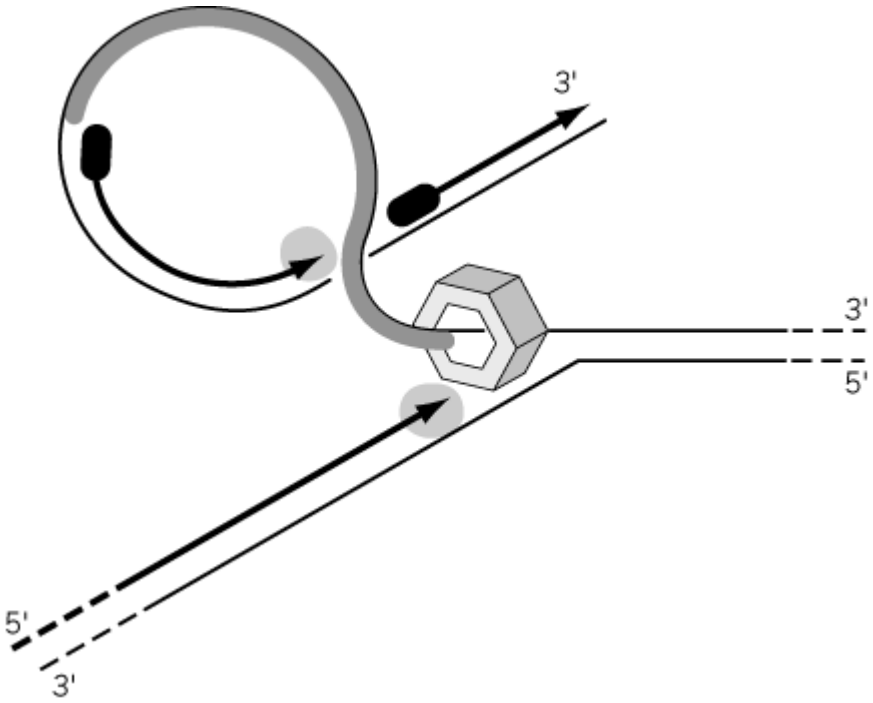
The replicated monomer genome necessarily has single-stranded 3′ ends; degradation of the RNA primer and complete erosion of the terminal repeat into unique sequences on the newly synthesized strand is normally catalyzed by gp6, a 5′ → 3′ double-stranded exonuclease. The direct repeat allows the formation of linear concatemers; although exonuclease-treated genomes can be circularized *in vitro*, circular forms of replicating T7 DNA are extremely rare *in vivo*, and linear molecules of three to ten genome equivalents, with only a single copy of the 160-bp terminal repeat at each genome junction, are found. As replication proceeds, the linear concatemers are converted into highly branched recombining and replicating structures that contain >100 genome equivalents. Recombination is independent of the host recombination functions and, in addition to replication functions, requires the single-strand DNA binding and strand-exchange properties of gp2.5, plus the gp4 helicase, the gp6 exonuclease, and the **Holliday junction**-resolving activity of the gp3 endonuclease (35-37). The latter ultimately resolves the recombining DNA into linear concatemers that are the substrate for the packaging machinery. Gp2.5 interacts physically with T7 DNA polymerase, and both recombination and bidirectional replication requires gp2.5. In addition to their role in replication and recombination, the gp3 and gp6 nucleases completely degrade the host chromosome; ~80% of the nucleotides necessary for replication are derived from *E. coli* DNA. Thus T7 DNA replication and recombination are inseparable. The overall rate of T7 DNA synthesis is very fast, and more than 200 genome equivalents are made in less than 10 min at 30°C. This high rate suggests that numerous replication forks are active, consistent with the idea that recombination intermediates can be converted into replication forks, as in **T4 phage**-infected cells. However, unlike T4 (and many other phages), T7 DNA replication is not necessary for late transcription (6). Mutants that fail to replicate their DNA have normal patterns of transcription; in fact, transcription of T7 DNA is almost over before DNA replication is initiated. The many nicks that accompany DNA replication and recombination are sealed by DNA ligase, either of the host or of T7. T7 ligase mutants plate normally, although their burst size is reduced on most *E. coli* strains. When *E. coli* ligase is defective, however, T7 ligase (gp1.3) becomes an essential protein (38).

T7 replication is extremely fast and, unless it is blocked, *E. coli* chromosome-derived nucleotides cannot be detected as acid-soluble material. Thymidine incorporation into DNA is a misleading measure of T7 replication rates because the nucleotide pools vary enormously throughout an infection. If the onset of replication is delayed, as after infection by *3.5* mutants, thymidine-uptake measurements underestimate the rate of DNA synthesis. Conversely, when nucleotide pools are

nearly exhausted near the time of cell lysis, thymidine uptake measurements grossly overestimate the replication rate.

Much of our understanding of T7 DNA replication has come from *in vitro* studies (Fig. 3). At the primary origin of replication, T7 RNA polymerase synthesizes primers of 10 to 60 nucleotides from both promoters upstream of the origin; there is no defined site where RNA synthesis stops and DNA synthesis begins. A hexamer of the gp4 primase/helicase, bound to the single-stranded DNA through its central hole, translocates 5′ → 3′ on the Okazaki fragment template strand (39). Hydrolysis of ribo- or deoxynucleoside triphosphates (dTTP being preferred *in vitro*) can be used as the energy source to unwind unreplicated DNA. Based upon the similarity of the nucleotide-binding change mechanism of the helicase with that of the F_1F_0-ATPase (see ATP Synthase), it has been suggested that rotational movement around the single-stranded DNA leads to unidirectional translocation along single-stranded DNA and consequent unwinding of double-stranded DNA (40). The helicase also interacts physically with both gp2.5 and DNA polymerase, to help make DNA synthesis more processive. Relative to the gp4B helicase, gp4A contains an extra 63 amino acid residues at the *N*-terminus that confer primase activity. The *N*-terminal extension contains a **zinc finger** that interacts with the sequences 3′-CTGG(G/T) or 3′-CTGTG in single-stranded DNA and synthesizes ribonucleotide primers 5′-ACC(A/C) or 5′-ACAC, which serve to initiate synthesis of Okazaki fragments (41). Mixed hexamers of gp4A and gp4B are formed *in vitro*, and phage mutants that make only gp4A are viable, suggesting that helicase unwinding is not constant, periodically pausing to allow primer synthesis. Synthesis on the leading and lagging DNA strands is tightly coupled. A replisomal complex consisting of T7 DNA polymerase, primase/helicase, and single-stranded DNA-binding protein simultaneously synthesizes both strands of DNA (42). Measurements of leading and lagging strand synthesis showed that they are coupled and are synthesized by distinct DNA polymerase molecules. The lagging strand polymerase cycles from one Okazaki fragment to the next; the length of the Okazaki fragments, which are initiated by primase, are thought to be controlled by single-stranded DNA-binding protein. Furthermore, the DNA loop predicted by coordinated synthesis on leading and lagging strands was observed using electron microscopy.

Figure 3. Schematic of a T7 DNA replication fork. Two molecules of DNA polymerase (gray circles) synthesize processively the leading and lagging strands (thick lines). A hexamer of the primase-helicase (nut-shaped) unwinds the template duplex ahead of the leading strand polymerase and synthesizes the RNA primers (black ovals). Single-stranded DNA is coated with single-stranded DNA binding protein (gray stripe). Note that all three components, DNA polymerase, primase-helicase, and single-stranded DNA binding protein, must interact for coupling of leading and lagging strand synthesis (42).



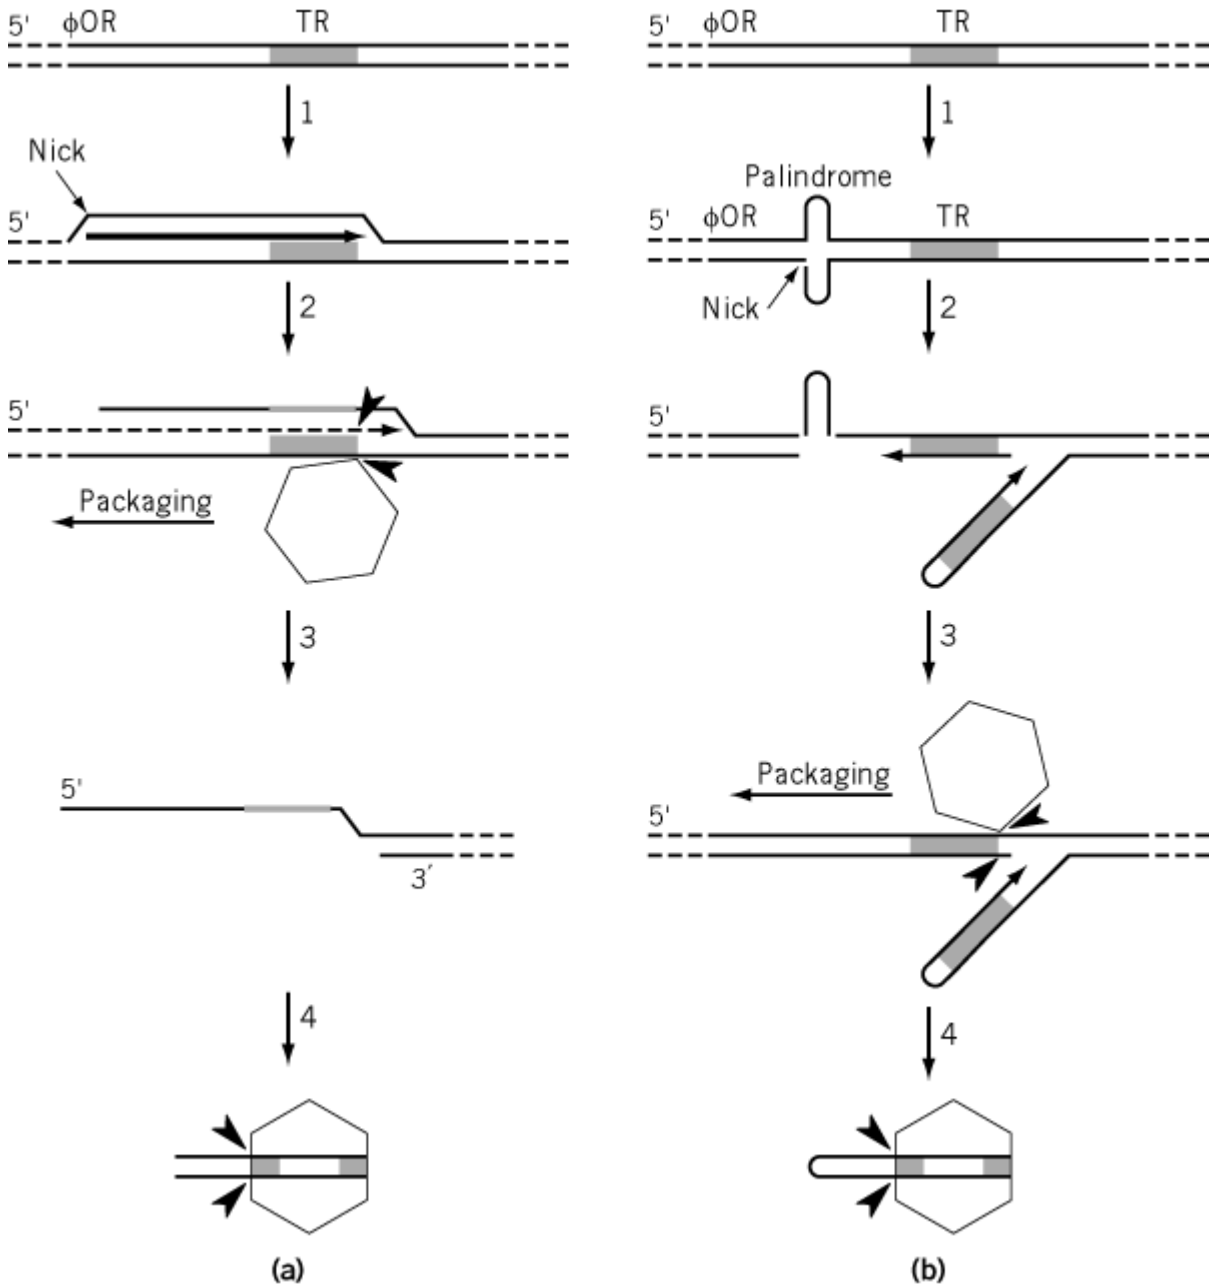
4.3. DNA Maturation and Phage Morphogenesis

Packaging of T7 DNA occurs using preformed proheads. Assembly of these may be initiated using gp10 around a scaffold of gp9, generating an incomplete prohead shell, a process that would be followed by insertion of the connector–core complex (gp8-[gp14+gp15+gp16]). Alternatively, the connector–core complex may serve to nucleate the assembly of the scaffold and the capsid protein. Unlike several other phages, T7 is known to grow in *groE* mutants, but mutants defective in other **chaperonins** do not appear to have been tested and could facilitate the formation of the connector. The T3 connector (which can substitute for T7 gp8 in an otherwise T7 particle), when isolated from phage particles or filled heads, exhibits 12-fold rotational symmetry, but T7 12-mers and 13-mers are found when gene *8* is expressed from a clone (43). It has been suggested that the 13-mer is incorporated into proheads and converted into the 12-mer during DNA packaging, perhaps triggering conversion of the prohead into the mature capsid, with the concomitant loss of the scaffolding protein to allow DNA packaging (44). How the multitiered core structure is assembled is not yet known.

The substrate for DNA packaging is a concatemer consisting of about 5 to 10 genome equivalents, but each genome requires a second copy of the terminal repeat to be synthesized to generate the mature, full-length genome (Fig. 4). Transcription from the ø *OR* promoter is known to cross the terminal repeat, but it pauses and terminates shortly thereafter. Termination at this site requires gp3.5 lysozyme, the absence of this protein leads to a defect in DNA maturation and packaging (45, 46). Transcription presumably originates from the upstream promoters ø *17* and/or ø*13* in ø *OR* deletion mutants. Using an *in vitro* system, packaging was shown to be dependent on transcription, and the demonstrated specificity for packaging concatemeric DNA resides in the transcribing polymerase. Furthermore, an interaction between T7 RNA polymerase and the packaging protein gp19 has been shown by genetic **suppressor** analysis (47).

Figure 4. Two models for duplicating the terminal repeat and packaging T7 DNA (**a**) 1. Transcription from øOR allows a nick to be made in the displaced nontemplate strand, providing a 3′-OH. 2. Strand-displacement DNA synthesis crosses the terminal repeat. 3. DNA packaging is initiated by a prohead and terminase proteins (gp18 and gp19), which create a double-strand break, forming the mature right end of the genome. Removal of the left-hand

genome (via packaging) reveals a template-primer on the genome to the right for DNA synthesis to complete duplication of the terminal repeat. 4. Packaging is terminated by a double-strand cleavage forming the mature left end of the genome and release of a small duplex DNA. (Adapted from Ref. 48.) (**b**) 1. The base of a palindrome in genomic DNA is nicked, allowing a hairpin with a 3′-OH to form; the position of the nick is about 350 bp downstream of *øOR*. 2. DNA synthesis extends the hairpin and crosses the terminal repeat. Primase-initiated DNA synthesis on the other strand completes duplication of the terminal repeat. 3. DNA packaging is initiated by a prohead and terminase proteins (gp18 and gp19), which create a double-strand break, forming the mature right end of the genome. 4. Packaging is terminated by a double-strand cleavage, forming the mature left end of the genome, and release of a small single-stranded hairpin DNA. (Adapted from Ref. 49.)



One model posits that a nick is made in the single-stranded, nontemplate DNA in a transcription complex (48). This nick can be extended by strand-displacement DNA synthesis to cross the terminal repeat. Packaging is then initiated by a double-strand break to form the mature, genetic right end of the DNA, and it proceeds leftward through that genome. The 3′-OH on a genome not yet packaged can now serve to prime DNA synthesis on the displaced strand, to complete the duplication of the terminal repeat; the mature genetic left end of the genome is formed by a second double-strand

cleavage event. This idea does not explain the presence of a novel hairpin structure that is found in replicating DNA and appears to be a kinetic intermediate in the formation of the genetic left end (49). A second model suggests that a nick is created in the template strand, creating a 3′-OH to serve as a primer for DNA synthesis. Synthesis can then duplicate the terminal repeat and terminate whenever the replication fork encounters a prohead that is in the process of encapsidating DNA. This DNA synthesis generates a single strand that can be a template for primase-primed DNA synthesis, enabling the second strand of the terminal repeat to be copied. Double-strand breaks form both ends of the mature genome. This idea (49) accounts for the existence of the hairpin structure that is found attached to an immature genome genetic left end, but it does not account for the role of transcription and gp3.5-mediated transcription termination in DNA packaging. The model is also not supported by the fact that the site of nicking (and thus hairpin formation) can be deleted in phage that exhibit no severe growth defect. Perhaps elements of both models are correct, but it is likely that T7 has evolved more than one mechanism to duplicate the terminal repeat and generate a mature genetic left end. Secondary mechanisms certainly exist, because deletion mutants that remove more than about 15% of the T7 genome (the minimum size that is packagable) do not recognize the normal genetic left end in concatemeric DNA and package a genome whose left end therefore lies within normally internal sequences.

Gp18 and gp19 form the packaging enzyme; six molecules of gp19 associate with the connector of the prohead with the help of ATP as an **allosteric** effector (50). The association may be with the inner face of the connector, which has six domains surrounding the channel (9). The small subunit gp18 associates with the DNA, which then combines with the prohead gp19 complex. A site-specific, double-strand break on a DNA concatemer then initiates the packaging process. This endonuclease activity requires proheads for specificity; in their absence, gp19 alone possesses a nonspecific endonuclease activity that is inhibited by added gp18. Translocation of DNA into the prohead is driven by ATP hydrolysis at an estimated rate of 350 bp/s at 30°C, and 1.8 bp of DNA is packaged per ATP molecule hydrolyzed (50-52).

Despite the fact that lysis of the T7-infected host cell is more abrupt and complete than cells infected by most other phages, little is known of the process. Genes *3.5* and *17.5* are known to be required, perhaps together with *18.5* and the hypothetical *18.7*, the latter potentially being the T7 homologues of l *Rz* and *Rz1*. Gp17.5 appears to be the T7 holin, and it may disrupt the membrane to form nonrefractile cell ghosts, allowing access of gp3.5 to the peptidoglycan to effect lysis and release of phage from cell debris (53). Lysis is only slightly delayed by *3.5* deletion mutants, however, and mutants defective in DNA replication are equally delayed for lysis. These observations suggest that some other factor, perhaps a product of DNA replication or maturation, is responsible for initiating cell lysis.

Aside from lysis, the entire T7 growth cycle has been modeled as a coupled set of 93 ordinary differential equations, using parameters derived directly from experimental data (54). The computer simulation treats the T7 genome as containing 122 distinct genetic elements and accurately portrays the various stages of T7 development, including genome entry, gene expression, the switch from *E. coli* to T7 RNA polymerase-mediated transcription, and DNA replication. The latest version of the model allows a predictive assessment of the fitness (ie, phage production per unit time) of any mutant T7, including those whose genetic elements have been scrambled relative to the wild type.

5. Host–Parasite Interactions

A number of natural *E. coli* strains, as well as other enterobacterial hosts, are nonpermissive for T7. In many cases, the nonpermissive host carries a prophage or plasmid, but in other situations the host gene(s) involved have not been identified. The most interesting cases are those where inhibition of phage growth is not due to DNA restriction or defects in adsorption, but where the initial stages of infection appear normal but later events are grossly aberrant (55).

The l *rex* genes inhibit the growth of a *5.5* missense mutant of T7, perhaps by a similar mechanism

to that of *rex*-exclusion of T4 *r*II mutants (3, 16, 56). Gp5.5 also binds to the small DNA-binding protein H-NS; although the latter is not required for T7 development, an H-NS mutant has been isolated that then requires T7 be 5.5^+ for growth (56). It is not known whether the above observations are related beyond the commonality of gp5.5. The plasmid Col Ib contains a gene that inhibits the growth of T7 *0.7* mutants (57). These mutants also fail to grow on certain *rpoC* mutants of *E. coli*, and it seems likely that the defect in both cases involves *E. coli* RNA polymerase. To explain why the gp3 endonuclease does not degrade T7 DNA when it is degrading the bacterial chromosome, it was originally suggested that RNA polymerase, when bound to DNA, provides some signal to trigger degradation (58). Perhaps gene *2* fails to inactivate the mutant or Col Ib-modified RNA polymerase completely and causes an infection to abort.

Gene *1.2* mutants fail to grow on cells that overexpress *dgt*, a dGTPase; the enzyme is inhibited by gp1.2 (59). The lower dGTP pool size in *dgt* overexpressing mutants (*optA1*) aborts phage DNA replication and triggers breakdown of the intracellular DNA. Suppressors of a gene *1.2* null mutation have been isolated that allow phage growth in *optA1* mutants; these appear to be altered in gene *5*, T7 DNA polymerase. Consistent with this idea is that several T4 gene *43* (DNA polymerase) mutator mutants that have increased $3' \rightarrow 5'$ exonuclease activity also fail to grow on *optA1* mutants (60).

T7 and most of its relatives, T3 being an exception, fail to grow in cells harboring the F plasmid (55). The only F function required for exclusion is *pifA*, a gene that is nonessential for conjugation or plasmid replication or maintenance. The F *pifA* gene interferes with the normal function of T7 genes *1.2* and *10* and causes inhibition of all macromolecular synthesis in abortively infected cells (61). The infection is aborted before about half of the infecting phages have translocated their entire genome into the cell (61); in the remaining half of the population, transcription over the class III region of the genome is grossly aberrant (62). T7 requires three mutations to grow in F-containing cells, a missense or null mutation in gene *1.2* plus two missense mutations in gene *10* (63). T3 gene *1.2* is responsible for that phage growing in the presence of F, and T3 *1.2* mutants respond like wild-type T7 when infecting F-containing strains. However, as in the case of T7, two missense mutations in T3 gene *10* can restore the ability of a *1.2* mutant phage to grow (64). The known functions of genes *1.2* and *10* do not yet provide a clear explanation for the inhibition of phage growth by F *pifA*. The proteins specified by gene *10* are not known to have additional roles beyond capsid shell formation, but normal capsid assembly by gp10 is not required for the infection to abort. The anti-dGTPase activity of gp1.2 also seems unrelated to exclusion by F, and T3 gene *1.2* mutants have been isolated that are excluded by F but retain the ability to grow on *optA1* hosts, and vice versa (65).

In the absence of other phage genes, plasmids expressing either T7 gene *1.2* or gene *10* kill cells containing PifA (66); the dysfunctions that occur as cells are dying are the same as those following an abortive phage infection, suggesting that the phage and F proteins interact with a host function. This cellular function has not been identified; it appears to be the same regardless of whether gp1.2 or gp10 interacts with PifA, and it can be protected by overexpression of the integral inner membrane FxsA protein (67). FxsA has no known independent function, and insertional inactivation or moderate overexpression of *fxsA* provide no obvious cellular phenotype. Nevertheless, if overexpression of an integral membrane protein suppresses F exclusion of T7, it is likely that the cellular location where T7 gp1.2 or gp10 interact with PifA is also the cell membrane.

Another abortive infection that involves expression of gene *10* is growth on *Shigella sonnei* D_2 371-48 (68). T7 and most members of the family fail to grow on this strain; midway through the infection cycle, there is a massive breakdown of the phage DNA, and the infection is aborted. A Q $\rightarrow$ P change at codon 62 of T7 gene *10* prevents DNA degradation and allows phage growth. As in F exclusion of T7, the trigger for the abortive infection appears not to require capsid assembly. T3 grows normally on the *Shigella sonnei* host, even though its capsid protein has the same sequence around codon 62. The difference between T3 and T7 in this context appears to reside in gene *1.3*, DNA ligase. T7-infected *Shigella sonnei* appear to be deficient in ligase activity, and gene *1.3* is

essential for T7 growth even when the gene *10-Q62P* mutation is present. Furthermore, a hybrid T7–T3 phage that contains T3 gene *1.3* productively infects the *Shigella sonnei* strain.

6. T7 as a Tool in Molecular Biology

6.1. Expression Vectors

Many RNAs and proteins can be produced in large quantities in *E. coli* using a gene expression system based on T7 RNA polymerase (69, 70). *E. coli* RNA polymerase does not recognize T7 promoters, and T7 RNA polymerase does not recognize *E. coli* or eukaryotic RNA polymerase promoters, nor does it recognize many sequences as transcription termination sites. T7 RNA polymerase is a single polypeptide chain enzyme that transcribes DNA at ~250bp/s at 30°C and is naturally resistant to rifampicin, an inhibitor of the *E. coli* enzyme. A wide variety of plasmid vectors have been developed for expressing genes under T7 RNA polymerase control, and they are available commercially, currently from Novagen, Stratagene, or Promega. The pET vectors, in particular, have features for a wide variety of cloning and expression projects, and gene *1* has also been cloned under arabinose promoter control in a pBAD plasmid. A typical vector places T7 gene *1* under *lac* promoter control, with the normal T7 promoter for the target gene modified by the addition of a *lac* operator sequence; thus both gene *1* and target gene expression are inducible by the addition of IPTG. If necessary, basal level synthesis of T7 RNA polymerase can be inhibited by the presence of the gene *3.5* plasmids pLysS or pLysE (S and E refer to the orientation [silent or expressed] of gene *3.5* relative to the vector tetracycline promoter). pLysS and pLysE are pACYC184-based plasmids that are compatible with the majority of cloning vector plasmids; pLysE is usually only necessary when the target gene is very toxic to *E. coli*. Addition of **IPTG** induces gene *1* to levels that overcome the inhibitory activity of the pLys plasmids. Use of the pLys plasmids often provides a secondary benefit, in that freeze-thawing cells, or treating them with the nonionic detergent Triton X-100, allows the gp3.5 lysozyme access to the peptidoglycan and promotes efficient cell lysis. In cases where the target gene is extremely toxic, gene *1* can also be delivered via infection by l CE6, a l phage derivative that expresses gene *1* from the l p_L promoter. The most commonly used host for overexpression is BL21(DE3), which contains gene *1* on a l prophage. BL21(DE3) lacks a Type I restriction system and the proteinases Lon and OmpT, features that can help cloning and prevent **protein degradation** during purification. It is not always appreciated that toxic proteins often turn on the *E. coli* SOS response system and induce the prophage from BL21(DE3); in such cases, the *E. coli recA* strain HMS174(DE3) can be a useful host. Other frequent causes of the failure to express at high levels include attempts to induce at saturation density, where the cells are no longer making much protein, and loss of the plasmid itself, or mutation of the target gene, either of which can occur if the gene product is toxic to the cell. The ampicillin used with many vectors can be degraded by any secreted b-**lactamase**, leading to the loss of selection for plasmid maintenance. Vectors that employ other antibiotics are less of a problem, but even these can be abused by serially propagating strains.

6.2. Display Vectors

T7 has also been modified as an epitope or protein display vector that is currently available as part of a kit from Novagen. The phage particle is stable to 1% SDS, 4 M urea or 2 M **guanidinium** chloride, 10 mM EDTA, 0.1 M **dithiothreitol**, and a pH range from 4 to 10. Note that T7 is not stable to the concentrations of acetic acid commonly used with the filamentous phage display systems, but the procedures for selecting T7 from a display library are otherwise comparable. The stability of the phage particle, plus the fact that the capsid protein gp10 exists in two forms, gp10A and gp10B, which are both incorporated into the phage particle, combine to make T7 a useful display tool. The frameshifted, *C*-terminal extension of gp10B is exposed on the outer faces of the icosahedral capsid, but it is not essential for phage growth; viable phage mutants exist that contain only gp10A or only gp10B. The usual display vectors make no gp10A and a truncated form of gp10B. Cloning sites have been introduced at the 3′ end of the modified gene *10B*, and a very high efficiency *in vitro* packaging extract is available. Foreign *C*-terminal extensions of up to about 50 amino acid residues have been engineered to replace the natural C-terminal extension of gp10B, and the resulting phages then

contain 415 copies of the fusion protein on the capsid surface. Extensions longer than about 50 residues can also be made, but these require use of a complementing plasmid that supplies gp10A; using current protocols, a 1200-amino-acid residue extension has been displayed on the phage surface at an average copy number of 0.1 to 1 per phage particle. Note that there is a size limit on the phage genome for efficient packaging into viable particles, and the T7 strains used to display short or long extensions are different.

6.3. A Vector for Studying Codon Usage

The gene *9* mRNA has been manipulated to provide vectors for examining the effects of rare, or low-usage, codons. Insertions can be made after codon 13, 223, or 307 of a 313-codon test gene (71). Insertion of nine consecutive CUA leucine codons after codon 13, but not after codons 223 or 307, strongly inhibited translation of the modified RNA, without concomitant inhibition of translation of other CUA-containing mRNAs. Surprisingly, this elegant system has not been widely employed to examine the effects of other low-usage codons.

T-Box Genes

T-box genes are members of a rapidly growing and highly conserved family of transcription factors that share a region of homology to the **DNA-binding** domain (T-box) of the mouse *Brachyury* (or *T*) gene product (1, 2). Most T-box genes have been found through experiments designed to identify genes that have specific activities in embryonic development or that cause developmental defects. T-box genes have been isolated from a wide variety of vertebrates and invertebrates, including *Caenorhabditis elegans* (roundworm), *Drosophila melanogaster*) (fruitfly), ascidians, echinoderms, amphioxus, *Xexonopus laevis* (frog), *Gallus gallus* (chick), *Danio rerio* (zebrafish), *Mus musculus* (mouse), and humans. T-box genes are expressed during gastrulation and organogenesis in derivatives of all three germ layers (ie, ectoderm, mesoderm, and endoderm). During embryogenesis, the spatial and temporal expression patterns of T-box genes are unique, although overlapping, indicating that they are differentially regulated during development (3). Mutations in T-box genes have been associated with defects of development in *Drosophila* (4), zebrafish (5), mouse (6), and humans (7-9). **Phylogenetic** analyses suggest that the origin of the T-box gene family predates the divergence of arthropods and chordates from a common ancestor more than 600 million years ago (10). Consequently, it is likely that T-box genes play critical roles in the development of all animal species. Identifying the elements that control T-box gene expression and those that are activated by T-box gene products are major areas of investigation.

1. The Brachyury (T) Gene

In 1927, Dobrovolskïa-Zavadskaïa first described the phenotype of a semidominant mouse mutant with a short, often slightly kinked tail (11). He named this locus *Brachyury* (Greek, *short-tail*) or *T* (*tail*). Mice that were heterozygous for a mutation at the *T* locus had only short tails, while homozygous *Brachyury* mutants were much more severely affected. They had a thickened primitive streak and lacked a notochord, and the mesoderm posterior to somite 7 was abnormal or absent. Additionally, the allantois of homozygotes failed to fuse with the chorion, causing embryonic death at 10.5 days postcoitum. Although *Brachyury* was one of the earliest well-documented mouse mutants, its molecular basis was not characterized for more than 60 years.

The mouse *T* gene, **cloned** in 1990, is the best studied of the T-box genes. It encodes a protein of 436 amino acid residues that localizes to the nucleus and activates transcription (6). The DNA-binding domain (T-box) of T is composed of 180 residues located in the amino-terminal portion of the protein. Analysis of deletion mutants indicates there are two activation domains and two repressor domains located toward the carboxyl terminus. X-ray crystallography demonstrates that the T-box of the frog homologue of *T, Xbra*, binds as a dimer to a 24-nucleotide **palindromic** DNA duplex, interacting with the major and minor grooves of DNA (12). The mechanism by which the T protein binds DNA appears to be unique among known transcription factors (12).

Brachyury is caused by a 200-kbp deletion that removes the entire *T* gene and effectively produces a null mutation. Consequently, the observed defects are thought to result from haploinsufficiency of T protein. In contrast, other *T* alleles (eg, T^{wis}, T^{c}, T^{c-2H}) are due to insertions and deletions that cause frameshift mutations and truncated T proteins (6, 13). These alleles produce more severe developmental defects and may act as dominant negative mutations (ie, the mutant protein perturbs the function of the normal protein). Homologues of the *T* gene have been isolated in human (*T*), frog (*Xbra*), chick (*T*), and zebrafish (*no tail* (*ntl*) or *zf-T*).

The *T* gene is located in a region of mouse chromosome 17 defined by four inversions that are called the *t* **haplotype**. The *t* haplotype contains at least two additional genes, *small t* (*t*) and *Brachyury the second* (*T2*), alleles of which produce phenotypes similar to *Brachyury*. Until about 20 years ago, *t* haplotypes were thought to be mutant alleles of the *T* locus. However, genetic and molecular tools have shown that the *t* haplotype is a chromosomal region containing many different genes that affect development, male fertility, and recombination (14). Thus, the *T* gene is only one gene within the *t* haplotype.

The main defect in mice lacking T protein is a failure to undergo appropriate gastrulation movements. Studies in the mouse have demonstrated that these aberrant movements during gastrulation may be related to the lack of formation of particular regions of mesoderm (eg, posterior mesoderm). This is consistent with the messenger RNA expression pattern of *T*: transcripts are first detected in the primitive streak at the onset of gastrulation and persist in this area as gastrulation proceeds, and *T* is expressed longer in cells fated to become axial and posterior mesoderm, the same regions absent in *Brachyury* (6, 13).

The actions of *T* homologues in zebrafish (*zf-T*) and frog (*Xbra*) appear to be similar to the roles of *T* in mouse, suggesting that *T* has been conserved functionally. Mutations in *zf-T* produce a phenotype similar to *Brachyury* in which caudal mesoderm is deficient (5). Overexpression of a dominant-negative *Xbra* construct produces a mutant phenotype in *Xenopus* that resembles homozygous *T* mutants in mouse and zebrafish (15). Mutations in the *dm-Trg*, the *Drosophila* ortholog of *T* (orthologous genes are genes that are direct descendants of a common ancestor), affect posterior structures that may be analogous to the posterior structures of vertebrates (4).

The *T* gene is an immediate-early response gene (ie, transcription is directly activated by a signal transduction pathway). In frog, *Xbra* can be activated by mesoderm-inducing factors, such as members of the transforming growth factor b family (eg, activin) and the fibroblast growth factor family. Furthermore, *Xbra* can alter the fate cells in a dose-dependent fashion (16). Thus, *T* genes appear to control the specification and differentiation of mesoderm subpopulations in the developing embryo.

2. The T-Box Gene Family

For a brief period of time, the *T* gene and its orthologs were thought to be the only members of a newly described family of transcription factors. However, further characterization of the *T* gene stimulated a search for, and the eventual isolation of many additional genes sharing a region of homology with the DNA-binding domain of the T protein. These genes compose the T-box gene family (Table 1). The largest number of known T-box genes have been identified in the mouse. However, the first *T* homologue to be identified, *optomotor blind* (*OMB*), was isolated in a *Drosophila* mutant with abnormal optomotor-turning behavior and an inversion on the X chromosome. The original variant allele is produced by a deletion in the **promoter** region that results in a dramatic reduction in *omb* expression. Other omb mutants, such as *bifid* and *Quadroon*, exhibit defects of wings and tergites, respectively. Thus, mutations in T-box genes may disrupt development of only specific subpopulations of mesoderm.

Table 1. Characterized T-Box Genes in Vertebrates and Invertebrates

T-Box Gene	*C. elegans*	*Drosophila*	Sea Urchin	*Ascidian*	*Amphioxus*	*Xenopus*	Newt	Zebrafish	Chick	Mc
		dm-Trg	*su-Ta*	*as-T* *ci-bra*	*amBra-1* *amBra-2*	*Xbra*	*cp*-T	*zf-T*	*ch-T* *ch-TbxT*	*mu*
Tbr-1						*x-Eomes*				*mu* *Tbi*

Tbx15						*nv-Tbox4*			*mu Tb*
Tbx16							*zf-tbx16*		
Tbx17	*ce-tbx17*								
T2			*as-T2*						

Phylogenetic analyses have been useful for reconstructing the evolutionary history and functional relationships among T-box genes. It appears that T-box genes arose from a common progenitor present in the most recent common ancestor of extant metazoans. Among different family members, the size of the T-box domain ranges from approximately 180–190 residues, and the amino acid sequence is highly conserved. However, the T-box may be located at various positions within each protein, and sequence similarities outside of the T-box are observed only for closely related family members. Thus, it appears that the DNA-binding activity between T-box family members has been retained, while the domains that may be involved in protein–protein interactions have diversified.

There are substantial data suggesting the existence of distinct subfamilies (eg, *T, Tbx2 / 3 / 4 / 5, Tbx6, Tbx1*, and *Tbr* subfamilies) of more closely related T-box genes that exhibit overlapping expression patterns and possibly functional similarities. Classification of specific T-box genes into subfamilies differs, depending on whether the genomic structure or T-box amino acid sequences are assessed (17). Most discrepancies arise, however, when distantly related genes are compared. For more closely related genes, different classification schemes produce similar results. As additional T-box genes are isolated and characterized, the complexity of subfamilies will likely increase.

3. The Role of T-Box Genes in Development

T-box genes have been implicated in a wide variety of developmental processes. The T-box genes *Tbx2, Tbx3, Tbx4*, and *Tbx5*, have well-defined orthologs in chick, mouse, and human. They appear to have arisen from an ancestral gene, *TBX2 / 3 / 4 / 5*, common to bony fishes and tetrapods.

Unequal **crossing over** produced the orthologous and tightly linked pairs *Tbx2 / 3* and *Tbx4 / 5*. Subsequent duplication of the chromosomal region generated *Tbx2/Tbx4* and *Tbx3/Tbx5* (10). Expression patterns of these T-box genes have been well characterized in chick and mouse[3], and some data are available for humans (7-9). Although there is moderate overlap between the expression patterns of nonorthologous genes, the expression patterns of orthologous genes are very similar between species. However, there are important differences between orthologous genes that may reflect functional recruitment of T-box genes for novel functions during evolution. For example, *Tbx4* and *Tbx5* are not expressed in chick allantois, but are expressed in the allantois of the mouse, suggesting that they may have been recruited in the evolution of the mammalian placental unit.

Tbx5 and *Tbx4* are broadly expressed in the developing embryo, although a major focus of investigation has been the role of *Tbx5* and *Tbx4* in vertebrate limb development (18, 19). *Tbx5* and *Tbx4* are expressed in the lateral plate mesoderm prior to limb bud initiation. In the chick and mouse, *Tbx5* is expressed exclusively in the forelimb, while *Tbx4* expression is limited to the hindlimb. In ectopic limbs induced in chick flank, *Tbx5* and *Tbx4* are differentially expressed in the anterior and posterior halves, respectively (18). These data suggest that forelimb and hindlimb identity may be specified by *Tbx5* and *Tbx4*, respectively (19).

Tbx6 is expressed in the paraxial mesoderm that will eventually form somite precursors. In the absence of *Tbx6*, cells destined to form posterior somites differentiate along a neural pathway (20). Thus, *Tbx6* appears to be required for specification of posterior paraxial mesoderm. Furthermore, the spatial expression pattern of *Tbx6* partially overlaps the expression pattern of *T*, suggesting that the two proteins may interact. This is further supported by the observation that *Tbx6* expression is downregulated in homozygous *Brachyury* mutants.

Tbx1 expression is first detectable in the anterior embryonic mesoderm. It is expressed in the mesenchyme of the first, second, and third pharyngeal arches and the epithelium of the first, second, and third pharyngeal pouches. The pharyngeal pouches form the tonsils, parathyroids, and thymus.

Tbr1 is expressed only in the postmitotic cells of the developing and adult telencephalon, and it may play a role in the differentiation of cells in the neocortex. Thus, it is somewhat distinct from other T-box genes (21).

4. T-Box Genes and Birth Defects

The medical importance of T-box genes as a cause of human birth defects is well established. Mutations in T-box genes have been associated with two autosomal dominant multiple birth-defect syndromes. Mutations in *TBX3* cause limb, apocrine, genital, and dental defects in ulnar–mammary syndrome (UMS) (7), and mutations in *TBX5* cause limb and heart defects in Holt–Oram syndrome (HOS) (8, 9). Most of the mutations observed in *TBX3* and *TBX5* are small insertions or deletions that produce frameshifts and a truncated protein product. It has therefore been suggested that UMS and HOS are caused by haploinsufficiency of TBX3 and TBX5 proteins, respectively. Missense mutations have also been identified in *TBX3* and *TBX5*, although their effects on transcription and/or protein function are unknown.

The tissues affected in individuals with UMS and HOS are a subset of tissues in which *Tbx3* and *Tbx5* are expressed in chick and mouse. In other words, development of most tissues in which *Tbx3* and *Tbx5* are expressed is normal in individuals with these conditions. This suggests that different tissues may require quantitatively different levels of normal TBX3 or TBX5 protein. Alternatively, other genes including T-box genes with expression domains overlapping *TBX3* and *TBX5* may be able to compensate for reduced levels of normal TBX3 and TBX5 protein. Such functional redundancy is also observed for other families of transcription factors that play prominent roles in development (eg, HOX genes).

The limb defects observed in individuals with UMS are characterized by deletions or duplications of the distal posterior elements of the upper limb. In contrast, the distal anterior skeletal elements of the upper limb are disrupted in individuals with HOS. This suggests that *TBX3* and *TBX5* may partly control patterning of the anteroposterior axis of the vertebrate upper limb. Thus, analogous to the role of *T* in specifying axial mesodermal subpopulations, *TBX3* and *TBX5* may specify mesodermal subpopulations in the upper limb.

The human homologue of *Tbx1* maps to a region of chromosome 22 that is commonly deleted in individuals with velocardiofacial (VCF) syndrome (22). VCF syndrome is characterized by defects of the palate, hypoplasia or aplasia of the thymus, and conotruncal heart anomalies. These defects are concordant with the expression pattern of *Tbx1* in mouse. However, many additional genes are deleted in individuals with VCF, and thus the role of TBX1 haploinsufficiency, if any, is unclear.

Since the identification of *T*, the T-box gene family has grown rapidly. Given the important and diverse roles that T-box genes play in embryogenesis, it will not be surprising if additional human birth-defect syndromes are found to be caused by mutations in T-box genes.

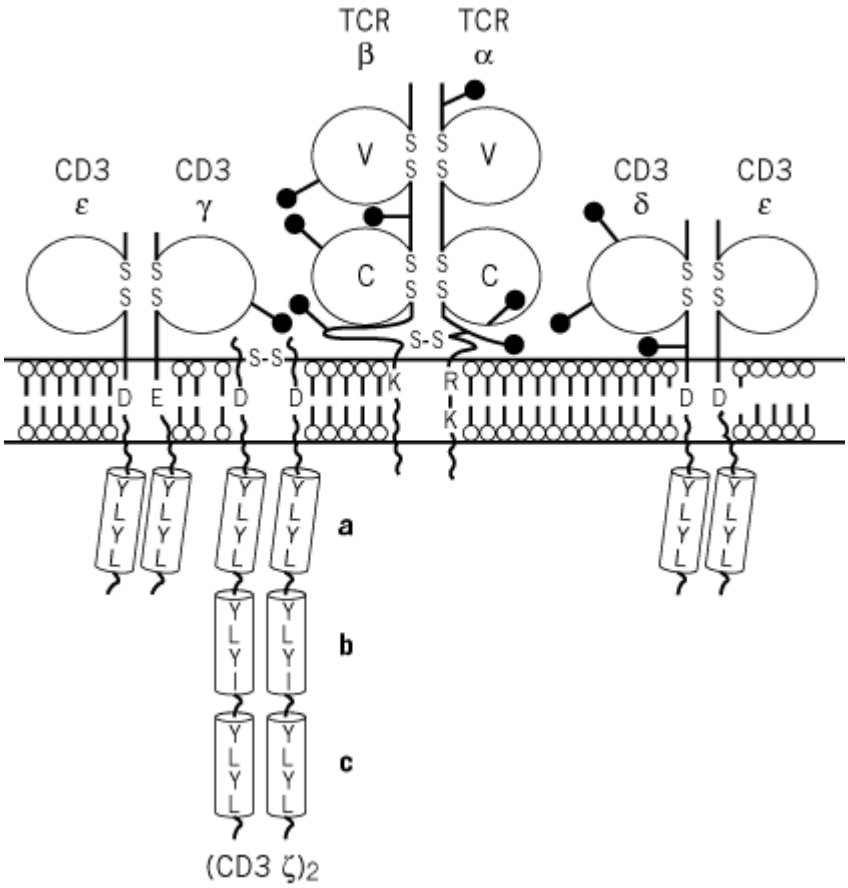
T-Cell Receptor (TCR)

Recognition of **antigens** by T cells is mediated by a specific receptor, called T-cell receptor (TCR). Each cell produces a unique TCR, as in the case of immunoglobulin biosynthesis. TCR has a general architecture resembling that of **immunoglobulins** and the B-cell receptor (BCR), although there are three main differences between them: 1. TCR recognizes **peptides** derived from the protein antigen after it has been processed and presented by antigen-presenting cells in close association with **multiple histocompatibility complex** (MHC) class I or class II molecules. 2. TCRs have no somatic mutations. 3. There is no soluble form of TCR, which always remains expressed at the surface of T cells.

TCR molecules are **disulfide-bonded** heterodimeric structures composed of one a and one b polypeptide chain, each having an immunoglobulin-like organization—that is, a variable NH_2-terminal **variable domain**, a constant C-domain, a hydrophobic **transmembrane** region, and a short cytoplasmic COOH-terminus (Fig. 1). These TCRa b are found on over 90% of circulating T cells; in addition, another type has been described as TCRg d, which has a somewhat similar organization, centered on the corresponding g d heterodimer, that is preferentially expressed in dermal and mucosal tissues.

Figure 1. Schematic domain organization of the TCR. The recognition module is that of a TCRa b. It is expressed at the cell surface with the CD3 signaling module, composed of g, d, ε, z, and h chains, assembled as indicated. CD3 chains contact protein **tyrosine kinases** by their ITAM (immunoreceptor tyrosine-based activation motif) motifs.



The organization of the TCR chain genes, as well as their controlled gene rearrangements by the same RAG1/RAG2 recombinase, are very similar to those of immunoglobulins. In humans, the TCRB locus contains 41 to 46 Vb genes, organized in 24 families, that recombine randomly to two sets of D(6 J)C b gene segments; TCRA has 50 Va genes, an unusually large number of Ja gene segments (56), and one Ca gene. Organization of the TCRD locus is peculiar, in that it is entirely contained within the TCRA locus; when the latter has rearranged, the TCRD locus is completely deleted. TCRD has a VDJ organization, with three Vd, four Jd, and one Cd. Finally the TCRG locus contains six Vg, five Jg, and two Cg genes. Similar to the situation described for the Ig heavy chains, the complementarity determining region 3 (CDR3) of the b chain is the most variable area of T-cell receptors (see Immunoglobulin Structure).

Another similarity to the BCR organization is the close association of the TCR heterodimer with the CD3 signaling module (Fig. 1). CD3 has a complex molecular structure, composed of five discrete polypeptide chains, g, d, ε, z, and h. Three have an external Ig-like domain (although its similarity with immunoglobulin (Ig) sequences is rather low), a transmembrane region, and a small cytoplasmic region. These chains are organized as two heterodimers, gε and dε, and contain on each of their cytoplasmic region one *immunoreceptor tyrosine-based activation motif* (ITAM) that provides interactions with cytosolic protein kinases, which are activated after stimulation of the receptor. Transmembrane regions of the three g, d, and ε chains contain a negatively charged residue that stabilizes the interaction with the TCR, which has positively charged residues in the corresponding transmembrane area. The z chains have only a very short external segment, a transmembrane region, and a long cytoplasmic region that contains three ITAMs that, upon **phosphorylation** by Fyn or Lck, bind and activate an important partner of the T-cell transduction cascade, ZAP 70. They form homodimers or, alternatively, heterodimers with a spliced form known as the h chain.

Two other molecules are of particular interest at the surface of T cells, namely CD4 and CD8, considered to be co-receptors because they bind MHC class II or class I, respectively, of antigen-presenting cells and thus may play an important role in docking the TCR onto the MHC–peptide complex. CD4 is a monomer consisting of four external Ig-like domains; D1 and D2 form a rigid rod 60 Å long, connected to D3 and D4 by a flexible hinge and one cytoplasmic region, which contacts the Lck tyrosine kinase. CD4 binds to the b2 domain MHC class II molecules, independently of the TCR–MHC–peptide complex, although there may be effects on their binding energies. CD8 is a disulfide-bonded a b heterodimer; each chain has a single Ig-like domain and a long extended segment that terminates with a cytoplasmic tail that also contacts Lck. CD8 binds to the a3 domain of MHC class I molecules.

The general TCR three-dimensional structure also resembles that of Ig domains; it consists of b-sheets and external loops that protrude out of the main structure. These loops make up the Va and Vb domains and are directly involved in recognition of the peptide–MHC complex, as recently confirmed by X-ray crystallographic structures determined independently by several laboratories. These loops contain the CDRs, which are also similar to those of Ig H and L chains (see Immunoglobulin Structure). Of prime interest is the first high-resolution structure of the complex of a human TCRa b bound to an HLA-A2-nonapeptide; it revealed that the TCR is oriented diagonally across the peptide binding site of the MHC molecule, with CDR1a lying between the MHC a1 and a2 helices, whereas CDR2a interacts with the MHC a2 helix. The CDR3a and CDR3b loops contact both the central and COOH-terminal regions of the bound peptide, but they also interact with the MHC a1 and a2 helices. CDR1a and CDR1b each contribute a single peptide-binding residue. CDR1b and CDR2b have no direct contact with the complex, although they approach the COOH-terminus of the MHC a1 helix. It would now be of great interest to get the complete structure, including the CD4 or CD8 co-receptors. A crystal structure of a complex between a CD8a homodimer and HLA-A2 has recently been reported, making unlikely a previous hypothesis that CD8 might also contact the TCR/CD3 ectodomains. One cannot exclude, however, indirect constraints on the detailed structure of the TCR, through conformations induced as a result of interactions between cytoplasmic partners that initiate the transduction cascade.

Finally, it is likely, in view of other recently published structures, that variations on the same general diagonal orientation provide a general view of TCR–MHC–peptide interactions, especially because there is an obvious degree of degeneracy in overall T-cell recognition, like that already mentioned for antibodies.

T-Complex, -DNA, -Region, -Strand

The T-complex is the **DNA** and associated proteins that are transferred from Agrobacterium to the **plant** cell during *Agrobacterium*-mediated cell transformation . This process is a fascinating example of interkingdom **gene** transfer. It is the physical basis of tumor formation by *Agrobacterium* and the basis of **vectors** used in the creating **transgenic** plants by *Agrobacterium*-mediated transformation that is so vital to plant genetic engineering.

The transferred, or T-, DNA of the Ti plasmids and Ri plasmids is the region of DNA transferred from the bacterium to the infected plant cell during transformation. The T-DNA is flanked and defined by 25-bp imperfect sequence repeats: TGGCAGGATATATTC(*or* G)XG(*or*A)T(*or*G) TGTAAA(*or*T)T(*or*C) (1). Different strains of bacteria contain Ti plasmids that have different T-DNA. Nopaline strains (eg, C58, T37) contain a Ti plasmid that has a single T-DNA of approximately 24 kbp. Octopine strains (eg, B6S3, Ach5) contain two regions of T-DNA, a 14-kbp T_L region and a 7-kbp T_R region. The T_L region is normally present in plant cells transformed by octopine strains of bacteria, and this region is the functional equivalent of the right-hand portion of the nopaline T-DNA. Interestingly, the T_R region is not always present in transformed cells and indeed, if present, may not be linked to the T_L region, suggesting independent transfer of the two DNAs.

The genes encoded by the T-DNA of Ti plasmids are generally involved in biosynthesizing the **phytohormones**, auxins, and cytokinins, or the **opines**. Opines are a novel source of fixed carbon and nitrogen synthesized by the host plant cell and are catabolized by the infecting bacteria. The Ti plasmid is generally grouped according to the opine whose biosynthetic gene is encoded by the T-DNA. The genes are not transcribed in the bacteria, but they become active once the T-DNA has integrated into the plant genome. Nopaline T-DNA encodes at least 13 transcripts, and the protein products of 7 have been defined: *iaaM* and *iaaH*, which convert L-tryptophan to the auxin indole-3-acetic acid, *via* indole-3-acetamide; *ipt*, that encodes isopentyl transferase, which mediates the synthesis of cytokinin; gene 5 leads to the accumulation of indole-3-lactate, an auxin antagonist; gene 6a is thought to be involved in secreting opines; nopaline synthase (*nos*) and agrocinopine synthase (*acs*) are genes resposible for synthesizing opines. Two genes on T_R are responsible for the synthesizing mannopine (transcript 1′ and 2′), and one gene encodes a product that converts mannopine to agropine (transcript 0′) (2).

The Ri plasmids can contain one or two T-DNAs, depending on the strain, analogously to Ti plasmids. The genes encoded by the Ri plasmid T-DNA differ, however, from those of the Ti plasmid. In contrast to the T-DNA genes of the Ti plasmid, the functions of the genes encoded by the Ri plasmid T-DNA are little understood, although the *rolA*, *B*, and *C* gene products disturb the response of the infected cell to phytohormones.

Transfer of the T-DNA to the plant cell is a multistep process that is similar to DNA transfer during bacterial **conjugation** (3). The proteins that mediate the transfer process are encoded by the virulence (*vir*) regions of the Ti and Ri plasmids. The transfer process is initiated by activation of the expression of the genes of the *vir* region on the bacteria that sense a wounded plant cell. *VirD* encodes four peptides, of which virD1 binds to the border repeats. VirD2 forms a complex with virD1 and introduces a single-strand nick in the DNA. Following nicking, a single strand of DNA is released by strand-replacement DNA synthesis, and this is called the T-strand. virE2 is a **single-stranded**, DNA-binding protein that it is thought, binds to the T-strand and protects it from **nucleases**.

The T-strand bound with virE2 and virD2 forms the T complex, and this is transferred to the plant cell. Transfer is mediated *via* a sexual **pili**-like organ, made up of peptides encoded by virB. Both virE2 and virD2 contain nuclear targeting signals (see Nuclear Import, Export), which, it is thought, help in targeting the T-complex to the nucleus. The mechanism of insertion into the genome is not completely understood, but it is considered similar to illegitimate recombination. A single

unrearranged T-DNA can insert into the genome, but multimers of T-DNA can occur at single sites within the plant genome, depending on the experimental transformation, the bacteria, and the T-DNA *vir* region combination used. Once integrated, the T-DNA is generally maintained stably and, if a single insert, is inherited in a Mendelian manner (4).

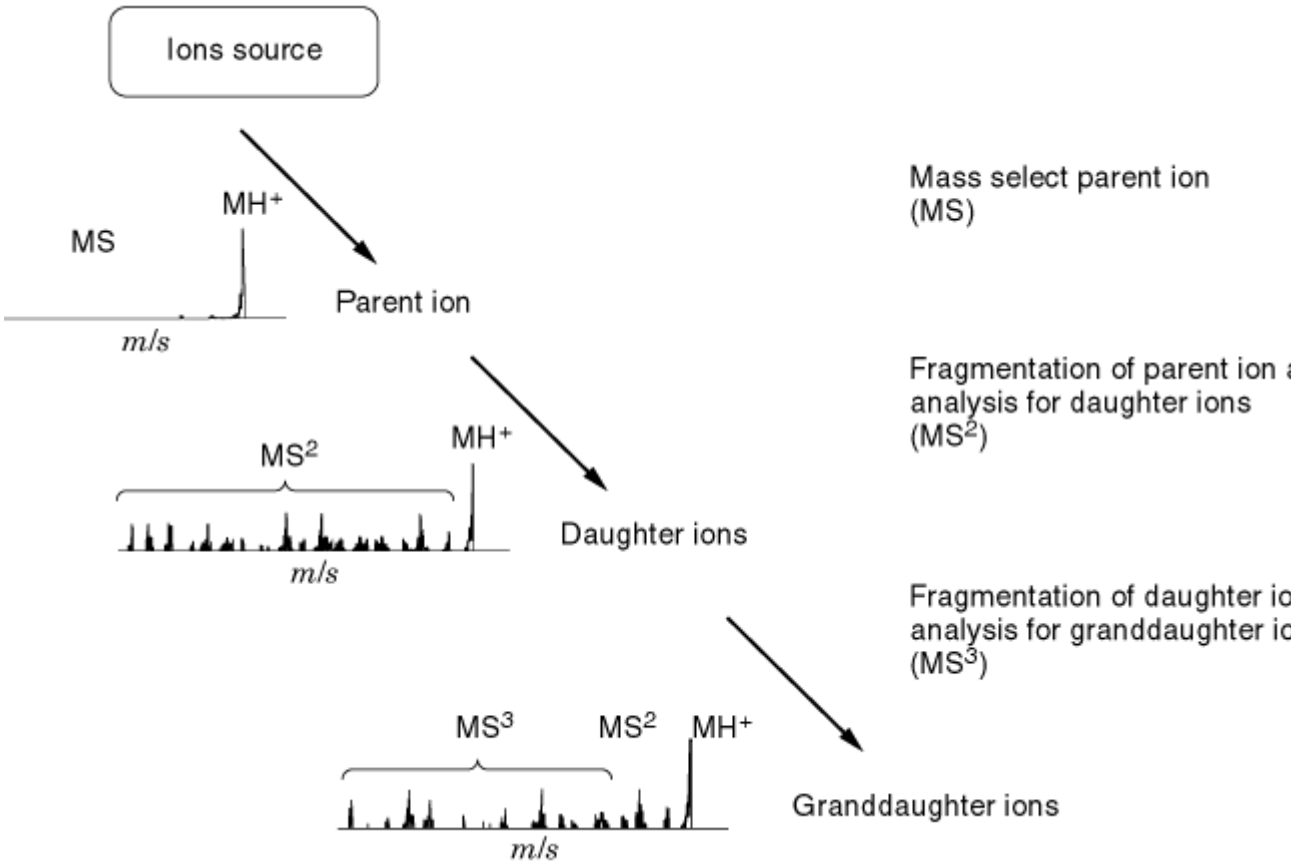
Tac Promoter

The tac promoter was artificially constructed from the *trp* and *lac* promoters. It is utilized by the prevalent form of the **RNA polymerase** from E. coli, the Es^{70} holoenzyme. It has consensus –10 and –35 regions, each obtained from a different parent promoter. The tac promoter was popular in the early 1980s for driving the overexpression of cloned genes (see **Genetic engineering**), but now it has largely been supplanted by systems based on the use of **bacteriophage** RNA polymerases and their promoters.

Tandem Mass Spectrometry

An important goal of mass spectrometry (MS) is the routine acquisition of complete sequence information for **biopolymers** such as proteins and oligonucleotides. The realization of this goal has significantly progressed as a direct result of the development of electrospray ionization (ESI) with tandem mass spectrometry. By typically using an *ion trap* or *triple quadrupole* mass analyzer, ESI serves to generate the intact molecular ion in the gas phase. The ion is then exposed to ion/molecule collisions with neutral atoms such as argon or helium. The resulting *collision-induced dissociation* (CID) results in fragment ions that can be mass analyzed. This ability to induce fragmentation and then to perform successive mass spectrometry experiments on these fragment ions is known as tandem mass spectrometry (abbreviated MS^n, where n refers to the number of generations of fragment ions being analyzed) and is illustrated in Fig. 1. Because the collision-induced dissociation behavior of **peptides** is already well characterized, tandem mass spectrometry is used routinely to acquire the partial or total sequence of small peptides (<3 kDa); it has also been used for short oligonucleotides.

Figure 1. Generation of fragment ions via collision-induced dissociation (CID) and the mass analysis (MS^n) of the proge fragment ions. The terms parent, daughter, and granddaughter ions are used in this discussion; however, precursor, produ second-generation product ions are also commonly used. In the MS^2 experiment the molecular ion MH^+ can be selected analyzer and made to undergo CID, which results in its fragmentation and the subsequent mass analysis of the fragment An MS^3 experiment can be performed by selecting a daughter fragment ion, exposing it to CID, and thus generating granddaughter fragment ions.



Another biopolymer sequencing method, *ladder sequencing* , was pioneered (1) for proteins and further developed (2) for oligonucleotides. This method uses matrix-assisted laser desorption/ionization (MALDI) mass spectrometry (MS) in combination with enzyme digestion or chemical digestion to generate sequence-specific ladders of proteins and oligonucleotides. For instance, protein ladder sequencing involves the simultaneous analysis of a mixture of peptides/proteins that have undergone a stepwise Edman Degradation (see Protein Sequencing). Ladder-generating chemistry generates a family of sequence-defining peptide fragments in which each differs from the next by one amino-acid residue. Once the mixture of peptides is obtained, the mixture can be analyzed by MALDI-MS, in order to generate a sequence ladder. The analysis of oligonucleotides by MALDI has also employed ladder sequencing technology using the time-dependence of exonucleases to generate the ladder. Electrospray ionization tandem mass spectrometry and MALDI ladder sequencing have both similarities and distinguishing features, which are summarized in Table 1.

Table 1. Characteristics of Mass Spectrometry-Based Sequencing Approaches

ESI Tandem Mass Spectrometry	MALDI-MS Ladder Sequencing
Picomole sensitivity	Picomole sensitivity
Partial (sometimes full) sequence information	Partial (sometimes full) sequence information
Range to about 25 residue peptides	Range to 150 residue peptides
Range to about 10 residue oligonucleotides	Range to about 50 residue oligonucleotides
Interpretation of data is reasonably involved	Interpretation of data is straightforward

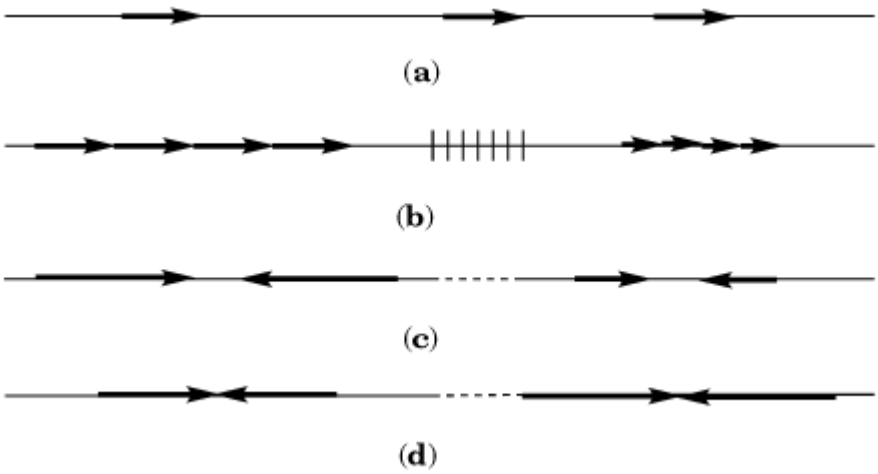
Tandem Repeats

A repeat, or repeating, **nucleotide sequence** is any of two or more identical segments of a longer sequence or identical segments of DNA. If the repeats are separate from one another, they are called dispersed or interspersed repeats. The repeats may also be contiguous, either head-to-head [inverted repeats] or head-to-tail, in which case they are called tandem repeats. Various types of repeats are outlined schematically in Figure 1.

Figure 1. Traditional schematic representations of various nucleotide sequence repeats. The continuous lines in direct repeats (**a**) and tandem repeats (**b**) may correspond to either single-stranded or double-stranded molecules. In inverted repeats (**c**) and **palindromes** (**d**), the continuous lines mean double-stranded molecules. The arrows indicate the direction of reading the sequence in the 5′ to 3′ direction; left-to-right arrows are read from one strand, whereas the right-to-left arrows are read from the complementary strand. Only double-stranded complementary symmetric palindromes are shown in the scheme. No conventional presentation exists for true palindromes.



The most conspicuous family of tandem repeats, typical of eukaryotes, is the so-called simple repeats, in which the repeating unit consists of only a few bases. These may appear in hundreds of tandem copies in many separate arrays. For example, $(TG)_n$ is the dominating simple repeat in the human and most eukaryotic **genomes**. Simple repeats are highly polymorphic, with a variable repeat copy number. Many of them are involved in biological functions in a copy number-dependent way, and the hypothesis has been put forward (1) that the tandemly repeating sequences may function to tune the nearby gene expression by changing the repeat copy number. This is consistent with the existence of so-called triplet expansion diseases associated with an excessive increase in copy numbers of certain tandemly repeating triplets, such as $(CGG)_n$ in the case of fragile X syndrome and $(CAG)_n$ in Huntington's disease (2). The expansion type diseases are not confined to only triplet repeats. Diseases caused by expansion of tandemly repeating units of other sizes also exist (3, 4).

Telomeric tandem repeats, eg, the human **telomeric** sequence $(AGGGTT)_n$, are important in maintaining intact the ends of chromosomes (5). It was already understood in the early 1970s that the absence of such regenerating repeats at the ends of the linear chromosomes would lead to incomplete replication of the chromosomes (6, 7).

Tandemly repeating sequences can amount to an appreciable proportion of the genome. In eukaryotes, most of these are satellite DNA sequences. Their G + C composition is frequently different from the bulk of the genomic DNA, so that the satellite DNAs are readily detected as satellite fractions by all techniques that are sensitive to the G+C content. Most satellite DNA is involved in the noncoding heterochromatin regions of the chromosomes. The size of the repeat unit of the satellite DNA can be a few to several hundred base pairs.

The coding sequences often form tandem (head-to-tail) arrays as well, both in eukaryotes (8) and in prokaryotes (9), as a result of gene amplification (see). For example, this is typical of **ribosomal** RNA genes.

Taq DNA Polymerase

The thermostable DNA-dependent DNA polymerase I, Taq DNA polymerase (Taq pol), is the most extensively used DNA polymerase for amplifying genetic material by the polymerase chain reaction (**PCR**) (1) and for **sequencing DNA**. Taq pol is obtained from *Thermus aquaticus*, an **archeabacterium** that thrives at elevated temperatures in deep thermal vents, and the enzyme is highly resistant to **denaturation** at elevated temperatures. Taq DNA polymerase is closely related to DNA polymerase I of *Escherichia coli* in both its primary and three-dimensional, tertiary structures. Both are single subunit enzymes with C-terminal polymerase and N-terminal 5′-3′ exonuclease **domains**. However, Taq pol lacks the 3′-5′ exonuclease (proofreading) function found in *E. coli* pol I and therefore cannot excise polymerization errors incurred during synthesis (2).

1. Properties

Taq pol has been **cloned** and overexpressed in *E. coli* The purified full-length protein is composed of a single subunit of 94 kDa with two distinct activities: 5′-3′ polymerase and 5′-3′ exonuclease. Taq DNA polymerase is highly thermostable, loses only 10% of its activity after 30 min incubation at 72 °C (which is the normal growth temperature for *Thermus aquaticus*), and 50% activity after 30 minute incubation at 95 °C (M. Suzuki and L.A. Loeb, unpublished results). Like DNA pol I of *E. coli*, Taq pol is susceptible to **proteolytic** cleavage and yields a small N-terminal fragment that has 5′-3′ exonuclease activity and a large C-terminal fragment that has polymerase activity. The large C-terminal fragment is analogous to the Klenow fragment of DNA pol I and is also called the KlenTaq or Stoffel fragment. It is thermostable, loses only 10% activity after 30 min incubation at 95 °C, and therefore is frequently used in polymerase chain reactions (PCR) and various sequencing protocols that involve prolonged incubations at elevated temperatures.

Taq pol conducts DNA-templated DNA synthesis with moderate accuracy, on average misincorporating only 1 in 9000 nucleotides (2). The predicted fidelity during PCR is one error per 400 bases after 25 cycles. The fidelity during PCR is enhanced twofold by using the truncated KlenTaq fragment instead of full-length Taq pol (3) and up to 10-fold by using other thermostable polymerases that have a 3-5′ exonuclease (proofreading) function. Specific methods that enhance the fidelity of Taq pol include incubation at low pH (5 to 6) or with reduced concentrations of $MgCl_2$. However, both of these methods decrease Taq pol activity and are generally incompatible with PCR, especially for amplifying long fragments.

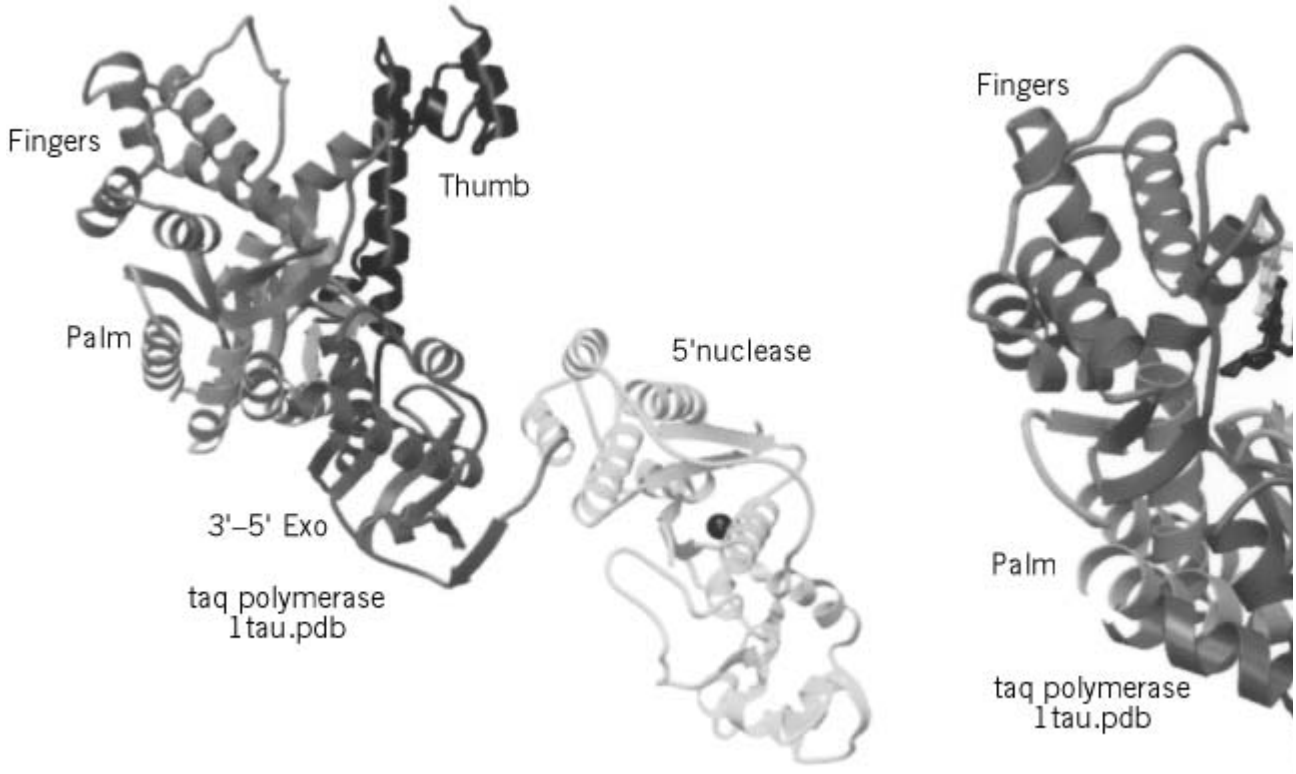
The two components of fidelity include (1) nucleotide misinsertion and (2) extension of the misinserted base. Taq pol extends mispairs at a very low efficiency: 10^{-3} for a T–G mispair to 10^{-6} for A–A mispair (4). Because of its relative specificity to extend only properly matched primers, Taq

pol is frequently used to detect specific *in vivo* mutations.

2. Structure

The **X-ray crystallographic** structures of all polymerases determined to date, including Taq DNA polymerase, resemble in overall morphology a cupped human right hand, complete with subdomains corresponding to the fingers (which bind the single stranded-template), palm (which binds the incoming deoxynucleoside triphosphate, DNTP) and thumb (which binds double-stranded DNA) (5, 6) (Fig. 1). The polymerase subdomains of Taq pol and the Klenow fragment are highly homologous and have 51% amino acid identity. In addition, the overall folding of the two polymerase domains in the three-dimensional structures are virtually identical and have an average (root mean square) deviation in alpha carbons of approximately 1.4 Å. The overall folding and location of the 3′-5′ exonuclease domain, which is 30 Å away from the polymerase active site, is also similar in both enzymes. Taq pol, however, lacks four loops found in the Klenow fragment on one side of the 3′-5′ exo site (5). In addition, four key amino acid residues believed to bind metal cofactors involved in the exonuclease reaction in the Klenow fragment (Asp424, Asp501, Asp355, and Glu357) are replaced by nonacidic residues in Taq pol (Leu356, Arg405, Gly308, Val310). These changes may explain why the 3′-5′ nuclease domain of Taq pol is inactive. A direct comparison of the Klenow and Taq pol structures also shows that Taq contains a more **hydrophobic** core and more favorable electrostatic interactions. Both of these properties may contribute to the greater **thermostability** of Taq pol (6).

Figure 1. Ribbon diagram of the Taq DNA pol structure in the absence and presence of double-stranded DNA. This poly
cupped human right hand. Residues of helix O located in the finger subdomain probably interact with the extended singl
I interact with the duplex portion of the DNA. The structure contains an inactive, vestigial 3′-5′ nuclease proofreading dc
catalytic site, and a functioning 5′-nuclease site located 70 Å from the active polymerase site.



Interestingly, the location of the 5′-3′ exonuclease active site, which probably functions in **nick translation** during DNA repair and during removal of Okazaki Fragments, is 70 Å from the polymerase active site. How polymerase and 5′-3′ exonuclease sites so far apart work in concert to leave a "repaired" double-stranded DNA with only a nick remains a mystery. The structure of Taq pol bound to blunt-end DNA has been described (7) (Fig. 1). Similar to the complexes with DNA of pol b-DNA and HIV reverse transcriptase, the DNA in the Taq pol active site adopts a structure that is a hybrid between A and B forms. As a consequence, the minor groove, which interacts with amino acid residues in the polymerase active site, is especially wider than in B-form DNA. It is thought that protein side-chains may form hydrogen bonds with the O2 atom of the pyrimidine ring and with the N3 atoms of purines (7). Because the positions of these two atoms are unchanged in A:T and G:C base pairs, these putative hydrogen-bond interactions between protein side chains and the last base pair may insure proper base pairing before nucleotide incorporation and thus enhance the fidelity of the polymerase.

3. Uses

Taq pol is used extensively in polymerase chain reactions to amplify genetic material. **PCR** involves incubation with the **gene** that is to be amplified in the presence of a polymerase, PCR primers that flank the gene of interest, all four dNTP, and magnesium . Briefly, each cycle of PCR involves three steps: (1) incubation at elevated temperature to separate the double-stranded DNA (typically 95°C); (2) incubation at lower temperature to allow primer/template annealing, and (3) incubation at a temperature for polymerization (1). Before the discovery of Taq pol, PCR involved manually adding a small amount of polymerase to the incubation mixture before each polymerization step because the polymerization was inactivated during incubation at elevated temperatures. The thermostability of Taq allows heat denaturation of DNA after each cycle without enzyme inactivation, thus allowing automation of PCR. In general, current PCR technology using full-length Taq pol allows amplification from one molecule to more than 10^5 copies of a target sequence, which can be as large as 5 kilobases. Even larger sequences are amplified by combining a truncated KlenTaq fragment with low levels of a thermostable polymerase that contains 3′-5′ proofreading activity (eg, Vent DNA polymerase or Pfu polymerase) (8).

PCR is used widely in research and clinical laboratories for diverse procedures including amplifying genes for cloning, diagnosis of diseases, and detecting levels of viruses. Taq DNA polymerase, which possesses weak RNA-templated DNA polymerase activity, is also used to synthesize double-stranded DNA from messenger RNA templates (9). However, this process, termed RT-PCR, is generally more efficient if a **reverse transcriptase** is used during the first cycle to generate single-stranded DNA and Taq pol is used in subsequent amplification cycles (10). Alternatively, a polymerase from the thermophilic bacteria *Thermus thermophilus* (TTH POL), which contains efficient RNA-templated and DNA-templated DNA polymerase activities in the presence of Mn^{2+}, can be used for RT-PCR (11). Because of its relative specificity to extend only properly matched primers, Taq pol I is used to detect specific mutations through PCR analysis, simply by choosing primers with a 3′ -terminus that is complementary to the mutant. Efficient amplification of the DNA in this procedure suggests the presence of a specific mutation. This protocol has been used successfully to detect mutations in the *ras* **oncogene** and common mutations resulting in inherited disorders.

3.1. Taq Pol in DNA Sequencing

Until recently, enzymatic DNA sequencing using Taq pol was marred because dideoxynucleotides (DDNTP) are not efficiently incorporated by Taq pol (its usage of ddNTP is 1000 times less efficient than that of dNTP in the presence of Mg^{2+}; Ref. 12). However, it has been recently shown that the substitution Phe667Tyr of Taq pol increases incorporation of ddNTP relative to dNTP 250 by 8000-fold (13). This mutated Taq (*Thermo sequanase*) enables cycle sequencing, thus producing accurate and analyzable sequences using either **radioactive** or **fluorescent** sequencing technologies (14).

3.2. Taq Pol in T/A Cloning

Taq pol shares a characteristic common to all polymerases that lack 3′-5′ exonuclease proofreading activity in that it incorporates nontemplated nucleotides (usually adenine) onto blunt-end DNA (15). This property is frequently used in molecular biology to ligate fragments of DNA in T/A cloning protocols. Briefly, PCR amplification of the sequence of interest results in a significant proportion of products containing a nontemplated adenine incorporated onto both 3′ ends. Then this PCR product is incubated in the presence of a **ligase** with a linear **vector** that contains 3′ thymine residues. The completed reaction results in a circular DNA that contains a cloned insert.

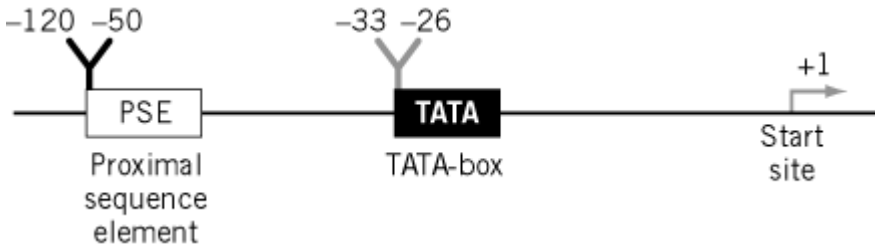
TATA Box

In higher eukaryotes, comparison of DNA sequences of a variety of **RNA polymerase**-II **promoters** revealed an A + T-rich **consensus sequence**, closely resembling the –10 Pribnow Box of bacterial promoters and centered approximately 30 base pairs (bp) upstream of the start site of transcription. This 8-bp element is called the TATA box because the maximum homology covers the first four bases, TATA (Fig. 1). It is also found in lower eukaryotes (such as *Saccharomyces cerevisiae*), although at variable distances from the start site, ranging from positions –30 to –120. *In vivo* as well as *in vitro* studies revealed the importance of this sequence for the initiation of accurate transcription.

Indeed, using *in vitro* transcription assays, it was shown that deletions encompassing part, or all, of the TATA sequence are detrimental for transcription (1, 2). Even a single base change within the TATA box drastically decreases transcription, indicating that the rate of transcription could be a function of the nature of the TATA-box sequence (3). The TATA sequence is involved in the selection of the transcription initiation site; accordingly, deletions of the original start site that leave the TATA box unchanged do not prevent transcription initiation, which still occurs approximately 30 bp downstream of the TATA element.

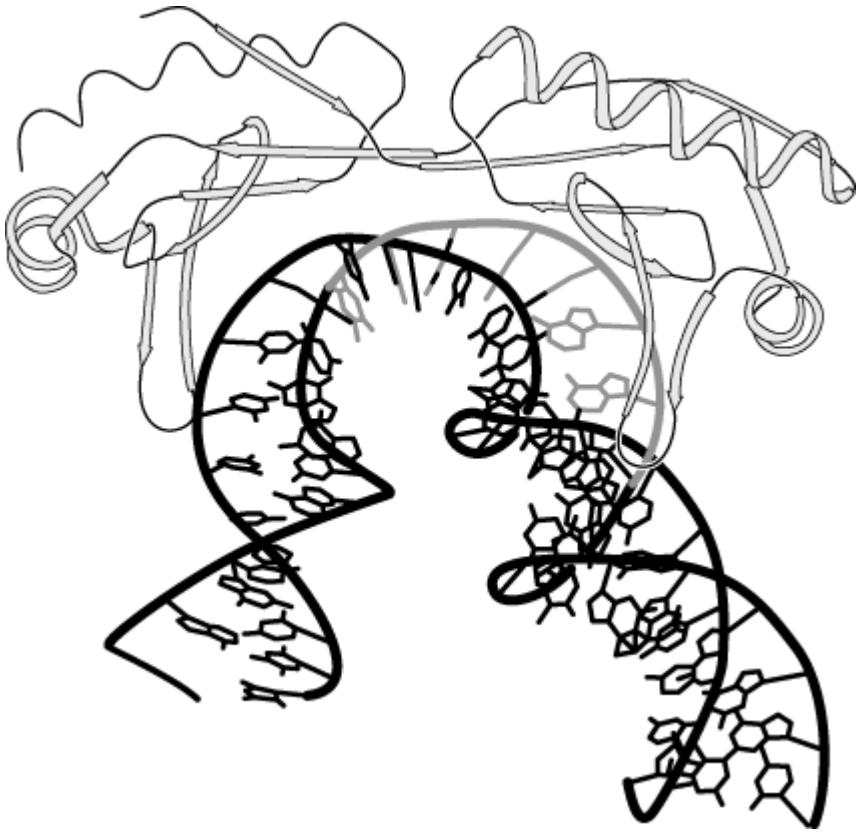
Figure 1. Organization of eukaryotic class II promoters.



Transcription requires correct positioning of RNA polymerase II on the promoter, in addition to other components called basal (or general) transcription factors. These factors participate in the formation of the preinitiation complex, which is nucleated by the binding of one of them, TFIID, on the TATA box. Targeting of the TATA box by TATA binding protein (TBP), a subunit of TFIID, allows the arrival of the other factors, either in a chronological (sequential) order or in a single step as a large complex, the RNA polymerase II holoenzyme.

X-ray crystallography studies show that the carboxy-terminal domain of TBP consists of two direct repeats of about 80 amino acid residues and resembles a saddle that sits astride the DNA (4, 5), contacting its minor groove (Fig. 2). Insertion of two phenylalanine residues of TBP between the two last base pairs of the TATA element induces a bend of about 80° in the DNA structure, which widens the minor groove but does not impede the base pairing (6). Bending the DNA around the TATA box allows contacts between regulatory factors bound to their specific sequence, on one side, and the basal transcription machinery on the other side. It could also prevent condensation of DNA in chromatin structure and repression of transcription. The importance of the DNA kinking varies, depending upon the nature of the TATA box and the surrounding sequences.

Figure 2. View of the TBP–TATA complex. The TATA sequence is shown in dark stippling, whereas the surrounding DNA sequences are in bold lines. TBP, which is displayed in light stippling in a ribbon representation, induces the kinking of the DNA (9).



The affinity of TBP for the TATA element probably determines the strength of the corresponding promoter—a strong promoter allowing a high rate of transcription. It is still unclear, however, whether TBP recognizes the primary TATA-box sequence or simply its three-dimensional structure. Such a structural mode of recognition has already been suggested for class I promoters, which lack a canonical TATA box. Even though DNA bending at promoters is induced by the TATA–TBP interaction, recent data demonstrate that TBP is able to bind in a lock-and-key fashion to a similar bent structure provided by DNA damage, such as cisplatin adducts or ultraviolet photoproducts (7). The requirement of TBP for transcription from a TATA-containing promoter has been challenged by the discovery that a complex of TBP-associated factors (TAFs) without TBP (called TFTC for TBP-free TAF_{II}-containing complex) could substitute for TFIID (8). TFTC does not bind the TATA-box itself, however, raising the possibility that another component does so during TFTC-mediated transcription.

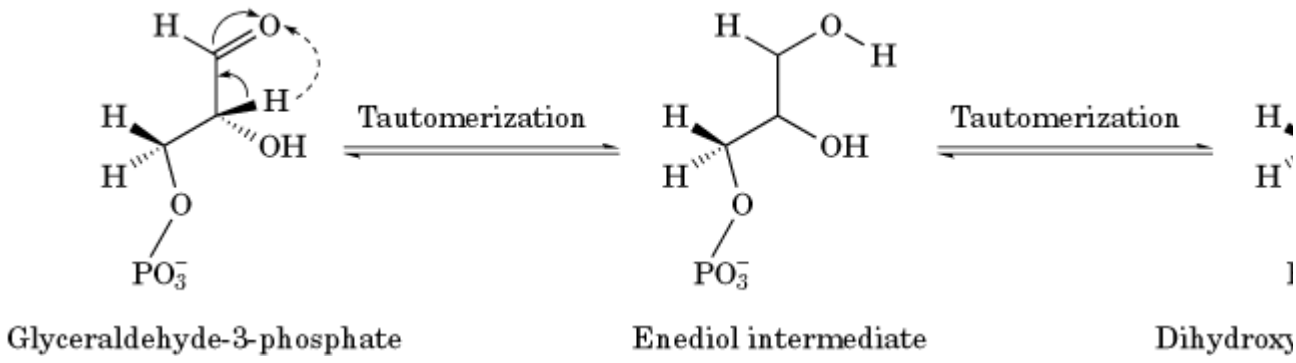
Tautomers

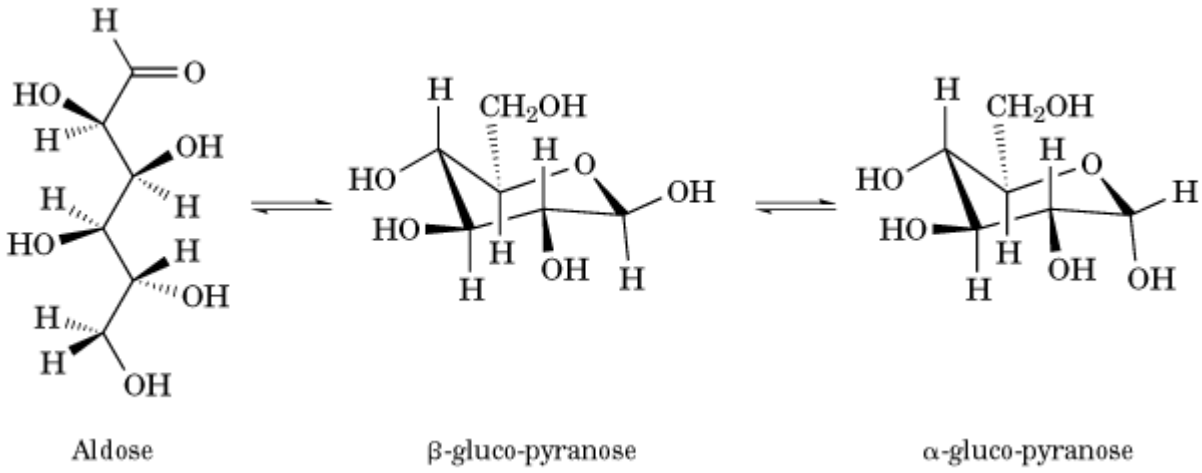
Tautomers are structural **isomers** that interconvert rapidly (1), so they will all exist in a solution of the compound at equilibrium at ambient temperature. The concept of tautomerism was introduced by Laar (2). In most cases, tautomers are generated by the structural and electronic rearrangements induced by moving a single proton (3). In the reaction catalyzed by triosephosphate isomerase, the substrate, glyceraldehyde-3-phosphate, the enediol intermediate, and the product, dihydroxyacetone-phosphate, comprise two tautomeric pairs. As shown in Figure 1, glyceraldehyde-3-phosphate and the enediol are structural isomers that result when a proton is transferred from C2 to the aldehyde oxygen, as indicated by the dashed arrow. Transfer of the proton is accompanied by a rearrangement of the electrons, as indicated by the solid curved arrows. Similarly, dihydroxyacetone-phosphate and the enediol intermediate are tautomers, as a single-proton transfer also permits their interconversion. Because of the imprecision of the phrase "rapidly," the property of being tautomers may not be transitive. For example, glyceraldehyde-3-phosphate and dihydroxyacetone-phosphate are not considered to be tautomers, although they are both tautomers of the enediol intermediate.

Figure 1. Two examples of keto-enol tautomerization. A proton from the a-methylene of either glyceraldehyde-3-phospl dihydroxyacetone-phosphate is transferred to the carbonyl; after the depicted electron rearrangement, a structural isomer



A second form of tautomerism important in biochemistry is the existence of both open-chain and ring forms of monosaccharides. Thus, the three common forms of glucose shown in Figure 2 are all tautomers, because they will interconvert rapidly in aqueous solution. The two cyclic pyranose forms are not only tautomers, but also **epimers** and **diastereomers**.

Figure 2. The three tautomeric forms of D-glucose. These are rapidly interconverting structural isomers. Note that the tautomeric forms differ by more than the rearrangement of a proton, consistent with Ingolds expanded definition (1).



The existence of tautomers can be detected spectroscopically, in that all the tautomeric forms may give rise to different spectral features. For glucose, it is possible to observe ^{1}H-**NMR** resonances from all three tautomeric forms. It is also possible to monitor their "rapid" equilibration in aqueous solution by following the difference in optical rotation after dissolving in water a pure crystal of either of the pyranose forms.

The equilibrium constant between tautomeric forms often is very far from 1, but the less favored tautomer may be the biologically active form. In **nucleic acid** bases, keto-enol tautomerism can change the hydrogen bond acceptor carbonyl to a hydrogen bond donor hydroxyl (4). Tautomeric forms of all four nucleic acid bases exist, but the rare tautomer occurs less than 0.01% of the time (5).

Telocentric Chromosome

Telocentric chromosomes appear by cytogenetic techniques to have their centromeres at the very end of the chromosome. True telocentric chromosomes do not exist, because the **telomeres** are at the tips

of the chromosomes. In contrast to the centromeres, there is little to distinguish telomeres from euchromatin, but molecular biological and genetic analysis suggest that the telomere has a unique structure and function distinct from the rest of the chromosome.

Telomerase

There is a high level of similarity in the sequence organization of the **telomeres** in eukaryotic chromosomes. Telomeres contain repeat sequences of six to eleven deoxyribonucleotides (see Terminal Repeats). All of these repeat sequences in vertebrates and in most other organisms end with guanines. Animal and **plant** telomeres contain the repeats: 5′-$T_{2–4}$ -$A_{0–1}$-G $_{3–4}$-3′. The sequence 5′-TTAGGG-3′ is at the end of all vertebrate chromosomes (1). The enzyme telomerase is a terminal transferase that elongates the G-rich strand of telomeres in the absence of a DNA template (2). A common feature of telomerases is their capacity to recognize single-stranded oligonucleotides ending with G at the 3′-terminus. First defined in *Tetrahymena*, the enzyme is a ribonucleoprotein containing an **RNA** template for the **DNA** sequence in the telomere. This templating activity enables eukaryotic chromosomes to maintain their length in spite of the incapacity of the normal chromosomal **DNA polymerases** to replicate the linear chromosomal DNA completely. This occurs because DNA replicates in a 5′ to 3′ direction so that one strand of the **double-helix** can be synthesized to the end, and the other strand cannot because DNA synthesis has to be primed with ribonucleotides. In the absence of telomerase activity, the progressively shortened chromosome would eventually lose genes.

In human **somatic cells**, telomeres become shorter with age, whereas their lengths are maintained in **germ cells**. This has led to the suggestion of reduced telomerase activity in somatic cells, which may contribute to the process of aging. Consistent with this hypothesis, mutations in *Saccharomyces cerevisiae* that lead to the progressive loss of telomeres eventually cause aneuploidy and senescence.

4. D. Kipling (1995) *The Telomere*, Oxford University Press, Oxford, UK.

Telomere

Telomeres are specialized **domains** found at the ends of eukaryotic chromosomes (1). They have specialized structures that protect the chromosomes from attack by **exonucleases**, prevent end-to-end fusion of the chromosomes, and promote complete replication of the ends of the linear **DNA** molecules present in chromosomes. Telomeric DNA has been studied in many organisms including

Tetrahymena and **yeast**. Chromosomes of *Saccharomyces cerevisiae* terminate in 250 to 650 bp of the simple repetitive DNA sequence C_{2-3}-A -$(CA)_{1-6}$. These are binding sites for a non-**histone** protein known as *r*epressor *a*ctivator *p*rotein (RAP) 1. Although some lower eukaryotic telomeres are organized in nucleosomes, those of a number of species, including *Tetrahymena* and yeast, display a protein-dependent protection from **nucleases** in which the size of the protected structure (<140 bp) differs from that anticipated for nucleosomes. This suggests either that non-histone nucleoprotein complexes exist in a regular array or that modified nucleosomes exist at the telomere. The RAP1 protein may be a participant in the non-histone protein-DNA complexes at the chromosomal ends of yeast. RAP1 interacts with yeast telomeres *in vivo* and is important for maintaining telomeric length. The protein is abundant (<4000 copies per cell) and fractionates with the nuclear scaffold. More recently, RAP1 has been used as a marker to localize yeast telomeres to the nuclear periphery in yeast (2). This localization depends on proteins SIR3 and SIR4, one of which, SIR3, is believed to interact with the tails of core histone H4. This observation suggests that RAP1, SIR3, SIR4, and the core histones might be involved in assembling a specialized nucleoprotein complex at the nuclear periphery in yeast. Proximity to the telomeres provides examples of the effect of chromosomal context on **gene expression** (see Position Effect).

Mammalian telomeres are composed of a tandem array of TTAGGG repeats. The length of the telomeric repeat sequences varies among **germ cells**, tumor cells, and **somatic cells**, indicating that the telomeres are a specialized variable component of the genome. Sperm telomeres are 10 to 14 kbp long, whereas telomeres in somatic cells are several kilobase pairs shorter and very heterogeneous in length. Telomere length in tumor cells is even shorter than in normal somatic cells. Specialized proteins also recognize mammalian telomeric DNA. One such protein, TTAGGG repeat factor (TRF), binds along the entire length of telomeric DNA. Short human telomeres (2 to 7 kbp long) have a very unusual chromatin structure, characterized by diffuse **micrococcal nuclease** digestion patterns. In contrast, longer telomeres (14 to 150 kbp in humans, mouse, and rat) have a more typical chromatin structure consisting of extensive arrays of close-packed nucleosomes (one every 150 to 165 bp). Human telomeres also fractionate in the nuclear scaffold fraction, consistent with the concept that telomeres assemble into an extended nucleoprotein complex with a specialized functional role (3).

Temperature Factor

The atoms of a molecule are not at rest but vibrate around an equilibrium position (see Molecular Dynamics). The higher the temperature, the stronger the vibration. In X-ray crystallography, the vibration affects the X-ray scattering by each atom. During an X-ray exposure, scattering is by a "time-averaged" atom, averaged over a great many positions of the atom around its equilibrium. Therefore, the X-rays see an atom that is larger than it really is. The larger the area over which the electron cloud of the atom is distributed, the weaker the atomic scattering. This is expressed in the

temperature factor. If the vibration is equally strong in all directions (spherically symmetrical), it is called isotropic vibration. Then the correction factor to be applied to the atomic scattering factor is given by

$$\text{Temp factor(iso)} = \exp\left[-B\frac{\sin^2\theta}{\lambda^2}\right]$$

where B is the thermal parameter of the temperature factor, q is the reflection angle, and l the X-ray wavelength. B is related to the mean square amplitude, $ovlu^2ovl$, of the atomic vibration by $B = 8p^2ovlu^2ovl$.

If the vibration is anisotropic, it is usually represented by an ellipsoid (replacing the sphere for isotropic vibration). Now six parameters are involved, three to define the length of the ellipsoid axes and three for their orientation. In elucidating a structure by X-ray crystallography, every atom requires determining three parameters for its position in the unit cell, plus one parameter (B) if the vibration is isotropic and six parameters if it is anisotropic. For macromolecular crystals, the amount of X-ray data is usually not sufficient to allow determining anisotropic temperature factors. However, it can be done for relatively small molecules or a very high resolution X-ray pattern (1).

Actual temperature factors are affected by the vibrations within a molecule and also by imperfections in the lattice of the crystal, over which all X-ray diffraction measurements are averaged.

Temperature Gradient Gel Electrophoresis

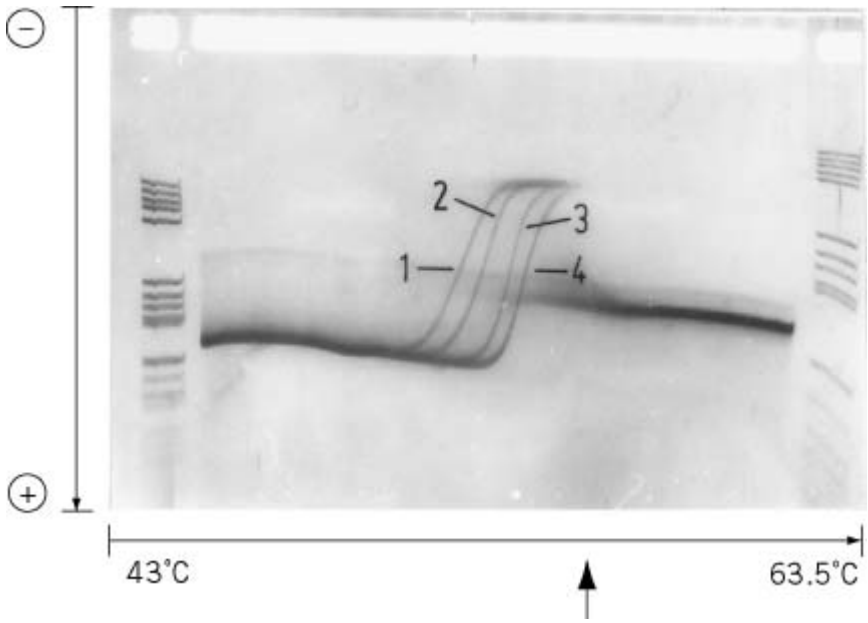
Temperature is a fundamental parameter for the structures of proteins and **nucleic acids**, which are usually unfolded by high temperatures and sometimes at low temperatures also (see Protein Stability). Varying the temperature can be combined with **PAGE** and used as the variable in transverse gradient gel electrophoresis to monitor the structures of proteins and nucleic acids and their thermal stabilities. In this technique, the sample is subjected to electrophoresis across the width of a slab polyacrylamide gel in which there is a gradient of temperature perpendicular to the direction of migration. Each molecule migrates at a constant temperature, but that temperature varies across the gel. In general, electrophoretic mobility increases with increasing temperature, but superimposed on this are any changes in mobility caused by a change in the macromolecular structure. If such changes are rapid and reversible, a continuous band is produced across the gel and through any of the temperature regions of such changes (see Transverse Gradient Gel Electrophoresis (Tgge)).

Proteins dissociate into subunits, if multimeric, and unfold at high temperatures, when they also tend to precipitate. Dissociation into folded subunits increases the PAGE mobility, whereas unfolding

causes a decrease. Temperature-induced unfolding is similar to that observed with urea (see Urea Gradient Gel Electrophoresis).

Temperature gradient gel electrophoresis is most useful with nucleic acids, because temperature has well-documented effects on the melting of **double helices**. The melting of an internal segment of a double-stranded DNA helix converts it into a circular random coil with a dramatic increase in the dimensions of the molecule. This greatly decreases the electrophoretic mobility through sieving polyacrylamide gels. Such melting is also rapidly reversed because the melted strands are held together by the residual double helix at either or both ends, so the two chains can rapidly reassociate. Consequently, this initial partial melting is observed as a continuous and abrupt decrease in mobility of the band (Fig. 1). At higher temperatures, the double helix is totally melted, and the two single strands dissociate. This is effectively irreversible during electrophoretic separation, so there is a discontinuity in the electrophoretic band at this temperature. The original band is replaced by a band that represents the individual single strands, which have increased PAGE mobilities because of their smaller size. But their mobility is less than that of the original double helix. If the dissociation is prevented by **cross-linking** the ends of the two chains, the original band remains continuous at high temperatures.

Figure 1. Temperature gradient gel electrophoresis of double-stranded DNA. The slab gel of 8% (w/v) polyacrylamide contained Tris-acetate buffer at pH 8.4, 0.2 m*M* EDTA, plus 8 *M* urea to lower the melting temperature to a practical range. As indicated, a linear temperature gradient was established across the gel during the electrophoretic separation. The sample was a mixture of two 138 base pair, DNA double helices, differing at only one base pair (C:G versus T:A), that were dissociated and then reannealed together, so that both homoduplexes (bands 3 and 4) and both heteroduplexes (bands 1 and 2) are present. The heteroduplexes have a single base mismatch and melt at temperatures lower than the two homoduplexes. From Ref. 1.



Mutations, in which one base pair is replaced by another, affect the stability of the DNA double helix and alter the temperature at which the mobility of the double-stranded DNA decreases. For example, bands 3 and 4 of Figure 1 differ in only one of 128 base pairs, yet they give distinct melting curves. Detecting mutations is more sensitive if there is a mismatch between the two strands. For example, the two heteroduplexes of the two homoduplexes of bands 3 and 4 of Figure 1 are present in bands 1 and 2, which have significantly lower stabilities.

Single-stranded nucleic acids can have complementary segments within the same chain, which

associate and cause the molecule to become more compact. An extreme example is the folded structure of transfer RNA. The melting of such segments is also observed by transverse gradient gel electrophoresis.

Temperature-Sensitive Mutation

Among the mutations that affect the function of a protein, some allow the protein to be active at the organism's normal temperature but inactive at either higher or lower temperatures. The former are temperature-sensitive (Ts) mutations and the latter are **cold-sensitive mutations**. Both are types of conditional lethal mutations. Classically, Ts mutations have been used to identify proteins encoded by specific genes. Once a Ts mutation is located on a gene, its encoded protein is identified by showing that it is temperature-sensitive in an *in vitro* assay.

Ts mutants are also a powerful genetic way to identify interacting proteins (see Protein–Protein Interactions) because a protein destabilized at one temperature may be stabilized by mutant versions of an interacting protein. For example, if a Ts **allele** of a given gene is identified, **suppressors** can be selected at the nonpermissive temperature. Most such suppressors have no **phenotype** in the absence of the first mutant allele, but some have a cold-sensitive phenotype. Then the gene responsible for the cold-sensitive phenotype can be identified, and it is a candidate for a protein that interacts functionally with the first protein, and suppressors of the cold-sensitive phenotype can be sought. Like all such suppressor analysis, these suppressors have to be allele-specific to be useful.

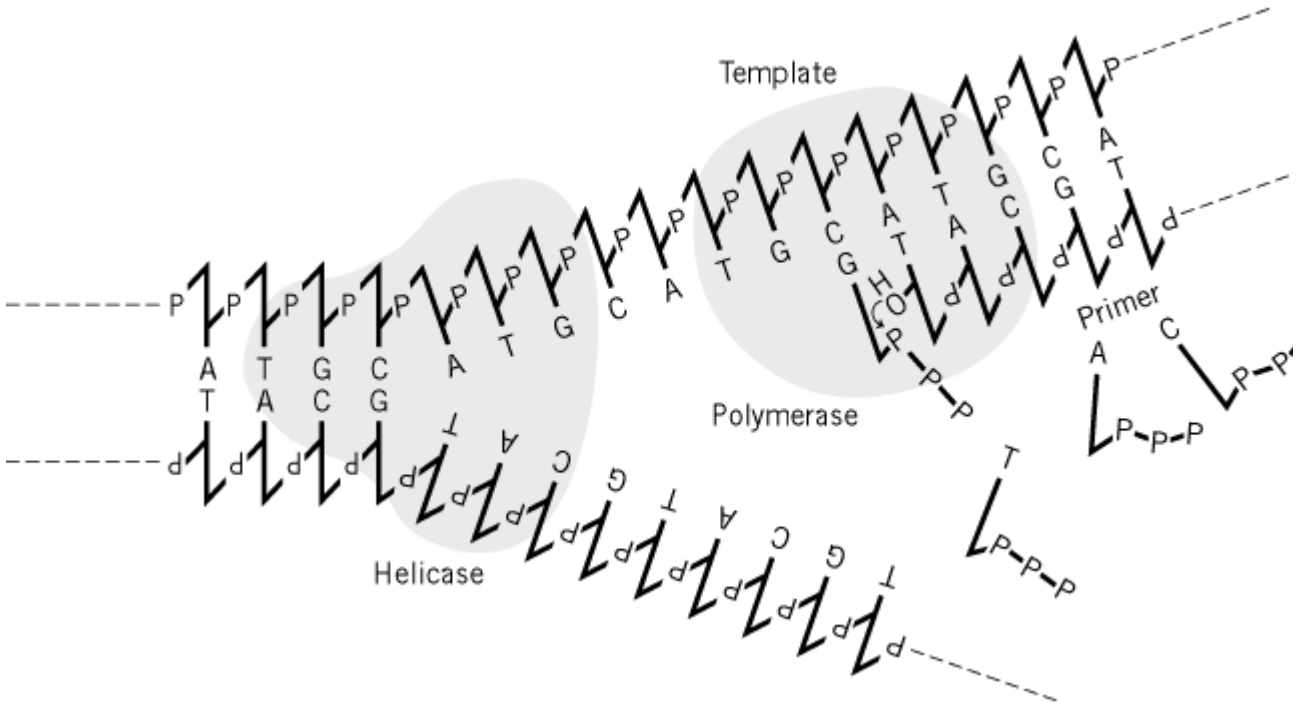
Template

A template is defined in the 1978 *Webster's New Collegiate Dictionary* as a molecule (such as **RNA**) in a biological system that carries the genetic code for another molecule. Also, the 1995 *Concise Oxford Dictionary*, Ninth Edition describes a template as the molecular pattern governing the assembly of a protein, etc. According to these broad definitions, **DNA** is the template for DNA (in DNA replication) and for RNA (in transcription), and RNA is the template for protein (in

translation). In other words, a template is a molecular entity essential for the transfer of genetic information from DNA to DNA to RNA to protein (the central dogma). More precisely, the word "template" is used when a molecule transferring information (the template) is in direct contact with the recipient molecule (the product). Therefore, in this sense, RNA is not a template for protein because no direct interaction between messenger RNA and the protein occurs during translation (see **Protein biosynthesis**). In cases which are the exception to the central dogma, viral RNA is synthesized from RNA using RNA as a template (see RNA viruses) and, moreover, DNA is synthesized using RNA as a template during the infection of retroviruses (see also **Reverse transcription**).

In DNA replication, the double helix is unwound, and each single-stranded DNA molecule is used as a template to synthesize a complementary strand. Since DNA undergoes **semi-conservative replication**, parental DNA serves as a template and becomes a component of the daughter DNA molecule. In transcription, in contrast, a DNA strand serves as a template for the synthesis of RNA that then dissociates from the template (see Transcription). **DNA polymerases** that assemble deoxyribonucleotides on the template DNA strand according to the Adenine (A):Thymine (T), Guanine(G):Cytosine (C) base complementary rule (Watson–Crick base pairing) require both a template and primer for the reaction to take place (Fig. 1). Consequently, DNA synthesis is preceded by the synthesis of small RNA molecules of fewer than 10 bp by RNA primase, which can initiate the synthesis of RNA complementary to the template DNA (see Okazaki Fragments). The primer RNA is eventually replaced by DNA through the lagging DNA strand extended from the region preceding the synthesis of RNA primer (see Replication Fork (Y-Fork Intermediate)). The template–product relationship through the base complementarity of A to T and G to C is not 100% accurate, but results in mis-pair formation once every 10^3 to 10^4 times. On the other hand, mis-pairs generally occur only once in 10^8 to 10^9 when genomes are replicated within the cell [(1)]. This is achieved by the proofreading activity of DNA polymerases themselves and by other DNA repair mechanisms.

Figure 1. DNA polymerase requires template and primer. At a growing replication fork, single strands of DNA provided by DNA helicase serve as temples for DNA polymerases. The enzymes synthesize phosphodiester bonds between the 3′(end of the primer, newly synthesized strand, and the deoxyribonucleotide-triphosphate that is base-paired correctly with template strand. Only synthesis of the leading strand is shown schematically here.



The template–product relationship is very important in the transfer of genetic information in biological systems. However, the physico-chemical nature of the relationship itself is not sufficiently accurate to perform the precisely regulated biological processes, and many proteins have been evolved to repair the errors that inevitably result.

Terminal Redundancy

Terminal redundancy is the existence of similar base-pair sequences at both ends of a linear **DNA** molecule. This is a common feature of many retroviral **genomes**. Many retroviruses and retrotransposons in the **eukaryotic** genome have identical or almost identical long terminal repeats (LTRs) at their ends. The length of the LTR is usually between 250 and 600 bp. There is less sequence conservation between the LTRs than within the body of the retrovirus or retrotransposon. The conserved sequences in the LTR required for retrotransposon function are the **promoter** sequences, sites of transcription and poly A addition, and short inverted repeats at the ends of each LTR. The activity of promoter sequences in LTRs is a potential source of genomic instability and inappropriate transcription within the chromosome (1). It has been proposed that a major function of the **methylation** of **CpG** sequences in vertebrates is to silence such transcriptional activity and to prevent transposition events. It is sometimes difficult to discriminate between *bona fide* promoters in chromosomal DNA and the evolutionary relics of LTRs (2).

Terminal Repeats

Telomeres consist of repeated **DNA** sequences, and these terminal repeats are synthesized by telomerase. A number of such distinct DNA sequences (Fig. 1) are utilized in **fungi**, protozoa, **plants** and animals. The existence of terminal repeats is important for replicating DNA at the chromosome ends and for assembling specialized nucleoprotein structures. General features of telomeric repeats include strand asymmetry in base composition in which the G-rich strand is oriented 5′ to 3′ toward the end of the chromosome. The G-rich strand can have a single-stranded terminus for at least some

of the cell cycle, which in turn may facilitate the formation of unusual DNA structures. In humans, the size of the repeat array varies from cell to cell or from tissue to tissue, dependent on telomerase activity. Heterogeneity in the length of the terminal repeats is caused by variation in telomerase activity and by loss of terminal sequences due to incomplete replication.

Termination Factor

Most textbooks end the description of protein biosynthesis with the release-factor-mediated release of the completed polypeptide chain from the peptidyl- transfer RNA. This is a gross oversight, because there is an additional crucial step in protein synthesis: recycling of ribosomes through dissociation of the termination complex (1). In bacteria, this process requires a ribosome-recycling factor (RRF, originally called ribosome-releasing factor). This process must be fundamental, because the gene for RRF is essential for cell growth, and the living cell must reuse the ribosome, release factors, and tRNA for the next round of protein synthesis. Upon release of the polypeptide chain, the ribosomal P and A sites remain occupied with a deacylated tRNA and a tRNA-mimicking release factor, respectively. A translocase is probably required to forward deacylated tRNA and release factor to the E and P sites of the ribosome, respectively. It is speculated that RF-3 or EF-G may catalyze this final translocation reaction. Alternatively, this post-release ribosomal complex may be dissociated directly by the action of RRF and RF-3 or EF-G (Fig. 1). Bacterial release factor RF-3 accelerates the dissociation of RF-1 and RF-2 from the ribosome in a GTP-dependent manner, and fast recycling of ribosomes requires both RF-3 and RRF (2).

Figure 1. An RF-3 recycle factor model (2). This explains how RF-3 accelerates the dissociation of RF-1 / 2 from the rit

tRNA.

Termination Of DNA Replication

DNA replication can be divided into three distinct steps: initiation, elongation, and termination. The bidirectional replication of a circular chromosome of bacteria terminates at a position where the two replication forks meet. Bacteria have developed a system that ensures termination will occur within a restricted terminus region. This is achieved by a combination of a DNA motif of 20 to 30 bp, called the *ter* sequence, and a cognate termination protein that recognizes *ter* sites and binds to them tightly.

Such systems were discovered in *Escherichia coli* and *Bacillus subtilis*, through the identification of the accumulation of Y-shaped replication intermediates at specific sites in the terminus regions (1), and they have been extensively characterized genetically and biochemically (2-4). The *E. coli* termination protein is encoded by the *tus* (terminus utilization substance) gene and has a molecular weight of 36 kDa (309 amino acid residues). The Tus protein specifically binds to the *ter* sites containing the **consensus sequence** of about 20 bp, and the Tus–Ter complex arrests a replication fork approaching from one direction but not from the other. This arrest is thought to be due to the orientation-dependent inhibition of unwinding of the DNA duplex by the DnaB DNA helicase at the apex of the replication fork (Fig. 1). Seven *ter* sites have been identified in the terminus region of the *E. coli* chromosome, as shown schematically in Figure 2. The clockwise replication fork can pass through the group1 *ter* sites, but if it arrives at the group2 *ter* sites before it meets the counterclockwise replication fork, it will stall there. Similarly, the counterclockwise replication fork will stall at the group1 *ter* sites if it has not met the clockwise fork. Thus, the termination event is regulated to occur in the terminus region opposite the *oriC* replication origin.

Figure 1. Polar inhibition of the DNA duplex unwinding by DNA helicases.

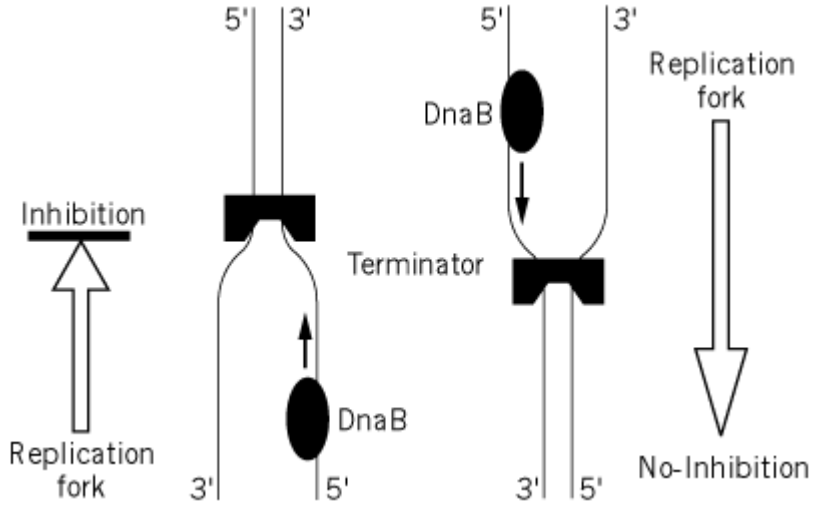

Figure 2. Location and orientation of seven *ter* sites on the *E. coli* chromosome (6).

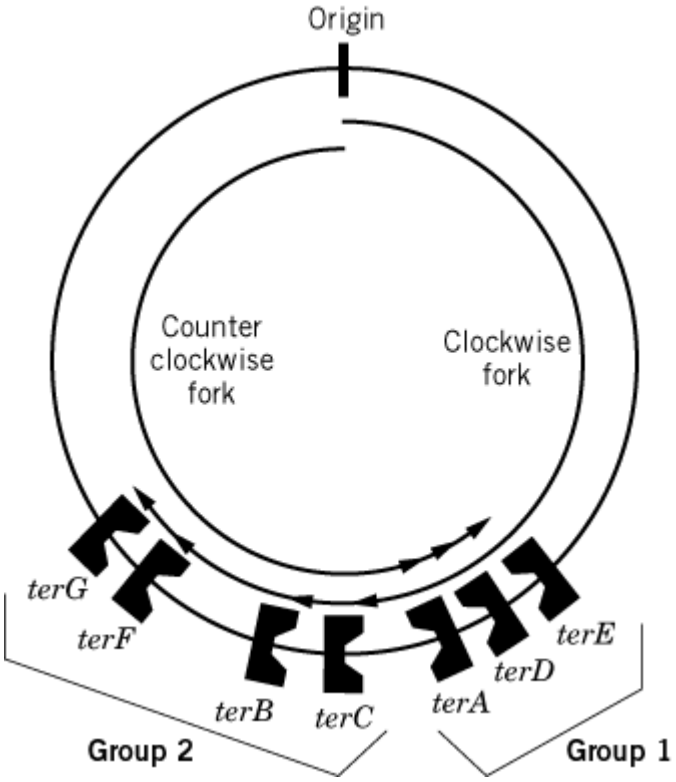

A similar system to that of *E. coli* is also present in *B. subtilis*. The *B. subtilis* termination protein, encoded by the *rtp* (replication termination protein) gene, binds to several *ter* sites on the chromosome arranged similarly to those found in *E. coli* (5). The Rtp–Ter complex can either arrest or permit the passage of the replication fork, depending on the direction of its approach. Furthermore, the *B. subtilis* Rtp–Ter system efficiently arrests the progression of the replication fork

in *E. coli*. However, the size (14.5 kDa, 122 residues) and amino acid sequence of Rtp protein are quite different from those of the *E. coli* Tus. Also, the functional *B. subtilis* arrest complex requires Rtp dimers to be bound to a longer *ter* sequence of about 30 bp in length.

The most intriguing aspect of the terminator–Ter complex is its polarity of the replication fork arrest, and two models have been proposed (6). One involves specific protein–protein interactions between the terminator and DNA helicase, and the other suggests a simple physical block of the complex (polar clump) against the action of the helicase. The findings that the Tus–Ter complex acts as a polar barrier to helicases of both prokaryotic and eukaryotic origins, and that the *B. subtilis* Rtp–Ter system efficiently arrests the progression of the replication fork in *E. coli*, support the latter model. The X-ray crystallography structures of the Tus and Rtp proteins have provided information about the molecular mechanism of the polar arrest (7, 8).

From an **evolutionary** point of view, *E. coli* and *B. subtilis* might have independently developed similar replication termination systems by convergent evolution, suggesting the advantage of the system for cell growth. However, the biological significance of the polar termination system is unclear. The terminator gene can be deleted without any apparent effect on cell growth in both *B. subtilis* and *E. coli*, indicating that chromosome replication can terminate wherever the two replication forks happen to meet. A similar system of polar replication fork block is characterized in the autonomously replicating plasmid R6K (9). Furthermore, fork-blocking sites have been reported in the **yeast**, pea, frog, and human genomes (10-13).

Tertiary Structure

Protein structure is classified in a hierarchical manner into primary structure, **secondary structure**, tertiary structure, and quaternary structure. The tertiary structure refers to the overall three-dimensional fold of the polypeptide chain of the protein. Some fibrous proteins (eg, collagen) adopt a regular repeating three-dimensional structure. In contrast, the tertiary structure of most proteins is much more complex and is formed by packing of the protein's secondary structural elements into one or more compact globular units (usually called **domains**). The tertiary structure provides information on the three-dimensional structure of each of the domains and on how the domains pack together. The complexity and diversity of protein tertiary structure gives rise to the complexity and diversity of protein function. Defining what a protein looks like, by determining its tertiary structure, is a significant step in understanding the biological function of that protein.

The tertiary structure of a protein is difficult to predict (see Protein Structure Prediction) but can be determined experimentally by protein X-ray crystallography, **nuclear magnetic resonance** (NMR) or cryoelectron microscopy. The stable folded tertiary structure of a protein conforms to certain rules of protein structure. For example, the side chains of most globular proteins are distributed in a nonrandom manner. Most **hydrophobic** residues are located in the inner core of the structure, and charged side chains are generally found on the surface. In addition, more than 90% of amino acid residues in a protein usually adopt backbone conformations that correspond to the **a-helices**, b-sheets, or turns type of secondary structure. These and other rules are used to assess the quality of experimentally determined structures and can be used to both assist and validate protein structure prediction.

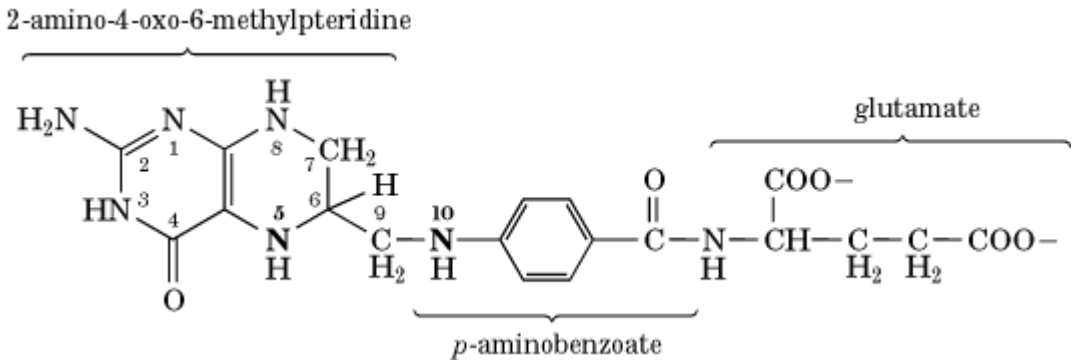
Tetrahydrofolate

The importance of folate compounds in metabolism has been established for over 50 years. Folate derivatives participate in a myriad of biosynthetic reactions involving transfers of groups containing a single carbon atom. For example, these functional units are essential components in the metabolism of the amino acids glycine, serine, methionine, and histidine, and the biosynthesis of purines and pyrimidines. Tetrahydrofolate (THF), the reduced form of folic acid, is the primary carrier of key components of the cellular machinery involving the mobilization and utilization of single-carbon functional groups at the methyl, methylene and formyl oxidation levels. Tetrahydrofolate derivatives serve as useful storage units of these functional groups that are not detrimental to the host organism, but are poised for reactivity when recruited by biosynthetic enzymes. Bacterial cells can synthesize THF, while it can be formed in mammalian cells either by intestinal microorganisms or by the

successive reduction of dietary folate by the enzyme dihydrofolate reductase to first 7,8-dihydrofolate and finally to 5,6,7,8- THF. THF consists of three functional groups: a bicyclic substituted pteridine, *p*-aminobenzoate, and a glutamic acid tail (Fig. 1). The glutamate tail can exist either as a single residue or as multiple copies linked in amide bonds through its g-carboxylate group. The most active forms of THF contain polyglutamyl tails.

Figure 1. Chemical structure of THF. The N^5 and N^{10}-nitrogen atoms that can carry one-carbon functional groups are in boldface.



One-carbon functional groups can be appended at position N ^{5}, N^{10} or bridged between the N^5 and N^{10} positions of THF (Fig. 2). The most reduced form of THF carries a methyl group at the N^5 position, the intermediate form carries a methylene group that bridges N^5 and N^{10}, and the most oxidized forms carry a methenyl, formyl, or formamino group at either the N^5 or the N^{10} position. Several functional groups, such as the methenyl, formyl, formimino, methylene, and methyl groups, can be interconverted while the carbon moiety is attached to THF. This feature allows a carbon group that was removed from one molecule in one oxidation state to be transferred to a second molecule in a different oxidation state. For example, N^{10} -formyl THF (the most oxidized) can be synthesized from THF, formate and ATP by the enzyme N^{10}-formyl THF synthetase. The newly generated N^{10}-formyl-THF can be dehydrated to form N^5, N ^{10}-methenyl-THF (most oxidized), which can be reduced to form N^5, N^{10}-methylene-THF (intermediate oxidation state), interconverted to N ^{5}-formyl THF, or deamidated to form N^5-formimino-THF (most oxidized). The reduced N^5, N^{10}-methylene-THF can be further reduced by the enzyme N^5, N^{10}-methylene-THF reductase to form the THF derivative N^5-methyl-THF (most reduced) which is an essential component in the conversion of homocysteine to methionine. N^5, N^{10}-methylene-THF is also generated from THF by the enzyme serine hydroxymethyl transferase, in the conversion of serine to glycine. All these THF derivatives can serve as either cofactor in a variety of biosynthetic and metabolic pathways, or as a means to neutralize and store activated one-carbon units that are byproducts of degradation reactions. Because THF and its derivatives are essential components in a number of biosynthetic reactions, folate-dependent enzymes are good targets for both antimicrobial and antineoplastic drugs.

Figure 2. The interconversions of one-carbon functional groups on THF. The N^5 and N^{10}-nitrogens and the one-carbon functional groups are in boldface.

Tetranitromethane

Tetranitromethane (TNM) is commonly used for the nitration of tyrosine residues in proteins. It has the structure $C(NO_2)_4$ and a molecular weight of 196.04. It is normally a pale yellow liquid with a melting point of +13.8°C and a boiling point of 126°C. TNM is prepared by nitrating acetic anhydride with anhydrous nitric acid. TNM is also used to detect double bonds in organic compounds.

Tetraploidy

Tetraploidy is common in **plants**. This type of **polyploidy** is characterized by four basic genomes in the cell nucleus with four copies of each of the chromosomes. If the chromosomes are identical (AAAA), the organism is called *autetraploid*. If the cell has arisen by hybridization between related species, followed by production of unreduced gametes, it is called *allotetraploid* (AABB). Because of their even number of chromosomes, both types of tetraploids undergo regular **meiosis**, and the tetraploidy is passed on to future generations.

Thalassemia

The term thalassemia comes from the Greek qalassa, the word for the Mediterranean sea. An earlier designation for the disorder was Mediterranean anemia , as the earliest cases were described in populations in that area, particularly in Italy and Greece. Subsequently, similar conditions occurred extensively in Africa and in Asia. The term Cooley's anemia is also used.

Thalassemia has proved to be a problem of hemoglobin (Hb) production. All Hb's are tetrameric proteins, composed of four polypeptide chains of two types, a and b. The a-type globin chains are coded in humans by a complex of **genes** on chromosome 16, and the b-type chains by a complex of genes on chromosome 11. The molecular formula for Hb is written a_2b_2, a_2d_2, etc., depending upon which combination of a-like and b-like polypeptides are involved.

Persons who have the classic Mediterranean version of thalassemia (thalassemia major) are severely anemic in childhood and have poor survival. Others in the same families may have mild anemia (thalassemia minor) that is not life threatening. Genetic studies indicated that the severe cases are caused by **homozygosity** for a gene that, in **heterozygous** combination with its normal **allele**, produces mild anemia. Studies of families in which hemoglobin variants were also segregating confirmed that most thalassemia mutations in the Mediterranean area and in Africa map to the b-globin gene complex on chromosome 11. Those that did not map to the b-globin complex, and this

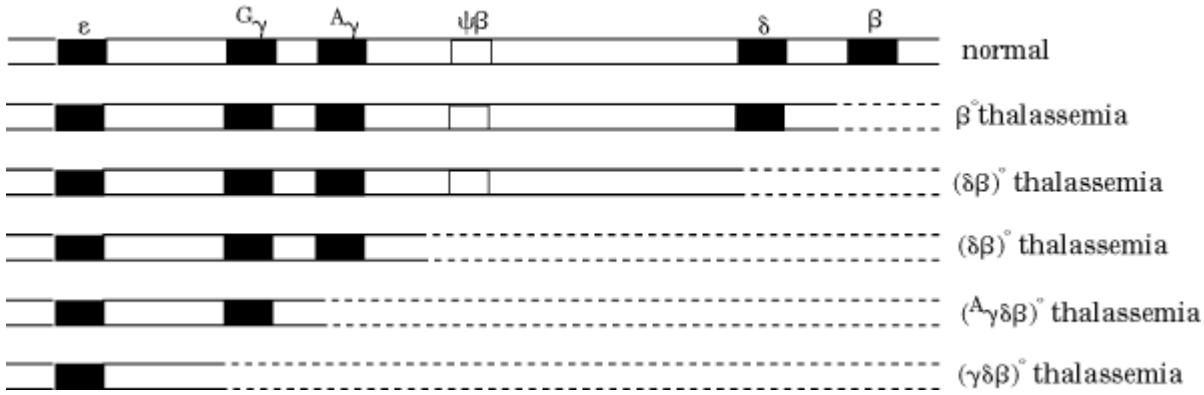
included most of the Asian examples, mapped to the a-globin gene complex on chromosome 16.

Because the hemoglobins looked structurally normal in thalassemia, it was at first thought that thalassemia is due to regulatory mutations in the globin complexes. Subsequently, it was observed that there are structural modifications of globins in the case of some, but not all, thalassemia mutations. Therefore, the definition of thalassemia has been expanded to included all mutations in the globin gene complexes that significantly reduce the production of functional globin.

1. Beta-thalassemia

Numerous mutations in the b-globin complex on chromosome 11 result in thalassemia. Some are single base-pair substitutions that may be in coding regions (**exons**), in **introns**, or in regulatory regions. Many gene deletions also have been identified. Figure 1, a diagram of the b-globin complex, shows examples of deletions associated with thalassemia. If any part of the b-globin gene is deleted, no b-globin is produced. If the deletion affects only the b-globin gene, the mutation is described as a b°-thalassemia mutation. Other globin genes would not be affected, but a child who is homozygous for a b° mutation cannot make Hb A (a_2b_2), the major Hb in children and adults. The g chains that are part of fetal Hb (Hb F; a_2g_2) function normally in the fetus and would do so in an adult were the g genes to remain active beyond the fetal period, as they do in the condition known as hereditary persistence of fetal hemoglobin . The d gene is active in b°-thalassemia, but the amount of Hb A_2 (a_2d_2) produced is insufficient to meet the requirement for oxygen transport.

Figure 1. Genetic structure of the human b-globin gene complex on chromosome 11. The yb locus is a nonfunctional pseudogene . Examples of deletion alleles associated with b-thalassemia are shown by the dotted line. Homozygous and heterozygous combinations of these alleles produce various forms of thalassemia, depending on the specific loci deleted. Gene positions and sizes are not drawn to scale.



Some deletions involve both the b and d genes, homozygosity for which would be designated (bd)°-thalassemia. Clinically, such patients are not different from those with b° thalassemia. Deletions that extend from the b gene into or beyond the g genes are described as (bgd)° mutations. In this case, fetal Hb and adult Hb synthesis is impaired, and fetuses homozygous for such mutations would be aborted. If the entire b complex is deleted, even embryonic Hb would not be made, and abortion of the embryo would occur. Several examples of b°-thalassemia are due to insertions or deletions of one or two nucleotides in the coding regions that produce frameshift mutations.

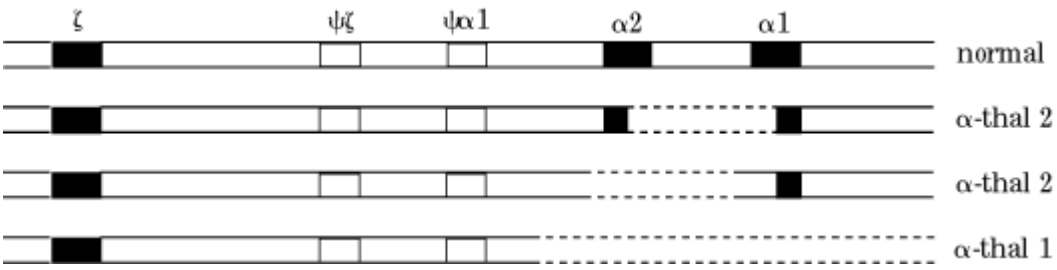
Some mutations greatly diminish transcription of the b-globin gene but do not abolish it completely. These are typically nucleotide substitutions, within coding regions or in introns, in untranslated regions of the transcript, or in regulatory regions. If the substitution is in the coding region, an

altered globin may be produced. In the case of Hb E, for example, a substitution in codon 26 of the b-globin gene changes the amino acid from glutamic acid to lysine and also creates a splice site that competes with the normal **splicing** position in codon 30. When normal splicing of the RNA occurs, Hb E is produced. Abnormal splicing yields no recognizable product. Mutations that lead to diminished synthesis rather than absence of b-globin are described as b^+-thalassemia mutations.

2. Alpha-thalassemia

Much of what has been said about b-thalassemias applies to the a-globin gene complex on chromosome 16. One difference, however, is the need for a-globin chains during the fetal period. The predominant Hb in the fetus is fetal Hb (Hb F, a_2g_2). Any major disruption of a-globin synthesis is detrimental to fetuses and to postnatal individuals. There is also a difference in structure between the a- and b-globin loci, as illustrated in Fig. 2. Normal chromosomes have two identical copies of the a-globin gene. Thus, a normal diploid genomic complement has four functional a-globin genes.

Figure 2. Genetic structure of the human a-globin gene complex on chromosome 11. There are two nonfunctional pseudogenes (y). Examples of deletion alleles associated with a-thalassemia are illustrated by the dotted lines. The deletion break points in the upper a-thal 2 allele are at homologous positions in the two a genes, creating a single fused functional a gene. Gene positions and sizes are not drawm to scale.



Mutations of the a-globin genes occur widely but are particularly common in Asia. There are two common mutant alleles. One has a deletion of one locus (called the a-thalassemia 2 allele), and the other has deletion of both loci (called the a-thalassemia 1 allele). This generates diploid combinations of chromosomes with 0, 1, 2, 3, or 4 a-globin genes. Phenotypically, it makes no difference how the sum of the genes is achieved, that is, a person who has two functional genes could either be homozygous for chromosomes with one gene each (homozygous a-thalassemia 2) or heterozygous for chromosomes with 0 and 2 genes (heterozygous a-thalassemia 1). Persons who have three functional a-globin genes are phenotypically normal. If only two functional genes are present, Hb levels are slightly lower than normal, and there is mild microcytosis. If only one functional gene is present, moderate hemolytic anemia occurs, along with other hematological symptoms. Hb H (b_4) precipitates in the red cells, and this form of thalassemia is also known as Hb H disease. A fetus homozygous for an a-thalassemia 1 chromosome has no functional a-globin genes. Some synthesis of z-globin chains occurs, forming Hb Portland (z_2g_2), but most of the Hb is in the form of Hb Bart's (g_4). Such fetuses have hydrops fetalis, severe anemia, and hepatosplenomegaly. Birth is premature, and the child is stillborn or dies shortly afterward. This condition is known almost solely in Asia, where the a-thalassemia 1 mutation is sufficiently common to produce homozygotes.

3. Combinations of thalassemia mutations with structural variants

One of the first indications that thalassemia is directly related to the globin genes came from observations on compound heterozygotes (double heterozygotes for a Hb variant and thalassemia).

Because b-thalassemia occurs in Africa, as does **sickle cell** anemia (Hb S) and Hb C, most of the early studies involved combinations of these variants. People who have a Hb S allele from one parent and a thalassemia allele from the other produce Hb S that has little or no Hb A. The red cells would sickle, although the condition is milder than typical sickle cell anemia, particularly if some Hb A is produced. Based on the proof that thalassemia mutations are allelic to b-globin loci in most Africans and the distinction between b^+ and b° mutations, the phenotypic effects became readily understood. The combination Hb-S/b°-thal has no potential to produce normal Hb A. Combinations with b^+ mutations produce reduced amounts of Hb A. Similar studies with the b-globin mutation that produces Hb C gave the same results, although the C/thal heterozygote has only mild anemia.

Combinations of structural mutations of a-globin loci that have a-thalassemia mutations are typically benign, unless the structural mutation is associated with depressed globin production. In that case, it would also qualify as a thalassemia mutation. An example is Hb Constant Spring, a widely occurring a-globin mutation in which the termination codon is replaced with a sense codon, causing translation to continue beyond the usual stopping point. The amount of this globin is greatly reduced. When it is combined with other a-thalassemia mutations, the clinical picture is much like it would be if the Hb Constant Spring gene were deleted.

The combination of a-thalassemia mutations with b-globin mutations ameliorates the impact of the b-globin mutations somewhat. For example, if a person is heterozygous for sickle-cell anemia and a-thalassemia 1, the ratio of Hb S to Hb A drops, apparently because the b^S-globin chains do not compete as effectively as b^A-globin chains for the limited supply of a-chains.

4. Population Genetics of Thalassemia

Thalassemia occurs predominantly in hot and tropical areas and in descendants of persons whose ancestral origins are from those areas. In different areas, however, quite different spectra of thalassemia mutations are prevalent. In the Mediterranean area and in Africa, most thalassemia is due to b-globin gene mutations. In Asia, mutations are predominantly in the a-globin genes. The most common mutation in the Mediterranean is a G to A substitution at position 110 of intron 1. This creates an alternative splice site at the 3′-end of the intron. Because some of the pre-mRNA is spliced correctly, this is a b^+-thalassemia. In the so-called Ferrara-type thalassemia, which occurs primarily in Italy, codon 39 of the b-globin gene is changed to a termination codon, producing a b°-thalassemia. In China and India, a common b°-thalassemia mutation involves a deletion of four nucleotides in codons 41 and 42. The Hb E mutation is a common cause of b^+-thalassemia in Asia.

The predominant a-thalassemia mutations are deletions. In Asia, either one or both a-globin genes on a chromosome may be deleted, generating the large number of combinations discussed earlier. In Africa, a-thalassemia also occurs, but only the chromosome from which one a-globin gene is deleted, is common. Thus the Hb H disease and hydrops fetalis observed in China are rare in Africa.

The frequent occurrence of thalassemia in Africa, Southeast Asia, and the Mediterranean area, but not in more temperate regions, raised the possibility that these detrimental genes have some counterbalancing selection. This was supported by the recognition that a different spectrum of mutations is involved in thalassemia in different areas. The areas in which thalassemia genes are common correspond generally to the occurrence of falciparum malaria, and it is now thought that persons with milder versions of thalassemia have increased resistance to falciparum malaria, as is the case with sickle cell anemia. See also Hemoglobin Mutations.

Thermolysin

Thermolysin is a zinc **metalloenzyme** that is secreted into the culture medium by the thermostable **microorganism**, *Bacillus thermoproteolyticus* (Fig. 1). It is an **endoproteinase** (E.C. 3.4.24.27) that catalyzes the hydrolysis of peptide bonds in which the NH- group is contributed by a **hydrophobic** amino acid residue (1). Thermolysin, as its name implies, is a useful enzyme for degrading proteins that are resistant to other proteinases, because it is remarkably stable in solution at fairly high temperatures (ie, 80°C). It can be used, therefore, under conditions where most other proteins are unfolded (denatured by heat), thus exposing susceptible peptide bonds to the enzyme. It does not contain any stabilizing disulfide bonds, but it contains four calcium ions that are important for stability (Fig. 1). Removal of calcium by treatment with EDTA or by mild acidic conditions rapidly abolishes activity, as a result of autolytic degradation. Thermolysin is typical of a family of bacterial neutral proteinases that have similar neutral pH optima, amino acid sequences, metal contents, and mechanisms of action. A natural product synthesized by actinomyces and secreted into the culture medium is a potent inhibitor of thermolysin and related neutral proteinases. It is known as phosphoramidon, and chemically it is *N*-(a-L-rhamnopyranosyloxyphosphinyl)- L-leucyl-L-tryptophan (2) (Fig. 2). The sugar part of this inhibitor is not essential for good inhibition, and in fact phosphoryl-leucyl-tryptophan is even more effective than phosphoramidon (K_i = 2nM versus 28 nM).

Figure 1. The three-dimensional structure of thermolysin. Only the backbone is depicted schematically as a ribbon, with arrows for b-strands and coils for a-helices. The dark sphere is the zinc ion at the active site, whereas the open spheres are stabilizing calcium ions.

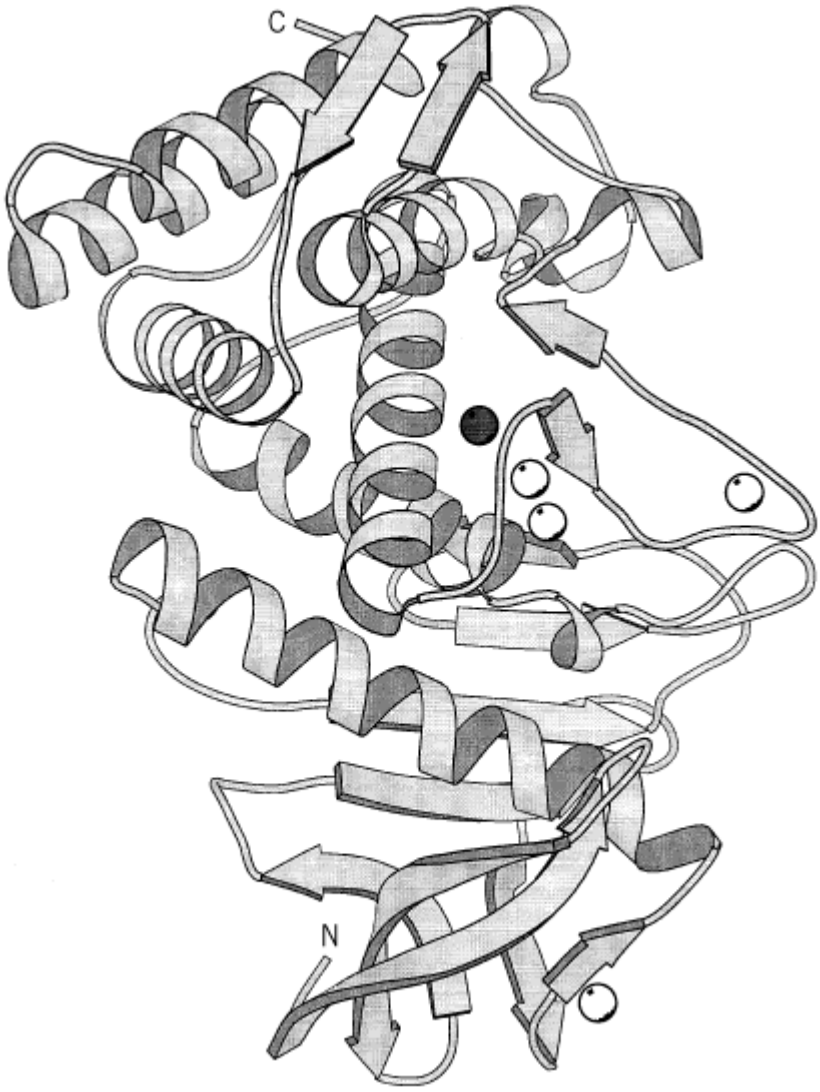

Figure 2. Chemical structure of phosphoramidon (rhamnose-phosphoryl-leucyl-tryptophan), an inhibitor of many bacterial metalloendopeptidases, such as thermolysin. Interaction of the phosphoryl group with the active site zinc contributes to the specificity of inhibition for this class of enzymes.

Thin Filament

The thin filament is the **actin**-based protein polymer that interacts with myosin to generate muscle contraction. The thin filament contains different actin-associated proteins in striated muscle and in smooth muscle. In striated (skeletal or cardiac) muscle it is interdigitated between the myosin-based thick filaments in a highly ordered lattice. It is approximately 100 Å in diameter (see Microfilament) and can have a length of ~110 μm. The striated muscle thin filament contains the regulatory proteins tropomyosin and troponin in addition to actin. X-ray fiber diffraction has been used to generate an atomic model of the actin-tropomyosin component of the thin filament (1). Skeletal striated muscle thin filaments also contain the giant molecule nebulin, which is believed to function as a regulator of thin filament length (2). Most thin filaments have a defined stoichiometry of one tropomyosin coiled-coil dimer and one troponin complex for every seven actin subunits. The troponin complex contains three subunits: troponin C (for calcium-binding), troponin I (for inhibitory), and troponin T (for tropomyosin-binding). The release of Ca^{2+} by the sarcoplasmic reticulum of striated muscle leads to the binding of Ca^{2+} by troponin T, and then to an azimuthal rotation of the tropomyosin–troponin complex about the actin filament. This unblocks the myosin-binding site on the surface of the actin filament, as proposed in the "steric-blocking" model for thin filament regulation (3). Recent evidence has suggested that the initial binding of myosin to F-actin is required for an additional shift of the tropomyosin–troponin complex that leads to full activation of the thin filament (4).

Within smooth muscle, the thin filament contains the actin-binding proteins caldesmon and calponin, in addition to tropomyosin. The regulatory role of these accessory proteins in smooth muscle contraction (where the main regulation resides on the myosin filaments) is much less understood than it is for striated muscle thin filaments, and structural studies have suggested that the roles of calponin (5) and caldesmon (6) in smooth muscle cannot be the same as that played by troponin in striated muscle.

Thin-Layer Chromatography/Electrophoresis

1. Chromatography

Thin-layer chromatography (TLC), in which the adsorbent is in a thin and uniform layer fixed on a suitable supporting plate of a material, such as glass or plastic, was first suggested by Izmailov and Shraiber in 1938 (1). This type of chromatography was not widely used until the late 1950s, probably because the development of paper and **gas-liquid** chromatography was proceeding rapidly at that time. Its rapid development began about 1956, mainly because of the work of Stahl (2, 3), who devised convenient methods for preparing plates and showed that TLC is applicable to a wide variety of separations.

In thin-layer chromatography, a solution of the sample in a volatile solvent is applied to the bottom of a TLC plate. When the spot has dried, the plate is placed vertically in a suitable tank with its lower edge immersed in the selected mobile phase. The mobile phase rises by capillary action, producing an ascending chromatographic separation and resolving the various components of the sample mixture into discrete spots. At the end of the run, the mobile phase is allowed to evaporate from the plate, and the separated spots are located and identified by physical and/or chemical methods.

Thin-layer chromatography has the advantage of performing a separation easily in a minimum of time and with a minimum of chemicals and instrumentation. TLC also offers good selectivity and a wide variety of possible chromatographic interactions. TLC run in a two-dimensional mode has more separating power than the well-developed **HPLC** method. Recent developments in TLC instrumentation make the field more and more exciting and provide increased possibilities for performing this technique with high accuracy (4).

2. Electrophoresis

The basis of electrophoresis is the differential migration rate of ionic molecules in an electrolyte solution under the influence of an applied electric field. Although electrophoresis is not in principle a chromatographic technique, it is used in conjunction with paper chromatography, and it provides an extremely useful method for separating charged substances, such as proteins and **nucleic acids**. Many forms of electrophoresis are carried out in gel media. Electrophoresis carried out on cellulose or paper strips is called zone electrophoresis. The capillary walls provide mechanical support for the carrier electrolyte in capillary zone electrophoresis. Detailed practice in electrophoresis is beyond the scope of this article, so interested readers are directed to a number of excellent monographs (5, 6).

Thiol Groups

Thiol groups are encountered in biological systems in cysteine residues and in cofactors such as lipoamide and lipoic acid. They are also called *sulfhydryl* and *mercapto* groups. When Zeise discovered C_2H_5SH in 1834, he called it "mercaptan" (corpus mercurium captans) because the formation of mercury derivatives was a striking characteristic. The thiol group is the most chemically reactive group that is normally encountered in biological systems. It is a powerful nucleophile that undergoes a wide variety of chemical reactions, many of which are exploited in its biological functions. A most important property is its tendency to ionize,

$$-SH \leftrightarrow -S^- + H^+ \quad (1)$$

to the thiolate anion, which is usually the reactive species. The nonionized thiol group is usually unreactive. Most alkyl thiol groups, such as those of cysteine residues, have pK_a values close to 9. Therefore, they are reactive only at alkaline pH values, where significant amounts of thiolate anion are present. The thiolate anion is known as a soft nucleophile, poorly solvated, highly polarizable, with vacant *d*-orbitals and nucleophilic power much greater than would be predicted from its basicity. Thiol groups have only very weak **hydrogen-bonding** capabilities.

Thiol groups under too many chemical reactions to catalogue completely. Only the most important are described here.

1. Oxidation

Thiol groups are readily oxidized by oxygen, especially in the presence of trace amounts of metal ions, such as Cu^{2+}, Fe^{2+}, Co^{2+}, and Mn^{2+}; it is likely that the complex of metal and thiol (see below) is the actual reactant with oxygen. Thiol groups may be oxidized to various oxidation states, but some of them are intrinsically unstable. In addition to the thiol form, only two oxidation states are generally encountered, the disulfide and the sulfonic acid. The disulfide is usually the end product of air oxidation:

$$2-SH + \frac{1}{2}O_2 \rightarrow -S-S- + H_2O \quad (2)$$

Disulfide bonds between cysteine residues are often found in proteins, especially those secreted from cells. These disulfide bonds are not produced by air oxidation, however, but are incorporated by the catalyst protein disulfide isomerase .

The sulfonic acids are produced by more potent oxidizing agents. For example, performic acid oxidizes both thiol and disulfide forms of Cys residues of proteins to cysteic acid, with the CH_2–SO^-_3 side chain. The intermediate sulfenate (–SO^-) and sulfinate (–SO^-_2) oxidation states are generally unstable and not normally present. They have been identified, however, when specifically stabilized in a protein structure, as in the case of the cysteine sulfenic acid that is involved in the catalytic mechanism of NADH peroxidase (1).

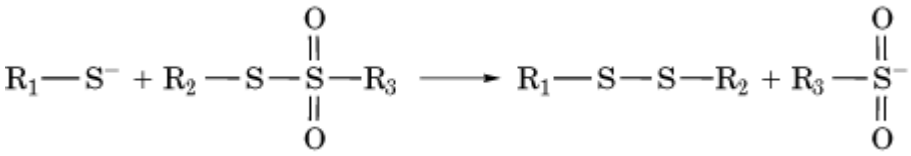
2. Thiol–disulfide exchange

Thiolate anions react rapidly with disulfide bonds, displacing one sulfur atom of the disulfide bond and taking its place:

$$R_1 - S^- + R_2 - S - S - R_3 \rightarrow R_1 - S - S - R_2 + R_3 - S^- \quad (3)$$

Such thiol–disulfide exchange reactions will continue among all the thiol and disulfide species present until an equilibrium mixture is generated. Thiol–disulfide exchange reactions are extremely specific, and that with 5,5′-dithio-bisnitrobenzoic acid (DTNB), or **Ellman's reagent**, is the most convenient and accurate method of assaying thiol groups quantitatively.

If one of the sulfur atoms of the disulfide is oxidized to the sulfonate, it does not take part in thiol–disulfide exchange, and only a single reaction will take place if the reagent is present in great excess over the thiol group:

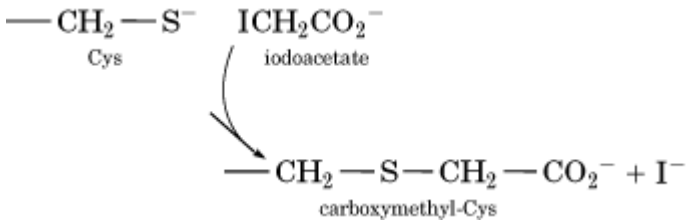


Such reactions are very useful for making specific mixed disulfide species in stoichiometric quantities. The same can be accomplished with thiocyanate derivatives in which the thiol displaces the cyanide ion:

$$-S^- + R - S - CN \rightarrow -S - S - R + CN^- \quad (5)$$

3. Alkylation

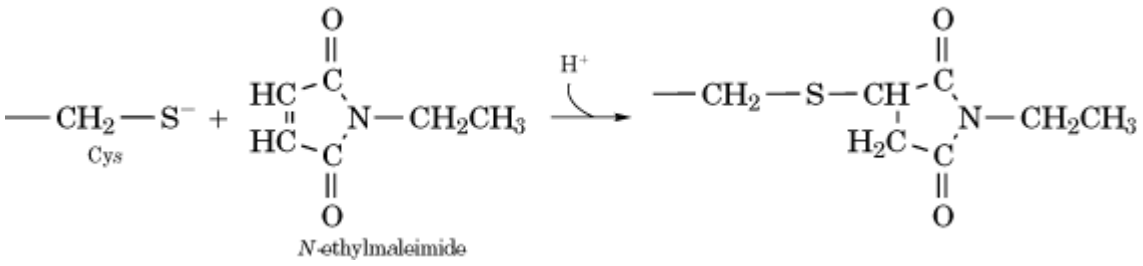
Thiolate anions react rapidly with alkyl halides, such as **iodoacetamide**, **iodoacetate**, and methyl iodide:



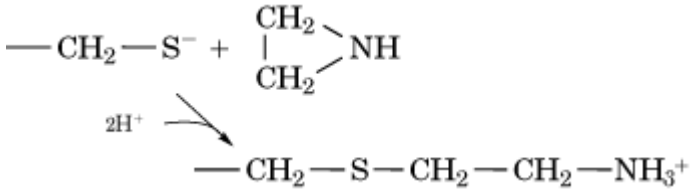
Such reactions are irreversible and the adduct generated is very stable.

4. Addition across double bonds

Thiolate anions are sufficiently nucleophilic to add across C=C double bonds, as in maleic anhydride. *N*-Ethylmaleimide is the classic reagent that is used most frequently to modify thiol groups:



Thiol groups can also open the ring of ethylenimine:



With cysteine residues in proteins, the resulting side-chain is now positively charged and is analogous to a lysine or arginine side-chain. Consequently, **proteolytic** enzymes such as **trypsin** will cleave the peptide bond after such a residue, so this modification is used frequently in peptide mapping studies of proteins.

5. Metal ions

Thiol groups form complexes of varying stabilities with a variety of metal ions. The most stable are those with divalent mercury, Hg^{2+}, but its divalency means that complexes with a variety of stoichiometries are formed. Consequently, univalent organic mercurials of the type R–Hg^{+} tend to be used instead, because they more reproducibly form one-to-one complexes with thiol groups. Such reactions with mercurials are the most obvious and one of the more useful ways to make heavy-atom derivatives for X-ray crystallography determination of protein structure (see Isomorphous Replacement).

Thiol complexes with silver are less stable than those of mercury, but univalent Ag^{+} reacts stoichiometrically and can be used to titrate thiol groups. Copper, iron, zinc, cobalt, molybdenum, manganese, and cadmium ions all form various complexes with thiol groups.

Thiol Proteinase

This class of proteinase (E.C. 3.4.22) catalyzes peptide bond hydrolysis by a mechanism that involves the thiol group of the side-chain of a cysteine residue. These enzymes are also known as *cysteine* or *sulfhydryl proteinases* . The thiol group interacts with the carbonyl group of the

substrate's peptide bond that is to be hydrolyzed and forms a thiol ester intermediate. A histidine side chain enhances the reactivity of the thiol group in much the same way that a serine hydroxyl group is activated in serine proteinases. Thiol proteinases tend to act at moderately acidic pH, about 5, and are the predominant hydrolases found in **lysosomes** and endosomes. A well-known thiol proteinase derived from the papaya plant is papain, the key ingredient in a commonly used meat tenderizer.

Any reagent that will react chemically with a sulfhydryl group will inactivate a thiol proteinase. **Iodoacetate** is such a nonspecific inactivator, whereas E64 [L-transepoxysuccinyl-leucyl-amido (4-guanidino) butane] is a more useful general inhibitor of thiol proteinases. Protein inhibitors present in blood plasma, and known as cystatins, block activity by covering the active site of the enzyme. Leupeptin, a peptide aldehyde, is another general thiol proteinase inhibitor that binds tightly to the catalytic center.

A thiol proteinase appears to be responsible for the activation of the precursor peptide that gives rise to the enkephalins, and E64 has been proposed as an inhibitor of prohormone processing (1). A thiol proteinase has been shown to be involved in the conversion of pre-renin to *renin*, which is the enzyme catalyzing the rate-determining step in the production of the hypertensive peptide, *angiotensin* II (2). *Cruzipain*, a thiol proteinase, has a critical function in the infectious disease trypanosomiasis, which affects millions of Central and South Americans and, hence, is a target for selective inhibition (3).

An important subclass of the cysteine proteinases includes the **interleukin**-1b converting enzyme, which converts an inactive precursor to a proinflammatory **cytokine** (4). These enzymes specifically cleave peptide bonds after aspartic acid residues and, hence, are called *caspases*. One member of this class, caspase-3, cleaves poly (ADP-ribose) polymerase and hence plays a key role in programmed cell death (see Apoptosis) (5), a process of fundamental importance to biology.

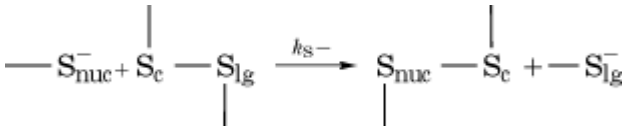
Thiol–Disulfide Exchange

Thiol Groups and disulfide bonds undergo a spontaneous chemical reaction, in which the thiol group displaces one sulfur atom of the disulfide bond in an S_N2 type of reaction:



(**1**)

This reaction is involved in very many biological phenomena, especially those involving the thiol groups of cysteine residues of proteins, thioredoxin, glutaredoxin, protein disulfide isomerase, glutathione, coenzyme A, dihydrolipoamide, and lipoic acid. This thiol–disulfide exchange reaction is unique in physical organic chemistry in its ability to break and reform a strong, directional, covalent, disulfide bond in water at room temperature reversibly at a rapid rate that can be varied over many orders of magnitude by controlling the pH. Nevertheless, it is one of the most specific chemical reactions used in molecular biology, and thiol groups and disulfide bonds tend not to react with other groups on proteins, nucleic acids, etc.

It is the ionized form of the thiol group that is the reactive species, so the rate of the reaction varies with the pH below the pK_a of the thiol group; typical biological thiol groups of cysteine residues have pK_a values in the region of 9. The reaction can be quenched by acidification, making the thiolate anion insignificant. Alternatively, such mixtures can be trapped irreversibly by rapidly reacting all free thiol groups with reagents such as **iodoacetamide**, iodoacetate, or ***N*-ethylmaleimide**. The thiol and disulfide species present in both equilibrium and kinetic trapped mixtures can be analyzed chemically, for example, by **HPLC** or NMR, under acidic conditions. The rate of a simple thiol–disulfide exchange reaction can be measured if the disulfide bonds reacting and being generated differ in their spectrophotometric properties. For example, cyclic disulfide bonds in 5- or 6-membered rings, such as that formed in **dithiothreitol**, absorb at 280 to 330 nm, whereas most linear disulfide bonds do not. Dynamic ^{1}H-NMR lineshape analysis and spin-transfer method have also been used to measure rate constants for simple model systems.

The three sulfur atoms involved in the reactions are generally labeled as the nucleophile (nuc), the central atom (c), and the leaving group (lg). The reaction occurs by the ionized thiolate anion nucleophile attacking one of the two sulfur atoms of the disulfide bond, which becomes the central atom, optimally along the axis of the S-S bond. The transition state for the reaction is expected to be a linear arrangement of the three sulfur atoms, equally spaced, and with the negative charge of the thiolate anion spread symmetrically, with more on the terminal atoms than on the central one. The rate constant for the reaction depends upon the electron affinities of each of the three sulfur atoms, which are conveniently measured by their pK_a values when thiol groups (1, 2). The second-order rate constant for the intermolecular reaction between model compounds can be predicted by these three pK_a values:

$$\log k_{\mathrm{RS}^-}(\mathrm{s}^{-1}\mathrm{M}^{-1}) = 4.5 + 0.59\mathrm{p}K_{\mathrm{a}}^{\mathrm{nuc}} - 0.40\mathrm{p}K_{\mathrm{a}}^{\mathrm{c}} - 0.59\mathrm{p}K_{\mathrm{a}}^{\mathrm{lg}} \quad (2)$$

$$\log k_{\mathrm{obs}} = 4.5 + 0.59\mathrm{p}K_{\mathrm{a}}^{\mathrm{nuc}} - 0.40\mathrm{p}K_{\mathrm{a}}^{\mathrm{c}} - 0.59\mathrm{p}K_{\mathrm{a}}^{\mathrm{lg}} - \log(1 + 10^{\mathrm{p}K_{\mathrm{nuc}} - \mathrm{pH}}) \quad (3)$$

Of course, it is not possible to measure just one thiol–disulfide exchange reaction, such as that of Eq. 2, for the thiolate anion will also react with the other sulfur atom of the disulfide bond, and the combined rates will be measured as any initial rate. Subsequently, the mixed disulfides formed will also react further with other thiol groups, leading to complex mixtures of disulfide and thiol species. The second-order rate constant for reaction of a typical, fully ionized thiol group with a typical cysteine disulfide bond is approximately 20s^{-1}M^{-1} at 25°C. The optimum pK_a for the attacking thiol

group, to give the largest rate, is the same as the pH of the reaction. A thiol with a greater pK_a value will have less ionized form; with a lower pK_a value, the thiol is ionized, but its nucleophilicity is lower.

The above considerations also apply equally to the reverse of the reaction, and the expected equilibrium constant can be estimated from Eq. 4 for the reaction in both directions. The equilibrium constant is pH-dependent if the attacking and leaving sulfur atoms have different pK_a values; it varies over the pH interval between the two thiol pK_a values. The equilibrium favors the thiol group with the lower pK_a value; just the opposite would have been predicted considering only the effect of ionization of the two thiol groups on mass action.

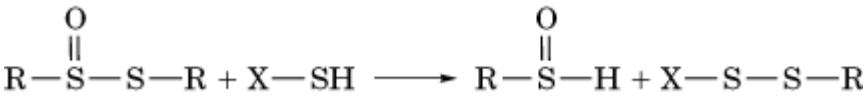
Of course, the reaction occurs more rapidly than predicted if there are positive charges near the disulfide bond, to attract the attacking thiolate anion, or if the disulfide bond is strained; for example, the strained disulfide bond of lipoic acid reacts considerably more rapidly than otherwise expected (1), which is accounted for about 3.8 kcal/mol of conformational strain in the 5-membered ring (the CSSC dihedral angle is only about 30° and not the favored 90°). Conversely, the reaction is inhibited by the presence of negative charges near the disulfide bond, if either the thiol or disulfide group is buried and inaccessible, or if there are bulky substituents adjacent to the sulfur atoms. Electrostatic effects on the equilibria of thiol–disulfide exchange reactions are small in magnitude, but occur in the expected direction. Formation of a mixed disulfide with unlike charges close on the two moieties is favored, while that with like charges is disfavored. Such effects are substantial only when the charged groups are on adjacent residues, and their magnitude can be decreased in magnitude by electrostatic screening with high salt concentrations.

The thiol–disulfide exchange reaction is routinely used in molecular biology when protein disulfide bonds (P^S_S) are reduced by reagents such as dithiothreitol or b-**mercaptoethanol**. In this case, two sequential thiol–disulfide exchange reactions are necessary, proceeding through a mixed disulfide between the reagent (RSH) and the protein:

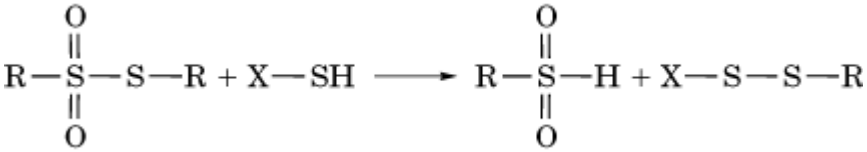
$$P^S_S + 2RSH \leftrightarrow P^{SSR}_{SH} + RSH \leftrightarrow P^{SH}_{SH} + RSSR \qquad (4)$$

Of course, thiol–disulfide exchange reactions are readily reversible, and the above reactions can be used to add disulfide bonds to a protein (see Protein Folding In Vitro).

The thiol–disulfide exchange reaction can be simplified if a mono- or dioxide form of the disulfide is used. The oxidation increases the reactivity, but only the nonoxidized sulfur atom undergoes thiol–disulfide exchange:



(5)



(6)

Consequently, the reaction stops at this stage and will be stoichiometric.

Some proteins, such as thioredoxin, glutaredoxin, and **protein disulfide isomerase** (**PDI**),

participate in thiol–disulfide exchange reactions much more rapidly than expected from the pK_a values of their active-site thiol groups (Eq.(3)). This is believed to be due to these proteins tending to bind noncovalently the molecules that they react with, as an enzyme binds its substrate, and to them actually stabilizing the transition state for the reaction, again like an enzyme. When present in small quantities, such proteins appear to catalyze thiol–disulfide exchange reactions between other thiol and disulfide compounds. They do this by reacting more rapidly with both the thiol and disulfide compounds, so they do not catalyze the direct reaction between them but instead provide a more rapid alternative reaction pathway (3).

Thioredoxin

Thioredoxin (Trx) is a 12-kDa **redox protein** that has a redox-active **disulfide bond** in its active site with the conserved sequence -Cys-Gly-Pro-Cys- (1, 2). The reduced form of Trx, Trx-$(SH)_2$, is a powerful protein disulfide reductase, and the disulfide in oxidized thioredoxin (Trx-S_2) is reduced by NADPH and the flavoenzyme thioredoxin reductase (3, 4). Thioredoxin, NADPH, and thioredoxin reductase, the thioredoxin system, exists in all living cells and is a hydrogen donor for synthesizing deoxyribonucleotides by **ribonucleotide reductase**, which is essential for DNA replication. The thioredoxin system plays a major role in maintaining a reducing environment in the cytosol. Thioredoxin catalyzes dithiol-disulfide oxidoreductions and has a large number of functions (reviewed in Ref. 5), for example, as a hydrogen donor for reductive enzymes, in phage T7 DNA replication, in filamentous phage assembly, in chloroplast **photosynthetic** enzyme regulation by light, in redox regulation of enzymes and transcription factors by thiol/disulfide redox control, in defense against oxidative stress, and as a secreted co**cytokine** in mammalian cells.

1. Structure

The three-dimensional **protein structures** of both oxidized and reduced thioredoxins have been determined in solution by both X-ray crystallography and **NMR**. They have the same globular “a/b sandwich” structure that is now called the thioredoxin fold. The active-site cysteine residues are located on a protrusion at the C-terminus of a beta-strand and at the beginning of an **alpha-helix**. The sulfur atom of the N-terminal Cys residue is solvent-exposed and its **thiol group** is the nucleophile that has a low pK_a value in Trx-$(SH)_2$. A unique conserved *cis* proline residue (Pro76) is adjacent to the active site, which is surrounded by a flat **hydrophobic** surface used in binding interactions with other proteins. Thioredoxin-fold proteins include a growing superfamily. Some have several thioredoxin **domains**, as in protein disulfide isomerase (PDI), which catalyzes formation of native disulfides in secreted proteins.

2. Thioredoxin Functions

Thioredoxin was originally defined as a hydrogen donor for *Escherichia coli* ribonucleotide reductase (1). This enzyme contains a disulfide bond after each catalytic cycle that is reduced by thioredoxin via its general disulfide reductase activity:

$$\mathrm{Trx-(SH)_2 + protein-S_2 \rightarrow Trx-S_2 + protein-(SH)_2} \quad (1)$$

The enzymes that reduce sulfate (PAPS reductase) and methionine sulfoxide also use thioredoxin as an electron donor (5). Trx-$(SH)_2$ in *E. coli* is essential for phage T7 DNA replication in its role as a subunit of T7 **DNA polymerase** (6). This enzyme is a 1:1 complex of the virally coded polymerase (gene 5 protein of 80 kDa) and the host Trx-$(SH)_2$ (7). The role of the bound Trx is to give the enzyme high processivity in DNA synthesis by forming a complex and does not involve electron transport. **Recombinant** exonuclease-deficient T7 DNA polymerase is widely used in DNA sequencing. *E. coli* cells that lack Trx (*trxA*$^-$) are viable because glutaredoxin and glutathione act as a hydrogen donor for ribonucleotide reductase (8). Thioredoxin, an abundant protein in *E. coli*, has about 10,000 copies per cell and increases in amount in stationary-phase cells. It is located at the plasma membrane at the junctions of the inner and outer membrane (Bayer's adhesion sites) (9). This may explain its role in assembly of filamentous phage, where Trx-$(SH)_2$ is essential (10), but Trx-S_2 is not. This also gives the phage assembly process a requirement for thioredoxin reductase. The localization of Trx at the plasma membrane in *E. coli* and its release from cells by osmotic shock is a basis for a Trx-fusion system for overexpressing proteins. Soluble fusion proteins are selectively released from cells by osmotic shock (11). Recently, the **gene** for a second *E. coli* thioredoxin, called Trx2 (*trxC*), has been **cloned** (12), and those **genomes** sequenced generally encode two or more thioredoxin genes.

The tryptophan **fluorescence** of *E. coli* Trx is strongly quenched by the disulfide bond in Trx-S_2 (13). Reduction to Trx-$(SH)_2$ results in three-fold increased fluorescence caused by a localized conformational charge that affects Trp28, whereas the conserved Trp31 still has a low quantum yield (13). The kinetics of oxidation or reduction of thioredoxin are readily measured by fluorescence. Such experiments demonstrated that Trx-S_2 is reduced by **dithiothreitol** (DTT) two orders of magnitude faster than the disulfide bonds of insulin and that Trx-$(SH)_2$ reacts four orders of magnitude more rapidly with the insulin disulfide bonds than DTT (4). This led to the realization that thioredoxin catalyzes the reduction of insulin disulfides by DTT. This can be used as a simple Trx assay by following the turbidity that results from insulin B-chain precipitation (4). The oxidation/reduction potential (E_o') of Trx-S_2/Trx-$(SH)_2$ is –270mV, and a Pro34His mutant has an E_o' of –235mV (14).

Unique chloroplast thioredoxins in photosynthetic organisms regulate several photosynthetic enzymes by light *via* electrons from **ferredoxin**-thioredoxin reductase (15). Trx_f regulates fructose-bis-phosphatase and Trx_m regulates malate dehydrogenase (16). In each case the enzyme inactive in the dark contains a disulfide bond that is reduced to activate the enzyme in light. Trx_h in the cytosol is reduced by NAPH and thioredoxin reductase.

Thioredoxin and thioredoxin reductase from mammals differ in some important respects from the prokaryotic proteins, and they were first purified to homogeneity from rat liver (17) (Table 1). Thioredoxin has roles in regulating many transcription factors by thiol/disulfide redox control that

keep critical thiol groups reduced (18). Trx is also a secreted cocytokine from both virally infected and normal cells (19). Secretion occurs by a mechanism that does not require a signal peptide (20). Measurements of human plasma levels of thioredoxin show a correlation with AIDS progression (21). Thioredoxin protects against oxidative stress as an electron donor to thioredoxin peroxidases (peroxiredoxins) (22).

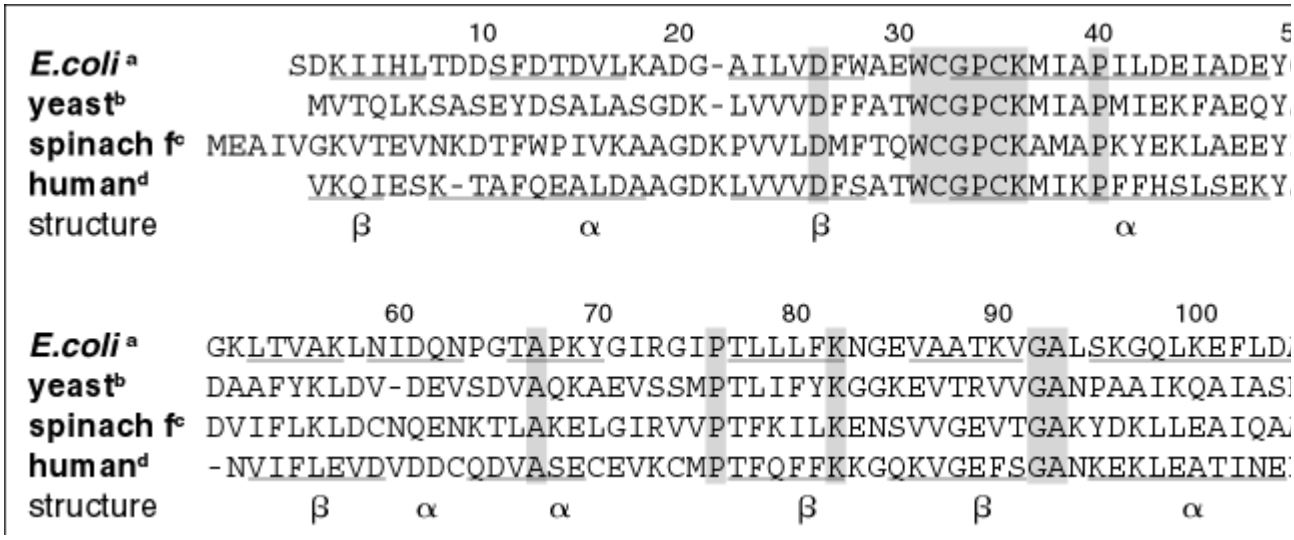
Table 1. Properties of Thioredoxin Systems

Organism	Thioredoxin	Thioredoxin Reductase
E. coli, yeast, plants	12 kDa	M_r 70,000 (2 subunits)
		Highly specific
Mammalian cells	12 kDa	M_r 116,000 (twosubunits)
	Inactivated by oxidationof structural SH-groups	*Broad substrate specificity,selenoprotein homologous to glutathione reductase*

3. Sequence Comparisons

Thioredoxins from archaebacteria to humans have 27 to 69% sequence identity to the well-studied *E. coli* thioredoxin, which indicates that all thioredoxins have similar three-dimensional structures (23). The amino acid chain length in all organisms studied thus far is approximately the same (see Fig. 1), and has an unusually low frequency of gaps. When gaps exist, they are only one residue long. In addition to the active site sequence Cys32 – Gly33 – Pro34 – Cys35, a number of residue positions are highly conserved (using the *E. coli* numbering): Asp26, Ala29, Trp31, Asp61, Pro76 (*cis*), and Gly92. Avian and mammalian thioredoxins contain additional nonredox active cysteine residues that are not involved in redox function but are implicated in regulation. Human thioredoxin forms an inactive intermolecular homodimer *via* a disulfide bond between Cys73 in each monomer (24). In general, residue substitutions among the thioredoxins occur predominantly on the surface of the molecule and distant from the active site.

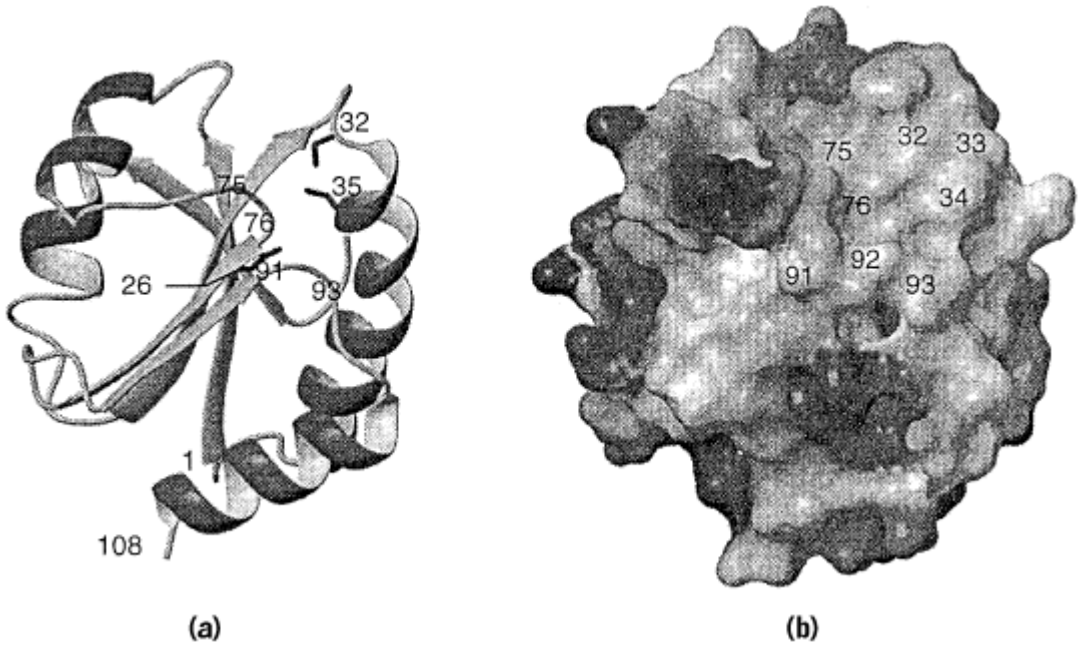
Figure 1. Amino acid sequence alignment of selected thioredoxins. Original references to the sequences are given in Ref sequences were aligned on the basis of the three-dimensional structures of *E. coli* (29) and human thioredoxins (30).



4. Thioredoxin Three-Dimensional Structures

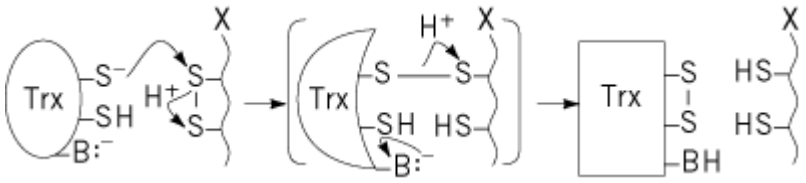
The first three-dimensional structure of a thioredoxin determined by X-ray crystallography techniques (25) was that of the oxidized *E. coli* protein. It consists of a five b-strands and four a-helices. The molecule is organized into an N-terminal bab and a C-terminal bba motif connected by an_a helix (Fig. 2). *E. coli* Trx can be cleaved proteolytically into two fragments by **trypsin** at Arg73, roughly between these two motifs. Although neither fragment alone is active enzymatically, they can reconstitute a native-like molecule that has enzymatic activity (26). The central five-stranded mixed b sheet lies between the second and last helices on one face and the connecting helix on the other.

Figure 2. Representative three-dimensional NMR solution structure of reduced *E. coli* thioredoxin, illustrating the active site cysteines (Cys32 and Cys35) and the hydrophobic interaction surface area. (**a**) Cartoon of the polypeptide backbone where the side chains of residues 26, 32, and 35 are displayed as sticks. (**b**) The molecular surface is colored according to the electrostatic potential (dark gray: positive, medium gray: negative, and light gray: uncharged). Residues are labeled at their approximate positions.



Several high-resolution thioredoxin structures have been determined by using both X-ray crystallography, for example, *E. coli* (27) and human (28), and NMR spectroscopy, *E. coli* (29) or human (30). Comparison of the available three-dimensional structures confirms the close structural similarity suggested by their sequence homology. Despite the biochemical evidence of functional differences between the oxidized and reduced forms of the *E. coli* protein (eg, with T7 gene 5 protein), structural differences between the two forms are subtle and localized to the active-site region (31). Differentiation between the two forms could be the consequence of increased accessibility of conformational states other than the ground state in the reduced form, relative to the oxidized forms. The N-terminal redox-active sulfur atom (Cys32) is located in a protuberance of the molecule and is accessible to solvent from one side in both oxidized and reduced forms of the protein. The pK_a of this thiol group is believed to be ~7 which is 1 to 2 pH units lower than normal. Adjacent to the accessible face of nucleophilic Cys32 is a large, relatively flat hydrophobic patch on the protein surface composed of atoms from residues Gly33, Pro34, Ile75, Pro76, Val91, Gly92, and Ala93 (Fig. 2). The existence of a single hydrophobic interaction surface is consistent with the broad specificity and covalent disulfide intermediate in the mechanism of thioredoxin action (Fig. 3). A number of charged side chains, for example, Glu30, Lys36 and Lys57, are on the opposite face of the protuberance, directly behind the active site cysteine residues, and are of possible mechanistic importance. Largely buried between these residues is the highly conserved Asp 26 which is believed to have an abnormally high pK_a of 7.5 (32) and has been proposed as the general base for deprotonation of the C-terminal (Cys 35) cysteine in the mixed-disulfide intermediate.

Figure 3. Mechanism of reduction of the disulfide bond of a protein substrate (X) by thioredoxin (Trx). Reduced thioredoxin (left) binds to a target protein via the hydrophobic interaction surface, followed by nucleophilic attack of the N-terminal active site thiolate on the target disulfide in a **thiol-disulfide exchange** reaction, resulting in a transient protein–protein mixed disulfide (center). Intramolecular attack by the second thiol group of Trx results in oxidized thioredoxin and reduced target protein.



5. Intermolecular Complexes

Structures of intermolecular complexes between thioredoxins and the proteins and fragments with which they interact have helped to elucidate the nature of the protein–protein interactions involved (7, 33, 34). The interface between Trx and its substrate protein includes the aforementioned hydrophobic interaction surface. Interestingly, human Trx binds substrate peptides in two essentially antiparallel orientations, with hallmark **hydrogen bonds** between the backbone of the substrate Cys residue and backbone atoms centered on the residue of Trx preceding the *cis*-Pro76. Thus, Trx can utilize the hydrophobic interaction surface to accommodate substrates that have little sequence homology and might also involve **molecular chaperone**-like conformational changes.

6. Thioredoxin Superfamily

A growing number of proteins contain thioredoxin-like structural motifs, and these proteins are now

called members of the thioredoxin superfamily. Proteins that contain the thioredoxin fold can be grouped into at least six classes: thioredoxins, glutaredoxins, DsbA, protein disulfide isomerase, **glutathione transferases**, and glutathione peroxidases (35). The thioredoxin fold common to each of these protein families consists of the bab and bba motifs, that have insertions or extensions of polypeptide chain. Although the sequence homology among these six classes is limited and no function or activity is common to all of them, there is a functional similarity common to four of these members. Thioredoxins, glutaredoxins, DsbA, and protein disulfide isomerase are redox-active proteins that contain a -Cys-X_1-X_2-Cys- active-site motif (where X represents any of the 19 commonly-occurring non-cysteine amino acids). Furthermore, although the remaining two proteins, the glutathione transferases and glutathione peroxidases, lack the -Cys-X_1-X_2-Cys- active-site motif, they share with the glutaredoxins a specific interaction with the ubiquitous cysteine-containing peptide glutathione. Interestingly, the orientation of the glutathione in the glutaredoxin and glutathione transferases is similar to that in the cysteine-containing segment of the REF-1 peptide in the complex with human Trx, possibly indicating an overall conserved mode of interaction.

Thioredoxin Reductase

Thioredoxin reductase (TrxR) contains the cofactor FAD and catalyzes the reduction of the disulfide form of thioredoxin (TRX -S_2) to the dithiol form (TRX -$(SH)_2$):

$$\mathrm{Trx-S_2 + NADPH + H^+ \xrightarrow{TrxR} Trx-(SH)_2 + NADP^+} \quad (1)$$

1. Thioredoxin Reductase in Prokaryotes, Yeast, and Plants

The dimeric enzyme from *Escherichia coli* is highly specific for NADPH. It has a Km (Michaelis constant) of 1.2 μM, and a K_m of 2.8 μM for Trx-S_2, It acts by a ping-pong mechanism and has a turnover rate of 2000 min^1 per FAD (see Kinetic Mechanisms, Enzyme). $NADP^+$ is a **competitive inhibitor** and has a K_i of 15 μM (1). The protein structure of the enzyme determined by X-ray crystallography shows surprisingly large differences from other members of the pyridine-nucleotide disulfide oxidoreductase family (2). The active-site sequence -Cys-Ala-Thr-Cys- is located in the N-terminal FAD **domain**, suggesting convergent evolution. An interesting exception to the rule of separate thioredoxin and thioredoxin reductase proteins exists in *Mycobacterium leprae*, where a functional hybrid protein is found (3).

2. Thioredoxin Reductase in Mammalian Cells

Mammalian thioredoxin reductase has properties strikingly different from the enzymes from *E. coli* or yeast (see Table 1 of Thioredoxin). The enzyme from rat liver, the first purified to homogeneity, is a dimer that has two FAD molecules and subunits with a molecular mass of 58 kDa (4). All mammalian thioredoxin reductases have a surprisingly wide substrate specificity (Table 1). In

particular, the enzyme reduces selenite directly and is a lipid hydroperoxide reductase (5). Recently, it was shown that human adrenocarcinoma thioredoxin reductase contains a selenocysteine (SEC) residue (6). The enzyme is **homologous** to glutathione reductase, and has an elongation that contains the conserved C-terminal sequence -Gly-Cys-Sec-Gly in human, rat, and bovine enzymes (Fig. 1). Insertion of Sec requires a selenocysteine-insertion sequence (SECIS), present in the 3′-untranslated region, to decode the UGA normal stop codon as selenocysteine (7). The -Sec-Gly sequence is required for catalytic activity, because its removal by carboxypeptidase digestion inactivates the enzyme (7). The selenocysteine in mammalian thioredoxin reductase explains its wide substrate specificity and inhibition by 1-chloro-dinitrobenzene (DCNB) (8). The latter compound selectively modifies both the Sec and Cys residues in the enzyme and induces a 30-fold increase in NADPH-oxidase activity in the alkylated enzyme (9). The requirement for selenium in the enzyme may explain why selenite is required to grow some cells in synthetic tissue-culture media. Tumor cells often have a strong up-regulation of TrxR (10), which may protect the cells. The selenocysteine nature of the enzyme also explains why it is inhibited by some drugs used clinically, such as gold thioglucose or nitrosourea compounds (11).

Figure 1. The primary structure of one mammalian thioredoxin reductase subunit from the rat that has 498 residues (7). The conserved N-terminal active -site disulfide region, which is identical to that of glutathione reductase (Cys-Val-Asn-Val-Gly-Cys, or CVNVGC), is shown, plus the conserved C-terminal (Gly-Cys-Sec-Gly, or GCUG) selenocysteine- containing sequence in the human, rat, and bovine enzymes. The positions of the FAD-binding, NADPH-binding, and interface domains are indicated.

Thiotemplate Mechanism Of Peptide Antibiotic Synthesis

Peptide antibiotics are unusual in that they contain many unusual and modified amino acid residues, even D-amino acid residues, and often have cyclic **polypeptide chains**. Although some are synthesized on ribosomes, in the usual manner of **protein biosynthesis**, and are then **post-translationally modified**, many have unusual, nonribosomal mechanisms of synthesis. The thiotemplate mechanism refers to this type of mechanism of forming peptide bonds sequentially to generate a polypeptide precursor of peptide antibiotics. The name was coined when thioester intermediates and the presence of 4′-phosphopantetheine, derived from coenzyme A, were discovered in an enzyme system catalyzing the synthesis of the cyclic decapeptide **gramicidin** S (1). It was suggested that amino acid residues were polymerized sequentially on enzyme subunits as thioesters attached to the 4′-phosphopantetheine swinging arm of a carrier protein. It transformed the fatty acid elongation cycle proposed by Lynen (2) to enzymatic peptide formation and introduced the concept of a protein template for assembly of a peptide sequence (3).

The thioester type of assembly mechanism has been established for a wide variety of peptides, including tyrocidine, bacitracin, polymyxin, enniatin, beauvericin, **actinomycin**, alamethicin, ferrichrome, cyclosporin, and the penicillin precursor peptide d-(L-a-aminoadipoyl)-L-cysteinyl-D-valine. It soon became apparent that it was the principal method of forming peptide bonds in the absence of ribosomes, and it has been shown to operate for at least 25 steps, polymerizing that number of amino acids specifically (4).

When it became evident that the protein template enzymes were unusually large structures, with masses often exceeding 500 kDa, Kurahashi introduced the term *multienzyme thiotemplate mechanism* (5). It was later pointed out, however, that the principle of the 4′-phosphopantetheine swinging arm did not account for all of the experimental observations, including (i) the accumulation of all intermediates preceding a certain step when the process was interrupted there, (ii) the loss of thioester formation, with retainment of adenylate activation, and (iii) constraints on the access of a single cofactor on an integrated carrier domain to 11 amino acid intermediates in a system like cyclosporin synthetase.

These issues were resolved after the amino acid sequences of several peptide synthetases were determined from the sequences of their genes (6). This revealed that the peptide synthetases had modular structures composed of (i) adenylate-forming activation domains, (ii) carrier proteins containing sites for attachment of the respective cofactor, (iii) condensation domains, and (iv) a variety of modification functions responsible for epimerization, methylation, cyclization and hydrolytic release of the precursor peptide. Most striking was the absence of conserved cysteine residues that had been implied by the thioester concept. It became obvious that each activation domain was associated with a carrier protein **homologous** to the *acyl carrier protein* of the fatty acid synthesis systems, and the subsequent addition of 4′-phosphopantetheine to the carrier proteins has been demonstrated by mass spectrometry. These findings have led to a further refinement of the process, which is now called the *multiple carrier thiotemplate mechanism* (7).

1. Multiple Carrier Thiotemplate Mechanism

To illustrate the multiple carrier thiotemplate mechanism, a scheme for the formation of a tripeptide is illustrated in Figure 1. Each amino acid, A^i, is adenylated and activated by a specific adenylation domain of the enzyme and then transferred to the thiol group of the pantetheine cofactor residing on its respective carrier domain, E^i-SH, as a thioester, E^i-S-A^i. Peptide bond formation is initiated with the amino acid that will be *C*-terminal, A^1, becoming linked to the next amino acid, A^2,

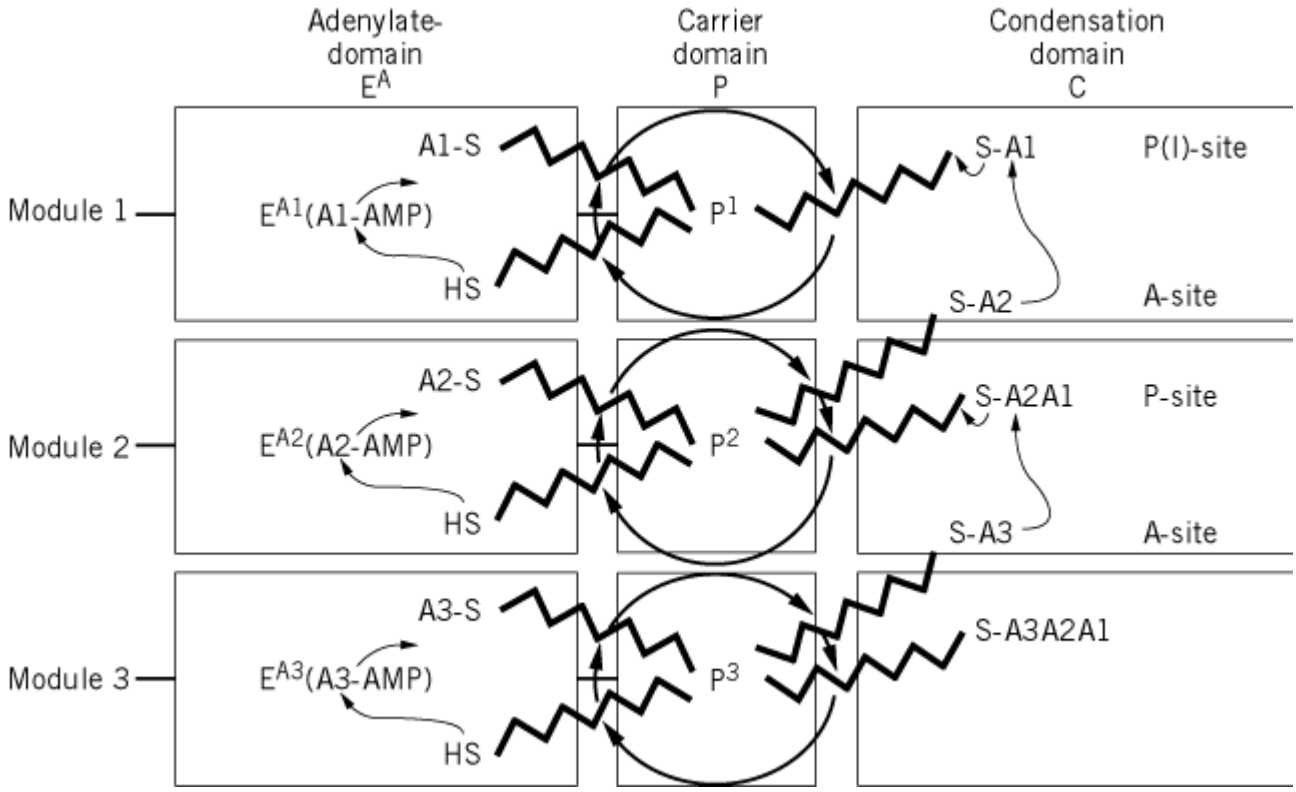
$$\mathrm{E^1-S\text{-}A^1 + E^2-S\text{-}A^2 \rightarrow E^2-S\text{-}A^2-A^1 + E^1-SH} \qquad (1)$$

Elongation proceeds similarly and sequentially, adding a third and further amino acid thioesters to the peptide:

$$\begin{aligned}&\mathrm{E^n-S\text{-}A^n-A^{n-1}-\cdots-A^1 + E^{n+1}-S\text{-}A^{n+1}}\\ &\quad\rightarrow \mathrm{E^{v+1}-S\text{-}A^{n+1}-A^n-A^{n-1}-\cdots-A^1 + E^n-SH}\end{aligned} \qquad (2)$$

In this way, a polypeptide chain is synthesized starting from the carboxyl terminus. At each step, the assembly process is specific for the amino acid to be incorporated and for the appropriate enantiomer, either D or L. Hydroxy acids can also be incorporated, and the corresponding ester bonds are formed similarly, using acyl intermediates. The process thus resembles in principle the ribosomal mechanism, in that there is transfer of an activated peptidyl intermediate to an aminoacyl intermediate (8). Release of the complete peptide chain occurs on the appropriate termination domain, either as the linear chain, which is produced by hydrolysis or aminolysis, or as the cyclic peptide or as peptidolactone.

Figure 1. Illustration of the multiple carrier thiotemplate mechanism, as elucidated for synthesis of the d-(L-a-aminoadipoyl)-L-cysteinyl-D-valine tripeptide b-lactam precursor (11). Each of the three amino acids is activated at a specific adenylation domain, E^A. Each adenylate domain is linked to a specific carrier domain, P^i. The aminoacyl moieti A^i of the A^i-AMP adenylates are transferred to the respective thiol groups of the 4′-phosphopantetheine cofactor, illustra by the thick zigzag line. Peptide bond formation occurs, in analogy to the ribosomal cycle, from amino acyl (A) and pept (P) sites on specific condensation domains. In the case of the initiation reaction, the P-site is called the initiation site, or I site. The tripeptide formed, A^3-A^2-A^1, is thioester bound and may be transferred for further elongation or released by a thiolesterase, as in penicillin formation.



The reactions linking the successive amino acids and analogues are thought to be catalyzed by the condensation domains; they are essentially irreversible. In addition, catalytic sites may be involved in the modification of the thioester intermediates, such as their *N*-methylation or epimerization and, especially in the case of polyketide biosynthesis, in the reduction and dehydration of the respective keto intermediate.

The key component of the thiotemplate mechanism is the acyl-, aminoacyl-, or peptidyl-carrier protein or domain, to which the respective intermediate remains attached covalently during the elongation cycle. Carrier domains can be identified readily by the conserved elements of their protein structure, including a cavity formed by three **a-helices**, an additional a-helix, and a variable loop containing the 4′-phosphopantetheine cofactor binding site (9). Addition of the cofactor to the carrier domain is catalyzed by a family of 4′-phosphopantetheine transferases, using coenzyme A (10). Condensation processes require at least one carrier protein, and stepwise processes involve the intra- or intermolecular transfer of acyl intermediates between two carrier protein proteins. The largest known thiotemplates contain 11 carrier domains in peptide biosynthesis, for cyclosporin, and six carrier domains in polyketide biosynthesis, for rapamycin.

The thiotemplate mechanism contrasts with the mechanism of formation of other small peptides, such as glutathione or peptidoglycan components, which are readily distinguished by (i) their use of phosphate to activate the amino acids, rather than adenylate, (ii) the absence of covalently attached intermediates, and (iii) the activation of peptide carboxyl groups, rather than amino acid carboxyls.

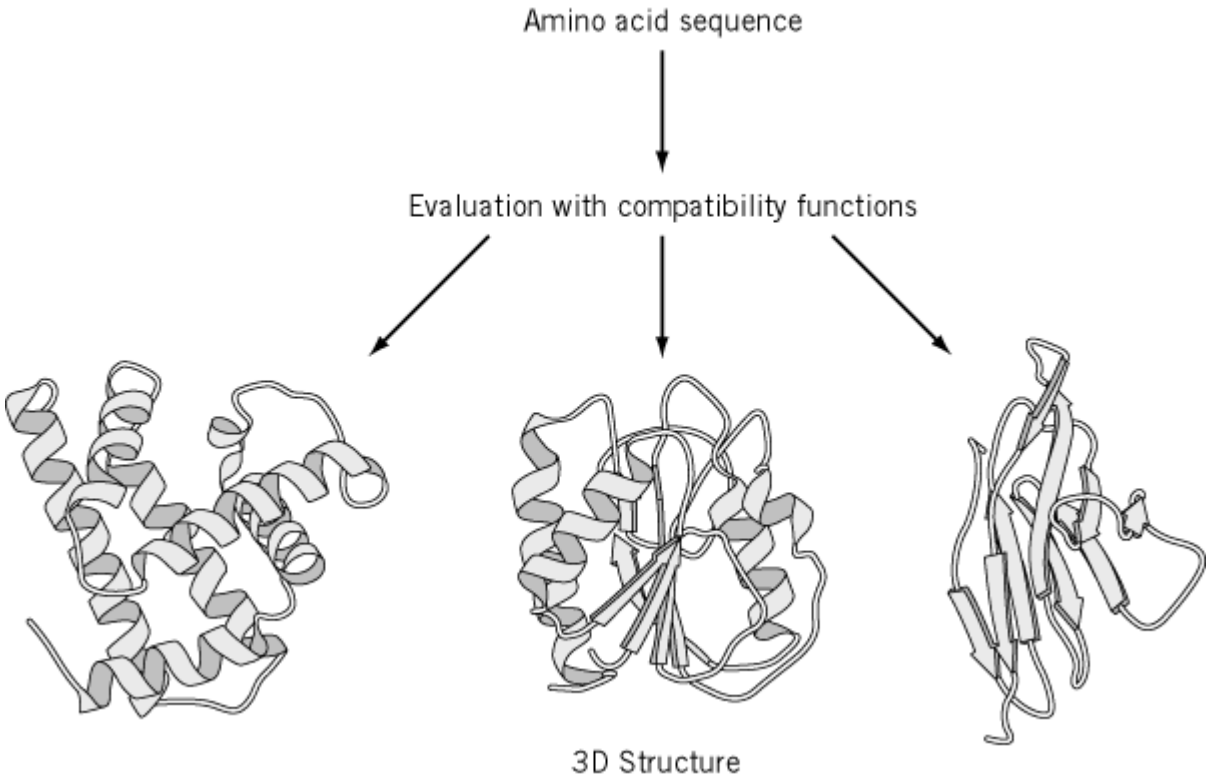
Threading Protein Sequences

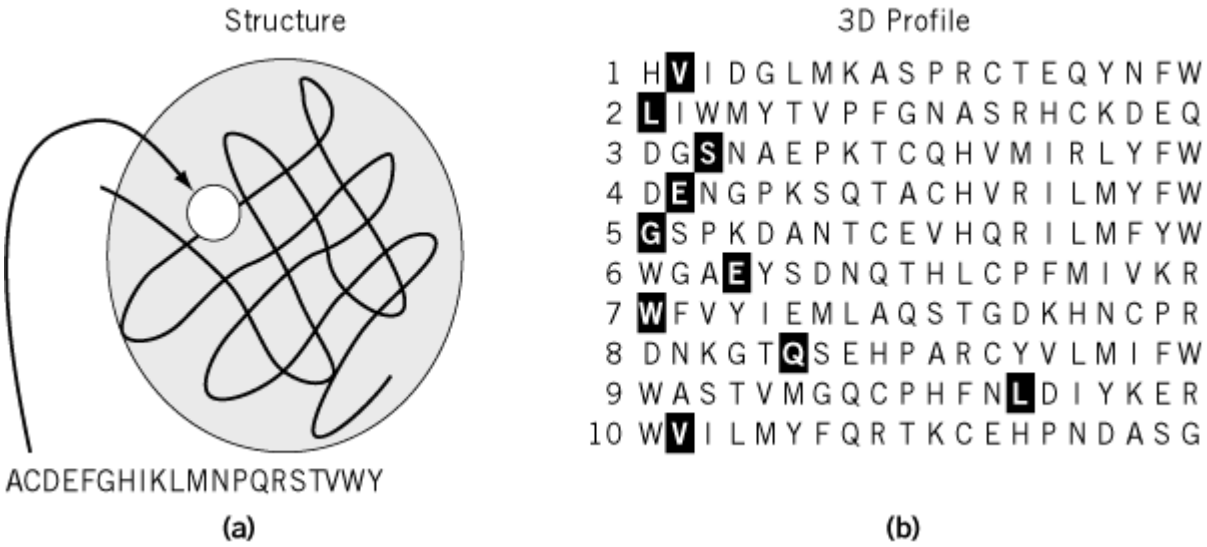
Formulation of the inverse folding problem, in which the amino acid sequence, or primary structure, most compatible with a given three-dimensional protein structure is sought, provided a clue to the problem of **protein structural prediction**, in which the three-dimensional structure is to be predicted from just the primary structure. Given a query sequence *a* of a protein of unknown structure (A), mount the sequence onto a number of known protein structures (B, C, D, etc.) one-by-one, using all feasible alignments of sequence to structure. Then, evaluate the fitness of sequence *a* to each one of the structures to find the structure most compatible with the sequence *a* (Fig. 1). If the structure so found is B, it is inferred that the structure A to be predicted is probably similar to B. This is called the "3D–1D compatibility method," "fold recognition," or "prediction by threading." It is an extension of the conventional comparison of sequences alone (1D–1D), but in principle is more effective in detecting similarities between proteins because the 3-D structure is more conserved during evolution than the sequence (see Homological Modeling). It is observed empirically that **homologous** natural proteins that arose by divergent evolution from a common ancestor and belong to a **gene family** share a common polypeptide fold. Moreover, the number of folds found in natural proteins is believed to be fairly limited (1). Because of the rapid growth of the protein structural database, it was logical for the threading approach to emerge. The logic of supposing that a known structure can be a model for a new protein arose from the inverse folding problem, but the difference lies in that the threading method considers a certain (query) sequence in relation to all possible model structures, whereas inverse folding considers a model structure in relation to all the possible sequences.

Figure 1. Protein structure prediction by threading. A query sequence is to be threaded through each of template structures taken from the structural database, and the sequence/structure fitness is quantitatively evaluated with compatibility functions to find a structure most compatible with the sequence.



In threading a given 1-D sequence through a given 3-D structure, there are a large number of possibilities, which is known as the alignment problem. Bowie (2, 3) was the first to solve this problem by applying the dynamic programming technique that had been fully developed in the field of aligning sequences, so-called homological searches (see Sequence Analysis). To reduce the magnitude of the computational problem, Bowie et al. (3) introduced the 3-D profile table, which was constructed from the model structure (Fig. 2). This is a (20×*n*) table, where columns of 20 amino acid residues are arrayed along the *n* residues of the structure. Each number in the table gives the fitness of the respective amino acid residue for a given residue site, which depends on its **secondary structure**, **hydrophilic/hydrophobic** environment, etc. Given such a 3-D profile table, it is straightforward to compare it with any sequence by using the dynamic programming algorithm and to obtain the optimum path, including gaps (i.e., the best 3-D–1-D alignment), plus the alignment score. In actual predictive procedures, a structural library that has been converted to a set of 3-D profiles is scanned with a query sequence to seek the model structure and alignment that gives the highest score (or lowest energy). If the score obtained is sufficiently high, a convincing prediction has been obtained. The computational time is no greater than that for the usual sequence homological search methods.

Figure 2. Construction of the 3-D Profile. (**a**) Each of 20 amino acids is placed one-by-one at a site of a given 3-D structure of a protein to evaluate its compatibility with the structural environment. A, C, D . . in the figure are one-letter codes of amino acids standing for Ala, Cys, Asp. ., respectively. The results are tabulated in a profile table (**b**). The example in this table was constructed from sperm whale myoglobin structure (PDB code: 1mbd). The profile table for the first 10 residue sites (one row corresponding to one site) shown consists of columns of the length equal to the total number of residue sites in the structure. In the profile table of this illustration, the 20 amino acids are sorted from left to right at each site, according to the compatibility score. Those amino acids in the native sequence that are highlighted sit on the left-hand side of the table, implying that they are energetically favorable to the structure.



In addition to finding the best 3D–1D alignment, it is important to evaluate the fitness between a sequence and a structure. Bowie et al. (3) used a simple measure, called the "single-body approximation," which considers a single amino acid residue in its entire structural environment. The Sippl potential (see Inverse Folding Problem) has a more advanced form of the two-body function defined for two interacting residues. Interactions between a central residue and all surrounding residues would give the total interaction energy for the central residue. The two-body function is not logically compatible with the 3-D profile, however, because the surrounding residues will not be known until after the alignment is fixed. This dilemma has been solved by the "frozen approximation" (4), in which it is assumed that the native amino acids of the model structure are in the surrounding sites. In this way, a combination of the Sippl-type potential (or others) with the 3-D profile treatment provides rapid and more reliable predictive methods (5).

Other types of methods can be envisaged for directly threading the entire sequence through a structure without using the 3-D profile, and they could be compatible with any type of potential functions. The problem, however, is the large number of alignments possible. Jones et al. (6) managed to solve the problem by introducing the double dynamic programming algorithm, which had been developed in pairwise comparisons of 3-D structures by Taylor (7). Alternatively, **Monte Carlo**-type optimizations may be used (8). The computations for these methods of direct threading are very time-consuming.

Many investigators have contributed to the development of various threading methods. To compare the effectiveness of each, a worldwide prediction contest, named (Critical Assessment of Techniques for Protein Structure Prediction CASP) has been held twice thus far, in 1994 and 1996 (9). A completely blind test was arranged so that all predictor would make their own predictions for target proteins, whose 3D structures were not yet known but were in the process of being determined. Then, an appointed assessor evaluated all of the predictions by comparing them with the structures that had subsequently been determined and presented the results at a joint meeting of all of the predictors. The results indicated that several predictions, but not all, actually inferred the correct folds of target proteins from their sequences alone (10). The sequence identity between the known and predicted proteins was around 20% or less, too low for any methods other than threading to identify the structural relationship. Therefore, the prediction contests clearly demonstrated the applicability of the threading method. At the same time, however, some drawbacks were revealed. One of them is the ambiguity often seen in 3-D–1-D alignments obtained by direct comparisons of structures (11). There are still problems to be overcome, and the method should be refined further. In any case, several successful examples uncovered by CASP were the first clear verification of the correct prediction of 3-D protein structures after a number of unsuccessful trials over many years.

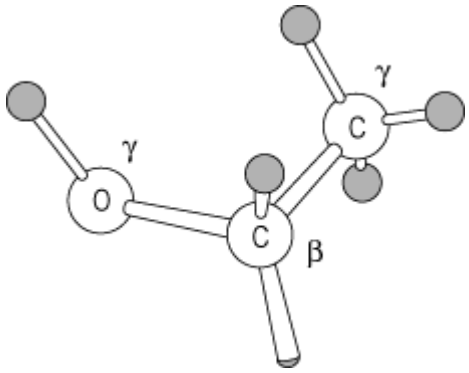
Threonine (Thr, T)

The amino acid threonine is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to four **codons**—ACU, ACC, ACA, and ACG—and represents approximately 5.8% of the residues of the proteins that have been characterized. The threonyl residue incorporated has a mass of 101.11 Da, a **van der Waals volume** of 93 $Å^3$, and an accessible surface area of 146 $Å^2$. Thr residues are changed moderately frequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with serine, alanine, valine, and lysine residues.

The side chain of Thr is dominated by its hydroxyl group:



This hydroxyl group is normally no more reactive chemically than is that of ethanol, so there are few chemical reactions that can modify Thr residues in a protein specifically and readily. The only reaction that is generally useful is acetylation with acetyl chloride in aqueous trifluoroacetic acid. Note that the side chain has a center of asymmetry at C_b and that only the one isomer occurs naturally.

The hydroxyl group is very polar and hydrophilic and can function as either a donor or acceptor in hydrogen bonds. Consequently, Thr residues can be fully buried in protein structures, and about 23% are, especially if their hydroxyl group is paired in a hydrogen bond. The hydroxyl group is situated sterically to interact with polar groups of the polypeptide backbone, which affects its conformation and reactivity. For example, peptide bonds adjacent to Thr residues are especially susceptible to acid hydrolysis. Thr residues do not favor the a-helical conformation, and they occur in folded proteins most frequently in beta-sheets.

In native proteins, Thr residues are frequently modified by the addition of oligosaccharides (see O-Glycosylation) and phosphate groups.

Threonine Operon

The four carbon atoms of aspartic acid in *Escherichia coli* are the precursors of the four carbon atoms of threonine. In addition, with pyruvic acid they contribute to the biosynthesis of lysine and diaminopimelate and, with the b-carbon of serine, to the biosynthesis of methionine (1). The reactions leading from aspartate to threonine are as follows:

$$\text{Aspartate} + \text{ATP} \longrightarrow \beta\text{-Aspartylphosphate} + \text{ADP} \quad (1)$$

$$\beta\text{-Aspartylphosphate} + \text{NADPH} \longrightarrow \text{Aspartate}\beta\text{-semialdehyde} + \text{P}_\text{i} + \text{NADP}^+ \quad (2)$$

$$\text{Aspartate}\beta\text{-semialdehyde} + \text{NADPH} \longrightarrow \text{Homoserine} + \text{NADP}^+ \quad (3)$$

$$\text{Homoserine} + \text{ATP} \longrightarrow \text{Homoserine-phosphate} + \text{ADP} \quad (4)$$

$$\text{Homoserine-phosphate} + \text{H}_2\text{O} \longrightarrow \text{Threonine} + \text{P}_\text{i} \quad (5)$$

Reaction 1 is catalyzed by the enzyme aspartate kinase I, encoded by the **gene** *thrA*; reaction 2 by aspartate semialdehyde dehydrogenase (*asd*); reaction 3 by homoserine dehydrogenase, encoded by *thrA*; reaction 4 by homoserine kinase (*thrB*); and reaction 5 by threonine synthase (*thrC*).

Note that both reactions 1 and 3 are catalyzed by a single bifunctional protein, aspartate kinaseI-homoserine dehydrogenaseI, encoded by *thrA*. Another bifunctional enzyme, aspartate kinase II-homoserine dehydrogenase II, is encoded by *metL*, whereas aspartate kinase III is encoded by *lys C*. The three aspartate kinases catalyze the same reaction and differ in the mode of regulating their activity and their synthesis (1).

The genes *thrA*, *thrB*, *thrC* are organized in this order in an operon, localized at min 0 on the *E. coli*

chromosome (2, 3). The full-length messenger RNA is 4860 nucleotides long (4, 6). The coding sequences of *thrA* and *thrB* are separated by only one nucleotide, whereas those of *thrB* and *thrC* are contiguous (5). Therefore the Shine–Dalgarno sequence of *thrB* is within the coding sequence of *thrA*, and that of *thrC* is within the coding sequence of *thrB*.

A strong **promoter** is located 190 bp upstream of the translation start of *thrA*. In addition to the transcripts initiated at this promoter, an internal promoter at the 3′ end of *thrA* allows the transcription of *thrB*, although with much lower efficiency (7). Translational coupling between *thrA* and *thrB* has been demonstrated (8). A detailed genetic map of *thrA* shows that the gene is indeed composed of two segments corresponding, respectively, to aspartate kinase I and homoserine dehydrogenase I (9).

Expression of the threonine operon depends on the intracellular concentrations of both threonine and isoleucine (10) by a mechanism called *multivalent repression* (11). In diploids, some derepressed mutations were cis-acting, while other mutations acted in trans. The trans-acting mutations affected either the threonyl-tRNA synthetase (12, 13) or the isoleucyl-*t*-RNA synthetase (14) (see Aminoacyl tRNA Synthetases). The cis-acting mutations were first thought to be operator mutants (15, 16) but were localized in a region of the gene that had all the characteristics of an **attenuation** mechanism: (*1*) the mRNA leader sequence shows the possibility of several mutually exclusive secondary structures; (*2*) there is a r-independent signal for transcription termination; (*3*) finally, the leader peptide sequence contains numerous threonine and isoleucine codons: Thr-Thr-Ile-Thr-Thr-Thr-Ile-Thr-Ile-Thr-Thr-Thr (17). Further study of derepressed mutants supports the attenuation mechanism (18). In particular, a mutant carrying a deletion of the leader sequence is derepressed (19).

The organization of the three genes is different in other species, such as *Bacillus subtilis* (20), *Corynebacterium glutamicum* (21), and *Pseudomonas aeruginosa* (22). In some of these organisms, there is a single aspartate kinase that is not covalently linked with homoserine dehydrogenase in a multifunctional protein (23).

Thrombin

Thrombin is the pivotal enzyme in the process of blood clotting or coagulation. It is the final proteinase of the proteolytic cascade, catalyzing the cleavage of two peptide bonds in its primary substrate fibrinogen, to generate fibrin, which subsequently polymerizes to form an insoluble clot. Thrombin has a multiplicity of additional functions, however, that contribute to both the amplification of blood clotting and its regulation. Thrombin promotes feedback activation of the coagulation cascade by activating the cofactors, factors V and VIII, as well as activating the proteinase zymogens, factors XI and XIII. Thrombin also stimulates the aggregation of blood platelets by activation of the thrombin receptor or PAR-1 (protease-activated receptor-1), one of four members of a sub-family of seven-transmembrane G-protein-coupled receptors, by a novel proteolytic "tethered ligand" mechanism (1). Thrombin also has anticoagulant properties and functions, because binding to the endothelial cell membrane protein thrombomodulin alters the specificity of thrombin, enabling it to activate another proteinase zymogen, protein C, which can, in turn, proteolytically inactivate factors V and VIII. Through activation of PAR-1, PAR-3, and PAR-4 thrombin can also mediate responses in a variety of cell types other than platelets, including endothelial cells, vascular smooth muscle cells and fibroblasts. Thus, despite its unique role in the generation of fibrin, thrombin can be viewed as a pleiotropic molecule, exhibiting both enzymatic and hormone-like properties.

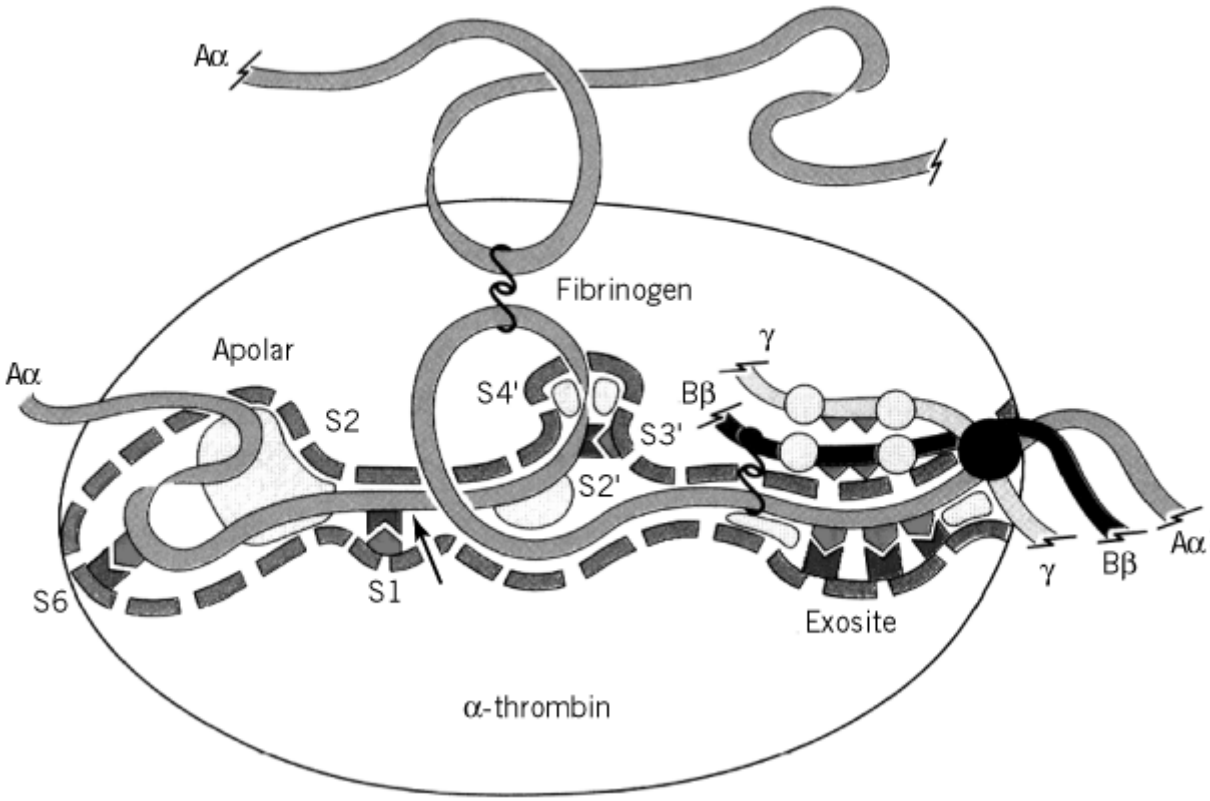
Thrombin itself is generated by limited proteolysis of prothrombin, a 579 residue single-chain glycoprotein (M_r 71,600) expressed in the liver as the product of a 19 kb gene comprising 13 introns and 14 exons located on chromosome 11. Prothrombin undergoes important post-transitional modifications in addition to N-linked glycosylation at Asn 78, 100 and 373. The first 10 N-terminal glutamic acid residues, contained within a single 32-residue domain (known as the *Gla domain*), are modified to g-carboxyglutamic acid (Gla) by a vitamin K-dependent carboxylase, a modification common to all of the "vitamin K-dependent" coagulation factors, namely, factors VII, IX, X, protein C, and prothrombin. This modification is signaled for by residues –17 to –1 of the preprothrombin sequence, adjacent to the secretion signal peptide at –43 to –18. These Gla residues chelate Ca^{2+}, leading to an ordering of the structure of the N-terminal structural domain, which is then able to bind to negatively-charged phospholipids. Prothrombin also contains two kringle domains that lack the lysine-binding properties of other kringle modules [see Plasminogen] and appear to have no discrete biological function, and the C-terminal serine proteinase domain. Structures for all the domains of prothrombin – specifically, fragment 1 (Gla-kringle), fragment 2 (kringle 2), and the serine proteinase domain – have been solved by X-ray crystallography and/or NMR. The structure of a-thrombin has been studied particularly extensively, in order to elucidate the molecular basis of its highly restricted substrate specificity.

The serine proteinase factor X_a in the prothrombinase complex [see Blood Clotting], activates prothrombin by cleavage at two positions (2). The first cleavage is at the Arg320-Ile321 peptide bond, generating "meizothrombin", a disulfide bond-linked two-chain proteinase that has a competent active-site, although lacking the specificity of mature thrombin. Subsequent cleavage at

Arg271-Thr272 liberates the N-terminal fragment 1·2, which retains the phospholipid binding characteristics of prothrombin, plus fully mature a-thrombin. In the absence of cofactors, factor X_a cleaves the same two peptide bonds in the reverse order, first generating fragment 1·2 and the catalytically inactive prethrombin 2, which is subsequently activated to a-thrombin. The loss of the N-terminal domains on activation is unique among the blood coagulation proteinases and results in thrombin having full activity in the solution-phase, with no cofactor requirements.

Thrombin consists of two disulfide-bridged polypeptide chains. The shorter A chain forms an integral part of the structure but not involved in catalysis. The B chain exhibits the characteristic fold of the trypsin-like serine proteinases, having two 6-stranded b-barrels with the equivalents of the catalytic residues Ser195, His57, and Asp102 (chymotrypsin numbering, corresponding to Ser525, His363, and Asp419 of thrombin, respectively) located at their interface. As with trypsin, substrate recognition involves a basic P1 residue, but thrombin has a much more extensive substrate recognition surface, as shown in Figure 1. Substrate recognition, and its very restricted specificity, is dictated largely by a number of unique insertion loops that border the active-site cleft, rendering it both deeper and narrower than that of chymotrypsin. These loops limit the access of many potential substrates and inhibitors to the active site, as well as imposing constraints on individual subsites. An example of this is the "60-loop" (a four-residue insertion at a position corresponding to Val60 of chymotrypsin), which restricts substrate P2 utilization to small hydrophobic residues, and forms part of the "apolar binding site" (3).

Figure 1. The active-site of thrombin. Schematic diagram showing the major interactions of the fibrinogen Aa chain with thrombin and highlighting extensive area involved in substrate recognition. Reprinted from *Trends Biochem. Sci.* **20**, The clot thickens: clues provided by thrombin structure, 23–28, Copyright (1995), with permission from Elsevier Science.



Substrate recognition by thrombin also involves the use of "exosites" to an unusually high degree.

These are regions of the active-site cleft far removed from the catalytic residues, the most significant of which is the "fibrinogen recognition exosite" (4). This is a cationic region to the "east" of the active-site (in the "standard orientation" shown in Figure 1). It is involved in catalytic interactions with fibrinogen and the thrombin receptor and non-catalytic interactions with thrombomodulin and the inhibitor hirudin (derived from the blood sucking leech *Hirudo medicinalis*). The latter is of particular interest as both the remarkable specificity and affinity (K_d ~10 fM) of this inhibitor are primarily dictated by this exosite interaction. The other major exosite is the heparin-binding site lying to the north-west of the active site (not shown in Figure 1), which is involved in the physiological inhibitory reaction with the serpin antithrombin bound to heparin or other sulfated glycosaminoglycans (5).

Many of the principles of substrate recognition elucidated in the extensive studies of thrombin will also apply to other serine proteinases with restricted substrate specificity; high resolution structures of them are also being solved.

Thymidylate Synthase

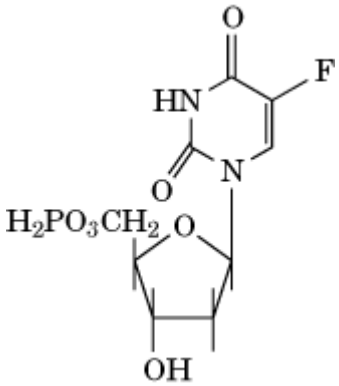
Thymidylate synthase (TS) shares with ribonucleotide reductase the distinction of being responsible for one of the two chemical differences between DNA and RNA. Just as ribonucleotide reductase carries out the production of deoxyribose at the nucleoside di- or triphosphate level, TS generates the methyl group of thymine, acting at the deoxyribonucleoside 5′-monophosphate level:

$$\mathrm{Deoxyuridine5'-monophosphate(dUMP)+5,10-methylenetetrahydrofolate \rightarrow thymidine5'-monophosphat}$$

This is the only known biological methylation reaction not involving S-adenosylmethionine or the synthesis of methionine itself. Aside from this distinctive role, the enzyme is of interest from several standpoints—(1) mechanistically, (2) as the first **enzyme** identified as an anticancer drug target, (3) as one of the most active current targets for computer-assisted drug design, (4) as the first **prokaryotic** protein shown to result from processing of a split gene, (5) as an agent in translational autoregulation, and (6) as a component of multifunctional proteins and multienzyme complexes.

1. A Target for Fluorinated Pyrimidines

In 1957, Friedkin and Kornberg (1) described a tetrahydrofolate-dependent enzyme that converts deoxyuridine monophosphate (dUMP) to thymidine monophosphate (dTMP) (Eq. (1)). The methyl group of dTMP was shown to originate as the methylene carbon of 5,10-methylenetetrahydrofolate (CH_2 = THF). This discovery of thymidylate synthase was intertwined with the early work of Heidelberger, who synthesized 5-fluorouracil and 5-fluorodeoxyuridine as potential anticancer drugs (2). Heidelberger had noted that tumor cells metabolize uracil much more rapidly than normal cells do, and he expected that substitution of fluorine for a similarly sized hydrogen atom might inhibit the cellular uptake and usage of uracil selectively in tumor cells. In 1958, the action of both fluorinated pyrimidines was shown by Cohen et al (3) to result from their conversion *in vivo* to the deoxyribonucleoside monophosphate 5-fluorodeoxyuridylate (FdUMP), which they



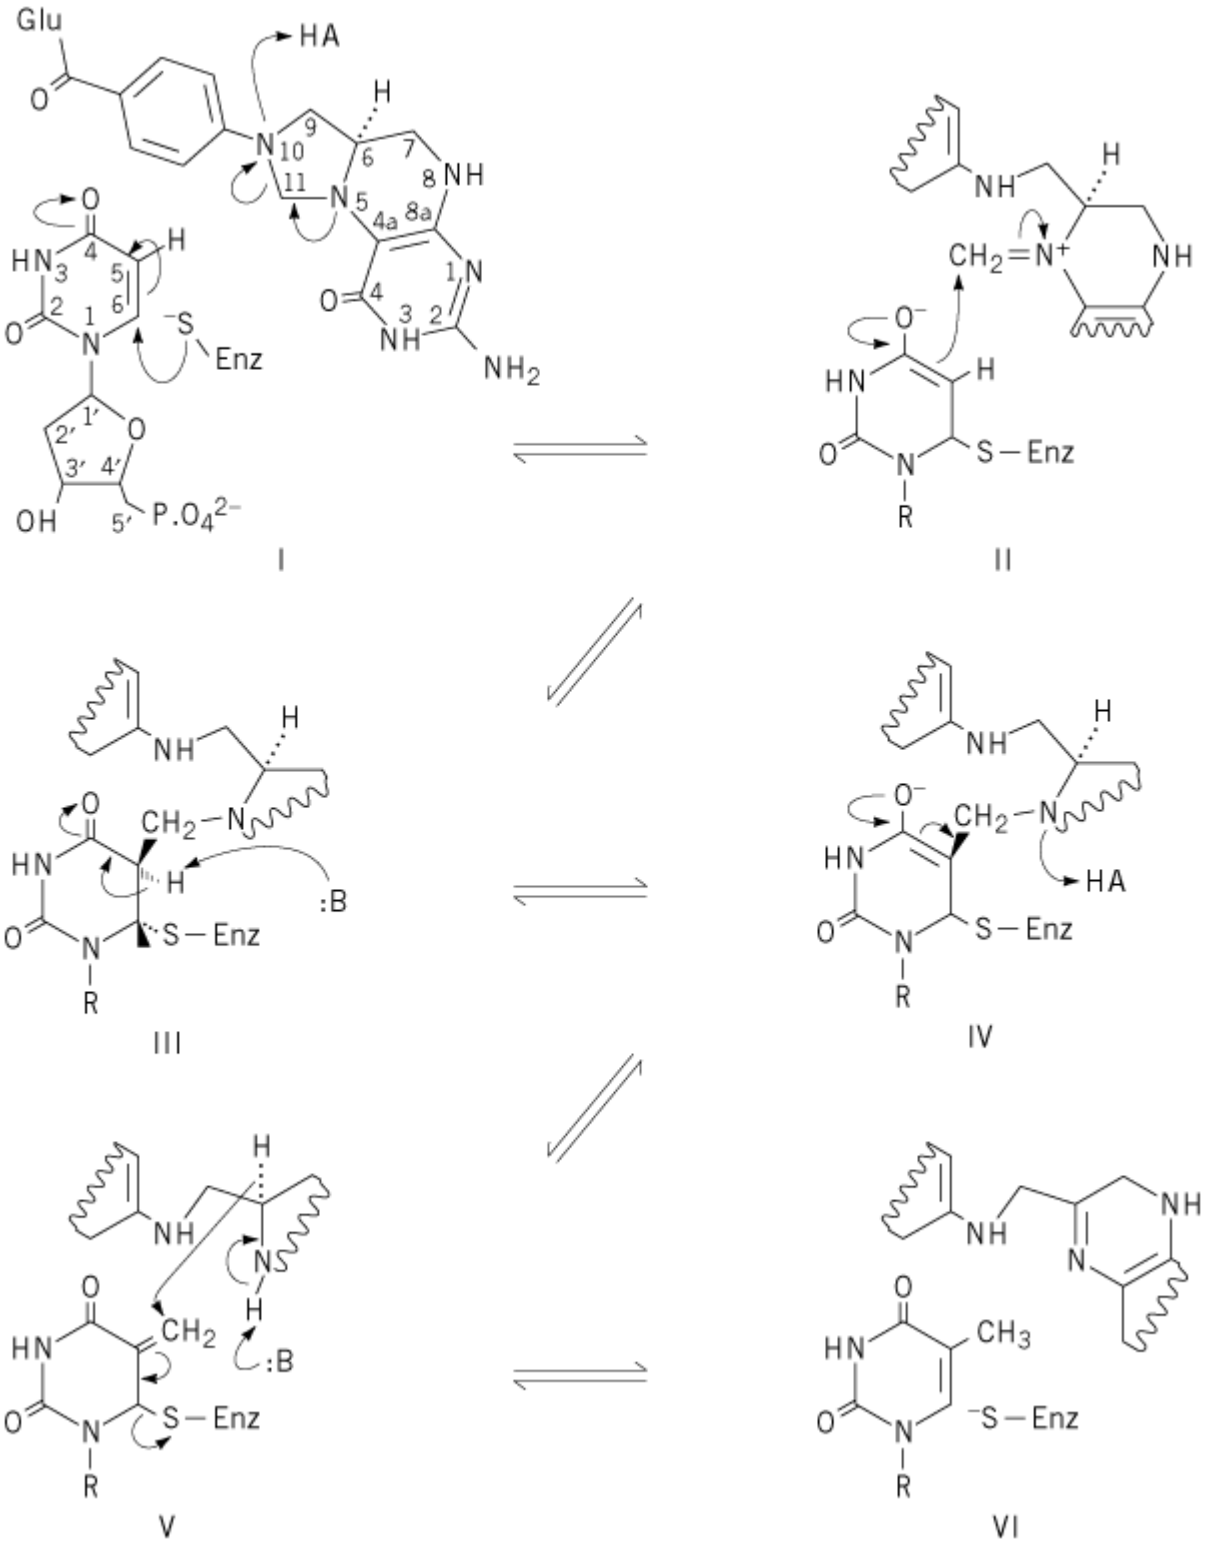
showed to act as a potent inhibitor of TS. Fluorine has a **van der Waals radius** close to that of hydrogen, for which it is substituted in the analogues. This substitution creates a kinetically irreversible inhibition, which eventually was shown to result from formation of a covalently bonded enzyme-inhibitor complex. This is a ternary complex, whose formation requires CH_2 = THF as well. These factors suggested that the structure of this complex would yield clues to the mechanism of action of the enzyme.

Another important early development was the demonstration by Friedkin and colleagues that the folate coenzyme serves as the agent, not only for transfer of a single-carbon functional group but also for reduction of that group from the methylene to the methyl level (4). Radioisotope labeling studies showed that both the methylene group and a hydride ion—the hydrogen linked to C6 of CH_2 = THF—were transferred to dTMP essentially without dilution. This is the only known reaction in which tetrahydrofolate serves as a **redox** cofactor. These findings suggested a bridged intermediate in which the methylene carbon of CH_2 = THF is linked transiently to C5 of the pyrimidine ring. Inhibition by FdUMP was postulated to result from formation of a similar complex, with the fluorine atom acting to prevent cleavage of the N5-methylene carbon bond.

But how does FdUMP bind covalently to the enzyme? Degradation of the ternary complex revealed a cysteine sulfur atom linked to C6 of the pyrimidine ring (reviewed in 5). These findings suggested

a mechanism for the reaction in which the cysteine thiol group initiates nucleophilic attack on C6, converting C5 into a nucleophile that attacks C11, the methylene carbon of 5,10-methylenetetrahydrofolate. Much evidence now supports the mechanism that is outlined in Figure 1.

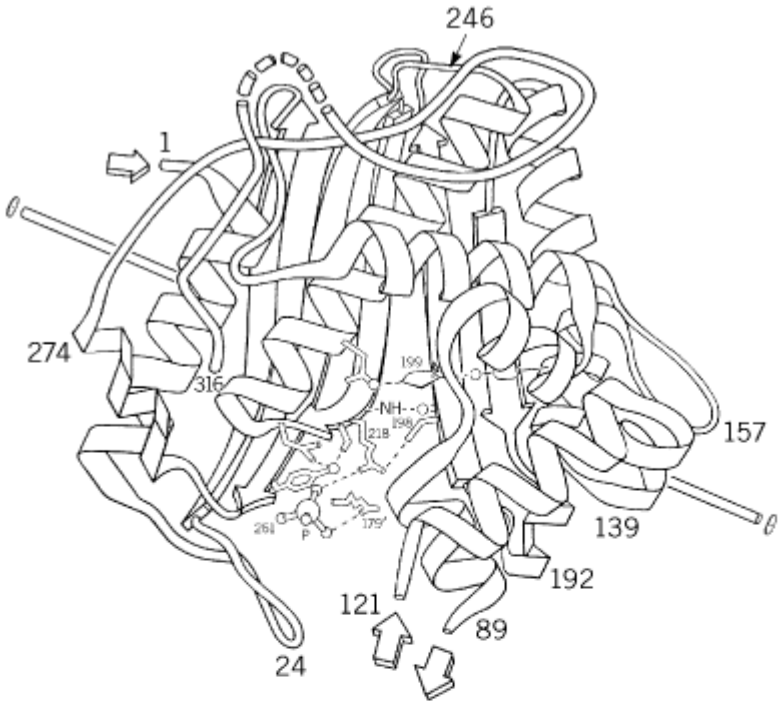
Figure 1. A plausible mechanism for the thymidylate synthase reaction, based on radiolabeling studies and the structure of the FdUMP—CH_2 = THF—TS ternary complex. In this complex, the C—F bond cannot be broken, which blocks the reaction at the stage of conversion of III to IV. Reproduced with permission from D. C. Hyatt, F. Maley, and W. R. Montfort (1997) *Biochemistry* **36**, 4585–4594.



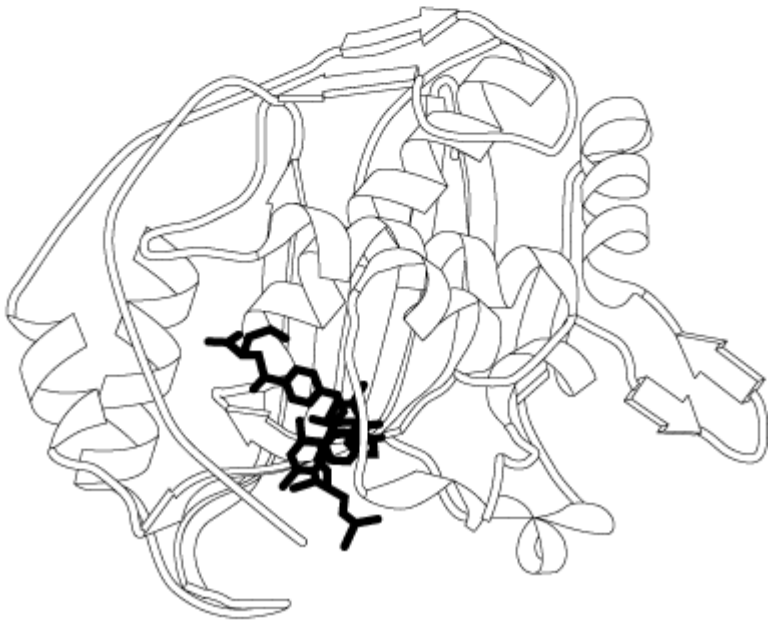
2. Structure of Thymidylate Synthase

TS from nearly all sources investigated is a homodimeric protein with a protomer size of 30 to 40 kDa. The enzyme is one of the most highly conserved proteins known, with some 18% of its residues invariant among the two dozen known sequences. The first X-ray crystallography structure reported was of the *Lactobacillus casei* TS (6). The structure shows two substrate-binding clefts, each comprising residues from both polypeptide chains. One such cleft is shown in Figure 2**a**, which also depicts conserved residues found within the cleft. Cys198 is the initiating nucleophile, and the nearby Arg218 is thought to lower the pK_a of Cys198, converting the thiol group to the reactive thiolate ion. Arg179′, from the other polypeptide chain, is thought to interact with the phosphate group on the substrate. Several nearby lysine residues (not shown) are thought to interact with the polyglutamate tail of the folate cofactor, which explains the observation that thymidylate synthase binds folate polyglutamates about 100-fold more tightly than the monoglutamate.

Figure 2. The crystal structure of thymidylate synthase. (**a**) One subunit of the *L. casei* TS dimer, showing (with numbers) conserved residues in the active site. Reproduced with permission from L. W. Hardy, J. S. Finer-Moore, W. R. Montfort, M. O. Jones, D. V. Santi, and R. M. Stroud (1987) *Science* **235**, 448–455. (**b**) One subunit of the ternary complex between *E. coli* TS, FdUMP, and CH_2 = THF. The ligands are bold, with the folate cofactor above and dUMP below. Reproduced with permission from D. C. Hyatt, F. Maley, and W. R. Montfort (1997) *Biochemistry* **36**, 4585–4594.



(**a**)

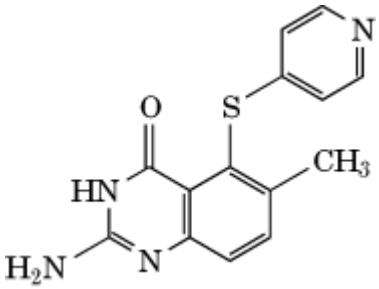


(**b**)

Several other crystal structures are now known for thymidylate synthase. Figure 2**b** shows the structure of the FdUMP—CH_2 = THF—enzyme ternary complex for one subunit of *Escherichia coli* thymidylate synthase. Detailed analysis of this structure (7) and others confirmed the interactions postulated from studies of the free enzyme, and it also helped to resolve some stereochemical anomalies of the reaction that had been revealed by radioisotope labeling experiments.

The availability of several TS structures, including that of the human enzyme, plus the attractiveness

of TS as a chemotherapeutic target, has made this enzyme one of the most active subjects of computer-assisted drug discovery research; compounds are being sought that bind as tightly as FdUMP but with greater selectivity and/or lower toxicity. In one approach (8), a docking program was used to identify known compounds that bind tightly in the TS active site. Phenolphthalein, a compound with no evident similarity to substrate or cofactor, was found to bind with an affinity in the micromolar range. Another approach (9) used computational analysis of the binding site to predict structures that would bind tightly in the cofactor site. One such compound, shown below, has no evident structural relationship to methylenetetrahydrofolate,



but it binds the enzyme with an inhibition constant (K_i) of around 30 nM.

Although the thymidylate synthase molecule contains two structurally identical substrate binding sites, considerable evidence indicates that TS displays **half-of-the-sites reactivity**, ie, that just one of the two sites is catalytically active. Consistent with this, Maley et al (10) found that simply mixing two inactive mutant forms of *E. coli* TS led to restoration of full wild-type activity, suggesting that mutant subunits had exchanged. Because one of the mutations affected the critical active-site cysteine residue (Cys146 in *E. coli*), only one functional active site per enzyme molecule was evidently enough to give full activity.

3. Thymidylate Synthase and Prokaryotic Introns

In bacteriophage T4, a virus-specific TS is encoded by gene *td*. In 1984, biologists were startled to learn that split genes were not confined to the eukaryotic kingdom, when Chu et al (11) showed that the T4 *td* gene contains a 1-kbp **intron**. Further analysis showed this and a handful of other prokaryotic introns to be of the Group I, self-splicing type. These and subsequent findings (12) have contributed to a lively debate over whether **introns** are evolutionarily ancient or recent.

4. Thymidylate Synthase and Translational Autoregulation

In eukaryotic cells, thymidylate synthase gene expression is closely aligned with the cell cycle, a fact that has led to detailed investigations of TS **promoter** structure and gene regulation. What is most novel about TS gene regulation, however, is that it is one of the first eukaryotic genes shown to be autoregulated at the level of translation (see Translation Repressors). TS protein has been shown *in vitro* to bind specifically to its own mRNA and to prevent translation of that mRNA (13). The ability of TS protein to inhibit its own synthesis was blocked by TS substrates or by FdUMP. The physiological significance of this autoregulation is not yet known.

5. Multienzyme Complexes and Multifunctional Proteins

Thymidylate synthase is associated structurally with functionally related enzymes. This was first shown in bacteriophage T4, where at least 10 enzymes of DNA precursor biosynthesis interact to form a complex, called dNTP synthetase, which evidently facilitates the flow of DNA precursors into DNA. Within this complex, an especially strong interaction links thymidylate synthase with the phage-coded deoxycytidylate deaminase, the source of most of the dUMP that is used by TS (14). Similar complexes have been described in eukaryotic cells although a role in coupling dNTP synthesis to DNA replication has not yet been established. Surprisingly, of those TS molecules that

have been shown to be localized within the nucleus (a prerequisite for the coupling of dNTP synthesis to replication), most are located in the nucleolus (15), a finding that suggests possible additional metabolic roles for the TS protein.

Quite different is the situation in protozoa and some **plants**, where TS exists as a bifunctional protein also containing dihydrofolate reductase activity. Kinetic analysis of the *Leishmania* DHFR-TS (16) shows that the dihydrofolate released by the TS reaction is channeled to the DHFR active site—transported from site to site without release from the enzyme surface—even though the active sites are 40 Å apart. Elcock et al (16) have ascribed this unusual behavior to the charge distribution on the enzyme surface. Because of its unusual structure and function, the bifunctional DHFR-TS is being actively studied as a target for antiparasitic drugs.

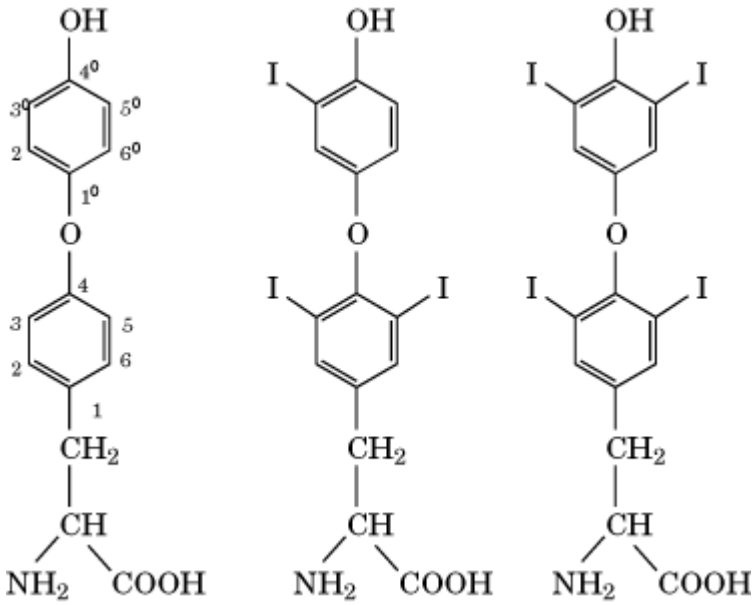
Thyroid Hormones

Thyroid hormones are iodinated derivatives of tyrosine that are synthesized in the follicular cells of the thyroid gland. The noniodinated thyronine can be regarded as the basic structure of these hormones (Fig. 1). 3,5,3′-Triiodothyronine (T3) is the major hormonally active derivative, whereas thyroxine (3,5,3′,5′-tetraiodothyronine, T4) has one-fifth of its biological activity. Biosynthesis of the hormones involves thyroglobulin, a tyrosine-rich protein stored in the follicle lumen. Iodine is oxidized to I_2 by a peroxidase of the follicular cells and then coupled covalently to tyrosine residues of thyroglobulin. The side chains of other tyrosine residues of thyroglobulin are subsequently coupled to the iodinated tyrosine residues, with the formation of diphenylether covalent bonds and completion of the basic thyronin structure. In this form, the thyroid hormones are still part of the thyroglobulin molecule. Under the stimulatory influence of thyrotropic hormone (TSH, thyrotropin), by way of a membrane receptor and activation of adenylyl cyclase (1), the iodinated thyroglobulin is taken up by the thyreocytes and degraded by proteolysis, and the freed T4 and T3 are released into the circulation. The bulk of T4 and T3 in the circulation is protein-bound. Only the free hormones can penetrate cells. In target cells, T4 is 5′-deiodinated to T3, which, at the cellular level, is the active hormone.

Figure 1. Structures of thyronine, T3, and T4.



Thyroid hormones exert a broad range of effects on cell growth, development, and metabolism. A classical effect of thyroxine, instrumental in delineating the mode of action of the hormone, is the triggering of amphibian metamorphosis (2). This change from larva to the adult animal is accompanied biochemically by a change in the mode of amino acid nitrogen excretion. Larvae excrete nitrogen in the form of NH^{+}_{4}, whereas frogs excrete it as urea. Thyroxine induces the biosynthesis of key enzymes involved in the production of urea by molecular mechanisms similar to those of steroid hormones. These hormones bind to intracellular **receptors**, belonging to the superfamily of nuclear receptors (3). Two T3 receptor genes have been found, *a* and *b*, located on human chromosomes 17 and 3, respectively. The respective receptors (TRa and TRb) have been identified. TRa is the c-erbA **protooncogene**. Two different isoforms of b (TRb1 and TRb2) have been isolated and exhibit tissue-specific expression. The receptors recognize the respective hormone response elements of DNA, to which they bind either as homodimers or as heterodimers with other nuclear proteins, such as RXR (retinoid X-receptor). In some cases, the receptor binds in the absence of hormone and acts as a repressor. Derepression is accomplished by its ligand binding to the receptor (4). In other cases, the hormone-receptor complex acts as a positive regulator of transcription.

Thyroid hormone deficiency during embryogenesis results in mental and somatic developmental defects (cretinism). Experimental extirpation of the thyroid gland leads to delayed growth and sexual maturation. In the fully developed organism, thyroid hormones show general metabolic effects, increasing metabolic rates, O_2 consumption, and thermogenesis. These effects result from the induction of the Na^{+}/K^{+} ATPase. The synthesis of RNA and proteins are also stimulated. Furthermore, the biosynthesis of other enzymes (eg, the mitochondrial glycerol-1-phosphate dehydrogenase) are also induced by the thyroid hormones. Thyroid hormones stimulate both lipogenesis and lipolysis. Lipogenesis is the result of induction of biosynthesis of enzymes of the lipogenic pathway (malate dehydrogenase, glucose 6-phosphate dehydrogenase, and fatty acid synthetase). In hypothyroidism, **lipoprotein** metabolism is altered, serum concentrations of LDL-cholesterol are increased, and hepatic lipase activity is decreased. Thyroid hormones reduce systemic vascular resistance, enhance cardiac contractility, and have a chronotropic effect. T3 stimulates transcription of myosin heavy-chain_a and inhibits expression of heavy-chain b-genes.

Ti Plasmid

The Ti plasmid of Agrobacterium *tumefaciens* is responsible for producing tumors on infected dicotyledonous **plants**. During the infection process, a defined region of **DNA**, the transferred or T-DNA, is transferred from the **bacteria** to the infected plant cell and integrated into the plant genome (see T-Complex, -DNA, -Region, -Strand). This natural form of genetic transformation is the basis of **vectors** used in plant genetic engineering for producing **transgenic** plants.

The Ti plasmid is a megaplasmid (approximately 220 kbp) present in a single copy in *A. tumefaciens*. Three types of Ti plasmid have been defined, octopine, nopaline, or agropine, depending on which **opine** is synthesized by the plant cells transformed by the corresponding T-DNA. Genetically the functions of the Ti plasmid can be defined as (1) oncogenicity, (2) nature of opines synthesized, (3) utilization of opines, (4) conjugative transfer of the Ti plasmid, (5) sensitivity to the bacteriocin agrocin 84, (6) host range, and (7) exclusion of **bacteriophage** AP-1 (1). Octopine and nopaline Ti plasmids share four regions of significant homology: the T-DNA; the virulence (*vir*) region, containing genes encoding proteins responsible for transfer of the T-DNA to the plant cell; the **origin of replication**; and a region responsible for conjugative transfer of the plasmid (2). The Ti plasmid is not stable in bacteria cultured above 30°C.

Because of their large size, the use of Ti plasmids in constructing plant transformation vectors was initially problematic. This was overcome, however, by creating cointegrative vectors. These are based on Ti plasmids into which foreign DNA to be transferred to the plant cell can be engineered by recombination.

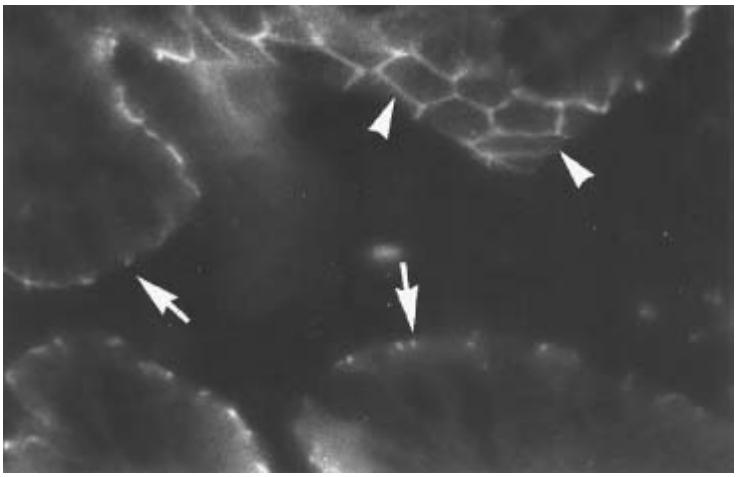
Tight Junction

The tight or occludens junction is a cell junction that occludes or regulates the permeability of paracellular channels. These junctions are widespread in simple epithelia and some endothelia, cell layers that function to divide physiological compartments within the body—for example, the epithelium of the intestine and the endothelium of the blood–brain barrier. In transmission electron microscopy, tight junctions appear as punctate areas where adjacent plasma membranes approach each other so closely that their outer leaflets seem to touch or fuse. By freeze fracture, they appear as continuous strands of particles located in the outer or P-face of the plasma membrane, with complementary grooves located on the inner or E-face. The strands may be single or may form a continuous anastomosing network (1). The junctions are zonular in nature, encircling the entire perimeters of cells within an epithelium or endothelium—hence their alternative name, zonula occludens (Fig. 1).

Figure 1. Tight junctions in small intestinal epithelium stained with antibody to ZO-1. Vertical sections through the cells show the concentration of staining at the extreme apicolateral borders (arrows), and transverse sections show the zonular nature of the junctions (arrowheads). (From Ref. 29, with permission from Chapman and Hall.)

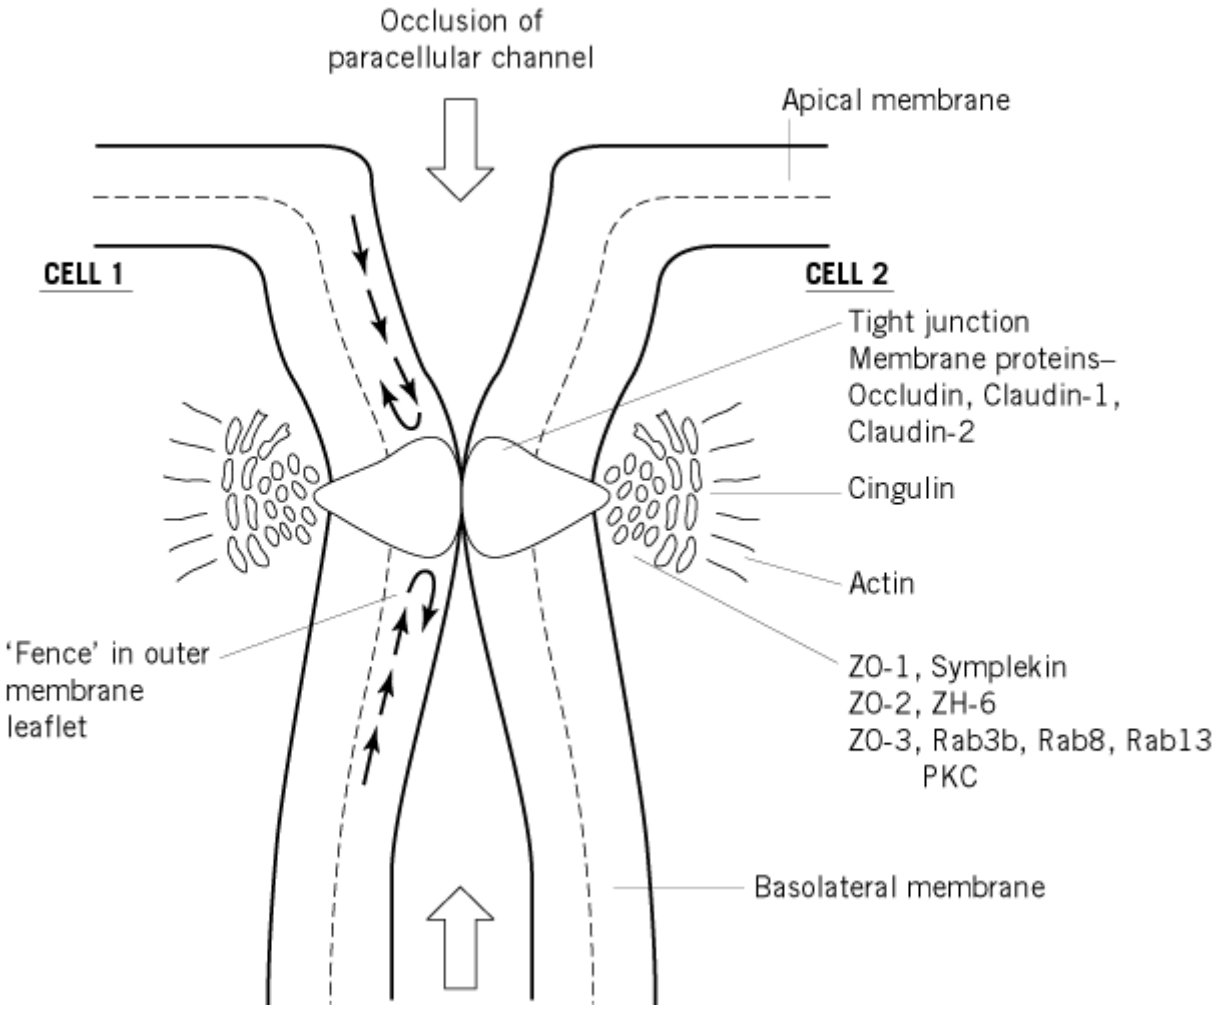


Tight junctions are largely impermeable to molecules with radii greater than 1.5 nm but are selectively permeable to ions (1, 2). Junctional permeability may be measured by determining the flux of cell-impermeable radioactive or labeled molecules across an epithelium. Restriction of the passage of ions results in an electrical resistance between one side of an epithelium and the other, called the transepithelial resistance (TER). This may be measured as an indication of tight junction function. Junctions that give rise to low TER are said to be "leaky," and junctions of high resistance are said to be "tight." Extremes of TER lie at 6 to 7 W/cm^2 for rat proximal tubule and 6×10^4 to $3\times10^5 W/cm^2$ for rat urinary bladder (2). Generally, the more strands seen in a junction by freeze fracture and electron microscopy, the higher the TER (1, 3).

Tight junctions also make an important contribution to the regulation of epithelial cell polarity (4). In simple epithelia, the protein and phospholipid compositions of the apical and basolateral plasma membranes differ. Molecules that are not anchored to the cytoskeleton are normally freely diffusible within the plane of the plasma membrane. Tight junctions have been shown to restrict the diffusion of molecules in the outer leaflet of the plasma membrane, thus confining them to either the apical or the basolateral domain. The regulation of paracellular channels is sometimes referred to as the "gate"

function of tight junctions, and the restriction of diffusion of membrane molecules is sometimes called the "fence" function (Fig. 2).

Figure 2. Diagrammatic representation of the structure of the tight junction, indicating its principal functions: (**a**) the "gate" function regulating paracellular permeability and (**b**) the "fence" function restricting diffusion of membrane components between the different membrane domains of the cell. (From Ref. 29, with permission from Chapman and Hall.)



Several molecular components of tight junctions have been identified. A major integral membrane component is the 60-kDa protein occludin, which has four **transmembrane** domains (5). This is directly involved in the formation of tight junction strands (6) and forms tight junction-like vesicular structures when overexpressed in insect Sf9 cells (7). Occludin also raises TER when expressed in epithelial cells (8), decreases TER when expressed in a *C*-terminally truncated form (9), and shows **cell adhesion** activity (9). Peptides corresponding to the second extracellular loop of occludin cause tight junction disassembly when applied to cells (10). However, ES cells in which the occludin gene has been deleted form good tight junction strands (11), indicating the existence of other integral membrane proteins. This led to the discovery of two more four transmembrane domain proteins, claudin-1 and claudin-2 (22.9 and 24.5 kDa), that localize to junctional strands (12).

The cytoplasmic components of tight junctions include three members of a larger family of proteins called membrane-associated guanylate kinase (MAGUK) proteins. These are ZO-1, ZO-2, and ZO-3 (13-15), with ZO-1 being the first discovered tight junction protein. These proteins characteristically

have DHR (discs-large homology region), **SH3** (src homology 3), and GuK (guanylate kinase) **domains** and are suggested to have membrane receptor clustering, cytoskeletal interaction, and signaling functions (16). Cingulin is a tight junction protein with a coiled-coil rod domain, showing some homology to the myosin heavy chain and suggesting the possibility of dimerization (17). It may form a filamentous network and mediate cytoskeletal associations. A number of potential regulatory proteins associated with tight junctions are three small GTP-binding proteins [rab3B, rab8, and rab13 (18, 19)], G-proteins, and protein kinase C (20). Tight junctions also contain a number of other proteins of unknown function, including 7H6 (21) and symplekin (22).

Numerous factors have been found to modulate tight junction permeability. Many may function through an effect on the actin cytoskeleton, which is associated either with the tight junction directly or the closely associated zonula adherens (see Intermediate Junction) (23). **Phosphorylation** of tight junction components, such as ZO-1 and cingulin, is also seen as important in regulation of both permeability and assembly (24, 25).

Maintenance of epithelial permeability barriers is vital to normal physiological function; and compromise of barrier function may be found in a variety of diseases, including inflammatory bowel disease and asthma (26, 27). Tight junction proteins are expressed very early in normal development, where they appear to be involved in polarity determination in the first epithelium, the trophectoderm (28).

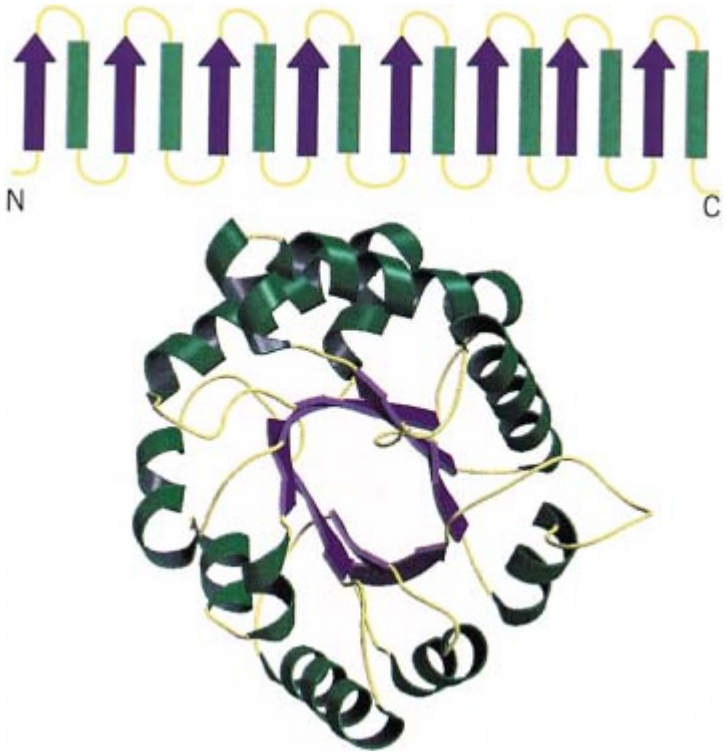
TIM Barrel

The TIM barrel is named after the protein triose phosphate isomerase, or TIM, in which this type of **domain** of a protein structure was first observed. The TIM barrel has a central cylinder or barrel of b-sheet formed from eight parallel b-strands, with strands 1 and 8 hydrogen bonded to each other to close the b-barrel. Each b-strand is connected to the next by a linking a-helix; the eight a-helices form a concentric layer surrounding the central parallel b-barrel. Both the strands and helices of the TIM barrel have a pronounced right-hand twist (Fig. 1). The topology of the TIM barrel gives rise to its other names, the $(ba)_8$ or $(a/b)_8$ barrel.

Figure 1. A TIM barrel. (**Top**) Schematic representation of the topology of the TIM barrel, with b-strands depicted as purple arrows and a-helices depicted as green cylinders. The connecting regions between the helices and cylinders are shown in yellow, and the *N*- and *C*-terminal ends of the motif are labeled. (**Bottom**) Schematic representation of the backbone of triose phosphate isomerase (1) showing a typical TIM barrel structure. The center of the barrel is formed from the b-strands forming a parallel b-sheet (shown as purple arrows), and the outer layer is formed from a-helices (shown as green coils) that connect the b-strands. The connecting regions between helices and strands are shown in yellow. This figure was generated using Molscript (2) and Raster3D (3, 4). See color insert.



This very common fold is found in many proteins with diverse functions and no detectable sequence identity, so their similar structures are thought to be an example of convergent evolution. Although the activities and sequences of these proteins vary, their active sites are all formed by loop regions at the carboxyl ends of the b-strands that connect to the a-helices. The particular enzymatic activity of the enzyme is dependent on the amino acid residues in these regions. The TIM barrel forms one of two major classes of a/b domains, and the other class is typified by the nucleotide-binding motif.

Tissue Culture

Tissue culture was originally understood to mean the maintenance and, in some cases, growth *in vitro* of small explanted fragments of tissue from an animal or plant, (1, 2), but it has become a generic term covering a wide range of *in vitro* cultivation techniques. Cell culture, where the tissue is dissociated into individual cells, which may be propagated adherent to glass or plastic, or in suspension, is the technique most widely used. Organ culture, where the tissue is not disaggregated, but maintained at the air–liquid interface as a complete fragment, is a method that retains the architecture of the tissue, but does not allow propagation. Maintenance of small fragments of tissue at the solid–liquid interface, that is, attached to the glass or plastic substrate (primary explant culture), permits the outgrowth of cells on to the substrate by migration and cell proliferation, and can give rise to a propagated cell line.

Tissue culture, defined in its generic sense, is used when it is important to regulate the physical and physiological microenvironment of the cells, maintain a consistent, validated stock of characterized cells, and/or minimize the use of laboratory animals. It also allows the introduction of exogenous genomic DNA with a high efficiency (see Transfection), the study of signaling mechanisms under controlled conditions with a purified population of cells, the measurement of cytotoxic and genotoxic responses, and the production of proteins with appropriate post-translational modifications (see Protein Engineering). Tissue culture, however, will not mimic *in vivo* conditions accurately, because of the difference in the cellular microenvironment, the absence of metabolizing enzymes normally found in the liver, and the difficulty of reproducing the fully differentiated cell **phenotype** *in vitro*. Continuous cell lines are also genetically unstable and often genotypically heterogeneous.

1. History

Opinions vary as to when tissue culture actually commenced, as there was a gradual transition from the earlier studies of pathologists with isolated fragments of tissue to the demonstration of actual growth (3). Tissue culture implies that the explanted tissue or cells can be maintained for more than a few hours and will display some aspect of growth. The first success in this area is usually attributed to Harrison (1), who was able to maintain spinal cord from frog embryo in a natural medium of clotted frog lymph for up to 4 weeks and observed outgrowth of nerve fibers from the explant. Others were able to repeat Harrison's observations and made attempts to passage the resulting cultures (4). Propagated cell lines (see Cell Line) were derived from the outgrowth of several types of tissue, but it was not until after World War II that extensive use was made of **trypsin** to passage cells, producing a single-cell suspension that could be divided accurately and even cloned (5).

Numerous attempts were made to generate new cell lines (6), assisted by the development of antibiotics, which were incorporated into culture media to prolong culture life without contamination. Subsequently, the development of laminar flow cabinets in the late 1960s and early 1970s provided a protected environment, facilitating aseptic technique without the necessity of continued culture in antibiotics. Around this same period, it was observed that cells could be stored frozen in culture medium, with a preservative added, for extended periods (7-9), and this gave further protection against loss by contamination or incubator failure. This led to a rapid proliferation of cell lines, and it was not until Gartler (10) initiated studies with enzyme polymorphisms, which could distinguish some cell lines from others by the **isoenzymes** characteristic of the original tissue, that a more serious contamination problem was discovered, namely, cross-contamination. This was confirmed by karyotype analysis (11), and by the mid-1970s, it was estimated that around 30% of all cell lines in current use in North America were cross-infected with HeLa Cells (12). Many of these, such as KB, Hep-2, Girardi heart, and Chang liver, are still in current use, often not identified by the user as HeLa-contaminated. This problem has been recognized by the major cell banks, who now label stocks suspected as carrying HeLa markers (13).

The continued use of antibiotics, combined with natural products, such as serum and trypsin, brought in another crisis when Barile (14) and others reported that large numbers of propagated cell lines were contaminated with mycoplasma, too small to detect readily without special staining, and not always as catastrophic to the culture as are most bacterial infections. These microorganisms were too

small to be filtered out by the sterilization procedures of the day and, once contaminating a cell line, were very difficult to remove. The development of a **fluorescent** staining technique (15) and other assays for mycoplasma detection, together with a reduced porosity of sterilization filters used in serum manufacture, means that contamination is readily detected, and further contamination preventable, by constant screening and use of materials from reputable sources. Nevertheless, mycoplasma contamination, introduced from infected cell lines, primary cultures, or the operator, is still widespread and requires constant vigilance to eliminate.

Modern tissue culture, carried out in high grade facilities with ultrapure water and media components and proper validation and authentication procedures, is now a highly reproducible technique employed in academic research laboratories, diagnostic laboratories, and industrial-scale production of biopharmaceuticals.

2. Types of Culture

2.1. Cell Culture

This is the maintenance and propagation of cells as a uniform monolayer or suspension (16). A cell culture may be derived from a tissue by three main methods of primary culture.

1. Primary explant technique. A small fragment of tissue is placed on the base of a culture vessel so that it adheres, either spontaneously, facilitated by scratching the plastic surface, trapping the tissue under a coverslip, or use of surface tension or clotted plasma. A primary culture arises by outgrowth from the explant across the surface of the dish.

2. Mechanical disaggregation. The tissue may be disaggregated by chopping with scalpels or scissors or by forcing the tissue through a mesh screen or syringe needle. The resultant suspension of cells and small fragments is allowed to settle and form an adherent cell monolayer on a glass substrate or the correct grade of plastic (see below).

3. Enzymatic disaggregation. Tissue may be disaggregated by incubation in a number of different proteinases; trypsin, collagenase, and Dispase are the most common. Trypsin requires the absence of serum, which contains trypsin inhibitors, but collagenase and Dispase are insensitive to proteinase inhibitors in serum. As for mechanical disaggregation, the resultant cell suspension, washed free of enzyme by centrifugation and resuspension, is allowed to settle to the base of the dish to form an adherent monolayer (17).

The outgrowth from a primary explant culture, or the monolayer generated from mechanically or enzymatically disaggregated cells, may be subcultured (see Cell Line) and transferred to fresh culture vessels (17). This process, also known as *passage* , is usually achieved by treating the monolayer with trypsin to dissociate the cells from each other and the substrate, resuspending the cells in fresh medium with serum (to inhibit the residual trypsin), and diluting into fresh culture vessels (17). After the first subculture the culture becomes a cell line (see Cell Line).

3. Organ Culture

Organ cultures are not as widely used as cell cultures, as they require considerably more effort to initiate and cannot subsequently be propagated. They do, however, provide a means to retain at least some of the histological structure of the tissue, and with it some of its phenotypic characteristics. Organ cultures can be maintained for up to 3 weeks (although longer periods have been recorded) and may contain areas of localized cell division, but growth is limited. Tissue, or preferably a whole organ, from the embryo survives better, and may show some net growth in culture, but the growth and cell survival are limited by the dimensions of the tissue explant. Under normal conditions (20% oxygen at atmospheric pressure), the radius of a spherical organ culture is limited to a maximum of 500 µm. The organ culture may extend in shape in two dimensions, as long as one dimension

remains at 500 µm or less. The inward diffusion of oxygen, and the outward diffusion of CO_2, are optimized by growing the tissue at the air–liquid interface; access to the nutrient medium is provided by a permeable support, usually a porous membrane on a stainless steel mesh grid. Organ cultures have been found particularly useful for cultivation of skin (18), fetal bone (20), and various embryonic organs during organogenesis (21).

4. Histotypic Culture

It is possible to create the cell–cell interactions provided by tissue-like densities, while still having the convenience and reproducibility of cell lines, by growing cell cultures to high cell densities. This can be achieved in several ways: (*1*) By growing cells in a filter well insert, where the cells are crowded, but adequate medium is provided by access to a relatively large reservoir (22); (*2*) growing cells as stirred aggregates, called *spheroids*; generated by growing the cells at high concentrations on agar or agarose in a multiwell plate, so that the cells form aggregates in the bottom of the meniscus generated by the agar in the well—these are then stirred at low speed in suspension; similar aggregates may be generated by growing cells in suspension in zero gravity in a slowly rotating chamber (23); and (*3*) Growing cells on the outer surface of perfused microcapillary bundles, where the cells are seeded in the outer chamber holding the hollow fibers, and medium is pumped through the fibers from a reservoir (24).

5. Organotypic Culture

Histotypic culture can be adapted to cocultivation of two, or more, different cell types, in an attempt to simulate heterotypic cell interactions, in addition to the homotypic cell interactions achieved in histotypic culture. Skin culture has become a classic example, where epidermal epithelium maintained in coculture with dermal fibroblasts embedded in collagen will generate well-differentiated keratinocytes expressing involucrin, filaggrin, and cross-linked keratin (25). The requirement for collagen is similar to many specialized cultures, which require elements of the extracellular matrix, such as collagen, laminin, and fibronectin, for proliferation and differentiation.

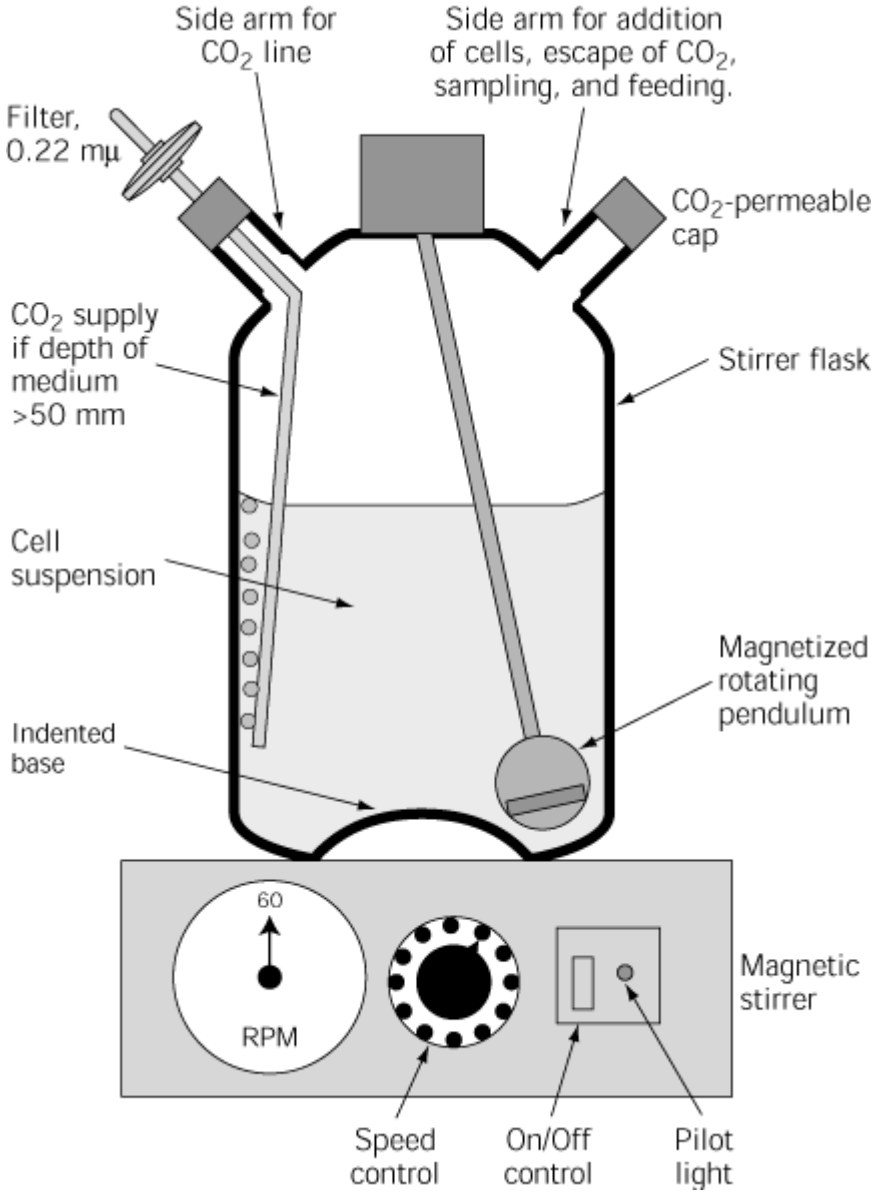
6. Monolayer and Suspension Cultures

Most normal cells attach to plastic and require to spread out on the plastic before cell division will commence (see Contact Inhibition). Attachment is mediated by transmembrane integrin receptors (see Cell Adhesion Molecules), which bind components of the extracellular matrix deposited on the substrate by the cells. Hence, coating the substrate with matrix molecules, such as fibronectin or collagen (26), or conditioning the substrate by previously culturing cells on it and removing them with detergent in water (27), can often facilitate cell attachment and subsequent proliferation.

Some cells will grow readily in suspension, either spontaneously (eg, murine ascites tumors) or by mechanical stirring (eg, HeLa-S_3) (Fig. 1). These cells are said to be *anchorage independent*, and the cultures are usually derived from the transformed cells of a tumor or from normal cells that have transformed *in vitro*, either spontaneously or following mutagenesis (see Neoplastic Transformation). Suspension cultures can be propagated in large bulk without elaborate mechanisms for increasing the surface area. Gas exchange is improved when the depth of medium exceeds 50 mm by sparging the medium with a mixture of 5% CO_2 in air.

Figure 1. Cross-sectional diagram of a stirrer vessel on a magnetic stirrer. The side arm at top right is used to add cell suspension and collect samples; it has a permeable cap to allow escape of CO_2. Filtered CO_2 in air is supplied via a filter to the side arm at top left; it is required if the depth of the culture medium exceeds 50 mm. Agitation is achieved by a magnet, enclosed in a glass pendulum, and is driven by the magnetic stirrer at ~60 rpm. (After design of stirrer vessel marketed by Techne, Cambridge, U.K.). Modified from Freshney's *Culture of Animal Cells, A Multimedia*

Guide, 1999, Wiley-Liss, New York.



Suspension cultures can be scaled up easily, deliver a large bulk of cells at one time, and do not need trypsin for harvesting the cells from the culture. They can also be maintained in a steady state of growth by regulating the rate at which medium is added to balance the rate of cell proliferation and by withdrawal of surplus cells. Such cultures are called biostats or vivostats and enable the concentrations of cells, nutrients, and products, and the pH, osmolality, and gas tension, to be kept constant over prolonged periods (28).

7. Culture Vessels

Cell cultures are usually grown in disposable plastic flasks, petri dishes, or multiwell plates, that have been treated with plasma discharge, or some similar process, to create a net negative charge on the surface of the flask. Flasks are preferable for long-term propagation, dishes for cloning or where direct access to the growth surface is required (and are cheaper), and multiwell plates for replicate sampling. Where a large number of cells is required ($>1 \times 10^9$), roller bottles, or multisurface propagators are required for attached cells, and large fermentors for suspension-grown cells.

TLCK (*N-P*-Tosyl-Lysine Chloromethyl Ketone)

This reagent was developed by Shaw and co-workers as a specific inhibitor of **trypsin** (1). Its design was based on the principle of affinity labeling, which couples substrate specificity with chemical reactivity to generate a covalent bond between the reagent and a functional group at the active site of an enzyme. In this case, the lysine part of the reagent confers specificity for trypsin and the chloromethyl ketone provides chemical reactivity (Fig. 1). Although trypsin is a serine proteinase, the reagent does not interact with the active site serine residue but instead alkylates the histidine residue that is part of the catalytic triad. The reagent has essentially no effect on the activity of **chymotrypsin** or other serine proteinases and is often used to inactivate the small amounts of trypsin present in purified chymotrypsin preparations. It is also often combined with inhibitors of other types of proteinases to prevent unwanted proteolysis that might occur during the course of protein isolation from cell or tissue homogenates (2).

Figure 1. Interaction of TLCK (tosyl-lysyl-chloromethyl ketone, ie, L-1-chloro-3[4-tosylamido]-7-amino-2-heptanone) with the active-site histidine side chain of a trypsin-like serine proteinase. The reaction product is catalytically inactive.

Tobacco Mosaic Virus

Tobacco mosaic virus (TMV) was the first **virus** to be recognized as a disease entity different from **bacteria** when Beijerinck (1) concluded that it was a new type of infectious agent, "Contagium vivum fluidum." Since then, it has spurred the development of various concepts of viruses, being, among other aspects, the first virus to be purified and crystallized and shown to be composed of protein and **RNA** (2). Details of the history of TMV are given in Fraenkel-Conrat (3).

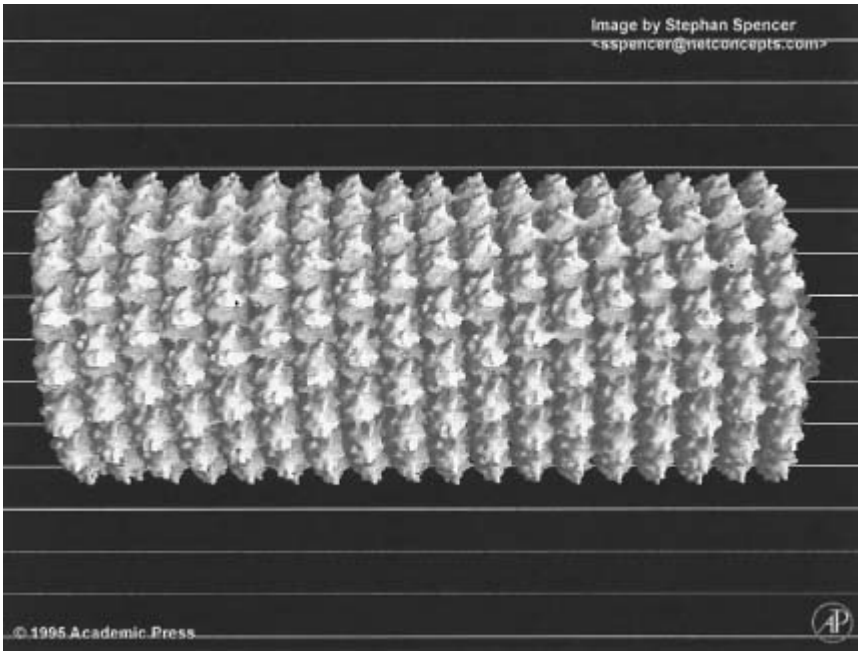
TMV is found worldwide and locally can cause an important disease in tobacco. It has a large host range, infecting at least 200 species from 30 families (4). The virus occurs in very high concentrations in infected leaves (> 10^6 particles per cell) and is very stable, even retaining its infectivity in nonsterile extracts at room temperature for more than 50 years (5). These properties make it very readily transmitted by contact between plants. Man is the main vector, either directly by handling infected and then healthy plants or indirectly by farm machinery. The virus survives in dead crop debris and thus can be transmitted to the next season's crop at planting time.

TMV is the type member of the tobamovirus genus, which contains 13 species and two other possible members.

1. Virus Structure

The **virions** of TMV are rod-shaped, 300 nm long, and 19 nm in diameter, and composed of a single-coat protein species encapsidating a single (+)-strand linear RNA molecule of about 6.4 kb. The detailed structures of the virions and coat protein subunits have been determined by electron microscopy and X-ray crystallography. In a virion, approximately 2100 subunits are closely packed in a single right-handed helix of pitch 2.3 nm and with 16 coat protein molecules per turn (Fig. 1). The RNA binds at a radius of about 4 nm, with three nucleotides per protein subunit. There is a central canal of about 2-nm radius. The length of the rod is determined by the length of the RNA, which is fully encapsidated.

Figure 1. The structure of part of TMV. The portion indicated includes 18 turns of the helical array, with $16\frac{1}{3}$ subunits/turn.The entire virus consists of about 128 turns.



Much is known about the detailed structure of the protein subunits and their interactions in forming the virion (6). The protein monomer aggregates in solution in various ways, depending on ionic strength, pH, and temperature (7, 8). The structure of one of these forms, a double disk of 17 subunits per disk that is an intermediate in virus assembly, has been determined by X-ray crystallography to 2.8 Å resolution. Up to a radius of 4 nm, no structure is resolved, which suggests a disordered state. Much of the rest of each protein subunit is made up of four **a-helices**, with their distal ends bound together by regions of b-sheet. Both the N- and C- termini of the polypeptide chain occur at the circumference of the disk. The subunits have polar and **hydrophobic** interactions with each other. In the virion, there are also electrostatic interactions, between both the RNA and protein one involving pairs of carboxyl groups with anomalous pK_a values (near pH 7.0) on adjacent subunits. It is thought that these carboxyl groups play an important role in particle assembly and disassembly.

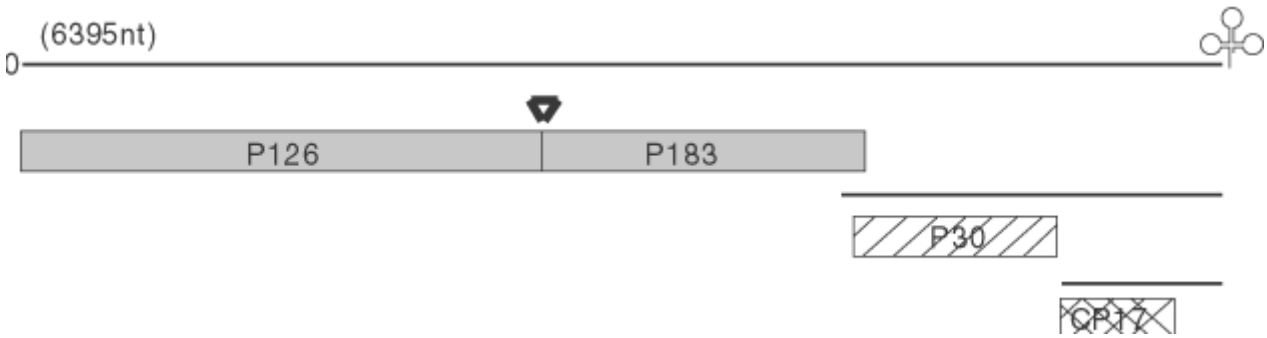
The self-assembly of TMV coat protein subunits has been studied extensively *in vitro* by the addition of virion RNA to coat protein preparations, which leads to the reassembly of virus particles. Assembly starts at a specific site on the RNA, termed the *origin of assembly*, which is a region of extensive stem-loop structures about 1100 to 900 nucleotides from the 3′ end. In the initial initiation event, the hairpin loop of the origin of assembly interacts with a double disk of coat protein subunits so that both ends of the RNA protrude from the same side of the disk. The hairpin loop opens up as the RNA intercalates between the two layers of the double disk, which changes to a helical (double-lockwasher) form. A second double disk adds to the first on the side away from the protruding RNA tails and, as it switches to a helical form, it interacts with the RNA 5′ to the origin of assembly. The helical rod continues to grow in the 5′ direction by the further addition of double disks, effectively pulling the RNA through the axial hole until all the RNA 5′ of the origin of assembly is encapsidated. The assembly in the 3′ direction is much slower than that in the 5′ direction and occurs by the addition of small aggregates of coat protein (A protein form) to the helical rod.

The *in vivo* disassembly of TMV involving the cotranslational disassembly mechanism is discussed under Virus infection, plant.

2. Virus Genome

The genome of TMV comprises 6395 nucleotides and codes for four, or possibly five, proteins (Fig. 2). The first **open reading frame**, encoding a protein of 126 kDa, ends in an **amber** stop codon, but this is occasionally *read through* to also give a protein of 183 kDa. These two proteins are involved in TMV replication and make up the viral **RNA-dependent RNA polymerase** of the "Sindbis virus supergroup." There are amino acid sequence motifs suggestive of a **methyl transferase** and **helicase** domain in the 126-kDa protein and of an RNA polymerase in the readthrough portion of the 183-kDa protein. There is a suggestion that the 54-kDa readthrough part of this protein might also be expressed independently from a subgenomic RNA. The other two downstream proteins, one at 30 kDa and the other at 17.6 kDa, are expressed from subgenomic messenger RNAs. The 30-kDa protein is involved in cell-to-cell movement (see Virus Infection, Plant), and the 17.6-kDa protein is the viral coat protein.

Figure 2. Genome organization of TMV. The upper line represents the single-stranded RNA genome; the circle at the 5′ end indicates the cap, and the tRNA-like structure at the 3′ end is also illustrated. The other two lines are the subgenomic RNAs. The open reading frames are shown by the boxes, and their position on the diagram indicates from which RNA they are expressed. The proteins are distinguished by their approximate molecular weights, in kDa. The stippled box (P183) indicates the RNA polymerase, that striped (P30) is the protein believed to be involved in movement, whereas that cross-hatched (P17) is the coat protein; ▼ indicates readthrough.



The viral RNA has a methyl guanosine cap and leader sequence of 67 nucleotides that is very AU-rich. This leader sequence, termed the W sequence, appears to have no secondary structure and enhances translation (9). The 3′-end folds into a **transfer RNA**-like structure and accepts histidine.

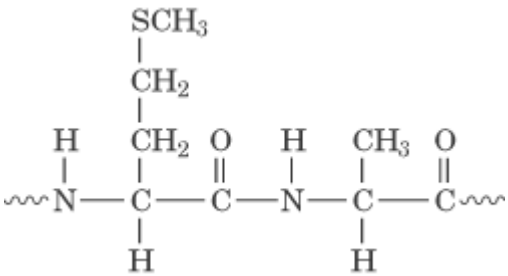
TOCSY Spectrum

Total correlation spectroscopy (TOCSY) is a type of two-dimensional nuclear magnetic resonance (NMR) spectrum in which cross peaks result from coherence transfers. For studies of biological macromolecules, TOCSY normally monitors hydrogen atoms (protons), with cross peaks present because of coherence transfer from hydrogen to hydrogen of the macromolecule. TOCSY is a powerful tool for making assignments of proton NMR signals to specific protons of the molecule being examined. The information provided in a TOCSY spectrum contains the data present in a correlation spectroscopy (**COSY**)–type experiment but includes additional cross peaks that arise because of coherence transfers to or from all protons in a network of spins.

The requirement for the appearance of cross peaks in a proton TOCSY spectrum is the presence of a collection of mutually spin-coupled protons. Consider the alanine residue in the segment of polypeptide shown below:



Protons of the methyl group are J-coupled to the proton attached to the a-carbon (J~7Hz), and the proton on the a-carbon is spin-coupled to the amide N–H proton (J~2–10Hz). The methyl protons are separated from the amide N–H proton by four chemical bonds; thus, the coupling constant between the methyl spins and the peptide N–H is too small to be resolved under typical experimental conditions. Because a resolved coupling constant is necessary for detectable coherence transfer, no such transfer between the methyl protons and the N–H proton would be expected in a standard COSY experiment. A pathway exists for such transfer, however, involving transfer of methyl proton coherence to the a-hydrogen and then transfer from the a-hydrogen to the peptide N–H. The results of these coherence transfers are seen in a TOCSY spectrum as cross peaks that are characterized by two chemical shift coordinates. The coordinate in one dimension corresponds to the precessional frequency of the coherence before transfer, whereas the other chemical shift coordinate corresponds to the chemical shift of the coherence after the coherence transfer process has taken place. In a TOCSY spectrum, an alanine residue will be represented by three diagonal peaks, corresponding to the shifts of the CH_3, C_aH, and N–H protons, and by six cross peaks, corresponding to all possible origins of coherence and all possible destinations for coherence transfer.

The usefulness of the TOCSY experiment becomes apparent on recognition that the spin-coupling constants are zero between protons on adjacent residues of a polypeptide, so that coherence transfers *cannot* take place between different amino acid residues of the polypeptide chain. A network of cross peaks in TOCSY can only arise from protons within the *same* amino acid. If coherence transfer takes place between all possible partners within a residue, the chemical shifts of all spins in that residue can be identified.

Some of the cross peaks present in TOCSY will also be present in a COSY spectrum of the same sample. A significant advantage of TOCSY over COSY is that all components of a TOCSY cross peak tend to be of the same sign, whereas COSY cross peaks have both positive and negative components. COSY cross peaks can therefore become self-canceling when the separation of the cross peak components is inadequate.

The critical element of a TOCSY experiment is the portion known as the isotropic mixing period, during which transfers of coherence take place. The length of this mixing time typically ranges from 20 to 70 ms. For values near the low end of the range, only coherence transfer to nearby spins takes place, and the TOCSY spectrum is similar to a COSY–type spectrum. For longer mixing times, coherence transfers over the entire spin-coupled network are possible. The extent of coherence transfer (reflected in the intensity of a cross peak) is a complex function of the spin-coupling constants in the network, the length of the mixing time, and the method used to achieve isotropic mixing. No assurance exists that an expected cross peak will indeed appear in the TOCSY spectrum for a specific mixing time; thus, for unambiguous identification of all possible coherence transfers in a particular spin system, it may be advantageous to have TOCSY spectra recorded using several mixing times.

The elements of the TOCSY experiment can be built into experiments that produce three-dimensonal or higher NMR spectra. (See also **NMR, COSY spectrum, Scalar coupling**.)

Tolerance, Immunological

Tolerance is a central notion in immunology, because the immune response has *a priori* the potential power of self-recognition, which implies the possibility of fatal aggression against self constituents (see Autoantibody, Autoimmunity, and Autoimmune Diseases). This is already present in the famous formula of *horror autotoxicus* put forward by Ehrlich in 1901. As the cells endowed with specific recognition, T cells and B cells, are permanently synthesized, an *ad hoc* mechanism must operate to prevent the emergence and expansion of potentially autoaggressive clones. Natural autoantibodies permanently circulate in the body, but these are not harmful because of their low concentration, low affinity, polyspecificity, connectivity, and germline-encoded nature.

The first known example of tolerance, given in all immunology textbooks, was the observation by Owen in the 1940 that, as a consequence of a natural cross-circulation of blood during fetal life, dizygotic twin calves have a mixed population of red cells and can accept grafts from each other. In 1953, Brent, Billingham, and Medawar showed that injection of **allogenic** lymphoid cells at birth

induced a tolerant state that allowed the treated newborn, once adult, to accept skin grafts from an animal of the same strain as the initial donor. This indicated that tolerance was an acquired phenomenon. It was also shown to be specific, because the pretreated animal rejected the graft of a third strain. This experiment was crucial for Burnet's proposals of the clonal theory that explained tolerance by elimination of the autoreactive lymphocytes (the "forbidden clones").

Some years later, tolerance induction was extended to soluble proteins, when it was observed that the nature of the immune response was very much dependent on the dose of immunogen administered. An antibody response is obtained only in a relatively narrow range, whereas low and high doses induce unresponsiveness, called low-dose and high-dose tolerance. The two phenomena appear to be different, because the high-dose tolerance tends to revert spontaneously as the antigen is eliminated catabolically, whereas the low-dose tolerance is long lasting. The mechanisms of tolerance are still subject to debate, because clonal deletion, anergy, and suppression have been proposed, and all are supported by a large body of data.

The acquisition of central tolerance takes place in the primary lymphoid organs—that is, in the thymus and in the bone marrow for T and B cells, respectively, where a screen for autoreactivity of newly emerging cells operates before they may enter the periphery. For T cells, this happens when $CD4^+CD8^+$ double-positive (DP) thymocytes that have just rearranged their T-cell receptor genes are subjected to negative selection in the thymic cortex (see Gene Rearrangement). It is accepted that thymocytes having a high affinity for major histocompatibility complex (MHC) peptides of the thymic environment are deleted. In fact, this is quite difficult to prove, and mechanisms to account for negative selection are still awaited.

B lymphocytes are screened for autoreactivity before leaving the bone marrow, at the immature B-cell stage, when expressing only IgM at their surface. When exposed to antibody directed against their heavy chain, m, these cells die, suggesting that their elimination in the bone marrow results from interaction with a multivalent antigen. This view is also supported by experiments with transgenic mice that express H and L genes encoding an antibody directed against $H\text{-}2^k$, an MHC class I molecule. In non $H\text{-}2^k$ mice, the B cells develop normally and express the transgenic antibody. In $H\text{-}2^k$ mice, a severe blockage of differentiation occurs at the preB stage, indicating that most B cells die *in situ*. This is a typical example of clonal deletion, as postulated by Burnet. It is of interest to note that blockage in this transgenic models may be leaky, because some level of endogenous gene rearrangement of light chain genes may occur, implying a transient reactivation of the recombinase. These new light chains may now associate with the transgenic m chain, resulting in the occurrence of antibodies endowed with new specificity. This mechanism, known as *receptor editing*, is both an additional mechanism to generate diversity and a way to rescue clones that otherwise would have been deleted. More sophisticated models of double transgenic mice have been studied, using transgenes for both the antigen and the corresponding antibody. In that case, tolerance is set up in two distinct ways. When the transgenic antigen is expressed as a membrane-bound molecule, B cells are deleted. When it is expressed as a soluble form, B cells are present, but anergized. No surface IgM is found, although cytoplasmic IgM is present. Furthermore, surface IgD is present that might also be linked to an alteration of the transduction cascade, which questions whether IgD might have a possible role in this type of tolerance.

Finally, it should be mentioned that tolerance may also be seen as the result of a network of regulation, possibly involving cytokines and an equilibrium between Th cells that might have an active suppressive effect. In this regard, the possibility of inducing dominant tolerance by grafting thymic cells from an exclusively epithelial origin is compatible with such a view, because this tolerant state can be transferred by lymphoid cells. This does not necessarily imply the existence of suppressor T cells as such, but could result from a systemic generalized regulation.

Experimentally induced tolerance may be broken, for example, by attempting stimulation with cross-reactive antigens. This opens the way to an approach to a better understanding of **autoimmune**

diseases, which certainly could be considered to be the consequence of a dysbalance in the regulation of the immune system, inducing a break in the physiological tolerance to self components.

Tomato Bushy Stunt Virus

Tomato bushy stunt virus (TBSV) was first described in England in 1935 (1) and has now been recognized in many countries in Europe, the Mediterranean regions, and North and South America. It causes economic problems in some countries, with tomato crops but is not generally recognized as a major problem. It has been found to infect several other plant species naturally, and its artificial host range is wide. Although the virus spreads readily through crops, no specific vector has been identified. It is transmitted by contact and through the soil and is found in rivers, which may account for its long-distance contamination. The virus occurs in high concentrations in infected plants, is stable, and is easily purified. Thus, it has been a good model for studies on virus structure and basic molecular biology.

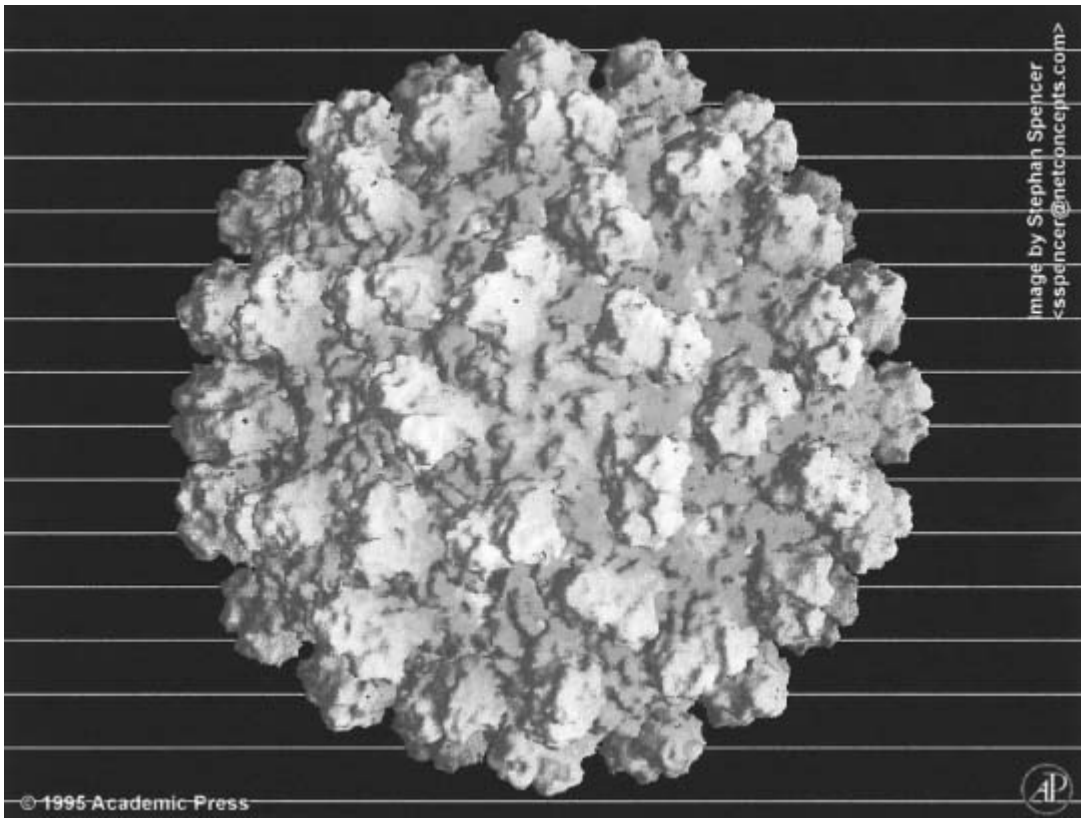
TBSV is the type member of the Tombusvirus genus, which currently contains 13 species.

1. Virus Structure

The **virion** of TBSV is isometric, with a diameter of about 30 nm (Fig. 1). It is composed of a single type of coat protein encapsidating a single (+)-strand linear **RNA** molecule of about 4.7 kb. The detailed structures of the virions and coat protein subunits have been determined by electron microscopy and X-ray crystallography. In fact, TBSV was the first virus shown to have **icosahedral symmetry** (2) and thus has formed the basis of our understanding of isometric virus structure. The 180 coat protein subunits of the virus particle are arranged in $T = 3$ symmetry (see Virus Structure), and the virion structure has been determined at 2.9 Å resolution. Each coat protein subunit comprises 387 amino acids, which are folded into three distinct **domains**. The N-terminal domain (the R domain) is composed of 66 residues, with a high proportion of basic amino acids, and interacts internally with the RNA. This is connected by an arm of 35 residues to the rest of the molecule, which is made up of the globular shell (*S*) domain (167 residues) and surface-protruding (*P*) domain (114 amino acids); the *S* and *P* domains are connected by a flexible hinge of five residues. The *P* domains are clustered as 90 dimers, which are important in virion assembly and stability. The *S* domain forms a barrel structure composed of eight Beta-Strand, which is now recognized as being characteristic of the coat proteins of many isometric viruses. The 180 coat protein subunits of the virus particles have three different **quasi-equivalent** conformations, which are necessary for icosahedral symmetry packing. The A and B conformations are very similar, with disordered N-

terminal arms. The C conformation has an ordered N-terminal arm that interdigitates with two other C subunit arms around the icosahedral three-fold axis.

Figure 1. The external surface of tomato bushy stunt virus, viewed down a local five-fold axis.



Three major interactions stabilize the virus particle: (1) electrostatic interactions between the *R* domain and genomic RNA, (2) a pH-dependent interaction between protein subunits that protonates above pH 7, and (3) an interaction involving Ca^{++} ions. The Ca^{++} links adjacent subunits via the carboxylate groups from the side-chains of **glutamate** and **aspartate** residues in the *S* domain.

2. Virus genome

The genome of TBSV comprises 4776 nucleotides and codes for five proteins (Fig. 2). The first **open reading frame**, encoding a protein of 33 kDa, terminates in an **amber** stop codon, but this is occasionally *read through* to yield a protein of 92 kDa (see Viruses, Plant). These two proteins are essential for virus replication, and it is thought that they make up the viral **RNA-dependent RNA polymerase**. The readthrough portion of the 92-kDa protein contains the motif of Gly-Asp-Asp (GDD) typical of such RNA polymerases. The third open reading frame encodes the viral coat protein and is expressed from a subgenomic 2.1-kb messenger RNA. The fourth and fifth open reading frames overlap each other, and both are expressed from another subgenomic RNA (0.9 kb). Mutagenesis indicates that both of these proteins are essential for full infection of the host, and there is a suggestion that the 22-kDa polypeptide is involved in cell-to-cell movement (3).

Figure 2. Genome organization of TBSV. The upper line represents the single-stranded RNA genome, and the other two lines are the subgenomic RNAs. The five open reading frames are shown by the boxes, and their position on the

diagram indicates from which RNA they are expressed. The proteins are distinguished by their approximate molecular weights, in kDa. The stippled box indicates the RNA polymerase, whereas the cross-hatched box is the coat protein; ▼ indicates readthrough.

Topogenesis

Integral membrane proteins are embedded in the lipid bilayer either by membrane-spanning a-**helices**, which for multispanning or oligomeric proteins form a helix bundle, or by b-strands forming a b-barrel. This is attested by the few solved three-dimensional structures of membrane proteins. As examples, Figure 1 shows the backbone structures of bacteriorhodopsin (1) composed of seven transmembrane a-helices, and of the matrix porin OmpF (2), a barrel of 16 antiparallel b-strands. b-Barrel proteins are found exclusively in the outer membranes of bacteria, mitochondria, and chloroplasts. Little is known about the process of their integration into the membrane. Because the **hydrophobic** surface is generated only when the b-sheet has assembled, it is likely that **protein folding** precedes insertion. In contrast, individual hydrophobic helices can fold and insert independently, and they can assemble into the bundle in a separate second step (3). This model is supported by refolding experiments and by the functional assembly of membrane proteins from separately expressed fragments (eg, Ref. 4). The basic topology of helical membrane proteins is thus defined in the first step, the insertion of membrane-spanning segments into the bilayer. The

determinants that direct topogenesis and the machinery that decodes them are largely conserved between prokaryotes and eukaryotes. In the best-studied systems, the cytoplasmic membrane of bacteria and the endoplasmic reticulum (ER) of eukaryotic cells, a hydrophobic signal sequence is recognized by a targeting system and guided to a gated hetero-oligomeric transmembrane channel. Exoplasmic hydrophilic portions of the polypeptide chain are translocated across the membrane, whereas apolar sequences of ~15 to 25 residues are released into the lipid bilayer as transmembrane a-helices. Their orientation is determined mainly by flanking charged residues, but also by their hydrophobicity and length, by their position within the polypeptide, and by the folding properties of adjacent polar domains. Our current understanding of topogenic determinants allows reasonably efficient prediction of protein topology. However, the molecular mechanisms by which the determinants are recognized have not been established yet.

1. Machinery for Membrane Targeting and Insertion

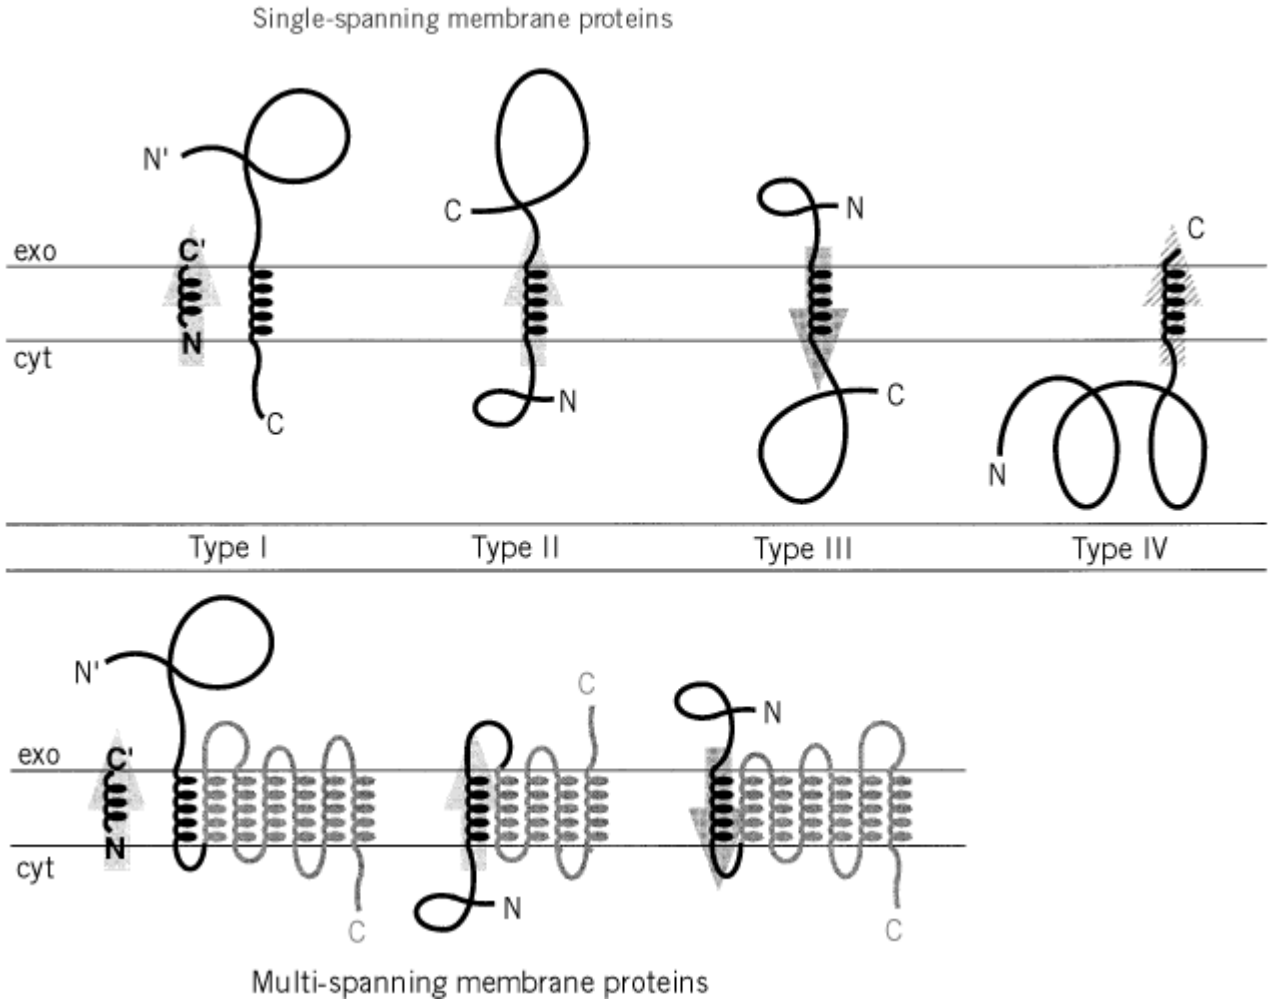
The machinery for targeting, translocation, and membrane insertion of proteins is largely conserved between prokaryotic and eukaryotic cells (5, 6). Secretory and membrane proteins are targeted to the membrane by signal peptides near the amino terminus of the polypeptide in a cotranslational or posttranslational process. In cotranslational targeting (which appears to be the predominant mechanism in mammalian cells, but not in yeast and bacteria), the signal is recognized by the signal recognition particle (SRP; Ffh-RNP in *Escherichia coli*) and is delivered to the translocation machinery by interaction with the SRP receptor (FtsY in *E. coli*). In posttranslational targeting, cytosolic **molecular chaperones** (eg, SecB in *E. coli*, Hsp70p in yeast) are required to keep the proteins in a translocation-competent state. In both cases, translocation and membrane insertion are mediated by a heterotrimeric complex, the Sec61 complex in eukaryotes and SecYEG in prokaryotes, which forms a proteinaceous channel. Reconstitution experiments showed that the

Sec61 complex in combination with SRP, SRP receptor, and (depending on the signal sequence) TRAM (translocating chain-associating membrane protein) is sufficient for cotranslational translocation (7, 8). Posttranslational translocation in yeast requires the heterotetrameric Sec62 / 63 complex, in addition to the Sec61 complex, as well as Kar2p as a luminal **translocation motor** (9). The minimal machinery in bacteria consists of the SecYEG complex and SecA, which serves to recruit secretory and membrane proteins to the membrane and to drive translocation by its ATPase activity (10, 11).

2. Classification of Membrane Protein Topologies

The determinants within a polypeptide that direct it to the membrane and that define its topology are largely conserved and interchangeable between prokaryotes and eukaryotes. Targeting and membrane insertion are initiated by signal sequences. Three types of signals can be distinguished that cooperate with the SecYEG or Sec61 translocation machinery (Fig. 2): cleaved signals, signal-anchor, and reverse signal-anchor sequences. Common to all of them is a stretch of apolar residues.

Figure 2. Classification of membrane protein topologies. The classification is based on the characteristics of the initial signal sequence (cleaved signal, signal-anchor, reverse signal-anchor, *C*-terminal signal), not just the final disposition of *N*- and *C*-termini. The arrows indicate the *N*-to-*C* direction in the signals to highlight the difference between signals translocating the carboxy-terminal or the amino-terminal sequence.(Modified after Ref. 20.)



Cleaved signals are typically composed of a positively charged amino-terminal segment of 1 to 5

residues, a central hydrophobic domain of 7 to 15 apolar residues, and a more polar carboxy-terminal segment of 3 to 7 residues at the site of cleavage by signal peptidase. Like signal sequences as a whole, signal cleavage sites are degenerate. The main characteristics are a preferred proximity to the hydrophobic domain and a strong preference for small uncharged residues at positions -1 and -3 with respect to the cleaved peptide bond (12). The signal is inserted into the translocon as a loop (13, 14), exposing the amino terminus to the cytosol and the carboxy-terminal cleavage site to the exoplasmic surface. The carboxy-terminal sequence is then translocated, either completely, resulting in a secretory protein, or up to a second topogenic element, a hydrophobic stop-transfer sequence. In the latter case, translocation is stopped, and the final protein is anchored in the membrane by the stop-transfer sequence. Such single-spanning membrane proteins with a processed exoplasmic *N*-terminus and a cytoplasmic *C*-terminus (ie, an N_{exo}/C_{cyt} topology) are classified as type I membrane proteins. Examples are glycophorin A and filamentous phage protein gpIII.

In contrast to cleaved signals, signal-anchor sequences are not necessarily located at the very amino terminus, and they lack a signal cleavage site. Their hydrophobic domains are longer, approximately 20 residues, which is sufficient to span the core of the lipid bilayer in an a-helical conformation and to anchor the final protein in the membrane. As for cleaved signals, the hydrophobic cores of signal-anchor sequences are flanked by predominantly positive charges toward the amino terminus and by negative or fewer positive charges toward the carboxy terminus. They also promote translocation of the carboxy-terminal portion of the polypeptide. The resulting type II proteins thus have an N_{cyt}/C_{exo} topology, as exemplified by the asialoglycoprotein receptor and the bacterial penicillin-binding protein Ib.

Reverse signal-anchor sequences, in contrast, promote translocation of the amino-terminal portion of the polypeptide, resulting in an N_{exo}/C_{cyt} topology without proteolytic processing. They differ from signal-anchors mainly by a reversed charge distribution in the flanking segments. Single-spanning proteins inserted by reverse signal-anchors are classified as type III membrane proteins (or, because of the identical final orientation, as “type I without cleaved signal” or “type Ib”). Examples are **cytocrome P-450** and bacteriophage Pf3 coat protein.

Multispanning proteins may be classified according to the most amino-terminal signal that initiates targeting and membrane insertion. For example, the thrombin receptor with an amino-terminal cleaved signal and seven-transmembrane domains (15) is a type I multispanning protein. Other members of the seven-transmembrane receptor family, such as the b-adrenergic receptor (16), are of type III, because they acquire the same topology with a reverse signal-anchor sequence. The erythroid anion transporter band 3 is an example of a multispanning type II protein: It consists of a 40-kDa amino-terminal, cytoplasmic domain, followed by a portion with 12 potential transmembrane segments (17), the first of which is likely to function as a signal-anchor sequence for targeting and insertion. Maltose transporter MalF and bacteriorhodopsin are prokaryotic examples of type II and type III multispanning membrane proteins, respectively.

Some membrane proteins do not span the membrane but are tethered to the exoplasmic leaflet of the bilayer by a lipid anchor. Bacterial lipoproteins are basically secreted proteins made with a cleavable signal sequence that is recognized by a specific lipoprotein signal peptidase (LspA) (18). Cleavage occurs at a cysteine residue that is first modified to diacylglycerylcysteine. In addition, the new amino terminus is also fatty acylated. In eukaryotes, a group of proteins is anchored in the membrane by glycosyl phosphatidylinositol (GPI ANCHORS) (19-21). These proteins are synthesized initially as type I single-spanning membrane proteins, generally without a hydrophilic cytoplasmic domain. In a transamidation reaction, the stop-transfer sequence is replaced, still in the ER, by a precursor GPI anchor consisting of phosphatidylinositol, a linear tetrasaccharide core (Man_3GlcN), and a phosphoethanolamine group.

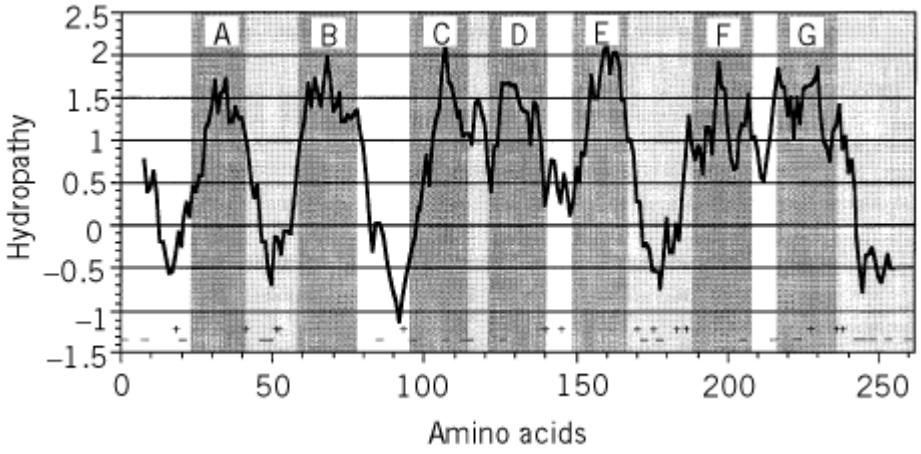
Another rapidly growing family of eukaryotic proteins, including cytochrome b_5 and the SNARE

proteins, lacks classical signal sequences. Instead, these proteins are inserted into the ER, and perhaps other membranes, by a carboxy-terminal hydrophobic domain that spans the lipid bilayer (Fig. 2, type IV proteins). Insertion is independent of the Sec61 machinery and is not well-characterized at present (22-24).

3. Prediction of Protein Topology

The first step in predicting the topology of a protein from its sequence is to identify the transmembrane segments. Most membrane-spanning helical segments can be identified by a hydropathy analysis that plots the average hydrophobicity of amino acid side chains for a window of 11 to 21 residues along the sequence (25, 26), as illustrated in Figure 3 for bacteriorhodopsin. Ambiguities arise because transmembrane segments of multispanning or oligomeric proteins may contain hydrophilic or even charged residues, thus resulting in a lower average hydrophobicity than expected for a helix exposed to the lipid blayer. In addition, adjacent relatively short transmembrane helices without a clearly hydrophilic spacer may be difficult to distinguish from a single relatively long helix.

Figure 3. Hydropathy plot of bacteriorhodopsin. The average hydrophobicity of a sliding window of 15 residues was calculated according to Kyte and Doolittle (25). Positive and negative residues are indicated with + and –. Exoplasmic, transmembrane, and cytoplasmic localization is indicated by white, dark gray, and light gray background, respectively. The transmembrane helices are labeled A–G.



The hydrophobic sequences of transmembrane segments do not provide useful clues as to their orientation in the bilayer, but the hydrophilic flanking sequences do. Statistical analysis revealed an enrichment of positive charges in cytoplasmic sequences and their depletion from exoplasmic ones (27). This applies to single- and multispanning proteins of eubacteria, archaebacteria, and eukaryotes (21), particularly also to signal sequences of any type. In prokaryotes, this observation was initially formulated as the “positive-inside rule” (27). For eukaryotic signal-anchor sequences, the charge difference between the two flanking segments, rather than the positive charge per se, correlates with the orientation: The cytoplasmic sequence generally carries a more positive charge than the exoplasmic one (28). The best correlation was found for the 15 flanking residues on either side of the apolar domain. The charge rule is also reflected in the structure of cleaved signals: The positively charged amino-terminus stays in the cytoplasm, whereas the carboxy-terminal end, which is depleted of positive charges, is translocated (29). The positive-inside and charge-difference rules are not restricted to the initial signal sequence, but they apply also to stop-transfer sequences and later transmembrane segments in multispanning proteins, although to a lesser degree in eukaryotic proteins than in prokaryotic (30, 31).

A combination of a hydropathy plot with the analysis of the charge distribution within the hydrophilic portions of a protein sequence yielded a useful algorithm to predict the topology [TopPred (30); also available on the internet: (site currently unavailable)]. If several related sequences are available, their alignments can be used for an improved topology prediction (32, 33) (site currently unavailable). An alternative algorithm is available for prokaryotic proteins that is independent of the charge distribution and uses the so-called dense alignment surface method (based on low-stringency dot-plots of the query sequence against a collection of non-homologous membrane proteins; (site currently unavailable)) (34).

The hallmark of b-barrel proteins are sequences of 7 to 9 residues, comprising one transmembrane strand of the b-sheet, in which every second side chain is apolar, to form the hydrophobic surface. Algorithms for the identification and topology prediction of b-barrel proteins have been developed exploiting, in addition, the typical accumulation of aromatic residues in flanking positions in porins (35) or employing a neural network (36) (http://strucbio.biologie.uni-konstanz.de/~kay/om_topo_predict.html).

To be certain about the topology of a protein, it has to be verified experimentally. A number of approaches to define the membrane sidedness of individual hydrophilic segments have been developed for this purpose (37). Exposure to the cell exterior or to the cytosol can be assayed by sensitivity to proteinases added to intact cells or to microsomes, respectively. Similarly, the accessibility of different segments to sequence-specific **antibodies** can be tested. In multispanning proteins, cleavage patterns may be difficult to interpret, and efficient antibodies against short loops may be hard to generate. Insertion of specific cleavage sites [eg, for factor Xa (37)], or of known antigenic epitopes (38) at various positions throughout the protein have been successfully used to map protein topology. In eukaryotes, *N*-**glycosylation** at a natural or an engineered site is conclusive evidence for luminal exposure of the sequence. Another approach involves the fusion of truncated portions of the protein to a reporter sequence whose localization can be easily determined (eg, by enzymatic activity). The prototype of this method is the use of PhoA fusions in bacteria as a sensor for its location (39). With all assays involving mutagenesis, it has to be kept in mind that the mutation may affect the protein's topology.

4. Topogenic Determinants of Single-Spanning Proteins

4.1. Charged Residues

Charged residues flanking the hydrophobic segment of signal sequences were confirmed by site-directed mutagenesis to function as topogenic determinants. Insertion of positive amino acids within 30 residues carboxy-terminal of a cleaved signal inhibited its function (40, 41), more effectively so in *E. coli* than in the mammalian ER (42). The reverse signal-anchor of cytochrome P450, a type III (N_{exo}/C_{cyt}) single-spanning protein, was converted to a type II ($N_{cyt}/ C_{exo)}$ signal-anchor by insertion of positively charged residues into the short polar amino-terminal domain preceding the transmembrane sequence (43-45). Mutation of flanking charges in the asialoglycoprotein receptor H1 and in the paramyxovirus hemagglutinin-neuraminidase, two type II proteins, caused only a fraction of the polypeptides to insert with the opposite type III (N_{exo} /C_{cyt}) topology (46-48).

Positive charges had a stronger effect on topogenesis than negative ones, and they were more effective the closer they were to the hydrophobic segment. In these and other studies (eg, Ref. 49), however, the asymmetric distribution of flanking charges in mutant proteins was not sufficient to generate a unique topology, indicating that additional factors influence topogenesis.

For bacteria, the simplest explanation for the topogenic role of charged residues is an involvement of the electrochemical potential across the membrane in the insertion mechanism. Indeed, the potential stimulates the translocation of chain segments containing negatively charged residues and inhibits translocation of positively charged segments in mutant forms of leader peptidase and M13 procoat, suggesting an **electrophoresis**-like membrane transfer mechanism (50, 51). In addition, the content of acidic phospholipids in the membrane was found to affect charge-dependent topogenesis (52). It

was suggested that anionic lipids prevent translocation of positive flanking charges, possibly by a direct, electrostatic interaction. No general membrane potential exists across the ER membrane. It appears likely that the topogenically active charges interact with components of the translocation machinery.

4.2. Folding of Hydrophilic Domains

The polypeptide needs to be largely unfolded for translocation across the membrane. For example, it was observed that the folding of a ubiquitin domain in a chimeric protein prevented its (posttranslational) translocation in yeast (53). In cotranslational translocation of type I or type II proteins, the docking of the ribosome to the Sec61 complex prevents premature protein folding (54, 55). The amino-terminal domain of type III proteins, however, is completed and potentially folded in the cytoplasm before the signal sequence emerges from the ribosome. Folding of this segment and its size are thus potential obstacles for transfer across the membrane. Truncation of the amino-terminal domain facilitated type III insertion of charge mutants of H1 and hemagglutinin-neuramindase (46, 47). In contrast, extension of the amino-terminal domain of H1 by the complete coding sequence of dihydrofolate reductase (197 residues) blocked amino-terminal translocation and forced the protein to insert with type II topology, despite the charge distribution of a reverse signal-anchor (56). Destabilizing point mutations in the reductase largely restored its transport through the membrane. Similarly, a 30-residue **zinc finger** domain, but not a defective mutant sequence, hindered insertion as a type III protein (56). The folding properties of the amino-terminal domain are thus a limiting factor for type III insertion, whereas the size (at least up to ~230 residues) does not appear to be a significant obstacle. The amino-terminal domains of natural type III proteins are relatively short (generally less than 100 residues). They probably evolved to be devoid of rapidly and stably folding sequences to ensure a unique topology.

Whereas in eukaryotes proteins of type I, II, and III all depend on the Sec61 machinery for insertion, bacterial translocation of amino-terminal tails can be independent of functional SecA and SecY (57-59) and sensitive to the size of the amino-terminal domain (57, 58).

4.3. Hydrophobicity

An influence of the hydrophobic segment of signal sequences on topogenesis was suggested by deletion experiments (60). Systematic analysis of signals with artificial hydrophobic domains consisting of oligoleucine sequences of different lengths revealed that translocation of the amino terminus was favored by long, hydrophobic sequences and that translocation of the carboxy terminus was favored by short ones (61, 62). The topogenic contributions of the hydrophobic sequence, the flanking charges, and the hydrophilic amino-terminal domain were additive. In combination, these determinants were sufficient to achieve unique membrane insertion in either orientation (62).

The topogenic contribution of the hydrophobic signal domain was also tested for natural signal sequences that did not conform with the charge difference rule (63). The results showed that the hydrophobicity of the signal is important for the correct and uniform orientation of proteins, particularly of those with unusual flanking charges.

5. Topogenesis of Multispanning Proteins

Extended stretches of apolar residues cannot be translocated across the membrane and are eventually released into the lipid bilayer as membrane-spanning segments. The length of the apolar segment and its hydrophobicity are the main criteria for a stop-transfer sequence (64, 65). For example, 19 successive alanine residues, but only 9 leucines, were required for efficient stop-transfer activity in the ER (66, 67). Subsequent charged residues, particularly positive ones, may increase the stop-transfer efficiency of shorter apolar sequences, but are not essential. Natural stop-transfer sequences are generally about 20 residues long to span the membrane comfortably and thus can also accommodate a few polar amino acids, which may be necessary for the protein's function.

It is an attractive model that multispanning proteins are generated by successive signal and stop-

transfer sequences, initiating with the most amino-terminal signal and proceeding sequentially toward the carboxy terminus (68). Each topogenic element might function independently in the order of appearance from the ribosome. Such linear insertion of successive transmembrane domains into the ER membrane has been demonstrated for artificial proteins composed of up to four repeats of type II signal-anchor sequences separated by relatively long hydrophilic spacers of 50 to 100 residues (69, 70). The first and third repeats inserted with a N_{cyt}/C_{exo} orientation, the second and fourth with the opposite N_{exo}/C_{cyt} orientation. The second insertion occurred at a time when the first exoplasmic loop was already translocated and could also be mediated by a mutant signal unable to interact with SRP (69). SRP is thus required only to target the first signal domain to the ER membrane, but not for insertion of subsequent segments.

However, model proteins with shorter hydrophilic spacer sequences of ~25 residues separating the transmembrane helices did not follow a strict sequential start–stop model of insertion (71). Positive charges introduced into exoplasmic loops inhibited their translocation, resulting in "frustrated" molecules in which potential transmembrane segments did not span the membrane. This demonstrated that sequences other than the initial signal may exert topogenic influence.

For bacteria, there is extensive evidence against a strictly linear insertion process in which the topology is determined by the first transmembrane domain followed by passive serpentine insertion of the subsequent helices. Deletion of individual membrane-spanning segments did not affect the topology of the following transmembrane domains toward the carboxy terminus (72-74). Positively charged residues play an important role and, inserted into normally exoplasmic loops, caused local disruption of insertion (75, 76). This reflects competition of conflicting signals within the polypeptide.

6. Conclusion

So far, topogenic determinants have been studied mainly by challenging the translocation machinery *in vitro* or *in vivo* with mutant proteins. Because the components of the machinery have been identified in both prokaryotes and eukaryotes, the molecular mechanisms of the insertion process can be analyzed more directly. In crosslinking experiments, it has been shown that signal-anchor sequences are already in contact with lipids early in the insertion process, suggesting lateral opening of the translocation channel (77), and how transmembrane helices exit into the lipid environment during the translocation process has been analyzed (78, 79). Further studies will be directed to determine in molecular detail how topogenic signals are decoded by the translocation machinery.

Topoisomer

The discovery of ring-shaped **DNA** molecules in the 1960s pointed to a connection between the topology of links and knots, subjects that had long been cherished in pure mathematics, and the molecular biology of DNA, by then a blossoming discipline following the unveiling of the **double-helix** structure in 1953. It became clear that the topology of DNA is deeply rooted in its double-helix structure. The discovery of **supercoiled** DNA in 1965 (1) laid the cornerstone for this realization; and the discovery of the DNA **topoisomerases**, enzymes that solve the topological problems of DNA (2), showed the biological importance of DNA topology. Topological problems arise in nearly all transactions of intracellular DNA, and Nature invented not one, but three or more, distinct subfamilies of enzymes to solve these problems. It also became clear that the topological problems of intracellular DNA did not originate from its circularity in some organisms, but from its extreme length in nearly all organisms.

1. Topoisomers (Topological Isomers)

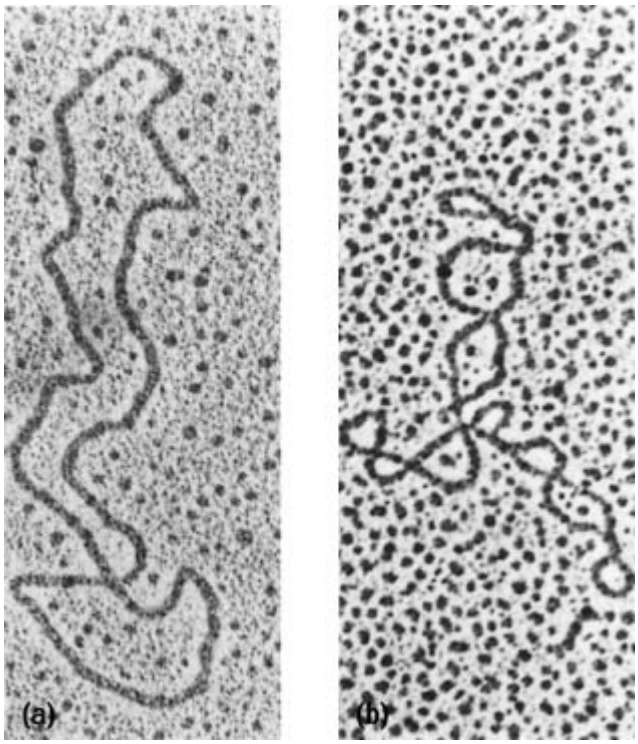
1.1. Supercoiled DNA

Several novel forms of DNA rings were identified following the discovery of circular DNA, of which the finding of supertwisted or supercoiled DNA in 1965 (1) is of particular importance. The supercoiling of a double-stranded DNA ring is best described in terms of a topological quantity called the **linking number**. Because of the double-helical structure of DNA, a DNA ring with two intact strands is comprised of a pair of multiply intertwined single-stranded rings. The pair of strands revolve around each other, and they cannot be separated without a break in at least one of them. The circular strands are thus topologically linked, and the order or degree of this topological linkage is specified by the linking number, Lk. The linking number can be defined as the minimal number of strand passage events that are needed to unlink the two strands of a DNA ring. In each event, one strand of the duplex DNA is transiently broken, the other strand is passed through the break, and the broken strand is then resealed. For a typical DNA in its most stable structure, called a *relaxed* DNA, the two complementary strands make one right-handed helical turn every 10.5 base pairs under physiological conditions; the linking number Lk^0 of a relaxed DNA ring N base pairs in length is thus $N/10.5$ under physiological conditions (3). In general, the helical structure of a DNA, and therefore the value of Lk^0 of a DNA of a given size, is dependent on its nucleotide sequence, as well as ambient conditions. A DNA segment of alternating cytosines and guanines, for example, may assume a left-handed double-helix structure under certain conditions, and such a segment would contribute a negative quantity to the overall Lk^0 of the DNA ring under these conditions.

The difference between Lk and Lk^0, called the *linking difference*, gives a measure of how far the topological state of a DNA ring deviates from its relaxed state. If the magnitude of $Lk - Lk^0$ differs significantly from zero, the DNA ring would be torsionally and flexurally strained. Such a strained molecule would assume a distorted shape, in much the same way as a torsionally unbalanced multistranded rope (Fig. 1). The descriptions "supercoiled," "superhelical," or "supertwisted" have been used interchangeably to describe such a molecule. Because both Lk and Lk^0 are dependent on the size of a DNA ring, the normalized quantity $s = (Lk - Lk^0)/Lk^0$, called the *specific linking difference*, is a convenient measure of the extents of supercoiling of DNA rings of different sizes. DNA rings that differ only in their linking numbers are topological isomers, or topoisomers. A topoisomer is negatively supercoiled if the pair of strands in it are significantly underwound ($Lk < Lk^0$ and $Lk - Lk^0 < 0$) and positively supercoiled if they are overwound ($Lk > Lk^0$ and $Lk - Lk^0 > 0$). DNA rings purified from bacteria and eukarea are usually negatively supercoiled, with values of s around –0.06.

Figure 1. Electron micrographs showing a relaxed (**a**) and a supercoiled (**b**) DNA molecule. The size of the DNA is

about 10,000 base pairs. To facilitate viewing, the apparent diameter of the double helix was made several times larger by coating the molecules with a protein. (From Ref. 43, with permission.)

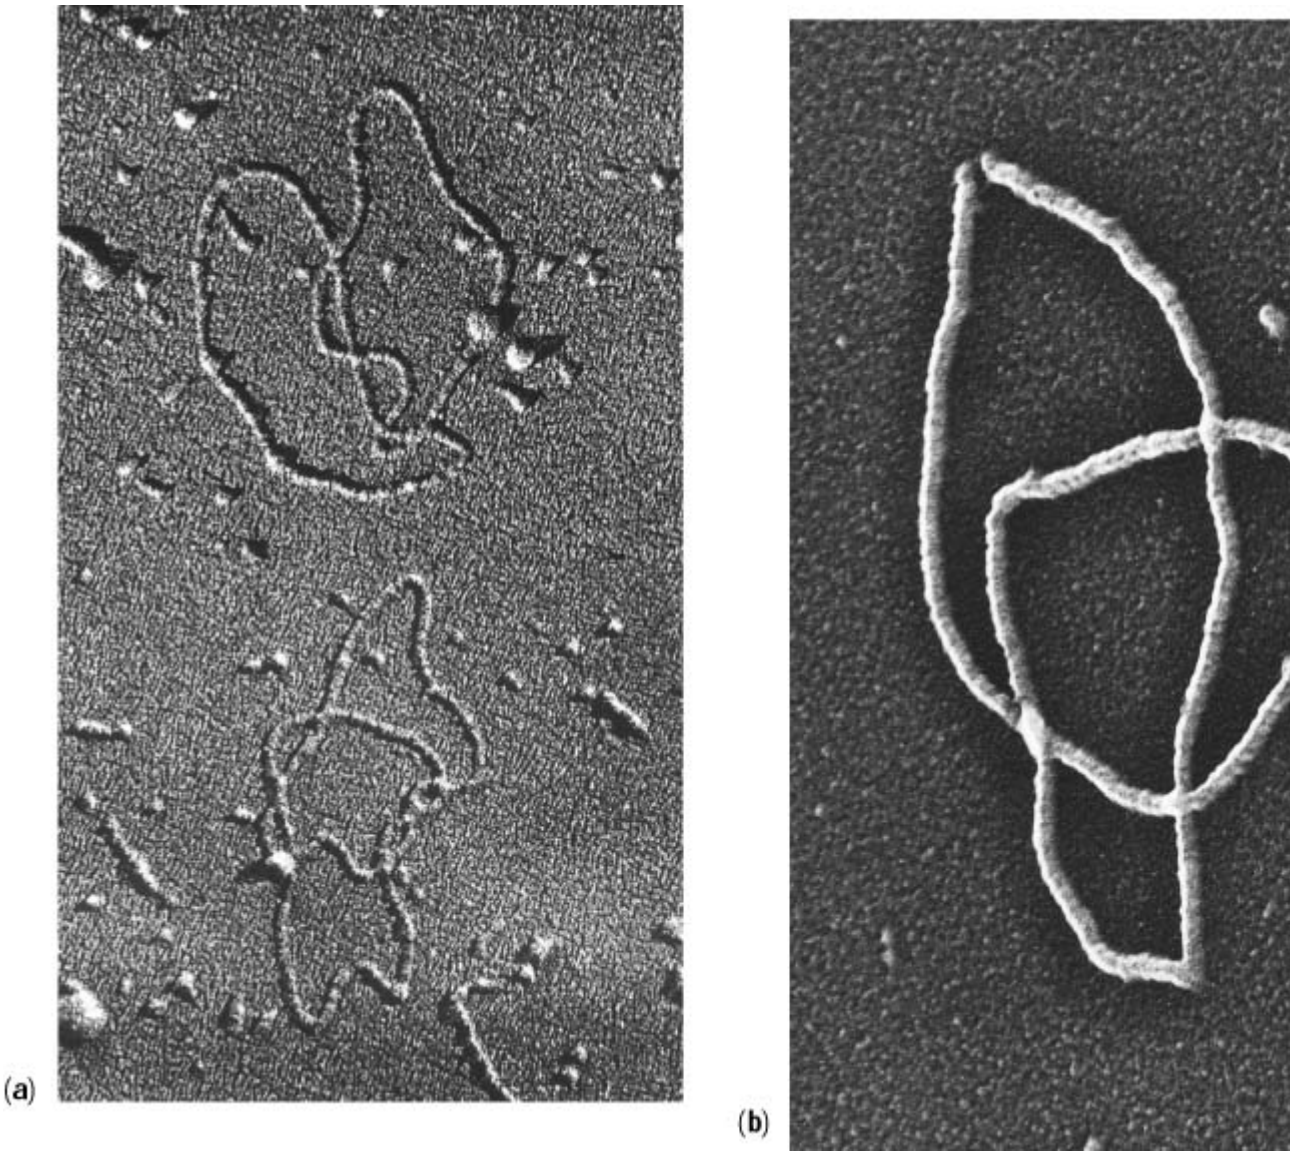


Supercoiled DNA is distorted in two major ways. First, the helical twist of the DNA is altered because of the topological strain. Second, there is a distortion of the overall shape of the ring, with the helical axis of the DNA taking on a spatial **writhe** (see Fig. 1). These two types of distortions are coupled, and their sum is determined by the linking difference (3, 4). Because of these distortions, a supercoiled DNA has unique properties relative to its relaxed topoisomer (4-8). A local unwinding of two strands of a DNA, for example, can be accomplished much more easily in a negatively supercoiled than in a relaxed DNA. Negative supercoiling of a DNA would, for example, facilitate the binding of proteins that preferentially bind to single-stranded or underwound duplex DNA, proteins such as the histone octamer complex that require left-handed wrapping of DNA around them, and planar aromatic molecules that **intercalate** in between DNA base pairs. Negative supercoiling of a DNA could also drive changes in the DNA helical structure that are otherwise thermodynamically unfavorable under physiological conditions, such as a change of an alternating CG sequence from the right-handed B-helical form to the left-handed Z-helical form (see Z-DNA), and the extrusion of a pair of hairpin structures from a **palindromic** sequence (cruciform formation). Positive supercoiling of a DNA, on the other hand, would disfavor processes that are favored by negative supercoiling. Both negative and positive supercoiling may also facilitate the binding of proteins to DNA crossovers or to bent DNA segments.

1.2. Catenanes and Knots

Catenanes and knots are also topoisomers of simple rings (Figs. 2a and 2b). Catenanes, or interlocked DNA rings, were prepared *in vitro* and found *in vivo* in 1967 (9, 10). Inside the cells, they can be formed by DNA replication, if the strands of the final stretch of unreplicated parental DNA come apart before their complete unraveling (11), or by recombination, if the joining of two distant sites in a DNA ring traps some of the DNA crossovers in between (12). Knotted DNA rings were discovered as the products of certain reactions *in vitro* in the 1970s (13, 14) and subsequently found in **plasmid** preparations (15).

Figure 2. (**a**) An electron micrograph showing two dimeric catenanes of simian virus 40 DNA. The viral DNA was isola cells grown under conditions that inhibit DNA topoisomerase II. (From Ref. 5, with permission; micrograph was origina Varshavsky.) (**b**) An electron micrograph of a knotted DNA ring. (From Ref. 5, with permission; micrograph was origin A. Stasiak.)



The discovery of DNA supercoils, catenanes, and knots helped to bring into focus the topological problems of DNA. How are the parental strands of a DNA ring unlinked during replication? Why are DNA rings isolated from cells negatively supercoiled? If catenanes can form by replication or recombination, how do they come apart? These topological problems are not limited to ring-shaped DNA molecules. Chromosomes in eukaryotic cells, for example, are linear in the topological sense because the ends of a chromosome are not joined. The chromosomes are probably organized into many loops inside the cells, however, and are therefore subject to topological constraints in much the same way as DNA rings. The extreme length of a chromosome also makes it difficult to disentangle the molecules through movements of their ends. The discovery of DNA rings in various topological forms greatly simplified the study of DNA topology, however, and provided the necessary tool in the search of enzymes, called the DNA *topoisomerases*, that can interconvert DNA topoisomers and solve all topological problems of intracellular DNA (see text below).

2. DNA Topoisomerases

2.1. Classification

DNA topoisomerases are enzymes that catalyze the interconversion of DNA topoisomers. In their presence, the DNA strands in a duplex DNA, or different duplex DNA segments in the same or different molecules, can move through each other. Although the discovery of this family of enzymes started around 1970 with the partial purification of an activity from *Escherichia coli* cell extracts that can remove negative supercoils (16), the term topoisomerase was not coined until nearly a decade later (17).

The DNA topoisomerases can be divided into two types (2). The type I enzymes catalyze linking number changes of topoisomers by introducing a transient break in one strand, passing the other strand through this break, and then rejoining the interrupted strand. They can also change the topology of double-stranded DNA catenanes or knots, provided that at least one of the strands contains a gap or nick. The type II enzymes catalyze the transport of one DNA double helix through another, using the transient breakage of both strands in one of them. These enzymes can interconvert linking number topoisomers, catenanes, or knots, independent of the presence of a gap or nick. In the interconversion between linking number topoisomers, a consequence of passing one duplex DNA segment through a transient break in another segment of the same DNA is that the linking number of the DNA is altered by two (18, 19). In linking number changes mediated by type I topoisomerases, each DNA strand passage event alters *Lk* by unity. The change of *Lk* in steps of two is a signature of type II DNA topoisomerases.

The type I enzymes can be further divided into the IA and IB subfamilies (2). The former includes bacterial DNA topoisomerases I and III, eukaryotic DNA topoisomerase III, and an enzyme “reverse gyrase” found in archaea; the latter includes eukaryotic DNA topoisomerase I and pox virus topoisomerase. The amino acid sequences and the biochemical properties of the type IA enzymes are very different from those of the IB enzymes. The type II DNA topoisomerases are found in bacteria, eukarea, and archaea. They were thought to form a single homologous subfamily, but recent work suggests that, in addition to the archetype type II enzymes, there is a new subfamily of enzymes in archaea, and perhaps in eukarea as well (20). These subfamilies are referred to as type IIA and IIB, respectively. *E. coli* has four topoisomerases: two type I enzymes DNA topoisomerases I and III, and two type II enzymes DNA gyrase (DNA topoisomerase II) and DNA topoisomerase IV. Bacterial gyrase is unique among type II DNA topoisomerases in that it can catalyze the negative supercoiling of a relaxed DNA ring; other type II enzymes can relax positively and negatively supercoiled DNA, but cannot supercoil a relaxed DNA. The budding **yeast** *S. cerevisiae* has three topoisomerases excluding any plausible type IIB enzymes: two type I enzymes DNA topoisomerases I and III, and one type IIA enzyme DNA topoisomerase II. Other eukaryotes are similar to yeast, but ther may be more than one member in each subfamily. In humans, two type IA, two type IB, and two type IIA **isozymes** are mnown.Genes encoding six human enzymes, DNA topoisomerases I, IIa, IIbDNA topoisomerases IIIa IIIb, have been located to chromosome regions 20q12-13.2, 17q21-22, 3p24, and 17p11.2-12 22q11-12, respectively (2, 21, 22).

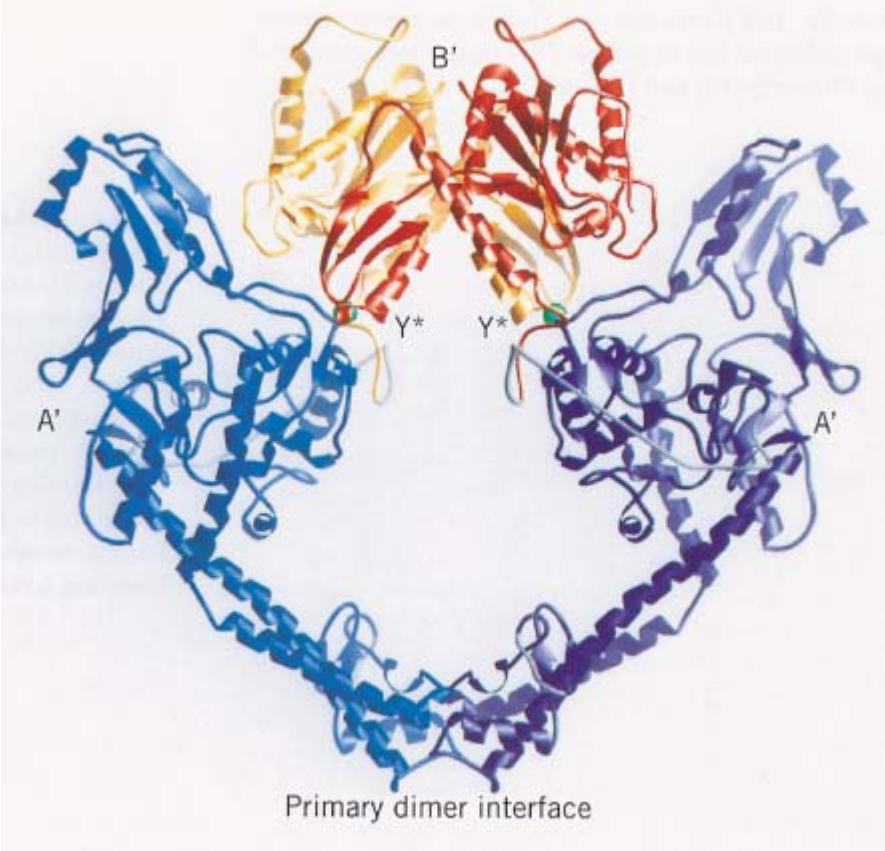
2.2. Mechanisms

How do the DNA topoisomerases perform their magic? First, they must catalyze the transient breakage of DNA strands. It was postulated in 1971 that this transient breakage involved transesterification between an enzyme hydroxyl group and a DNA internucleotide phosphodiester bond (16). Nucleophilic attack of the enzyme hydroxyl on a DNA phosphorous would form a covalent enzyme–DNA bond and break a DNA phosphodiester bond, generating a deoxyribose hydroxyl group in the process. Rejoining of the broken DNA would then ensue by a second transesterification reaction, which could be the microscopic reversal of the first: The deoxyribose hydroxyl group would attack the phosphorous in the covalent enzyme-DNA link, rejoining the DNA strand and breaking the enzyme–DNA link. This postulate has been confirmed, and DNA cleavage by all DNA topoisomerases is found to go through a covalent enzyme–DNA intermediate in which a DNA phosphoryl group is linked to the phenolic oxygen of an enzyme tyrosine residue. For the type

IA and type II enzymes, in the covalent intermediate the tyrosyl residue is linked to a DNA 5′-phosphoryl group; for the type IB enzymes, a DNA 3′-phosphoryl group. The particular tyrosines in a number of DNA topoisomerases have been identified (2); and the positions of the tyrosines in several enzymes, such as in the type IA enzyme *Escherichia coli* DNA topoisomerase I (23) and a type II enzyme *Saccharomyces cerevisiae* DNA topoisomerase II (24), can be seen in their three-dimensional structures determined by X-ray crystallography (Figs. 3 and 4; see also (28, 29). Side chains in addition to the active-site tyrosines are also involved in stabilizing the attacking and leaving groups during covalent catalysis.

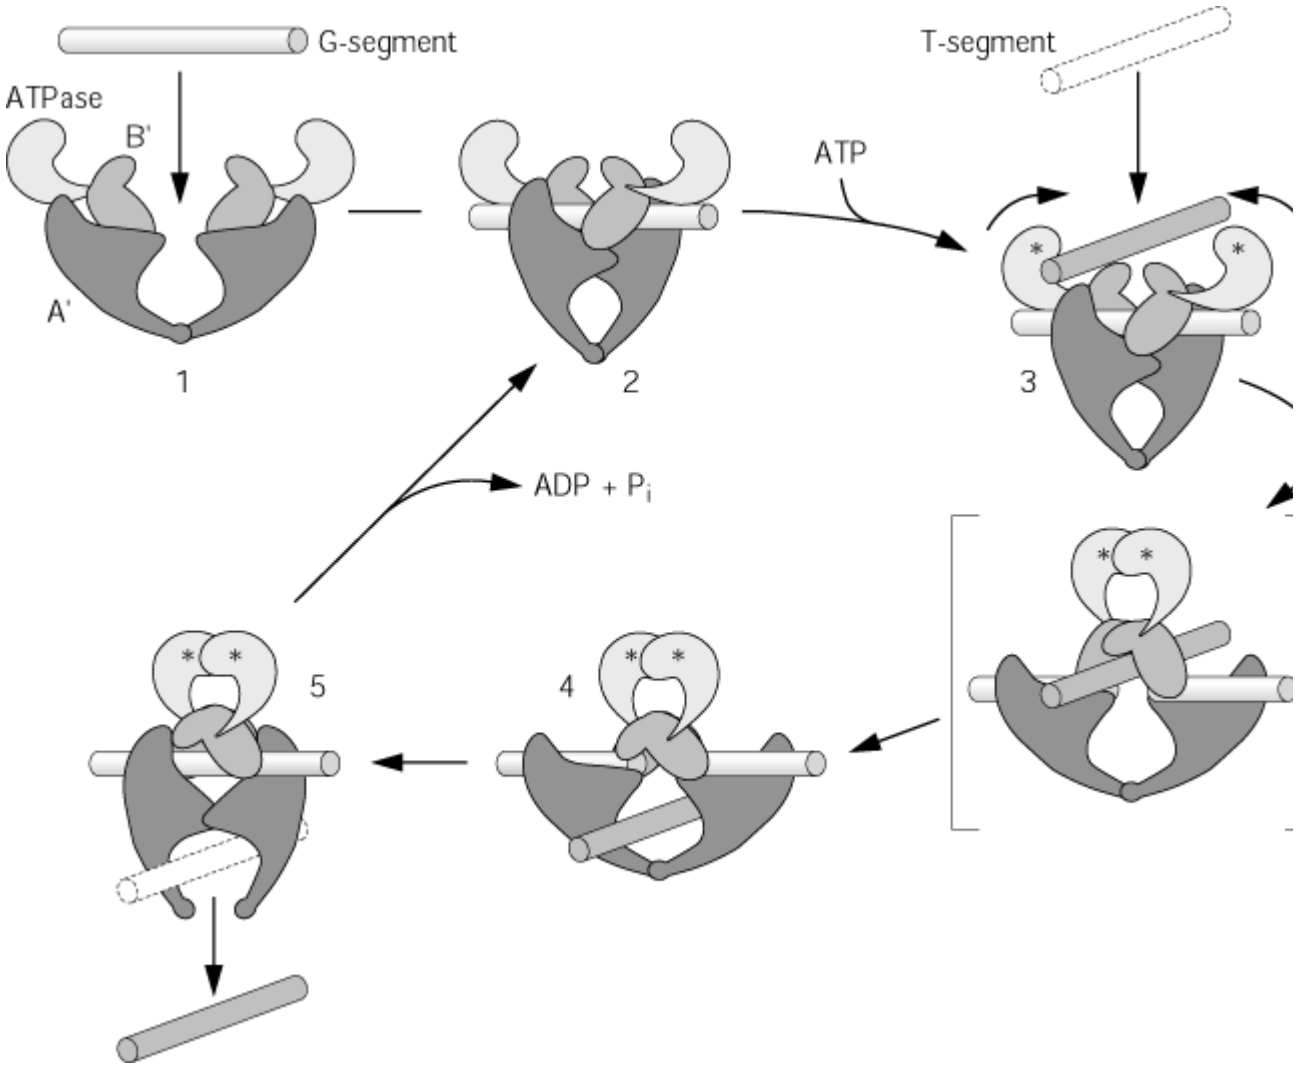
Figure 3. A ribbon illustration of the crystal structure of a 67-kDa *N*-terminal fragment of *E. coli* DNA topoisomerase I. Drawing is based on the coordinates of the structure reported in Ref. 21. This fragment can bind and cleave single-stranded DNA, but cannot remove supercoils from a duplex DNA ring (21). The four domains I to IV are colored in white, blue, green, and yellow, respectively; the active site tyrosine, Tyr319, is located in domain III and shown in red. See color insert.

Figure 4. A ribbon illustration of the crystal structure of a 92-kDa fragment of yeast DNA topoisomerase II. This fragment is comprised of amino acid residues 410 to 1202 of the intact enzyme. It can bind and cleave double-stranded DNA, but lacks the ATPase domain located in the *N*-terminal region of the intact enzyme and cannot catalyze DNA transport (23). The pair of active-site tyrosines in the dimeric enzyme are represented by two green spheres labeled Y*. A′ and B′ refer to two regions of the polypeptide, from residues around 660 to 1202 and from 410 to around 660, respectively; the A′ fragment corresponds to the *N*-terminal two-thirds of the A-subunit of bacterial gyrase, and the B′ fragment corresponds to the *C*-terminal half of the B-subunit of bacterial gyrase. (From Fig. 3a of Ref. 24, with permission.) See color insert.



Second, each enzyme must mediate the passage of DNA strands. Recent biochemical and three-dimensional structural studies of yeast DNA topoisomerase II have led to a molecular model of how a single type II enzyme molecule couples ATP binding and hydrolysis to the transport of one DNA double helix through another (24, 25). This is illustrated in Fig. 5. The enzyme acts as a dimeric protein clamp, with each half composed of several fragments denoted by ATPase, B′ and A′ (drawing **1** of Fig. 5; the ATPase fragment is composed of the *N*-terminal portion of the polypeptide from amino acids 1 to 409, the B′ fragment from 410 to about 660, and the A′ fragment from around 660 to 1202). Either in the free form (**1**), or when bound to a DNA segment called the G-segment (**2**), the clamp can close and open through formation and disruption, respectively, of contacts between the pair of ATPase domains. The opening and closing of this protein gate, termed the *N*-gate because of the proximity of the ATPase domain to the *N*-terminus of the polypeptide, are modulated by ATP binding and hydrolysis: ATP-binding closes the N-gate, which reopens after ATP hydrolysis and the release of the hydrolyzed products (ADP and orthophosphate). When the N-gate is in the open state, a second DNA-segment, called the T-segment, can enter the gate (**3**). This entrance is probably facilitated by weak but favorable enzyme-DNA interaction. When the clamp closes upon ATP-binding, a T-segment that has entered the clamp is trapped. Steric repulsion between the trapped T-segment and the closed ATPase domains is believed to force open the enzyme-mediated DNA-gate in the G-segment, as well as expel the T-segment into the large cavity below the T-segment (**3** and **4**). This expulsion relieves the steric repulsion, and the DNA gate returns to the more stable closed state. The closing of the DNA-gate contracts the size of the hole containing the T-segment, however, and thus forces the T-segment to exit through a second protein gate, called the C-gate, formed by amino acid residues 1031–1046 and 1114–1130 of the yeast enzyme (**5**). Following ATP hydrolysis and product release, the closed enzyme clamp reopens (**2**) to complete a cycle of DNA transport. All type IIA enzymes are likely to catalyze DNA transport in a similar way.

Figure 5. The transport of one DNA double helix through another by a type IIA DNA topoisomerase. The macromolecules involved are drawn to scale in this illustration. Each half of the dimeric enzyme is composed of three parts denoted by ATPase, which represents the *N*-terminal 409 amino acid stretch containing the ATPase domain, and B′ and A′ are the fragments defined in the legend to Figure 4. The DNA G-segment, within which a transient break is to be introduced to open a gate in it, and T-segment, which is to be transported through the DNA gate, are shown as rods. The asterisk (*) represents a bound ATP. See text for a description of the model. (From Fig. 5 of Ref. 24, with permission.)



The unique ability of bacterial gyrase to catalyze negative supercoiling can be attributed to its ability to orient the T-segment relative to the G-segment: In the complex between gyrase and DNA, a 140-b long DNA segment is wrapped right-handedly around the enzyme (26), which positions the T-segment for transport through the G-segment in a directional way. For the other members of the type IIA subfamily, the relative orientation of the G- and T-segment is determined by the DNA conformation, which always favors the removal of supercoils (2, 27).

How the type IA enzymes mediate DNA strand passage is less clear. In the crystal structure of a larg fragment of the type IA enzyme *E. coli* DNA topoisomerase I (Fig. 3), the polypeptide is found to fold into four distinct domains. Domains I and IV form the "base" of the structure, which is connecte through a pair of long strands to the "lid" formed by domains II and III (23). The active site tyrosine, Tyr319, is located in domain III at the junction between this domain and the base. This strategic location suggests that there are likely large movements between the lid and the base during the various steps of strand cleavage and passage (23). Following the cleavage of a DNA strand, for example, domain III with the covalently attached 5′-end of the broken DNA would presumably be lifted away from the base to generate a gap between the domains sufficiently large for the passage of another strand or perhaps even a double-helical DNA segment. After strand passage, this gap would

have to close again to allow rejoining of the cleaved strand, and further movements of the domains would be needed for the enzyme to return to a state ready for the next cycle of reaction. The molecular details of these movements are unknown. Unlike the reaction catalyzed by the type II enzymes, in which DNA transport is coupled to ATP binding and hydrolysis, DNA strand transport i reactions catalyzed by the type IA enzymes does not involve a high-energy cofactor (with the exception of "reverse gyrase"). Therefore for the majority of the type IA enzymes, changes in enzyme–DNA interactions in the various steps must play crucial roles in the ordered processing of th reaction (23). Conceptually, instead of viewing the enzyme as the mover and shaker and the DNA as the passive substrate, both should be thought of as integral parts in the orchestration of the intricate reaction steps.

For the type IB enzymes, the solution of the crystal structure of a large fragment of a pox virus topoisomerase (28), and several crystal structures of catalytically active fragments of human DNA topoisomerase I in complex with DNA (29), has provided much insight into their mechanism. The type IB enzymes are structurally similar to a family of tyrosine recombinases including phage l integrase and a phage P1 site-specific recombinase called Cre. In the human DNA topisomerase I-DNA complexes, the bilobed protein clamps around the duplex DNA and the contacts mostly DNA phosphate groups (29). Based on these structures and earlier biochemical studies, a detailed mechanism of the type IB enzymes has emerged (28-31).

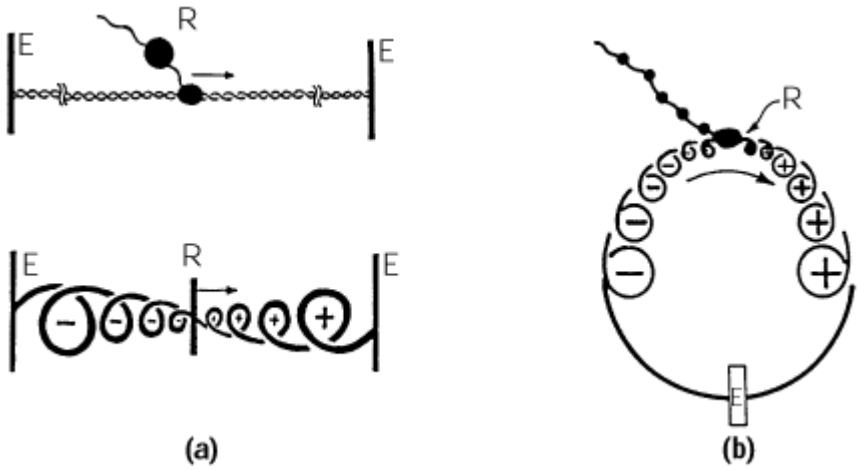
An interesting aspect of DNA strand passage by a type I enzyme is the number of passages that can occur in each strand breakage and rejoining event (18, 32, 33). This issue is closely related to the sta of the transiently cleaved DNA strand: One end of the broken strand is attached covalently to the active-site tyrosine, but what about the other end? In the enzyme-bridging model, the other end is als postulated to be enzyme-bound through noncovalent interactions. In this model, each transient cleavage would allow only one strand passage event. Strand passage would be mediated by movements of the enzyme–DNA complex, and the cleaved strand would have to be rejoined before either end can dissociate from the enzyme. In the DNA rotation model, in the covalent intermediate the enzyme is closely contacting only the side of DNA containing the covalently attached DNA end. The other side of the DNA could therefore rotate around a single bond in the uncleaved strand acros the cleaved bond. In the latter model, the enzyme would have a passive role in strand passage, and multiple strand passage events could be achieved by multiple rotations of one side of the cleaved DNA relative to the other side. To relax a supercoiled DNA with a linking difference of $Lk - Lk^0$, th enzyme-bridging model would require $Lk - Lk^0$ events of strand breakage and rejoining, but the DN rotation model could require as few as one single event. Biochemical and kinetic experiments sugge that the type IA enzymes are likely to follow the enzyme-bridging mechanism (34) and that the type IB enzymes are likely to follow the DNA rotation mechanism (35). The crystal structures of human DNA topoisomerase I in complex with DNA are also suggestive that the type IB enzymes can allow multiple strand passage events during each round of DNA breakage and rejoining (30).

3. Biological Ramifications of DNA Topology

The topological properties of DNA rings are rooted in the double-helix structure of DNA. One majo cause of catenane formation, for example, is the incomplete removal of helical intertwines between the parental strands of a replicating DNA (11). Supercoiling of intracellular DNA is also closely tied to the translocation of macromolecular assemblies along a helical DNA template (36). In Fig. 6, the movement of a transcribing **RNA polymerase** along its template is illustrated. The helical geometry of the template would require that the transcriptional ensemble, including the RNA polymerase, the nascent transcript attached to it, and proteins bound to the nascent transcript, be rotated around the DNA as transcription proceeds. But what if a transcription ensemble is prevented from rotating around its template? For example, in bacteria, where transcription and translation are coupled, nasce polypeptides of a membrane protein would be made before the termination of the messenger RNA. These mRNA-attached polypeptides could become attached to the cell membrane and would thus prevent the entire transcriptional assembly from rotating around the DNA template. Interaction

between RNA polymerase and template-bound regulatory proteins could also prevent the rotation of the transcription ensemble around the DNA. In either case, the DNA would be forced to rotate relative to the transcription ensemble. The DNA in front of the moving polymerase would become overwound or positively supercoiled, and the DNA behind the polymerase would become underwound or negatively supercoiled (36).

Figure 6. Supercoiling of the DNA template by transcription (36). (**a**) Because of the double-helix geometry of the DNA, a transcriptional ensemble R (including the RNA polymerase, the nascent transcript attached to the polymerase, and proteins associated with the transcript) would rotate around the DNA as transcription proceeds (upper drawing). If the ensemble is prevented from turning around the DNA, owing to, for example, the anchoring of the ensemble through the association of the polymerase with a template-bound regulatory protein or through insertion of mRNA-associated polypeptides into membranes, then the DNA would be forced to turn around its helical axis. In such a case, positive supercoils (+ signs) would be generated ahead of the ensemble and negative supercoils (– signs) behind it (lower drawing). In (**a**), the ends of the DNA segment are shown to be anchored to hypothetical elements denoted by E. In general, E represents a barrier to the rotation of DNA around its helical axis, as illustrated in (**b**) for a circular DNA template. In bacteria, gyrase appears to be primarily responsible for the removal of the positive supercoils and DNA topoisomerase I the negative supercoils; in eukaryotes, DNA topoisomerase I or II can remove both. (From Ref. 48, with permission.)



The close link between DNA topology and the double-helix structure of DNA also foretells the influence of DNA topology, and thus the involvement of DNA topoisomerases, in nearly all aspects of cellular transactions of DNA. In replication, for example, these enzymes are needed for the separation of the parental strands. In *E. coli*, the action of gyrase, perhaps augmented by the other topoisomerases, is necessary for the unlinking of the strands of the ring-shaped chromosome. In yeas propagation of the replication forks requires DNA topoisomerase I or II. A type II enzyme is also needed to unlink DNA catenanes or pairs of intertwined chromosomes at the time of their segregatio (2). In *E. coli*, this role is mainly fulfilled by DNA topoisomerase IV; in yeast, by DNA topoisomerase II.

In transcription, one or more DNA topoisomerases is involved. In bacteria, gyrase is believed to be the enzyme primarily responsible for the removal of the positive supercoils ahead of the transcriptio apparatus, and DNA topoisomerase I is believed to be responsible for the removal of the negative supercoils behind (36). Excessive supercoiling is likely to pose problems for cellular processes. In *E. coli*, inactivation of DNA topoisomerase I stimulates hybrid formation between the nascent RNA an the template strand of DNA, which is presumably a consequence of excessive negative supercoiling (37). This kind of **R-loop** formation is detrimental to the cell, especially in strains lacking ribonuclease H, which hydrolyzes the RNA strand in the hybrid. Participation of eukaryotic DNA topoisomerases in **gene regulation**, through their association with other proteins involved in the

initiation of transcription, has also been suggested (2).

Replication and transcription are two of the better-studied cellular processes involving one or more DNA topoisomerases. These enzymes have also been implicated in chromosome condensation and decondensation, recombination, the maintenance of genome stability, and DNA repair. Few other enzymes are involved in so many important and different cellular processes.

4. Topoisomerase-Targeting Toxins, Antibiotics, and Anticancer Agents

Shortly after the discovery of bacterial gyrase, two different classes of **antibiotics** represented by **nalidixic acid** and coumermycin were found to target the enzyme (38-40). Extensive studies showed that nalidixate, a member of the fluoroquinolone class of antibiotics that includes ciprofloxacin and norfloxacin, acts by trapping the covalent complex between DNA and gyrase, and coumermycin acts by inhibiting the gyrase ATPase activity. These drugs have similar effects on bacterial DNA topoisomerase IV, and their primary target in a bacterium could be either one or both of the two type IIA DNA topoisomerases, depending on the particular bacterium and the particular drug (41, 42). Th quinolone class of drugs are widely used. The trapping of the covalent enzyme–DNA complex appears to lead to cell killing through arrest of cell division. In addition to these antibiotics, two very different plasmid-encoded toxins were also found to target bacterial gyrase. The *ccdB* or *letD* gene product of the *E. coli* F plasmid appears to interact with the A-subunit of gyrase to prevent DNA fro rejoining after the formation of the gyrase–DNA covalent intermediate (43). This cytotoxicity facilitates the stable inheritance of the plasmid, because it also encodes a labile antidote of the toxin. Another gyrase-targeting toxin, microcin B17, has been identified in strains of *E. coli* bearing one of group of naturally occurring plasmids. This toxin is first expressed as a 69-residue peptide, which is then extensively processed to give a 43-residue product with four thiazole and four oxazole rings (44).

In the 1980s, a number of antitumor agents were shown to target eukaryotic DNA topoisomerase II b trapping the covalent DNA–enzyme complex (45, 46). These agents include the clinically useful drugs doxorubicin, etoposide, and mitoxantrone. A plant alkaloid, camptothecin, was found in 1985 to trap the covalent complex between DNA and eukaryotic DNA topoisomerase I, and several of the camptothecin derivatives have since been developed for cancer treatment. Topoisomerase-targeting cytotoxic agents that act by inhibiting one or more topoisomerases, rather than trapping a covalent intermediate, such as the gyrase inhibitor coumermycin and the eukaryotic DNA topoisomerase II inhibitors bisdioxopiperazines, are presently of limited clinical use but are of potential in future developments of anticancer, antibacterial, antifungal, and antiparasitic therapeutics.

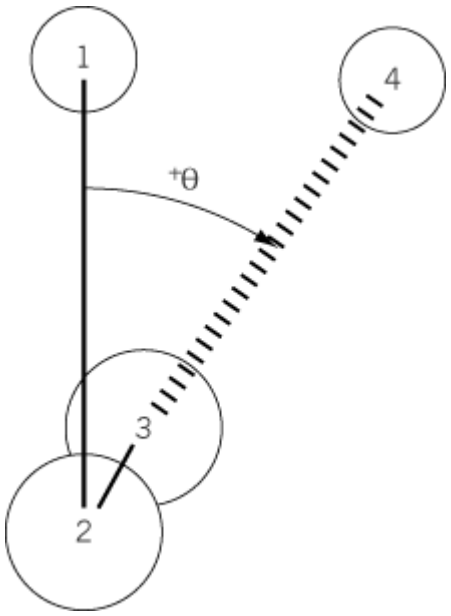
Suggestions for Further Reading

49. For introductory accounts of DNA topology and DNA topoisomerases, see W. Bauer, F. H. C. Crick, and J. H. White (1980) Sci. Am. **243**, 118–133 (1980); J. C. Wang (1982), Ref. 47; and J. C. Wang (1994), in Ref. 46. A 1976 article by F. H. C. Crick (Proc. Natl. Acad. Sci. USA **73**, 2639–2643) also touched upon several interesting aspects of DNA topology. For more detailed and more recent studies, see the various chapters in the monographs given in Refs. 4, 45, and 46 and the reviews on DNA topoisomerases (2, 30), and references therein. References 45 and 46 contain a number of chapters on therapeutics targeting various DNA topoisomerases.

Torsion Angle

Torsion angles within a molecule are defined by four atoms connected by three bonds. To determine the torsion angle of the bond connecting atoms 2 and 3, an observer sights down this and measures the angle that the bond between atoms 1 and 2 must be rotated through to become eclipsed with the bond between atoms 3 and 4 (Fig. 1). The torsion angle is taken as positive if the front bond is rotated in a clockwise direction (1).

Figure 1. The torsion angle defined by four atoms connected by three covalent bonds. The clockwise rotation of the bond in front so as to be superimposed on the bond in back defines a positive torsion angle q. For biological macromolecules, the backbone torsion angles are defined by four contiguous backbone atoms.



Torsion angles are preferentially given between –180 and +180° (2). This convention results in polypeptide torsion angles being 180° less than originally defined by Ramachandran (3) (see Ramachandran Plot). For polynucleotides, the torsion angles are defined by the conventions adapted by the IUPAC (4).

There is a technical difference between torsion angles and **dihedral angles**. A dihedral angle is defined by two planes containing four distinct atoms that are not necessarily sequentially covalently bonded. This is not possible with the definition of torsion angle.

Molecules that differ in torsion angles, ie, rotation about a single bond, are rotamers (see Stereoisomers). Torsion angles about single bonds may be described qualitatively, as well as quantitatively. The torsion angles are divided by three criteria: as positive and negative, as *syn* and *anti*, and as periplanar and clinal (Fig. 2, see bottom of page) (5). To give a qualitative description of the torsion angle, the abbreviation for all three divisions is given in Figure 2(d). The designation of torsion angles is of some importance, since this designation defines the difference between most conformations.

Figure 2. Classifications of torsion angles. They are grouped by three criteria: (**a**) positive and negative rotation, (**b**) *syn* and *anti*, and (**c**) clinal and periplanar. This gives rise to the eight different rotamers, shown with their two-letter abbreviations in Figure 2(**d**).

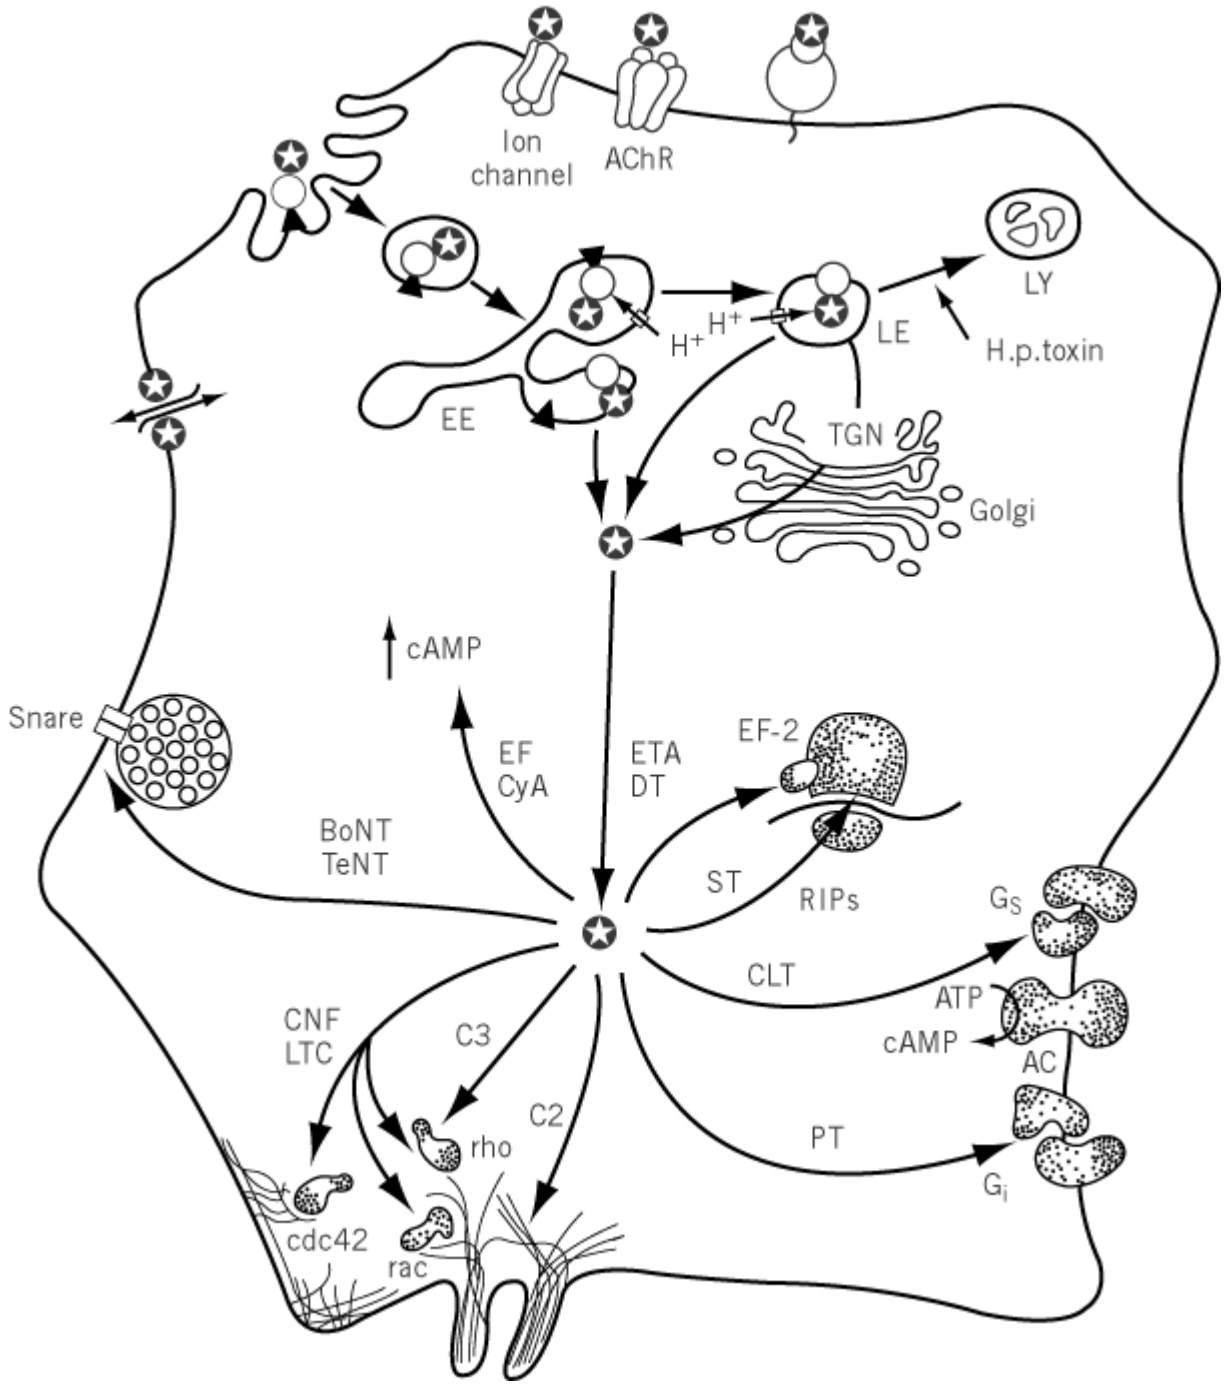
Toxins

Thousands and thousands of living organisms of different complexity, from **prokaryotes** to **plants** and animals, produce and release a variety of toxins (1-5). A toxin can be generally defined as any substance that causes damage to the normal physiology of living organisms. Most toxins are produced with the objective of increasing the chance of survival of the toxin-producing species. Toxins can be of any chemical complexity, from the very simple formic acid to the long polypeptide chains of clostridial toxins. They are the end-result of a long-term evolution of the toxin-producing organism in its environment and hence reflect its particular life style. Thus, by learning about the mechanism of action of a toxin, we can, at the same time, learn about important physiological aspects of the living species interacting with the venomous organism. This concept has been summarized by Claude Bernard, after his classical studies on the mechanism of action of curare, “Poisons are chemical scalpels for the dissection of physiological processes.”

Most, if not all, animal protein toxins play a role in the prey–predator relationship and are delivered by the venomous animal with the intention of immobilizing a prey or of warning a predator (2, 3). The effects of their action have to develop very rapidly. Given these premises, it is no surprise that many animal toxins act on cell surface **receptors** of neuronal or muscle cells and their privileged site of action is the neuromuscular junction . The preferred target molecules are the nicotinic or muscarinic acetylcholine receptors and protein **channels** specific for **sodium**, **potassium**, or **calcium** ions (Fig. 1). Depending on the particular binding site, they can cause inhibitory paralysis (eg, by blocking the sodium or calcium channel function) or excitatory paralysis (eg, by prolonging the opening time of the sodium channel). An inhibitory action is frequently used to immobilize a prey, particularly when it has dimensions larger than those of the venomous animal itself, whereas an excitatory action is more frequently used to “warn” predators, because an excitatory stimulus is memorized much better than an inhibitory one. Most venoms contain a variety of toxins, with different targets and mechanisms of action (1-5). Several snakes produce, in addition to neurotoxins, hemorrhage factors that interfere with the coagulation cascade or degrade extracellular matrix proteins (3). Other preferred targets are membrane phospholipids, which are hydrolyzed to smaller components, thereby altering the integrity and permeability barrier of the plasma membrane (6, 7).

Figure 1. Cellular interactions of protein toxins. This schematic picture summarizes the large array of interactions of known toxins (indicated by a star) with cells. A very large number of toxins bind to ion channels or cell surface receptors, causing their inactivation or activation (top part). Other toxins form pores or channels across the plasma membrane (left). Many toxins display their activity inside cells. They bind to a receptor () via a binding part (o) and enter the endocytic pathway through early endosomes (EE) and late endosomes (LE). They may be transported retrogradely up to the **Golgi** cisternae and endoplasmic reticulum or proceed to **lysosomes** (LY), where they are degraded. At some stage along these intracellular pathways, the catalytic toxin subunit (indicated by a star) crosses the intracellular membrane and translocates into the cytosol, where it recognizes and modifies specifically a target molecule. The *Helicobater pylori* toxin (H.p. toxin) causes a swelling of a hybrid LE-LY compartment. The edema factor of *Bacillus anthracis* (EF) and adenylate cyclase of *Bordetella pertussis* (CyA) elevate the cellular **cAMP** level. Diphtheria toxin (DT) and exotoxin A from *Pseudomonas aeruginosa* (ETA) **ADP-ribosylate** the elongation factor 2 and block protein synthesis. Shiga toxins (ST) and the ribosomal-inactivating toxins (RIPs) remove a single adenine residue from the 28S ribosomal RNA and stop protein synthesis. Cholera toxin (CLT) and related toxins ADP-ribosylate the G_s subunit of hormone-coupled adenylate cyclase complex and elevate the levels of cAMP. Pertussis toxin (PT) ADP-ribosylates the G_i subunit of hormone-coupled adenylate cyclase complex, as well as other **G proteins**, and causes an increase of cAMP. The colony necrotic factor of *Escherichia coli* (CNF), large clostridial toxins (LCT), and small clostridial C3 affect actin polymerization-controlling proteins of the **ras** superfamily, whereas the clostridial C2 and related toxins ADP-ribosylate directly G-actin. Tetanus neurotoxin (TeNT) and botulinum neurotoxins (BoNT) are zinc-endopeptidases, which cleave specifically three protein components of the neuroexocytosis apparatus and block exocytosis.



Plants produce a variety of toxins including proteins that kill **eukaryotic** cells by inactivating their ribosomes, thereby blocking protein synthesis (8). These toxins act slowly, in contrast to animal toxins, whose rapidity of action is essential. They exert their activity inside cells and exploit endocytosis to enter into the **cytosol**. The role of such toxins in plant survival is not clear, but they have been suggested to protect plant tissues and seeds from parasites (8). As well as plants, microorganisms do not depend on speed of action, and many bacterial toxins act slowly, but effectively, inside cells or on the plasma membrane. Microorganisms that live on or inside animals coevolve with their host much more rapidly than animals with their prey. Thus, they have developed, and still do, a larger variety of strategies to modify the host physiology in such a way as to promote their multiplication and/or spread, or to counteract the inflammatory and immune defense responses (9). Microbial toxins are part of these strategies, and they hit on vital physiological functions of animals by modifying selected cell targets (Fig. 1) (10). Many of them alter cell responses by

binding to particular receptors as superantigen toxins or endotoxins do. Endotoxins are lipopolysaccharides of the outer membrane of many **gram-negative** bacteria, which induce the release of **cytokines** upon binding to inflammatory cells. Other toxins alter the plasma membrane permeability barrier, and cells die by colloid-osmotic lysis and/or by loss of cytosolic components. Several bacterial protein toxins are enzymes acting inside cells, and their structural organization reflects the need to enter into cells to perform their activity (10, 11). Together with the plant toxins mentioned above, these protein toxins are known as A-B toxins, because they consist of two parts: A (active) is an enzyme connected via a peptide linker and a single disulfide bond to polypeptide B (binding), which is responsible for cell binding and internalization. Figure 1 depicts schematically the route of entry of A-B toxins into cells, a four-step process that begins with binding to a cell surface receptor. These proteins are activated by specific cleavage of the peptide linker by bacterial or tissue proteinases or by cell surface-associated proteinases, such as furin, which cleaves between positively charged residues (12). Binding is rapidly followed by internalization of the toxin–receptor complex inside **vesicles** (second step), whose nature depends on the toxin receptor: Different toxins travel different vesicular trafficking pathways inside the cell. In any case, in order to display its toxic activity, the A subunit has to leave the vesicle lumen and translocate across the membrane into the cytosol (third step), where it modifies its target (fourth step) and intoxicates the cell. The yield of the process of toxin cell entry may be low, but this is compensated by a catalytic type of activity that leads to the inactivation, one after the other, of all target molecules present in the cell. At variance from most animal toxins, which act on a one-to-one basis, at least in principle, one single copy of A is sufficient to intoxicate a cell completely. So far, five different enzymic activities have been found associated with proteins that act intracellularly (Table 1). The cellular and systemic effect of such activities depends on the role of the target molecule in cell function and of the intoxicated cell in the physiology of the poisoned organism.

Table 1. Catalytic Activities, Targets, and Cell Effects of Bacterial Protein Toxins with Intracellular Targets

Toxin	Activity	Target	Effect
DT	ADP-ribosyltransferase	EF-2	Blockade of protein synthesis and celldeath
ETA	ADP-ribosyltransferase	EF-2	Blockade of protein synthesis and celldeath
CLT	ADP-ribosyltransferase	G_s, G_t, G_{olfs}	Increase cAMP
LT	ADP-ribosyltransferase	G_s, G_t, G_{olfs}	Increase cAMP
PT	ADP-ribosyltransferase	G_i, G_o, G_{gust}	Increase cAMP
C_2	ADP-ribosyltransferase	Actin	Inhibition of actin
C_2-liketoxins	ADP-ribosyltransferase	Actin	Polymerization, depolimerization of F-actin
C_3	ADP-ribosyltransferase	Rho	Depolymerization of F-actin

		Cdc42	actin
C.s. LCT	Glucose-transferase	Rac, Ras, Rap	Breakdown of stress fibers
C.n.	Toxin N-acetyl-glucosamine transferase	Rho, Rac, Cdc42	Depolymerization of F-actin
STs	Adenine-glycohydrolase	r-RNA 28S	Blockade of protein synthesis and celldeath
EF	Adenylcyclase	None	Increase cAMP
CyA	Adenylcyclase	None	Increase cAMP
TeNT, BoNT/B			
BoNT/D, /F, /G	Metallo-protease	VAMP	Inhibition of exocytosis
BoNT/A, /C, /E	Metallo-protease	SNAP-25	Inhibition of exocytosis
BoNT/C	Metallo-protease	Syntaxin	Inhibition of exocytosis

A-B toxins can be divided into two groups on the basis of the structural organization of the B portion: (1) oligomeric B toxins (cholera toxin, shiga toxins, etc.) and (2) three-domain toxins (diphtheria toxin, clostridial neurotoxins, etc.) that are composed of a two-domain B polypeptide chain plus an A domain. These latter toxins use their carboxyl-terminal B domain to bind to a protein receptor and enter the lumen of intracellular compartments that are acidic. Low pH induces the transition from a neutral conformation to an acidic one, capable of inserting both the A and B subunits into the lipid bilayer. There is evidence that the B amino-terminal domain forms a transmembrane channel, open laterally to lipids, that mediates the membrane translocation of A (10, 11). This event and the release of A in the cytosol are coupled to the reduction of the intersubunit disulfide bond, which appears to be the rate-limiting step of the entire cell entry process. Oligomeric B toxins bind to the saccharide moiety of glycolipids or **glycoproteins**, localized on the apical membrane of epithelial cells. Their mode of cell entry is less understood than that of the three-domain bacterial toxins, but they do not appear to depend on low lumenal pH to translocate A into the cytosol.

As depicted in Figure 1, the various toxins attack different intracellular targets with a variety of consequences. Plant toxins, diphtheria, shiga, and pseudomonas toxins block protein synthesis and cause cell death. However, the majority of protein toxins with intracellular targets do not kill the cell; instead, they alter cell structure and and/or physiology in such a way as to promote bacterial proliferation and/or spread. Nonetheless, cellular alterations can be such as to be incompatible with the survival of the tissue or organism.

TPCK (*N*-*P*-Tosyl-Phenylalanine Chloromethyl Ketone)

This reagent was developed by Schoellman and Shaw as a specific inhibitor of **chymotrypsin** (1). Its design was based on the principle of affinity labeling, which couples substrate specificity with chemical reactivity to generate a covalent bond between the reagent and a functional group at the active site of the enzyme. In this case, the phenylalanine part of the reagent confers specificity for chymotrypsin, while the chloromethyl ketone provides chemical reactivity (Figure 1). Although chymotrypsin is a serine proteinase, the reagent does not interact with the active site serine residue but instead alkylates the histidine residue that is part of the catalytic triad. The reagent has essentially no effect on the activity of **trypsin** or other serine proteinases and is often used to inactivate the small amounts of chymotrypsin present in purified trypsin preparations. It is also often combined with inhibitors of other types of proteinases to prevent unwanted **proteolysis** that might occur during the course of protein isolation from cell or tissue homogenates (2).

Figure 1. Reaction of TPCK (tosyl-phenylalanyl chloromethyl ketone, ie, L-1-chloro-3-[4-tosylamido]-4-phenyl-2-butanone) with the active-site histidine side chain of a chymotrypsin-like serine proteinase. The reaction product is catalytically inactive.

Tracking Dyes

In gel electrophoresis using discontinuous buffer systems, disc electrophoresis, dyes migrating with a net mobility intermediate between that of the leading and trailing ions of a moving boundary are used to mark the moving boundary ("tracking dyes"). They are used to monitor the extent of electrophoresis, and the mobilities of electrophoretic bands within samples are often expressed relative to those of the tracking dye.

Bromphenol blue is the most popular example of a tracking dye, being used generally in SDS-PAGE, but it, like any other dye, is limited in this function by its net mobility. Thus, it may mark a chloride/glycinate moving boundary (stack) in SDS-PAGE incorrectly. This happens when it is displaced by the faster-migrating micellar **SDS**, as occurs in a typical polyacrylamide gel of

moderate or low concentration. Only after molecular sieving effects start to retard micellar SDS (eg, in a 12% (w/v) gel) can bromphenol blue occupy and correctly mark the boundary. By contrast, the dye pyroninY , when complexed with SDS, has a mobility greater than that of micellar SDS and marks the boundary correctly at low gel concentrations. As a result of its binding of SDS, however, it is large and is retarded by molecular sieving at gel concentrations greater than about 12% (w/v), so as to migrate behind the moving boundary front. At even higher gel concentrations, even a small dye like bromphenol blue is retarded by sieving behind the moving boundary (1). Thus, tracking dye stacking needs to be tested by comparing its position on the gel with that of the boundary determined more directly, such as by precipitation or radioactivity of the leading or trailing ions. Since a moving boundary front (stack) marked by a tracking dye is frequently used to define the characteristic relative mobility (R_f) of a band, that R_f is valid only in the gel concentration range in which the tracking dye migrates with the moving boundary front. Beyond that gel concentration range, the dye cannot be used to define the R_f.

In gel electrophoresis in a continuous buffer, any dye can be used for the calculation of the R_f of a band at any gel concentration. In contrast to the stacked dye in a discontinuous buffer system, however, the relatively small molecular weight dye band spreads rapidly by diffusion in proportion to the migration distance, so that its usefulness as a reference band for R_f measurement progressively diminishes with the time of electrophoresis.

Trans Configuration

Trans is a prefix that is used to describe the configuration of molecules, indicating that two substituents are on opposite sides of a bond or ring (1). The alternative, when the substituents are on the same side, is denoted by cis configuration. In specifying the *trans* configuration about a double bond, the prefix (*E*), for the German entgegen, is preferred (2). The term *trans* is sometimes used in specifying a conformation when the torsion angle approaches 180°. To avoid confusion, it is preferable to use ***anti*** for describing conformations.

Trans-Acting

Trans-acting is the effect of one **gene** on the activity of another regardless of whether or not the two are physically linked. The term is used in contradistinction to cis-acting which describes the situation where physical linkage (usually close) of genetic elements is necessary for interaction.

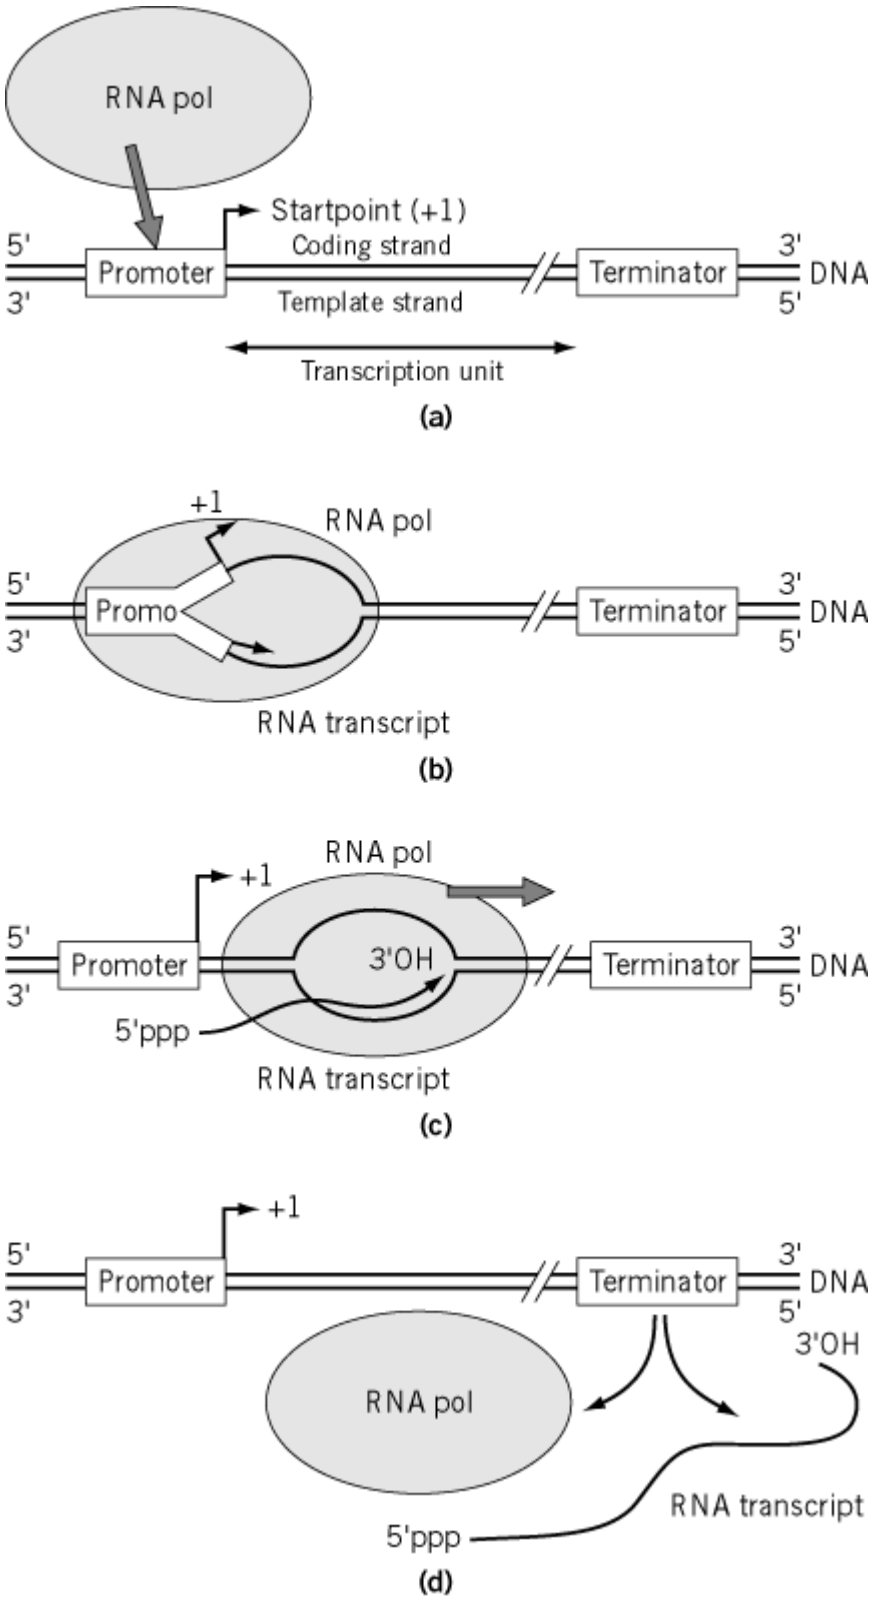
In the networks of gene interactions that play such a major part in the controls of metabolism and development, *trans*-activity of genes, through their protein products, is the general rule. Among *trans*-acting genes are all those that encode **transcriptional factors** and proteins whose binding is necessary for the function of enhancer sequences, proteins involved in intron splicing (see *introns*, *spliceosomes*), and proteins of chromatin complexes.

In general, proteins that function by binding to DNA or (for splicing control) to RNA are all *trans*-acting and the nucleic acid sequences to which they bind are *cis*-acting. However, in the fly *Drosophila melanogaster* there are some examples of DNA sequences that act in *trans*, enhancing the activity of a *cis*-positioned gene and also, to some extent, of the *trans* homologue, if the latter lacks an enhancer of its own. This unusual phenomenon, called *transvection*, depends on the close pairing of homologous chromosomes in somatic cells of *Drosophila*.

Transcription

Transcription transfers the genetic instructions from the DNA template to RNA and is the first step in expression of the genome . This highly regulated process consists of the synthesis of an RNA molecule by an **RNA polymerase** (RNA pol) that reads the template (or noncoding) strand of the DNA; the primary transcript will therefore carry the same genetic message as the other DNA strand, namely the coding strand. The synthesis of RNA involves the formation of a partial heteroduplex between the DNA template strand and the growing RNA transcript, leading to a bubble structure. RNA pol catalyzes the formation of successive phosphodiester bonds between the 5′-triphosphate group of nucleotide precursors and the 3′-OH group of the last nucleotide of the nascent RNA polynucleotide chain; the growth of the RNA chain proceeds in the 5′ to 3′ direction. Transcription is generally divided into four steps (Fig. 1): (i) Preinitiation involves the recognition of particular sequences constituting the promoter by the transcriptional apparatus, including the binding of RNA pol and opening of the double-stranded DNA around the initiation site; (ii) initiation is usually considered to be the formation of the first phosphodiester bond of the transcript; (iii) elongation begins with clearance of the promoter, which refers to the escape of RNA pol from its anchorage site on the promoter; the enzyme then progresses along the gene to elongate the RNA transcript, leading to concomitant movement of the bubble structure by successive unwinding and rewinding of the DNA duplex; and (iv) finally, termination occurs when the elongation complex encounters a terminator sequence, with subsequent release of both RNA pol and the RNA product. Depending on the type of gene from which it derives, the primary transcript will undergo differential processing to give rise to various types of RNAs: **ribosomal** RNA, transfer RNA, **small nuclear RNA**, or messenger RNA that are further **translated** into proteins.

Figure 1. Major steps of the transcription process. (**a**) Promoter recognition; (**b**) initiation; (**c**) elongation; (**d**) termination.

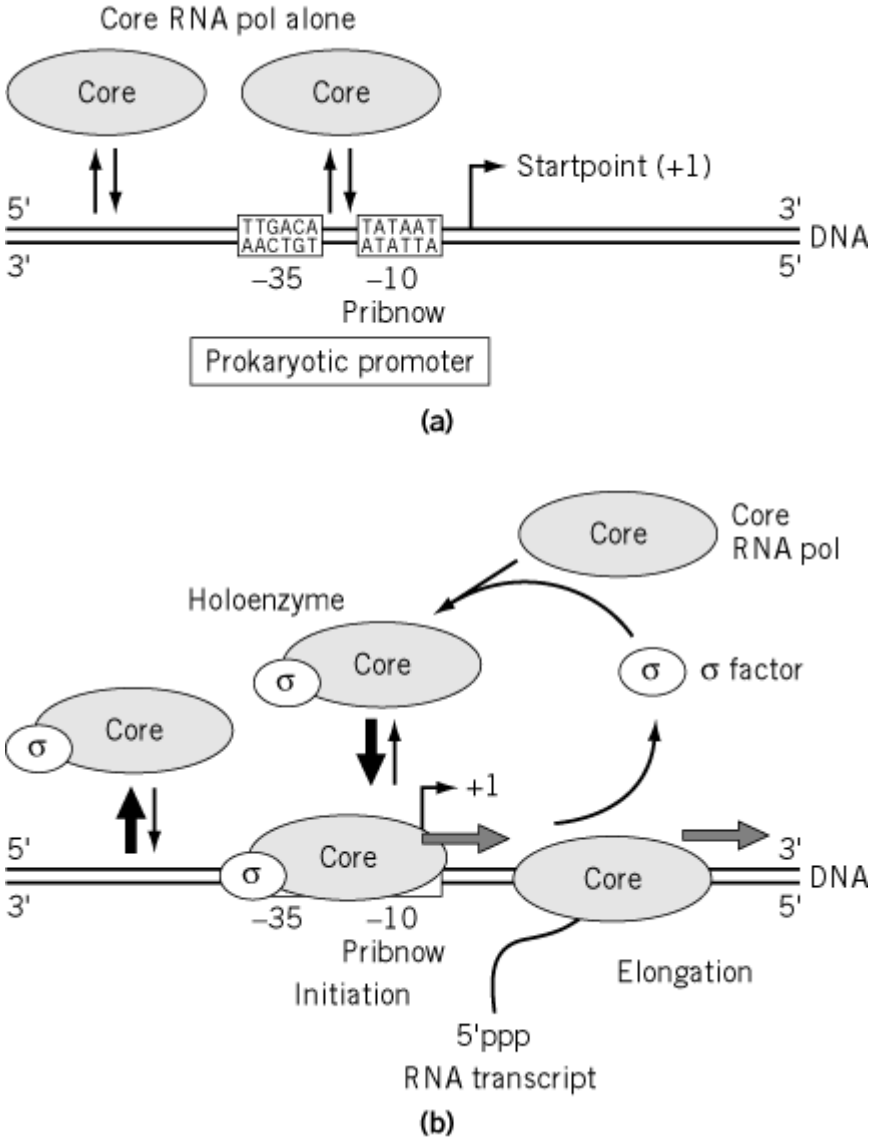


Although the general scheme of transcription has been conserved during evolution, some noteworthy differences exist between the prokaryotic and the eukaryotic systems; these include the promoter structure, the components of the transcription machinery, the function of accessory factors, and the mode of regulation.

1. Transcription in Prokaryotes

Prokaryotes possess a single RNA pol to synthesize all RNAs. RNA pol is composed of only five subunits: four of them constitute the core enzyme (a_2bb') and the last, called the sigma factor, associates with the core to form the holoenzyme. The b and b′ subunits together form the catalytic center, whereas the two a subunits maintain the structural conformation. Accurate initiation of transcription occurs only in the presence of holoenzyme. The s factor confers promoter specificity in two ways: It destabilizes nonspecific RNA pol–DNA complexes, while at the same time promoting formation of a stable RNA pol–promoter complex. As soon as short transcripts (10 to 15 nucleotides) have been synthesized, s dissociates from the transcription complex, and the core enzyme continues elongation (Fig. 2).

Figure 2. Accurate initiation from a prokaryotic promoter requires RNA polymerase holoenzyme. Core polymerase forms non-productive complexes with either nonspecific or promoter DNA sequences (**a**). Association of s factor with core polymerase, to generate holo-polymerase, confers promoter specificity and allows accurate initiation of transcription. When the RNA product reaches a length of 10 to 15 nucleotides, s is recycled in other initiation events (**b**).



Prokaryotic promoters are characterized by four conserved features: (i) the startpoint, also called the

initiation or start site (+1), usually a purine; (ii) the Poly A, a short A-T-rich sequence located at the –10 position; (iii) an element located around the –35 position; and (iv) the fixed distance that separates both of these elements (16 to 18 bp). During transcription initiation, RNA pol covers a region extending from –50 to +20 around the start site by interacting with the Pribnow box and the –35 element. The –35 sequence is recognized by the RNA pol, whereas subsequent opening of the promoter from nucleotides –10 to +3 depends on the Pribnow box.

During elongation, the core polymerase may pause following the formation of secondary structure within the nascent RNA. The presence of pausing sites is also linked to termination events. Termination occurs through two mechanisms: (i) The signal of arrest at the end of the gene is provided by a G-C-rich **palindromic** sequence, followed by a poly-A sequence; transcription of these sequences leads to the formation of a stable hairpin directly followed by a poly-U sequence (Fig. 3a). Once the hairpin structure has induced pausing of the polymerase, the poly-U/poly-A heteroduplex allows further release of the transcript and the enzyme. (ii) Termination may require the presence of the hexameric releasing factor rho, which exhibits an RNA-dependent Operonsand an **RNA–DNA helicase** activity (Fig. 3b). Rho binds the RNA upstream of the rho-dependent terminator and subsequently translocates along the transcript. Termination most likely occurs upon interaction with the RNA pol stalled at the rho-dependent terminator. Consistently, rho is able to interact with the b subunit of the enzyme. Similarly, Nus A factor regulates transcription by increasing the tendency of RNA pol to pause.

Figure 3. Models for termination of prokaryotic transcription. (**a**) Factor-independent termination: Transcription of palindromic and polyA sequences from the factor-independent terminator leads to the formation of a hairpin structure (*h*) and to a poly-U sequence, respectively. The hairpin induces pausing of the polymerase; together with the adjacent polyA–polyU hybrid, this promotes transcription arrest and release of the RNA transcript and the RNA polymerase. (**b**) Rho-dependent termination: Termination factor rho binds the RNA transcript upstream of the rho-dependent terminator and migrates toward the elongating polymerase. Termination occurs when rho catches up the polymerase pausing at the terminator. The factor NusA facilitates termination by increasing the frequency of pausing.

Prokaryotic genes are clustered in operons; an operon is controlled by a single promoter and contains several genes all devoted to the same metabolic pathway, such as lactose catabolism in the case of the ***lac*** operon. Regulation of transcription is performed essentially at two stages: (i) At the initiation level, variation in the pattern of transcribed operons can result from the use of different s factors, each specific to a type of promoter. In this respect, events such as **sporulation** or response to **heat shock** are driven by a cascade of s factors. The host RNA pol can be substituted by a newly synthesized viral RNA pol upon bacteriophage infection. An alternative pathway requires ***trans*-acting** factors that bind to the **operator** element, a specific sequence generally located nearby the promoter, to enhance (activators) or repress (repressors) the initiation of transcription. (ii) When the elongating RNA pol encounters a first termination sequence, it may either stop or continue to transcribe adjacent genes. This will depend on factors that fasten on the elongating polymerase after having bound to a specific site on the DNA or on the transcript. In the case of **antitermination** factors (or antiterminators), RNA pol will read through the stop signal, but some other factors exist that will increase its propensity to stop, probably by inducing frequent pausing. At some operons, the phenomenon of **attenuation** can also occur, when transcription is intimately coupled with translation: progression of the ribosome along the nascent RNA modulates the formation of secondary structures, enabling RNA pol to read through intrinsic terminators (or attenuators).

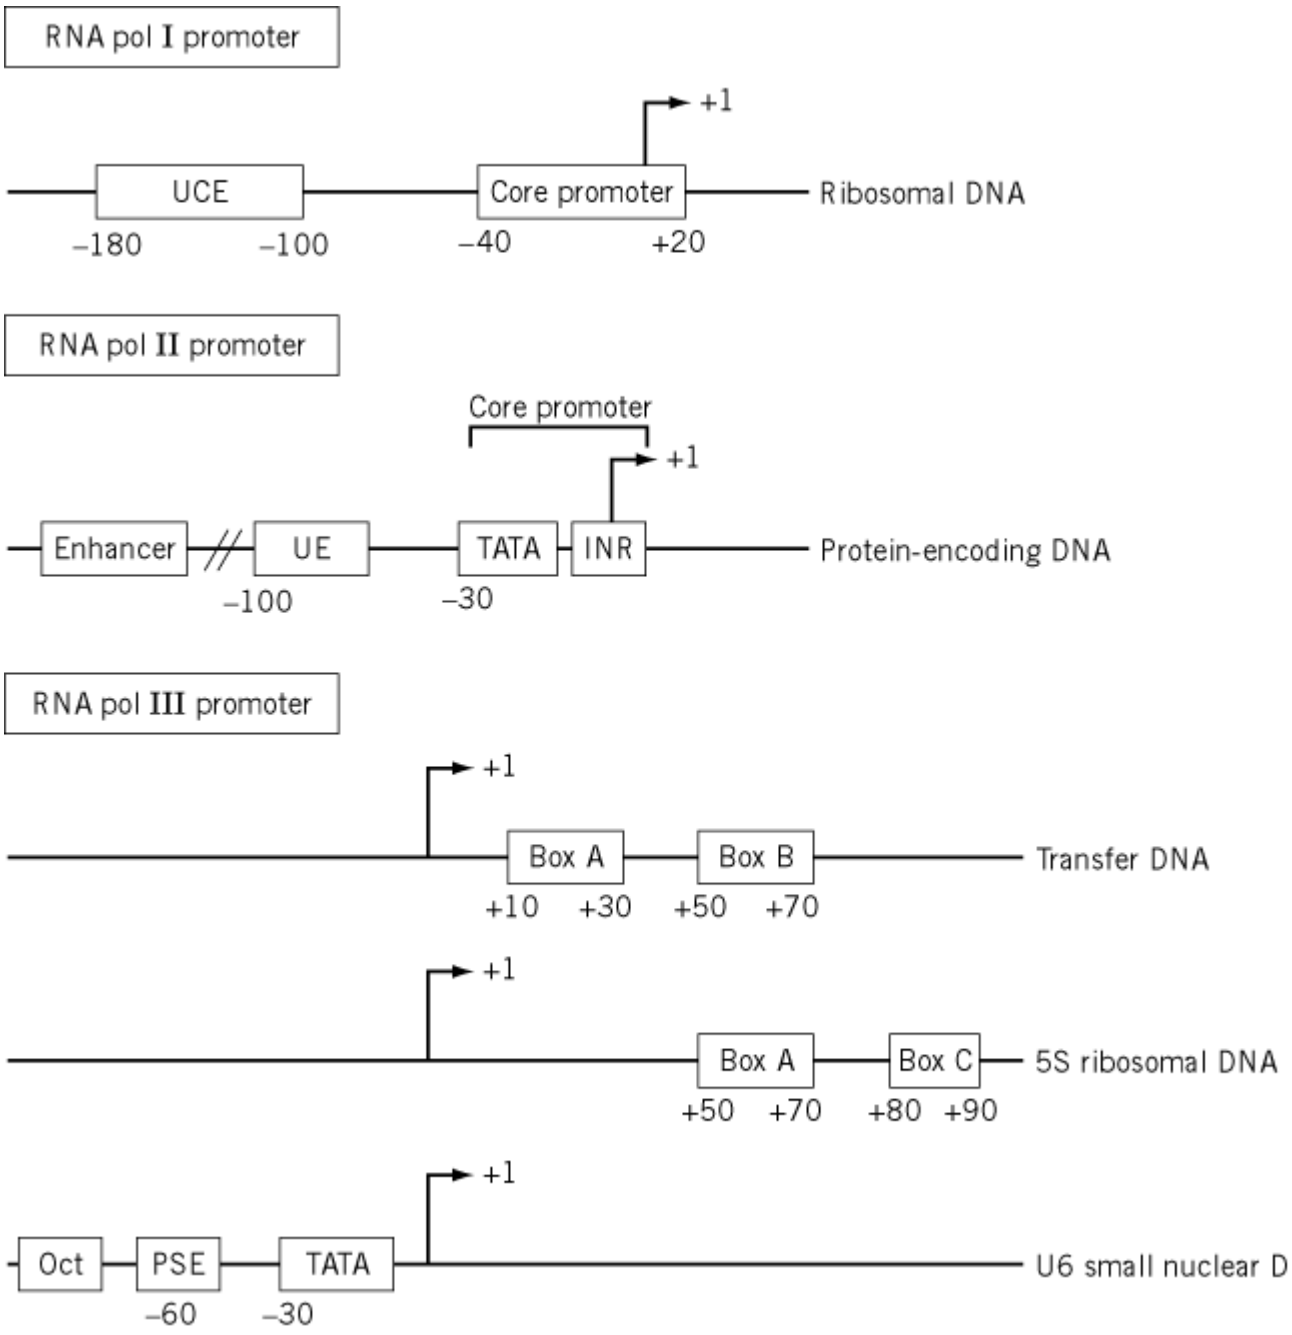
2. Transcription in Eukaryotes

Consistent with a higher complexity in the genome organization, the transcription process in eukaryotes involves a much larger number of proteins than in prokaryotes. There are three different RNA polymerases, each specialized in transcription of a particular class of genes:

1. RNA pol I transcribes ribosomal RNA genes.
2. RNA pol II transcribes protein-encoding genes and certain small nuclear RNA (sn RNA) genes.
3. RNA pol III gives rise to small RNAs such as transfer RNAs, 5 S rRNA, and snRNAs.

Each enzyme is composed of at least 12 subunits, three of which are common to all enzymes. They initiate RNA synthesis from three different types of promoters (Fig. 4). Moreover, promoter recognition by any RNA pol is absolutely dependent upon preliminary binding of accessory factors.

Figure 4. Different classes of eukaryotic promoters. TATA box (TATA) and initiator element (INR) constitute the RNA polymerase II core promoter. UCE, upstream control element; UE, upstream element; Oct, octamer sequence; PSE, proximal sequence element. +1 indicates the startpoint.



RNA pol I promoters include a core promoter (or selector) and a regulatory upstream control element (UCE). Both elements contain a G-C-rich sequence that is recognized by the ancillary factor UBF1. UBF1 allows the binding of the SL1 factor on the promoter, before RNA pol I finally joins the initiation complex (Fig. 5a). RNA pol III promoters present more diversity in their structure (Fig. 4). Downstream (or internal) promoters contain two conserved sequences (the box A sequence associated with either box B or box C), whereas upstream promoters possess a TATA-box element, in addition to Oct (octamer) and PSE (proximal sequence) regulatory elements. Positioning of RNA pol III on these promoters is mediated by the transcription factor TFIIIB. TFIIIB binds to the promoter either independently via the TBP subunit (TATA-binding protein) when a TATA-box sequence is present, or through the assistance of TFIIIA and TFIIIC in the absence of any TATA-box (Fig. 5b).

Figure 5. Initiation from different eukaryotic promoters. Positioning of RNA pol I (**a**) and RNA pol III (**b**) on class I and promoters, respectively. UBF1 and SL1 refer to class I transcription factors, and IIIA, IIIB, and IIIC to class III transcrip subunit common to the "positioning" factors SL1 and IIIB. Transcription of protein-encoding genes is much more complex and requires two sets of factors (see Enhancer): (i) The basal or general transcription factors (GTFs) are necessary for transcription from a minimal promoter; they assemble onto the promoter to form, together with the RNA pol II, the preinitiation complex (PIC). (ii) The sequence-specific factors bind their cognate upstream elements, or enhancers, and then interact with the GTFs in order to regulate transcription. These interactions can be mediated by certain intermediary factors or coregulators.

An RNA pol II promoter (or core promoter) is generally composed of two conserved elements, either alone or functioning in synergy: a TATA-box element, usually located 30 nucleotides upstream of the start site in higher eukaryotes, and an initiator element (Inr) encompassing the start site. Promoter recognition is mediated by the binding of the basal factor TFIID through its TBP subunit sitting astride the TATA-box sequence. The role of TFIID is dual: First, by anchoring the PIC to the promoter, it will position RNA pol II and select the startsite; second, it will induce a bend in the DNA structure that reduces nucleosome packaging from the chromatin and brings regulatory proteins, already bound to the DNA, closer to the promoter. Transcription from TATA-less promoters also uses TBP; in that case, binding of TFIID results from recognition of Inr by its TAF subunits (TBP-associated factors) or additional factors.

The association of TFIID with the promoter nucleates the assembly of the PIC, allowing the arrival of the other five GTFs in addition to RNA pol II in a sequential order. Alternatively, the TFIID/promoter complex can be targeted in a single step by the RNA pol II "holoenzyme" complex (Fig. 5c). In addition to RNA pol II, this holoenzyme includes a subset of GTFs, as well as additional factors, such as SRB proteins (for suppressor of RNA pol B), that constitute the mediator or SRB complex (in yeast) and mediate transcriptional activation. In the stepwise assembly model, TFIIB joins the TFIID-promoter complex, contacting bent DNA both upstream and downstream of the TATA box, thus stabilizing the complex. A specific TFIIB recognition element (BRE), located just upstream of the TATA box, exists at certain promoters. The binding of TBP can also be stabilized by TFIIA, which may relieve inactivation by certain factors, such as MOT1, DR, or NC. The RNA pol II/TFIIF complex then targets the promoter. Completion of the PIC assembly occurs after the successive binding of TFIIE and TFIIH. Opening of the DNA region encompassing the startpoint (nucleotides –9 to +2), which gives the RNA pol II access to the template strand, requires both of these factors, in addition to ATP hydrolysis, except in the case of **supercoiled** DNA. The multisubunit complex TFIIH is the only GTF that possesses several known enzymatic activities: ATP-dependent DNA helicase activity probably separates the two DNA strands, while its DNA-dependent Polyadenylation activity could provide part of the energy. In addition, the cdk7 subunit is able to **phosphorylate** the *C*-terminal domain (CTD) of the largest subunit of RNA pol II. TFIIE not only recruits TFIIH in the PIC but also stimulates TFIIH kinase and ATPase activities. CTD-phosphorylation occurs concomitantly with initiation, converting the unphosphorylated form of RNA pol (IIa) into the hyperphosphorylated elongating form (IIo). Phosphorylation facilitates escape of the elongation complex during promoter clearance by severing contacts between CTD and components of the initiation complex.

TFIIF remains associated with RNA pol II during elongation, together with four additional elongation factors: TFIIS, p-TEFb, elongin SIII, and ELL. These factors control the rate of mRNA synthesis by regulating the processivity of RNA pol. TFIIS and p-TEFb allow the arrested complexes to recover elongation activity. The p-TEFb factor, which also exhibits a CTD-kinase activity, is thought to regulate the phosphorylation state of RNA pol II, thus stabilizing the elongation-proficient conformation. Termination requires the presence of two sequences downstream of the transcribed gene: the signal for polyadenylation of the transcript, followed by a pausing site. Cleavage of the 3′ end of the RNA, mediated by three factors (CPSF, CstF, CF), is necessary for termination to occur.

Transcription regulation involves interaction of the sequence-specific factors, bound to their cognate DNA elements, with the basal transcription machinery. This interaction can be either direct or mediated by cofactors like TAFs, SRB proteins, or TIFs (transcription intermediary factors). The specific elements are located at variable distances from the core promoter: Upstream elements (UEs) such as the CAAT box or GC box are usually found between positions –50 and –100, whereas enhancers or **silencers** act at distances up to tens of thousands of base pairs, either upstream or downstream of the startpoint. Activation factors usually possess a **DNA-binding** domain (DBD) and an activation domain (AD) (see -cyclic AMP, cAMP)). Some of them are inducible, either newly synthesized or activated, before they stimulate transcription via their response element. Activation includes various mechanisms, such as the recruitment of GTFs onto the promoter or removal of repressor proteins.

Repression of the transcription is usually coupled to DNA compaction into nucleosomes; derepression thus requires chromatin remodeling, most probably involving complexes such as SWI/SNF, which is part of the RNA pol II holoenzyme in yeast, or NURF (nucleosome remodeling factor). Some proteins also act as repressors of transcription by either counteracting activators or impeding the assembly of the PIC.

Over the past decade, the combination of biochemistry and molecular biology has shed some light on our understanding of the molecular bases of human diseases. Unexpectedly, a variety of human genetic disorders are linked to defects in RNA pol II transcription machinery. For example, defects in TFIIH result in xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy. Mutation of the VHL **tumor suppressor** gene, the product of which regulates elongin SIII, affects the elongation process and results in the von Hippel–Lindau disorder; and mutations in the **cyclic AMP** response element-binding protein (CREB) binding protein (CBP), which is involved in coactivation process, are found associated with the Rubenstein–Taybi syndrome.

Transcription Factors

The expression of eukaryotic gene is controlled tightly with respect to both time and space. While there are many control points during gene expression, the control of initiation of transcription is, for most genes, the most prominent among them.

The production of RNA from a DNA template is catalysed by RNA polymerases (RNAP). The RNA polymerase holoenzyme of *Escherichia coli*, a protein of molecular weight 465 kD, is composed of a core enzyme with the subunit composition a_2bb', which is responsible for RNA polymerisation (1, 2), and a sigma factor that directs the holoenzyme to the promoters of genes (3-5).

The most simple types of RNA polymerases are found in bacteriophages. The RNAP of T7 bacteriophage is a single subunit enzyme of molecular weight 99 kD (6), but it is composed of domains with specific functions (7). For example, the relative locations of the active site and the domain for promoter recognition allow the orientation of the polymerase on the template to be defined. The specificity of T7 RNAP is controlled by a loop consisting of approximately 40 amino acid residues. A single point mutation within this loop is sufficient to switch the specificity of the enzyme from the T7 promoter sequence to that of the T3 promoter (8).

While all prokaryotic RNA polymerases are capable of recognizing gene promoters and initiating transcription from the proper start point, the efficiency of transcriptional initiation is further modulated by trans-acting factors known as transcription factors. Transcription factors are called repressors or activators, depending on whether their effect is to decrease or increase the level of transcription. Because of relatively high efficiency of RNA synthesis by prokaryotic RNAPs, the main theme for regulation in prokaryotes is repression.

Eukaryotes have three distinct RNA polymerases that catalyze nuclear gene transcription (9). RNAP-I and -III catalyze the production of ribosomal RNA and transfer RNA, respectively, while RNA-II [the structure of this multisubunit protein has recently been solved at a resolution of 2.8 Å (10)] is responsible for the synthesis of all messenger RNA. The eukaryotic RNAPs have between 8 and 14 subunits and a molecular weight of approximately 500 kD. The purified enzymes can catalyse low-level template-dependent transcription of RNA, but, despite their structural complexity, these enzymes are unable to recognize the promoter of genes and depend fully on a set of auxiliary proteins known as general transcription factors to initiate transcription from the corresponding class I, II, and II gene promoters (11).

In the case of transcription by RNAP-II, the basal transcription factors necessary for low-level transcriptional initiation from the proper start point have been separated into biochemically defined fraction referred to as TFIIA, -B, -D, -E, -F, H, and -J (12-15). Subsequent cloning and biochemical analyses have shown that many of these fractions consist of multiple proteins. For example, TFIID consists of the TATA box binding protein (TBP) and 8 to 12 tightly bound TAFs (TBP-associated factors) (16, 17). A low resolution structure of TFIID was obtained by electron microscopy and single particle analysis (18, 19). TFIID appears to adopt the structure of a horseshoe with a deep groove that most likely should accommodate the DNA.

The stupefying complexity of biological processes like embryonal development make it obvious that gene expression must be exceedingly tightly controlled (e.g., see Refs 20-22). For the initiation of RNA synthesis, this is achieved through the action of transcription factors. These proteins bind with high affinity to their target DNA sequences and regulate the rate of transcription through interaction with the basal transcriptional machinery. Because of the low efficiency of the basal transcriptional

machinery, most eukaryotic transcription factors are activators.

The specificity of transcriptional initiation is controlled through the interaction of transcription factors with their DNA-binding sites in the promoter and enhancer regions of genes, so it is vital to understand the forces that govern the recognition of DNA by proteins. Nature has used a modular approach to assemble transcription factors. The individual domains within a transcription factor, such as, for example, the DNA-binding domain and the transcriptional activation domain, are thereby, to a first approximation, independent of each other. As a consequence, the properties of the DNA-binding domains can be studied in the absence of the activation domains. The limited amount of structural data available for activation domains is in sharp contrast with the wealth of information about the DNA-binding domains of transcription factors.

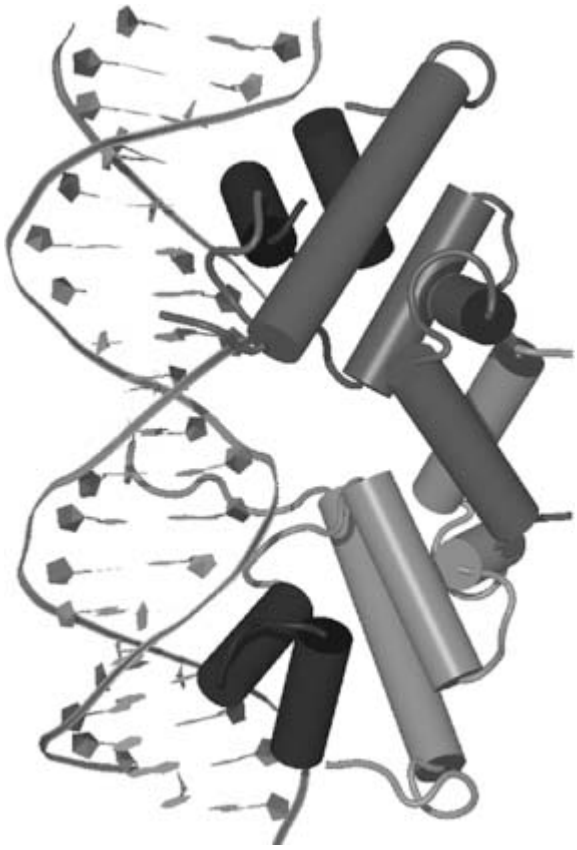
1. DNA-Binding Motifs Observed in Eukaryotic Transcription Factors

One of the central observations that emerged from X-ray crystallographic and NMR-spectroscopic studies and sequence comparison is that most DNA-binding proteins can be grouped into families based on the structural motif that they rely on for sequence-specific DNA recognition (23). Each of these motifs contains a simple element of secondary structure complementary to the structure of the DNA (24).

2. Helix-Turn-Helix Motif

The helix-turn-helix (HTH) motif was the first DNA-binding motif to be discovered, and extensive structural and functional studies have been performed with many HTH proteins (25, 26), including l-phage and 434-phage Cro repressors (27, 28), the DNA-binding domains of l- and 434-phage repressors (29-32), Lac repressor (33-36), that of the *trp* operon (37-40), the *E. coli* transcriptional activator cyclic AMP receptor protein (CRP)/catabolite gene activator protein (CAP) (41), *E. coli* inversion stimulation factor (FIS) (42), *Salmonella* hin recombinase (43), and the *E. coli* biotin repressor (44). Comparison of the structures of these proteins revealed a shared DNA recognition motif consisting of an a-helix, a turn of four amino acid residues, and a second helix (Fig. 1) (26) (see Helix-Turn-Helix Motif). The structural arthitecture of the HTH-motif relies on a hydrophobic core through which the two a-helices pack together. The second helix (recognition helix) interacts with the major groove of the DNA. Interestingly, the isolated HTH motif is not a stable protein domain and, unlike most other DNA binding motifs, relies on other parts of the proteins for stability.

Figure 1. The global structure of the DNA complex of the N-terminal domain of l-repressor (29). The protein binds to the DNA as a dimer with one monomer contacting each half site of the O_L1 operator. The recognition helix fits snugly into the minor groove of the DNA, while the second helix of the HTH-motif binds across the major groove. Note that the HTH motifs are stabilized through interactions with the remainder of the repressor subunits. The N-terminal extension of one subunit wraps around the DNA to contact the minor groove. The HTH-motifs of each monomer are a darker shade of grey. a-Helical regions of the protein are represented as cylinders.



The crystal structure of MarA, a member of the AraC prokaryotic transcriptional activator family, shows a bipartite HTH motif (45). This motif if composed of seven a-helices and folds into two structurally similar subdomains, which both contain an HTH motif and which are connected by helix-4. The recognition helices of either HTH-motif are inserted into adjacent major groove segments on the same face of the DNA. Because of the rather low separation of 27Å, the DNA is bent by 35°. The DNA complex of the *E. coli* transcription factor Rob displays a similar architecture, but only the N-terminal HTH domain engages the major groove of the unbent DNA (46).

3. Homeodomain

If the definition of the HTH motif is relaxed to also allow for longer loops, then many eukaryotic transcriptional regulators can be included. For example, the structures of the yeast mating type protein a-MAT (47, 48), as well as those of the *Drosophila* homeotic proteins Engrailed (49) and Antennapedia (50-52) revealed that they contained an HTH motif. Unlike the prokaryotic HTH domains, isolated homeodomains can fold correctly and bind to DNA with specificity similar to that of the parent protein (24, 53). The overall structure of these homeodomains is visualized rather easily (Fig. 2) (24, 54, 55). Helices 1 and 2 pack against one another in an antiparallel fashion. Helix 3 is amphiphatic, and the hydrophobic face packs against the first two a-helices to which it oriented perpendiculary. Helices 2 and 3 form the HTH motif. The main contacts between homeodomains and DNA are made by residues of helix 3, which lies in the major groove of the DNA and by amino acids in an N-terminal extension.

Figure 2. The overall structure of the DNA complex of the homeodomain of the *Drosophila* protein engrailed (49). The amino-terminal arm of the homeodomain contacts the minor groove of the DNA. Helix 3 contacts the major groove of the DNA and, together with helix 2, constitutes the HTH-motif. The a-helical regions of the protein are represented as cylinders.

Winged HTH-proteins include two or more b-sheets packed against the core of the three a-helices that form the HTH-motif. An extended loop that connects the two b-sheets adjacent to the recognition helix is involved in DNA-binding through contacts to the phosphate backbone. Members of this class include Elk-1 (56), SAP-1 (57), and PU.1 (58) of the ETS family of transcription factors and IRF-1 of the interferon regulatory factors (59).

Besides proteins containing a homeodomain, the eukaryotic HTH family of transcriptional regulators also includes the POU domain proteins (60), yeast heat shock regulatory factor (61), histone H5 (62), rat hepatocyte nuclear factor 3g (63), and the product of the murine c-Myb proto-oncogene (64, 65). The DNA binding motif of Oct-1 contains two HTH-motifs, namely a canonical homeodomain and a POU-specific domain, that, despite poor sequence homology, resembles the HTH motif of the repressors of phage l and 434, except for an extended loop-structure connecting the two helices (66, 67).

The paired domain, which is found in transcription factors such as paired and gooseberry from *Drosophila* and the mammalian Pax1 to Pax9, contains two structurally independent domains (68, 69). The N-terminal domain comprises a short region of antiparallel b-sheet followed by a type II b-turn, three a-helices with a fold resembling the classical homeodomain, and an extended C-terminal tail. The C-terminal domain contains a fold that is similar to a homeodomain.

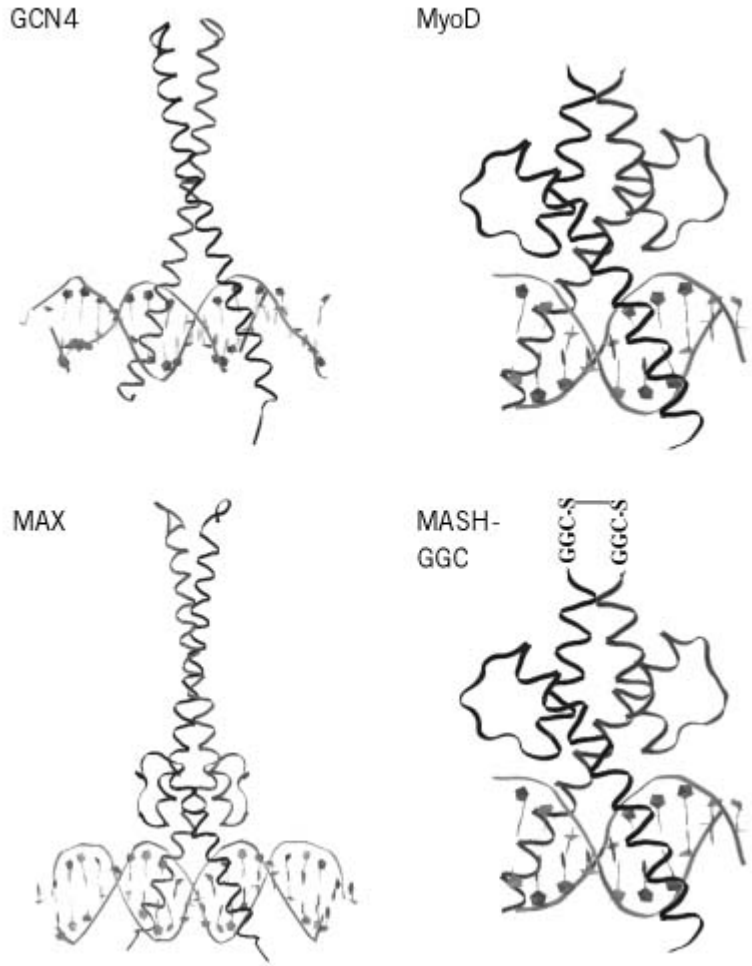
4. MADS-Box Proteins

These proteins have the function of DNA-binding and dimerization integrated into a single protein design. They bind to DNA as a homodimer, and the primary DNA-binding element is an antiparallel coiled coil of the two amphiphatic a-helices (helix-1), one from each subunit. The basic residues of these two a-helices fit into the major grove of the DNA double helix (see MADS-box proteins).

5. Basic Leucine Zipper, Basic Helix-Loop-Helix, and Basic Helix-Loop-Helix Zipper Motifs

The proteins of the basic leucine zipper (BZ), the basic helix-loop-helix (BHLH), and the basic helix-loop-helix-zipper (BHLHZ) families of transcription factors use similar strategies for DNA binding. They all bind to DNA as dimers through a N-terminal recognition helix consisting of clusters of basic residues. The basic region is directly adjacent to the dimerization motif. X-ray structures of GCN4 (70) and Pap1 (71) show that dimerization is mediated by the zipper domain, which contains a heptad repeat of leucine residues (Fig. 3) (70-73). The leucine residues from two zipper domains pack tightly against each other, thereby stabilizing the overall structure of a coiled coil.

Figure 3. The structures of the DNA complexes of the DNA-binding domains of the BZ protein GCN4 (70), the BHLH protein MyoD (74), the BHLHZ protein Max (76), and the engineered MASH-GGC (139). For MASH-GGC, the tripeptide Gly-Gly-Cys was added to the C-terminal end of the BHLH subunit.



Structural of the BHLH proteins MyoD (Fig. 3) (74) and E47 (75) complexed to DNA showed that, in this class, dimerization occurs through a left-handed parallel four-helix bundle. The helices are connected by extended loops.

Combination of the BZ motifs and BHLH motifs led to the BHLHZ family, characterized by a

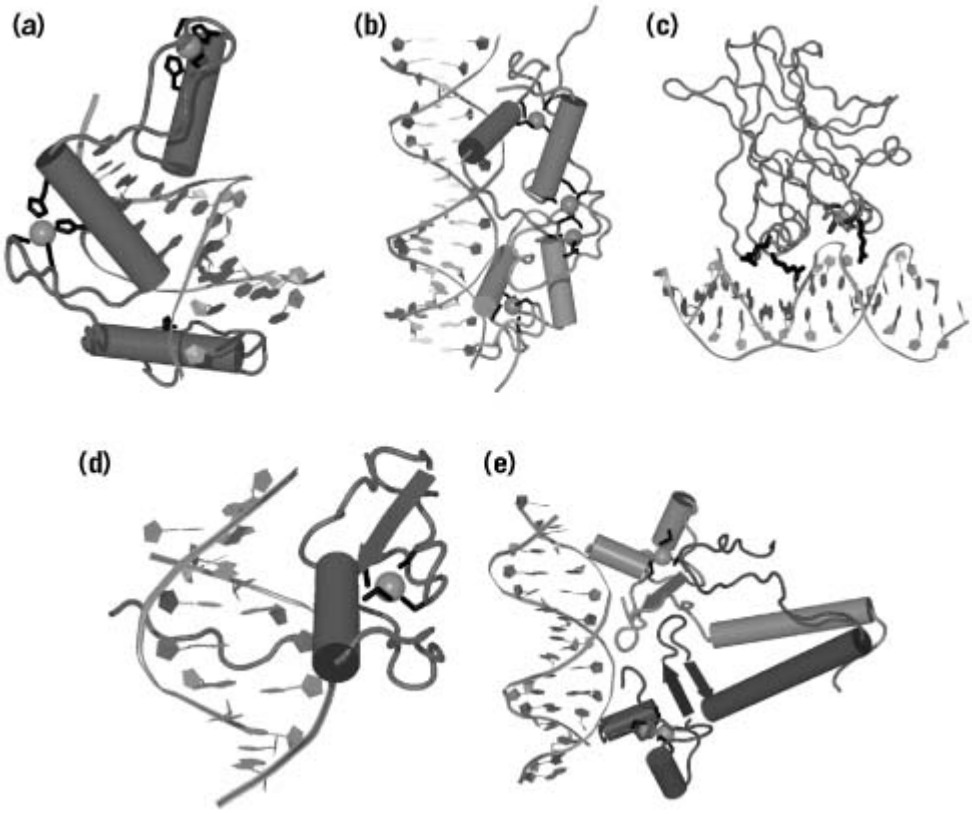
leucine zipper domain that extends from the C-terminus of the BHLH domain (Fig. 3) (76, 77). The zipper domain adds substantial buried surface area to the dimerization domain, thereby increasing both the stability and the DNA binding specificity of the protein (*vide infra*) (see Leucine zipper and helix-loop-helix motif).

6. Zinc Containing DNA-Binding Domains

The family of zinc-bearing DNA-binding motifs is the largest group of eukaryotic transcription factors, and it has been estimated that perhaps 1% of all mammalian genes encode zinc-finger proteins (78, 79). Their abundance might be a consequence of the structural economy of stabilizing modular protein folds through metal ions (80). In sharp contrast to the structural similarities observed within the DNA binding families described above, diversity appears to be the hallmark of the zinc-containing DNA-binding domains. To date, seven subfamilies of Zn-containing proteins have been characterized:

1. Zinc fingers have the same canonical bba structure, stabilized through a hydrophobic core and a tightly bound zinc ion that interacts with two cysteine residues of the second strand and two histidine residues that are part of the a-helix (Fig. 4a). Finger specificity seems to depend on three amino acid residues just before and within the a-helix that make specific contacts to the DNA (81-87). Zinc fingers occur in multiples connected by flexible linkers and can be viewed as independent DNA-binding units. The structures solved comprise ADR1 (88) and SWI5 (89) from yeast, murine Zif 268 (81, 90), the human factors MBP-1 (91), and GLI (92), *Xenopus* Xfin (93), and the *Drosophila* tramtrack protein (94).

Figure 4. Structures of zinc-containing transcription factors. The a-helices and b-sheets are represented as **cylinders** and **arrows**, respectively. (**a**) The global structure of the DNA complex of the three zinc finger peptide of murine Zif268 (81, 90). The three zinc fingers track along the major groove of the DNA, which is contacted through residues of the recognition a-helix, which is part of the bba structure. This domain is held together through a tightly packed hydrophobic core and a Zn ion coordinated to two cysteines and two histidines. (**b**) Overall structure of the dimeric DNA-binding domain of estrogen receptor complexed with DNA (98, 99). In each monomer, one Zn ion stabilizes the conformation of the recognition helix, which fits into the major groove of the DNA, while the second Zn helps stabilize the dimer interface. Each of the Zn ions is coordinated by the side chains of four cysteine residues. (**c**) Ribbon drawing of the DNA complex of the p53 tumor suppressor core domain (108). The core domain structure consists of a b-sandwich that serves as a scaffold to orient a loop-sheet-helix motif and two large loops, the conformation of which is stabilized by a tetrahedrally coordinated zinc. The zinc is bound by the side chains of three cysteines and one histidine residue. The Zn domain orients the side chain of an arginine residue that contacts the minor groove of the DNA, while two arginine residues of the loop-sheet-helix motif mediate contacts with the major groove. (**d**) Illustration of the DNA complex of the DNA binding domain of the chicken erythroid transcription factor GATA-1, (103). A single Zn ion is used to stabilize the core domain of GATA-1, which consists of two irregular antiparallel b-helix. The a-helix and the loop connecting the two antiparallel sheets interact with the major groove of the DNA, while the carboxy-terminal tail wraps around the DNA to contact the minor groove. The b-sheets and the a-helices of GATA-1 are represented as **arrows** and **cylinders**, respectively. (**e**) The structure of the DNA complex of the yeast transcriptional activator PPR1 (106). Two zinc ions are coordinated by six cysteines in each of the two PPR1 subunits. The two central cysteine side chains, thereby, contact both zincs. The two zinc domains lie above the major groove of the DNA, and the DNA contacts are mediated through the residues of the a-helical recognition helices.

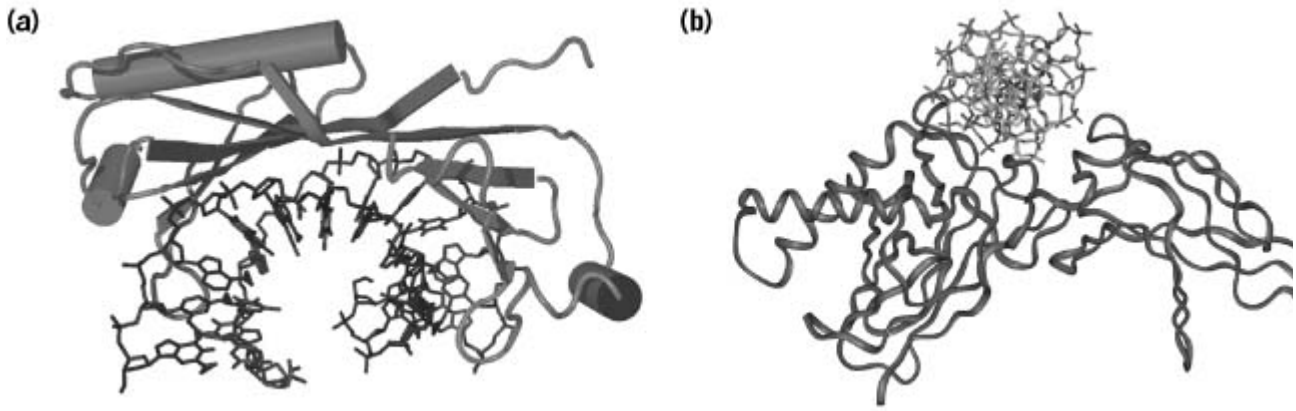


2. The structures of the DNA-binding domains of the glucocorticoid (95-97) and estrogen (98, 99) receptors, the retinoic acid receptor-b (100), and the retinoid X receptor-a (101) revealed a second type of Zn-containing DNA binding motif (Fig. 4b). It has eight cysteine residues; four from each of two peptide loops bind to two zinc ions (78, 95-102). The cysteine residues are, thereby, located C-terminal to an a-helix that fits into the major groove of the substrate.
3. An a-helix located just N-terminal of the cluster of four cysteine residues in the GATA-1 group of Zn-containing DNA-binding proteins also interacts with the major groove (Fig. 4d) (103). The GATA-1 domain is the only known Zn-containing DNA-binding protein that relies on only a single metal core to bind to DNA with high affinity.
4. The yeast proteins GAL4 (104, 105) and PPR1 (Fig. 4e) (106), as well as the fungal protein PUT3 (107), also use an a-helix for interaction with the major groove of the DNA; they contain a unique Zn-binding motif in which six cysteine residues are coordinated to two spatially close Zn-ions (104-106). Two of the cysteines bind simultaneously to both zinc atoms.
5. The tumor repressor p53 (108) (Fig. 4c). The core domain structure of the tumor suppressor p53 (108) consists of a b-sandwich that serves as a scaffold for two large loops, which are held together, in part, by a tetrahedrally coordinated zinc and which interact with the major grove of the DNA and for a loop-sheet-helix motif (Fig. 4c).
6. The human transcriptional elongation factor TFIIS (109, 110). NMR studies revealed that the Cys4 nucleic acid binding domain of the human transcriptional elongation factor TFIIS consists of a three-stranded b-sheet (b-ribbon) (109, 110). The X-ray structure of yeast RNA polymerase II revealed six zinc-binding proteins. The C-terminal Zn-binding module of Rpb9 and Rpb12 fold into a ribbon motif similar to that described for TFIIS (111, 112).
7. Subunit Rpb10 of RNA polymerase from *Methanobacterium thermoautotrphicum* contains an unusual $CysX_2CysX_NCysCys$ Zn binding motif. The Zn atom is located at one end of an unusual cluster of three a-helices (113).

7. DNA Recognition via b-Sheets

Whereas most of the proteins described above rely on an a-helix for the formation of contacts with the major groove of the DNA, the prokaryotic repressors P22 Arc (114-116), P22 Mnt (117, 118), and MetJ (119, 120) use a pair of anti-parallel b-sheets to contact the major groove. No eukaryotic protein is known that uses a b-sheet to contact the DNA's major groove. However, the X-ray structures of DNA complexes of the TATA box-binding proteins (TBPS) (121-124) showed that DNA binding is mediated by TBP's curved eight-stranded antiparallel b-sheet, which provides a concave surface for contacts with the bases in the minor groove and with the phosphate backbone (Fig. 5A). The chromosomal protein Sac7d of the hyperthermophile *Sulfolobus acidocaldarius* uses the triple stranded b-sheet (b3-b4-b5), which is part of a larger five-stranded incomplete b-barrel, capped at the opening by a C-terminal a-helix (125).

Figure 5. **Figure** (**a**) Global conformation of the TBP-DNA complex (122). The protein binds the TATA box from the minor groove side and bends the DNA into the major groove. The a-helices are represented as **cylinders**, and the b-strand are represented as **arrows** (**b**) Structure of the human NF-kB p52 homodimer-DNA complex (128). DNA binding relies a b-barrel with an s-type immunoglobulin fold and is mediated by protein loops.



Runx1-CBFb (126), NFAT (127), NF-kB (128), p53 (129), STAT (130), and the Brachyhury T-Box family of proteins (131) rely on a b-barrel with an s-type immunoglobulin fold for DNA binding. DNA binding is mediated by loops that extend from one end of the Ig-motif (Fig. 5B).

8. Interactions between Transcription Factors

The observation that eukaryotic transcriptional regulators bind to relatively short DNA sequences with modest DNA-binding specificity indicates that nature has chosen a combinatorial approach to regulate transcriptional initiation in eukaryotes. Thus, many genes can be differentially regulated through the use of various combinations of relatively few transcription factors. If the binding reactions of individual transcription factors to their respective sites are independent of one another, the specificities multiply (corresponding to the sum of the free energies of the individual binding reactions). For example, the binding reaction of a MEF-2C dimer and a MyoD/E12 heterodimer to a myogenin minimal promoter containing only an E-box and a MEF-2C binding site (22) would be characterized by a DNA-binding specificity of 1.2×10^3.

DNA-binding reactions, however, often show a high degree of cooperation. A particularly well-characterized case is the cI repressor of bacteriophage l. It binds to the three 17 bp binding sites O_R1,O_R2, and O_R3 of the right l-operator with different affinities and specificities. Therefore, if cI

repressor binds to an artificial DNA sequence containing O_R1,O_R2, and O_R3 separated by linkers long enough to "isolate" the binding sites from one another, the affinity and specificity observed are simply the product of the individual binding reactions. However, the binding reaction of cI repressor to the wild-type operator O_R is highly cooperative, and the quaternary complex with the wild-type sequences is stabilized by 4.8 kcal/mol relative to the case where the binding sites are isolated (132). Of course, cooperative binding relies on a properly folded repressor, and, therefore, it is likely that the specificity of binding is also increased approximately 4,000-fold because the non-specific complex is simply a loose association between the proteins and the DNA. Similarly, two Arc repressors bind cooperatively to the 21 bp Arc operator. When the left or the right operator half-site is occupied by an Arc dimer, the affinity of the second dimer is increased approximately 5,900-fold (133).

The eukaryotic transcriptional activator MyoD binds cooperatively to two sites in muscle-specific enhancer sequences (134). It is known, however, that the specific and non-specific DNA complexes of BHLH-proteins like MyoD are rather similar (135-137). The increases in the DNA-binding affinity might, therefore, not lead to an increase in the DNA-binding specificity. Interestingly, the DNA-binding specificity of basic helix-loop-helix (BHLH) proteins can be affected by alterations of the dimerization motif. The DNA-binding specificity of the bHLHZ transcription factor USF, for example, is dependent on the presence of the coiled-coil domain because its removal led to a dramatic reduction of the DNA binding specificity (138). The BHLH-protein MASH-1 binds to DNA with low sequence specificity (136). When the tripeptide Gly-Gly-Cys was added to the C-terminal end of the BHLH domain, however, a disulfide bond could be formed between the Cys residue of each monomer (Fig 3), and the affinity for E-box containing DNA was increased, while the stability of the complex with heterologous DNA was reduced (139). A similar increase in the DNA binding specificity of MASH-1 was obtained when the C-terminus of the first BHLH subunit was covalently linked to the N-terminus of the second through the introduction of a peptide linker, to generate a "single-chain dimer" (140). Circular dichroism spectroscopy revealed that, like wild type MASH-BHLH, the "single-chain dimers" of MASH-1 adopted only partly folded structures in the absence of DNA, but they underwent a folding transition to mainly a-helical conformations on DNA binding. The affinity of the "single-chain dimers" for E-box containing DNA sequences was increased almost 30-fold when compared with wild-type MASH-BHLH, while the stability of the complex with heterologous DNA was only 10 times greater. The free energy of transferring a protein molecule from a nonspecific to a specific site was, therefore, increased more than threefold through the introduction of the peptide linker.

Covalently linking the subunits of MASH-1, either through a disulphide bond or through a peptide linker, might reduce the number of conformations accessible to the protein in the disordered state and, therefore, diminish the entropic penalty that accompanies folding and DNA-binding. Limiting the number of accessible conformations of the basic region of BHLH-proteins could stabilize the complex with specific DNA and destabilize the complex with nonspecific DNA sequences, thereby increasing the overall DNA-binding specificity. (NMR) spectroscopic studies showed that, while the flexibility of side chains at the protein-DNA interface is restrained when compared with the uncomplexed state, it is still greater than the flexibility of side chains in the protein core (141). A precedent for such a mechanism is provided by the tryptophane repressor of *E. coli.* Replacing Ala77 with valine results in a local stabilization of the DNA-binding domain of the repressor, reduced conformational flexibility (142), and increased specificity through reduced affinity for nonspecific DNA (143). Similarly, metallopeptide complexes containing two copies of a peptide comprising the basic and the spacer region of the bZ protein GCN4 assembled into a dimer through a bis(terpyridyl) iron(II) complex displayed increased site specificity when compared with native GCN4 (144). A similar observation was made with a single-chain variant of the P22 Arc repressor, in which the subunits were connected through a 15-residue peptide linker (145).

Substitution of Cys for Va152 of the Lac repressor, which permits disulfide formation between the two N-terminal DNA binding domains, resulted in an increase in the stability of the operator

complex by approximately six-fold relative to the wild-type protein (146). This increased affinity derives from the decreased entropic cost in properly orientating the two N-terminal domains for operator binding.

Within an eukaryotic cell, similar increases of the DNA binding affinity and specificity might result from the interaction with other components of the transcriptional machinery. While one side of helix-1 of BHLH proteins directly contacts the major groove of DNA, the other side is exposed to the solvent providing an ideal contact surface for additional proteins. The significantly reduced DNA binding specificity of BHLH proteins when compared with proteins containing an HTH-motif might, in part, be the consequence of the fact that the conformation of the recognition helix in the latter is stabilized through interactions with other parts of the protein (26). Such interactions should reduce the conformational flexibility of the recognition helix, thereby increasing the specificity of the proteins.

MASH-1, a BHLH protein that promotes the differentiation of neuronal precursor cells, could be converted into a protein capable of inducing myogenesis in fibroblasts by replacing Leu130 of MASH-1 with lysine and introducing an additional turn into its basic recognition helix (147). These changes did not significantly alter the DNA binding properties of the proteins in cell free conditions. Crystallographic data for the DNA complexes of MyoD suggested that Leu130 pointed away from the DNA into the solvent. The identity of the amino acid in position 130 appeared to be important for protein-protein interactions that might affect the DNA binding specificities displayed by BHLH-proteins in vivo and could, thereby, form the molecular basis of the different physiological properties of the myogenic and neurogenic BHLH proteins.

Similarly, both the human T-cell leukemia virus type-1 Tax protein (148-150) and the hepatitis B virus protein pX (151) affect the DNA binding properties of their target proteins. The nonhomologous proteins Tax and pX interact with the basic region of bZ proteins to enhance their DNA-binding affinity and discriminate between peptide-DNA complexes based on the identity of the DNA target site (148, 152, 153). Consistent with the model presented above, binding of Tax and pX to various bZ proteins also changed their relative affinities for different DNA-binding sites (150, 151), thereby providing a molecular rationale for the altered transcriptional patterns observed in infected cells (154-157).

The Hox-gene products are a set of transcription factors that are important for the embryonic development of multicellular organisms (158). Surprisingly and contrary to the high specificity of their biological function, many Hox proteins, such as *Drosophila* Ultrabithorax (Ubx), display only modest DNA binding specificity on their own. However, together with the homeoprotein Extradenticle (Exd) (or Pbx1, which is the mammalian homologue of Exd), they bind DNA as heterodimers with significantly increased affinity and specificity (159, 160). The homeodomains of the heteodimer bind in a tandem manner to opposite faces of the DNA. The co-operative interactions arise from the YPWM amino-acid motif of Ubx that forms a reverse turn and inserts into a hydrophobic pocket on the Exd homeodomain surface (161) (Fig. 6). Similarly, the homeodomain protein MATa2 and the MADS box protein MCM1 exemplify combinatorial control in determining the mating type in *Saccharomyces cerevisiae* (162). The otherwise flexible amino-terminal extension of the MATa2 homeodomain forms a b-hairpin in the complex that grips the MCM1 surface through parallel b-strand hydrogen bonds and hydrophobic interactions (163). This interaction, together with MCM1 induced DNA bending, which brings the two proteins into closer contact, forms the basis of the observed cooperation. Similar cooperative binding was observed for the ternary DNA complexes of SAP-1 and SRF (164), MATa2 and Matal (165), an OCA-B (OBF-1, Bob1) peptide and the Oct-1 POU domain (166), and NFAT1 and the heterodimer of Fos and Jun (127).

Figure 6. The DNA complex of Ubx and Exd (161). The Ubx homeodmain is shown in **black** and the Exd homeodomain in **grey**. The **dissolved line** represents the disordered linker, which connects the YWPM motif to the

Ubx homeodomain. This motif contacts a hydrophobic pocket of the Exd homeodomain, which is the source of the cooperative interaction between the two proteins.
