on the same polypeptide chain (11). A second system of protein phosphorylation in eubacteria corresponds to the sensor kinase/response regulator, often termed the two-component system (12). In such systems, a sensor kinase, generally membrane-associated, phosphorylates itself on a histidine residue in response to external stimuli [eg, chemoattractant, nutrient, osmotic pressure, etc. (Fig. 1**b**)]. The phosphoryl group is then transferred to an aspartic acid residue located on a distinct protein or on the same polypeptide chain, the response regulator, triggering the appropriate biochemical response. This type of signal transduction seems to be evolutionarily very ancient, because it has now been also identified in Eucarya and Archea (10). In the third phosphorylation system, described thus far only in bacteria, the phosphoryl group donated by phosphoenolpyruvate (PEP) is passed down a chain of phosphorylatable proteins (9). Phosphorylation of these proteins occur on histidine and cysteine residues (Fig. 1**c**). Such PEP-dependent systems are implicated in a wide variety of regulations, including carbohydrate metabolism, transcription, and adenylate cyclase. Protein phosphatases are less well-characterized in prokaryotes. Relatives of the PPP phospho-serine/threonine protein phosphatases gene family have been identified in Archea and in eubacterial bacteriophages (10). Finally, it should be noted that bona fide tyrosine phosphorylation has been demonstrated in bacteria, as well as the presence of potential tyrosine phosphatases that bear a similar sequence signature to that of eukaryotic tyrosine phosphatases in their active site (10).

3. Phosphorylation in Eukaryotes

Regulatory protein phosphorylation in eukaryotes occurs primarily on serine, threonine, and tyrosine residues (Fig. 1**a**). The great majority of the protein kinases responsible for the phosphorylation of these residues have a conserved catalytic **domain** that belongs to a single gene family. It has been estimated that more than a thousand different protein kinases can be coded in the genome of higher eukaryotes (13, 14). The genome of *Saccharomyces cerevisiae* contains genes for 113 such conventional protein kinases (15). Interestingly, a number of lipid kinases have a catalytic domain related to that of conventional protein kinases. Some of these enzymes are capable of autophosphorylation; and at least one of them, DNA PK, is a genuine protein kinase, stimulated by the ends of double-stranded DNA (16). In addition, histidine kinases related to the bacterial two-component system have been identified in several eukaryotes (Fig. 1**b**). They are, for example, involved in the responses of yeast to osmotic shock (17) and of plants to ethylene (18). An original group of serine kinases related to histidine kinases corresponds to the mitochondrial protein kinase that phosphorylates a-ketoacid dehydrogenases (11).

The catalytic domains of regulatory protein phosphatases in eukaryotes belong to several gene families: Serine/threonine phosphatases belong to two gene families of metal-requiring enzymes, PPP and PPM (19), whereas tyrosine and dual-specificity phosphatases form a superfamily of genes that have a common signature sequence in their active site (Cys–X_5–Arg) and a common catalytic mechanism. These enzymes are grouped in four families: classical phosphotyrosine phosphatases (PTPs), low-molecular-weight PTPs, VH1-like dual-specificity phosphatases, and cdc25-like dual-specificity phosphatases (20).

4. Specificity of Protein Phosphorylation

Protein kinases display a high degree of substrate specificity. First, the vast majority phosphorylate either serine/threonine or tyrosine side chains, whereas only a few kinases have a dual specificity, for both threonine and tyrosine. In addition, protein kinases are highly sensitive to the immediate environment of the phosphorylated residue (21). Thus, specific **consensus sequences** have been identified for many of them (Table 2). In some cases, the specificity also depends on higher-order determinants, such as interactions between the protein substrate and the protein kinase at sites located at distance from the phosphorylated residue. In living cells, the proximity between the protein kinase and its substrate plays an important role. This is achieved by specific targeting mechanisms, which enrich the kinase concentration at particular sites of the cell (22, 23). There are also a number of scaffolding proteins that associate several enzymes, including kinases and/or

phosphatases and their substrates (24). In the case of protein phosphatases, the nature of the sequence surrounding the phospho-amino acid to be dephosphorylated seems generally less critical than in the case of protein kinases; and the role of higher-order determinants, as well as that of targeting processes, appears fundamental (25, 26). It should be pointed out that, with the exception of some monosubstrate systems, there is no perfect match between the substrate specificity of most protein kinases and phosphatases, implying a complex intertwining of the regulation by these enzymes.

Table 2. Examples of Consensus Phosphorylation Sites for Protein Kinase

cAMP-dependent protein kinase	Arg/Lys-Arg-Xxx-Ser*
Ca^{2+}-calmodulin-dependent kinase II	ArgXxxXxxSer*/Thr*
Protein kinase C	Arg/Lys (Xxx)1-2 Ser*/Thr* Xxx-Arg/Lys
Casein kinase 1	*Acid*-Xxx-Xxx-Ser*
Casein kinase 2	Ser*/Thr* Xxx-Xxx Asp/Glu
MAP-kinases, cyclin-dependent kinases	Ser*/Thr* Pro
EGF-receptor tyrosine kinase	Glu/Asp-Tyr*-*Hyd*

5. Methods to Study Protein Phosphorylation

5.1. General Methods to Study the State of Phosphorylation of Proteins

(detailed descriptions of methods can be found in Ref. 27-30). The most commonly used approach is metabolic **radiolabeling** of cells of interest with ^{32}P-orthophosphoric acid (sometimes called "front-phosphorylation"). ^{32}Pi is taken up by cells, incorporated into endogenous ATP (as well as in many other phosphorylated molecules), and used to phosphorylate proteins, lipids, and nucleic acids. Labeled phosphoproteins can be studied by electrophoresis (usually two-dimensional gel electrophoresis) or following **immunoprecipitation** with specific **antibodies**. However, proteins are often phosphorylated on several sites, which can have different physiological meanings, and other approaches are required to analyze independently the phosphorylation of each of them (see below). Moreover, the amount of ^{32}P incorporated in a given site does not reflect directly the stoichiometry of phosphorylation of this site, but rather the turnover rate of the phosphoryl group. That is, a site phosphorylated at a high stoichiometry but with a low turnover rate (eg, "constitutive phosphorylation") will appear poorly labeled, whereas a residue phosphorylated at a low stoichiometry, but with a high turnover rate, will appear intensely labeled. The levels of labeling are also dependent on the specific activity of the intracellular ATP pools, which may vary, depending on the cell population or physiological status. Therefore, other methods have been developed to avoid these pitfalls. In "back-phosphorylation" assays, proteins of interest are isolated in conditions in which their phosphorylation state is preserved. They are then phosphorylated stoichiometrically *in vitro* with g^{32}P-ATP and a purified kinase, active on the phosphorylation site of interest. Thus, the higher the level of phosphorylation of the site *in vivo*, the lesser radioactive phosphate is incorporated *in vitro*. The use of this method is limited, however, by the requirement for a highly active purified protein kinase and by its low sensitivity. An alternative approach that is enjoying considerable success is the use of phosphorylation-state-specific antibodies. Some of these

antibodies react with a phosphorylated amino acid, almost independently of its sequence environment. For example, antibodies specific for phospho-tyrosine are extremely useful tools in the study of protein tyrosine phosphorylation. Moreover, specific antibodies can be raised against synthetic phosphopeptides encompassing the phosphorylated site of a protein of interest. Such antibodies are specific for a given protein phosphorylated at a particular site, and they provide powerful tools that can be used for immunoblotting, immunocytochemistry, and other approaches.

Phosphoproteins are often studied by one- or two-dimensional electrophoresis. In nondenaturing conditions (eg, **isoelectrofocusing**), the presence of a phosphorylated residue shifts the electrophoretic mobility of the protein toward a more acidic form. In the presence of **SDS**, phosphorylation of a protein may have no effect on its electrophoretic mobility, or it may increase its mobility and its apparent size. The slowing of the protein mobility by phosphorylation during SDS-PAGE is often attributed to a decrease in the charge density due to decreased binding of SDS to the phosphorylated protein. In contrast, it is noteworthy that phosphorylation at specific sites may increase the mobility of some rare proteins in SDS-PAGE.

5.2. Methods for Identifying the Phosphorylated Amino Acid(s)

Following prelabeling with ^{32}P or *in vitro* phosphorylation with g ^{32}P-ATP, the nature of the phosphorylated residues can be determined by acid hydrolysis of the peptide bonds and separation of phospho-serine, phospho-threonine, and phospho-tyrosine by thin-layer electrophoresis. Phospho-histidine and phospho-aspartate are extremely acid-labile and cannot be identified by this approach. On the other hand, the resistance of phospho-tyrosine to alkaline pH is used to study this phospho-amino acid preferentially. The phosphopeptides generated by partial **proteolysis** of a ^{32}P-labeled phosphoprotein with specific endoproteinases can be studied by two-dimensional phosphopeptide maps (usually a combination of thin-layer electrophoresis and chromatography). Such two-dimensional phospho-**peptide maps** are very useful for comparing the sites phosphorylated on the same protein under various circumstances, *in vivo* or *in vitro*. Phosphopeptides can also be separated by high-performance liquid chromatography (HPLC) and, if sufficient amounts of material are recovered, submitted to automatic protein sequencing, allowing the identification of the phosphorylated residue and its surrounding protein sequence. The use of powerful technologies of matrix-assisted laser desorption/ionization (MALDI) mass spectrometry now provides an interesting alternative approach to identify phosphorylation and other post-translational modifications. Site-directed mutagenesis of individual residues (replacement of a “phosphorylatable” residue by a “nonphosphorylatable” one—for example, replacement of a serine or a threonine by an alanine, or of a tyrosine by a phenylalanine) is often used to test the phosphorylation of a precise residue. Although this approach is extremely useful, it should be kept in mind that the information obtained is indirect and that such mutations may have consequences on other properties of the protein other than preventing phosphorylation of the mutated residue.

6. Effects of Phosphorylation on the Properties of Proteins

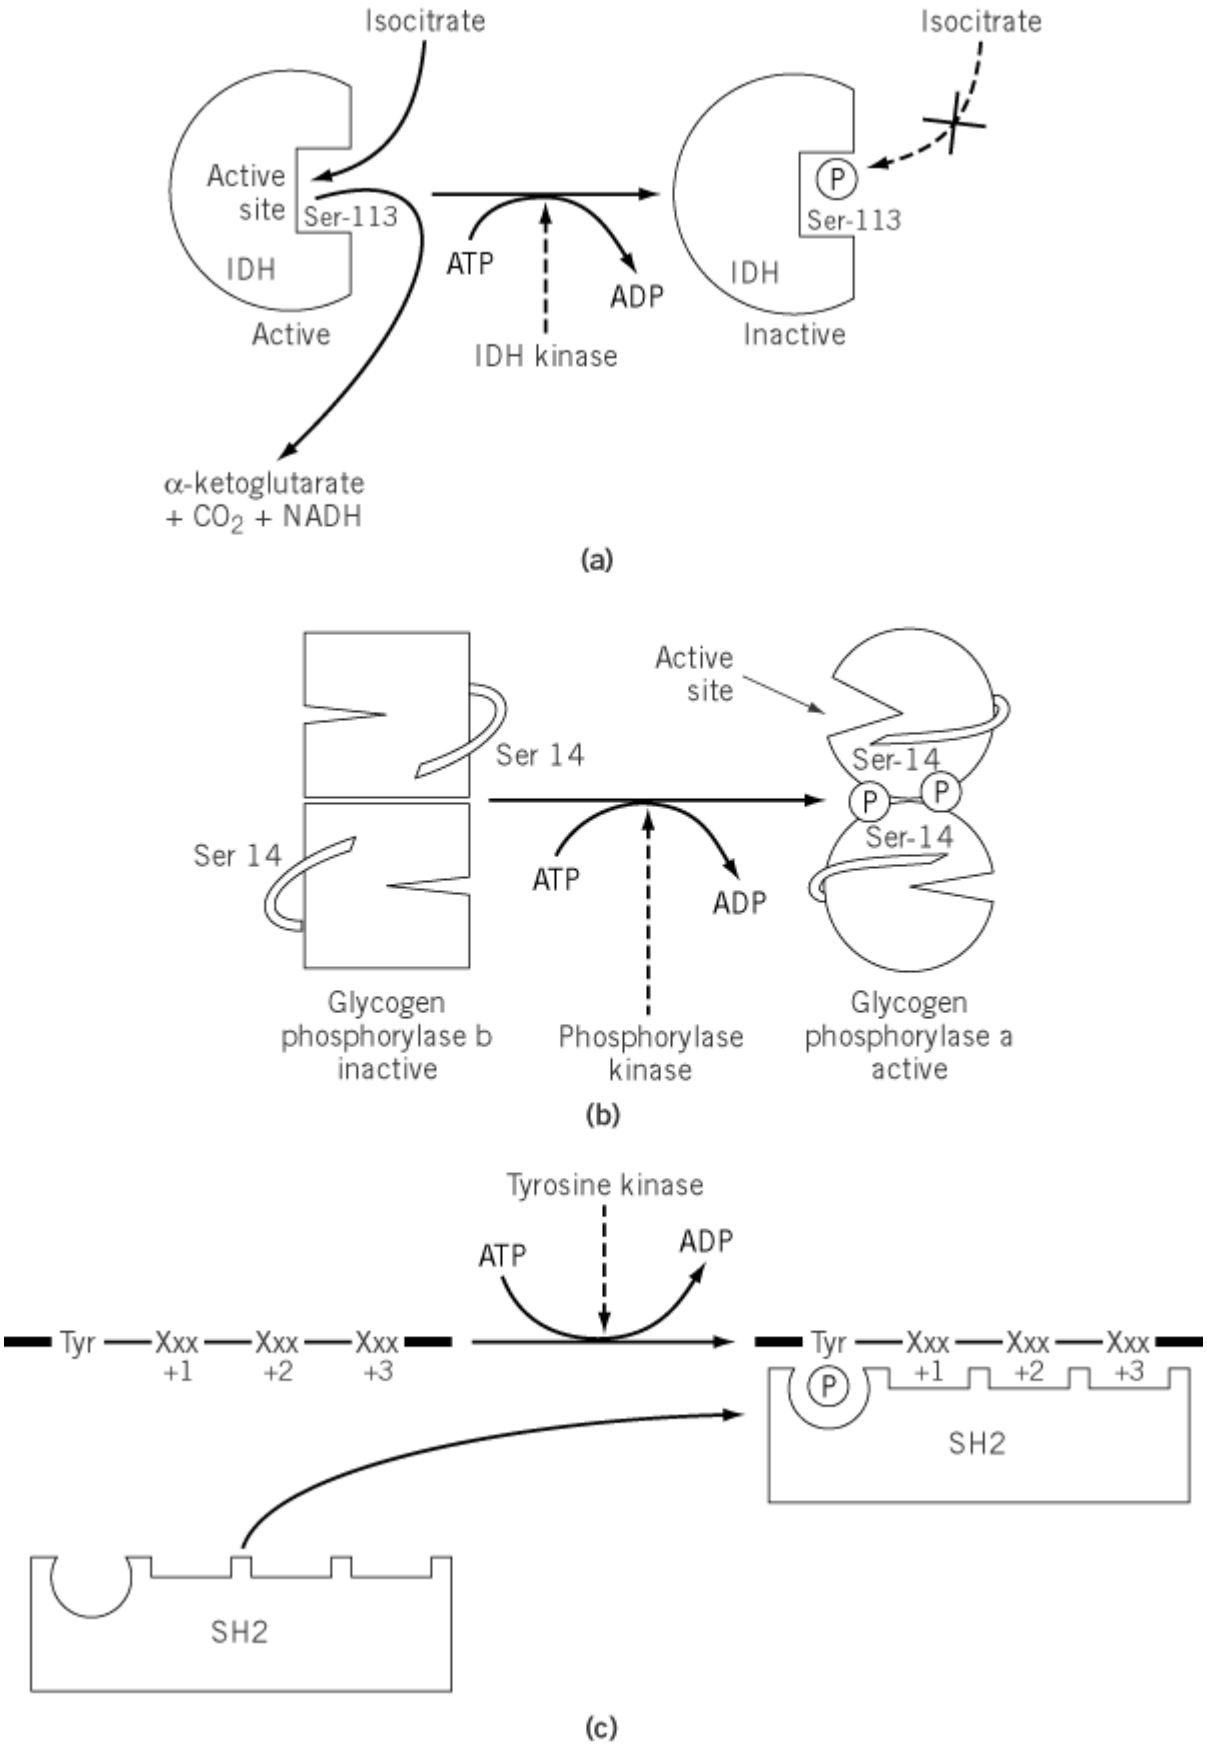
The effects of phosphorylation on the properties of many proteins are known to be functionally important. They include the activation or inhibition of enzymes, the opening or closing of **ion channels**, the increase or decrease in the activity of transcription factors, the aggregation or disassembly of **cytoskeletal** components, and many other effects. There are only a few cases, however, in which the precise molecular mechanism by which phosphorylation of a specific residue brings about the functional changes observed is known in detail. The consequences of the phosphorylation of an amino acid residue can be only local, or they can be amplified in the three-dimensional protein structure. Phosphorylation can also alter the interactions of a protein with others. A phosphate group being bulky and highly charged (two negative charges at physiological pH), its presence alters dramatically the properties of the amino acid side chain to which it is bound. It is often attempted to mimic the consequence of phosphorylation of a residue by its mutation to a negatively charged amino acid (**aspartate** or **glutamate**). In some cases, such mutations reproduce some of the effects of phosphorylation, while they prevent the normal phosphorylation of the

corresponding residues. However, the size and the charge of the carboxyl group are less than those of a phosphoryl group, accounting for the many failures of this approach.

6.1. Local Effects of Phosphorylation on the Properties of Proteins

One example of a protein in which phosphorylation modifies dramatically the activity of an enzyme by a local action on the active site is isocitrate dehydrogenase (IDH), an enzyme regulated by phosphorylation in plants and bacteria. In the unphosphorylated state, IDH is active and catalyses the oxidative decarboxylation of isocitrate to a-ketoglutarate, a critical step in the Krebs citric acid cycle. In the presence of high levels of ATP, IDH is switched off by phosphorylation, and citrate is funneled to the glyoxylate cycle, a biosynthetic pathway that allows plants and bacteria to grow on acetate. *Escherichia coli* IDH is phosphorylated on Ser113 by an enzyme that is also able to dephosphorylate the same residue (a tandem kinase/phosphatase; see above). Ser113 is located in the substrate binding site, near the active site of the enzyme (31). Phosphorylation of this serine prevents isocitrate binding by steric hindrance and electrostatic repulsion (Fig. 3**a**).

Figure 3. Effects of phosphorylation on proteins. (**a**) Local effects of phosphorylation on isocitrate dehydrogenase (IDH). IDH transforms isocitrate into a-ketoglutarate, with concomitant production of CO_2 and reduction of NAD^+ in NADH. In *E. coli* IDH, phosphorylation of serine-113 in the active site prevents the binding of the substrate and inactivates the enzyme. (**b**) Allosteric activation of glycogen phosphorylase by phosphorylation. Phosphorylase is a homodimer; phosphorylation of Ser14 in both subunits leads to rearrangement of the amino-terminal region, modification of the subunit interaction, and changes in the tertiary and quaternary structure of the enzyme, making the active site more accessible to the substrate. (**c**) Regulation of SH2-domain binding by tyrosine phosphorylation. When particular protein sequences are phosphorylated on tyrosine residues, they bind with high affinity to specific SH2 domains. The presence of phosphotyrosine is necessary for the binding, but the specificity of the interaction is achieved by the recognition by the SH2 domain of the residues on the carboxy-terminal side of the phosphorylated tyrosine (Xxx +1, +2, +3). See the text for references. Ⓟ, phosphate.



Another example of a well-studied local effect of phosphorylation is provided by the structural studies of protein kinases themselves (32). For the protein kinases to be active, a peptide loop in the

vicinity of the active site, termed the *activation loop* or *T loop*, must be correctly positioned. In many protein kinases, the correct positioning of the activation loop requires its phosphorylation on one or two residues. Interestingly, in some cases the phosphorylation appears constitutive (eg, protein kinase A), whereas in others (eg, mitogen-activated protein kinases, MAP kinases) the phosphorylation of the activation loop is a fundamental regulatory step, catalyzed by a specific activating protein kinase.

6.2. Effects of Phosphorylation on the Overall Structure of Proteins

Phosphorylation of a single residue can have dramatic consequences on the tertiary structure and quaternary structure of a protein, as demonstrated by the study of the X-ray crystallography structure of glycogen phosphorylase in the phosphorylated and nonphosphorylated states (33). Phosphorylase is a homodimer, and phosphorylation occurs on a serine in the amino-terminal region of each peptide chain (Ser14), located strategically at the subunit interface. Phosphorylation of this serine leads to the reorganization of the amino terminus of each subunit and the modification of its interaction with the other subunit. As a consequence, the enzyme is stabilized in a form in which the active site, located at a distance from the phosphorylated serine, becomes more accessible to the substrate (Fig. 3**b**). In this case, the effects of phosphorylation on the structure of the enzyme are comparable to those occurring during classical **allosteric** activation, except that the effects of phosphorylation are due to a covalent modification of the enzyme, and not to ligand binding.

6.3. Effects of Phosphorylation on Protein–Protein Interactions

Protein phosphorylation can have dramatic regulatory effects on protein–protein interactions, as disclosed by the study of protein tyrosine phosphorylation. Indeed, a 100-residue domain first identified in Src, after which it was termed Src-homology 2 (**SH2**), and then found in many other proteins, was shown to bind specific peptides phosphorylated on tyrosine (34, 35). Phosphorylation of the tyrosine residue is necessary for binding, but the specificity of the interaction is achieved by the recognition of additional residues, located on the carboxy-terminal side of the phosphorylated tyrosine, by the SH2 domain (Fig. 3**c**). Binding of SH2 domains to specific peptide sequences phosphorylated on tyrosine residues allows the clustering of enzymes directly or via adapter proteins, around activated growth-factors receptors. Such enzymes, including **phosphatidylinositol-3-kinase**, **phospholipase Cg**, or **guanine-nucleotide exchange factors**, are thus brought into the vicinity of their membrane-associated substrates. SH_2-mediated clustering triggers the cascades of reactions responsible for the effects of growth factors. SH2 domains can also have very different functions, such as maintaining a protein in an inactive state, as in the case of Src-family tyrosine kinases (36, 37). A carboxy-terminal phosphorylated tyrosine is involved in an intramolecular interaction with the SH2 domain, placing the enzyme in a closed conformation unable to reach its substrates. Activation results from dephosphorylation of the carboxy-terminal tyrosine, or by displacement of the SH2 domain by a competing phosphopeptide. Additional domains that interact specifically with phosphorylated proteins have been identified, including PTB domains (phosphotyrosine-binding) (38) and 14–3–3 proteins, whose interaction with their partner proteins appears to require phosphorylation of the latter on a serine residue (39).

7. The Place of Protein Phosphorylation in the Signal Transduction Networks

Many signal transduction systems in cells use several modules whose hierarchical organization allows powerful amplification and precise modulation. Protein phosphorylation is involved in most of these transduction systems, either as an output mechanism, by altering the properties of target proteins, or as a module of information processing. Indeed, phosphorylation reactions in cells often occur in cascades in which activation of a first protein kinase phosphorylates and activates a second protein kinase, which, in turn, phosphorylates and activates a third kinase, and so on. This situation may account in part for the very large number of protein kinases, and it apparently has a number of interesting properties (40, 41). First, phosphorylation cascades allow amplification of the signal: One molecule of the first activated kinase can phosphorylate several secondary kinases, which can each phosphorylate several tertiary kinases, and so on. Another property of these cascades is to acquire kinetic properties, such as positive or negative **cooperativity**, similar to those of allosteric enzymes,

even if the kinases composing the cascade themselves follow classical Michaelis–Menten kinetics . Thus, protein kinase cascades can convert graded inputs into switch-like outputs (42). Finally, the kinase cascades provide many levels of regulation and possible cross-talks between different regulatory pathways. Thus, it is likely that the organization of protein kinases in cascades confers strong evolutionary advantages, as attested by the very high degree of conservation of many of these cascades.

8. Examples of Phosphorylation Dysfunction in Human Diseases

As mentioned above, virtually all intracellular biological processes are regulated to some extent by protein phosphorylation. Thus, it is not surprising that dysfunction of these reactions may be responsible for some pathological states, including in humans. Protein kinases and phosphatases regulate cell growth, and a number of mutations leading to the uncontrolled activation of phosphorylation pathways are oncogenic (43, 44). Several oncogenes are tyrosine kinases (eg, v-Src, v-Fyn, v-ErbB, Met) or serine/threonine kinases (eg, Raf1, Mos) that are activated by mutation, whereas it is the loss of function of protein tyrosine and phospholipiol phosphatase PTEN that is oncogenic (45). Loss of function of protein kinases is also responsible for various genetic diseases, including immune deficiency by the absence of g-globulins [mutation of a nonreceptor tyrosine kinase in Bruton's disease (46)], intestinal palsy [mutation of a receptor tyrosine kinase Ret in Hirschprung's disease (47)], or myotonic dystrophy [mutation of a serine/threonine kinase (48)]. Conversely, protein phosphatases are used as weapons by some pathogenic organisms. For example, one of the virulence genes of *Yersinia* bacteria, including the agent of bubonic plague, is a phosphotyrosine phosphatase (49). Some environmental toxins exert their effects by stimulating protein kinases irreversibly (eg, stimulation of protein kinase C by oncogenic **phorbol esters**) or inhibiting protein phosphatases (inhibition of serine/threonine phosphatases by okadaic acid or microcystins, which are responsible for food poisoning) (50). On the other hand, the immunosuppressant drugs that have allowed the recent progress in organ grafting, cyclosporin A and FK506, act by inhibiting calcineurin, a Ca^{2+}/calmodulin-dependent protein phosphatase (51). Thus, the large number of protein kinases and phosphatases, and their involvement in numerous biological functions, has prompted many investigators to try to develop specific inhibitors or activators of these enzymes as potential therapeutic tools.

Phosphotransferase

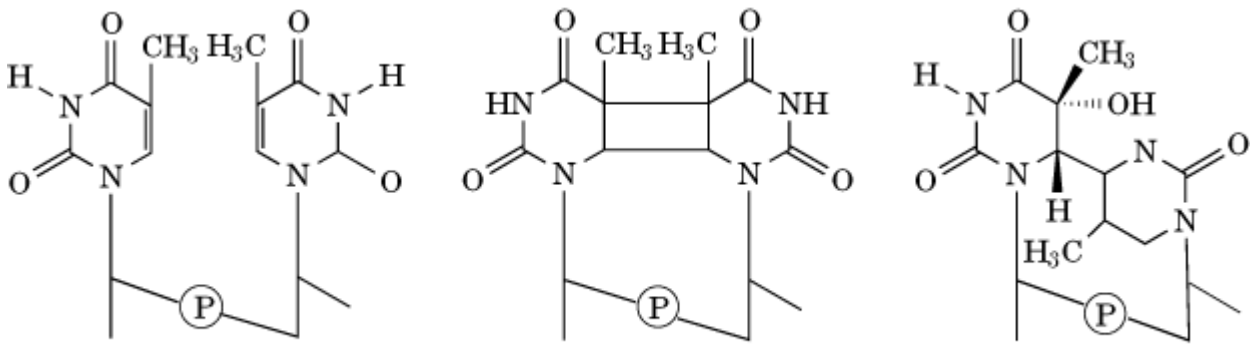
Phosphotransferases form a large group of enzymes that are involved with the transfer of a g-phosphoryl group from ATP, or another nucleoside triphosphate, to an acceptor molecule (see Kinase). They are divided into groups according to the identity of the phosphoryl group acceptor. These acceptors can be alcohols and carboxylic acids, as well as nitrogenous and phosphorylated compounds . All phosphotransferases have an essential requirement for a bivalent metal ion (see Metal-Requiring Enzymes).

Photolyase/Photoreactivation

Photoreactivation is the reversal of the effects of ultraviolet (UV) light (200 to 300 nm) by simultaneous or subsequent exposure of the organism to near UV-visible (300 to 500 nm) light (1, 2). Photoreactivation prevents the induction by UV light of growth delay, mutation, and cell death. Although several factors contribute to the phenomenon of photoreactivation, the main mechanism involved is the reversal of UV-induced pyrimidine dimers in DNA by the enzyme called photoreactivating enzyme, or DNA photolyase (3). DNA photolyase is the only known enzyme to employ light energy to catalyze a chemical reaction (3).

The two major lesions induced in DNA by UV light are cyclobutane pyrimidine dimers (Pyr<>Pyr) and [6–4] photoproducts (Pyr[6–4]Pyr) (Fig. 1). There are separate photolyases that are specific for Pyr<>Pyr and for [6–4] photoproducts (4, 5), but no known enzyme can act on both lesions. The structures and reaction mechanisms of the two types of photolyases are similar and may be summarized as follows. Each consists of a single polypeptide chain of 55 to 65 kDa containing a chromophore that acts as a photoantenna (folate or deazaflavin) and a catalytic cofactor ($FADH_2$) (6-9). It binds to the photodamage in DNA in a light-independent manner, producing a relatively stable enzyme-substrate complex. Upon exposure to light, the enzyme breaks the bonds that link the two pyrimidines to one another, generates standard canonical bases as products, and then dissociates from the repaired DNA. In contrast to many other enzymatic reactions that involve **electron transfer**, catalysis by photolyase involves a cyclic electron transfer and is not a **redox** reaction, in that upon completion of the enzymatic reaction the redox states of the enzyme and the substrate remain the same (6).

Figure 1. The two major photoproducts produced in DNA by ultraviolet light from (**a**) thymine dinucleotide: (**b**) the cyclobutane thymine dimer, and (**c**) the [6–4] photoproduct. Similar photoproducts arise from other adjacent dipyrimidines in DNA.



1. Evolution

Photolyases are flavoproteins, yet the primary sequences of the apoenzymes do not reveal any obvious homology to the signature sequences found in other flavoproteins (4). Instead, photolyases have remarkable sequence homology to blue-light photoreceptors (10), which regulate circadian rhythms in organisms ranging from mustard to humans (11-13). It appears that the necessity for the flavin cofactor to function from the light-excited state has imposed unique constraints on the flavin binding site of photolyase/blue-light photoreceptor family of proteins, such that the active-site geometry of these proteins is different from all other flavoproteins that carry out catalysis with ground-state flavin.

The distribution of the members of the photolyase/blue-light photoreceptor family in the biological world does not fit a readily defined pattern of evolutionary selection. The coliform bacterium *Escherichia coli* contains photolyase, but the soil bacterium *Bacillus subtilis* does not. The budding **yeast** *Saccharomyces cerevisiae* has the enzyme, but the fission yeast *S. pombe* does not. *Drosophila melanogaster* possesses cyclobutane pyrimidine dimer photolyase, [6–4] photolyase, and blue-light photoreceptor (14), while humans lack photolyase but express two blue-light photoreceptor proteins. Table 1shows the expression pattern of this class of proteins in select members of the "three kingdoms of life": bacteria, archaea, and eukarya. No general rules emerge from this table. The only rules that appear to have arisen from investigations of these groups of proteins are the following. (i) Cyclobutane photolyase has been detected in bacteria, plants, and animals through marsupial animals (15), but it has not been found in placental mammals such as human (16) and mouse. (ii) The [6–4] photolyase has been found in plants, insects (*Drosophila*), and some vertebrates (Xenopus, rattlesnake), but not in mammals such as human or mouse, nor in bacteria. (iii) Blue-light photoreceptors have been found in plants (Arabidopsis, mustard) and animals (*Drosophila*, human, and mouse), but not in bacteria. (iv) Of all bacterial and eukaryotic **viruses** investigated, photolyase has, so far, been found only in a grasshopper virus.

Table 1. Distribution of the Photolyase/Blue-Light Photoreceptor Family of Proteins in the Biological World

Bacteria		Archaea			Eucarya	
E. coli	***B. subtilis***	***M. thermoauto***	***M. janaschii***	***S. cerevisiae***	***D. melanogaster***	***H. sapiens***

Photolyase	Yes	No	Yes	No	Yes	Yes	No
[6–4] Photolyase	No	No	No	No	No	Yes	No
Cryptochrome	No	No	No	No	No	Yes	Yes

The tissue distribution of photolyase in animals that possess the gene is rather surprising. It is highly expressed in *Drosophila* ovaries, where it is expected to protect germ cells from UV damage. However, it is also expressed in all internal organs of opossum, including high levels of expression in the brain. Considering the nocturnal nature of the opossum, and the low probability even in bright daylight of UV and photoreactivating light penetrating the skull of the opossum, this expression pattern remains enigmatic.

2. Structure

Photolyases consist of a single polypeptide of 500 to 700 amino acid residues and two noncovalently bound cofactors/chromophores. One of the chromophores is always flavin adenine dinucleotide (FAD), and the other is either a pterin (methenyltetrahydrofolate in the case of *E. coli* and *S. cerevisiae* photolyases) or deazariboflavin. Deazariboflavin is considered an ancient molecule, and photolyases with this cofactor have been found only in a few organisms that are capable of synthesizing this uncommon cofactor: *Aspergillus nidulans, Streptomyces griseus*, and *M. thermoautotrophicum*. Most other photolyases characterized to date, including those from *E. coli, S. cerevisiae, D. melanogaster*, and marsupials, contain a pterin as the second chromophore. Only two [6–4] photolyases have been characterized in detail, those of *D. melanogaster* and *X. laevis*, and both contain a pterin as the second chromophore (17). Blue-light photoreceptors from mustard, *A. thaliana*, and humans contain FAD and a pterin (11, 12).

The structures of *E. coli* and *A. nidulans* photolyases have been determined (18, 19). Even though the two enzymes are only 39% identical in sequence, they have remarkably similar structures, such that the traces of C [a]; atoms are superimposable. The enzymes consist of two well-defined domains: an *N*-terminal a/b domain, which is connected to the *C*-terminal **alpha-helical** domain through a long inter-domain loop. The folate or the deazariboflavin chromophores are located in a crevice separating the two domains. In the *E. coli* enzyme, the folate is close to the surface of the protein and hence is not tightly bound to the enzyme; furthermore, its orientation is not optimal for energy transfer to the FAD cofactor. In contrast, the deazariboflavin chromophore in *A. nidulans* photolyase is deeply buried between the two domains, and it has a more favorable orientation relative to FAD for efficient energy transfer between the chromophores. Thus even though center-to-center distances between the two chromophores in the two photolyases are about 17 Å, the energy transfer from the second chromophore to FAD is more efficient (97% to 70%) in *A. nidulans* photolyase than in that of *E. coli* (20). The helical domain is made up exclusively of a-helices that are packed in two rather compact clusters. The FAD is buried between these two clusters, and the flavin and adenine rings of the cofactor are in the unusual *cis* conformation in both photolyases.

The crystal structures of both enzymes also reveal how they bind to DNA. A plot of the surface potential of the enzyme reveals a longitudinal groove traversing both the a/b and the a-helical domains that is paved with positive charges. At its center is a hole that has the shape and size appropriate for cyclobutane pyrimidine dimer. The bottom of the hole is made up by the flavin ring. These structural features suggest that the DNA lies in the positively charged groove through ionic interactions between the DNA backbone and the positive charge of the side chains and that the dimer “flips out” of the duplex into the hole within the enzyme. Following repair, the flipped-out dinucleotide would undergo a conformational change upon transformation of the dimer into two

monomers, which would force the bases out of the hole and assist the repaired DNA to dissociate from the enzyme. Biochemical data indicate that [6–4] photolyase also employs a "flip-out" mode of complex formation during catalysis.

3. Reaction Mechanism

Photolyase works by the classical Michaelis–Menten kinetic mechanism; that is, the enzyme and substrate form a noncovalent complex that is converted to an enzyme–product complex after catalysis and eventually dissociates to yield product and free enzyme. The light-dependence of this catalysis step is unique to photolyase.

3.1. Binding

Photolyase, unlike some other high-specificity DNA-binding proteins, does not rely on diffusion along the linear DNA molecule to recognize its substrate. Similarly, the enzyme, in contrast to most proteins that bind to DNA in a sequence-specific manner and hence require double-stranded DNA, binds to its cognate lesions in single- and double-stranded DNA with almost equal affinities (21). This property of the enzyme, combined with the fact that the enzyme can bind the photoproduct even in a dinucleotide form and repair it with high affinity, are consistent with a model in which the enzyme binds mostly to the backbone of the damaged strand and flips-out the photolesion into the catalytic hole for repair.

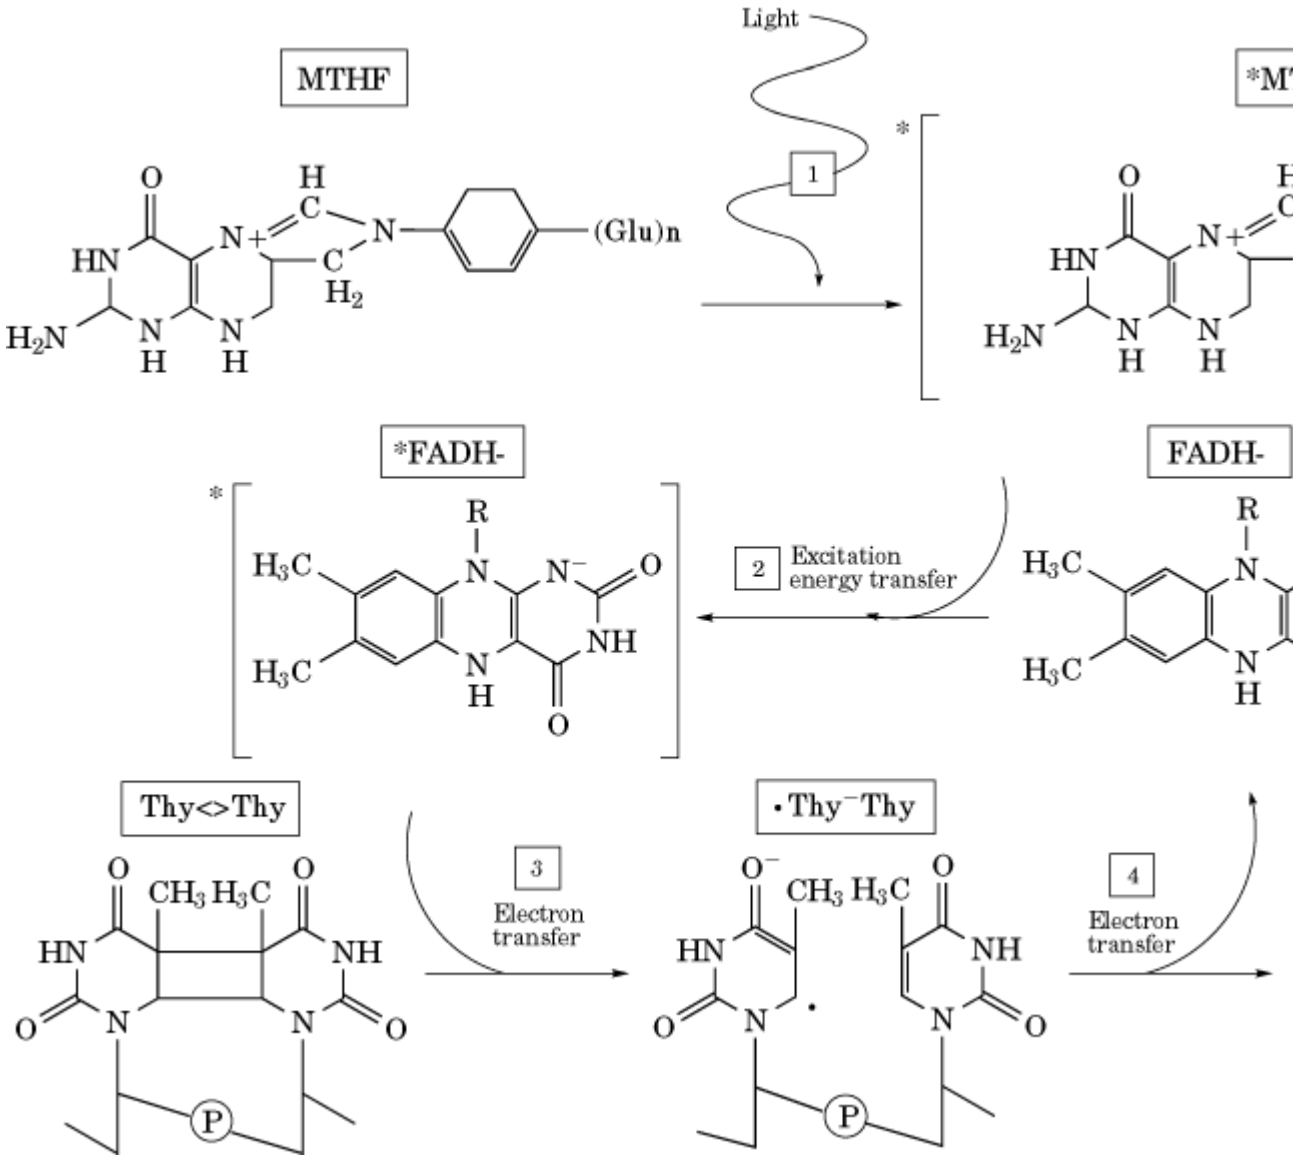
3.2. Catalysis

A most extraordinary aspect of catalysis by photolyase is its absolute dependence on light. According to the Woodward–Hoffman rule on symmetry in molecular orbitals, the symmetry of molecular orbitals in a chemical reaction is conserved between reactants and products. A corollary of this rule is that photochemically allowed reactions that proceed from the lowest unoccupied molecular orbitals (LUMO) are thermally forbidden; and conversely, thermally allowed reactions that proceed from the highest-occupied molecular orbitals (HOMO) are photochemically forbidden. In line with these rules, the cyclobutane ring of Pyr<>Pyr is stable at pH 1 and 160 °C for 6 h, but it is reversed to pyrimidine monomers with 240-nm light with a quantum yield of about 1.0. Surprisingly, however, even though photolyase utilizes light energy to catalyze the repair, the reaction is not a photochemical reaction in the strict sense, because it does not involve photoexcitation of the pyrimidine dimer, either directly or indirectly. Consequently, splitting of Pyr<>Pyr by photolyase does not break the rule of conversation of orbital symmetry. The enzyme accomplishes this feat by converting the Pyr<>Pyr into a radical, which then readily proceeds, thermally, to monomers. Light (300 to 500 nm) is used simply to excite the cofactor of the enzyme into a strong reductant capable of donating an electron to the relatively inert Pyr<>Pyr.

Having thus stated the general features of catalysis, the specifics for Pyr<>Pyr photolyase can be summarized as shown in Figure 2. The enzyme binds to its substrate independent of light, and the reaction proceeds upon exposure to light as follows (6). First, a photon is absorbed by the photoantenna (pterin or deazaflavin) to excite the chromophore to the excited singlet state. Second, the photoantenna transfers the energy by dipole–dipole interactions to $FADH_2$ with either 70% (pterin) or 97% (deazaflavin) efficiency. Third, the excited singlet state of $FADH_2$ transfers an electron to Pyr<>Pyr with about 100% efficiency, generating flavin neutral radical and Pyr<>Pyr radical anion. Fourth, the Pyr<>Pyr radical anion splits to pyrimidine monomers, concomitant with electron transfer back to restore the flavin to its catalytically active state. The reaction is a photoinitiated cyclic electron transfer, which results in bond rearrangement without changing the redox status of the reactants.

Figure 2. Photoreactivation photocycle for photolyase. The active site of the enzyme complexed to substrate is shown. (pterin) absorbs a near-UV photon. (2) The excited singlet-state pterin transfers energy to $FADH^-$ by dipole–dipole intera

FADH⁻ transfers an electron to the thymine dimer (4). The thymine dimer anion radical collapses to two thymines, conc
the flavin neutral radical.



The [6–4] photolyase functions in a similar manner (17, 22), with one important exception. Formation of [6–4] photoproduct encompasses joining of C6 of the 5′ base to the C4 of the 3′ base via a sigma bond, accompanied by transfer of the group at the C4 position (–NH or –OH) of the 3′ base to the C5 position of the 5′ base. Thus, simple cleavage of these new bonds would not restore the bases to normal. Hence, before the photoinduced cleavage of these bonds, the enzyme converts the “open form” of [6–4] photoproduct to an oxetane intermediate in which the NH or OH that was transferred to the C5 position of the 5′ base is shared by the C5 of the 5′ base and the C4 of the 3′ base (22). When the oxetane intermediate receives an electron from the active-site flavin, the resulting radical intermediate collapses to the two original bases, with back electron transfer to restore the flavin radical to its catalytically active form (Figure 3).

The blue-light photoreceptors that exhibit 40% to 60% sequence identity to photolyases (10) have absolutely no repair activity (11). They are photoreceptors for regulating plant growth or for photoentrainment of the circadian clock in animals (13). However, the reaction mechanism of these molecules is not known at present.

Photon Correlation Spectroscopy

Dynamic light scattering is a method for measuring the diffusion of macromolecules within a solution due to Brownian motion. It differs from “classical” or “static” light scattering, which permits the measurement of the molecular weight and radius of gyration of macromolecules from the light they scatter at varying scattering angles. Dynamic light scattering measures instead the intensity fluctuations of the scattered light on the timescale of 10^{-3} to 10^{-9}s. The frequencies of these fluctuations depend on how rapidly the molecules are moving by diffusion. These measurements require lasers, which provide light of high intensity, collimation, monochromaticity, and, most

importantly, spatial and time coherence; the last attributes mean that the light is emitted from the laser as a continuous wave rather than as short bursts.

The physics underlying dynamic light scattering is complicated (1). In simple terms, the moving macromolecules will *Doppler-broaden* the otherwise monochromatic incident radiation. The scattered intensity will fluctuate because of *beating interference* of scattered waves of different, but similar, wavelengths; the situation is analogous to the fluctuations in intensity of a radio channel caused by interference from another radio channel of a very close wavelength. This broadening of the originally monochromatic light is why the technique is often referred to as *quasi-elastic light scattering* (QLS). The detector sends the intensity signal to a special computer, called an *autocorrelator*, which compares or correlates the intensity at different times; for this reason, the technique has another term, *photon correlation spectroscopy* (PCS). How rapidly the intensity fluctuates over short periods of time, or delay times, t, is represented by how a parameter known as the *normalized intensity autocorrelation function*, $g^{(2)}$ (t), decays as a function of t. The superscript "(2)" is used to indicate that it is an intensity, as opposed to an electric field "(1)," autocorrelation function. Many data sets of $g^{(2)}$(t) as a function of t are accumulated and averaged. The degree of averaging necessary depends on the incident laser intensity and the size and concentration of the scattering macromolecule (at a given concentration; larger molecules scatter more). For globular proteins, sufficient data can usually be acquired within one to several minutes.

Analysis of how the normalized intensity autocorrelation function $g^{(2)}$(t) decays as a function of t can be used to evaluate the translational diffusion coefficient, D_t. For dilute solutions of spherical or near-spherical (ie, globular) macromolecules, the variation of $g^{(2)}$(t) with t can be represented by the simple logarithmic equation

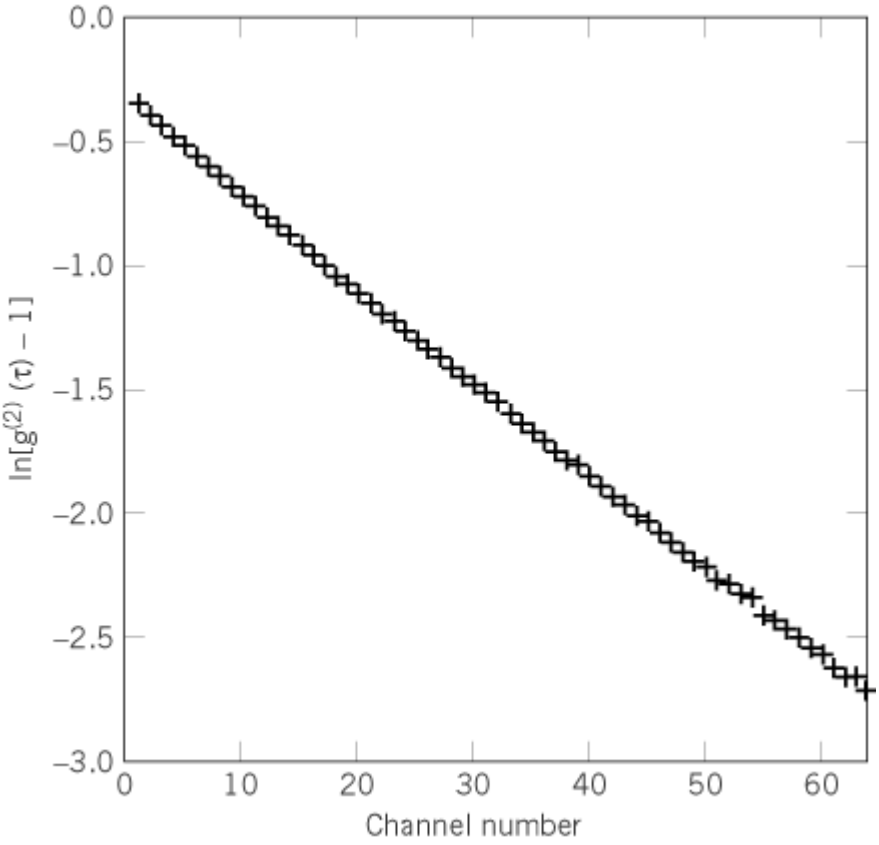
$$\ln[g^{(2)}(\tau) - 1] = -2D_t k^2 \tau \qquad (1)$$

where the parameter *k* is known as the *Bragg wave vector*, whose magnitude is defined by

$$k = (4\pi n/\lambda)\sin(\theta/2) \qquad (2)$$

where *n* is the refractive index of the medium, q is the scattering angle, and l is the wavelength of the incident light. Consequently, the value of D_t can be found from a plot of $\ln[g^{(2)}(t) - 1]$ versus t. Figure 1 illustrates an example for the motility protein dynein.

Figure 1. Dynamic light scattering of a solution of dynein. The channel number is a measure of the delay time, q (see Eq. (1) of the text).



Two important practical conditions need to be noted: (*1*) the value of D_t is sensitive to the temperature, which needs to be accurately controlled or, at the very least, monitored during the measurement; and (*2*) the scattering signal is very sensitive to the presence of trace amounts of dust or aggregation products; solutions and the scattering cell or cuvette need to be scrupulously clean and free of particulates. The samples must be filtered and centrifuged and the vessels washed. Special filling devices have been constructed to minimize this dust problem (2).

The value of D_t can be converted to the standard conditions of water at 20.0°C and extrapolated to zero sample concentration (see Diffusion). An additional extrapolation is necessary if the macromolecule is not globular. There is an extra term on the right-hand side of equation 1 that arises from rotational diffusion at finite angles q. This term approaches zero as q does. Therefore, it is necessary to make the measurements of D_t at a number of angles q and to extrapolate to zero angle (or Bragg vector k). The extrapolations to zero sample concentration and to zero angle q (or k) can be performed simultaneously on a biaxial extrapolation plot known as a *dynamic Zimm plot* (3). If an angular extrapolation is not necessary, a scattering angle of 90° is usually chosen, and fixed-angle instruments are usually set at this angle. At lower angles, the problems due to contamination with large particles (see (*2*) above) are accentuated.

If a sample is heterogeneous, it is possible, at least in principle, to obtain a distribution of diffusion coefficients after various assumptions and mathematical manipulation of the autocorrelation data; these methods have been reviewed (4), and several commercially available computer programs are available. A more simple way of representing heterogeneity is with the *polydispersity factor* (PF), which is obtained by comparing linear with quadratic or more complex fits of the normalized autocorrelation function decay data (5).

Measurements can be made very rapidly with dynamic light scattering, and it is possible to follow

biomolecular assembly–disassembly processes that occur on a timescale of minutes. An example of the swelling of southern bean mosaic virus in response to the removal of bound Ca^{2+} ions is given in Fig. 2 (6).

Figure 2. Following the dynamics of a process using dynamic light scattering: effect of removal of calcium ions (by adding EGTA at 10 min) on the hydrodynamic radius (r_H) of southern bean mosaic virus (adapted from Ref. 6).

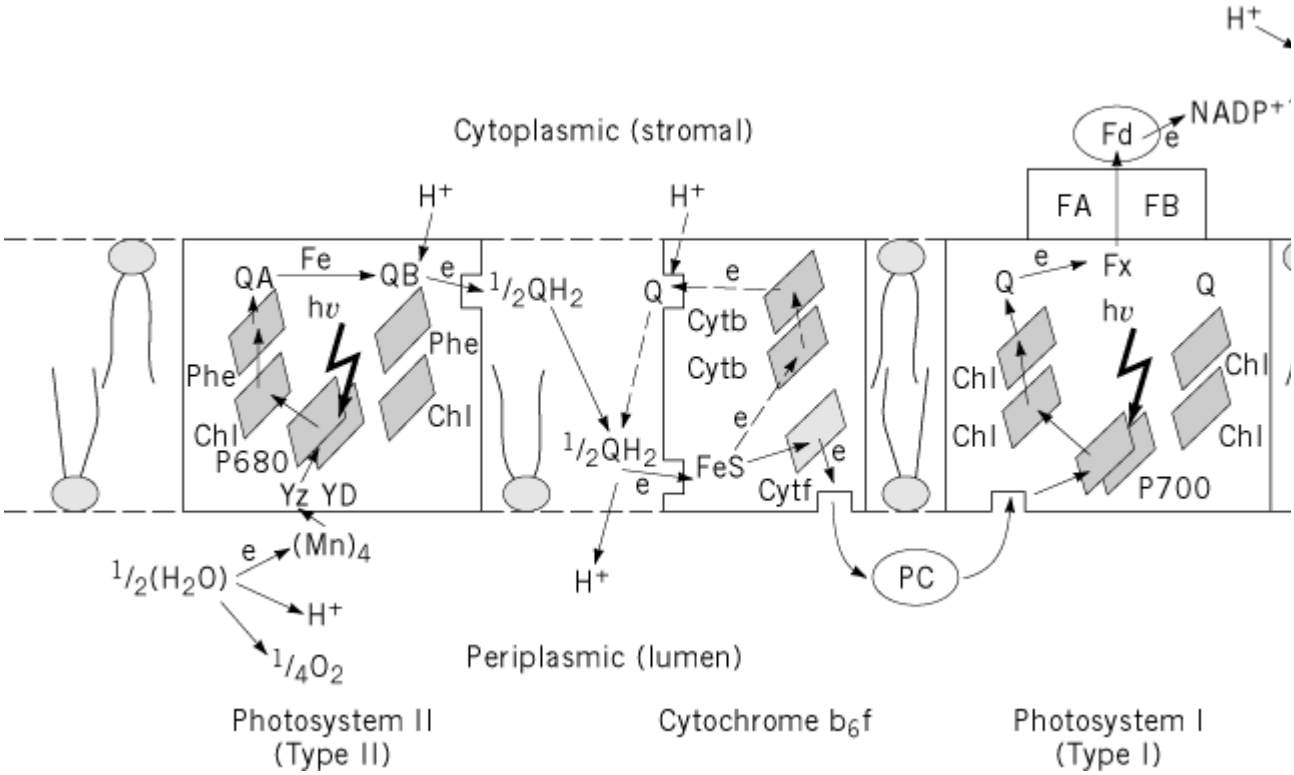
Photosynthesis

Photosynthesis is the **energy transduction** process whereby solar light energy is converted into a chemical form and used for the synthesis of organic molecules. Photosynthesis takes place in higher plants, algae, and certain bacteria. It involves light-induced **redox** processes in which carbon dioxide becomes reduced. The ability to use water as an electron source distinguishes the oxygenic photosynthetic organisms—eukaryotic plants and algae, plus prokaryotic cyanobacteria and prochlorophytes, from the nonoxygenic photosynthetic bacteria. Photosynthetic organisms evolved more than 3.5 billion years ago, and they are the origin of current biomass, as well as of fossil fuels.

In all types of photosynthetic organisms, the photosynthesis reaction can be divided into two major phases: (*1*) the light reactions and (*2*) the carbon fixation reactions (the Calvin cycle). The light reactions lead to the production of ATP and NADH or NADPH. These molecules are required for the subsequent CO_2 fixation and the formation of trioses, glucose, and more complex carbohydrates. The primary energy conversion is driven by redox-active pigment-protein complexes known as photosynthetic reaction centers. Together with light-harvesting complexes and electron transport components, such as cytochromes, **iron-sulfur proteins**, and quinones, the reaction centers catalyze electron and proton transport across a biological membrane to create a proton motive force. In analogy with the respiratory process in mitochondria and bacteria, this proton motive force drives the synthesis of ATP (adenosine triphosphate) by the enzyme ATP synthase.

In oxygenic photosynthesis, $NADP^+$ is reduced by **electron transfer** from two reaction centers, photosystem II and photosystem I, which are coupled in series (Fig. 1). The electrons are supplied by photosystem II through its unique ability to oxidize water, leading to release of molecular oxygen. The nonoxygenic photosynthetic bacteria contain only one reaction center and typically use organic or inorganic compounds as reductant to reduce NAD(P), or they perform cyclic electron transport to produce ATP. Two groups of reaction centers (type I and type II) are present among the various photosynthetic bacteria and have been shown to be highly analogous to photosystem I and photosystem II of oxygenic photosynthesis, respectively (1).

Figure 1. Light-driven, noncyclic electron transport in oxygenic photosynthesis. Two types of photosynthetic reaction ce linked in series, connected by a cytochrome b_6f complex, to extract electrons and protons from water and to make them a reduction of $NADP^+$ and ultimately CO_2. The quinone reduction is driven by a type II reaction center called *photosystem* the reaction center responsible for creating sufficient reduction potential to reduce $NADP^+$ via FeS centers is a type I rea called *photosystem I*. Photosystem II and photosystem I are evolutionary related to the type II reaction center of purple b type I reaction center of green sulfur bacteria, respectively (see Fig. 2). Both types of reaction center are depicted as havi cofactors arranged around a two fold symmetry axis as revealed by X-ray crystallography (3, 6). *Chl* is chlorophyll-*a*; *Ph* (in the case of photosynthetic bacteria these cofactors are either bacteriochlorophyll or bacteriopheophytin). A "special" interacting chlorophylls, which act as the primary electron donor (P_D), is called *P680* for photosystem II and *P700* for ph is plastoquinone in photosystem II and phylloquinone in photosystem I. *Fe* is a nonheme iron; F_x, F_A, F_B are low potent centers, and F_D is ferredoxin. $(Mn)_4$ is the cluster of manganese atoms involved in the oxidation of water; Y_Z and Y_D are tyrosine residues—the former are on the main route of electron transfer. Arrows show electron transfer paths. The two ph are functionally connected by the cytochrome b_6f complex, which oxidizes the reduced quinone (QH_2, plastoquinol) and copper-containing extrinsic protein, plastocyanin (*PC*). Because quinones are normally 2 electron/2 proton acceptors, the cytochrome complex accepts two electrons, one reducing an iron–sulfur center (*FeS*) and the other reducing a low poten cytochrome (*cytb*). The reduced FeS center donates an electron to cytochrome (*cytf*). The other electron participates in qu dependent cyclic electron transport, involving high and low potential b-type cytochromes, which functions as a proton pu developed from reference 1.



In eukaryotic organisms, photosynthesis occurs in specialized cell organelles (**chloroplasts**) enclosed by a double outer membrane (envelope) and an internal membrane system (thylakoid membrane). This organelle contains, like the mitochondria, its own DNA. The thylakoid membrane harbors the two photosystems, the light-harvesting antenna, electron transport components, and the ATP synthase (CF_0-CF_1). Despite their prokaryotic nature, cyanobacteria have a photosynthetic thylakoid membrane that is differentiated from the plasma membrane. In nonoxygenic photosynthetic bacteria, various forms of invaginations of the cell membrane give rise to so-called *chromatophores*, to which the photosynthetic light reactions are confined. The reduction of CO_2 and the subsequent enzymatic reactions of the Calvin cycle take place in the cytoplasm of prokaryotic cells or in the soluble stromal compartment of chloroplasts. The photosynthetic apparatus is remarkably adaptable to various stress conditions, in particular to short- and long-term changes in light intensity. Under severe light stress, however, photosystem II can suffer from oxidative damage leading to (photo)inhibition of photosynthesis.

1. Photosynthetic Reaction Centers

Photosynthetic bacteria are rudimentary in a general biological perspective, but they have been extremely useful as simple experimental model organisms to elucidate the structure and function of the photosynthetic light reactions and to understand the evolution of photosynthesis (2). These bacteria can be classified into two major groups based on their types of reaction centers: (*1*) green-sulfur bacteria (eg, *Chlorobium limicola*) and heliobacteria (eg, *Heliobacterium chlorum*, *Heliobaccillus mobilis*) use low potential iron–sulfur clusters as electron acceptors, and their reaction centers are designated FeS type or type I; and (*2*) purple bacteria (eg, *Rhodobacter sphaeroides*, *Rhodopseudomonas viridis*, *Rhodpirillum rubrum*, *Chromatium vinosum*) and green gliding bacteria (*Chloroflexus aurantiacus*) have type II reaction centers with pheophytin and two quinone molecules as electron acceptors.

X-ray crystallographic, functional, and genetic analyses have revealed that photosystem I and

photosystem II of oxygenic photosynthesis are closely related to the bacterial type I and type II reaction centers, respectively (Fig. 1).

The reaction center is the most vital part of the photosynthetic apparatus in which the primary light-induced redox processes take place (1). The type I and II reaction centers have a similar basic architecture, and they function using essentially the same mechanistic principle. Both use a "special pair" of chlorophyll or bacteriochlorophyll molecules as the primary electron donor (P_D) and a (bacterio-) chlorophyll (type I) or a (bacterio-)pheophytin (type II) as primary electron acceptor (P_A). When excited by light, P_D donates an electron to P_A within a few picoseconds, and the radical pair $P_D^+P_A^-$ is formed:

$$P_DP_A \xrightarrow{h\nu} P_D^*P_A \rightarrow P_D^+P_A^-$$

The primary donor and acceptor are arranged in the reaction center in such a way that the primary charge separation occurs across the lipid bilayer of the photosynthetic membrane.

The stability of this primary charge separation is ensured by rapid transfer of the electron from P_A^- to the secondary electron acceptors A_1, A_2, and so on and by passing an electron to P_D^+ from secondary electron donors D_1, D_2, and so forth:

$$D_2D_1P_D^+P_A^-A_1A_2 \rightarrow D_2D_1^+P_DP_AA_1^-A_2 \rightarrow D_2^+D_1P_DP_AA_1A_2^-$$

In type I reaction centers, A_1 is a quinone, while A_2 is a low potential 4Fe–4 S cluster (F_x). The donors are typically *c*-type cytochromes or the copper protein plastocyanin (in oxygenic electron transport only) (see Electron Transfer Proteins). In the type II reaction center, quinones constitute both the A_1 (Q_A) and A_2 (Q_B) acceptors. These are normally plastoquinone or, in purple bacteria, ubiquinone. In the bacterial type II centers, cytochromes are often the electron donors, while in oxygenic photosynthesis the electrons are provided by the unique system of water oxidation. The primary donor of photosystem II (P680) is a powerful oxidant in its $P680^+$ form. In fact, $P680^+$ is the most oxidizing species found in living organisms (E_m = +1.1V), enabling extraction of electrons from water (see Electron Transfer Proteins and Redox Enzymes). Oxidation of water requires the accumulation of four oxidizing equivalents, which are necessary to abstract four reducing equivalents from two water molecules to produce one molecule of dioxygen (O_2). The water-oxidation system involves a cluster of four manganese atoms that are converted to higher valence in a stepwise manner by four separate photochemical events (the *S*-state cycle) involving P680 and a redox-active tyrosine residue in the reaction center.

1.1. Type II Centers

Determination of the high-resolution three-dimensional structure of the purple bacterial reaction center was a landmark in photosynthesis research (3). The structure revealed an approximately twofold symmetrical relationship of the prosthetic groups (Fig. 1) and the two protein subunits (L and M) that bind them. These two subunits each possess five transmembrane helices and have very similar structures, forming a heterodimeric structure. The two bacteriochlorophylls of the primary electron donor, P_D, form a special pair at the periplasmic side of the chromatophore membrane. Following the structure across the membrane, the next cofactors are two additional bacteriochlorophylls, then two bacteriopheophytins, followed by two quinones in the Q_A and Q_B sites near the cytoplasmic surface. All the duplicated cofactors (Fig. 1) are related by a twofold axis passing through the special P_D pair and a nonheme iron located midway between the two quinones. Notably, despite this approximate twofold symmetry, the electron transfer to Q_B via Q_A occurs

exclusively along one branch, while the other branch is inoperational (Fig. 1). It is still not clear whether the bacterial chlorophyll located between the primary donor and the bacteriopheophytin is directly involved in the charge separation process as a redox-active species. The symmetry of the reaction center is broken by the H subunit, which has a single membrane-spanning alpha-helix and a globular **domain** at the cytoplasmic side of the membrane. Furthermore, there is a four-heme cytochrome present on the periplasmic side in most purple bacteria.

Functional and compositional analyses of oxygenic photosynthesis have revealed that photosystem II carries out electron transfer reactions similar to those occurring in the reaction centers of purple bacteria (3). On the acceptor side, photosystem II has pheophytin, Q_A and Q_B plastoquinone molecules, as well as the nonheme iron (Fig. 1), and electron transfer occurs with similar rate constants. Furthermore, the two protein subunits of the photosystem II reaction center (D_1 and D_2) show homology with the L and M proteins and form a heterodimeric structure similar to the bacterial reaction center. This has been confirmed by the structure of photosystem II obtained at 0.8 nm resolution by electron microscopy . In contrast to the bacterial reaction center, two photosystem II complexes are tightly associated to form a dimeric structure (4).

P680 is probably a dimer of chlorophyll molecules, but the relative orientation of the chromophores and their degree of exciton interaction seem to differ somewhat from the bacterial primary donor. Most significantly, photosystem II differs in its donor properties, allowing the extraction of electrons from water (Fig. 1). Most experimental observations suggest a close association between the active manganese cluster and the reaction center heterodimer.

Despite all the redox components required for the light-induced electron transfer from water to plastoquinone being associated with the D_1/D_2 reaction center heterodimer, photosystem II contains as many as 25 different subunits (1). These are encoded either by chloroplast or nuclear genes designated *psbA*-X. Closely associated with the reaction center is cytochrome b559, which is not a part of the main electron transfer chain but instead protects against photodamage. Most subunits are integral membrane proteins and span the membrane, but three extrinsic proteins are located at the inner thylakoid surface to stabilize the manganese cluster and to sequester the Ca^{2+} and Cl^- ions that are also required for water oxidation. A peculiar feature of the complex is the relatively large number (up to 10) of small proteins with only one membrane-spanning segment. Two chlorophyll- *a*-binding proteins, CP47 and CP43, serve as inner light-harvesting antenna closely associated with the reaction center. Each contains 40 chlorophyll-*a* molecules and possesses 6 transmembrane domains; they are complemented by an outer antenna constructed of various pigment-protein complexes, depending on the taxonomic group (see text below).

1.2. Type I Centers

Of the type I reaction centers, photosystem I is the best characterized, partly due to the 0.4 nm-resolution structure of the complex obtained from a thermophilic cyanobacterium (6). Notably, the basic three-dimensional structural arrangement of photosystem I is the same as for the type II center, despite its different content of redox-active groups. Photosystem I has the twofold symmetry with the axis passing through the chlorophyll-*a* dimer of the primary donor (P700) and a 4Fe–4 S center (Fig. 1). Two additional pairs of acceptor chlorophyll molecules occur along this axis. A fourth pair of chlorophyll molecules appears to connect those of the reaction center and of the light-harvesting antenna. The photosystem I reaction center is a heterodimer composed of two large reaction center subunits (*PsaA* and *PsaB*), each possessing 11 membrane-spanning segments. In contrast to the type II center, the two reaction center subunits also harbor the inner light-harvesting antenna of about 100 chlorophyll-*a* molecules. The 22 a-helices of the PsaA and PsaB proteins are arranged in such a way that 5 helices from each subunit form a central reaction center portion, in analogy with the D_1/D_2 and L/M heterodimers. The additional 12 a-helices are located on either side of this central portion and harbor the antenna chlorophylls. This arrangement should be compared to the inner chlorophyll-*a* antenna of photosystem II composed of two distinct proteins, CP47 and CP43, together comprising

12 membrane spanning helices (4).

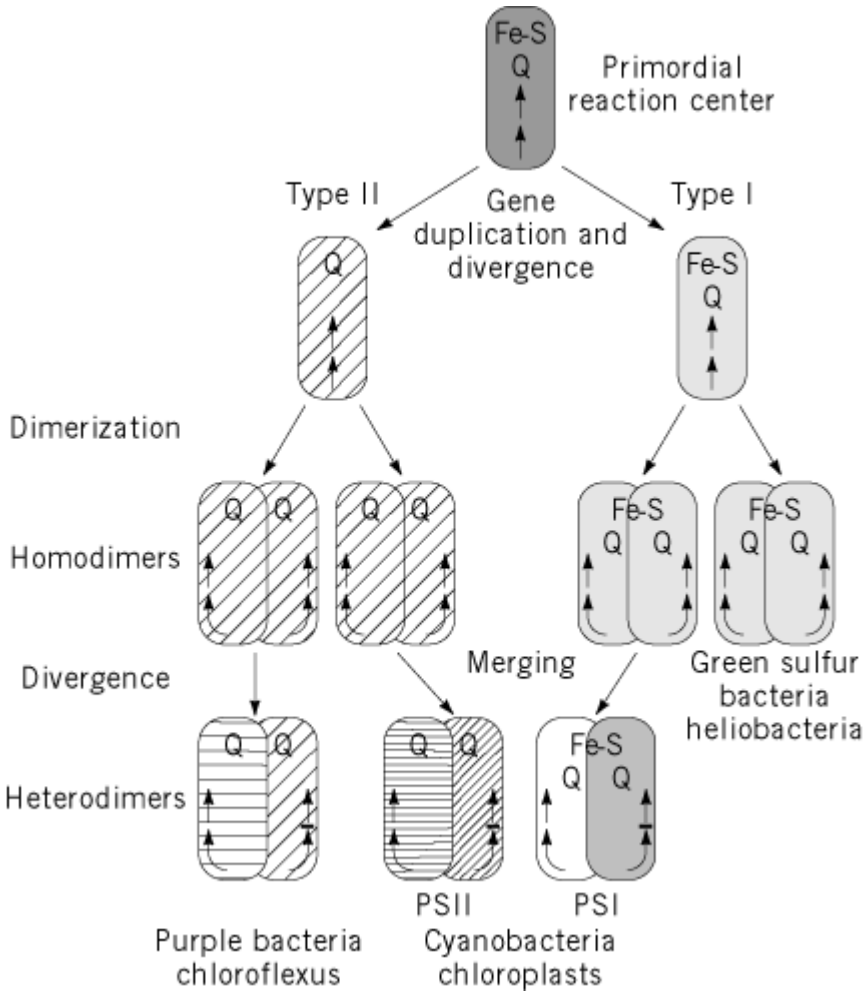
Photosystem I is also a multisubunit complex of both nuclear and chloroplast genetic origin, with up to 15 different subunits (*PsaA* - *PsaM*) (5). *PsaC*, an extrinsic subunit at the outer stromal surface (Fig. 1), provides ligation for two acceptor FeS clusters (F_A and $F_{B)}$. There are also subunits providing docking sites for ferredoxin and plastocyanin (see Azurin) at the acceptor and donor sides of the reaction center, respectively. The eukaryotic photosystem is complemented by an outer antenna of chlorophyll-*a*/*b* -binding proteins (LHCI). In cyanobacteria, but probably not in plants, the photosystem I complex is trimeric.

No structural information is yet available for the nonoxygenic type I reaction centers of green sulfur bacteria or heliobacteria. There is compelling evidence that these photosynthetic bacteria have homodimeric reaction centers despite the same overall arrangement of the redox active groups as in photosystem I. It is therefore assumed that these bacterial reactions centers are evolutionarily more primitive and ancestral to the heterodimeric reaction centers (7, 8).

1.3. Evolutionary Aspects of Photosynthesis

The occurrence of two different but analogous reaction centers, composed of two related, yet distinct protein subunits, provides insight into the evolution of photosynthesis (1, 7, 8). In the beginning, there was probably a primordial reaction center composed of one single subunit (Fig. 2), which may have evolved to a homodimeric structure with both electron transfer branches operational. Then a gene duplication took place in early evolution, the heterodimeric reaction centers were generated by divergent evolution, and one of the electron transfer branches was closed. It is assumed that the ancestral reaction center contained both quinone and iron–sulfur acceptors, but that the latter were lost in the type II centers. Later the two types of reaction centers were linked to pave the way for current oxygenic photosynthesis (Fig. 2). It is not clear when the ability to oxidize water was acquired, but no single type II reaction center able to split water has been identified. The chloroplast of eukaryotic photosynthetic organisms is generally assumed to have its evolutionary origin in symbiotic ancestors of cyanobacteria.

Figure 2. Evolution of photosynthetic reaction centers. A primordial reaction center containing both quinones and Fe-S centers as electron acceptors, evolved into type I and type II centers, where the latter lost their FeS component. Gene duplications and divergence gave rise to homodimeric, and finally heterodimeric, reaction centers where only one electron transfer route is operational. In cyanobacteria, the two types of reaction centers merged to pave the way for oxygenic photosynthesis (see Fig. 1). The scheme is developed from References 6 and 7.



2. Light-Harvesting Protein Complexes

The evolution of type I and type II reaction centers has been matched by the development of a multitude of different light-harvesting pigment–protein systems. This enables photosynthetic organisms to use the entire solar spectrum and provides versatility with respect to the surrounding light environment. In bacteria there are typically 40 chlorophyll-containing molecules per reaction center, while in plants this number could be several hundred (2). The correct organization of the various pigments within the antenna systems is crucial in order to ensure efficient energy transfer. Following absorption of a photon by one of the antenna pigments, the excitation moves from pigment to pigment via so-called resonance energy transfer, until being trapped in the reaction center. These ultrafast processes can now be followed by femtosecond (10^{-15}s) flash spectroscopy.

Purple bacteria have two types of light-harvesting protein complexes, designated LHI and LHII (9). They are composed of two small proteins (a and b) that each span the membrane once and bind bacteriochlorophyll-*a* and carotenoids. LH1 is closely associated with the reaction center (L, M, and H subunits). LH2 is located more peripherally and functions as an outer and variable antenna. The structure of LH2 has been determined to high resolution by X-ray crystallography (9). The complex has a donut shape with 9 a-subunits forming a hollow cylinder with 1.8 nm inner and 3.4 nm outer radii. All the pigments are located between these cylinder walls. The bacteriochlorophylls are ligated to histidine residues. Eighteen molecules form an overlapping ring located toward the outer membrane surface, while nine are located more toward the inner portion of the membrane. The latter are perpendicular to the other bacteriochlorophylls and with the bacteriochlorophyll ring parallel to the membrane surface. The carotenoids are arranged in close association with the bacterial

chlorophylls. This ring of chlorophylls allows the excitation to become delocalized over a large area, thereby facilitating the energy transfer to LHI, which is likely to have a structure similar to LHII. Purple bacteria can also contain bacteriochlorophyll-*b*, in addition to bacteriochlorophyll-*a*. Typically, purple bacteria can harvest light in a very broad interval of the spectrum, even above 1000 nm.

Green sulfur bacteria have a peculiar antenna system in *chlorosomes*, which appear as bag-like structures on the inside of the cytoplasmic membrane (2). They contain a complex mixture of bacteriochlorophylls *c, d*, and *e* assembled into rod elements approximately 5–10 nm in diameter. Notably, chlorosomes contain very few proteins, and the polymeric structures are maintained primarily by pigment–pigment interactions. A water-soluble baseplate bacteriochlorophyll-*a* protein complex sandwiched between the chlorosomes and the cytoplasmic membrane provides the link between the chlorosome antenna and the reaction center chlorophylls. Green sulfur bacteria can absorb light up to 850 nm. Heliobacteria do not contain an outer antenna but manage with the inner bacteriochlorophyll-*a* antenna of its type I reaction center.

Cyanobacteria use water-soluble protein structures known as *phycobilisomes* as outer light-harvesting antenna (10). A phycobilisome contains several hundreds of phycobilin pigments (phycocyanin, phycoerythrin, or allophycocyanin) covalently bound to the phycobiliproteins. The organization of a phycobilisome involves rod-like structures composed of 5 to 6 elements that are connected to a tricylindrical core of phycobiliproteins carrying allophycocyanin. The excitation energy migrates, via the core, from the peripheral rod sections to the CP47/CP43 inner chlorophyll-*a* antenna, and finally to the D_1/D_2 reaction center. The phycobilosomes are located at the outer thylakoid membrane surface facing the cytoplasm and connected to photosystem II via nonpigmented linker proteins.

The plant photosystems have chlorophyll-*a/b*-binding (CAB) proteins as their outer light-harvesting antenna (10). Altogether there are ten different but related nucleus-encoded CAB proteins: 6 associated with photosystem II and 4 with photosystem I. These are all integral membrane proteins, each with a molecular weight of about 25 kDa and with three transmembrane-spanning regions. The CAB proteins noncovalently bind approximately half of the chlorophyll-*a* and all of the chlorophyll-*b*, as well as a majority of the carotenoids. Most attention has been paid to the major CAB protein complex of photosystem II, designated LHCII. It is the most abundant thylakoid protein complex and, apart from a crucial function in light harvesting, is essential for maintaining the thylakoid membrane organization and to adjust the antenna of photosystem II in response to short- and long-term fluctuations in the light environment. LHCII normally exists as a trimer. Each monomer has been estimated to bind up to 14 chlorophyll molecules, one chlorophyll molecule for every 15 amino acids, indicating a very tight packing. The structure of LHCII has been determined to 0.34 nm resolution by electron crystallography (11).

Green algae have basically the same outer light-harvesting antenna as plants. In brown algae, the CAB proteins are homologous to the plant CAB proteins. Interestingly, the CAB proteins are not unique to eukaryotic organisms, since the prokaryotic *prochlorophytes* have a similar kind of light-harvesting proteins. On the other hand, eukaryotic red algae have no CAB proteins, but phycobilisomes similar to those of cyanobacteria.

The carotenoids of the various light-harvesting complexes and reaction centers not only play a role in light-harvesting but are also essential as protectants against oxidative damages.

3. Electron Transport

3.1. Oxygenic Photosynthesis

Photosystem I and photosystem II are linked in series via plastoquinone, the cytochrome b_6f complex, and plastocyanin (Fig. 1). When the secondary plastoquinone acceptor of photosystem II

(Q_B) has received two electrons, it is protonated and leaves its binding site on the D_1 protein. This Q_B site is the major target for several commercial herbicides, such as atrazine and diuron. The reduced plastoquinone interacts with the Q_0 site of cytochrome b_6f. This cytochrome complex is analogous to the mitochondrial cytochrome bc_1, whose structure has been solved to high resolution. The photosynthetic cytochrome complex contains four redox centers: one heme *c* (*f*), two hemes *b*, and a high potential Rieske 2Fe–2 S cluster. The redox components are ligated to three protein subunits: cytochrome *f* and cytochrome b_6, which are both plastid-encoded, and the nucleus-encoded Rieske FeS protein. Altogether, the complex contains at least five subunits. It performs quinol oxidation via cytochrome b_6f, involving a so-called Q cycle, which translocates twice the number of protons that could be translocated by the plastoquinone/plastoquinol oxidoreduction alone. The electrons are eventually linked via cytochrome *f*, the FeS center and plastocyanin to photosystem I, reducing $P700^+$. The final step in noncyclic electron transfer is the reduction of $NADP^+$, which is mediated by ferredoxin and the ferredoxin- $NADP^+$ reductase, a flavoprotein.

Noncyclic electron transport gives rise to proton transport into the inner (lumen) thylakoid compartment, via cytochrome b_6f and the plastoquinone/plastoquinol oxidoreduction (Fig. 1). In addition, protons are translocated into the lumen as a consequence of the oxidation of water. Cyclic electron transfer leading to transmembrane proton transport can occur around photosystem I and cytochrome b_6f, although the precise mechanism is still under debate. The proton motive force created by non-cyclic or cyclic electron transport substantiate the chemiosmotic coupling theory of ATP formation.

3.2. Nonoxygenic Photosynthesis

The simplest form of electron transport occurs in purple bacteria (2). The electrons from the quinol formed at the reaction center are transported back to the primary donor via a cytochrome bc_1 complex and at least one other cytochrome. This light-driven cyclic electron transfer is coupled to ATP production via a proton motive force. Purple bacteria do not possess noncyclic electron transport in the classical sense. A reductant can donate electrons into the quinone pool or to a cytochrome, but these reductants are not sufficiently strong to reduce NAD^+ directly. Instead, this is performed via “reversed” electron transport involving a NADH dehydrogenase enzyme. Some of the energy from the light-mediated cyclic electron transfer is used to drive these reactions.

Photosynthetic bacteria containing type I reaction centers are able to perform non-cyclic electron transport using other compounds as reductants, for example, simple sulfur components (2). The iron-sulfur centers on the acceptor side have redox potentials that are sufficiently low to allow reduction of NAD^+. In addition, sulfur bacteria and heliobacteria can perform cyclic electron transport coupled to ATP formation.

4. Carbon Dioxide Fixation and Photorespiration

The conversion of carbon dioxide to carbohydrates occurs in a cyclic process, called the *Calvin cycle* or the *photosynthetic carbon reduction cycle*. These reactions take place in the cytoplasm of prokaryotic cells or in the stroma of chloroplasts, mediated by at least a dozen enzymes. In the first step, ribulose-1,5-bisphosphate (RuBP) reacts with a molecule of carbon dioxide, thereby forming two identical C3 molecules of 3-phosphoglycerate, 3-PGA. This reaction is catalyzed by **ribulosebisphosphate carboxylase** (Rubisco), which is the most abundant protein on earth, and in eukaryotes consists of eight copies each of a small and a large subunit. In subsequent reactions, 3-PGA is converted into hexose and pentose phosphates, which requires 3 mol of ATP and 2 mol of NADPH per mole of CO_2 fixed. Hexose phosphates are converted to starch or are exported from the chloroplast via the phosphate translocator as triose phosphates. RuBP is regenerated from 3-PGA in reactions requiring further input of NADPH and ATP. The activities of some of the Calvin cycle

enzymes are regulated and coupled to the redox state of the electron transport chain via thioredoxin (12).

A proportion of RuBP is oxygenated by Rubisco, which also can function as an oxygenase, in a potentially wasteful reaction (in terms of quantum efficiency of CO_2 fixation), to form phosphoglycolate and 3-phosphoglycerate. This reaction is called *photorespiration* . The major part of the carbon flow to glycolate is returned, via the photosynthetic carbon oxidation cycle, back into the Calvin cycle. Production of 1 mol of CO_2 results in the net consumption of 7 mol of ATP and 4 mol of NADPH. Although photorespiration lowers the quantum efficiency of CO_2 fixation, it is an important side reaction because it can dissipate excess energy under unfavorable conditions, thereby preventing oxidative damage to the photosynthetic apparatus. In addition, photorespiration provides a link between the carbon and nitrogen cycles and can provide additional ATP to the mitochondria and the cytosol. Under conditions of a short supply of carbon dioxide, such as under conditions of water stress when the leaves close their stomatas to reduce water loss or at elevated temperatures, photorespiration is enhanced.

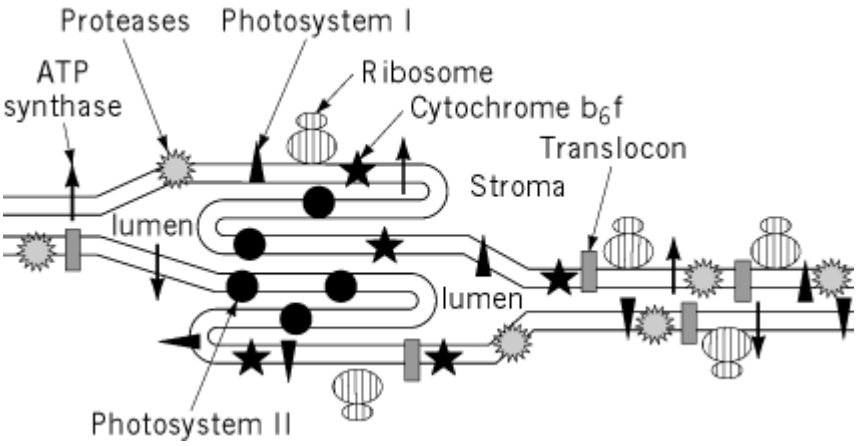
In the so-called C4 plants, photorespiration is strongly reduced (12), and the primary carboxylation reaction is of phosphoenolpyruvate (PEP), involving an enzyme that has a much higher affinity for CO_2 than Rubisco. In this carboxylation reaction, 4-carbon carboxylic acids are formed (hence the name C4 plants) in specialized mesophyll cells and are then transported to the bundle sheath cells. There they are decarboxylated, and the concentrated CO_2 is assimilated into the Calvin cycle via Rubisco. The photorespiration is kept low because of both the elevated CO_2 levels and the very low proportion of oxygen-evolving photosystem II centers in the bundle sheath cells.

5. Thylakoid Membrane Organization

5.1. Thylakoid Membrane Heterogeneity

The thylakoid membrane is a lipid bilayer that is composed mainly of galactolipids with an unusually high level of unsaturation and encloses an aqueous compartment, the lumen. The thylakoid membrane shows a strong lateral heterogeneity (5), in terms of both protein and lipid compositions (Fig. 3). A substantial amount of the membrane is folded into stacks (“grana stacks”), where the outer membrane surfaces are in close contact. The extent of stacking varies greatly with plant species and light conditions. The stacked regions contain mainly photosystem II, whereas the unstacked, stroma-exposed membranes contain photosystem I and the ATP synthase (Fig. (3)). The intermediate electron carrier cytochrome b_6f is distributed over both membrane regions. Destacking of the membrane and randomization of the protein complexes occurs when divalent cations (mainly Mg^{2+}) are depleted. In cyanobacteria, there is no thylakoid stacking or lateral segregation between the photosystems.

Figure 3. Schematic model of thylakoid membrane organization and its lateral heterogeneity. The thylakoid membrane is a lipid bilayer that encloses an aqueous compartment, the lumen. The proteins and protein complexes within the thylakoid membrane are unequally distributed over the stacked and stroma-exposed membrane regions.



5.2. Biogenesis and Maintenance of the Thylakoid Membrane

Chloroplasts develop from structurally very simple proplastids, which consist of an envelope, a nucleoid with DNA fibrils, a small number of ribosomes, and some flattened thylakoid membrane sacs that appear to be continuous with the inner membrane of the envelope. Development of the proplastid requires light, several chromophores, and multiple nuclear genes, all acting together through several signal transduction chains in a tightly regulated process. When leaves develop in total darkness, so called etioplasts are formed, which contain no chlorophyll and no thylakoid membrane system. These etioplasts consist of lipid-rich cube-like structures called prolamellar bodies, containing mainly the light-regulated enzyme protochlorophyllide reductase and its pigment substrate protochorophyllide. Within a day of illumination of the etioplast, chlorophyll is synthesized and an active thylakoid membrane system is formed.

Biogenesis of the thylakoid membrane system involves the synthesis of at least 70 to 85 proteins of the four main photosynthetic protein complexes (5). Many of these proteins are encoded in the nucleus; after synthesis in the cytosol, they are imported into the chloroplast and targeted and inserted into the thylakoid membrane. To increase targeting efficiency to the chloroplast and to prevent missorting to other organelles, these nucleus-encoded proteins are synthesized with a **signal sequence** that is recognized by a receptor on the outer envelope surface (13). After nucleotide triphosphate-driven import into the chloroplast, this signal sequence is cleaved off by a stromal peptidase . Targeting to the thylakoid is facilitated by a second signal sequence, or via information within the mature protein. Different pathways for targeting and insertion into the membrane have been found, and a number of structurally important components, such as the **Sec** machinery and a signal recognition particle (SRP) have been identified (14). It should be noted that most chloroplast-encoded proteins do not contain a signal sequence. The chloroplast-encoded thylakoid proteins are inserted into the membrane either co-translationally or post-translationally, possibly by mechanisms similar to those in *Escherichia coli*. Most proteins that form the central functional core of each photosynthetic complex are chloroplast-encoded, whereas the more peripheral proteins are nuclear-encoded. To achieve the proper stoichiometry of the different proteins, regulation of synthesis takes place at transcriptional, translational, and post-translational levels, via various signal transduction chains and through feedback mechanisms.

The two photosystems and the cytochrome b_6f complex contain in total at least 15 different cofactors and many different pigments. The biosynthesis of these cofactors and pigments is tightly linked to the synthesis and accumulation of the proteins. Very little is understood, however, about the mechanisms of this coordination.

It has become clear that, in addition to the proteins of the photosynthetic complexes, there must be a fairly large number of proteins involved in the biogenesis and maintenance of the complexes.

Several functions must be performed during these processes: biosynthesis and ligation of cofactors, membrane insertion, folding, and degradation of the proteins. Notably, these auxiliary proteins are mostly located in the stroma-exposed thylakoid regions (Fig. 3).

Recently, members of several classes of these enzymes have been discovered, and most of these auxiliary proteins are encoded in the nuclear genome. Some of these genes have an eukaryotic origin, whereas many originate from prokaryotic chloroplast predecessors. Sequencing of various bacterial genomes, such as those of *Synechocystis* 6803 and *E. coli* and the ongoing sequencing of the higher plant genome of *Arabidopsis thaliana* and other plant species, will prove helpful in identification of the components involved in biogenesis of the photosynthetic apparatus.

5.3. Short- and Long-Term Adaptation to the Environment

The photosynthetic apparatus is constantly regulating its activity, in response to both the quantity and the quality of light, as well as the varying demands for metabolic end products of the light and dark reactions (NADPH, ATP, glucose, etc). The two photosystems operate in series but do not have the same action spectrum. Photosystem II can use light at wavelengths below 680 nm, whereas photosystem I can use wavelengths up to 700 nm. Maximal absorption of the outer antenna of photosystem I (LHCI) is 5 nm red-shifted (thus to lower energy level) compared to that of photosystem II (LHCII). Thus, changes in color of the light will affect the relative activities of the two photosystems. For optimal quantum use, it is important to balance the activities of the two photosystems, and several short- and long-term adaptive and regulatory processes must occur. The demand for ATP and reducing equivalents by the dark reaction shows several-fold variations on changing environmental conditions, such as cold, heat, or water stress, and also during different stages of plant development (eg, vegetative growth, senescence).

On a short-term timescale (milliseconds to minutes), light energy can be redistributed via disconnection of the major CAB protein (LHCII) from photosystem II (5). This process is driven by redox-controlled phosphorylation of LHCII. The disconnected LHCII can migrate along the thylakoid membrane to photosystem I and thereby redistribute absorbed light energy. This reversible process is called the *state transition*. Some of the light absorbed by CAB proteins can also be dissipated in the form of heat. This heat dissipation is probably occurring through formation of exciton traps through the reversible conversion of xanthophyll pigments. Furthermore, cyclic electron flow from photosystem I back into the plastoquinone pool could help to balance the activities of the two photosystems and to alter the ATP/NAPDH ratio.

If the short-term adaptations are not sufficient, the quantities of the structural components of the photosynthetic apparatus are changed through their regulated biosynthesis and proteolysis. Various signal transduction chains that respond to different environmental conditions exist to make these dynamic changes possible.

5.4. Light-Induced Stress, Photoinhibition and Repair

If the adaptation and regulatory processes described above are not sufficient, damaging oxidative reactions can occur. Several scavenging mechanisms, such as superoxide dismutases and exciton transfer to carotenoids, are present in the thylakoid to quench toxic oxygen species. The main target for photoinhibitory damage of the photosynthetic apparatus is photosystem II, especially its D_1 reaction center protein. Consequently, the D_1 protein has a much shorter lifetime than any other photosynthetic protein. Photoinactivation of photosystem II function can occur either on its donor side, when electron donation to P680 is limiting, or on its acceptor side, when the quinones become overreduced. Since photosystem II is not functional without the D_1 protein, plants have evolved a very efficient repair mechanism. Two important features of this repair mechanisms are (*1*) a controlled disassembly of photosystem II, to ensure that the other, undamaged, protein subunits of photosystem II are not proteolyzed and can be recycled; and (*2*) tightly coupled proteolysis and synthesis of the D_1 protein through an as-yet unidentified mechanism.

Photosynthetic Reaction Center

The photosynthetic reaction center is a **redox**-active complex of pigments and proteins that is the most vital part of the **photosynthetic** apparatus. All reaction centers have similar basic architectures, and their functions follow essentially the same mechanistic principles. They use a “special pair” of chlorophyll molecules as a primary electron donor (P_D) and a chlorophyll or pheophytin as the primary electron acceptor (P_A). On excitation by light, P_D donates an electron to P_A, and a radical

pair $P_D^+P_A^-$ is formed. This primary charge separation is stabilized by transfer of the electron to secondary acceptors and by passing an electron to P_D^+ from secondary donors. The donors and acceptors are arranged in the reaction center in such a way that the primary charge separation occurs across the lipid bilayer of a photosynthetic membrane. The redox components are ligated to two distinct, but related, membrane-spanning proteins. In oxygenic photosynthesis in plants, algae and cyanobacteria, two reaction centers, photosystem I and photosystem II, are coupled in series. Photosystem I belongs to the type I reaction centers, which contain FeS clusters as electron acceptors and are also found in nonoxygenic green sulfur photosynthetic bacteria. Photosystem II belongs to the type II reaction centers, which contain quinone acceptors and are also present in purple bacteria. The two types of reaction centers are thought to be related evolutionarily. The structures of photosynthetic reaction centers are known primarily through X-ray crystallography, in particular from the elucidation of the reaction center of purple bacteria. See Photosynthesis for further details.

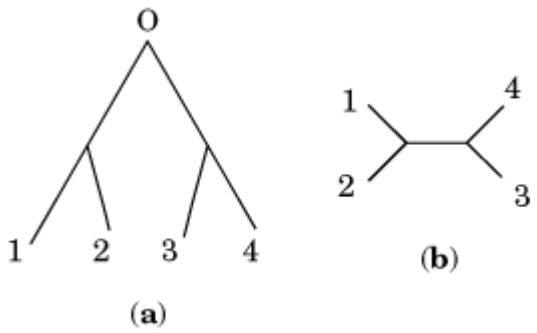
Phylogenetic Tree

A phylogenetic tree is a tree-like presentation of the **phylogenetic** relationships among species or **genes** . In particular, a phylogenetic tree can be constructed by using evolutionary distances between amino acid or **nucleotide sequences** (see Sequence Analysis). The tree obtained by this construction is called a “molecular phylogenetic tree” or simply a “phylogenetic tree.”

The methods for constructing a phylogenetic tree can be separated into two major categories, depending on the target traits. These are character-based methods and distance-based methods (1, 2). For example, the maximum-likelihood (ML) method (3) for constructing a phylogenetic tree is a character-based method, whereas the neighbor-joining (NJ) method (4) is a distance-based method. In most instances, the following procedures are used to construct a phylogenetic tree: First, the nucleotide (or amino acid) sequences to be compared are aligned simultaneously with each other. When the number of sequences to be compared is more than two, the alignment is called a “multiple alignment.” A character-based method, such as the ML method, can then be used immediately. For the distance-based methods, on the other hand, the number of nucleotide or amino acid substitutions is estimated for all possible combinations of sequence pairs. Using the substitution numbers as evolutionary distances, one is able to use distance-based methods, such as the NJ method.

Phylogenetic trees are either rooted and unrooted trees (see Fig. 1). The rooted tree has an ancestral node, but the unrooted tree is just a network without any ancestral node. The ML methods give a rooted tree, whereas the NJ methods produce a network or unrooted tree. It is, however, possible to identify the ancestral node in a phylogenetic tree that has been constructed by the NJ method. If a particular gene sequence is known to be apparently the most remotely related one to other sequences, it is included as an outgroup into a set of sequences to be compared when a phylogenetic tree is constructed. Then, the branching point between the outgroup and all other sequences can be identified as an ancestral point. Note that if the outgroup is related very remotely to other genes, the substitution numbers may not be estimated correctly because of the so-called saturation effect.

Figure 1. Schematic representation of (**a**) rooted and (**b**) unrooted phylogenetic trees.



When a phylogenetic tree is constructed by using gene sequences, the tree obtained (the "gene tree") may be different from the tree of species (the "species tree") that has been constructed utilizing information other than sequences, such as the fossil record. In particular, if paralogous genes are included in the analysis, the phylogenetic tree will not be the same as the species tree. This is because paralogous genes, by definition, do not follow the speciation process. Thus, special attention to paralogous genes is required when the species tree is inferred from the gene tree. A species tree can be constructed only by comparing orthologous genes.

Phylogeny

Phylogeny is the evolutionary relationship among organisms or **genes** that takes into account the time and the divergence process from a common ancestor. When evolutionary relationships among organisms are studied by the techniques of molecular biology, the subject and the phylogeny obtained are called "molecular phylogeny" (1). Molecular phylogeny can be studied by immunological methods, protein electrophoresis, DNA-DNA **hybridization**, and amino acid and **nucleotide sequences** . For example, the immunological method utilizes the fact that cross-reactions in antibody–antigen interactions are stronger for closely related organisms than for distantly related ones. With this method, however, quantitative analysis has been difficult. Now the numbers of nucleotide or amino acid substitutions are used, as evolutionary distances, primarily to reconstruct the phylogeny of genes or proteins (see Phylogenetic Tree).

Previously in the study of phylogeny, controversy existed between cladistics and phenetics. Cladistics is the study of the pathway of evolution, in which the ancestor–descendant relationship is always discussed with the topology of a rooted phylogenetic tree, called a "cladogram" (see Phylogenetic Tree). On the other hand, phenetics is the study of the relationship among a group of organisms on the basis of the degree of similarity between their molecular, phenotypic, and anatomic traits. A tree-like network presenting phenotypic relationships is called "phenogram." When a molecular clock exists, it is generally considered that a phenogram and a cladogram at the molecular level become identical to each other.

When the phylogeny of closely related organisms or genes is studied, for example, for individuals or **alleles** within a given population, it may be better to call it genealogy rather than phylogeny. Molecular genealogy is important for the study of genetic relationships among individuals or their alleles. The coalescence time is the shortest time for individuals or alleles to share the common ancestor in a given genealogy, and this can give useful information about the time and degree of genetic diversity in the ancestral population (2).

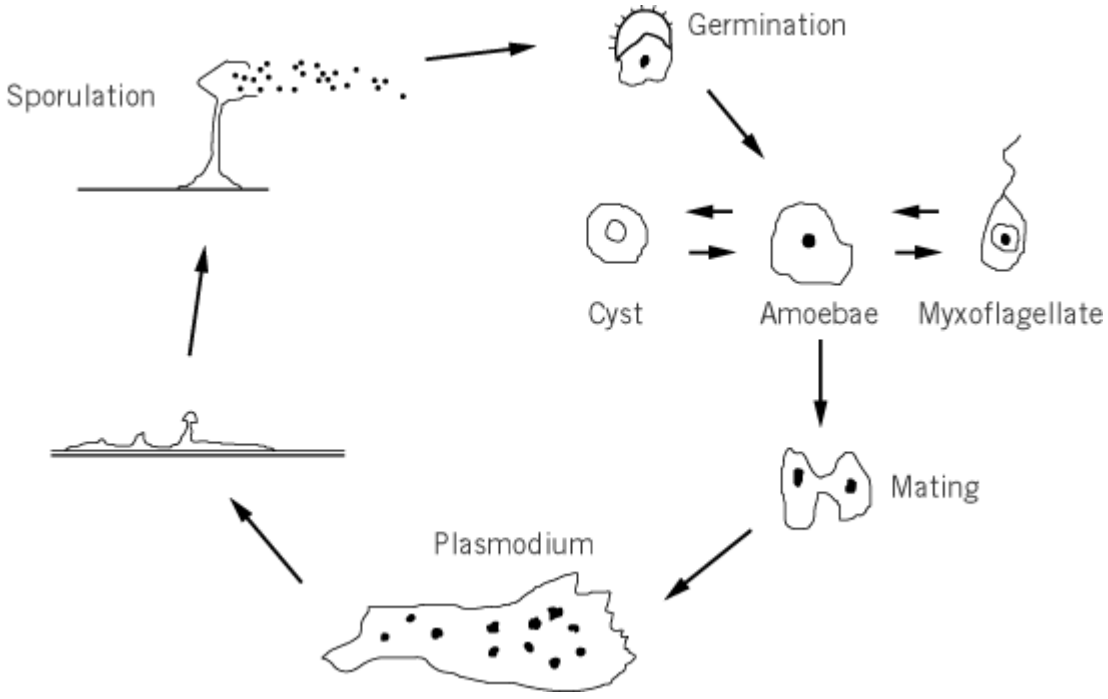
Physarum

The acellular slime mold *Physarum polycephalum* has been studied in the laboratory extensively as a model eukaryotic organism. This soil amoeba has provided insights into many basic cellular functions. It is most famous for its complex developmental and sexual cycle. In the laboratory, it can be maintained in several forms, including a plasmodium that is basically an enormous singe cell containing several thousands of synchronously dividing **nuclei**. A simplified schematic of its developmental cycle is shown in Figure 1.

Figure 1. Schematic diagram of the *Physarum* developmental cycle.



In conditions that are not limiting in terms of food or moisture, *Physarum* is usually found in the plasmodium form. When the food supply begins to dwindle, the cell can either migrate to find more or begin the process of sporulation. In early stages of sporulation, cytoplasmic projections are formed that are filled with haploid nuclei. As the process continues, structures called *fruiting bodies* are constructed, and the nuclei packed in a protective shell and become spores. A mature fruiting body can rupture and spread the spores over the immediate area, where they remain dormant until conditions become right for germination or they can get carried to a more favorable place by wind or insects.

When conditions are optimal, the spore germinates, releasing a haploid cell. This amoeba can search for food and can transform into a flagellate swimming form if it encounters water. Interestingly, this transition between the amoeba and myxoflagate forms occurs quickly and does not require additional protein biosynthesis, only rearrangement of existing components. If the amoeba encounters unfavorable conditions, it can change into a dormant and resistant form called a *cyst*. Amoebae can also mate or fuse with others, and the resulting cell grows into the plasmodium.

The *Physarum* genome is complex. The nuclei in the plasmodium form are a mixture of haploid and **diploid**. There has also been reported extrachromosomal linear DNA that can be maintained even upon transformation into yeast cells (1). There appear to be substantial differences between strains and under different growth conditions. One strain was reported to have about 70 chromosomes, containing a total of 1 to 5×10^9 base pairs of DNA (2).

A wide variety of genetic tools have been developed for manipulation of *Physarum*. Mutations can be created, and the resulting phenotypes analyzed in many ways. Extrachromosomal plasmids have been constructed into a family of vectors useful in stable or transient expression of heterologous genes. Multiple selectable markers systems are available, allowing the construction of strains in which complementation can be used to analyze the functions and interactions of proteins. Homologous recombination has been shown to occur, allowing gene knock outs and gene replacements to be made.

Of particular interest in *Physarum* is a complex system of photoreceptors and signaling that controls the onset of sporulation (3). The naturally synchronous cell cycle of *Physarum* plasmodium has been especially interesting, because fluctuations of inositol phosphate levels appear to be involved in its control (4).

Studies using the acellular slime mold *Physarum polycephalum* as a model eukaryotic organism have made contributions to our understanding of basic cell functions. Interesting insights will continue to be made using this soil amoeba in the laboratory.

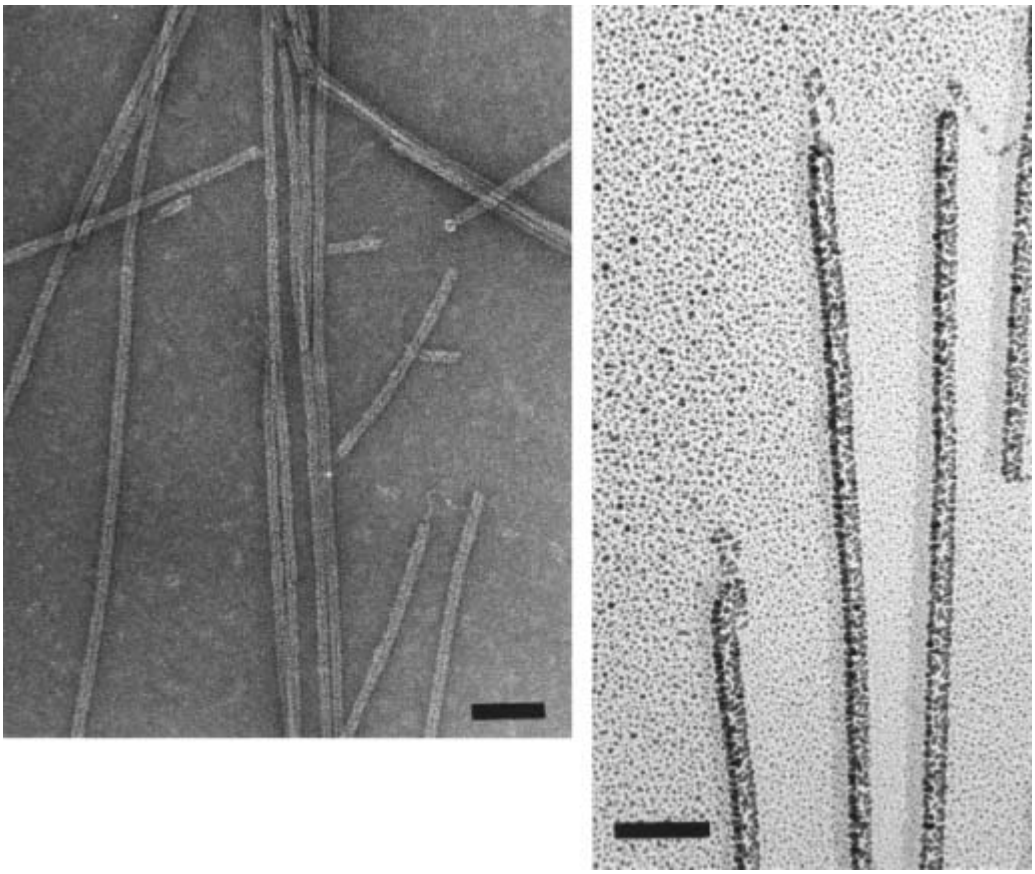
Pili

Adhesion pili are fairly stiff, filamentous structures, typically about 6.8 nm in diameter and about 1 µm in length, that protrude from a **bacterium** and provide specific attachment sites between the bacterium and some target cell (Fig. 1). The pili (or *fimbriae* as they are also known) terminate in a flexible fibrillum about 2.5 nm in diameter. The link between the bacterium and the cell is maintained during mechanically challenging situations *in vivo*, but the pili undergo significant structural rearrangement as a consequence. **Single-particle reconstruction** work has shown that the pilus may unwind without depolymerizing to produce a fibrillum-like structure, thus generating a filament as much as five times its original length whilst maintaining a high degree of structural coherence (1). A wide variety of pili exist *in vivo*, and these include the mannose-binding type I pili of the *Enterobacteriaceae* family and the gonococcal type IV pili. The data suggest that pili from all sources have a conserved structure and a similar morphology.

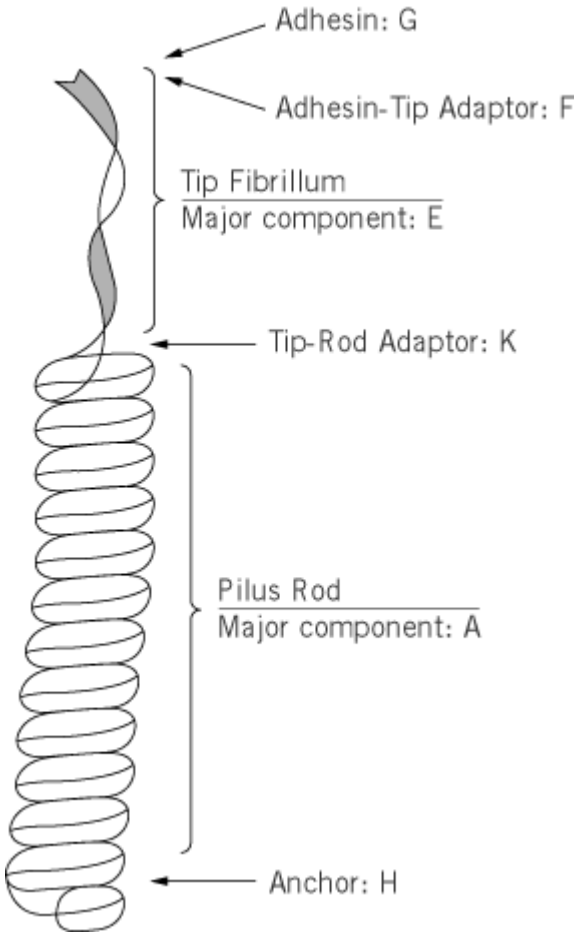
Figure 1. Electron micrographs of (left) negatively stained and (right) metal-shadowed P pili from *E. coli* that cause pyelonephritis. The 2.5-nm-diameter fibrillum extending from the end of the pilus is clearly shown at right. Bar = 50 nm. (Courtesy of E. Bullitt and L. Makowski.)



P pili, the surface appendages of *Escherichia coli*, have been particularly well characterized by X-ray fiber diffraction, scanning transmission electron microscopy (STEM), and three-dimensional reconstruction methods (1, 2), and for that reason they are described here in more detail. The pilus of

diameter 6.8 nm contains approximately 1000 copies of a single protein (PapA) of molecular weight 16.5 kDa (Fig. 2). Pili-terminating fibrillae are composed of proteins known as PapE, PapF, and PapK. The former two proteins position PapG at the tip of the fibrillus: PapG is a digalactose-binding molecule and is responsible for binding to the host (1). PapA, PapE, and PapF are similar in sequence, especially at their *C*-termini where they bind to PapD, the periplasmic **molecular chaperone**. The crystal structure of PapD (3) reveals a pair of **domains**, each comprising an antiparallel b-barrel, linked by a hinge region. PapH appears to stabilize the attachment of the pilus to the outer membrane of the bacterium. The assembly of P pili also requires PapC, an outer membrane protein.

Figure 2. Schematic of the position of proteins in P pili. (From Ref. 4, with permission.)



Fiber X-ray diffraction patterns from orientated pili are consistent with a helical structure having about 33 subunits in 10 turns (2). This helix is characterized by an axial repeat of 24.45 nm, a pitch length of 2.445 nm, a rise per subunit of 0.742 nm, and 3.30 subunits per turn. Measurements of the mass-per-unit length determined using STEM were consistent with each subunit comprising a single PapA molecule. Three-dimensional reconstruction methods yielded similar helical parameters based on a structure with 23 subunits in seven turns (an axial repeat of 17.43 nm, a pitch length of 2.49 nm, a rise per subunit of 0.758 nm, and 3.28 subunits per turn: Fig. 3). These values are also very similar to those reported for type I pili from *E. coli* (pitch length 2.32 nm and 3.125 subunits per turn), in which a single pilin (FimA) predominates. This protein has about 25% sequence identity with PapA and would be expected to have a similar three-dimensional conformation. Using rotary shadowing, the handedness of the P pili helix has been determined. The three-start helix with a pitch length of about 9 nm has been visualized directly and is left-handed. Hence, the fundamental one-start helix is

right-handed. The pili have an off-centered helical cavity (the radial coordinate of the center of the cavity is about 0.5 nm) with approximate dimensions 2.5 by 1.5 nm (1). Channels emanating out from the cavity link it to the outside of the pilus. The shape of the PapA molecule is not yet known, but it has been suggested that its long axis may lie along the same direction as the one-start helix, thus facilitating a possible structural transition to the more extended helical form arising from the response of the pili to mechanical stress. Bullitt and Makowski (1) have proposed that the relatively stiff pilus can be transformed to a flexible fibrillum if the interactions between the PapA molecules on adjacent turns of the one-start helix are broken and if there is a rotation of the domains along the direction of the one-start helix. PapA, as well as some of the other Pap proteins, would thus be expected to be elongated under these conditions. Because the mass-per-unit-length of a fibrillum is about one-fifth of that of the pilus, it is possible that the pilus could be extended fivefold. As a result, many pili with different lengths would be able to bind the cell simultaneously, thus providing stronger adhesion than if the pili were of fixed length. In that case they would have a greater chance of being broken individually when under shear.

Figure 3. Three-dimensional reconstruction of P pili from electron microscopy and image analysis. P pili are 6.8 nm in diameter and have a helical symmetry with 23 subunits in seven turns. The pitch length of the helix is 2.49 nm, and the axial rise per residue is 0.758 nm. *E. coli* may utilize plastic deformation of P pili to withstand shear forces in the host cell environment, extending the pilus to a thin fibrillum-like structure to maintain attachment to the target cell. Bar = 2.5 nm. (Courtesy of E. Bullitt and L. Makowski.)

Pinocytosis

Pinocytosis is a form of endocytosis that is mediated by several different vesicular mechanisms and is responsible for both receptor-mediated and fluid-phase endocytosis. **Clathrin** -mediated endocytosis is the best-characterized pinocytic pathway and, in some cell types at least, is the major pathway for pinocytosis.

0.1. Clathrin-Dependent Endocytosis
The uptake of most receptor-bound ligands and extracellular fluid is mediated by endocytic clathrin-coated vesicles, typically 100 to 150 nm in diameter (1). These form constitutively from plasma membrane clathrin-coated pits during most of the cell cycle, but their formation, in common with other membrane trafficking events, does not occur during mitosis. Clathrin-coated vesicle assembly is initiated by the multifunctional AP-2 adaptor protein complex. The recruitment of AP-2 from the cytosol is poorly understood, but it may involve binding to inositol phospholipids and possibly to a polypeptide receptor [two related adaptor complexes, AP-1 and AP-3, are involved in vesicular transport from intracellular compartments (2)]. Membrane-bound AP-2 provides sites for attachment of cytosolic clathrin triskelions, which assemble either as flat lattices or invaginating lattice structures (see Clathrin). Clathrin assembly is required to drive membrane invagination at the cell surface, although local concentrations of specific lipids also contribute to membrane deformation.

AP-2 also provides binding sites for a spectrum of other proteins that are required structurally or catalytically for the formation of coated vesicles. These include amphyphysin, **dynamin**, EPS-15, synaptojanin, AP180/CALM, and the endophilins (SH3p4, SH3p8, SH3p13) (3). The precise roles of these proteins are still being established. Dynamin is currently the best characterized. This 100-kDa GTPase is recruited to coated pits *via* the **SH3** domain of amphyphysin and is required for pinching off (scission of) invaginated coated vesicles (1). GTP hydrolysis is required for a conformational change in dynamin that leads to fusion of the membrane at the neck of an invaginated vesicle. Cells that express dominant-negative mutant forms of dynamin do not internalize transferrin and other ligands taken up by receptor-mediated endocytosis. Moreover, the *Shibire* mutant of *Drosophila*

melanogaster has a temperature-sensitive defect in dynamin. At the nonpermissive temperature, *Shibire* mutants are paralyzed because they cannot release clathrin-coated vesicles, which is required to regenerate synaptic vesicles. Dynamin has also been implicated in forming of caveolae and non-clathrin vesicles (4, 5), but these processes are not well understood, and the full extent of dynamin function is still to be clearly established. Rab5 and RabGDI are also required for coated vesicle budding (6), and this may reflect some quality-control mechanism to ensure that endocytic-coated vesicles also include the correct SNARE proteins and allow the subsequent targeting and fusion of the vesicles with early endosomes.

Clathrin-dependent endocytosis is inhibited by treatments that interfere with the functions of the regulatory proteins, such as cytosolic acidification, hypertonic medium, or K^+-depletion, or by overexpressing modified forms of key protein components (clathrin hub domains, GTP-bound dynamin, amphyphysin-SH3 domains, Eps15 AP-2-binding domains), all of which act as dominant negatives (7). Under these conditions clathrin-dependent, receptor-mediated endocytosis (e.g., transferrin uptake) is blocked. Although the overexpression, for example, of dominant-negative dynamin blocks clathrin-dependent endocytosis, fluid-phase endocytosis is unaffected or only partially affected, suggesting that there is also a clathrin-independent pathway for constitutive endocytosis. Although this clathrin-independent pathway may be active to some extent under normal conditions (its contribution to total endocytosis may vary in different cell types ranging from <10% in baby hamster kidney cells to ≈ 50% in hepatocytes), its activity may be up-regulated when clathrin-dependent endocytosis is effectively blocked (8). The molecular basis of this clathrin-independent pathway is not known, but there are several other pathways that could mediate fluid-phase uptake (see later).

Following endocytosis, clathrin-coated vesicles must be uncoated to allow fusion with early endosomes. Uncoating, which is ATP-dependent and requires the proteins auxilin and hsc70, releases clathrin, AP-2, and the other vesicle components, allowing them to be reused (9).

0.2. Clathrin-Independent Endocytosis

Caveolae, or plasmalemmal vesicles, are flask-shaped (60 to 80 nm in diameter) invaginations seen on the cytoplasmic aspect of the plasma membrane in many cell types. It is believed that they form by the oligomerization of a coat protein, caveolin (VIP-21). The function of caveolae is unclear. In endothelial cells, they mediate transcytosis, but in other cells they may provide an alternative endocytic route, although their net contribution to total endocytosis is likely to be small. Caveolae function in the concentration of a subset of cell-surface proteins, including **GPI-anchored** molecules, such as the folate receptor, and may internalize these components. Caveolae have also been implicated in the entry of **SV40 virus**. The caveolar membrane has a characteristic lipid composition distinct from the bulk of the plasma membrane and includes a relatively high cholesterol content. Thus drugs that preferentially bind cholesterol, such as filipin or nystatin, disrupt caveolae structurally and functionally. This distinctive membrane lipid composition also includes a concentration of the ganglioside GM1. GM1 functions as the receptor for **cholera toxin** and, in keeping with this, the endocytic uptake of cholera toxin is caveolae-mediated. Dynamin (see previous) has also been implicated in the pinching off required to release caveolae into the cytosol, presumably using the same mechanism as in clathrin-mediated endocytosis (4, 5). Caveolae also function in **calcium signalling** and signal transduction, and purified caveolae contain heterotrimeric G proteins, , Src family protein kinases, and protein kinase C. Certain cell types, for example lymphocytes, lack VIP-21/caveolin and identifiable caveolae, suggesting that caveolar function is not essential for cell viability. The fate of internalized caveolae is unclear, and it has been suggested that they may fuse with early endosomes.

Plant Genetic Engineering

Plant genetic engineering is defined as the creation of a complete **plant** containing a fragment of foreign **DNA** stably inserted into its nuclear genome. During the last 15 years, the majority of the world's most significant crop plants have been transformed. Apart from a significant impact on plant research in general, the products of **transgenic** plants are currently entering the marketplace and, indeed in some cases, are achieving market dominance.

Plant transformation relies on inserting foreign DNA into a single plant cell, followed by regenerating that cell into a complete plant. Often this process relies on **totipotency**, the unique ability of isolated plant cells, when cultured in the presence of plant hormones, to divide to form an undifferentiated callus that, in turn, is induced to form shoots and roots and thus a complete plant. Two general means are available for transferring foreign DNA to plant cells, ***Agrobacterium***-mediated transformation and naked DNA uptake.

Agrobacterium is a soil **bacterium** that contains a tumor-inducing Ti plasmid. During *Agrobacterium*-mediated transformation, a defined fragment of the Ti plasmid, the so-called transferred or T-DNA (see T-Complex, -DNA, -Region, -Strand), is transferred from the bacterium to the infected plant cell and integrated stably into the plant nuclear genome. The T-DNA is delimited by 25-bp imperfect border repeats. Transformation **vectors** based on the T-DNA have been developed and can be grouped into two types, cointegrative and binary. Cointegrative vectors are based on a Ti plasmid in which the body of the T-DNA within the border sequences has been replaced by a defined sequence of DNA. Foreign DNA contained on an appropriate **plasmid** is introduced into *Agrobacterium* and integrated into the cointegrative vector by recombination. Binary vectors are based on plasmids stable in both *Escherichia coli* and *Agrobacterium*. They contain T-DNA border sequences between which foreign DNA can be **cloned** to be transferred to the plant genome. Then, the binary vector is transferred to a host *Agrobacterium* that contains a Ti helper plasmid which contains functions necessary for gene transfer to plant cells, but lacks a T-DNA. Because cointegrative vectors are based on the Ti plasmid, they are very stable in *Agrobacterium*, but they can be difficult to work with in practice. On the other hand, binary vectors can be handled with relative ease, although they are unstable in *Agrobacterium* and continued antibiotic resistance selection is required to maintain them (1).

Transformation using *Agrobacterium* requires direct contact between the plant cell and the infecting bacteria. In practice, this is achieved by cocultivation of *Agrobacterium* with isolated plant cells or explants, such as leaves, roots, or tubers. In this case, bacteria are incubated with plant material, and transformation occurs over a period of about two days. Then, the plant material is washed to remove

excess bacteria and cultured further to allow plant regeneration (1). Recently, a novel nontissue culture approach of transformation has been described using the model plant Arabidopsis. Here the developing floral buds of intact plants are vacuum infiltrated with the *Agrobacterium* . The plants are washed, allowed to recover, and selfed. From progeny seeds, transgenic plants can be selected by growth on antibiotics to which resistance is encoded by the foreign DNA contained on the transformation vector (2). It has been generally assumed that *Agrobacterium*-mediated transformation is limited to the obvious natural hosts of *Agrobacterium*, the dicotyledonous plants. Recently, however, it has been established that *Agrobacterium* can be used effectively to create transgenic monocotyledonous plants, such as rice (3).

Naked DNA uptake was developed for two reasons: (1) as a means of transforming plants whose cells, or tissues, are not amenable to culture and to high-frequency *Agrobacterium* transformation; (2) because of the possibility of using nonspecialized plant transformation vectors in transformation. Naked DNA transformation uses standard bacterial plasmids as vectors. The only requirement is that the plasmid contains a gene linked to a plant-specific promoter that is functional in transgenic plants. Several methods are available to transfer foreign DNA into plants. The two techniques used most frequently with isolated cells, treatment with **polyethylene glycol** and electric discharge or electroporation (see Transfection), achieve relatively high frequencies of transformation, which generally result in measurable activity of the transferred gene constructs after approximately one day. This allows transient expression assays, for example, to test the expression of specific promoter/gene constructs. Cells transformed in this manner can also be regenerated to intact plants as described previously. Naked DNA can also be introduced into plant cells by particle bombardment. This involves coating gold or tungsten particles with DNA and using a gas or electric discharge to project the particles into target cells. This can be used to study transient expression in intact tissue, but its greatest practical application has been to insert foreign DNA into explants from which shoot or root organogenesis can occur (4).

In both *Agrobacterium*-mediated transformation and naked DNA uptake, the foreign DNA stably integrates into the nuclear genome of the plant. *Agrobacterium*-mediated transformation can result in inserting a single unrearranged fragment of DNA that represents the T-DNA. In transgenic cells resulting from naked DNA uptake,however, the DNA might be rearranged and can occur as multimers.

Upon insertion into the genome, a gene linked to a plant-specific promoter is expressed in a pattern determined by that promoter. A variety of reporter genes have been developed to allow direct selection for the growth of transgenic material (for example, resistance to kanamycin, hygromycin, or herbicides) or for screening for expression (for example, histochemical staining with **b-glucuronidase** or **fluorescence** resulting from expression of the jellyfish green fluorescent protein). An increasing variety of promoters are available to produce expression in most plant tissues (for example, the 35 S-RNA promoter derived from cauliflower mosaic virus) or expression in a tissue-specific manner (for example, tapetum-specific expression). Recently promoter constructs have been developed so that the expression of specific genes can be induced in defined tissues following the external application of an inducing substance, such as glucocorticoids (5).

Gene expression can also be inactivated in transgenic plants, by the expression of either antisense oligonucleotides (6) or sense constructs of the target gene, a phenomenon known as cosuppression. The exact mechanism by which cosuppression occurs is not known nor is the reason for the instability of transgenic expression that often occurs in some plant lines (7).

In addition to transferring foreign genes to the genomes of plants, transformation in plants can be considered a form of insertional mutagenesis. This is the basis of *gene tagging*, where a defined sequence of DNA inserts into the genome and knowledge of this sequence allows recovering the flanking plant sequence from mutant genomes by **hybridization**, **PCR**, or plasmid rescue. Either transposable elements transferred to a novel plant host or T-DNA can be used in gene tagging. The latter has the advantage of producing single insertions, simplifying genetic analysis, but requires

screening large numbers of mutant individuals following a transformation experiment. The transposable element approach has the advantage of using populations of mutant individuals produced by genetic crossing. Each individual contains multiple transposon insertions, thus reducing the number of mutants that need to be screened for a mutant phenotype. The construction of gene tags can vary. For example, at their borders they can contain a reporter gene lacking a promoter, so that expression of the reporter gene occurs only if it is inserted into the genome near a promoter (8, 9). Another example is the use of a tag that contains transcriptional **enhancers**, so that expression of flanking genes becomes activated following insertion of the tag into the plant genome (10).

Plant genetic engineering has had a profound effect on basic plant biology. Transgenic plants have been used to study the mechanism of gene expression and the developmental and biochemical consequences of the expression or inhibition of the expression of various genes (11).

The creation of transgenic plants has begun to have a profound effect on agriculture because of the steady appearance of genetically engineered crop plants. These include plants tolerant of herbicides or resistant to insect predation and viral infection. Interestingly, plants altered in developmental events or biochemical processes have also gained a place in the agronomic marketplace. Possibly the most widely known example of this is the tomatoes engineered, using antisense technology, so that the polygalacturonidase gene, which is normally involved in the softening of fruit, is not expressed during fruit development. These tomatoes have delayed ripening (12). Another interesting example is the potatoes engineered so that they contain a changed starch content and quality for industrial processes (13). The acreage of transgenic crops planted is steadily increasing worldwide (14). This technology is, however, not without its opponents. Concerns have been raised as to transfer of the transgenes from transgenic plants to local plant relatives, increasing the weediness of certain plant species, and the creation of products that may induce unexpected allergies in consumers.

Plant Hormones

Development of higher organisms—plants as well as animals—is largely based on a coordinate division, expansion, and differentiation of cells. This coordination is primarily based on cell-to-cell communication over short and long distances and is orchestrated by messengers of various chemical nature. One class of signaling molecules contains the hormones, characterized by their ability to exert, most often, specific effects over a distance and by their capacity to act at very low concentrations. This entry presents a brief overview of the current state of the art in the field of plant hormones, or phytohormones.

Since the first discovery of phytohormones, approximately 70 years ago, dedicated efforts of plant physiologists and biochemists have produced a wealth of data on their chemical nature, pathways of biosynthesis and metabolism, possible conjugates, transport mechanisms throughout the plant, and physiological functions (1). Studies have been based traditionally on the correlation of the effects observed upon exogenous application of hormones with changes in their endogenous concentration. A major disadvantage of this approach is that it remains uncertain whether the effect reflects the normal physiological role of the hormone. Another problem arises from the fact that the distribution of the growth regulator over the entire plant body is largely unpredictable. Moreover, problems of uptake and rapid metabolism were not uncommon. The use of inhibitors had the additional drawback of potential lack of specificity. In the past decade, our knowledge of the molecular basis of plant hormone biology has made a giant leap forward, mainly owing to molecular genetic studies of mutants in thale cress (Arabidopsis *thaliana* (L.) Heynh.). Molecular techniques have allowed the unraveling of mechanisms by which phytohormones control tissue-specific and developmentally regulated responses. Genetic engineering enables changes in internal concentration or perception of a hormone in a temporally and spatially controlled manner. Moreover, several applications in agriculture and horticulture are being explored (2-4). Introduction of bacterial hormone biosynthesis genes (mainly from Agrobacterium *tumefaciens*) into plants has confirmed much of the classical view of hormone action (5).

Our current understanding of the biosynthesis, perception, signal transduction, control of **gene expression**, and effects of each class of phytohormones are presented in the separate entries. Six classes of compounds are recognized as true phytohormones: **auxins, cytokinins, gibberellins, abscisic acid, ethylene**, and brassinosteroids. Other growth regulators, such as polyamines, oligosaccharides, and salicylic and jasmonic acids, also influence plant growth and development. For a description of their effects, see recent reviews (6-8).

It is important to stress that plant hormones do not play exclusive roles in development, but that they instead act coordinately at different stages. The most direct indication for this characteristic is their overlapping physiological roles (1). This cross-talk is most certainly based on molecular interactions between factors regulating signal transduction and feedforward or feedback loops of different hormone pathways. Moreover, environmental cues can exert an additional level of control on plant hormone abundance and activity. Thus, hormone signaling pathways are probably integrated with those participating in phototransduction, control of the biological clock, nutrient sensing, and stress (9). Given the redundancy of involvement of signaling intermediates, such as **G proteins,**

phosphorylation cascades, and calcium signaling, mechanisms should exist to maintain accuracy of individual signaling chains (10). Much of the specificity might derive from a restricted spatial distribution of signaling components together with their assembly in complexes, called *transducons*. The latter would consist of a module of receptors, receptor targets, and downstream signaling factors, presumably coupled by 14–3–3 proteins (11). Such scaffolding proteins have been demonstrated in signaling pathways in bacteria and in yeast (12, 13). Interactions between different transduction cascades could be exerted by components that navigate between them—for example, second messengers or mobile protein **kinases** (14).

With the current progress in sequencing of the genome of *Arabidopsis*, plus the technical advances that allow rapid map-based cloning, creation of large tagged-mutant collections (15), and production of **knockout** mutants by homologous recombination (16), it can be predicted that the molecular controls of hormonal pathways and their target genes will be unraveled at a dazzling pace in the next few years. The puzzle of inter- and intracellular hormonal networking will soon come of age.

Plasmalemma

Plasmalemma (plasma+Gr. lemma = pellicle) is a membrane structure that is synonomous with the plasma membrane of cells. There are other usages of the term. In sea urchin eggs, it is the vitelline membrane covering the hyaline plasma layer; upon fertilization the vitelline membrane thickens and becomes the fertilization membrane, which separates from the plasma membrane lying just beneath. In **amoeba**, it is the outermost membrane, which also contains many filamentous structures. In **plants**, it is the external membrane of the cytoplasm; under osmotic stress in hypertonic salt solutions, plant cells undergo *plasmolysis*, where the plasmalemma separates from the cellulose wall of the cell. (See also Membranes.)

Plasminogen

Plasminogen is one of the most abundant **zymogens** of **serine proteinases** in mammalian species; it is expressed constitutively in the liver and is present in blood at 200 μg/mL. The activated proteinase, plasmin, is one of the most active, because of its broad substrate specificity. The activation system for plasminogen is therefore a powerful and potentially promiscuous **proteolytic** system, which consequently has mechanisms for its strict regulation. The most fundamental of these is the ability of plasminogen to bind to various insoluble matrices (ie, fibrin and certain cell-surface components), a process regulating both the activation of plasminogen (see Plasminogen Activators) and the inhibition of plasmin.

The binding properties of plasminogen are mediated by its various kringle domains. Plasminogen is a mosaic protein composed of a 77-residue *N*-terminal **domain**, five kringle modules, and the serine proteinase domain. The kringle modules each contain a binding site for lysine or other w-amino carboxylic acids. Kringle 1 binds these ligands with the highest affinity (**dissociation constant** K_d = 10 μ*M* for 6-aminohexanoic acid) and represents the archetype for this binding site. It contains both anionic and cationic centers, with an intervening **hydrophobic** depression (1, 2). The cationic center is not present in all kringles, such as kringle 5, and these have a preference for ligands lacking a carboxylate function. Therefore, plasminogen can interact with the side chains of internal lysine residues, as well as those at the *C* -termini of proteins degraded by proteinases with a specificity for basic residues, including **trypsin**, or plasmin itself. The latter mechanism may act to amplify the plasminogen activation system.

The gross conformation of plasminogen is dramatically affected by kringle-binding ligands (3). In the absence of such ligands, it adopts a compact conformation, due to poorly understood interactions between the *N*-terminal domain and the kringle modules. Exogenous kringle-binding ligands disrupt these interactions and cause an extension of the molecule to approximately double its length. This conformational change can also be accomplished by proteolytic removal of the *N*-terminal peptide,

generating Lys78-plasminogen (to discriminate between them, the native molecule is often referred to as *Glu1-plasminogen*). The conformation of plasminogen has a very marked effect on its activation, with the extended or "open" form being activated at least 10-fold more efficiently. The absolute difference in activation rates may be much larger, as the "closed" form is in equilibrium with the "open" form in the absence of exogenous ligands. Thus the physiologically relevant substrate form of plasminogen is thought to be that bound to various surfaces in the "open" conformation.

Plasmin free in solution is very rapidly inhibited by the serpin a_2-antiplasmin, which is dependent largely on an initial interaction between the C-terminal region of the inhibitor with the lysine-binding site of plasmin kringle 1 (4). Hence, plasmin inhibition is decreased when these sites are occupied by binding to fibrin or cell surfaces (5). Plasmin and plasminogen have moderate affinities for these surfaces (K_d~1 μM),. with dissociation half-lives of the order of minutes. Thus binding of plasminogen and subsequent dissociation of plasmin, respectively, regulate the activation and inhibition of this proteolytic system.

One final notable feature of plasminogen is its potential to attain proteolytic activity in the absence of the activation cleavage at Arg561–Val562. The non-enzymatic bacterial protein streptokinase binds to the serine proteinase domain of plasminogen and induces a conformational change, with the formation of a functional active site. This has full activity against peptide substrates, but the specificity of the complex against macromolecular substrates is changed from that of plasmin to that of a plasminogen activator. Therefore, "catalytic" amounts of streptokinase can rapidly lead to full activation of plasminogen. Although this property is used clinically to generate plasmin activity *in vivo*, an equivalent endogenous mechanism has not been detected.

Plasminogen Activators

Mammalian species have two plasminogen activators, urokinase- or urinary-type plasminogen activator (uPA) and tissue-type plasminogen activator (tPA), that are the products of separate genes and members of the chymotrypsin family of serine proteinases. Both are mosaic proteins with a modular structure similar to that of the blood coagulation proteinases to which they are closely related [Blood Clotting]. The two plasminogen activators provide an excellent example of the regulatory potential made available by the modular construction of these proteinases. Although catalyzing the same reaction, *i.e.* specific hydrolysis of Arg560-Val561 of plasminogen, gross differences in the organization of the N-terminal modules of the plasminogen activators, together with subtle differences in the serine proteinase domain, lead to remarkably different functional properties. These are reflected in their biological roles with tPA being predominantly responsible for plasmin-catalyzed fibrin dissolution, whereas uPA is thought to be responsible for generating plasmin activity in the context of extracellular matrix degradation and thus to be involved in tissue

remodeling and invasive cell migration (*e.g.* tumor invasion and metastasis; vascular remodeling) (see Urokinase).

1. *tPA*

tPA is composed of five independent domains; an N-terminal fibronectin type-I (finger) module, an EGF-like module, two kringle modules and the serine proteinase domain. It is secreted primarily by vascular endothelial cells as a single-chain glycoprotein of 527 residues (M_r 66,000). This single-chain form also undergoes a plasmin-catalyzed "activation" cleavage (Arg275-Ile276) to give a disulfide-bridged two-chain molecule. However, uniquely among the serine proteinases, the catalytic activities of these two forms are very similar. They vary by approximately 10–20–fold in the absence of cofactors, but in the presence of fibrin [see "Fibrinogen"] as a cofactor their activities are essentially indistinguishable. Molecular modeling and mutagenesis studies suggest that the "active zymogen" nature of tPA is largely due to Lys429 (Lys156 in chymotrypsin numbering); in the absence of a proteolytically exposed N-terminal a-amino group at Ile276, it can form a salt-bridge with Asp477, substituting for the interaction between the a-amino group of Ile16 with Asp194 in chymotrypsin (1). The crystal structure of two-chain tPA is compatible with this hypothesis (2).

Fibrin has a dramatic effect on the on the activities of both forms of tPA. The catalytic efficiency increases up to 1000-fold, as a result of a large reduction in the K_m (Michaelis constant) for plasminogen and a more modest increase in the value of the catalytic rate constant k_{cat} (3). More than one mechanism appears to be responsible for these kinetic effects. Fibrin principally enhances plasminogen activation by provides a template for the coincident binding of enzyme and substrate in a ternary complex. In contrast to the binding of uPA to uPAR, the interactions between tPA and fibrin responsible for this binding are complex and not fully elucidated. The fibronectin type-I and the lysine-binding properties of the second kringle module are involved, with sites in the serine proteinase domain also implicated. Secondary to this template effect, fibrin also appears to induce conformational changes in the serine proteinase domain of single-chain tPA, bringing it to catalytic equivalence with two-chain tPA, and increasing its activity against small peptide substrates. Whether these are direct effects or result from the significant interdomain interactions that exist in tPA is presently undetermined.

In addition to its fibrinolytic role, analysis of $tPA^{-/-}$ knock-out mice has revealed a role for tPA in the brain, in both normal and neurodegenerative situations. The proteolytic activity of tPA is implicated in the plasticity and reorganization of synapses involved in various learning processes, although it is not known whether plasminogen activation is required in these processes or whether tPA acts on other substrates. tPA is also involved in neuronal cell death following excitotoxin stimulation of the hippocampus and in ischemic stroke. The former process is known to require plasminogen activation, with plasmin acting to degrade laminin, an important extracellular matrix component in the central nervous system (4).

Plasmogamy

Plasmogamy occurs when two different cells fuse with each other and the **cytoplasm** of both is joined. During **fertilization**, plasmogamy occurs when the **sperm** has entered the cell membrane of the **egg** and a male and a female **pronucleus** develop. However, plasmogamy in animal **reproduction** is unusual in that the amount of cytoplasm of the two **gametes** is disparate. The **oocyte** is one of the biggest cells in the body and contains most of the cytoplasm, whereas the spermatozoon is a very specialized cell that contains only very small amounts.

The length of time it takes the sperm head to fuse with the oocyte cytoplasm depends on the species. In general, fusion takes place during **meiosis** of the oocyte. These divisions are necessary, as the primordial germ cells remain **diploid** until ovulation commences at the beginning of puberty under the influence of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). During growth and oogenesis, the oocyte becomes temporarily **tetraploid** and undergoes two meiotic divisions, resulting in the extrusion of polar bodies. Formation of the first polar body involves a cytoplasmic protrusion at the **animal pole**. The cytoplasm is not divided equally among the two cells, however, and the polar bodies contain less material than the remaining oocyte. The first polar body in a number of different species appears to be a miniaturized cell. The second polar body appears after the second meiotic division and contains a variable amount of cytoplasmic contents. In most cases, however, the fate of the polar bodies is a degenerative process. During this stage of fertilization, the formation of crenations along the vegetal pole occurs, along with redistribution of cytoplasmic compounds.

Upon sperm entry, which is the first step that can be considered a unification in which the cytoplasms are joined, a number of events are triggered. Sperm entry itself is mediated by an adhesion protein named *fertilin* (previously known as PH-30). The a-subunit of fertilin is involved in mediating the binding of sperm and egg plasma membranes (1); there is also evidence for adhesive activity of an egg b1 integrin -mediated interaction (2). These gene products are expressed by the ADAM **gene family** and are processed during sperm maturation (3, 4).

The first measurable event during plasmogamy is a rapid depolarization of the plasma membrane on sperm entry. This process is used in some species to prevent more than one spermatozoon from entering the egg. In sea urchins, eggs with a fertilization potential greater than 0 mV are not polyspermic. Maintaining a potential of +5 mV causes a block of fertilization. If the applied voltage is lowered below 0 mV, fertilization will occur and, if the potential is maintained below –30 mV, the eggs will become polyspermic. These observations indicate that a rapid change in the potential of the plasma membrane is a first reaction of the egg to sperm entry. The change in polarity occurs concomitantly with the influx of calcium (see Calcium Signaling). The release of calcium and of the cortical granules occurs in a sort of wave, starting from the point of sperm entry. Within the cell, the pH is raised, which is assumed to be another factor of egg activation, along with enhancing or

initiating **protein biosynthesis**, **DNA replication**, **messenger RNA** polyadenylation, glucose-6-phosphate dehydrogenase activity, potassium conductance, glycogenolysis, and thymidine uptake. These events go together with the **pronucleus** development and **chromatin** condensation. The cortical granule reaction does not seem to be affected by the raised pH.

Exocytosis of the cortical granules is another event that occurs during plasmogamy. The contents of the granules trigger the conversion of the ZP2 and ZP3 **glycoprotein** receptors for sperm to ZP2f and ZP3f, respectively, which are the inactivated forms. In the mouse, rabhilin-3A is involved in the process of calcium-dependent exocytosis on fertilization (5).

There are several explanations for the calcium release mechanism: It can be mediated by **inositol triphosphate** (IP_3) or be IP_3-independent, or it can be mediated by **G-protein** or **tyrosine kinase**-linked enzymes. It has been shown that IP_3 and **diacylglycerol** are involved in a number of **signal transduction** processes and that IP_3 is involved in the autocatalytic cycle of calcium release at fertilization (6). These observations have led to the assumption that the sperm induces an initial production of IP_3, but the mechanism of IP_3 generation has not been elucidated. In addition to this theory, the production of IP_3 and diacylglycerol is assumed to be linked to proteins, as their involvement was shown in several species in which G-proteins triggered the formation of IP_3 . Up until now, however, no corresponding molecules were found that could support this kind of sperm-induced egg activation. It was also shown, in sea urchins, that ryanodine is able to induce calcium release through ryanodine receptors, which are distantly related to the IP_3 receptors. In experiments with agonists and antagonists of the IP_3 receptor, the involvement of both systems in calcium release was observed. When the IP_3-induced calcium release was blocked, however, other systems were not able to compensate. At this time, it must be assumed that a number of mechanisms act together to induce calcium release, but the initial triggering mechanism is still not clear.

Plastocyanin

Plastocyanins belong to the family of cupredoxins [ie, relatively small (~10 kDa, 97–104 amino acid) blue single copper proteins, including **azurins**] involved in **electron transfer** (1). They are

found in the thylakoid lumen of **chloroplasts**, where they function as electron carriers in oxygenic photosynthesis from cytochrome *f* in the b_6f complex to $P700^+$ of photosystem I (2).

The three-dimensional (3-D) protein structure of plastocyanin isolated from the poplar tree was the first one of the family to be determined, in 1978 (3). Since then, structures of other (algae and plant) plastocyanins have been determined, either by X-ray crystallography or by nuclear magnetic resonance (NMR) methods. In parallel, the oxidized poplar plastocyanin structure has been refined to 1.22 Å resolution (4), and its reduced form structure has also been determined (5). Despite sequence **divergence** among plastocyanins of algae and vascular plants, their 3-D structures are remarkably conserved. It is a barrel-shaped molecule, constructed of eight antiparallel **b-strands** (Fig. 1). The metal-binding site is at one end of the b-barrel and consists of (a) a copper ion coordinated in a trigonal bipyramidal geometry with the thiolate of a cysteine residue and two imidazole nitrogens of histidine residues in the trigonal plane and (b) a methionine sulfur and a remote carbonyl oxygen atom occupying axial positions. This cordination sphere is typical of the blue or Type 1 (T1) copper site in all cupredoxins (1). The protein's intense blue color is due to a $\pi S \rightarrow Cu(d_{x^2-y^2})$ligand-to-metal charge transfer involving the thiolate ligand as the electron donor, and it has a molar extinction coefficient of ~3000 M^1cm^1. This is more than 100 times larger than that found for simple Cu(II) complexes (6, 7). A second characteristic property associated with the blue T1 Cu(II) site is an EPR spectrum (see **Electron paramagnetic resonance**) displaying a hyperfine splitting in the $g_{\|}$region, due to interaction of the copper nuclear and electron spins, which is exceptionally narrow (~0.008 cm^1 and approximately 50% smaller than those of ordinary copper complexes. This is attributed to delocalization of the unpaired $Cu(d_{x^2-y^2})$electron onto the Cys(S) *p*p orbital, thus reducing the nuclear–electron interaction. The unique spectroscopic properties are due to the T1 Cu (II) site structure and are assumed to be related to the electron transfer function of cupredoxins in general (6-9). The relationship between these unusual properties and the electron transfer reactivity is a central issue in studies of biological electron transfer proteins.

Figure 1. The three-dimensional structure of plastocyanin. The copper center with its ligands is seen near the top of the molecule, just below the “Northern” hydrophobic patch. The negatively charged residues are centered at the right-hand side of the figure.

The **oxidation–reduction potentials** of Cu(II)/Cu(I) in plastocyanins (~350 mV) are higher than generally observed for copper complexes. The metal–protein interactions within this site maintain the Cu(II) away from a square-planar geometry, toward a distorted tetrahedral geometry. This explains the relative stabilization of the Cu(I) state relative to Cu(II). Structure-imposed Cu → L p-backbonding has been proposed to account further for stabilization of the cuprous state, because strong p-interaction with the *d*p orbitals results in an increase of the ligand field strength (9-11).

A flat **hydrophobic** surface present at one end ("north") and a patch with pronounced negatively charged residues on one side of the protein barrel (east) characterize the plastocyanin surface. Both the negative and the hydrophobic patches were proposed to be involved in the interactions of plastocyanin with its physiological reaction partners (12, 13). In eukaryotic plastocyanins, this negatively charged patch surrounds a nearly conserved residue, Tyr83, that has been implicated to act in one proposed electron transfer pathway. The shape and charge distribution around the negative patch make it a unique region on the surface of the molecule in both plant and algae plastocyanins. The hydrophobic surface located at the "north" end of the molecule surrounds His87, the only solvent-exposed copper ligand and hence an obvious site for electron transfer (14). This patch consists of at least eight amino acid residues that are conserved in eukaryotic plastocyanins, with no charged or polar residues in this region. The solvent-accessible surface of this hydrophobic patch is approximately 550 Å ^{2}. The side chain of Phe35, the only large residue in this area, lies along the surface of the molecule, without extending significantly into the solvent. The flatness of this patch suggests that it is important for the interaction of plastocyanin with its reaction partners. Significantly, all the cupredoxins of known structure contain a hydrophobic area surrounding their solvent-exposed copper-liganding histidine residue.

Considerable details of the structure–function relationship of plastocyanin were attained in recent years. These have established that the electron transfer activity is indeed confined to the exposed

histidine residue in the flat patch, while the tyrosine residue surrounded by the negative patch has apparently a role in formation and proper alignment of plastocyanin in its electron transfer complex formed with P700 in the photosynthetic reaction center of photosystem I (15, 16).

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) is a growth factor that exerts multiple biological activities in many cell types and tissues. PDGF exists in three forms. Each form consists of a homo- or heterodimeric combination of two genetically distinct but structurally related polypeptide chains, A and B. PDGF chains play important roles in connective tissue development. Mice deficient in B chain lack mesangial cells in their kidneys and develop cardiac and other microvascular abnormalities. PDGF A chain-deficient mice manifest generalized lung emphysema due to the absence of alveolar myofibroblasts. PDGF isoforms exert their effects on target cells by binding to two structurally related protein tyrosine kinase receptors, alpha (a) and beta (b). The alpha receptor binds to the A or B chain, whereas the beta receptor binds only to the B chain. Differences in their biochemical properties and the relative abundance of receptor subunits and or PDGF chains determine the biologic responses to PDGF.

Upregulation of PDGF chains and receptors has been implicated in the pathogenesis of diverse conditions, including carcinogenesis, atherosclerosis, glomerulonephritis, and pulmonary and hepatic

fibrosis. Molecular and genetic approaches have demonstrated an essential role for PDGF and its receptors in the development of connective tissue in the kidney, lung, cardiovascular, skeletal, and nervous systems.

1. Historical background

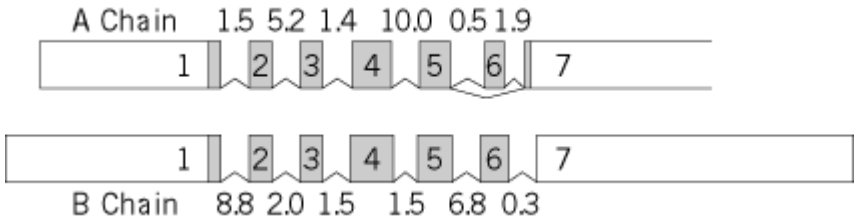
PDGF was first recognized as serum-associated growth-promoting activity for smooth muscle cells (1), fibroblasts (2), and glial cells (3). It was subsequently purified by different groups from human platelets (reviewed in Ref. 4). The 30-kDa protein was found to consist of two separate polypeptide chains linked by disulfide bonds. The two chains were eventually separated by reverse-phase **HPLC** and referred to as A and B chains, based on their order of elution. On sequencing, the B chain turned to out to be identical to $p28^{SIS}$, the transforming protein of simian sarcoma virus (SSV). This finding provided the first link between growth factors and **oncogene** products and suggested a mechanism by which oncogene products subvert the mitogenic pathway and stimulate cell growth and transformation. Platelet PDGF now appears to be a mixture of PDGF-AB, -BB, and -AA (5-7). The cloning and availability of complementary DNAs encoding for both the A and B chains have allowed the production and isolation of the recombinant proteins using different expression systems. The subtle differences in the biological activities of the various purified PDGF isoforms could later be explained by their receptor-binding specificity and subtle differences in their signal transduction pathways.

Ligand-binding and **affinity-labeling** techniques demonstrated the presence of a specific 185-kDa PDGF receptor (4). Furthermore, PDGF stimulated an intrinsic protein **tyrosine kinase** activity of the receptor and resulted in the **phosphorylation** of specific cytoplasmic substrates. The murine beta receptor was cloned by Yarden et al. (8) and by Rönnstrand et al. (9), followed by the alpha receptor (10, 11).

2. Structure and Function of PDGF Isoforms

PDGF A and B are hydrophilic soluble proteins that share approximately 51% amino acid identity in the mature human proteins, and there is 35% similarity between *Xenopus* PDGF A and mouse PDGF B. Each chain is, however, more highly conserved between species, with *Xenopus* and mouse PDGF A sharing 71% similarity and mouse and human PDGF B, 89%. Their gene structure and organization are also remarkably similar (Fig. 1) (12). Both chains are synthesized as larger precursor molecules that are extensively processed. The A chain is the product of a single gene located on chromosome 7 that contains seven exons and gives rise to one of two differentially spliced variants (see Alternative Splicing). The "long" variant, a **prepropeptide** of 211 residues, is synthesized with a signal peptide of 20 residues, a propeptide sequence of 66 residues, and a mature chain of 125 residues. The "short" 196-residue variant shows a 20-residue signal sequence, a 66-residue propeptide, and a 110-residue mature form (13-15). The difference between the long and short variants is the result of alternative exon usage, with the long form using exon 6 (18 residues), but not exon 7, and the short form using exon 7 (3 residues), but not exon 6 (14). Within exon 6 lies an approximately 10-residue sequence that signals cell retention (14, 16, 17). The short variant contains no retention sequence and is secreted (18, 19). No mechanism for *C*-terminal processing of the long form of the A chain has been reported, and it is not clear whether this variant is secreted (20, 21). This sequence mediates interaction with heparan sulfate proteoglycans. Therefore differential compartmentalization of the chains may have important biologic implications. PDGF A is probably subject to both *O*-glycosylation and *N*-glycosylation, whereas PDGF B has only *O*-glycosylation. Recombinant PDGF binds and is biologically active, however, suggesting that glycosylation is not required for its activity (22).

Figure 1. Schematic illustration of the organization of the PDGF A- and B-chain genes.



The B chain is also the product of a seven-exon gene located on chromosome 22. The B-chain gene is now known to be identical to the human c- *sis* gene, the normal human cell counterpart to the monkey v- *sis* (simian sarcoma) virus gene (23). The protein coded for by c-*sis* is a 27-kDa, 241-residue prepropeptide with a 20-residue signal sequence, 61-residue propeptide, and 160-residue "mature" polypeptide (13, 24). *C*-terminal cleavage of the mature B chain occurs in two stages, with a **trypsin-like** cleavage after residues 111–160, followed by a carboxypeptidase cleavage of the remaining arginine at residue 110 (20, 23, 25), resulting in a final mature product of 109 residues and 12 kDa. A retention sequence (residues 212–216) has also been identified in the B-chain *C*-terminus. As with the long variant of chain A, failure to remove this peptide also results in B-chain glycosaminoglycan retention (16, 17, 26). Dimerization of the A and B chains involves two interchain disulfide bonds mediated by eight conserved cysteine residues; four of these residues are essential for transforming activity (15, 27). The X-ray crystallography structure of PDGF-BB dimer (28) consists of four irregular antiparallel **beta-strands** and a 17-residue amino-terminal tail. Of the eight disulfide-bonded cysteine residues, six form a knotted arrangement and two form two interchain disulfide bonds. The edges of the four-stranded **beta-sheets** form the dimer, which results in the majority of intersubunit contacts being between the first two strands of the b-sheet and with the *N*-terminal tail. The total accessible surface buried is estimated to be 2200 $Å^2$, and most of the buried residues are **hydrophobic** in nature.

There is little to modest expression of PDGF or PDGF receptors in normal adult tissue, but expression is markedly upregulated during disease processes and development. PDGF expression in cultured cells is regulated by the culture conditions, as well as soluble factors and cell matrix organization. The expression of PDGF chains can be regulated at the levels of transcription, translation, and post-translational modification, as well as protein secretion. Released PDGF is rapidly sequestered by binding to a-2 macroglobulin, a circulating 720-kDa glycoprotein that binds B-chain-containing PDGF isoforms, BB and AB (29). PDGF binding results in its rapid clearance via a-2 macroglobulin receptors (30).

Transcription of the PDGF genes can be modulated by diverse extracellular stimuli, such as mitogens, cytokines, tumor promoters, shear stress, and oxygen concentration. The response of the PDGF genes to these stimuli is complex, as is the cell type– and developmental stage–dependent transcription, depending on the interaction between specific DNA elements and regulatory transcription factors. PDGF A and B promoters contain a TATA box located at approximately 30 bp upstream of the transcription initiation site. The PDGF B promoter contains a phorbol ester response element and sequences that can bind Ets-, AP1-, and Sp1-like transcription factors. It also contains a shear stress response element that interacts functionally with the transcription factor NF-kB. It is noteworthy that these sites often overlap, making regulation of transcription of genes even more complex. Transcription of PDGF B promoter also requires the presence of the gene's entire first intron. The PDGF B-chain gene is subject to negative transcriptional regulation by a mechanism that has not yet been elucidated.

Contrary to the PDGF B promoter, the PDGF A promoter is exceptionally G/C-rich. Eight consensus binding sites for the transcription factor Sp1 are located within the first 1000 bp upstream of the transcription initiation site. Moreover, the first 600 bp of the promoter contain at least six binding sites for transcription factors Egr-1 and Wilm's tumor-associated WT-1. Depending on the cell type,

Egr-1 can either activate or repress the activity of the PDGF A promoter. A PMA-responsive element and serum response element are also present in this promoter. A negative transcription regulatory element is located between –1.9 and –0.9 kb (31). **Zinc-finger** transcription factors, including Sp1, Sp3, and Egr-1, have recently been shown to mediate high B-chain expression in aortae of newborn rats (32).

Two transcripts of the PDGF B gene are induced in endothelial cells in response to cycloheximide and transforming growth factor b1 (TGF-b1). Transcription initiation of the 2.8-kb messenger RNA starts 15 nucleotides upstream of the translation start site, while a 3.0-kb transcript starts at 200 nucleotides further upstream. Similar truncation of the 5′ untranslated region contributes to the marked increase in the 2.6-kb transcript in the developing rat brain (33). The expression of a truncated PDGF B mRNA species provides a mechanism of escape from the potent translation inhibitory action of the exon 1-derived 5′ untranslated sequence. Choriocarcinoma cell lines express a 2.6 kb PDGF mRNA species; transcription is initiated at an alternative promoter located within intron 1 and lacks the coding sequence for the signal peptide of the PDGF B-chain precursor. The resulting protein product may be targeted directly to the nucleus in the presence of a nuclear localization signal encoded by exon 6 of the PDGF B gene.

The PDGF A gene uses two **promoters**. The regular transcription start site is located approximately 35 bp upstream of the TATA box, whereas an alternative initiation site is located 470 bp downstream of the first site, but still 380 bp upstream of the translation initiation site.

PDGF chain expression may be also regulated at the level of mRNA stability, as well as at the level of translation. In general, the varying levels of PDGF B mRNA result from differences in transcription rate of the gene, rather than from differences in mRNA stability. The PDGF B mRNA half-life varies between 1 and 3.5 h. The 1-kb-long leader of the 3.5-kbp PDGF B transcript can potently inhibit translation *in vitro*. The inhibitory activity is partly relieved during megakaryocytic differentiation of K562 cells, when transcription of the PDGF B gene is strongly induced. The 179-nucleotide-long sequence immediately upstream of the PDGF B-gene open reading frame is important for the relief of translation repression. The PDGF A 5′-untranslated sequence contains three ATG codons, potential start codons, the function of which are unknown. The region between +99 and 184 bp relative to the PDGF A transcription start site, which lacks an ATG codon, inhibits translation in rhabdomyosarcoma cells, an effect overcome by sequences located between +184 and +338 bp. In summary, PDGF chains are regulated in a highly complex fashion at multiple levels in a cell- and tissue-specific manner.

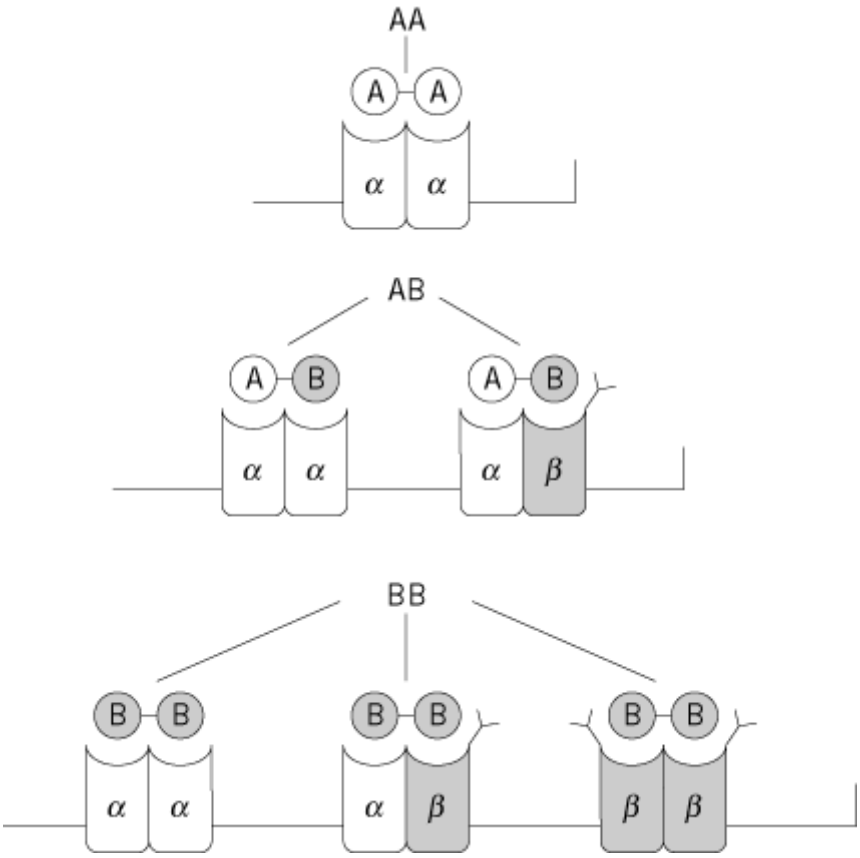
Alternative splicing of PDGF mRNA was first recognized as a regulatory mechanism of PDGF A-chain transcripts. The resulting PDGF A mRNA species are expressed in a variety of normal tissues and transformed cells and in diverse mammalian species (34). Alternative splicing of PDGF B mRNA occurs in a recombinant retrovirus that expresses the wild-type PDGF B chain and induces fibrosarcoma in mice. Provirus derived from the tumors lack a 149-base sequence derived from exon 7 as a result of alternative splicing (35).

There is evidence for posttranslational modulation of PDGF. PDGF protein activity may be regulated by an extracellular glycoprotein, a secreted protein, acidic and rich in cysteine (SPARC), which binds to the B chain-containing isoforms and inhibits binding to the receptors (12). Thrombin stimulates release of PDGF B by selective **proteolytic** cleavage of the membrane-associated PDGF precursor protein (36). It is evident that regulation of PDGF chain expression is complex and that the regulation of the two chains is discordant and cell- and tissue-specific. There is very little information available as to the transcriptional machinery that regulates PDGF A or b chain *in vivo* in disease or development.

3. PDGF Receptors

Two distinct human transmembrane binding proteins for PDGF have been identified, a 170-kDa a-receptor (PDGF-Ra) (37) and a 190-kDa b-receptor (PDGF-Rb) (38). The two receptor proteins are structurally related and consist of an extracellular portion containing five **immunoglobulin**-like domains, a single transmembrane region, and an intracellular portion with a protein tyrosine kinase domain. The two chains have 44% overall sequence identity (39, 40). A functional PDGF receptor is formed when the two chains of a dimeric PDGF molecule each bind one of the above receptor molecules, resulting in bring them into proximity and their dimerization, and activation (Fig. 2). In addition, a 90-kDa soluble form of PDGF-Ra, consisting of the extracellular domain, has been found in cell culture medium and in human plasma (41). Although each subunit of dimeric PDGF binds to one receptor monomer, it is unclear whether these PDGF subunits need to be covalently linked. Recent evidence suggests that noncovalently linked B chains are able to activate the PDGF receptor (42). PDGF-Ra binds each of the three forms of PDGF dimers with high affinity. Although PDGF-Rb binds both PDGF-BB and PDGF-AB with high affinity (K_d = 0.5p*M* and 1–2.5 n*M*, respectively), it has not been reported to bind to PDGF-AA (43, 44). The apparent high-affinity binding of the AB dimer to the b receptor must be interpreted with caution, however. Although PDGF-AB can bind to mutant 3T3 cells expressing only b receptors, it requires hundred-fold more PDGF-AB to dimerize the b receptors and activate the cells than is required for cells also expressing a receptors. This required concentration is probably not physiologically relevant (44).

Figure 2. Dimerization of PDGF receptor subtypes (a and b) by PDGF isoforms.



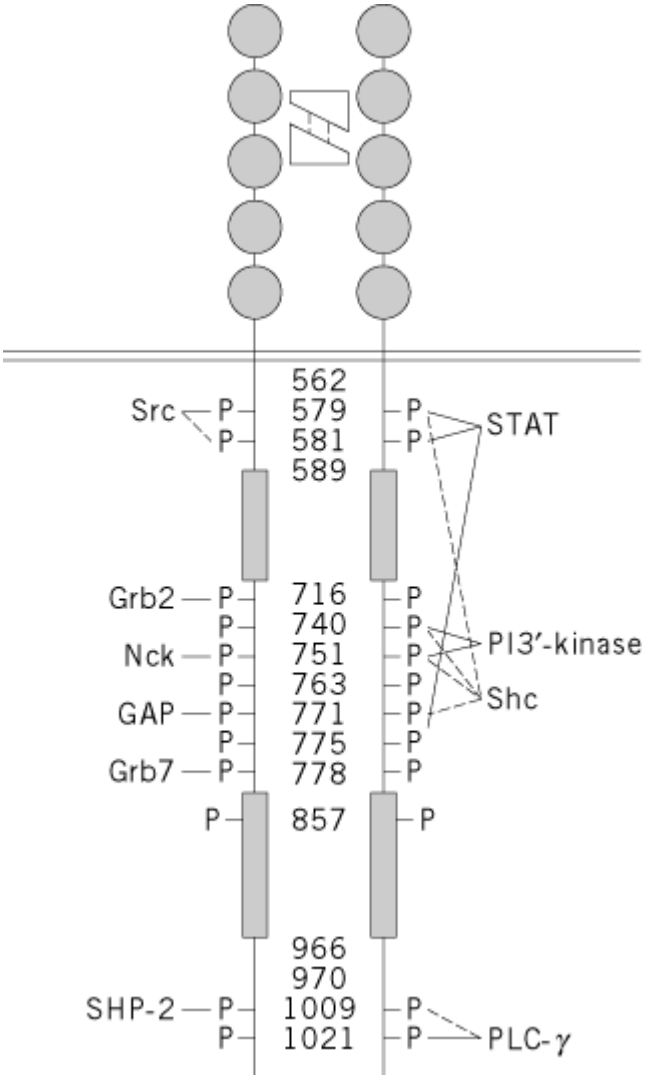
PDGF receptors are differentially expressed and regulated in a cell- and tissue-specific manner. Cells known to express only a receptors include oligodendroglial progenitors, liver endothelial cells and mesothelium (43), and platelets (45). Cells expressing only b receptors include central nervous system capillary endothelium, neurons, and monocytes/macrophages (46). Cells showing coincident expression of a and b receptors include smooth muscle cells, fibroblasts (43), Schwann cells (47),

and mesangial cells (48). The relative abundance of the a and b receptors dictate the biologic activities of the PDGF isoforms. PDGF receptors, particularly the b receptor, are upregulated in inflammatory, proliferative, and fibrotic diseases. In tissue culture studies, very few factors that regulate the a or b receptor have been identified (49). The molecular mechanisms that regulate receptor gene expression are not known. Regulatory sequences in the 5′-flanking region of the murine b receptor has been cloned. A 2.0-kb sequence appears to confer constitutive b-receptor expression in transgenic animals using reporter genes (50-52).

The signals transduced by the two receptors and their biological effects share similarities, but are not identical (53). Some effects are specific, however; for example, cell-surface actin reorganization or ruffling is mediated solely by the b receptor. PDGF binding to cells induces receptor internalization and downregulation (54). PDGF stimulation follows activation of its intrinsic tyrosine kinase activity, with phosphorylation of several substrate proteins, including the receptor itself (55). This ligand-induced autophosphorylation is an intermolecular mechanism (56). After ligand stimulation, human PDGF-Rb has at least eleven phosphorylated tyrosine residues (Fig. 3). Two of these are in the juxtamembrane region of the receptor (Tyr579 and Tyr581), seven are in the kinase insert sequence of the receptor (Tyr740, Tyr751, Tyr762, Tyr763, Tyr771, Tyr775, and Tyr778), another is in the second tyrosine kinase domain (Tyr857), and the last two are in the cytoplasmic tail downstream of the tyrosine kinase domain (Tyr1009 and Tyr1021) (34, 57-60). The autophosphorylated tyrosine residues serve as binding sites for several signaling proteins, which contain an **Src** homology-2 (**SH2**) domain. One of these proteins is **phospholipase C**-g1 (PLC-g1), which binds directly to phosphorylated directly to Tyr1009 and Tyr1021. After binding, PLC-g1 is tyrosine-phosphorylated by the receptor, which is required for enzymatic activity. Activation of PLC-g1 by PDGF-R stimulates hydrolysis of $PtdInsP_2$ (phosphatidylinositol diphosphate) to generate $InsP_3$ (inositol trisphosphate) and DAG (diacylglycerol), which mobilize intracellular calcium and activate protein kinase C, respectively (61) (see Inositol Lipids and Phosphates). Mutation of tyrosine residues that specifically bind PLC-g1 in the PDGF receptor results in loss in phosphoinositide turnover, as well as loss of mitogenesis (62, 63). Phosphatidylinositol-3 kinase (PI-3K) is a heterodimer of a 110-kDa catalytic and a 85-kDa regulatory subunit that consists of only SH2 and SH3 domains (64). The SH2 domain of PI-3K binds to phosphorylated Tyr740 and Tyr751 in the PDGF receptor-kinase insert (57, 63). After binding, PI-3K becomes activated and produces D3-phosphorylated inositides. Initial reports suggested that protein kinase C-z could be the downstream target of PI-3K, since D3 inositides can activate this enzyme *in vitro* (65). It is now established that these lipids serve to recruit another **serine/threonine protein kinase**, PKB/Akt, to the membranes, where it is phosphorylated and activated by PDK1 and PDK2. Akt has been shown to mediate the effects of PI-3K on cell survival and differentiation, glycogen metabolism, and protein synthesis (66). Mutation of the two tyrosine residues that bind PI-3K results in loss of PDGF-induced cell proliferation (67). PI-3K has also been implicated in receptor internalization (68) and in PDGF-induced chemotaxis and actin reorganization (69), but some responses are cell-specific. PDGF also stimulates the **Ras** pathway. A protein tyrosine phosphatase, SHP-2 (PTP-1D), can bind to the phosphorylated Tyr1009 at the carboxy-terminal end of the receptor, and serve as the docking site for a Grb2/SOS complex. Grb2 is an adaptor molecule, composed of only SH2 and SH3 domains and devoid of catalytic activity, and SOS is a guanine nucleotide exchange factor for Ras, promoting the exchange of GDP to GTP on Ras, thereby activating it (70). Ras, in turn, recruits and activates another serine/threonine protein kinase, Raf-1 (71), whose activity is increased in PDGF-stimulated cells (72, 73). Activated Raf-1 activates the MAP kinase cascade. Ras is important in the mitogenic signal of PDGF (74). It is noteworthy that Ras-GAP (for GTPase-activating protein), the enzyme that terminates the Ras signal, can also be recruited on the activated PDGF receptor (on Tyr771), probably allowing a fine tuning of the Ras signal. The two tyrosine residues in the juxtamembrane region of the PDGF receptor are a docking site for some members of the Src family of protein tyrosine kinases, namely, c-*src*, c-*fyn*, and c-*yes* (75). The role of Src family of tyrosine kinases in regulating phases of the cell cycle is the subject of intense investigation. For instance, Src is not required for PDGF-Rb to induce mitogenesis (76), but it is recruited and activated by PDGF-Ra, and apparently phosphorylates Shc (77). Nck is another adaptor molecule, like Grb2, made of SH2 and

SH3 domains, that binds to the activated PDGF receptor (78). Again, its precise function in PDGF signaling is unknown. Recently, a novel, Ras-independent pathway has been described. Janus kinase-1 (JAK-1) as well as signal transducer and activator of transcription (STAT)-1 and -3, are also activated by PDGF (see JAK/STAT Signaling). STAT proteins contain SH2 and SH3 domains and are tyrosine-phosphorylated; they dimerize and translocate to the nucleus, where they may induce specific subset of genes. The JAK family of tyrosine kinases are involved in the activation of STAT proteins. However, STAT1a is recruited and can be directly phosphorylated by PDGF-R (79).

Figure 3. Schematic illustration of the interaction between the autophosphorylated PDGF-Rb and downstream signal transduction molecules. A ligand-induced dimeric receptor complex is shown. Ig-like domains in the extracellular region are represented by filled circles. The numbers of all intracellular tyrosine residues are indicated. The kinase domain is represented by filled rectangles. The specificity in the interaction between SH2 domain molecules and autophosphorylated tyrosine residues is indicated; solid lanes indicate high affinity interactions, and broken lines interactions of lower affinity.



PDGF signaling is negatively regulated by a class of protein–tyrosine phosphatases (PTP) called low molecular weight (LMW)-PTP. These LMW-PTP are cytosolic enzymes that translocate to the membrane fraction on stimulation by PDGF, where they dephosphorylate PDGF-R (80). LMW-PTP interfere mainly with PDGF activation of the Src and JAK-STAT pathways (81).

The role of PDGF receptor signaling in mediating specific biologic responses in different cells or different environments remains an enigma. Much work is still needed to understand the protein–protein interactions that may be involved, as well as identification of additional molecules.

4. Biology of PDGF

Aberrant expression of PDGF or its receptors is likely to be involved in the stimulation of the growth of certain tumors. However, it also plays a part in the development of certain nonmalignant disorders involving excess of cell migration and proliferation. In considering the role of PDGF in different disease processes, it is important to take into account the fact that the level of the ligands and receptors can be modulated by a network of other cytokines or soluble factors.

4.1. Strategies for Genetic Analysis of PDGF Function

Targeted disruption of the genes coding for PDGF A and B chains, as well as the a and b receptors, has been accomplished. The PDGF-B and -Rb null phenotypes are embryonically lethal and strikingly similar (82, 83). At late gestation (E17-19), homozygous mutants develop general hemorrhaging and edema. At the time of birth, many homozygotes still display life signs. The data thus far indicate the existence of a developmental defect of the blood vessel wall that appears to be the major cause of bleeding. Both PDGF-B and PDGF-Rb null mutant embryos display a developmental defect of the kidney glomerulus that consists of a complete lack of mesangial cells, smooth-muscle-like vascular pericytes that regulate blood flow in glomeruli, filtering units of the kidney. A capillary tuft is not formed. Rather, a few, or a single, microaneurysm-like capillary loop fill out the Bowman's space. Basement membrane, endothelial and epithelial cells are present. Heart defects are also seen in the PDGF B null mutant embryos but not in the PDGF-Rb null mutants, suggesting that PDGF-Ra, which is widely expressed in the heart, may compensate for the absence of PDGF-Rb. Cerebral vessel microaneurysms are also present in the brain of the PDGF B chain null mutants (84). Defect or absence of vascular pericytes derived from connective tissue, which are essential for the normal development and integrity of the capillary wall, seems to be the mechanism underlying cutaneous bleeding (purpura) and microaneurysm formation in the mutant embryos. Recent studies utilizing chimeric mice from b-receptor-null and wild-type cells indicate that their receptor plays a role in recruitment of smooth muscle cell progenitors to sites of epithelium and endothelium (85).

PDGF-A null mice were found to develop until birth and live for a few weeks postnatally, at which time they appeared severely growth retarded. These mice suffer from generalized lung emphysema, with resulting atelectasis mixed with hyperinflated regions (86). Genotyping of large numbers of offspring at various embryonic ages reveals that there is also a loss of PDGF-A null embryos during early gestation (86). There is a loss of approximately 50% of the PDGF-A null homozygotes before E10, but the causes of this loss and the mutant phenotype at this early stage are currently unknown. Following implantation, PDGF-A and -Ra soon adopt an appositional expression pattern; later in development, PDGF-A appears generally expressed in epithelial tissues and PDGF-Ra in mesenchymal tissues (87, 88 89). It is likely that the early embryonic loss of PDGF-A null homozygotes interferes with epithelium-to-mesenchyme signaling. The PDGF-A null embryos surviving beyond E10 appear slightly growth-retarded at E16-P2, after which point the growth retardation becomes increasingly severe. From approximately 2 weeks of age, the PDGF-A null homozygotes are invariably less than 50% the size of heterozygotes or wild-type litter mates. At 3 weeks of postnatal age, the PDGF-A null mice have invariably developed a severe generalized lung emphysema. Histologically, grossly enlarged distal air spaces are seen without signs of subcompartmentalization by alveolar walls. The mature alveolar septa contain alveolar smooth muscle cells (also called contractile interstitial cells) embedded in deposits of elastin. In the PDGF-A null lungs, several defects associated with the alveolar smooth muscle cells were found. A population of PDGF-Ra-positive cells was identified in the normal E18.5 lung, which had the expected distribution of a putative alveolar smooth muscle cell progenitor. Such cells were absent from the mutant lungs. However, many other sites of PDGF-Ra expression, in both lung and other tissues, remained unaffected in the mutant mice. It was therefore proposed that alveolar deficiency in

PDGF-A null lungs reflects the failure of a population of PDGF-Ra-positive smooth muscle cell progenitors to develop during late stage gestation of the mouse (86).

The phenotype of the homozygous PDGF-Ra mutants differs somewhat from the patch mutant mice, which harbor several deletions, including the PDGF-Ra gene. Homozygotes of the PDGF-Ra mutants die during embryonic development and exhibit incomplete cephalic closure similar to that observed in a subset of the patch mutants. There is also increased apoptosis of migrating neural crest cells and deficiency of myotome formation, which leads to alterations in mutant vertebrae, ribs, and sternum. This phenotype also differs from that of PDGF-A null mutants, suggesting the existence of compensatory mechanisms probably mediated by the PDGF B chain and b receptor.

5. Concluding Remarks

PDGF and its receptors play an integral role in inflammatory, proliferative, and fibrotic disorders. Its role in carcinogenesis is based on circumstantial evidence and has received a new impetus with the recent discovery of the beta receptor translocation in leukemia.

The role of signal transduction pathways in mediating specific biologic activities is a subject of intense investigation, and the development of specific inhibitors of the receptor and of the signaling molecules may open new avenues of therapeutic potential. Therapeutic trials utilizing selective inhibitors of PDGF-R signaling are currently underway in humans with soft tissue tumors and should provide valuable information as to the contribution of PDGF to tumor growth.

Analysis of PDGF ligands and receptor-deficient mice has helped to clarify their role in development. One major interesting finding in the single gene targeting approach, ie. ligand or receptor, is the length of survival of embryos lacking one such gene, considering the widespread distribution of PDGF chains and their receptors at early stages of development. Moreover, the phenotype of PDGF A mutant mice differs from that of the a-receptor mutants. The phenotype of the B chain mutant mice is also somewhat different from that of the b-receptor mutants. This is most likely due to the fact that signaling by the remaining ligand or receptor can still occur in any null embryo. In the PDGF B null mutant embryo, PDGF A can signal through the a and b receptors. Precise localization of the coproduction patterns of ligands and receptors in the normal and abnormal tissue should help interpret the data obtained in the single-gene targeting approach. Further analysis of double-receptor and double-ligand mutants is underway and should help further understanding the requirement and precise role of PDGF during embryogenesis. Quantitative chimeric mice studies should further help determine its role in development and disease.

Pleckstrin Homology (PH) Domains

The pleckstrin homology or PH domain is a ~100 amino acid protein module found in numerous different types of human protein and is one of the must abundant non-enzymatic protein modules found in the human genome. The draft human genomes available in early 2001 claim in the one case 252 and the other 193 genes encode proteins encoding PH domains (1, 2). Both draft genomes agree that genes encoding proteins containing SH2 and SH3 domains are significant less numerous than this. PH domains are also very abundant in the proteins of *Drosophila*, *C. elegans*, yeast and protistans, suggesting a very early evolutionary origin and therefore presumably fundamental importance in eukaryotic biology. Proteins containing PH domains are associated with cellular signaling, cellular membrane dynamics and the cytoskeleton, and defects in some of these proteins are associated with a variety of cancers and other serious human diseases. These domains generally mediate the membrane localization of the proteins in which they are found, although individual PH domains appear to do this in quite different ways as a result of their surprisingly variable binding and functional properties. Some PH domains bind primarily to membrane phospholipids, others bind both lipids and membrane associated proteins while still others bind primarily to membrane associated proteins. Recent evidence suggests that the PH domain superfamily is even larger than originally thought, since protein tyrosine binding (PTB) and Enabled/Vasp homology 1 (EVH1) domains, which have virtually no sequence identity with the "classical" PH domain, nevertheless have the same 3D structure. Apparently the PH domain structural prototype has been widely used and heavily modified during evolution and other families of the PH domain superfamily may be discovered as more protein 3D structures are determined.

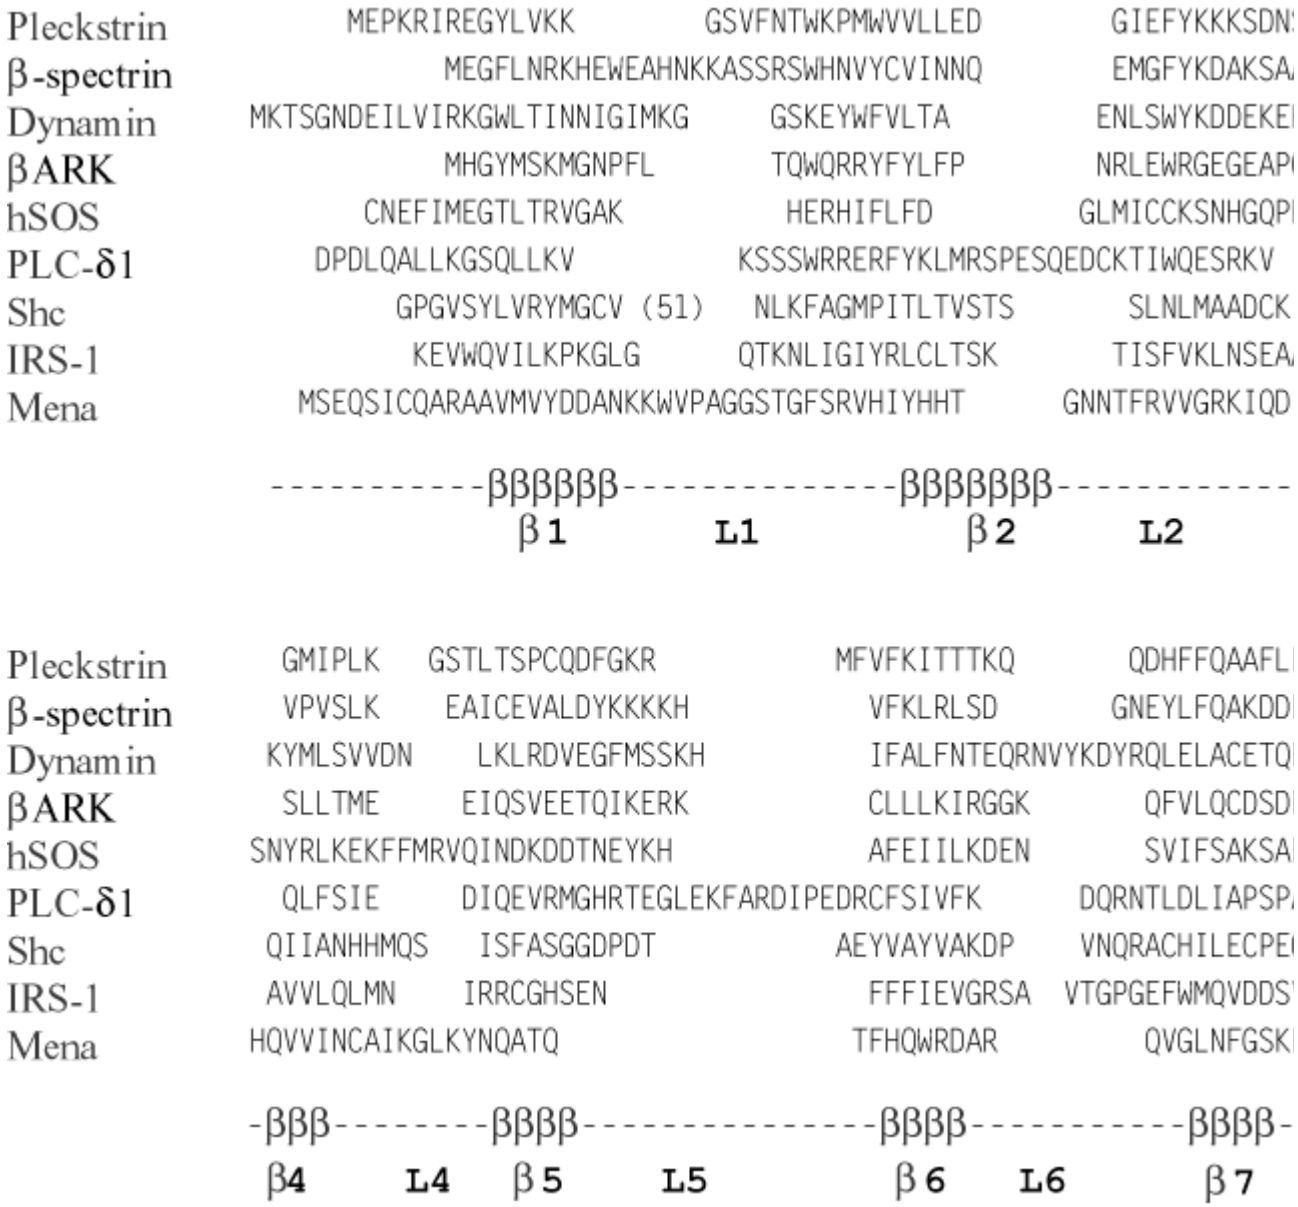
Table 1. Brief Overview of Proteins with PH Domains

" Classical " PH domains	**Kinases.** Tec/Btk family, bARK family, Rac/Akt/Protein kinase B family.
	G-protein related. Ras-GAP, Ras-GRF, Trio, ARNO.
	Cytoskeletal. Syntrophin, AFAP110, Kinesin Kif-1B, b-spectrin isotypes.
	Signaling adapters. Grb-7, Grb-10, IRS-1, Gab-1, DOS.
	Membrane associated. Dynamin family, Oxysterol binding protein.
Dbl subfamily of classical PH domains; PH domains adjacent to Dbl homology domains.	**Dbl Family.** Dbl, Bcr, Vav, SOS, FGD1, Bcr and several others contain PH domain next to a Dbl homology (DH) domain, which activates Rac/Rho family small G proteins by stimulating GTP binding. Several (e.g. Tiam-1, FGD1) also contain classical PH domains.

Phospholipase C sub family of classical PH domains.	**Phospholipase C family.** All have a N-terminal PH domain which has been shown to bind strongly to PIP2 and IP3 in the case of PLC d1. PLC d and g isotypes also contain a second classical PH domain.
PTB domains	**Shc family.** Shc isotypes and several more distantly related proteins.
	IRS-1 family. IRS-1, IRS-2, 3 and 4, Dok, FRS-2 and others.
	Others. Numb, X11 and relatives. Many PTB domains bind to tyrosine phosphorylated peptides in activated receptor tyrosine kinases (Shc, IRS-1 families), others bind non-phosphorylated peptides in other membrane proteins (X11, Numb).
Enabled/Vasp Homology 1 (EVH1) domains	**EVH1 family.** Enabled (Drosophila ena and mammalian Mena), EVL, VASP, Wiskott-Aldrich syndrome protein (WASP) family. All bind to Pro rich peptides in various actin associated proteins. Invariably at N-terminus of molecules in which they are found.

PH domains were first described in a total of less than 20 molecules in 1993 (3, 4). These reports generated considerable interest partly because many of these molecules, such as for example mammalian son of sevenless (mSOS), p120 ras-GAP, ras-GRF and dynamin, had already been widely studied. The reason the PH domain had been overlooked in these and other molecules is that the defining amino acid sequences are a series of poorly conserved peptides interspersed with linkers which are even less well conserved in sequence and length (figure 1). Sequences of this type were difficult to identify with BLAST, FASTA and most other available sequence analysis programs, which worked best with relatively long regions of alignment. However several PH domains somewhat more divergent in primary sequence were quickly described using various kinds of sequence profiling and more specialized search methods. These included PH domains found in the Bruton's tyrosine kinase (Btk) family of src related non receptor tyrosine kinases, the signaling adapter IRS-1 and in the b-adrenergic receptor kinases 1 and 2 (bARK) (5, 6). More divergent but still convincing PH domains were described in the Dbl family of proto-oncogenes (5) and at the N-termini of all phospholipase C (PLC) isotypes (7). The Dbl and PLC families of sequences contain a C-terminal region with key conserved amino acids convincingly similar to that of the other PH domains, but are harder to align in the region corresponding to the N-terminal ~85 amino acid (figure 1). However they do have a similar content of charged, hydrophobic and turn promoting amino acids throughout the sequence alignment, and, for the purposes of this article, the original PH domains and those found in the Dbl and PLC molecules will be referred to as “classical” PH domains.

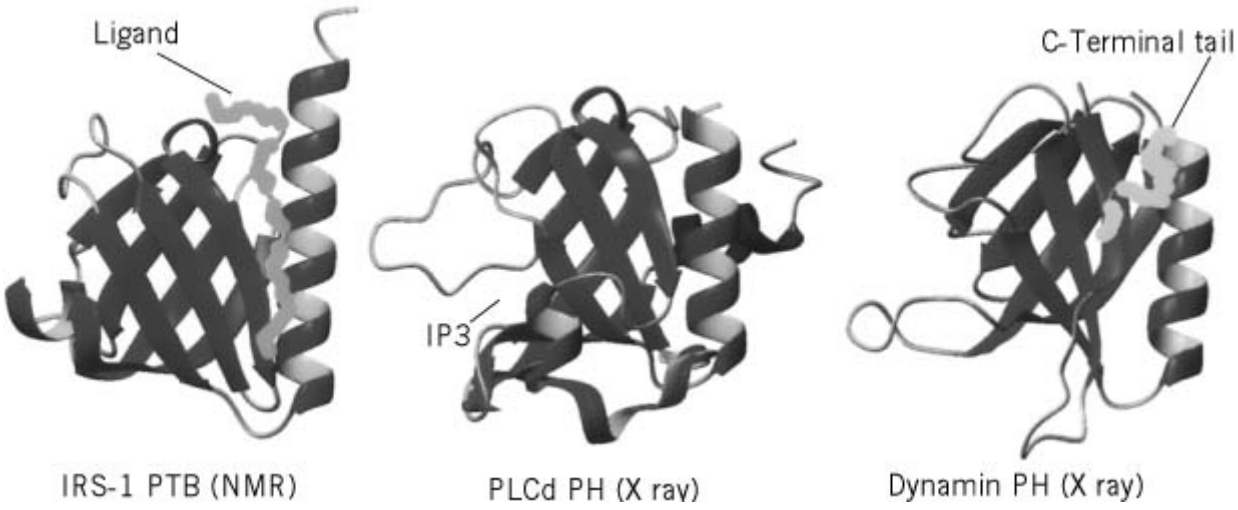
Figure 1. Alignment of PH domain structures current determined along with consensus structure. Large hydrophobic am charged amino acids (D, E, K, R, H) are all bold and shaded.



At the time of writing the 3D structures of numerous classical PH domains have been determined, including the N-terminal PH domain of pleckstrin, PH domains of b-spectrin from two species, dynamin, bARK1, mSOS, phospholipase C-d1, Btk and Grp1. Despite the lack of sequence conservation, all of these structures are very similar, composed of an N-terminal sandwich containing of 4 antiparallel b-strands overlaying 3 antiparallel strands which together form a compact wedge shape, the wide end of which is capped by a single C-terminal a-helix (see figure 2). The regions of b-strand and a-helix correspond to the better conserved regions of the sequence alignment shown in figure 1, while the loops in the structure correspond to the less conserved regions. The compact PH domain structure has the N and C termini very close together, a feature also seen in SH2, SH3 and many other modular domains.

Figure 2. Structure of IRS-1 PTB domain, PLC-d1 PH domain and dynamin PH domains, all in complex with ligands. The basic structure of 7 antiparallel b-strands capped by a C-terminal a-helix is preserved in each case, although the length, amino acid sequence and conformation of the loops between these segments are not conserved. The peptide ligand for the IRS-1 PH/PTB domain and the binding site for IP3 on PLC-d1 are also indicated, showing the diversity

of type and location of ligand binding sites on these domains. Figure taken from reference 57, with permission.



This basic PH domain structure is shared by at least two other classes of modular binding domain. The first class is typified by a region of the adapter molecule Shc and relatives, which was shown to include a novel type of phosphotyrosine binding domain (8). Independently a region of the adapter molecule IRS-1 C-terminal to the classical PH domain was shown to contain a phosphotyrosine binding site, and represents the prototype for a further family of domains found in IRS-2, IRS-3, IRS-4, Dok and FRS-2 (9, 10). Shc and IRS-1 bind phosphotyrosine containing peptides of similar consensus sequence, though binding specificity resides in the amino acids N-terminal to the Tyr residue and so is functionally quite different from the mechanisms by which SH2 domains bind phosphotyrosine containing peptides. These regions became known as PTB (i.e. protein tyrosine binding) domains. Since the amino acid sequence of the Shc and IRS-1 PTB domains show no superficial similarities with the classical PH domains it was surprising that both domains were found to be structurally similar to classical PH domains (11, 12), and both can be considered part of the PH domain superfamily (Figure 2). Similarly sequence similarities defined the Enabled/Vasp Homology 1 (EVH1) domain found in *Drosophila* Enabled, mammalian Enabled (Mena), VASP, EVL, Wiskott-Aldrich syndrome protein (WASP), Homer and others (13). EVH1 domains contain a specific binding site for specific Pro rich sequences found in a variety of actin associated proteins (13). Surprisingly the structure of two different EVH1 domains were recently shown to be similar to that of classical PH and PTB domains (14, 15), so that EVH1 domains also belong to the PH domain superfamily. When the amino acid sequences are aligned structurally, PTB and EVH1 domains show few identities and no absolutely conserved residue compared to PH domains. However all three types of domain are rich in large hydrophobic amino acids such as Trp, Phe and Tyr and also rich in small turn promoting amino acids Gly, Ser, Ala and Pro. The short C-terminal region of all three corresponds to an amphipathic a-helix which never contains any Pro residues. This C-terminal region contains a large hydrophobic amino acid, almost always a Trp residue in classical PH domains, followed four amino acids C terminal by another large hydrophobic amino acid, frequently a Leu or Ile residue (these two positions are indicated by asterisks in figure 1). This region is also always rich in acidic amino acids, particularly in the linker between the seventh b strand and the C-terminal a-helix. While it is possible that the structural and sequence similarities between classical PH domains, PTB domains and EVH1 domains are fortuitous, it seems much more likely that the basic PH domain fold has been elaborated greatly during evolution, producing a peculiarly versatile family of binding domains. This hypervariability would also account for the difficulty of identifying member of the PH domain superfamily by sequence relationships alone.

Proteins with classical PH domains frequently contain enzymatic modules such as protein kinase domains (e.g. Btk family Tyr kinases, Protein kinase B (PKB, also known as Akt or Rac kinase)

Ser/Thr kinases, the b-adrenergic receptor Ser/Thr kinases), various phospholipid modifying domains (Phospholipase Cb, g and d, PI-4 kinase) or domains which regulate small G proteins (e.g. Dbl family proto-oncogenes, p120 Ras-GAP, Ras-GRF, mSOS, Sec7 family proteins). Many other PH domain containing proteins are components of the cytoskeleton (e.g. certain b-spectrin isotypes, the syntrophins, actin filament associated protein AFAP-110, the kinesin family protein Kif1b) or belong to the family of so-called "adapter" molecules (e.g. IRS-1, Shc, Grb7, Gab1), which contain binding sites of various types but have no intrinsic enzymatic activity. The types of molecules which contain classical PH domains are generally similar to those which contain SH2 and SH3 domains and in several cases (e.g. Phospholipase Cg, Btk family tyrosine kinases, the Vav Dbl family proto-oncogene) all three domain types are found in the same molecule. Proteins with classical PH domains frequently also contain Pro rich peptides which can potentially bind specific SH3, WW or other Pro rich peptide binding domains (e.g. mSOS, dynamin, Grb-7 and Grb-10) or Tyr phosphorylation sites which can bind to specific SH2 domains (e.g. AFAP-110, IRS-1, Shc). A few molecules contain multiple classical PH domains (e.g. pleckstrin, PLC g, Tiam-1), and one family of proteins, typified by ARAP3, has no less than 5 of these domains (16). PH domains often neighbor enzymatic domains, and in some cases this relationship appears to be obligatory. For example every known Dbl homology (DH) domain is flanked at the C-terminus by a PH domain (17), and this PH domain is vital for the normal cellular function of the DH domain (18, 19). Finally PH domains are found somewhat more frequently than expected by chance at the extreme N or C-termini of proteins. PTB domains are found in molecules such as IRS-1, Shc, Numb and X11 which generally seem to function as membrane associated signaling adapters (10). In the IRS-1 and Dok families of molecules PTB domains are found immediately C-terminal to a classical PH domain, while in most other molecules the PTB domain is at the extreme N-terminus (10). EVH1 domains are found in non enzymatic molecules which associate with membranes and the actin cytoskeleton and which might be referred to as cytoskeletal adapters (13). EVH1 domains are invariably at the extreme N-terminus of molecules in which they are found, as are many classical PH domains. PTB and EVH1 domains, like some PH domains, are therefore found in adapter molecules, in support of the view that all three domain types are evolutionarily related.

The exact function of PH domains has been controversial, and much of the controversy no doubt occurred because it was expected that these domains, like SH2 and SH3 domains, would have one predominant class of ligand. However current evidence suggests that PH domains have a surprising variety of binding partners. Some bind directly to membrane phospholipids, some to other generally membrane associated proteins and some to both membranes and proteins. The affinity and specificity of these interactions are quite variable. Many PH domains bind phosphatidylinositol 4,5 bisphosphate (PIP2) and in some cases inositol 1,4,5, trisphosphate (IP3) (20-24). While some of these affinities are high, in the nM range, most are of relatively low affinity and specificity but may nevertheless be biological significant. Other PH domains such as those in PKB and Btk family kinases show preferential and high affinity and specificity binding for phosphatidylinositol 3,4,5 trisphosphate (PIP3), phosphatidylinositol-3,4-bisphosphate (PI-3,4-P2) or the PIP3 head group inositol-1,3,4,5-tetrakiphosphate (IP4) (24-26). PKB and Btk kinases become membrane localized by their PH domains following activation of PI-3 kinases which generate PIP3 and PI-3,4-P2. The binding sites for PIP2 on pleckstrin, b-spectrin and PLC-d1 PH domains involve primarily the L1 and L5 linkers (23) (27, 28). However the phosphoinositide binding sites the dynamin and Btk PH domains appear to involve primarily the L1 and L3 linkers and would therefore be on different faces of the PH domain (24, 29). A consensus from these studies is that PH domains which are rich in basic residues in the N-terminal b-strand region generally bind lipids with higher affinity and specificity than those with fewer basic amino acids. The recent inclusion of PTB domains into the PH domain superfamily is supported by the finding that certain of these, namely those of Shc and mDab1, bind phospholipids through interactions mediated by the basic N terminal b-strand regions (30-32). EVH1 domains however have not so far been shown to bind directly to lipids and generally lack a concentration of basic residues in this N-terminal segment.

Protein binding by PH domains is if anything even more variable. The well studied bARK1 PH domain binds to the b g subunits of trimeric G-proteins (Gb g), albeit with higher affinity if the

peptide sequence immediately following the PH domain is included, and PH domains from several other proteins have been reported to bind Gb g *in vitro*, though the binding was rather variable and in most cases not as robust as the Gb g-bARK interaction (33). Much evidence suggests that some of these may also bind *in vivo* (34-38). PH domains of Rac/Akt/PKB and Btk protein kinases have also been reported to bind to protein kinase C isotypes (39). More recently several PH domains have been reported to bind actin directly, though strong actin binding, like Gb g binding, was not seen with every PH domain tested (40). In addition the PH domain from a member of the Btk family was shown to bind the FERM domain of FAK, the focal adhesion kinase (41), and the PH domain of IRS-1 was shown to interact with PHIP, a protein required in vivo for efficient phosphorylation of IRS-1 by the activated insulin receptor complex (42). The theme that emerges is that PH domain binding is generally to a protein which is associated with the membrane, so that these protein-protein interactions may be functionally similar to direct lipid binding as described above. PTB domains certainly fit into this pattern since many of them bind to tyrosine phosphorylated peptide sequences found in activated receptor tyrosine kinases. However, in a similar fashion to classical PH domains, PTB domains show distinctly and somewhat surprisingly different types of binding. For example the Dab PTB domain, paradoxically, binds to peptides similar in sequence to those of other PTB domains but only if they are not tyrosine phosphorylated (31). The PTB domains of Numb and X11 also recognize uniquely different peptide consensus sequences but only if they are not tyrosine phosphorylated (10). Recent studies of Numb suggest that this PTB domain has at least three not obviously related in vivo binding sites for other proteins (43). Finally the various EVH1 domains bind to Pro rich sequences in their target molecules, although the exact peptide binding site on the domain is slightly different in the two currently known structures, the EVH1 domains of Mena and Homer (14, 15). We can only conclude that the various different types of classical PH domain, PTB and EVH1 domains bind a bewildering variety of unrelated protein ligands, and may bind them using different parts of the 3D structure. Nevertheless it is noteworthy that, as noted for classical PH domains, almost all of the described PTB and EVH1 domain ligands are associated with cellular membranes either as integral lipid components or as membrane associated proteins.

Probably the best studied classical PH domain is that of bARK1, which binds both PIP2 and Gb g. PIP2 binding is of low affinity and is mediated by the N-terminal b-strand region of the PH domain, while Gb g binding is mediated by an interaction mapped to the C-terminal a-helix and some following sequence (44). This region is now known to correspond to an a-helical extension from the PH domain (45). The peptide following the PH domain contains two serine residues, Ser 670 and Ser 685, which may become phosphorylated in vivo and which regulate Gb g binding. Ser 670 can be phosphorylated by MAP kinase and inhibits Gb g binding (46), while Ser 685 can be phosphorylated by Protein Kinase A and enhances Gb g binding (47). Clearly there is considerable potential for regulatory complexity in the regulation of PH domain binding interactions if bARK1 is typical, and similar regulation of membrane binding may also occur. The presence of both a phospholipid and a protein binding site on the same small protein module naturally suggests allosteric regulation of binding. The bARK1 PH domain responds to both PIP2 and Gb g, and both ligands function in a co-ordinated manner apparently to regulate the membrane binding of the bARK PH domain (48, 49). To date the significance of phosphorylation on this cooperativity has not been examined. Studies of dynamin, an abundant protein important in endocytosis which contains a PH domain adjacent to a GTPase domain shows that PIP2 activates the GTPase while Gb g inhibits it and that the affinity of dynamin for Gb g is increased in the presence of PIP2 (50). These effects are presumably mediated by the dynamin PH domain and, if so, provide another glimpse of the potentially complex regulation of binding interactions by this domain. More recently Gb g was shown to act through the PH domain of PLC-b2 and PLC-b1 to regulate these enzymes in vivo (37, 38), and Gb g was shown to bind to the PH domain of Btk and also to regulate Btk enzymatic activity but by binding to a site independent of the PH domain (51).

Making functional sense of this variety of binding sites has been controversial. However in almost every case the domain binding involves direct or indirect membrane association, and it seems reasonable to conclude that PH, PTB and EVH1 domains all function in this way, to target molecules, by a variety of different mechanisms, to the membrane. It may be that the multiple

binding properties attributed to several PH domains are typical, and similar multiple binding partners remain to be discovered for other PH, PTB and EVH1 domains. It has been pointed out that the compact 7 b-strand, 1 a-helix structural template presenting a set of hypervariable peptide loops is an arrangement somewhat similar to that seen in the antibody variable region (52). These authors proposed that the PH domain may actually function like an antibody variable region, defining a binding activity which can be quite different in different molecules.

Proteins with PH domains are involved in many serious human diseases. One striking example is the Dbl family of proteins, many of which were discovered in gene transfer experiments using tumor DNA (17). Oncogenic forms of these proteins frequently have N-terminal deletions but always retain the Dbl homology (DH) domain and the adjacent PH domain. Since the DH domain is a guanine nucleotide exchange factor for Rac/Rho/Cdc42 family small G proteins, defects in these molecules presumably result in aberrant regulation of these important small G proteins. Point mutations in the non-receptor tyrosine kinase Btk are causative of Bruton's X-linked agammaglobulinaemia, a serious human immunodeficiency in which B cells fail to develop, resulting in a severely compromised immune system (53). Some of these mutations directly affect the binding of the Btk PH domain to PIP3 and IP4 (24, 54). The ubiquitous PKB Ser/Thr kinases may be virally transduced and rendered oncogenic by a combination of overexpression and fusion to viral GAG protein, which renders the PKB component constitutively membrane localized (55, 56). The EVH1 domain containing protein WASP is mutated in patients with Wiscott-Aldrich syndrome (WAS), and the majority of these mutations are found in the EVH1 domain. WAS patients have severe defects in platelets and T cells due to aberrant organization of the actin cytoskeleton. There are many other examples of human diseases associated with particular defects in PH domain superfamily molecules, underlining the importance of these domains in the normal regulation of cellular function.

In summary, PH domains are a very large family of protein modules based on a conserved structural module of 7 antiparallel b strands followed by a single a-helix. This family is so variable as to be virtually unrecognizable by primary amino acid sequence alone, so that definitive recognition of new classes of PH domain will only come from further structural work. This family of modules is also surprisingly variable in terms of binding properties, and the best current functional explanation for this is that PH domains are the cellular equivalent of the antibody molecules, a structurally conserved unit with hypervariable loops which can be evolutionarily modified to produce binding sites for virtually any ligand. The central theme seems to be the regulation of membrane binding, though this appears to be achieved in a bewildering variety of different ways. In conclusion, the fundamental role of PH domains is probably to direct and regulate the formation of protein-membrane and specific protein-protein interactions, allowing the formation of a wide variety of specific and membrane associated signaling complexes.

Pleiotropy

A single mutation can cause more than one change in phenotype, in which case it is called pleiotropic. The mutation is also be said to have pleiotropic effects. An example is a mutation in a gene encoding a global regulatory protein.

Ploidy

Ploidy is the number of complete sets of chromosomes (or **autosomes**) in a cell. Haploid (or euploid) cells have a ploidy of one, **diploid** cells a ploidy of two, **triploid** cells a ploidy of three, etc. Polyploid cells have more than the normal chromosome content. Deviations from complete sets of chromosomes are described by aneuploidy.

PMSF (Phenylmethylsulfonyl Fluoride)

A number of *sulfonyl halides* have been found to be helpful in the study of proteins and other biological molecules. One of the most useful is phenylmethylsulfonyl fluoride (PMSF). It is a crystalline solid of low toxicity that is a potent, irreversible inhibitor of **chymotrypsin** and other serine proteinases (1). Aqueous solutions of PMSF undergo slow hydrolysis, but it is reasonably stable in anhydrous alcohol (2). When used to minimize protein degradation during isolation procedures, it is added to buffer solutions prior to use by 100-fold dilution from a stock 50 mM solution in isopropanol (3). The product of reaction with chymotrypsin is the phenylmethylsulfonyl ester of the active site serine (Figure 1). Although this ester is quite stable, it is possible to regenerate the active enzyme by incubation under acidic conditions (pH 2) for several hours (4). It is also possible, under alkaline conditions, to convert the product to *anhydrochymotrypsin* in which the active site serine residue becomes a dehydroalanine residue (4).

Figure 1. Interaction of PMSF (phenylmethylsulfonyl fluoride) with the active-site serine hydroxyl group of a serine proteinase.

Point Accepted Mutation

The point accepted mutation (PAM) is a measure of the rate at which point mutations that substitute one amino acid residue for another have been incorporated in a **gene** lineage during evolution . A PAM is sometimes used as a unit of **evolutionary divergence**. In practice, one PAM is equivalent to a unit of evolutionary divergence in which 1% of the amino acid residues of the protein product of a gene have been changed. On the basis of this PAM model of evolution, Dayhoff et al. (1) invented the amino acid substitution matrices in which the substitution scores between a pair of different amino acids are proportional to the natural log of the ratio of the target frequencies to the background frequencies (1). The background frequencies are the frequencies of each possible substitution, which would be determined simply by the overall frequencies of the different amino acids if the changes were purely random. The target frequencies are the observed substitution frequencies, which are biased toward substitutions of similar amino acids that do not seriously undermine the protein function. To estimate the target frequencies, pairs of very closely related sequences were used to collect mutation frequencies corresponding to 1 PAM, followed by extrapolation of the data to a distance of 250 PAMs. The PAM250 matrix is given in Figure 1 (see top of next page). This matrix is often used for both aligning sequences and conducting homology searches.

Figure 1. The PAM250 score matrix. The amino acid residues are indicated by their one-letter abbreviations. The values given are the natural logarithms of the frequencies with which the pairs of amino acid residues have been changed during evolution in proteins of known sequence. This value reflects both the probability of the codons for the two residues being interconverted by mutation and the effect that such a mutation will have on the function of the protein. Negative numbers indicate changes that are disfavored; positive numbers correspond to changes that occur

more frequently, and they are shaded.

Poison Sequence

Poison sequence is a general term used to describe **nucleic acid** or amino acid sequences whose presence in a molecule prevents that molecule from carrying out a normal function, such as replication of **DNA**, **intron** splicing, or translocation of a membrane protein. Most often, however,

the term “poison sequence” describes a sequence of DNA that cannot be **cloned**. In certain cases, poison sequences are used as experimental tools.

Plasmid pBR322 poison sequences have been identified that prevent efficient replication of recombinant SV40 virus-pBR322 **shuttle vectors** constructed to move DNA between bacterial and mammalian cells for **mutagenic** studies. Deletions near the pBR322 **origin of replication** increase vector replication efficiency, indicating that sequences near the pBR322 origin inhibit (poison) SV40 replication in mammalian cells (1).

Some poison sequences make it extremely difficult to clone complete sequences of DNA, cause the deletion or rearrangement of inserts, and frequently result in the loss of the poison sequence (2, 3). The presence of a poison sequence in the *gag* gene of the mouse mammary tumor **virus** (MMTV), for example, makes it difficult to study the pathogenicity of the virus, because for many years the full sequence could not be cloned in an intact state for further studies (3). Other examples of poison sequences are those that prevent **splicing** of premessenger RNA *in vitro* (4) and the highly polar cytoplasmic **domain** of *Escherichia coli* **leader peptidase**, which acts as a “translocation poison” sequence that prevents membrane insertion of hydrophobic domains of the protein (5).

Various uses are made of poison sequences. For example, poison sequences are used to create positive-selection cloning **vectors**. A toxic sequence or gene is cloned downstream from multiple cloning sites, and the poison sequence prevents bacterial growth unless it is inactivated by inserting of a DNA fragment into one of the cloning sites (6). In a different type of experiment, a poison sequence that interfered with gene expression when placed into an intron was used to study illegitimate recombination of mammalian cell chromosomes by selecting for mutations that eliminate or alter the poison sequence (7).

Pol **Gene**

The *pol* gene of retroviruses contains coding sequences that specify retroviral enzymes involved in (i) **replication** of the RNA genome, **reverse transcriptase** (RT) (ii) integration of double-stranded proviral DNA, integrase (IN), and (iii) **proteolytic** maturation of precursor polyproteins that accompany virion budding, **protease** (PR) (Fig. 1). In many lentiviruses, a deoxyuridine triphosphatase (DU or dUTPase) **domain** has also been identified between the RT and IN **open reading frames**, and it may play a role in viral expression in different cell types. Over the last decade, these enzymes have been the subject of intense scrutiny due to the emergence of HIV and AIDS and the continuing search for therapeutic agents. Except for human foamy virus (and perhaps

other spumaviruses), where an independent **mRNA** for *pol* enzymes has been established, the *pol* gene is translated as a larger *gag-pol* polyprotein that constitutes ~5% of the total virion *gag* content. Mechanisms for differential synthesis of virion structural and enzymatic proteins (translational **suppression** and ribosomal frameshifting) are outlined in Retroviruses. For unknown reasons, ribosomal frameshifting occurs after the PR coding region of avian viruses, with the consequence that this enzyme is synthesized at about a 20-fold molar excess over RT and IN. The possibility that PR plays an accessory structural role in avian retroviruses has been considered but is as yet unproven. Because the avian PR is considerably less active than its counterpart in other retroviruses, overexpression may be a means of correcting this defect. General features of each of these enzymes are presented in the following sections.

Figure 1. The *pol* open reading frame of HIV-1. The sizes of the three *pol*-derived enzymes, PR, RT/RNase H, and IN, a recognition sites for PR-mediated maturation of the *pol* polyprotein (**a**). Ribbon diagrams represent the structure of each fragment containing the catalytic core of IN has been crystallized. In the absence of supportive evidence, this is represen antivirally active that are in clinical use (Sequinavir, Lamivudine) or under investigation (chicoric acid).

(c)

0.1. Protease

Viral PR controls events whereby *gag* and *pol* proteins are released from each other during budding. Loss of PR activity through site-directed mutagenesis does not impair virion assembly, but the resulting particles are noninfectious. In the strictest sense, PR might be considered a zymogen because it must be released autocatalytically from the precursor polyprotein to fulfill these events. Because the active form of all retroviral proteases is a dimer, therefore it follows that maturation events must be preceded by association of larger *gag-pol* precursors into dimers. The notion that precursors can dimerize is not unreasonable because most, if not all, of the components they encode exist in either dimeric or multimeric states. However, within this dimer, the cleavage sites that dictate PR excision lie on either side of the catalytic site, suggesting that its removal from the precursor occurs via *trans* cleavage (2).

Before their three-dimensional structures, were elucidated amino acid sequence analysis indicated

that the retroviral enzyme is distantly related to a class of cellular carboxyl proteinases (renin, **pepsin**, cathepsin D, and the erythrocyte membrane aspartyl proteinase), a common feature of which is the sequence -Asp-Thr/Ser-Gly- at the active site. However, the two types of enzymes have major structural differences. Although the bilobed nature of the cellular enzyme provides a mechanism for duplicating the active site -Asp-Thr/Ser-Gly- motif, retroviral PR is a dimer of identical subunits, each of which contributes one copy of the active site. Subunits of the PR monomer (which vary in size from 99 to 126 residues), intertwine at their N- and C-termini to form a four-stranded, antiparallel b-**sheet**. A binding cleft above the active site accommodates the peptide substrates of precursor polyproteins. Detailed crystallographic analysis of the PR from HIV and ALSV has indicated that four residues (denoted P4 to P1 and P1′ to P4′ (see Proteinase Inhibitors, Proteins) on either side of the scissile bond (P1–P1′) are accommodated in the binding cleft of the homodimer at their respective enzyme subsites (S4-S1 and S1′-S4′). The entrance to the binding cleft is covered by "flaps" that undergo considerable reorganization after substrate binding.

N-terminal amino acid **sequencing** of mature *gag* and *pol* proteins, recently superseded by highly accurate determination of their molecular weights via **mass spectroscopy**, has been used to determine the PR cleavage sites in precursor polyproteins of many retroviruses. Most cleavage sites are **hydrophobic** and can be grouped into two classes based on the nature of the residue downstream of the scissile bond (P1′). Type I sites prefer a proline residue at P1′, whereas Type II sites prefer alanine, leucine, or valine at this position. Although there is significant sequence heterogeneity when cleavage sites are compared, the various retroviral PR are not readily interchangeable with respect to heterologous peptide substrates, indicating that sequence and structure combine to provide specificity. For HIV, an exhaustive substrate analysis has provided an invaluable framework for developing potent and highly selective peptide-based inhibitors containing a nonhydrolyzable P1–P1′ bond. The structure of Sequinavir, developed by Hoffmann-La Roche, is illustrated in Fig. 1. However, the success of this strategy is dampened by the rapid rate at which resistance is achieved by the virus, caused in part by the promiscuity of the retroviral polymerase.

0.2. Reverse Transcriptase

Converting the single-stranded viral RNA genome into double-stranded proviral DNA, uninterrupted by ribonucleotides, is the responsibility of a single viral enzyme, reverse transcriptase (RT). These events require a combination of RNA- and DNA-dependent DNA synthesis, together with a degradative activity to remove RNA from the RNA–DNA replicative intermediate (ribonuclease H or RNase H). The two enzymatic activities reside in different domains of the enzyme, and in certain circumstances they can be physically separated into enzymatically active polypeptides. Structural similarity between the retroviral RNase H domain and its bacterial counterpart, coupled with the observation that RT encoded by the mitochondrial plasmid of **Neurospora** lacks this domain (which is supplied in the form of a mitochondrial RNase H), suggests that the retroviral polymerase evolved from an ancestral **DNA polymerase** by sequestering an RNase H domain from its host. In doing so, this provides a convenient means by which the polymerizing and degradative activities are coordinated during replication, avoiding the dependence on a host-coded function.

Despite common catalytic mechanisms, retroviral RTs differ significantly in quaternary structure. The isolated form of MLV RT is an ~80–kDa monomer, although recent evidence suggests that DNA synthesis is catalyzed by a homodimer. In contrast, HIV and related lentiviral RT are heterodimers of 66 and 51 kDa subunits (p66 and p51, respectively). These enzymes are derived from the same gene but differ inasmuch as partial PR-mediated maturation of the p66/p66 homodimer removes a copy of the C-terminal RNase H domain from one subunit. The heterodimeric avian enzyme represents an unusual scenario whereby the smaller a subunit contains the DNA polymerase and RNase H domains and the larger b subunit contains these and the entire integrase (IN) polypeptide. Whether it is advantageous to retain a second copy of the RNase H domain (e.g., MLV and ALSV) or a copy of IN (ALSV) remains to be established.

A major advance in understanding the retroviral polymerase has been elucidation of the three-

dimensional structure of HIV-1 RT cocrystals containing either the nonnucleoside inhibitor Nevirapine (3) or double-stranded DNA (4). Based on the anatomical resemblance to a right hand, subdomains of the larger or p66 subunit have been designated “fingers,” “palm,” “thumb,” and “connection,” the last of which connects the DNA polymerase and RNase H catalytic centers (Fig. 1). These four subdomains are duplicated in the smaller p51 subunit. However, alternative folding has the consequence that the p51 connective subdomain masks its DNA polymerase catalytic center, that is, catalytic activities in the parental heterodimer, are mediated by p66. The necessity for asymmetrical organization of identical subunits is not immediately clear, although the smaller HIV polypeptide has been implicated in both accommodating the tRNA replication primer and resistance to nonnucleoside drugs. Subdomains of both subunits contribute to the nucleic acid binding cleft, which is capable of accommodating ~18 bp of duplex. The p66 thumb participates in binding and translocating the template–primer duplex, whereas its N-terminal finger subdomain interacts with the single-stranded template. Catalytic events occur within the palm subdomain, mediated in part by an aspartic acid triad (Asp110, Asp185, and Asp186).

During replication, RT must accommodate three structurally diverse nucleic acid substrates. **Minus-strand** synthesis initiates from an A-form RNA duplex, thereafter continuing along a non-A, non-B RNA-DNA hybrid. In contrast, B-form duplex DNA occupies the nucleic acid binding cleft during **plus-strand** synthesis. Surprisingly, the cocrystal of RT and duplex DNA indicates that the nucleic acid is more A-form at the polymerase catalytic center, B-form at the RNase H catalytic center, and bent over an angle of 45° between the two (see DNA Structure). Whether all nucleic acid duplexes adopt a similar geometry within RT and other related nucleic acid-polymerizing enzymes remains to be established. In addition to the HIV-1 enzyme, a fragment of MLV RT that contains the finger and palm subdomains has been crystallized and shows the same general features.

A second and equally important function of the retroviral polymerase is mediated by its C-terminal RNase H domain, which degrades the RNA moiety of the RNA–DNA replication intermediate relatively nonspecifically (under appropriate conditions, this domain hydrolyzes duplex RNA, although the biological significance of this has not been established). At later stages in replication, a more precise role for RNase H involves generating the appropriate polypurine tract (PPT) 3′-terminus for initiating of plus-strand synthesis and removing minus- and plus-strand primers from nascent DNA. The use of highly purified recombinant enzymes and model heteropolymeric template–primer combinations has allowed a detailed analysis of RNase H function. Crystallographic data indicates that accommodating an RNA–DNA hybrid in the DNA polymerase catalytic center positions the RNA strand ~18 nucleotides upstream for endonucleolytic cleavage, a notion that has been validated experimentally. However, RNase H-mediated events do not cease here but continue along the template in a 3′- to 5′- direction to within eight nucleotides of the primer terminus. The two hydrolytic functions, designated “polymerization-dependent” and “polymerization-independent,” are clearly necessary for replication steps where nascent DNA is transferred within or between strands of the RNA genome. In such model systems, the accepted notion is that RNase H activity is directed by RT, whose polymerase catalytic center is appropriately positioned over the 3′-terminus of a recessed DNA primer. During minus-strand synthesis, however, short RNA fragments remain hybridized to a considerably longer DNA, making a DNA 3′-terminus unavailable to “direct” RNase H activity. Under these conditions, it is now clear that the replicating enzyme positions itself over an RNA 5′-terminus to catalyze the same sequence of hydrolytic events.

Structural similarity between the RNase H of bacterial and retroviral origin has prompted several biochemical and biophysical studies of the isolated retroviral domain. Although it folds correctly, this HIV-1 domain lacks activity, attributable in part to the observation that the RNase domain is not released intact during maturation of the p66/p51 heterodimer, but lacks important N-terminal structural elements. Secondly, an a-**helix** of the bacterial enzyme implicated in nucleic acid binding (a-helix C) has been eliminated from the HIV-1 domain. This most likely reflects structural modifications that accompanied acquisition of RNase H activity by an ancestral RT because the majority of nucleic acid binding would be assumed by the polymerase domain. Unlike HIV RT, the

RNase H domain of the MLV enzyme retains a-helix C and can be removed from the polymerase domain in an active form. When administered in combination with anti-PR drugs, nucleoside-based RT inhibitors such as Lamivudine (Fig. 1) are currently proving highly effective as antiviral agents.

0.3. Integrase

Insertion of the provirus into the host genome is accomplished by a two-step mechanism, for which a dimeric or higher order form of the C-terminal *pol* component, IN, suffices (1). The first event (in the cytoplasm) involves site-specific cleavage at the 3′-end of each viral LTR 5′ to the conserved -C-A- dinucleotide to expose new 3′-OH ends. Subsequently, a concerted cleavage-ligation reaction, involving these OH ends as attacking **nucleophiles** in a transesterification reaction, generates staggered cuts in the host DNA, allowing covalent linkage of the viral 3′-ends. The 5′-ends of viral RNA are flanked by short gaps, which are repaired by cellular enzymes. *In vitro* studies with model duplex DNA substrates and recombinant proteins from human and avian retroviruses have been instrumental in uncovering mechanisms of integration. Structurally, IN can be divided into three distinct regions: (i) an N-terminal domain of ~50 amino acids; (ii) an ~150-residue catalytic core; and (iii) a C-terminal domain of some 100 residues.

The N-terminal domain is characterized by a constellation of histidine and cysteine residues commonly associated with the DNA binding "**zinc finger**" motifs of transcriptional regulators, although the spacing between residues of the IN motif is slightly larger. Despite a high degree of conservation between this domain of IN proteins, its removal does not have a deleterious effect on its processing and joining activities. The isolated N-terminal domain also has no affinity for DNA, although this may not reflect its function in the parental enzyme. However, the N- and C-terminal domains may associate establish higher order forms of IN necessary for activity. The central portion, or catalytic core, of IN is characterized by a constellation of invariant amino acids -Asp-Asp -(35 residues)- Glu- which is a hallmark of the superfamily of **nucleases** and **phosphotransferases** (one member of which is the RNase H domain of retroviral RT). Simultaneous joining of both LTR ends 4- to 6-bp apart to target DNA implies that IN should function minimally as a dimer. This has in fact been observed in crystals of the catalytic core. The least conserved portion of retroviral IN is the C-terminal domain, with which a relatively nonspecific DNA binding function is associated. As determined for the catalytic core, the isolated C-terminal polypeptide exists as a dimer, which has spawned the theory that duplex DNA may be accommodated within a dimer of this domain. Supporting crystallographic data of intact IN that contains its DNA substrate(s) are currently unavailable.

The absence of a cellular counterpart makes HIV IN an especially attractive target for therapeutic intervention. Unfortunately, although a substantial number of inhibitors have been reported by using *in vitro* biochemical assays, these have little effect *in vivo*. A major barrier is their inability to penetrate target cells. However, chicoric acid (Fig. 1) and derivatives do not suffer from these problems, and they may herald a first generation of potent antiviral agents.

0.4. Deoxyuridine Triphosphatase

In lentiviruses, such as FIV, EIAV, CAEV and visna maedi, and the D-type retroviruses MPMV and SRV a fourth open reading frame that encodes a protein of ~20 kDa has been identified between the RT and IN genes. Originally designated a pseudoprotease from amino acid sequence analysis, more recent analysis of virion-associated and recombinant proteins has unambiguously demonstrated that this protein contains deoxyuridine triphosphatase (dUTPase) activity. Cellular dUTPase plays an important role in **nucleic acid** biosynthesis, where it hydrolyzes dUTP to dUMP and pyrophosphate and thereby provides a substrate for thymidylate synthase . In doing so, this provides a mechanism for minimizing **uracil** incorporation into DNA, which would be potentially **mutagenic**. Biochemical characterization indicates that the active species of the cellular and retroviral dUTPase is a trimer.

Why this activity is acquired by a limited number of retroviruses is not immediately clear. One clue may come from studies with **herpes simplex virus** (HSV), a DNA virus whose genome also encodes a dUTPase. Although eliminating dUTPase activity does not result in loss of viral infectivity, such

mutants have reduced neurovirulence and neuroinvasiveness *in vivo*. Because dUTPase levels are low in terminally differentiated or nondividing cells, it has been hypothesized that certain retroviruses retain this activity to permit high-level replication in macrophages. In support of this, equine macrophages support growth of wild-type EIAV but not a variant genetically manipulated to remove dUTPase activity, although this mutant virus replicates efficiently in nonmacrophage cell lines.

Polar

Molecules or groups of atoms bearing significant positive or negative charges, even if only partial, are said to be *polar*. These molecules or groups often contain O, S, or N atoms that can act as hydrogen bond acceptors or donors, allowing them to interact with other groups possessing charges of opposite sign or with solventwater, which is itself highly polar because it bears partial positive and negative charges. Molecules or groups that bear full electrostatic charges, such as the $-NH_3^+$ and $–COO^–$ groups of amino acids in neutral solution, are especially polar and difficult to remove from water. In a strict sense, polarity is best measured by determining the *dipole moment*. In a more practical sense, hydrophilicity or hydrophilic character provides a useful index of a molecule's polarity, by measuring experimentally the difficulty of removing it from solvent water.

Polar Plasma

Although, formerly, it was hypothesized that **germ cells** share the same origin as **somatic cells** and that these develop to primordial germ cells during embryogenesis, it is now known that this is not the case. During the first stages of embryonic development, an event takes place that determines which of the cells will become somatic and which will become germ cells. It is amazing that the decision as to which of the cells are to transfer the genetic information to the next generation in later life is made so shortly after fertilization. Some somatic cells are certainly involved in forming the genitalia, the urogenital tract, and the Wolfian and the Mullerian ducts, and also in developing the embryonic gonads. However, these allow a later invasion by the primordial germ cells that have a different origin and are located at the posterior end of the fertilized egg, as has been demonstrated in insect cells. Thus, it is of interest to determine what factors make cells become germ cells.

In a number of species, there are factors that are necessary for germ line formation, and these are

accumulated in a certain region of the egg, the so-called polar plasma (or pole plasm). In *Drosophila* embryos, germ plasma is located in the posterior pole region. In transplantation experiments, it was shown that the pole plasma contains the determinants to form a germ line. This finding was supported by experiments with eggs in which the polar plasma was inactivated by ultraviolet (UV) irradiation: Development of an abdomen and of germ cells failed (1). Thus, it was assumed that cytoplasmic compounds determine the fate of the future germ line cells. Given that there is virtually no gene transcription at the very early stages of cell division from the genome of the embryo, it is likely that maternal **genes** direct early cell differentiation and the development of germ cells. These gene products were identified by selecting females with homozygous maternal-effect mutants. The genes and gene products found thus far include: tudor, ***oskar***, ***staufen***, *vasa*, ***nanos***, *valois*, *cappucino*, and *spire*. Deletion of these genes causes failure to produce germ cells and/or abdomen because either a direct effect on a subsequent **gene expression** is missing or the localization of gene products to the posterior end is lost on egg activation.

The protein *nanos* is essential for germ line formation in *Drosophila*. Pole cells lacking activity of this protein do not become functional germ cells (2), as they fail to migrate into the gonad. *Nanos* is therefore a protein necessary for transport of germ cells.

The proteins *oskar, staufen, vasa*, and *tudor* are necessary for the assembly of the pole plasm (3, 4). *Staufen* is required for localization of *oskar* RNA and translation. The localizations of *vasa* and *tudor* are dependent on *oskar* protein, a transcription factor, and are required for accumulation of *oskar* protein at the posterior pole. Mislocation of *oskar* protein to the anterior pole results in the formation of germ cells at the anterior pole, thereby indicating the importance of correct transport and localization of transcription factors. *Tudor* is concentrated in the polar granules and is involved in two distinct determinative processes in embryogenesis. Mutations of the *tudor* gene affect the later segmentation of the abdomen and the determination of the primordial germ cells (5). The *mago nashi* locus encodes an essential product for germ plasma assembly. The gene product is necessary for the specification of the anterior-posterior axis and the dorsoventral coordinates (6). *Vasa* is also necessary for the formation of polar granules and germ cells (7). Further, mitochondrial large ribosomal RNA was identified in the germ plasm to act as a cytoplasmic factor that induces pole cell formation; it is tightly associated with polar granules, the distinctive organelles of the germ plasm. Also, Hsp83, a member of the Hsp90 **molecular chaperone** family, seems to be a component of the posterior polar plasma.

The polar plasma and the germ line cells may be of interest for attempts to clone individuals. Although fully differentiated cells are probably not able to return to their totipotent stage, primordial cells appear to retain omnipotence for at least 30 days, as has been shown in cattle.

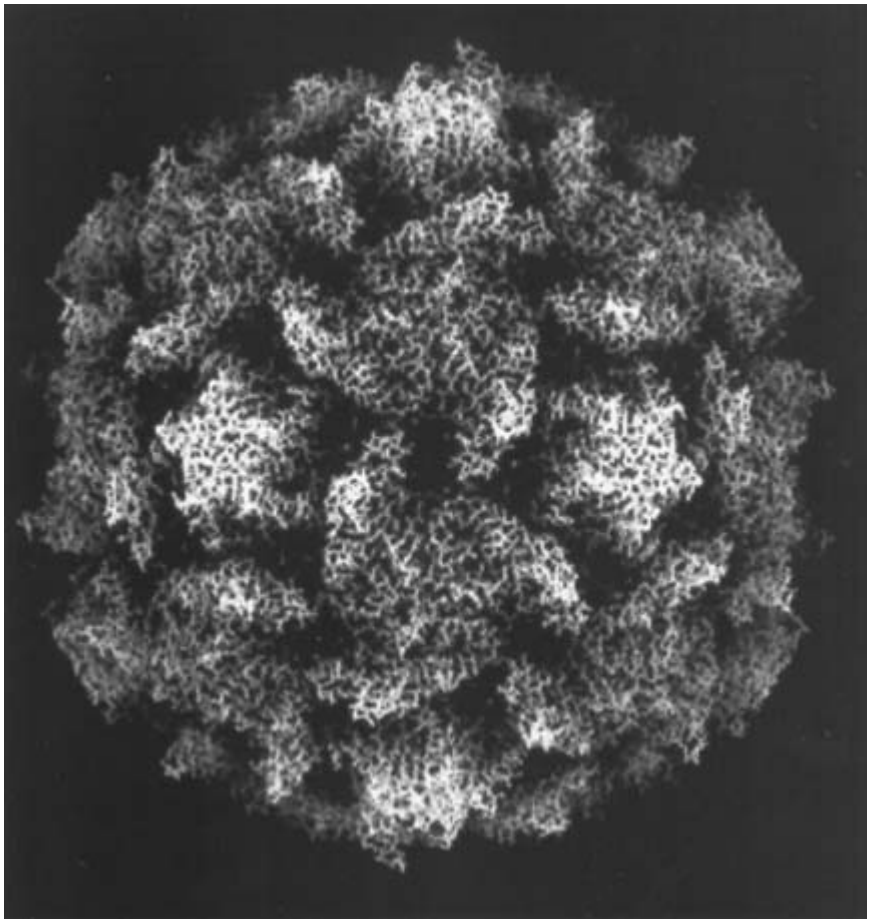
Poliovirus

Poliovirus, the causative agent of poliomyelitis, is a human enterovirus that belongs to the family *Picornaviridae* (see Rhinovirus) and contains a single-stranded RNA genome. The precise three-dimensional structure of the icosahedral virion particle was elucidated by X-ray crystallography studies (Fig. 1). These structural investigations indicated that the virion particle is composed of 60 copies each of the viral capsid proteins VP1, VP2, VP3, and VP4 and indicated the structures of the neutralizing **epitopes** and viral attachment sites, called the "canyon" (see Rhinovirus), to the poliovirus receptor (PVR) on the surface of permissive cells.

Figure 1. Three-dimensional structure of poliovirus.Courtesy of Drs. James M. Hogle and Robert Grant, Harvard Medical School.



The genome of poliovirus has messenger RNA polarity, is approximately 7500 nucleotides in length, is **polyadenylated**, and is linked covalently at its 5′ end to a small protein called VPg. The RNA itself is infectious; cells transfected with the RNA produce progeny virions that are infectious. The complementary DNA corresponding to the entire genome is also infectious. This infectious cDNA clone blazed a trail in the field of the molecular genetics of poliovirus.

The nucleotide sequence of viral mRNA in infected cells is essentially identical to that of the virion RNA, but the VPg is missing in the mRNA. Poliovirus mRNA harbors a long 5′ untranslated region (UTR) of approximately 740 nucleotides in length that is important for synthesis of viral RNA and proteins. A possible cloverleaf-like structure formed by the 5′-proximal end of the RNA (approximately 90 nucleotides) is a probable *cis*-element that regulates the synthesis of the plus-

strand RNA. The following sequence of 400 to 500 bases makes up the internal ribosomal entry site (IRES), which directs the viral translation initiation step in a manner independent of whether or not there is a **5′-cap**. The IRES is assumed to carry a number of secondary structures, and multiple host cellular factors are required for its functions. Polypyrimidine-tract binding protein (PTB), La protein, and poly-riboC binding protein (PCBP)-2 are thought to be involved in the translation initiation process, although these cellular proteins are usually distributed mainly in the nucleus.

Attenuated strains were developed in 1950s and have been used efficiently as oral live vaccines. The vaccine strains can grow well in the human alimentary tract and elicit neutralizing antibodies against the virus, but they have a very poor replicating capacity in the central nervous system (CNS). Thus, the virulent and attenuated strains differ in their CNS tissue responses. Molecular genetic analysis of the CNS response to poliovirus revealed that the phenotype was determined primarily by the IRES region. Thus, it is possible that the CNS response of the virus is the reflection of CNS-specific expression of the IRES function.

The mRNA has a unique long open reading frame that encodes the large viral precursor polyprotein. The large polyprotein is cotranslationally cleaved by viral proteinases 2A and 3C to form the viral capsid proteins VP1-4 and the viral replication proteins 2A, 2B, 2C, 3A, 3B, 3C, and 3D. Among the latter, 2A and 3C are proteinases, 3B is VPg, and 3D is RNA-dependent **RNA polymerase**. VPg is importantly involved in the initiation of the viral RNA synthesis. In addition to the final processed products, intermediate proteolytic fragments such as 3AB (3A + 3B) and 3CD (3C + 3D) are also considered to play important roles in the initiation step of viral RNA synthesis.

Poliovirus infects only primates, and other animal species are generally not susceptible to the virus. This species-specificity of poliovirus has long been considered to be determined by PVR protein. PVR is known to be a member of immunoglobulin superfamily. Transgenic mice carrying the human *PVR* gene were actually susceptible to poliovirus. A line of such transgenic mice is now approved to be an animal model for poliomyelitis, in addition to a monkey model.

Poly A

The 3′ ends of almost all messenger RNA from **eukaryotes** consist of a homopolymer of adenosine residues that is added post-transcriptionally by polyadenylate polymerase in the polyadenylation reaction (1, 2). The length of this poly A tail is variable and ranges between approximately 20 and 250 residues, depending on the mRNA. The poly A tail has also been implicated in RNA stability and in the regulation of translation (3, 4). It is important to note that the poly A tail is not a static modification, but a dynamic one, which can be shortened or lengthened. This can be exemplified by analyzing the length of the poly A tail of a specific mRNA during different times of development. This may be important for developmental regulation of **gene expression** (2, 3).

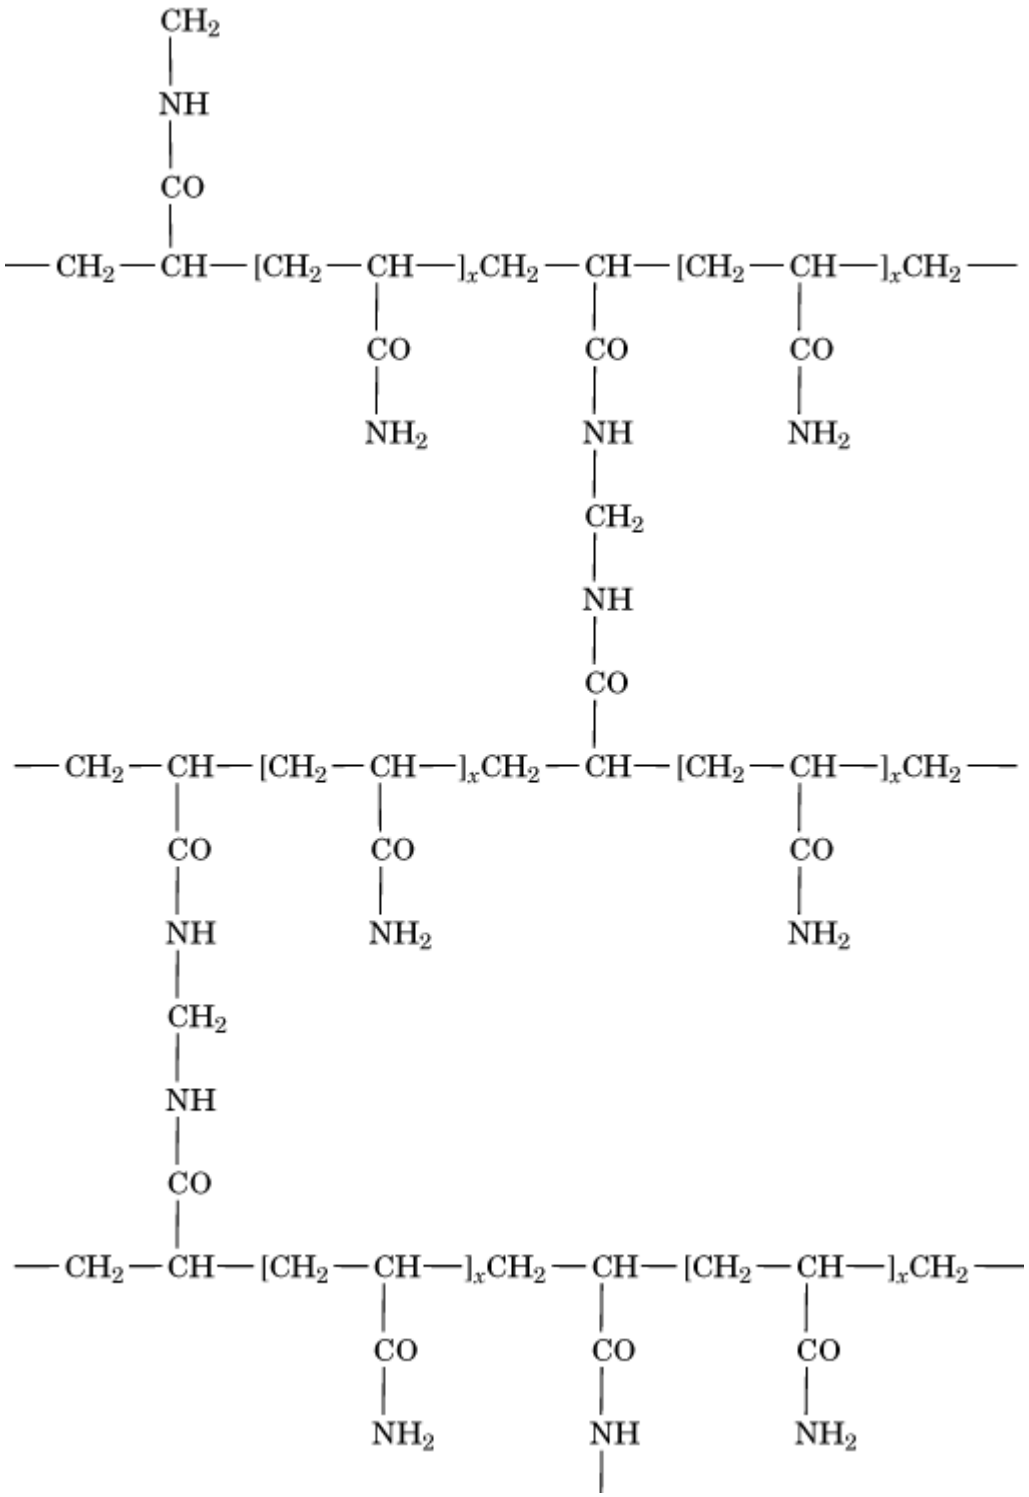
Polyacrylamide

For over 30 years, polyacrylamide has been, and still is, the building material for gel electrophoresis with the widest range of pore sizes. It is suitable for resolving by electrophoresis, on the basis of size, shape, and conformation, species with molecular weights ranging from a few hundred daltons to those of large particles the size of a **microsome**. Gel concentrations in the range of 3% to 50% (w/v) acrylamide are practical. Polyacrylamide gel electrophoresis is commonly abbreviated as PAGE .

Polyacrylamide (Fig. 1) is formed by polymerization of the monomer acrylamide by a complex polymerization reaction that is catalyzed by free radicals. Thus, to obtain a reproducible polymer, along with a high degree of conversion of monomers to polymer, a considerable number of parameters need to be controlled, especially the following:

1. the purity of the monomers, especially the absence of acrylamide polymers and of acrylic acid;
2. purity and concentrations of the free-radical donors that initiate the polymerization;
3. levels of inhibitors (eg, free-radical captors, especially oxygen);
4. temperature;
5. pH;
6. divalent metal concentrations;
7. the reaction time, which roughly determines the degree of polymerization.

Figure 1. Elements of a Bis-crosslinked polyacrylamide gel network. The linear polyacrylamide chains are depicted horizontally, the Bis crosslinks vertically.



A large number of polymerization initiator species are available, but only three are commonly used: persulfate, tetramethylethylenediamine (TEMED), and riboflavin activated by light. Persulfate and TEMED together are effective polymerization catalysts in the alkaline pH range. Acidic gels are more effectively polymerized in the presence of all three catalysts combined in optimal ratios. Even in the alkaline range, photopolymerization of riboflavin in the presence of persulfate will produce gelation within the desired time, about 10 min for analytical-scale gels, coupled with precise control of the time at which polymerization starts by the start of illumination.

Polyacrylamide is normally crosslinked with N,N′-bisacrylamide (Bis) (Fig. 1). The crosslinking

retards progressively the rate of migration of macromolecules as the fraction of Bis is increased from 0% to 5% of the total acrylamide monomers; beyond that, the retardation diminishes with further increased crosslinking, and it becomes negligible when acrylamide and Bis are copolymerized in equal amounts (1). Polyacrylamide that has not been crosslinked is able, however, to separate some DNA conformations that crosslinked polyacrylamide cannot. More generally, the pore architecture of crosslinked vinyl polymers like polyacrylamide can be varied greatly through choice of a large number of crosslinking agents (2) or initiator conditions (3, 4). Lateral aggregation of gel fibers brought about by inclusion in the polymerization mixture of hydrophilic polymers, such as polyethylene glycol, produces large pores (5). Furthermore, the retardation of molecules in a polyacrylamide gel can be modulated by the average length of the polyacrylamide chains. The chain length and the effective pore size are inversely related, and the average chain length can be controlled through the polymerization conditions. The effective "pore size" of the network is defined by the ratio of the diameter of one covalent polyacrylamide particle to the average distance in three dimensions between polymer chains. If this ratio is too small, or if it exceeds unity, molecular sieving ceases or, at least, diminishes. The average chain length is directly related to the molecular sieving effect of the network. When the average chain length is decreased through excessive initiator concentrations or by the presence of inhibitors during polymerization, the effectiveness of sieving decreases. Also important for molecular sieving is the distribution of crosslinks. Crosslinking agents that enter into the growing polymer chain more slowly than the monomer tend to give rise to an uneven distribution of crosslinks ("nodules"), which increases the effective pore size. Polyacrylamide chains lacking crosslinks form gels above 10% monomer concentration, and those with crosslinks form gels above 3% monomer concentration. Uncrosslinked polyacrylamide excels in network homogeneity but is less effective than crosslinked polyacrylamide in the molecular sieving of proteins.

Freshly prepared polyacrylamide is an oxidative medium containing, in part, peroxide-type uncharged oxidizing agents that cannot be removed by pre-electrophoresis alone. Electrophoresis of charged reducing agents, such as thioglycolate, loaded prior to, or with, the protein sample, is often needed to overcome the oxidative effect of polyacrylamide on proteins.

Polyacrylamide has good adherence to glass walls, and it can even be prepared covalently bound to them, rendering it compatible with vertically oriented apparatus. In horizontally oriented apparatus, polyacrylamide can be firmly bonded to thin plastic sheets (GelBond-PAG); this allows for the preparation of thin gels, compatible with the high field strengths that enhance resolution.

Polyadenylate Polymerase

Addition of the poly A tail to a messenger RNA precursor requires the action of polyadenylate polymerase, a single-subunit enzyme that catalyzes addition of the adenosine homopolymer to the 3′ end of the pre-mRNA (1). The sequence of the catalytic **domain** of the enzyme is conserved within **eukaryotes**. Under normal conditions, the enzyme is highly specific, polyadenylating only those pre-mRNA that have gone through the cleavage step of cleaving the precursor near its 3′ end, to generate the site for poly A addition, and still have the cleavage and polyadenylation stimulatory factors bound to the sequence signaling polyadenylation, AAUAAA (2, 3) (see Polyadenylation). Under appropriate conditions *in vitro*, however, it can polyadenylate any RNA that has a free 3′ hydroxyl group; this is commonly referred to as the nonspecific reaction.

Polyadenylation

Many messenger RNAs (mRNAs) are modified after transcription by the addition of multiple AMP moieties at the 3′ terminus in both prokaryotic and eukaryotic organisms, but the biochemical mechanism of poly(A) addition and the function of the tails are significantly different in the two types of organisms. In eukaryotes, a large multiprotein complex recognizes specific sequences in the 3′ untranslated region (3′ UTR) of the transcript leading to the cleavage of the mRNA. The combined action of poly(A) polymerase, a poly(A)-binding protein, and a cleavage/polyadenylation specificity factor (CPSF) subsequently leads to the addition of poly(A) tracts that vary in length from organism to organism (1). Poly(A) tails have been implicated in conferring stability to mRNA transcripts, promoting their efficiency of translation and having a role in the transport of processed mRNA from the nucleus to the cytoplasm (2, 3). In addition, recent studies suggest a relationship between mRNA splicing and polyadenylation (1). Taken together, polyadenylation in eukaryotic organisms apparently plays an important role in the regulation of gene expression and possibly development.

In contrast, poly(A) tail addition in prokaryotic organisms only seems to require an available 3′ terminus and poly(A) polymerase (4). Furthermore, unlike in eukaryotes, only a small proportion of each prokaryotic mRNA is polyadenylated at any given time (5). Because the presence of a poly(A) tail on a prokaryotic transcript appears to target the molecule for rapid decay (4, 6), poly(A) tails are also most likely involved in gene regulation, but primarily from the perspective of controlling mRNA decay rates (4, 7). Another distinction between prokaryotes and eukaryotes is that 23S rRNA is the most prevalent polyadenylated species in *Escherichia coli* (4).

The discovery of enzymes in both prokaryotes and eukaryotes that could add poly(A) tails to RNA molecules occurred in the early 1960s (8, 9). However, it was another 10 years before poly(A) tails

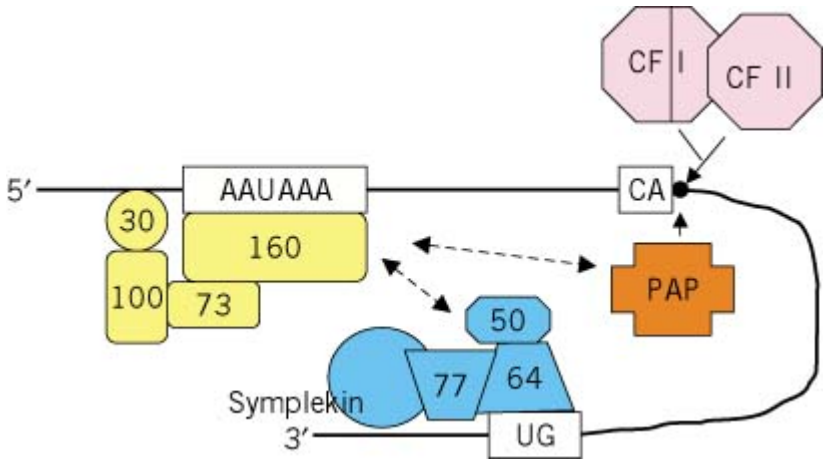
were actually identified as a post-transcriptional modification of eukaryotic mRNAs (10-12). Although the possibility of poly(A) tails in the bacteria *E. coli* was raised in 1975 (13), it was not until 1978 that solid evidence was presented for their existence (14). Subsequently, it has been shown that the length of the actual poly(A) tails varies from organism to organism [*E. coli*, 10–40 residues (6); yeast, ≈90 residues (15); vertebrates, ≈300 residues (16)].

1. Eukaryotes

The enzyme responsible for the actual addition of the poly(A) tail, poly(A) polymerase, appears to be ubiquitous in eukaryotic organisms, **archaea**, and both *Gram-negative* and **Gram-positive** bacteria. The prokaryotic and eukaryotic enzymes form part of a large superfamily of nucleotidyltransferase proteins that share significant amino acid homology in their amino termini (17, 18). The enzymes employ ATP to add AMP moieties to the 3′ termini of RNA substrates.

In the case of the mammalian poly(A) polymerase, the length of the tail is directly related to the processivity of the addition reaction (19). Although poly(A) polymerases are single-subunit enzymes, the process for the selection of polyadenylation sites in eukaryotic transcripts involves both a large number of proteins and in most cases specific polyadenylation signals. The site recognition systems have been studied extensively in both mammals and yeast (20). In the mammalian system, there are three essential features of the polyadenylation element (Fig. 1). The polyadenylation signal sequence (AAUAAA) is normally located 10 to 30 bases upstream of the cleavage/polyadenylation site. A second motif that is GU rich is located 20 to 40 nucleotides downstream of the cleavage site (Fig. 1). Finally, a CA dinucleotide immediately 5′ to the cleavage site is preferred but not absolutely required (21).

Figure 1. Outline of the mammalian polyadenylation machinery. The three *cis*-acting RNA elements associated with the selection of a polyadenylation site are shown in rectangular boxes. The solid black circle denotes where the mRNA is cleaved to generate the polyadenylation site. The numbers inside the yellow and blue boxes indicate the subunit sizes in kDa. Yellow boxes are the components of the cleavage/polyadenylation specificity factor (CPSF). Blue boxes indicate the subunits of the cleavage stimulation factor (CstF). The pink octagons are the two cleavage factors (CF I and CF II). The vertical line in the CR I octagon indicates a dimeric protein. PAP is poly(A) polymerase. The double-headed dashed arrows indicate protein–protein interactions. This figure is loosely adapted from Refs. 20 and 25, and is not drawn to scale.



In addition to the cis-acting sequences, at least four protein factors are required to generate a 3′ terminus for polyadenylation in eukaryotes. These include the cleavage/polyadenylation specificity factor (CPSF), which consists of four distinct polypeptides (160, 100, 73, and 30 kDa) (1). The 160-kDa subunit appears to bind directly to the AAUAAA recognition signal, but its specificity appears

to be increased in the presence of the other CPSF subunits (1). Various data also suggest that the 160-kDa CPSF subunit interacts with poly(A) polymerase.

A second recognition protein is the so-called cleavage stimulation factor (CstF) that consists of three subunits (77, 64, and 50 kDa) and interacts at the downstream GU-rich element (Fig. 1) (1). The 64-kDa protein contains an **RNA-binding** domain (22); the 77-kDa subunit has been shown to associate with the 160-kDa CPSF subunit, indicating physical contact between CPSF and CstF. The nuclear protein **symplekin** has recently been shown to assist in the assembly of the CstF complex (23).

Although the CPSF and CstF protein complexes have been extensively studied, the multisubunit cleavage factors, CF I and CF II (24), associated with the actual mRNA cleavage reaction, remain poorly characterized. The CF I complex consists of two subunits (68 and 25 kDa). The exact composition of CF II remains to be determined. At the present time it has not been determined which protein factor(s) contain the actual endonuclease activity (25).

Once the polyadenylation site has been generated through the interaction of CPSF, CstF, CF I, and CF II, polyadenylation is initiated by poly(A) polymerase. However, another protein, called poly(A)-binding protein II (PAB II) plays an integral role in mediating the length of the tall (26). PAB II binds to the poly(A) tail early in its synthesis, and helps form a quatenary complex between the substrate RNA, CPSF, and poly(A) polymerase. This complex helps to provide the processivity of the polyadenylation reaction, because dissociation of the complex leads to a cessation in poly(A) tail elogation.

All eukaryotic polyadenylation systems are not idential. There are significant differences between the poly(A) addition process in yeast and in mammalian cells, but many of the proteins involved do share considerable sequence homology (20, 25). Yeast homologues of all four CPSF subunits have been identified along with several additional factors (1). Furthermore, it appears the mammalian AAUAAA and GU-rich elements are replaced by an A-rich positioning element along with an AU efficiency element (27). This would suggest that although there may be differences in the actual factors involved in 3′ end formation, the basic process of polyadenylation in eukaryotic organisms has been functionally conserved (25).

2. Prokaryotes

In contrast to the well-characterized mammalian and yeast polyadenylation systems, polyadenylation in bacteria is still only partially understood. Recent experiments have demonstrated that the poly(A) levels in *E. coli* are regulated by controlling the amount of **poly(A) polymerase** I (4). In addition, there is a competition between the synthesis of poly(A) tails by poly(A) polymerase I and their degradation by 3′ → 5′ exonucleases such as **RNase II** and polynucleotide phosphorylase (28). Interestingly, poly(A) tails in *E. coli* can contain non A residues (4), which are added by polynucleotide phosphorylase working biosynthetically (29). In this reaction, nucleoside diphosphates are employed instead of nucleoside triphosphates. In the absence of poly(A) polymerase I, all of the residual poly(A) tails are synthesized by polynucleotide phosphorylase (29). Thus, unlike in eurkaryotes, there are at least two distinct enzymes that can synthesize poly(A) tails in *E. coli.* Interestingly, it has just been reported that in spinach chloroplasts, all the poly(A) tails are synthesized by polynucleotide phosphorylase (30).

Although the *E. coli* poly(A) polymerase I is both functionally and structurally related to eukaryotic poly(A) polymerases (17, 18), at the current time there is no evidence for a specific polyadenylation signal, because poly(A) tails can be located at many different sites within a particular transcript (4, 31). The poly(A) tails synthesized in the bacterium appear to target specific mRNAs for more rapid degradation (4, 6, 32), but it is not clear whether polyadenylation in *E. coli* has any other functional role beyond its involvement in mRNA decay. Amino acid sequence comparison among the many newly sequenced bacterial genomes has demonstrated that poly(A) polymerases are found in most

prokaryotes.

3. Use in Purification of mRNA

From a practical perspective, polyadenylation has provided scientists with a powerful method for selecting specific mRNAs that can be converted into DNA and subsequently cloned (see cDNA Libraries). In this fashion, it has been possible to isolate the coding sequences for a large number of eukaryotic genes. The method involves initial enrichment of polyadenylated RNA by passage of total cellular RNA over a solid support matrix containing oligo(dT) molecules. In eukaryotes, the polyadenylated RNA will bind to the column, whereas the bulk of the RNA (ribosomal and transfer RNAs) will pass through the column. With bacterial RNAs, some rRNA will be associated with the column because they contain poly(A) tails. The polyadenylated RNA can then be eluted and used as a template for the enzyme **reverse transcriptase** using an oligo(dT) primer. The RNA/DNA hybrid can then be converted to fully double-stranded DNA in a second reaction involving **RNase H** and reverse transcriptase or a **DNA polymerase**. These fully double-stranded DNAs can be cloned into an appropriate vector for further analysis. Since poly(A) tails exist in both eukaryotes and prokaryotes, this method can be used with almost any organism.

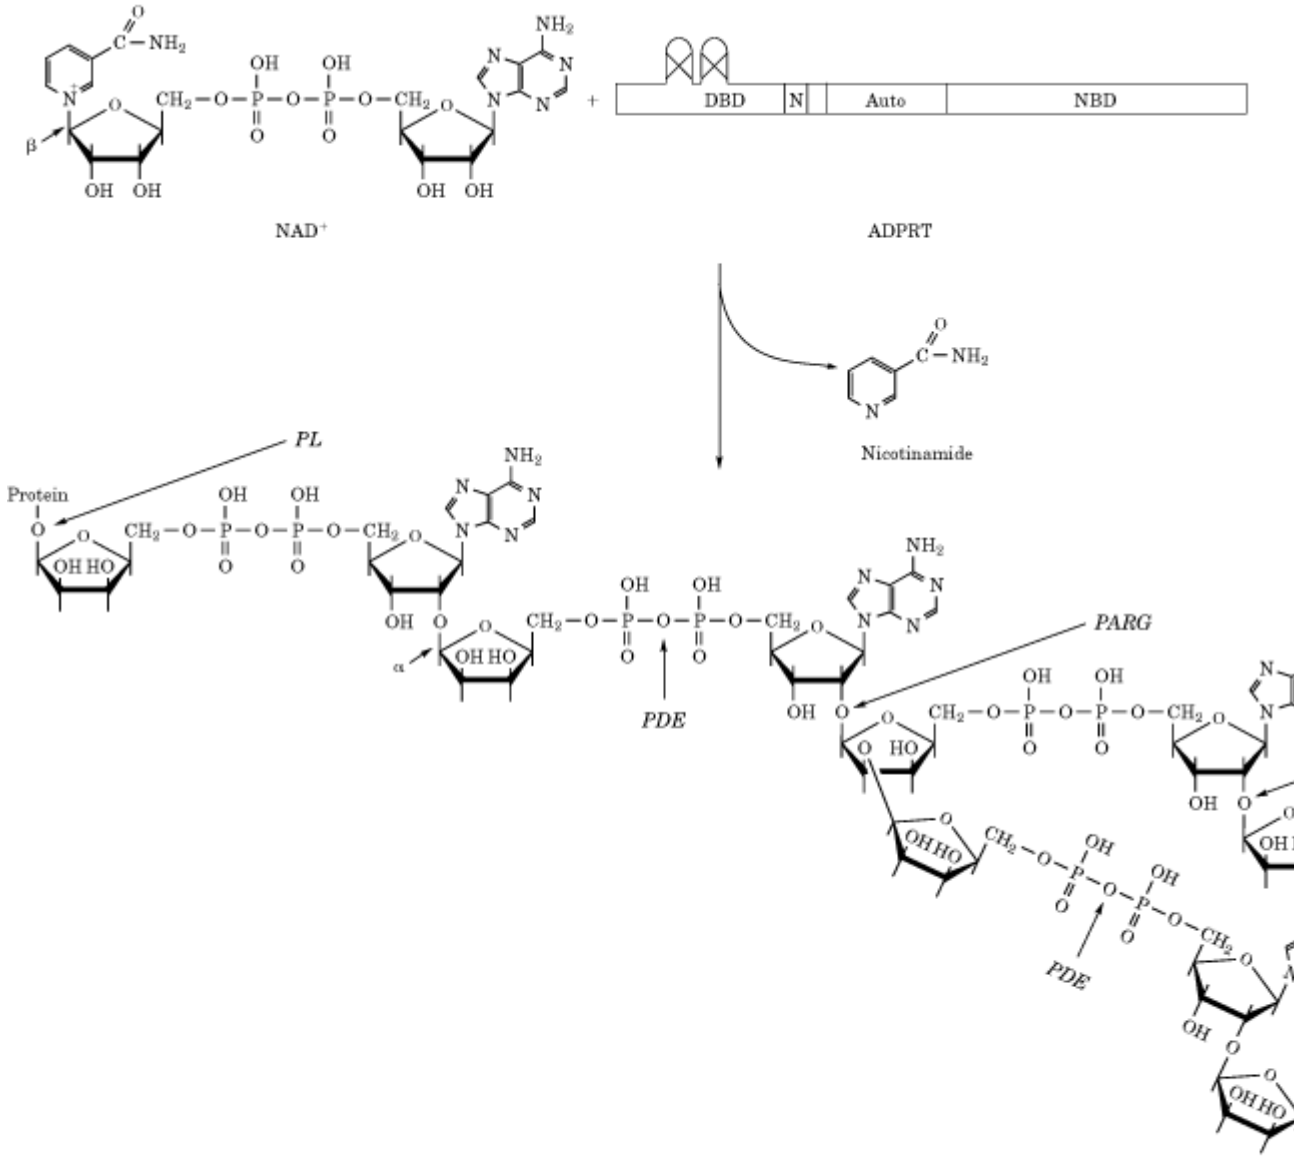
Poly(ADP-ribosyl)ation

Poly(ADP-ribosyl)ation is a post-translational modification, and plays a role in regulating central cellular processes in eukaryotes. Poly(ADP-ribosyl)ation is catalyzed by the enzyme AND$^+$ protein (ADP-ribosyl) transferase polymerizing (EC.2.4.2.30). The specific inhibition of poly(ADP-ribosyl) ation in cells enhances the cytotoxic effects of carcinogens consistently. Therefore, poly(ADP-ribosyl)ation has long been considered to function in cellular surveillance of genotoxic stress. The most abundant enzyme responsible for this activity is poly(ADP-ribose) polymerase-1 (PARP-1). PARP-1 has been isolated and extensively characterized. PARP-1 has been demonstrated to specifically recognize and bind to DNA single-strand breaks and is, therefore, regarded as a "molecular nick sensor." In an immediate response to the occurrence of DNA lesions, PARP-1 synthesizes polymers of ADP-ribose. Although not essential, PARP-1's activity has been shown to greatly facilitate DNA base excision repair. Recently, several other enzymes catalyzing this kind of modification have been identified. The discovery and characterization of further PARP enzymes suggest new functions for poly(ADP-ribosyl)ation, such as in regulation of telomere elongation and cellular transport.

The first report that led to the discovery of (ADP-ribosyl)ation was published in 1963 (1). It was observed that incorporating radioactively labeled ATP into the acid-insoluble fraction of a nuclear preparation from chicken liver was stimulated 1000 times by nicotinamide mononucleotide (NMN). The polymer product was later identified as poly(ADP-ribose). The synthesis of poly(ADP-ribose) depends on the availability of AND$^+$, which is synthesized from NMN and ATP. PARP enzymes use NAD$^+$ as substrate and form poly(ADP-ribose), with a concomitant release of nicotinamide (Fig. 1). Multiple units of ADP-ribose are transferred onto glutamic acid Therefore, it was suggested that PARP-1 could be an element of the G_2 checkpoint. Under conditions of severe damage, PARP-1 activation may cause depletion of the cellular NAD$^+$ pool and thereby can trigger cell death. During

the onset of apoptosis, specific interleukin-converting enzyme proteinases are activated, which results in the appearance of specific proteolytic PARP-1 fragments (14). These proteolytic products are therefore considered as markers of apoptosis.

Figure 1. Poly(ADP-ribosyl)ation reaction: The functional domains of mammalian PARP-1 are schematically represente including two Zn-finger motifs (indicated by the x loops) and a nuclear localization signal (N), the automodification (Au domains are indicated. A PARP-enzyme catalyzes the polymerization of (ADP-ribose) moieties and the transfer to protei with concomitant release of nicotinamide. The conformation (a or b) of glycosidic bonds in NAD^+ and poly(ADP-ribose involved in polymer catabolism are indicated. PL, protein lyase; PDE, phosphodiesterase; PARG, poly(ADP-ribose) glyc



In living cells poly(ADP-ribose) polymers possess a half-life of only a few minutes, due to the activity of specific catabolizing enzymes. The cleavage sites are indicated in Figure 1. Poly(ADP-ribose) glycohydrolase is the physiological counterpart of PARP enzymes, and cleaves the polymers

with high specificity for the glycosidic bounds, generating free ADP-ribose (15). The transient nature of poly(ADP-ribose) synthesis makes this reaction also well-suited for the putative regulation of other cellular processes. At about the same time, resulting from independent research approaches, several new proteins with partial homology to the catalytic domain of PARP-1 were identified: PARP-2, PARP-3, vault-PARP (VPARP), and tankyrase (see Table 1). Interestingly, also an alternative catalytic active form of PARP-1 was isolated (sPARP-1), which appears to be a short product resulting from an alternative initiation event in the PARP-1 gene (16). Of the new PARP members PARP-2 bears the strongest resemblance to PARP-1, and might also be functionally similar (17). VPARP was isolated from vault complexes and is a 193-kDa protein containing a catalytic-active PARP domain (18). Only little is known about vault particles; however, it is speculated that these largest known ribonucleoprotein complexes serve a carrier function. Therefore, poly(ADP-ribosyl)ation by VPARP might play a role in regulation of cellular transport. Another nuclear PARP enzyme, tankyrase was identified through its interaction with the telomere-specific DNA-binding protein TRF1 (7). TRF1 is a negative regulator of telomere elongation, and if poly(ADP-ribosyl) ated, is released from binding to telomeres (7). Thus, tankyrase may function as a telomer-length regulator by promoting telomere elongation via poly(ADP-ribosyl)ation of TRF1 (19). Database search analyses indicate that the number of PARP-related proteins still is growing (Table 1). For example, recent studies have revealed a tankyrase homolog, termed tankyrase 2 (20).

Table 1. Enzymes Involved in Poly(ADP-ribose) Metabolism

Name of Enzyme	Alternative Designations	Chromosomal Location	Cellular Distribution	Putative Functions in Regulation of
PARP-1	ADPRT	1q41-q42	Nucleoplasm	DNA base excision repair
	PARS		Damaged DNA	Recombination
	ADPRT1		Centromeres	Transcription
	pADPRT-1			Cell cycle
				Cell death
PARP-2	ADPRT2	14q11.2-q12	Nucleoplasm	DNA base excision repair
	pADPRT-2		Damaged DNA	
	ADPRTL2			
	ADPRTL3			
PARP-3	ADPRTL3	3q22.2-q21.1		
PARP-4	ADPRTL4	22q11.1		
VPARP	VAULT3	13q11	Cytoplasm	Cellular transport

	ADPRTL1		Vault particles	
			Nucleoplasm	
			Mitotic spindle	
Tankyrase	PARP-5	8q	Telomeres	Telomere length
	Tankyrase-1		Mitotic centrosomes	
	TNKS		Nuclear pore	
			Golgi complex	
Tankyrase-2	TNKS-2	10q23.1	Microsome fraction	Signal transduction pathways
PARG		10q11.23	Nucleoplasm Cytoplasm	Catabolysis of poly(ADP-ribose)

In resting cells, the natural content of detectable poly(ADP-ribose) is rather low, therefore the most important questions continue to be how and when PARP enzymes are activated and what are their relevant substrates of modification. The activation of PARP-1 in response to DNA damage is well understood. The characterization of the mechanisms for activation of the other PARPs will gain further insights into the biological roles of poly(ADP-ribosyl)ation.

Polyamino Acids

Polyamino acids are **polymers** of varying lengths that are formed from only one (or sometimes a few) amino acid(s). Both polyamino acids and proteins are polymers formed from amino acids, but the difference is that proteins have a defined and complex sequence usually including all 20 different natural amino acids. The first peptides to be formed by chemical peptide synthesis were polyamino acids such as polyglycine, polyserine, and polylysine. These served as important models for structural and conformational studies.The two polyamino acids polyglycine and polyproline form an unusual helical backbone **secondary structure**.

[See also Polymer and Proteins.]

Polyclones

The term *polyclone* was introduced by Crick and Lawrence (1) and is intimately linked to the concept of compartments in development of the fruit fly *Drovophila* (2, 3). Compartments are well-defined parts of the body characterized by the lineage of their constituent cells; they are formed exclusively by the descendants of a small group of neighbor cells. The term *polyclone* is used to emphasize that each compartment always arises from more than one cell; the initial number varies from 5 to 50 cells. The descendants of each cell of the original group (the *founder polyclone*) will populate different regions of the adult compartment in different individuals but, together, the polyclone will always, in all individuals, construct the same region of the fly.

The polyclone is a unit of cell lineage in development. Compartmentalization is a reiterative process; during development, a polyclone can be subdivided into daughter polyclones, which will form specific subregions of the original compartment. The compartment/polyclone work provided, for the first time, a description of developmental segregations in development, that is, how to subdivide an organism into its constituent parts.

Although there were previous hints from lineage analyses in *Drosophila* and in the milkweed *Oncopeltus* (4), compartments were demonstrated as a result of the development of the *Minute technique* (5). This method allowed the production of marked clones that were able to proliferate more rapidly than surrounding cells and to reach very large size. These clones could nearly fill entire adult regions but would never transgress the boundaries of the compartment; thus, these fast-growing clones delineated compartments. These were originally described for the thoracic and cephalic imaginal disks, but they were later found for the rest of the body also. The first compartmentalization events take place in early embryogenesis and affect all the germ layers, indicating that the whole body is compartmentalized.

Compartmentalization is an epigenetic subdivision of the body into parts—polyclones. These are not only fundamental units of cell lineage but also units of genetic control of development (6) and of growth and proliferation (7). Moreover, recent results (8) have demonstrated that compartment borders play a critical role in the signaling mechanisms involved in pattern formation.

1. Units of genetic control of development

A principal property of polyclones, and a basic tenet of the compartment hypothesis, is that polyclones are the realm of action of some key regulatory **genes** that establish developmental programs in groups of cells. For example, the identity of the body segments along the anteroposterior axis is specified by the *Hox* genes, whose domains of function and expression are delimited by compartment boundaries, indicating that *Hox* genes recognize polyclones as units of their expression.

Similarly, other genes involved with the specification of more discrete body regions become activated in specific polyclones. For example, the subdivision of embryonic metameres into anterior (A) and posterior (P) polyclones is followed by the activation of the **homeobox** gene ***engrailed*** in each P polyclone, whereas it is permanently turned off in the A polyclones. Thus, the P polyclone is the developmental unit of *engrailed* function, which gives P cells their specific identity.

A similar phenomenon occurs later, during the development of the wing (and presumably the haltere) disk, when a compartment boundary appears separating dorsal versus ventral polyclones (2, 3). All the cells of the dorsal polyclone, and none of the ventral, acquire activity of the homeobox gene *apterous*, which gives them specific dorsal identity (9).

2. Units of growth

Polyclones appear to be units of size control in development. This is indicated by the Minute

experiments (5), in which a fast-proliferating clone can fill as much as 80% to 90% of the compartment, yet it is of normal size. There must be a mechanism restricting the proliferation of the other cells of the polyclone in order to build a compartment of normal size. This mechanism has been called “cell competition” and operates within compartments (7).

3. Compartment borders as sources of morphogens

Recent work (8, 10) has shown that compartment borders play a key role in patterning processes. In the development of the wings and legs, signaling (through the Hedgehog product) from P polyclone cells across the anteroposterior compartment border to the adjacent A polyclone cells triggers the production of the morphogen *decapentaplegic*, which then diffuses to both polyclones. Similarly, the dorsoventral compartment border in the wing is the source of the signaling molecule *Wingless* .

Polycomb Group

The *Drosophila* Polycomb group (PcG) comprises approximately 13 identified **genes** whose products are involved in **silencing** the transcription of target genes. Additional genes that contribute to PcG-dependent silencing are postulated to exist (1, 2). Although the list of genes that are regulated by the PcG continues to grow, PcG genes are defined primarily as negative regulators of the homeotic genes of the **Antennapedia** (ANT-C) and **bithorax** (BX-C) gene complexes. The homeotic genes must be correctly expressed throughout embryonic, larval, and pupal development in order to instruct the cells within each body segment correctly as to their respective segmental identities. Misexpression of homeotic genes results in the inappropriate development of specific body parts in place of normal structures. For example, ectopic expression of the *Antennapedia* gene

in head cells causes legs to develop in place of antennae. Expression of homeotic genes during early embryogenesis is controlled initially by transcription factors that are encoded by the segmentation genes. However, the segmentation proteins are degraded shortly after the expression patterns of homeotic genes are established. From that point onward, continuing through larval and pupal development, PcG proteins are responsible for maintaining the silenced states of homeotic genes in cell lineages in which they are initially repressed by segmentation proteins. A second group of proteins, encoded by the **trithorax** group (trxG) genes, are required to maintain the fully active states of homeotic genes in those cell lineages in which they are meant to be expressed. It is generally believed that control of target gene expression by these opposing groups of proteins involves modification of chromatin structure.

All PcG proteins that have been studied sufficiently are nuclear proteins that bind to chromosomes in a DNA-sequence-dependent manner and are either largely or completely co-localized on polytene chromosomes. Multiple PcG proteins have been shown to **immunoprecipitate** together from fly embryo extracts, further demonstrating their *in vivo* association. Several have been shown to interact directly *in vitro* . Only one identified PcG protein possesses **DNA-binding** activity. Thus, the PcG proteins appear to function as components of multimeric protein complexes, and the association of most PcG proteins with target loci must be mediated by protein–protein interactions. The varied and pleiotropic **phenotypes** produced by most PcG mutations, however, and recent biochemical and immunoprecipitation studies collectively suggest that multiple PcG complexes composed of different combinations of proteins may exist at different loci *in vivo* (3-5).

PcG homologues have been identified in nematodes, vertebrates, and even plants. Molecular, biochemical, and genetic analyses of these **homologues** suggest that PcG-dependent silencing has been conserved throughout evolution across a wide **phylogenetic** spectrum.

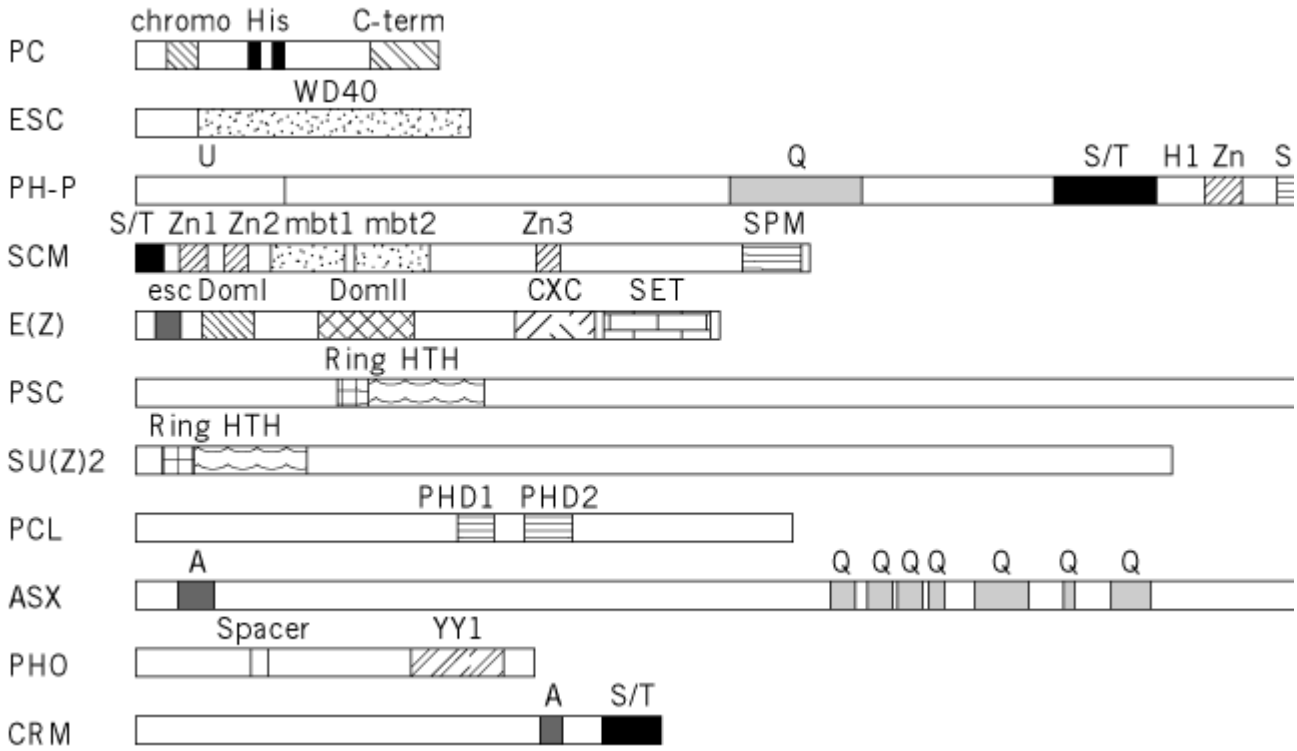
1. Members of the Polycomb group

This section includes a description of each individual *Drosophila* PcG gene, its protein product, and nonfly homologues (if identified).

1.1. Polycomb (Pc)

Mutant alleles of *Pc* were first identified on the basis of their dominant adult homeotic phenotypes, which were later found to be due to derepression of homeotic genes. For example, many *Pc* heterozygotes display partial transformation of second legs into first legs—that is, mesothoracic legs into prothoracic (6); this is caused by ectopic expression of the *Sex combs reduced* gene (of the ANT-C) during larval development (7). This is most easily apparent by the ectopic development of specialized bristles called sex combs, which normally are only found on the first legs of males, on the second legs. It is on the basis of this phenotype that *Pc*, and subsequently some of the other PcG genes, were named. Homozygous *Pc* mutants die as embryos and display posteriorly directed homeotic transformations of most body segments (8). The function of *Pc* in regulating homeotic genes is conserved in its mammalian homologue *M33*. Knockout mutations of *M33* causes posterior transformations of the axial skeleton of mouse embryos (9). Furthermore, expression of M33 in *Drosophila* partially rescues *Pc* mutant phenotypes, demonstrating conservation of the biochemical activity of PC, and probably that of other PcG proteins with which it interacts (10).

Figure 1. Diagrams of the primary structures of PcG proteins and likely domains identified by sequence analysis. PC: ch domain (chromo), His-rich region (His), conserved C-terminal region (C-term); ESC: WD40 repeats (WD40); PH-P: Un region not found in PH-D (U), Gln-rich region (Q), Ser/Thr-rich region (S/T), H1 domain, Zn finger (Zn), SPM domain (SCM: Ser/Thr-rich region (S/T), three Zn fingers (Zn1, Zn2, Zn3), mbt repeats (mbt1 and mbt2), SPM domain (SPM); E binding domain (esc), Domain I (DomI), Domain II (DomII), CXC domain (CXC), SET domain (SET); PSC and SU(Z) fingers (Ring), helix-turn-helix regions (HTH); PCL: two PHD fingers (PHD1 and PHD2); ASX: Ala-rich region (A), G regions (Q), Cys cluster (Cys); PHO: Spacer region of homology with YY1 (Spacer), Zn-finger-containing region with h to YY1 (YY1); CRM: Ala-rich region (A), Ser/Thr-rich region (S/T).



PC protein binds to about 100 euchromatin sites on polytene chromosomes, including the locations of known target genes, such as the ANT-C and BX-C (11, 12). This strongly suggests that the homeotic genes are only a few among the many genes that are regulated by PcG proteins. PC is 390 amino acid residues in length, with a predicted relative mass of 44 kDa, although it migrates at a higher molecular weight on SDS-PAGEgels, and it is composed of at least two functional **domains** . The N-terminal chromo domain is 58% identical to a 48-residue region of the heterochromatic *Drosophila* HP1 protein (13), which is involved in position-effect variegation (PEV) (14). The chromo domain is required for polytene chromosome binding by PC, whereas the evolutionarily conserved C-terminal domain is not (15). However, deletions of this region do alter the subnuclear distribution of PC in diploid embryonic nuclei, but not as dramatically as do mutations in the chromo domain. (16). A chimeric HP1-PC protein, in which the HP1 chromo domain is replaced by that of PC, binds to both heterochromatin and to the normal euchromatic PC sites, and it recruits other PcG proteins, including endogenous PC, polyhomeotic (PH), and Posterior sex combs (PSC), to heterochromatin (17). Consistent with these observations, biochemical studies suggest that the PC chromo domain is capable of forming multimers *in vitro* (18). Conflicting results have been reported, however, regarding the ability (or inability) of PC to self-associate (19, 20). The function of a histidine-rich region in the middle portion of PC has yet to be defined.

PC is a component of large (~2MDa) multiprotein complexes and co-fractionates with PH in *Drosophila* embryo extracts (21). *In vivo* association of PC and PH is confirmed by their co-immunoprecipitation and co-localization on polytene chromosomes (21). PC and PH both also co-immunoprecipitate with PSC (19). PC does not directly interact with PH, but it does bind PSC *in vitro* and in yeast **two-hybrid assays** . PSC binding does not require the PC chromo domain (19), but *in vivo* PC-PH complexes are disrupted by mutations in the chromo domain (4). *Xenopus* homologues of PC and PSC, XPC, and XBMI-1, respectively, interact directly, demonstrating evolutionary conservation of this relationship (20). Conservation of this multiprotein complex is further demonstrated by *in vivo* association of M33, BMI-1, MEL-18 [BMI-1 and MEL-18 are mouse homologues of PSC (22, 23)], and Rae28/MPH-1 [a mouse homologue of PH (24, 25)] (24).

1.2. extra sex combs (esc)

Unlike other members of the PcG, *esc* appears to be involved only in regulation of the homeotic genes and is primarily only required during embryogenesis, during the window of time when PcG-dependent silencing is established (26, 27). Therefore, it has been proposed that ESC protein may somehow recognize the repressed state of these target genes and, through interactions with other PcG proteins, contribute to the assembly of silencing complexes (26, 28, 29). The 425-residue ESC protein has a relative molecular mass of 48 kDa. Apart from a short N-terminal region that includes a **PEST sequence**, ESC is composed primarily of seven WD40 repeats (26, 28, 29), which are likely to fold into a b-propeller toroid protein structure (see Beta-Sheet) (30). The primary activity of WD40 repeat domains, which are found in a wide variety of proteins with unrelated biological functions, is to interact with other proteins (31). One ESC-binding partner is another PcG protein, Enhancer of zeste [E(Z)] (32). Evolutionarily conserved residues within two adjacent ESC loops that project above the toroidal plane are required for E(Z) binding *in vitro* and are essential for ESC activity *in vivo* (30, 32). The physical relationship between ESC and E(Z) is conserved in their mouse and human homologues (3, 5, 32). The mouse embryonic ectoderm development (EED) protein shares 55% amino acid identity with ESC, although their N-termini are not well conserved (33). Human and mouse EED are identical (32). Homozygous *eed* mutant mouse embryos display posteriorly directed homeotic transformations, which is consistent with conservation of *esc* function in mammals (33). The Caenorhabditis *elegans* maternal-effect sterile genes, *mes-2* and *mes-6*, are required to maintain germline-specific transcriptional silence (34) and are homologues of *E(z)* and *esc*, respectively (35, 36). No other PcG proteins have been identified in sequence database searches of the *C. elegans* genome (36). This suggests that the function of ESC–E(Z) complexes may be at least partially independent of other PcG proteins.

1.3. polyhomeotic (ph)

The *ph* locus is tandemly duplicated and composed of two transcription units with largely redundant functions (ph^P and ph^D). Homozygotes with mutations in either gene alone are viable. However, mutations that disrupt both ph^P and ph^D are embryonic lethal when homozygous and produce posteriorly directed homeotic transformations. Embryos that also lack maternally produced *ph* fail to develop beyond the blastoderm stage (37). ph^P and ph^D encode 167 kDa and 149 kDa proteins, respectively (38, 39). The PH^P protein contains 193 N-terminal residues that are not found in PH^D. Otherwise, the two proteins are extremely similar. Both contain glutamine repeats, a Ser/Thr-rich region, an unusual Cys_4 **zinc finger**like repeat, and two regions, H1 and SPM, that are highly conserved in Rae28/MPH1 protein, a mouse homologue (24, 25). The H1 region binds to PSC protein, which may account for the indirect association of PH and PC *in vivo* (19). Interaction of BMI-1 with the human homologues of PH, HPH1, and HPH2, demonstrates conservation of this relationship (40). The largely **alpha-helical** SPM domain, which is related to a more divergent motif called the SAM domain that is found in proteins with a wide variety of functions (41), is most similar to 60-residue regions of the fly Sex combs on midleg (SCM) PcG and the **tumor suppressor** l(3)mbt proteins (42). Both the PH and SCM SPM domains are capable of forming homodimers, as well as heterodimers, with each other (43). *In vivo* association of PH and SCM is demonstrated by their complete co-localization on polytene chromosomes.

1.4. Enhancer of zeste [E(z)]

In addition to its role in maintaining the silence of homeotic genes, *E(z)* is also involved in the repression of the *white* gene by *zeste* [1] (44-46). This latter function is shared by *Scm*, *Psc*, and *Suppressor 2 of zeste* [*Su(z)2*] (46). Complete lack of *E(z)* activity blocks cell proliferation (47, 48). Consistent with a role in general chromatin organization, 45 identified binding sites almost completely co-localize with those of other PcG proteins, plus low levels of E(Z) protein appear to be ubiquitously distributed along the euchromatic arms of polytene chromosomes (49). The 760-residue (87 kDa) E(Z) protein is composed of multiple functional domains. The 116-residue C-terminal SET domain is a region of homology shared by the fly trithorax (TRX) (50), SU(VAR)3-9 (a suppressor of PEV) (51), and trxG ASH1 proteins (52). Numerous other SET domain proteins have been identified in organisms ranging from yeast to humans (53, 54). The E(Z) SET domain has recently

been shown to bind mammalian myotubularin, a dual-specificity **phosphatase**, and the myotubularin-related protein Sbf, which functions as an antiphosphatase due to lack of phosphatase activity (55). Presumably, by tethering either phosphatase or antiphosphatase to target loci, one function of SET domain proteins, including E(Z), may be to modulate the state of phosphorylation of other chromatin proteins, and thus their activities. The E(Z) CXC domain is a **cysteine** -rich region that flanks the SET domain on the N-terminal side and is required for chromosome binding (49). Domains I and II are two evolutionarily conserved regions in the N-terminal half of E(Z), whose functions are yet to be defined (53). A 33-residue domain near the N-terminus binds ESC protein (32). E(Z) is required throughout development in order to maintain the silence of homeotic genes (45, 48, 56), whereas ESC is primarily only required during early embryogenesis (26, 27). Therefore, ESC-E(Z) complexes may contribute to the establishment of homeotic gene silencing, and E(Z) may play a transitional role in maintaining their permanent silenced states. *E(z)* is also involved in the regulation of a wide variety of genes independently of *esc* (46, 57, 58) and, indeed, also appears to contribute to trxG-dependent transcriptional activation during larval development (59). Since *esc* is only involved in the early silencing of homeotic genes, E(Z) must interact with proteins other than ESC at other target loci and at other developmental stages.

E(z) homologues have been identified in mice [Ezh1/Enx2 (53); Ezh2/Enx1 (60)], humans [EZH1/ENX2 (61); EZH2/ENX1 (53, 62, 63)], *C. elegans [mes-2* (35)], and Arabidopsis *thalania [curly leaf* (*clf*) (64) and *medea* (65)]. Most strikingly, like *E(z), Arabidopsis clf* is involved in maintaining, not initiating, the silenced state of a homeotic target gene. Thus, the function of E(Z) has been conserved across kingdoms.

1.5. Posterior sex combs (PSC)

Psc mutations produce dominant anterior transformations of adult legs and suppression of the *zeste* ^{1} eye color (46, 66). Homozygous *Psc* mutant embryos exhibit posteriorly directed homeotic transformations and ectopic expression of homeotic genes (1, 67, 68). Mouse homologues of *Psc* [and *Su(z)2*], *bmi-1*, and *mel-18* are a proto-**oncogene** and tumor suppressor gene, respectively (69-71). Knockout mutations of the mouse *bmi-1* or *mel-18* genes produce posteriorly directed homeotic transformations of the axial skeleton and ectopic expression of homeotic genes (72, 73). These mutants also exhibit defects in T- and B-lymphocyte development, in addition to a variety of other maladies. Overexpression of *bmi-1* in transgenic mice produces opposite, anteriorly directed transformations (74).

PSC protein is 1603 residues in length, with a relative mass of 170 kDa (22). It contains an ~200-residue region (the HR domain) with 37.4% identity to a similar region in the SU(Z)2 protein. The HR domain includes a Cys_3–His–Cys_4 RING finger, followed by a **helix-turn-helix** (HTH) motif, which binds to the H1 domain of PH protein (19). The HTH and RING finger regions bind to PC protein (19). PSC is largely, but not completely, co-localized with PC and PH on polytene chromosomes (75, 76), which is consistent with both their *in vivo* association and the involvement of PSC in regulation of genes independently of PC and PH. The BMI-1 RING finger is required for subnuclear localization (24). Although the MEL-18 RING finger is able to bind DNA (77), this activity has not been demonstrated for PSC.

1.6. Polycomblike (Pcl)

Originally identified as a dominant enhancer of *Pc* (78), homozygosity for *Pcl* alleles results in embryonic lethality and moderate posteriorly directed homeotic transformations (1). *Pcl* encodes an 857-residue protein that is ubiquitously expressed in embryonic nuclei and completely co-localized with PC on polytene chromosomes (12). The sequence of PCL is unique, with the exception of two adjacent PHD fingers near the middle of the protein. The PHD finger motif has a Cys_4–His–Cys_3 pattern and spans approximately 50 to 80 amino acid residues (79). Interestingly, three other *Drosophila* PHD finger-containing proteins are members of trxG: TRX, ASH1, and ASH2. Thus, although the function of PHD fingers has yet to be elucidated, this suggests that these trxG proteins and PCL may possess common biochemical activities. For example, if the PHD finger is a protein–

protein interaction motif, this shared domain may permit interaction with a common binding partner.

1.7. Sex combs on midleg (Scm)
Individuals that are homozygous for **null** *Scm* **alleles** die as embryos and display mild posteriorly directed homeotic transformations (1) and ectopic expression of abd-A (42). The 877-residue SCM protein, which completely co-localizes with PH on polytene chromosomes, contains several motifs shared by PH, Rae28/MPH1, and l(3)mbt (42). In addition to the SPM dimerization domain, SCM contains two Cys $_2$–Cys$_2$ zinc fingers that have spacing unlike other Zn fingers [PH, Rae28/MPH1, and l(3)mbt each contain a single copy of similar zinc fingers], and two copies of ~100-residue repeat, three of which are present in l(3)mbt but absent from PH and Rae28/MPH1. The null or strongly hypomorphic *Scm*^{XF24} allele contains a deletion of most of the C-terminal SPM domain, demonstrating the importance of this domain for SCM function (42).

1.8. Additional sex combs (Asx)
Mutant *Asx* alleles were initially identified on the basis of their PcG-like embryonic homeotic phenotypes (1). *Asx* alleles also increase the severity of homeotic transformations produced by *trx* mutant alleles (80). In addition, *Asx* is a dominant enhancer of PEV, which is more typical of trxG genes (81). Therefore, like E(Z), ASX protein may be involved in both PcG-dependent silencing and trxG-dependent activation. *Asx* encodes a novel 1668-residue protein with a relative mass of 182 kDa (80). Noted features include two alanine-rich regions near the N-terminus, multiple glutamine repeats, and a cysteine cluster near the C-terminus with an unusual spacing of Cys residues. ASX binds to about 90 sites on polytene chromosomes; 70% of these overlap with PC, PH, and PSC binding sites, while 30% are unique. This reinforces the idea that, although ASX is required for PcG-dependent silencing of many target genes, including the homeotic genes, it may function independently of PcG proteins at many others.

1.9. pleiohomeotic (pho)
Individuals that are homozygous for *pho* null alleles die during pupal development. Those reaching pharate adult stage display posteriorly directed transformations of legs and partial antenna to leg transformations, characteristic of PcG mutations (82, 83). Lack of maternally produced *pho* results in embryonic lethality and severe defects (84). *pho* encodes the *Drosophila* homologue of the mammalian transcription factor YY1, which is a DNA-binding zinc-finger transcription factor (85). Binding sites for the PHO protein (520 residues in length) have been identified in multiple Polycomb-response elements (PREs), including each of the BX-C PREs, an *Scr* PRE, and the ***engrailed*** *cis*-regulatory region (85, 86), which is also regulated by the PcG (57). Thus far, PHO is the only PcG protein shown to possess sequence-specific DNA-binding activity. Therefore, PHO may play a central role in assembling PcG protein complexes at PREs.

1.10. cramped (crm)
Males that are **hemizygous** for mutant alleles of the X-linked *crm* locus exhibit proximodistal transformations of leg segments, in addition to anterior transformations of legs that are typical of PcG mutations (87). These mutant phenotypes are enhanced by mutations in *Pc* and *mus209*, which encodes proliferating cell nuclear antigen (PCNA) (88). PCNA is essential for DNA replication, suggesting a possible connection between PcG-dependent silencing and DNA replication. Both *crm*^{sa} and *mus209*^{B1} also suppress PEV (88, 89). *crm* encodes a novel 693-residue protein with a relative mass of 75 kDa (88). It contains one alanine-rich region and a serine/threonine-rich region near the C-terminus. CRM is a nuclear protein that is ubiquitously expressed and associated with embryonic diploid chromosomes during interphase, but not during mitosis. CRM and PCNA appear to be co-localized in both embryonic and polytene nuclei, and both display subnuclear patterns different from those of PC.

1.11. multi sex combs (mxc)
Adult viable and pupal lethal alleles produce homeotic phenotypes typical of other PcG mutations. Careful analysis of recessive lethal alleles has also revealed a tumor suppressor function (90). In

addition, lack of *mxc* activity specifically blocks cell proliferation in the germline (91). Cloning of the mxc gene has not been reported.

1.12. Sex combs extra (Sce)
Sce homozygotes derived from heterozygous mothers die as first instar larvae, with weak posteriorly directed homeotic transformations. *Sce* homozygotes derived from *Sce* mutant female germlines display extreme homeotic transformations (84). *Sce*'s identity as a PcG gene is further supported by genetic interactions with other PcG mutations (67, 92). Cloning of the *Sce* gene has not been reported.

1.13. super sex combs (sxc)
Putative null *sxc* homozygotes die as pharate adults and display homeotic transformations. Absence of maternal and zygotic expression results in embryonic lethality and mild posteriorly directed homeotic transformations (93). Cloning of the *sxc* gene has not yet been reported.

1.14. Enhancer of Polycomb [E(Pc)]
Mutant *E(Pc)* alleles do not by themselves produce homeotic phenotypes, making it questionable whether to categorize *E(Pc)* as a PcG gene. They do, however, enhance the severity of phenotypes produced by other PcG mutations (94, 95). Therefore, it is likely that E(PC) protein contributes some biochemical activity that is associated with PcG-dependent silencing. Unlike most PcG genes, *E(Pc)* is also a suppressor of PEV, suggesting that it may provide a connection between these two groups of proteins that are involved in chromatin-mediated transcriptional regulation (81). Cloning of the *E (Pc)* gene has not yet been reported.

1.15. Suppressor 2 of zeste [Su(z)2]
Like *E(Pc), Su(z)2* alleles do not by themselves produce homeotic phenotypes. Mild interactions have been observed between *Su(z)2* alleles and a few PcG loci. For example, the recessive embryonic lethality of *Su(z)2* null alleles is partially suppressed by *pho* alleles, and dominant gain-of-function *Su(z)2* phenotypes are partially suppressed by *Sce* (96). SU(Z)2 protein binds to many of the same polytene chromosome sites as other PcG proteins (76). This observation, in addition to the presence of the HR domain that it shares with PSC, suggests that SU(Z)2 probably contributes to a similar aspect of chromatin-mediated transcriptional regulation but may not be involved in regulation of some PcG target genes, such as the homeotic genes. The *Su(z)2* gene is located adjacent to the *Psc* gene. The RING finger-containing HR domain of SU(Z)2, which is conserved in PSC and homologous proteins from other organisms, is responsible for locus-specific polytene chromosome binding (97).

2. Mechanisms of PcG-dependent silencing

PcG-dependent silencing requires the presence of DNA sequences that are referred to as Polycomb-response elements (PREs) (98), which are distinct from both promoters and enhancers of target genes and can control their activities over distances of 20 to 30 kbp. When placed within P element transgenes, PREs convey PcG-dependent silencing upon reporter genes (98) and create new PcG protein binding sites at their sites of insertion (99). Such studies have narrowed the sizes of PREs to a few hundred bp; however, it is likely that additional weak PREs are located close to the primary PREs, since larger PRE-containing fragments exhibit more consistent silencing and PcG protein binding (100). Comparison of the sequences of different PREs has revealed little concerning their mechanism of action. PREs contain binding sites for GAGA factor (101), the product of the trxG *Trithorax-like* gene (102), suggesting that GAGA factor chromatin remodeling activity may contribute to both trxG-dependent activation and PcG-dependent silencing. However, GAGA alone cannot be responsible for PRE activity, since GAGA binding sites are present at many genomic locations that do not function as PREs. Recently, binding sites for the PcG PHO protein have been identified in multiple PREs (86), suggesting a central role for PHO in PcG complex assembly.

Although we are beginning to learn more about the activities of individual PcG proteins, and it

appears that they function as components of multimeric protein complexes and require the presence of a PRE in order to silence a target gene, a great deal about PcG-dependent silencing remains mysterious. What is unknown or unclear may be broken down into three major questions.

2.1. 1. How do PcG proteins recognize the repressed state of target genes?

Most PcG proteins are ubiquitously distributed, at least in embryos, yet they only silence target genes in those cell lineages in which the genes are initially repressed by gene specific transcription factors, such as the products of segmentation genes. So far, there is no solid evidence indicating how this may happen. It is possible that one or more PcG proteins may interact with a repressor, such as HB or Kruppel (KR), leading to the recruitment of additional PcG proteins, but no such interaction has yet been detected. Alternatively, one or more PcG proteins may somehow recognize the repressed conformation of target genes (103). Such distinguishing features could include (1) lack of enhancer-promoter loop formation; (2) repressor-dependent availability of PcG binding site(s), or that of a protein that assists in the assembly of PcG silencing complexes; or (3) some other characteristic of repressed chromatin that distinguishes inactive from active genes. Whatever the mechanism, it may only be possible to establish PcG silencing *de novo* during embryogenesis. Reporter genes within a P element that also contains a GAL4 upstream activating sequence and a PRE from the BX-C exhibit PcG-dependent silencing. If a pulse of GAL4 is expressed from a second transgene during larval development, this silencing can be overridden, but only transiently. If, however, the pulse of GAL4 expression occurs in embryos, activation is maintained throughout development (104). Therefore, some protein or activity that is necessary for establishment of PcG silencing must exist in embryos and not in larvae. One PcG protein that fits this description is ESC, which is only required during embryogenesis. Given the specificity of *esc* for homeotic gene repression, however, other protein(s) would be needed to provide that function at other PcG target genes.

2.2. 2. What is the mechanism of PcG-dependent silencing?

Several alternative models for PcG-dependent silencing have been proposed. They fall into three general categories.

2.2.1. Chromatin accessibility models

The basic idea of chromatin accessibility models is that PcG proteins modify the chromatin structure of target genes in some way that sterically blocks activators from binding to their DNA targets in enhancer and/or promoter regions. On the basis of the shared presence of the chromo domain in PC and in the heterochromatic HP1, which is involved in PEV, it was first proposed that PcG complexes fold target genes into compacted heterochromatin-like states (13). PEV is another example of transcriptional silencing, which results when a normally euchromatic gene is juxtaposed with heterochromatin (105). Expression of that gene in some cell lineages, and its repression in others, may depend on whether it is packaged into a condensed heterochromatic state. Additional sequence motifs, such as the SET domain, subsequently have been identified that are shared by PcG/trxG and heterochromatic proteins that are involved in PEV (50-52). Therefore, it is likely that there exist some mechanistic similarities between heterochromatin and PcG complexes, at least at the level of the biochemical activities of individual proteins. PcG-dependent silencing shares some phenomenological similarities with PEV. For example, within P element constructs, PREs convey variegated expression patterns of the *white* reporter gene that are reminiscent of PEV repression of the $white^{mottled4}$ allele (106, 107). Zink and Paro (108) have provided evidence suggesting that such variegated expression results from competition for target-site binding by PcG proteins and activators, and that binding of PC or an activator (in this specific study, GAL4) to a target gene is mutually exclusive. *In vivo* **cross-linking** studies originally suggested that PcG proteins coat target genes, such as the BX-C, supporting the heterochromatin-like model (109). However, refined experimental techniques now suggest that they are limited to PRE-containing regions and that different combinations of proteins may associate with different sites (4).

Selective exclusion is a variation of the chromatin accessibility model, in which PcG complexes may screen proteins on the basis of size, shape, or some other quality. For example, the PcG is able to

block GAL4-activated transcription of a reporter gene by **RNA polymerase** II in *Drosophila* embryos, but cannot block transcription by T7 RNA polymerase (110). McCall and Bender (110) have proposed several alternative mechanisms of selective exclusion that might explain these observations. The PcG may modify the distribution or structure of **nucleosomes** in some way [e.g., by causing the deacetylation of core histones (111)] that inhibits DNA binding by some proteins, but not others. Alternatively, PcG complexes may themselves directly exclude binding by some other proteins on the basis of size or shape. Or PcG proteins could interact directly with and inhibit binding by specific proteins that are required for transcription by RNA polymerase II (e.g., activators, basal transcription factors, or accessory proteins such as the SWI/SNF complex). The distinguishing feature of all these variations of the selective exclusion model is that they propose relatively subtle modifications of chromatin structure compared to the heterochromatin model.

2.2.2. Enhancer interference model

It has been proposed that the PcG does not necessarily prevent transcription factors from binding to target genes but prevents them from activating transcription (112, 113). This could involve blocking enhancer-promoter loop formation or in some other way preventing activators from interacting with the basal transcription machinery. In support of this model, PcG proteins that are tethered to reporter plasmids in mammalian tissue culture cells have been shown to repress transcriptional activation in transient expression assays (112). This ability to repress varies with transcription factors that have different activation domains, suggesting an effect on activation but not access. These observations are also consistent with some versions of the selective exclusion model, in that the effects on different activators may be due to the exclusion of different accessory proteins that may be required for activation by some, but not other, transcription factors. The ability of the PcG to block GAL4-activated transcription by RNA polymerase II, but not transcription by T7 RNA polymerase (110), may also be explained by enhancer interference. In this scenario, the PcG might not prevent GAL4 from binding to DNA but might block its interaction with basal transcription factors or accessory proteins that are needed for RNA polymerase II transcription. This interpretation, however, would be in conflict with the mutually exclusive binding of PC and GAL4 to polytene chromosomes (108).

2.2.3. Subnuclear compartmentalization

It has been suggested that PcG-dependent silencing may sequester target genes in transcriptionally inert nuclear compartments (114). This model is supported by two lines of observations. First, in restriction enzyme digestions of intact chromatin, PcG-dependent silencing does not have a detectable effect on access of the enzymes to recognition sites located within target genes (114). The second comes from analogy to PEV, in which silenced genes are associated with centromeric heterochromatin (115, 116). However, intranuclear distribution of PcG proteins does not correlate with high concentrations of DNA, demonstrating that silenced genes are not sequestered to heterochromatic regions (117). In addition, in some cells, one adjacent gene may be active, the other silent. Therefore, sequestering, if it occurs, must be on a microcompartmental level.

2.3. 3. How is the silenced state propagated through the cell cycle?

Once the silenced state of target genes is established during embryogenesis, it must be maintained through many cycles of cell division. This requires the continuous activity of all PcG proteins, with the exception of ESC, and continued presence of a PRE. Excision of a PRE results in loss of silencing, demonstrating that protein–protein interactions and/or chromatin modification alone are not sufficient to propagate the silenced state (118). Maintenance is particularly perplexing in light of recent observations that PC, PH, and PSC dissociate from chromatin during mitosis (117). It is not known if all PcG proteins behave in a similar manner, or if residual levels of one or more PcG protein remain associated with silenced loci. Should any PcG protein(s) not dissociate from chromatin during mitosis, it might provide nucleation sites for the reformation of silencing complexes. Given the DNA-binding activity of PHO and the presence of PHO binding sites in all of the major BX-C PREs, PHO may bind PREs (either remain bound throughout mitosis or rebind following telophase) and, through protein–protein interactions, direct the binding of other PcG proteins. This would be consistent with the continued requirement of PREs to maintain silencing. If PHO, or some other PcG protein, remains bound to PREs through mitosis, this may be sufficient to

reassemble silencing complexes at the correct loci. If, however, a protein such as PHO dissociates from DNA during mitosis, some other mechanism must distinguish silenced from active PcG target genes. This could involve chromatin modification. For example, histone deacetylation could mark the chromatin of silenced genes. In this model, a combination of PHO binding sites and local chromatin modification might be sufficient for PcG complex reassembly.

A remarkable feature of the aforementioned GAL4 activation of a PRE-containing transgene is the transmission of the active state to a fraction of the progeny of the treated individual (104). Thus, the GAL4-induced derepressed state may be propagated through meiosis, fertilization, and many additional mitotic divisions during development. Two alternative explanations have been proposed. The active state may be maintained by trxG proteins (104). Alternatively, this may reflect disruption of the normally silent state of germline chromatin by the pulse of GAL4 expression in germline as well as somatic cells, which would then permit the zygote to receive the transgene in the exceptional depressed state (104, 111).

3. Nonhomeotic functions of PcG proteins

Drosophila PcG proteins are involved in the regulation of many genes other than the homeotic genes, although these interactions are not as well characterized. Mammalian PcG proteins are required for proliferation and activation of **hematopoietic** cells (9, 73, 119, 120). A plant homologue of E(Z) (*medea*) restricts cell proliferation during embryogenesis (65), and worm homologues of E (Z) and ESC are involved in germline-specific silencing (35, 36). Thus, PcG proteins appear to perform an evolutionarily ancient transcriptional silencing function that has been adapted for the regulation of different genes and/or other developmental purposes in phylogenetically dispersed organisms.

Polyglycine

Polyglycine is the name given to the polyamino acid formed from glycine. Like proteins, the polyglycine polymer is formed by condensation of the amino group of one amino acid and the carboxyl group of another amino acid. On the other hand, proteins have a defined and complex sequence that includes all 20 of the amino acids, but polyglycine is a homopolymer formed only from glycine residues.

Glycine is the simplest amino acid residue, having a hydrogen atom as its side chain. Furthermore, unlike the other amino acids, glycine is not **enantiomeric**. The relatively small size of the glycine side chain confers greater conformational flexibility to the polyglycine backbone compared with the backbone of other amino acid polymers. The polyglycine backbone adopts primarily two **conformations**, called poly(Gly) I and poly(Gly) II. Poly(Gly) I is an antiparallel rippled (rather than pleated) **b-sheet** (1). Poly(Gly) II is a helical conformation with three residues per turn and no intrachain hydrogen bonds (2) and is similar to the poly(Pro) II conformation of polyproline . The backbone of collagen, a structural protein that has a distinctive repeating unit in its **polypeptide** sequence corresponding to Gly–X–Y, where X is often proline, adopts a conformation like that of poly(Gly) II or poly(Pro) II.

Polyglycine may also represent an unusual post-translational modification; up to 34 glycyl units have been observed covalently bound to the g-carboxyl group of *C*-terminal **glutamic acid residues** in tubulin (3).

Polylinker

A polylinker is a short **DNA** sequence containing two or more different sites for cleavage by restriction enzymes. Polylinkers are introduced into **vectors** to make cloning easier by providing

sites that allow cloning DNA, cut with any of a number of different restriction enzymes, into a single **plasmid**. They are useful for cloning a DNA fragment that has a different **cohesive end** at each end (ie, was produced by cutting out a DNA fragment from a molecule with two different restriction enzymes). When a plasmid cut with two different enzymes is **ligated** to a DNA fragment containing the two cohesive ends present in the plasmid and then the ligation mixture is **transformed** into **bacteria**, most of the transformants contain the desired recombinant plasmid in which one molecule of the fragment is precisely oriented in the plasmid. In contrast, when a DNA fragment is cloned into a plasmid cut with a single enzyme, so that both cohesive ends are the same, it recircularizes, and this produces a high background of transformants lacking an insert. This background is not present when the two ends of the fragment are different. Furthermore, the insert has a single orientation, whereas a fragment with identical cohesive ends inserts in either orientation with equal probability. Pairs of polylinkers are available that have the same set of sites, but in opposite orientation, to allow cloning the fragments in either orientation (i.e., pUC11 and pUC12). Polylinkers became somewhat less important once **PCR** became available because it is possible to introduce any desired restriction site into the PCR product by designing primers that incorporate the desired restriction sites.

Polymer

A polymer is a large molecule, or macromolecule, composed of many copies of repeating units joined together to form a long chain. Polymers can incorporate many thousands of atoms and have extremely high molecular weights. Such large molecules are ubiquitous in nature, and many are essential for life. Naturally occurring polymers include wool, cotton, wood, silk, and rubber. Of particular interest to the molecular biologist are **biopolymers** such as proteins, **nucleic acids**, and carbohydrates. A diverse range of man-made polymers has been developed, including plastics, synthetic fibers, and paints.

The long chain, or backbone, is the constant or repeating part of the polymer (Fig. 1). The side chains, or functional groups, attached to the backbone can be variable. Homopolymers are polymers in which the repeating units are chemically and stereochemically identical. Both the backbone and side chains of homopolymers are constant throughout the length of the polymer. **Polyethylene glycol** and polyacrylamide are homopolymers commonly used in molecular biology. The repeating monomer units of these two reagents are ethylene glycol and acrylamide, respectively.

Figure 1. Schematic representation of a polymer, showing the repeating nature of the backbone (X). The side chains (Y) connected to the backbone are constant in homopolymers but variable in copolymers.

Heteropolymers, or copolymers, are formed from two or more kinds of monomer unit. The arrangement or order of the repeating units in copolymers can be either sequential or random. Proteins and nucleic acids are examples of biological copolymers (**biopolymers**) that have a specific sequence. The repeating units of proteins are the 20 different naturally occurring amino acids, and the repeating units of nucleic acids are the nucleotides.

Polymerase Chain Reaction

The polymerase chain reaction (PCR) was originally described in 1986 (1) and since then has become one of the most frequently used and widely applied techniques in molecular biology. In its simplest form, two oligodeoxyribonucleotides (oligos) are used to select a specific target sequence from a mixture of **DNA** molecules and to act as primers for DNA extension using the target DNA as template . Multiple rounds of template **denaturation**, primer **annealing**, and extension by **DNA polymerase** result in specific amplification of the target sequence. Because PCR is sufficiently sensitive to detect and amplify even one molecule of target DNA from a complex mixture of DNA molecules, it has proved a useful technique in many diverse fields. Various improvements and numerous variations on the original technique have enabled PCR to be used for a wide variety of applications, including cloning known and unknown sequences of DNA, genome and **genetic mapping**, **gene expression** studies, diagnostic purposes, analysis of ancient DNA, **sequencing**, and **mutational** analysis. The following is a survey of many of the common PCR techniques and applications.

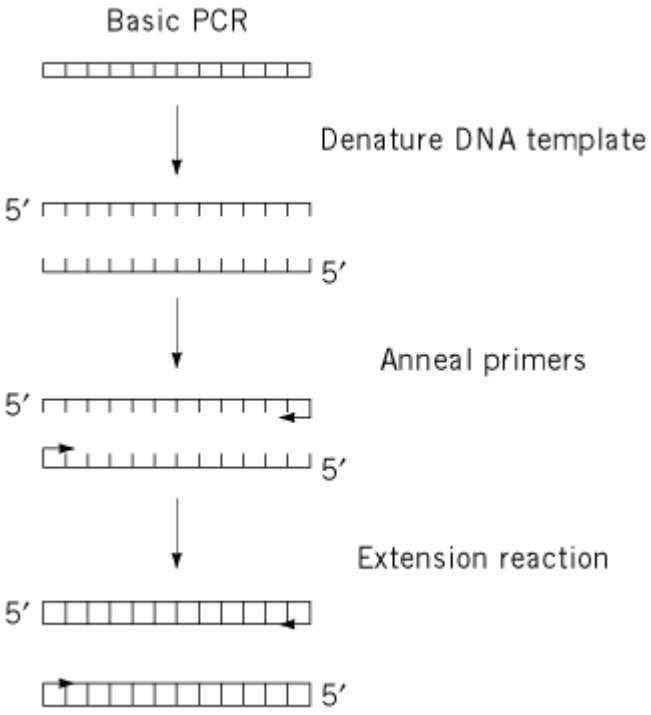
1. The Standard PCR Technique

In the standard PCR technique (Fig. 1), two oligos are designed to be complementary to the end sequences of the DNA to be amplified (the target sequence, or amplicon). These oligos, or PCR "primers," are complementary to opposite strands of the double-stranded DNA and are generally 15 to 25 nucleotides in length. DNA synthesis primed from the two oligos results in selective amplification of the complementary strands of DNA contained between the two primers. Amplification occurs during repetitive cycles of synthesis that repeat the following three steps: (1) denaturation of the double-stranded DNA template; (2) annealing of the two primers to the single-stranded template; and (3) extension of the primers by a thermostable DNA polymerase. In theory, every cycle doubles the number of target sequences, although in practice PCR is not quite that efficient. The reaction mix includes the following: the DNA sample, two primers that "select" DNA to be amplified; the thermostable DNA polymerase to extend the primers; an excess of the four deoxynucleotides A, T, G, and C needed for DNA synthesis; and generally 10 m *M* Tris-HCl buffer, 50 m*M* KCl to provide the proper ionic strength, and Mg^{2+} as a cofactor (optimal Mg^{2+} concentrations may need to be determined for each reaction). Each step in the cycle is performed at a different temperature, and PCR machines are available to perform the temperature cycling automatically. Denaturation occurs at 94 to 96°C, and extension by polymerase is generally at 72°C. The temperature of the second step, primer annealing, is crucial and depends on the sequence of the primers, the concentration of the components of the PCR mix and the salt concentration. If the temperature is too high, not enough of the primers anneal to template DNA to have an efficient PCR, but a low annealing temperature allows nonspecific priming and results in spurious amplification products. The $T_{\mathbf{m}}$ (temperature when half the molecules are double-stranded and half are single-stranded) is often used for the annealing temperature and then adjusted up or down if necessary. If

the primer is 18 bases long or less, the T_m can be estimated by the following formula:

$$T_m = 4°C(\text{number of GC base pairs}) + 2°C(\text{number of AT pairs})$$

Figure 1. Basic PCR. The polymerase chain reaction uses multiple rounds of DNA denaturation, primer annealing, and primer extension to amplify a specific target sequence. First, double-stranded template DNA is denatured by brief incubation at 95°C. Secondly, primers that select the target sequence are annealed to single-stranded template DNA at a temperature determined by the length and sequence of the primers. Finally, the temperatre is raised to 72°C to permit primer extension by a thermostable DNA polymerase, thus producing double-stranded target sequence. Each cycle of PCR repeats the same three steps, using the newly synthesized target DNA as additional PCR template. Thus, each round of PCR theoretically doubles the previous number of target sequences. Millions of copies of the target sequence are synthesized after multiple rounds of PCR. Horizontal arrows represent PCR primers. Double-stranded DNA is represented by horizontal lines joined by short vertical lines. The vertical lines represent the Watson–Crick base pairs.



1.1. Template

Standard PCR can be performed on any single-stranded or double-stranded DNA starting material: **genomic** DNA, **viral** DNA, cloned sequences, crude cell lysates, or ancient DNA, for example. Because the target sequence is amplified, only small amounts of starting material are needed (the amounts can vary from as little as a single molecule up to nanogram amounts of cloned DNA or microgram amounts of genomic DNA). Because of the sensitivity of PCR, even a small amount of contaminating DNA is amplified if it is complementary to the PCR primers. Therefore, it is important to perform proper controls and to use special precautions when contamination can interfere with interpretation of the data (see **Analysis of ancient DNA** below).

The DNA polymerase used in PCR is specific for DNA, but it is possible to analyze messenger RNA using PCR methods by incorporating a **reverse transcriptase** (RT) step to convert mRNA into double-stranded complementary DNA, known as RT-PCR. The reverse transcription and PCR can be performed by a single enzyme, r*Tth*, because it has both RT and polymerase activities.

1.2. Primers

There are various considerations when designing PCR primers. Although the 3′ end of the primer, especially the final two bases, is important for specificity and should be complementary to the target sequence, it is possible to attach noncomplementary sequences to the 5′ end, for example, restriction enzyme sites (to facilitate cloning of PCR amplicons) or **promoters**. GC pairs are more stable than AT pairs (GC pairs have three hydrogen bonds and AT pairs have two), and it is preferable to have either G's or C's at the 3′ end of the primer and an overall GC content of 45 to 55%. Computer programs are available to help design the most efficient PCR primers for known sequences. Ideally the T_m of both primers should be the same within 1 to 2°C so that they both anneal specifically at the same annealing temperature. To prevent primer–primer binding and a decrease in efficiency of the amplification, primers must not be complementary to themselves or to each other.

Nested primers are used to increase the specificity of the reaction and to obtain larger amounts of amplified DNA. A second PCR is carried out using two "nested" primers that are complementary to sequences located 3′ to the original primers, within the amplified DNA. The nested primers are used to reamplify a product, using a small amount of DNA from the original PCR product as a template.

For some experiments, it is necessary or more efficient to amplify a number of different products simultaneously in a single reaction, using different primers. This is termed *multiplex* PCR. For multiplex PCR, it is important to optimize primer choice and reaction conditions to eliminate spurious amplification products.

1.3. Polymerase

Various thermostable DNA polymerases are available that withstand the repeated high temperatures used for the denaturation step. *Thermus aquaticus* DNA polymerase (Taq) is commonly used and, although it has a low error rate, it is sufficiently accurate for most applications. If accuracy is crucial to the experiment, it may be necessary to use a polymerase having an inherent 3 ′-5′ exonuclease ("proofreading") activity, such as *vent* polymerase (2). For amplifying targets longer than 10 kb, extralong PCR (XL PCR) conditions must be used, and it is important to use a polymerase that has proofreading activity, because it is thought that errors result in termination of synthesis (3).

2. Cloning PCR Products

Taq polymerase frequently adds a single adenosine nucleotide to the 3′ end of double-stranded DNA, thus making the products of a PCR reaction unclonable because of their "ragged" ends. These ends can be **filled-in** with T4 DNA polymerase and then **blunt-end ligated** into a vector. Alternatively, it is possible to clone the PCR products directly into special vectors having 3′ T overhangs flanking the insertion site. A third possibility is to incorporate a restriction site into the primers that then is cut to yield **cohesive ends** for cloning.

3. Applications of the Polymerase Chain Reaction

3.1. Amplification of DNA: Cloning Substrate or Diagnostic Tool

PCR is useful because it allows identifying and isolating one or a few copies of a specific target sequence from a complex background. This permits rapid cloning of known sequences without the preparation of a **library** for gene isolation. PCR is also useful for screening for the presence of pathogens, even when only a small amount of sequence information is available for the pathogen (4). Production of amplified product using pathogen- specific primers signals the presence of the pathogen in the sample.

3.2. Manipulation of DNA

Because PCR primers can be designed to have a restriction site incorporated at the 5′ end, it is possible to use PCR to amplify entire genes or portions of genes for **genetic engineering** purposes. This is helpful when restriction sites in the sequence of interest are too frequent or limiting and DNA must be moved from one vector to another or DNA sequences must be deleted or juxtaposed.

3.3. Gene Cloning with Degenerate Primers

PCR is used to clone genes even when the exact sequence of the gene of interest is not known, for example, when a gene sequence has been determined by reverse translation of a protein sequence. In this case, a mixture of oligos (a degenerate primer) is used that represents all of the possible coding sequences. Then the resulting amplified DNA is labeled and used as a **hybridization** probe for screening a cDNA library to isolate the actual coding sequence.

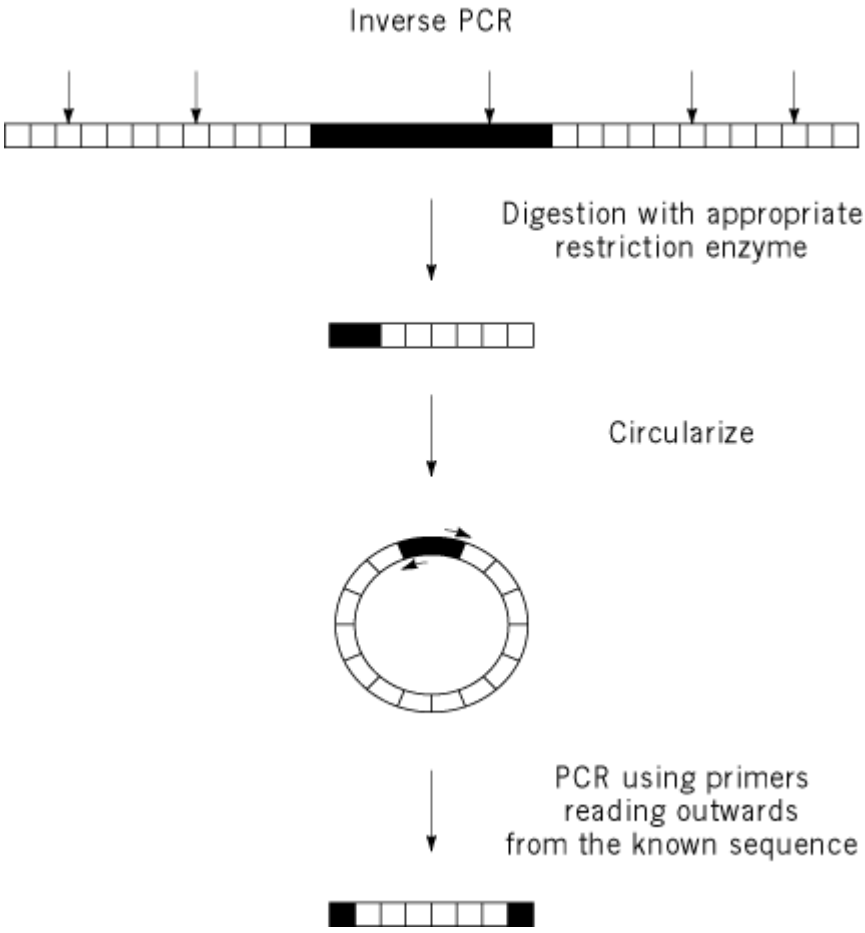
3.4. Recombination and Site-Directed Mutagenesis

Linear DNA molecules having homologous ends recombine *in vivo* in *Escherichia coli*, and two linear products that recombine to form a circle containing an **origin of replication** and a selectable marker are used to **transform** *E. coli*. Primers with appropriately homologous 5′ ends are used to amplify the DNA sequence of interest from a plasmid or a genome and to amplify a cloning vector. If the linear molecules are used to transform *E. coli*, recombination between the two molecules results in the DNA being inserted into the vector (5). Specific mutations are introduced into insert DNA sequences by using mismatched primers to amplify the sequence of interest, but this method is useful only for creating mutations at the ends of sequences. Other methods have been developed to create mutations elsewhere in the amplified DNA, for example, mutagenesis by overlap extension (6). First, the DNA sequence of interest is amplified as two separate but overlapping fragments by using two different sets of primers. The region of overlap includes a mismatch contained in both of the two overlapping (but oppositely oriented) central primers. Then the two PCR products are mixed, denatured, and reannealed. The annealed products that have their overlap at the 3′ end of each molecule act as primers extending each other to produce the full-length target DNA containing the new mutation. Using this method, a mutation is engineered anywhere in the target DNA.

3.5. Cloning Unknown Flanking Sequences: I-PCR and RACE

Inverse-PCR (IPCR) is often used to clone unknown DNA that flanks known sequences, such as DNA adjacent to **yeast artificial chromosome** (YAC) ends or the DNA flanking a transposon insertion (see Transposon Tagging). The starting DNA is digested with a restriction enzyme that cuts near the end of the known sequences and also at an undefined site in the flanking DNA (Fig. 2). Ligation is performed under conditions that encourage intramolecular events, so that a circular DNA molecule is formed containing a small amount of known DNA adjacent to a small amount of unknown DNA. Two PCR primers are designed to prime outward from the ends of the known DNA, so that the unknown DNA between them is amplified and then can be cloned and used in further studies.

Figure 2. Inverse PCR. Inverse PCR is used to clone unknown DNA flanking known DNA, for example, genomic DNA flanking a transpoon insertion. Total genomic DNA is isolated and digested with a restriction enzyme that releases a small piece of one transposon end and which cuts fairly frequently in the genomic DNA. Restriction enzyme digestion results in a DNA fragment containing the transposon end joined to a small piece of flanking DNA. The digested DNA is ligated under conditions that favor self-ligation, resulting in the formation of circular molecules. PCR is carried out using primers that read outward from the known transposon sequence into the unknown flanking DNA. Multiple rounds of PCR result in specific amplification of the unknown genomic DNA flanking the transposon. Vertical arrows represent restriction enzyme cleavage sites in the genomic DNA and the inserted transposon. The solid black rectangle represents the transposon insertion sequence. Horizontal lines joined by short vertical lines represent double-stranded genomic DNA. Horizontal arrows represent transposon-specific PCR primers.



The *rapid amplification of cDNA ends* (RACE) procedure is a method for obtaining full-length cDNAs from a known partial cDNA sequence, and it is used to obtain either the 3′- or 5′-ends of cDNAs. For isolation of 3′-ends, mRNA is reverse translated into cDNA using a primer (the RT primer) consisting of oligo(dT) followed by a unique sequence. Then PCR amplification is carried out using a primer specific to the known sequence and a primer (Primer U) specific to the unique sequence of the RT primer. Then nested PCR is performed to improve specificity. To clone 5′ ends, reverse translation is carried out using a primer (Primer K) specific to the known cDNA sequence, reading toward the 5′ end. A poly A tail is appended to the first strand cDNA, and the RT primer utilized for 3′ RACE is used to synthesize the second strand of cDNA. Then PCR amplification is carried out using a gene-specific primer upstream of Primer K in conjunction with Primer U. Again this amplification is followed by nested PCR. 5′- and 3′-RACE are used to isolate full-length cDNAs in a few days, compared to the weeks needed to screen cDNA libraries and analyze library clones. This is done by coamplifying the target with an internal control and then comparing the ratio of target to control. The control is either an endogenous or exogenous gene or mRNA.

3.6. Genomic and Genetic Mapping Using PCR

Many different PCR-based mapping techniques have been described. PCR-based techniques are used to map sequences to specific segments of cloned DNA, such as yeast or bacterial artificial chromosomes (YACs or BACs), **cosmid** contigs, or segments of chromosomes (using radiation hybrid mapping techniques). All that is needed is a set of sequence-specific PCR primers. For example, a sequence-tagged-site (STS) consists of two PCR primers that specifically amplify the 3′ untranslated region of a gene. In humans, YAC pools and **somatic cell** human-rodent hybrids are screened for the presence of the amplified STS PCR product to determine the STS map location (8). The presence of a PCR product indicates that the YAC or somatic cell hybrid contains the STS

sequence.

PCR-generated markers are also useful for creating genetic maps, rapidly producing markers for fine-mapping, and integrating genomic and genetic maps. PCR markers are used like any other **phenotypic** or DNA marker [eg, **restriction fragment length polymorphism** (RFLP) marker] to analyze differences among individuals in a population. DNA polymorphisms amplified by using repeat-specific primers [eg, Alu sequences in humans (9), **microsatellite** markers in plants (10)] have proved especially useful markers for mapping or for fingerprinting individuals. Arbitrary primers used to detect a large number of DNA differences between parental strains rapidly, and these random amplified polymorphic DNAs (RAPDs) are also used for mapping (11). RAPDs are detected between a pool of DNA from mutant progeny and a pool of DNA from wild-type progeny, where the progeny result from a genetic cross between two polymorphic strains, one of which carries the mutation. This allows rapid identification of a large number of RAPD markers in the region of the mutant gene and greatly facilitates cloning of genes located in regions of the genome that lack physical markers.

Because PCR markers are amplified by using sequence-specific primers, they can be used to position genes on both genetic and genome maps. For example, PCR methods have been used to map 47 expressed sequence tag (EST) sequences that are similar to plant disease-resistance genes (12). YACs containing the sequences were identified, and genetic map positions were obtained for those ESTs located on previously unmapped YACs. Several ESTs mapped to regions harboring genetically mapped disease-resistance loci, thus providing candidate disease-resistance genes.

3.7. Analysis of Gene Expression

A large number of PCR-based methods have been developed for analyzing gene expression. The sensitivity of PCR makes it especially useful in analyzing rare transcripts that cannot be analyzed by **Northern blotting** techniques. For known sequences, quantitative PCR is used to analyze relative levels of gene expression in different tissues or after different treatments.

Various PCR-based methods have been developed to identify and isolate differentially expressed genes (see Subtractive Hybridization). Two of the most commonly used procedures are representational difference analysis (RDA) (13) and differential display (14). RDA is used to select for genes expressed in only one mRNA population (the tester mRNA) compared to a second mRNA population (the driver). After cDNA synthesis and amplification of both populations, adapters are ligated only to the tester cDNA population (T-adapters). The tester and driver are mixed, denatured, and hybridized so that common sequences between the populations form tester–driver hybrids. Because of the excess of driver in the hybridization mix, only tester-specific sequences form tester–tester molecules. These are amplified using T-adapter-specific primers and used for further studies. RDA results in identifying a set of tissue- or treatment-specific cDNAs.

Differential display uses an arbitrary primer to amplify cDNAs obtained from different mRNA samples randomly. One primer ($5'$-T_{11}NN, where NN are any two specific nucleotides) selects only cDNAs that have the nucleotides NN immediately adjacent to the poly A tail. When PCR is carried out using this primer in conjunction with a random 10-mer primer, the same subset of cDNAs is selectively amplified in each sample analyzed. PCR reactions from the different samples are run side by side on sequencing gels, so that gene expression differences can be visualized as bands present in one lane and absent in another. The bands of interest are cut out of the gel and the DNA eluted, cloned, and used for further analysis. This method is useful for analyzing many different tissues or treatments at once, but a large number of different primers is needed to survey for differences in all of the cDNAs in a sample.

PCR *in situ* methods have also been developed (see ***In situ* hybridization**). This method uses labeled PCR probes to amplify sequences *in situ* in cells or tissue samples. *In situ* PCR is useful for visualizing the location of rare transcripts that are difficult to visualize by normal *in situ*

hybridization methods.

3.8. Sequencing (see DNA Sequencing)
PCR is used to amplify DNA before cloning and sequencing, or the amplified DNA is sequenced directly without prior cloning. The sequence results differ between the two strategies. If a cloned piece of DNA is sequenced, only one sequence is determined, even if there are several different sequences in the PCR product. Direct PCR sequencing, however, surveys the entire mixture of amplified sequences in the sample. Thus, for example, if the sequence being analyzed has two allelic forms, the sequence will be unambiguous at the positions where both alleles are identical but will represent both bases equally at the sites of difference. Double-stranded PCR products are sequenced directly, or single-stranded products are produced by asymmetric PCR. Several asymmetric PCR methods have been described. For example, PCR amplification is carried out with an excess of one primer over the other. Alternatively, the template is amplified first by using equal amounts of both primers, and then a second reaction is carried out using one primer in excess over the other. Thermal asymmetric PCR utilizes primers that have a T_m difference of 10°C to create an asymmetric PCR reaction. Double-stranded product is produced during 20 to 25 rounds of PCR using the lower T_m as the annealing temperature. Then subsequent rounds of PCR are carried out at the higher T_m to produce a single-stranded sequencing product.

3.9. Special Uses: Analysis of Ancient DNA and Forensics
The sensitivity of PCR (its ability to detect even one target molecule in a complex mixture) and the fact that PCR is used to amplify products from unclonable DNA samples (when the DNA has not been highly purified or when it is partially degraded) have made PCR a valuable tool when the starting material is limited or of poor quality. For these reasons, PCR has proven especially useful in analyzing ancient DNA isolated from, for example, museum specimens, slides, frozen mammoths, or insects in amber. In dealing with such variable and limited starting material, it is essential that special controls (eg, no template and control extract amplifications) and precautions (eg, multiple extracts from independent tissue samples, phylogenetic inferences) be taken to ensure the authenticity of the ancient DNA sequences analyzed.

PCR is used in forensic science for much the same reasons that it is applied to analyzing of ancient DNA. It enables the production of sufficient high-quality sample material for further analysis. Additionally, analysis using PCR-based markers is much more rapid than earlier methods, such as RFLP analysis, for matching samples (such as blood samples or sperm) to individuals.

4. Conclusion

This brief survey of various PCR methods and applications indicates the wide variety of uses for this simple technique and the large number of variations derived from the initial PCR procedure. Because of the sensitivity, flexibility, and simplicity of PCR, the uses and variations of the polymerase chain reaction will undoubtedly continue to multiply in the future.

Polymerases

Polymerases represent a broad class of enzymes whose roles are central to **replicating** and expressing **genes**. This family of enzymes functions during DNA replication and RNA transcription to synthesize a **nucleic acid** from the genetic information encoded by the template strand. Polymerases are unique because these enzymes take direction from another molecule, a polynucleotide substrate. The nucleic acid template is either DNA or RNA, as is the strand synthesized, so polymerases can be divided into (1) DNA-dependent DNA polymerases; (2) RNA-dependent DNA polymerases; (3) DNA-dependent RNA polymerases; and (4) RNA-dependent RNA polymerases. Most polymerases involved in DNA replication and RNA transcription function in a **multienzyme complex**. During replication this complex (known as the replisome) must be proficient in unwinding double-stranded DNA, initiating synthesis encoded by a single-stranded template (priming), incorporating deoxynucleoside triphosphates (synthesis), excising improperly templated nucleosides (**proofreading**), reducing DNA secondary structures on the template strand, unwinding the DNA topology, and joining up the synthesized strand. Proteins involved at the **replication fork** include **helicase**, primase, polymerase, 3′-5′ exonuclease, single-stranded DNA binding proteins, **topoisomerase**, and **ligase**. During gene transcription, the multiprotein complex

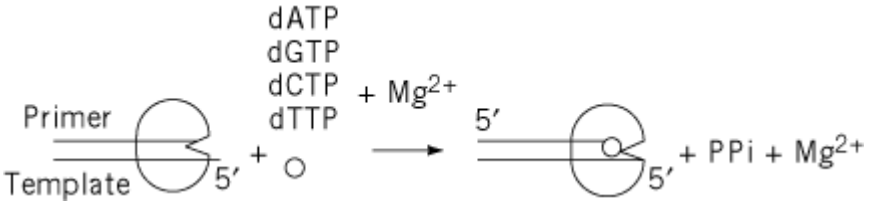
also contains components that have diverse function necessary for efficient initiation, elongation, and termination of RNA transcripts.

The structure of DNA discovered by Watson and Crick in 1953 contains complementary bases that interact via hydrogen bonds. It suggested a mechanism of DNA replication in which each of the two strands of DNA is a template for the synthesizing a new DNA strand. This **semiconservative replication** mechanism involves generating two daughter duplexes, each containing one parent strand and one newly synthesized strand. DNA replication is an enzymatic process as discovered three years later by Arthur Kornberg and colleagues by experiments in which extracts of *Escherichia coli* were incubated with nucleic acid in the presence of **radiolabeled** deoxynucleoside triphosphates (dNTP). Almost fifty years after this discovery, we continue to search for the precise mechanism of nucleic acid polymerization and the enzymes involved during transcription and replication in various organisms.

1. Basic Enzymology

A general function of polymerases is to incorporate a nucleotide directed by a template onto a growing primer terminus. The generalized mechanism of DNA polymerization involves sequentially (1) binding the polymerase to its template primer; (2) binding the appropriate dNTP to the pol-DNA complex; (3) nucleophilically attacking the 3′-OH of the primer on the alpha phosphate of the dNTP, resulting in phosphodiester bond formation (Fig. 1); (4) releasing the pyrophosphate generated; and (5) translocating the polymerase toward the new 3′-OH of the primer. Polymerases catalyze these steps, and the products generated after each step are primers extended by one nucleoside in a 5′-3′ direction and a pyrophosphate moiety. This phosphoryl transfer reaction is typically template-directed, such that adenine is incorporated opposite a template cytosine, etc. This template-directed reaction is highly accurate, and mistakes (such as misincorporation of thymine across from guanine) occurr only once per 5×10^3 to 1×10^6 nucleotides polymerized, depending on the polymerase (1).

Figure 1. General mechanism for nucleotide incorporation by polymerases. Upon binding to a DNA or RNA template, polymerases incorporate complementary nucleotides. Selection of the proper nucleotide is governed by stable Watson–Crick hydrogen bond interactions, proper base stacking interactions, and the geometry of the polymerase active site, which can exclude improperly paired bases. DNA polymerases incorporate 2′-deoxynucleotides, whereas RNA polymerases incorporate nucleotides containing a 2′-OH group within the ribose. The product of one such phosphoryl transfer reaction is a DNA or RNA primer extended by one nucleotide and a pyrophosphate group, which is displaced from the polymerase active site.



2. Evolution

Because polymerases play a pivotal role in replicating and expressing genetic material, the amino acid sequences of the same polymerase from related organisms are conserved, and their sequence alignments are often used for **phylogenetic** purposes. Protein sequence analysis of diverse polymerases has identified three regions of homology, motifs A, B, and C (2). Structural and mutagenetic data have been used to attribute functional roles to these regions. It is believed that both motifs A and B bind to the base and sugar rings of the incoming dNTP, motif B also binds portions

of the template, and motif C binds to the divalent cation **cofactors** (Fig. 2). Other generalizations from sequence alignment studies include the following: (1) All classes of polymerases (excluding complex **RNA polymerases**) have motifs A and motif C in common, and both of these motifs contain an invariable Asp residue that binds a divalent metal cofactor (3). (2) Mammalian DNA polymerase b and **terminal deoxynucleotidyl transferase** represent unique polymerases, evolutionarily distinct from all other known polymerases (2, 4).

Figure 2. Amino acid sequence alignment of conserved motifs in polymerases. The amino acid residues are given with one-letter abbreviations. Bold letters represent amino acids that are identical across all families of polymerases. Positions generally occupied by hydrophobic residues are represented by "h," and those typically containing hydrophilic residues are represented by "p." Hyphens indicate nonconserved loci. The listed motifs are from Ref. 2.

3. X-Ray Crystallographic Structures

The three-dimensional structures of all polymerases solved to date (ie, Klenow fragment, **HIV**-1 **reverse transcriptase**, **bacteriophage** T7 RNA polymerase, pol b, Taq DNA polymerase, *Bacillus* DNA polymerase and bacteriophage RB69 DNA polymerase) morphologically resemble a "cupped human right hand." In the HIV-1 reverse transcriptase, DNA binds across the palm subdomain, the finger subdomain interacts with single-strand portions of the template, and the thumb subdomain "grips" the duplex portion of the DNA (5). In each of these structures, the polymerase active site, where the incoming dNTP binds, is located in the palm subdomain (6). The active sites of all of these polymerases, including a b hairpin loop region where a conserved Asp residue is located, are superimposable. These polymerases have a catalytic triad composed of either three Asp residues or two Asp and one Glu, which function initially to bind the phosphate of the incoming dNTP/divalent cation complex and subsequently to assist the phosphoryl transfer catalysis (7). These diverse polymerases preserve similar architectures suggesting that they probably also exhibit similar mechanisms.

4. Properties

Among the most important properties of polymerases that guarantee the accurate replication of DNA or RNA are (1) fidelity (a measure of the accuracy of the polymerase) and (2) processivity (a measure of how many nucleotides are incorporated before the substrate dissociates). Polymerases exhibit varying degrees of fidelity, ranging from one misincorporation per 5000 to one per 10^7 nucleotides polymerized (8, 9). Those that incorporate the proper templated nucleotide at high efficiency are termed high-fidelity enzymes, and those that frequently misinsert a nucleotide are termed low-fidelity. Several polymerases contain a 3′-5′ exonuclease subdomain (ie, a *proofreading* subunit) which increases the fidelity of the enzyme by approximately 10- to 100-fold.

The fidelity of polymerases is determined by one of several procedures. Fidelity of DNA synthesis was initially measured by utilizing polynucleotide templates consisting of only one or two types of nucleotides, such as an alternating poly d(A-T) template, and measuring the extent of misincorporation of radioactive cytosine or guanine nucleotides (10, 11). Greater sensitivity has been obtained with biological reversion assays, in which misincorporation by DNA polymerase results in the converting an **amber** mutation (ie, stop codon) in a **plasmid** into one that encodes an active, full-length protein (12). The forward mutational assays developed more recently offer the additional advantage of determining the mutational spectrum, that is, the types of misincorporated nucleotides catalyzed by the polymerase (13). *LacZ* has been most extensively utilized in these forward mutational assays as a reporter gene for studies on the mutational spectrum of DNA polymerases. Upon transformation of the copied plasmid (which encodes the *LacZ* gene) into *E. coli* and plating the transfected bacteria in the presence of **X-gal** (which is converted to a blue staining metabolite by the protein encoded by the *LacZ* gene, **b-galactosidase**), the fidelity is determined simply by counting the number of blue and white colonies resulting from functional (or nonmutated) or nonfunctional (or mutated) *LacZ* gene, respectively (see **Blue-white selection**). Sequencing the *LacZ* gene mutants determines the mutational spectrum. The fidelity of incorporation is also determined kinetically by comparing the ratio k_{cat}/K_m of the incorrect nucleotide to that of the correct nucleotide, this ratio directly reflects the efficiency of nucleotide incorporation (14). As a second step, the same assay measures the fidelity of extension by using primers that terminate in a noncomplementary nucleotide and measuring the incorporation of complementary nucleotides onto the end of this primer (15).

Processivity refers to the number of nucleotides incorporated per binding event of the polymerase with the template-primer complex. The processivity values of different polymerases range from one nucleotide to about ten thousand. The processivities of several polymerases involved in genomic replication are enhanced upon binding to a second protein, termed the processivity factor. For example, to fulfill their roles efficiently during DNA replication in **eukaryotes**, DNA polymerases d and ε associate with a homotrimer that has 36-kDa subunits of proliferating cellular nuclear antigen (PCNA) which form a "**sliding clamp**" (16). Phage T4 gene 45 protein (17) and *E. coli* beta (18) similarly augment the processivity of T4 DNA pol and pol III, respectively, by acting as "sliding clamps" bound to the polymerase, thus preventing its dissociation from DNA.

5. General mechanism

The kinetic pathway, including the rates of association and dissociation of DNA polymerase with the template-primer and with dNTP, has been established for T7 DNA polymerase, the Klenow fragment of *E. coli* polymerase I (19), pol b, and HIV reverse transcriptase (20). DNA polymerases bind DNA tightly and have **dissociation constants** (K_d) ranging from 1 to 50 nM. The apparent K_m (Michaelis constant) of the incoming dNTP is approximately 5 to 50 μM. Subsequent to dNTP binding, polymerases undergo a conformational change that brings the alpha phosphate of the incoming nucleotide into proximity of the 3′-OH of the primer. It is thought that this conformational change enhances the discrimination between properly paired and mispaired nucleotides, thus ensuring that even relatively error-prone polymerases, such as HIV reverse transcriptase, incorporate the correct nucleotide 99.98% of the time. Polymerases that have higher fidelity presumably contain a more constrained active site during the conformational change step. The **rate-limiting step** during the incorporation of a single nucleotide in **steady-state** reactions is polymerase dissociation from the DNA, that is, the rate of dissociation is slow (20).

6. *In Vivo* Roles of Various Polymerases

DNA-dependent DNA polymerases are primarily involved in DNA replication and DNA repair in organisms that contain a DNA genome (e.g., **eukaryotes**, **prokaryotes**, bacteriophages including T3, T4, T7, FX 174, and DNA **viruses**, including **Epstein–Barr**, cytomegalovirus, and other **Herpes**-related viruses). In eukaryotes, it is believed that polymerases d and ε conduct much of the

synthesis of the leading and lagging strands, and polymerase a synthesizes the RNA primers and extends these primers by adding a limited number of nucleotide residues. Mutational analysis in **yeast** has shown that each of these three proteins is essential for growth and DNA replication.

In addition to DNA replication, DNA-dependent DNA polymerases are also involved in DNA repair. Specifically, these polymerases bridge gaps in DNA resulting from excising damaged or mispaired bases. It is thought that polymerases d and ε are essential for filling large DNA gaps during mismatch repair (which leaves a gap of thousands of nucleotides), nucleotide excision repair (which leaves about a 30 nucleotide gap), and a subset of base excision repair pathways that leave large patches of 5 to 10 nucleotides (21). Polymerase b is highly efficient at filling gaps of six nucleotides or less, making it the ideal candidate for a subset of base excision repair that leaves short patches of less than 5 nucleotides (22). The newly discovered pol z in yeast (the pol domain is the product of the Rev3 gene that associates tightly with the product of the Rev7 gene, forming the functioning Rev3-Rev7 complex) is efficient at bypassing bulky lesions (23). This polymerase might be involved in synthesizing DNA across damaged regions that have yet to be repaired.

In addition, eukaryotes contain a unique polymerase, **terminal deoxynucleotidyl transferase**, which extends a DNA primer in the absence of a template (24). Considering that terminal deoxynucleotidyl transferase is found only in **immune**-competent cells, it is a reasonable conclusion that this enzyme is involved in generating immunological diversity (25). *E. coli*, the most studied prokaryote, contains three polymerases: Pol I, II, and III (26). Pol III is the primary replicative polymerase for both leading and lagging strands, whereas Pol I is involved in filling gaps during base excision and nucleotide excision repair. The function of Pol II is unknown.

DNA-dependent RNA polymerases are generally involved in expressing genetic material (see Transcription). Eukaryotic cells contain four types of such RNA polymerases, which interact with numerous transcription factors during initiation, elongation, and termination of transcripts. Eukaryotic RNA pol I is located in the nucleolus at 40,000 copies per cell. It synthesizes the large (35 to 47 S) RNA of ribosomes. RNA polymerase II is located in the nucleoplasm at 40,000 copies per cell and functions primarily to synthesize messenger RNA precursors and several types of **small nuclear RNA** (snRNA). RNA pol III is located in the nucleoplasm in 20,000 copies per cell and functions in the synthesis of transfer RNA and small (5 S and 7 S) ribosomal RNA. Mitochondriaof eukaryotes also contain a mitochondrial RNA polymerase, a monomeric enzyme encoded by the nuclear genome that is responsible for transcribing mitochondrial genes.

Prokaryotic DNA-dependent **RNA polymerase** is typified by *E. coli* RNA polymerase, which is composed of six subunits of five unique proteins: a (which functions as a backbone onto which the other proteins bind); b (assists in DNA binding); b′ (contains part of the active site); and s (contributes to initiation). The s subunit dissociates after initiation of the transcript, leaving behind the core polymerase. Bacteriophage DNA-dependent RNA polymerases are unique because they are single-subunit polymerases that do not require transcription factors. Some examples of these polymerases include T7, T3, and SP6 RNA polymerases. These polymerases are highly processive (>1000 nucleotides synthesized per binding event) and are used widely in laboratories to generate RNA transcripts *in vitro*.

RNA-dependent DNA polymerases and RNA-dependent RNA polymerases are generally encoded by **viruses** and **transposons** . RNA-dependent DNA polymerase (which also includes **reverse transcriptase**) is encoded by **retroviruses, LINEs, copia elements**, retroelements, and **hepatitis** B virus. It functions in the complicated life cycles of these organisms to convert their RNA genomes to DNA.

RNA-dependent RNA polymerases are encoded primarily by RNA viruses, such as **polio, hepatitis** virus type C, rhinovirus, and Colxsackie. They function to replicate the viral genome and potentially to transcribe viral genes.

Polynucleotide Phosphorylase

Polynucleotide phosphorylase (PNPASE, polyribonucleotide: orthophosphate nucleotidyltransferase, EC 2.7.7.8) was the first enzyme to be discovered that catalyzes the synthesis of polyribonucleotides with a 3′,5′-phosphodiester bond [reviewed in (1, 2)]. In the forward reaction, long polyribonucleotides, $[\ _pN]_n$, are synthesized from various nucleoside diphosphates ($_{pp}N$ or NDP), and inorganic phosphate, P_i is eliminated. In the reverse reaction, PNPase is a processive 3′ → 5′ exoribonuclease that catalyzes the phosphorolysis of polyribonucleotides, liberating nucleoside diphosphates:

$$\text{nppN} \rightleftharpoons [\text{pN}]_n + \text{n P}_i \qquad (1)$$

In a processive reaction, the enzyme catalyzes the reaction completely on one RNA molecule before commencing on another, so that the substrate does not leave the enzyme during the reactions.

PNPase was discovered by Grunberg-Manago and Ochoa during a study of the mechanism of biological phosphorylation in *Azotobacter vinelandii* (*A. agilis*) (3-5). Studies of the nature of ribonucleotide incorporation into nucleic acids led to the recognition of the same enzyme in *Escherichia coli* cell-free extracts (6, 7). The enzyme was also isolated from *Micrococcus luteus* (formerly *M. lysodeikticus*) (8) and subsequent work has shown that it is widely distributed among **bacteria**.

PNPase has been the subject of many studies. It was employed as a tool for synthesizing model nucleic acids and for solving many important biological problems. Thus, establishing the genetic code was facilitated by the ability of PNPase to catalyze the synthesis of heteropolymers and triplet nucleotides. The advances made in understanding the physicochemical properties of **polynucleotide chains** and their **hybridization** reactions and the synthesis of polynucleotide **inducers** of interferon are additional examples of the role played by the enzyme. Renewed interest in PNPase arose with the finding that the enzyme is associated in a multiprotein complex that is involved in messenger RNA (mRNA) degradation, and it may serve other important physiological functions.

0.1. Properties

0.1.1. Distribution and Purification

PNPase is widely distributed among a variety of **aerobic**, **anaerobic**, **halophilic**, and **thermophilic** bacteria (2, 9). The properties of the enzyme differ somewhat in various bacterial species. About 10% of the total activity is found attached to washed *E. coli* ribosomes, probably bound to mRNA (10), but immunoelectron microscopy indicates that most is located in the **cytoplasm** (11). Some enzyme activity is also found in membrane **vesicles** isolated from *E. coli* cells (12). In several other bacterial species, however, the enzyme is primarily found associated with the cell membrane (2, 13). PNPase was also isolated from **plants** (14, 15), where it is localized in the **chloroplasts** (16, 17). The enzyme is scanty in animal cells. Some activity was reported to be associated with the endoplasmic reticulum ribosomes (18, 19) although, the results could result from a combination of other enzymes (20). PNPase was purified from a wide variety of microorganisms (1, 2). Essentially homogenous preparations have been obtained from *E. coli* (21-25), *A. vinelandii*. (5, 26), *M. luteus* (27, 28), *V. costicola* (29), *S. antibioticus* (30) and many other bacterial species (2).

Most of the bacterial PNPase preparations are primer-independent forms, which catalyze *de novo* polymerization processively. Primer-dependent forms are derived from limited digestion by trypsin of PNPase from *M. luteus* (31). PNPase preparations from *Bacillus stearothermophilus* (21), *Thermus thermophilus* (33), and cucumber leaves (15) show primer dependency. More recently, amplification of the enzyme with recombinant DNA techniques in *E. coli* cells allowed its efficient purification and was used to raise polyclonal antibodies (11, 34).

0.1.2. Metal Ion Requirement and Properties of PNPase

Magnesium ions are required for the reactions catalyzed by PNPase but can be partially replaced by

Mn^{2+} (1, 7, 22, 35) or other divalent cations, such as Co^{2+}, Ni^{2+}, Cd^{2+}, Cu^{2+}, and Zn^{2+}, although with much lower efficiencies (2, 35, 36). Polymerization of GDP with *E. coli* PNPase, however, proceeds efficiently only in the presence of Mn^{2+} at 60°C (37). A mutant PNPase from *E. coli* Q13 requires Mn^{2+} rather than Mg^{2+} (38). Purified PNPase is unstable above 55°C and is rapidly and irreversibly inactivated at 65°C (1, 22, 25, 39). The *M. luteus* (40) and the *C. perfringens* (41) enzymes are less stable. The *E. coli* PNPase is stabilized against heat inactivation by the presence of NDPs or oligoribonucleotides with a free 3′-OH terminus (39).

PNPase is sensitive to **proteolytic** digestion, which may account for differences in subunit structure and catalytic properties of PNPase from various sources [see (2)]. Thus, native PNPase from *M. luteus* is primer-independent, catalyzes *de novo* polymerization processively, and is only slightly stimulated by oligoribonucleotides. Limited trypsin digestion of the native enzyme alters its polymerization activity without affecting its ability to phosphorolyze polynucleotides. The trypsinized enzyme (form T) catalyzes elongation of primers by a random mechanism and is stimulated by oligonucleotides (32, 42-44).

The *de novo* polymerization of NDPs, particularly at low Mg^{2+} concentrations, is preceded by a lag period, which may be overcome by adding polynucleotides or short oligonucleotide primer molecules with a free 3′-hydroxyl group (21, 22, 45). The oligonucleotide primers are incorporated into the polymer synthesized by PNPase from *M. luteus* (46), and their effect is maximal in the polymerization of GDP, which proceeds with a slow rate in the absence of such primers (47). These primers also accelerate the NDP↔P_i exchange reaction (22, 45, 48). The ADP↔P_i exchange reaction is inhibited by poly(U), but not by poly(A), poly(G) or poly(C) (49). When blocked with a 3′-terminal phosphate moiety, oligonucleotides inhibit the polymerization reaction and exchange reactions (48, 50, 51). Several modified NDPs, such as 6-azauridine diphosphate, block the catalytic activity of PNPase (52). A heat-stable polypeptide activates the ADP↔P_i exchange reaction (7, 22). Depending on the source of the enzyme, poly- L-lysine and other polyamines stimulate or inhibit enzyme activity (2). The actions of several other chemical agents that inhibit the catalytic activity of PNPase have been extensively summarized (1).

0.2. Structure

0.2.1. Molecular Weight

PNPase from *E. coli* is composed of three identical subunits (25, 53). Each contains 711 amino acids and has a molecular mass of 77,122 Da (54). A higher molecular weight of 84 to 88(±5)*kDa* is observed by SDS-PAGE, which is attributed to the acidic character of PNPase (25, 53). PNPase from *M. luteus* is also active as a homotrimer (25, 55). The molecular weight of the entire enzyme from *E. coli* has been determined by **sedimentation equilibrium**, **gel filtration**, **sucrose gradient centrifugation**, and gel electrophoresis under nondenaturing conditions. In the latter method, enzyme activity can be visualized after electrophoresis by incubating the gels in the presence of ADP and Mg^{2+}, followed by staining the poly(A) formed *in situ* with **acridine** orange in the presence of lanthanum chloride (56). Other *in situ* methods for visualizing active enzyme molecules have also been published (2). The molecular weight of purified *E. coli* PNPase determined by sedimentation equilibrium ranges from 214 to 252(±20)*kDa*) [see (2)]. The molecular weight and the physical and chemical properties of *M. luteus* enzyme are very similar (28). In crude extracts *E. coli* PNPase displays microheterogeneity, and higher level forms are detected, which may arise from the association of an additional polypeptide subunit (53). In some other bacterial species, PNPase shows considerable heterogeneity in the composition of its subunits, which may result from limited proteolysis of the enzyme. PNPase from cucumber leaves is a complex of three subunits, possibly not identical, of about 50 kDa each (15).

0.2.2. Complexes with Other Proteins

Sucrose gradient centrifugation and gel filtration detect the presence of PNPase in higher molecular weight complexes. These PNPase forms arise from association with enolase (53), an essential

glycolytic enzyme. Furthermore, it was found that PNPase is associated in a multicomponent complex called the degradosome, together with ribonuclease E (RNase E, an endoribonuclease). Association between the two enzymes requires the presence of an intact C-terminal region in RNase E, whereas this region is not required for the catalytic activity of RNase E (57). Several additional proteins are found in this complex, including a **"DEAD box" RNA helicase** and enolase (58-60), a **heat shock** protein, DnaK (61), and sometimes GroEL, a chaperonin that mediates protein folding and assembly (62). The average molar ratios of the proteins in the complex were estimated from silver-stained gels at 1.0: 0.9: 0.93: 1.8 for RNaseE: PNPase: RNA helicase: enolase (61). Only 5 to 10% of the cellular enolase is thought to be in the complex. Most of the PNPase and enolase in a cell are found in a binary complex, not in the degradosome (59). Chloroplast PNPase is also associated with an endonuclease that is homologous to RNase E (17). The physiological roles of this multiprotein complex is discussed in the section dealing with the function of PNPase.

0.2.3. The PNPase gene

The *pnp* gene for *E. coli* PNPase (54) is part of an operon together with the ribosomal protein S15 gene (*rpsO*). These two proteins are expressed differentially following processing of the *rpsO-pnp* transcript by RNase E and RNase III (63, 64). Two RNA-binding **domains** have been characterized in the C-terminal amino acid sequence of PNPase. The first domain, the KH module, is also found in many hnRNP proteins, in a number of other RNA-associated proteins from human and yeast cells, and in *E. coli* ribosomal protein S3 and the transcription factor NusA. The structure of the KH module determined by NMR consists of an antiparallel, three-stranded **b-sheet** connected by two **a-helical** regions (65). The second RNA-binding domain is strongly homologous to each of the four homologous stretches in the middle and C-terminal parts of ribosomal protein S1 (54). The structure of this S1 motif of PNPase consists of a five-stranded, antiparallel b-barrel (66). Conserved residues on one face of the barrel and adjacent loops form the putative RNA-binding site. The structure is very similar to that of **cold shock** proteins, suggesting that all these proteins are derived from an ancient nucleic acid-binding protein. The RNA-binding motifs of PNPase are believed to be involved in the processive nature of the phosphorolysis reaction. The three RNA-binding domains in trimeric PNPase might allow the enzyme to associate with adjoining regions of the same polynucleotide (54). This suggestion is supported by the observation that proteolytic cleavage of PNPase leads to 62-kDa subunits that still associate to form an active enzyme but have lost the ability to bind oligonucleotides more than 11 nucleotides long. Moreover, the processive nature of the reaction of the modified enzyme was also reduced (67).

The sequences of the *pnp*A genes from *E. coli* (54), *B. subtilis* (68), *H. influenzae* (69), and *Photorhabdus luminescence* (70) indicate polypeptide chains of 705 to 711 residues of similar sequence. For example, those from *B. subtilis* and *E. coli* are 50% identical. That from *S. antibioticus* codes for an **open reading frame**, corresponding to 740 amino acids, and is 44% identical to the *E. coli* enzyme (30). There are two highly conserved domains near the C- and N-termini in these sequences, but overall homology is apparent along the entire molecule. Spinach chloroplast PNPase (17) is strikingly homologous (43% identity, 63% similarity) to *E. coli* PNPase (54). The chloroplast PNPase is longer than *E. coli* PNPase by at least 75 amino acids at the N-terminus, which probably represents a unique domain of the chloroplast protein. The content of acidic residues (14.2%), together with its low content of basic residues (12.65%), predicts an acidic protein with an isoelectric point of 5.07 for the *E. coli* enzyme, as compared to a value of 6.1 estimated by isoelectric focusing (25).

0.2.4. Reactions Catalyzed

PNPase catalyzes the reversible polymerization of NDPs to polyribonucleotides and inorganic phosphate (Eq. 1). Each of the four common NDPs can serve separately as a substrate for the polymerization reaction, leading to formation of homopolymers. Polymerization of a mixture of NDPs that contains different bases results in producing a random copolymer. The enzyme does not require a template and cannot copy one. The polymerization of GDP by *E. coli* PNPase is very slow (37), but copolymerization of GDP with the other NDPs is readily achieved (1). Polynucleotides are synthesized *de novo* in the 5′ → 3′ direction *via* a processive mechanism.

The mechanism of chain initiation and formation of the first internucleotide bond involves the reaction between two NDP molecules, one of which serves as the accepting 5′-terminus. Analysis of the newly synthesized polynucleotides reveals that they contain a monophosphate group at the 5′-terminus, rather than the expected 5′-pyrophosphate group (2, 55, 71, 72). The pyrophosphate linkage may be broken before or concomitant with the formation of the first internucleotide linkage, although other mechanisms cannot be ruled out (55). In addition, ApA and pApA do not undergo phosphorolysis but accumulate as resistant end-products of poly(A) degradation (73, 74). This implies that the initiation of *de novo* polymerization involves an initial irreversible step.

Under suitable conditions, the enzyme also catalyzes the elongation of a primer oligonucleotide with a free 3′-terminal hydroxyl group:

$$\mathrm{R} + \mathrm{nppN} \rightleftharpoons \mathrm{R[pN]_n} + \mathrm{n\ P_i} \qquad (2)$$

where R represents the oligonucleotide primer with at least two nucleoside residues and a free 3′-terminal hydroxyl group. Elongation of oligonucleotide primers may occur by a nonprocessive mechanism (1, 43). Thus, the trypsinized T form of PNPase from *M. luteus* has a reduced *de novo* polymerization activity but readily elongates the 3′-end of an oligonucleotide primer. The elongation is nonprocessive, and only small oligonucleotides are formed (43).

In the reverse reaction, PNPase serves as a 3′ → ′5′ exoribonuclease and releases NDPs sequentially from the 3′-OH terminus of polynucleotide substrates The phosphorolysis reaction proceeds stepwise, starting from the 3′-OH terminus of polyribonucleotides, to liberate nucleoside diphosphates. PNPase readily degrades single-stranded polyribonucleotides (75). The progress of the phosphorolytic reaction, however, depends on the secondary structure of the RNA and is impeded or stopped when the enzyme encounters stable stem-loop structures (11, 76). Thus, the enzyme acts more slowly on transfer RNA, ribosomal RNA (67, 75-79), or messenger RNA [except for the **poly (A)** tail, which is degraded rapidly (80)]. The rate and extent of phosphorolysis is increased by raising the temperature (75, 80) or by adding 2 M urea (78). PNPase phosphorolyzes short oligonucleotides by a nonprocessive mechanism (1, 81-84) but long polynucleotides by a processive mechanism (44, 67, 81). Arsenate can replace phosphate ions in degrading polynucleotides by PNPase, which produces labile 5′-phosphorylarsenate nucleotides (85, 86). Aminoacylated tRNA chains are substrates of PNPase (87), but polyribonucleotides with 3′-terminal phosphate groups are not (9). Kinetic analysis indicates that multiple subsites exist for the interaction of the enzyme with polynucleotides and oligonucleotides (73) .

PNPase also catalyzes an exchange reaction between ^{32}P-labeled inorganic phosphate and the b-phosphate of nucleoside diphosphates:

$$\mathrm{Ribonucleoside} - {}^{31}\mathrm{P} - {}^{31}\mathrm{P} + {}^{32}\mathrm{P} \rightleftharpoons \mathrm{Ribonucleoside} - {}^{31}\mathrm{P} - {}^{32}\mathrm{P} + {}^{31}\mathrm{P} \qquad (3)$$

This reaction is apparently a result of combined polymerization and phosphorolytic reactions that occur under approximate equilibrium conditions. The kinetic parameters of the exchange reaction are similar to the polymerization reaction. No evidence was found for reversible formation of a covalent, nucleoside monophosphate–enzyme complex (2, 9, 22).

0.3. Reaction Mechanisms

The processive phosphorolytic degradation of long polyribonucleotides and of tRNA by PNPase (67, 88) implies that the affinity of the enzyme for its polymeric substrate must be very high, presumably resulting from the presence of multiple binding subsites on the enzyme. On the other hand, the degradation of oligonucleotides, at least up to a chain length of six nucleotide residues, proceeds by a nonprocessive, random mechanism. The transition between the two mechanisms is still not clear.

One would expect that, once the enzyme has processively degraded a polymer to its minimum chain length of six nucleotide residues, the oligonucleotide should be released and accumulate in the reaction mixture until all of the polymer chains are degraded. Such an accumulation of oligonucleotides, however, has never been observed. The only oligonucleotide found in sizable amounts during phosphorolysis is the dimer, which cannot be phosphorolyzed. The $\boldsymbol{K_m}$ (Michaelis constant) of the *E. coli* PNPase for oligo(A)s of chain length three to six decreases from 210 mM to 50 mM as chain length increases. The presence of a 5′-phosphate residue only affects the K_m values of the tri- and tetranucleotides. For long polymers, the K_m is much smaller (of the order of 10 nM polymer). The transitional length to this very low K_m is greater than 10 and fewer than 40 nucleotide residues (89) . The diversity of mechanisms probably results from the existence of different binding sites on the PNPase molecule, but the details need to be elucidated.

0.4. Physiological Function

Upon its discovery, the enzyme was named polynucleotide phosphorylase, suggesting that it is involved in RNA degradation rather than synthesis (4). However, structured RNAs, such as rRNA and tRNA, are attacked slowly, whereas nonstructured homopolymers are rapidly phosphorolyzed (75, 77). Because mRNA was believed to be nonstructured then, it was suggested that the role of the enzyme is to degrade mRNA. An unequivocal demonstration of a biological function was lacking, however, for a number of years. *E. coli* contains another 3′ → 5′ exonuclease, RNase II. This enzyme hydrolyzes single-stranded RNA processively by releasing nucleoside 5′-monophosphates from the 3′-end. (90-93). The activities of these two exonucleases vary in different bacterial species. In *E. coli* extracts, about 90% of the degradative activity is hydrolytic and due to RNase II, 10% due to PNPase, whereas in *B. subtilis* most of the degradative activity is phosphorolytic (94).

Studies of mutants defective in these enzymes indicate that the final breakdown of mRNA *in vivo* depends on both PNPase and RNase II. Single mutant strains that lack only one of these enzymes are viable, whereas the absence of both enzymes leads to inviability in *E. coli* (95, 96) and in *B. subtilis* (97). The physiological effects of these exonucleases are influenced by the stability of the secondary structure at the 3′-end of mRNA. PNPase is less sensitive to such an obstacle than RNase II. Thus, PNPase completely degrades strongly structured tRNA molecules (67, 88), whereas RNase II cannot (98). RNase II also stalls at 3′-terminal hairpin structures of mRNA (99-101). It is believed that the decay of mRNA in *E. coli* is initiated by endonucleolytic cleavage that creates a so-called entry site for the two exonucleases (101).

Endonucleolytic cleavage is the rate-limiting step for mRNA degradation and is catalyzed by RNase E (102-105) or occasionally by RNase III (63, 64, 106-109). The observation that RNase E and PNPase form a large complex *in vivo* with at least two and perhaps more proteins, the RNA degradosome (see previous), raises the intriguing possibility that these enzymes cooperate in the coordinated regulation of RNA processing and degradation. Following an endonucleolytic cleavage by RNase E, the newly formed 3′-end would be directly attacked by PNPase. In this way, the PNPase-RNase E association in the degradosome would eliminate a slow step in which a free PNPase molecule must find the 3′-end of the mRNA. The degradosome also contains an ATP-dependent RNA helicase that aids in degrading structured RNA molecules by PNPase by unwinding RNA structures that impede its processive activity.

Degradation of RNA stem-loop structures by the degradosome has an absolute requirement for ATP and is inhibited by **antibodies** to the helicase. Interestingly, inactivation of RNase E does not inhibit the ATP-promoted degradation of RNA by the degradosome. Thus, PNPase and helicase can degrade structured RNA without endonuclease cuts (59). At least two more proteins, DnaK and enolase, are present in this complex. DnaK is also part of the degradosome and is involved in many cellular processes including the **heat shock** response. The association of the heat shock protein, DnaK, and the cold shock protein, PNPase, with RNase E raises the possibility that these proteins are involved in folding this very large enzyme complex in response to changes in the environment (61).

Enolase is also part of the degradosome but is an essential glycolytic enzyme, so that a role in RNA metabolism would not be obvious. It is possible that phosphoenolpyruvate is required to generate deoxynucleoside triphosphates (see following).

The secondary structure of RNA-OUT, the **antisense RNA** that regulates Tn10/IS10 transposition, provides greater resistance to degradation by RNase II than to PNPase (110). Moreover, the presence of RNase II protects RNA-OUT against PNPase degradation, and *rpsO* mRNA, coding for ribosomal protein S15, is also stabilized significantly by the presence of RNase II (111). The protection observed was attributed to the formation of a stable RNA-RNase II complex that sequesters the 3′-end of the transcript, making it no longer accessible to PNPase. Further studies, however, have provided a somewhat different explanation (112). Using a synthetic partially duplexed RNA as substrate, RNase II disengages from its substrate upon stalling at a region of secondary structure and reassociates with a new 3′-end. The stabilization of antisense RNA-OUT and of *rpsO* mRNA by RNase II are thus thought to be due to the removal of the 3′-overhang, rather than to the formation of a stable RNase II complex. Removal of the single-stranded 3′-overhang reduces the affinity of RNase II for the transcript and the ability of PNPase to bind and initiate phosphorolysis of RNA. In support of this theory, *in vitro* synthesized RNA that is trimmed back to a region of secondary structure with purified RNase II is not a substrate for PNPase (112). This also explains the role of poly(A) polymerase in mRNA degradation. Although polyadenylation has commonly been regarded as a special feature of eukaryotic mRNA (113-115), there are many reports of poly(A) tails on bacterial RNA [see (116-118)]. Recent work has implicated PNPase and the product of the *pcnB* gene, coding for poly(A) polymerase, in the degradation of RNA I, a highly structured, small, untranslated, antisense inhibitor of the replication of ColE1 replicons (119). Polyadenylation also destabilizes the mRNA encoding ribosomal protein S15 (118, 120) and regulates the decay of mRNA in general (121). These results support the idea that polyadenylation facilitates the exonucleolytic degradation of structured RNA, particularly by PNPase. Degradation of the mRNA encoding ribosomal protein S20 also depends on both oligoadenylation and PNPase activity. It is not sensitive to attack by RNase II and, in contrast to its stimulation of PNPase activity, polyadenylation of the 3′-end of S20 mRNA cannot overcome its natural resistance to RNase II action (99). It also appears that the degradation of polyadenylated RNA by PNPase takes place without endonucleolytic cleavage by RNase E. It seems probable that the poly(A)-dependent degradation of RNA in *E. coli* exists largely to facilitate exonucleolytic degradation of highly folded RNA fragments.

It was suggested that PNPase plays a role in supplying precursors for DNA synthesis. The NDPs released by RNA phosphorolysis can be later reduced to the deoxy versions (see Ribonucleotide Reductases) and incorporated into DNA after phosphorylation. Thus, the proposed key role for PNPase is to couple mRNA turnover to DNA synthesis (92, 122, 123).

An intriguing function of PNPase is its requirement for the development of competence in *B. subtilis* (68), which is the ability to take up exogenous DNA. It is a highly regulated phenomenon in *B. subtilis* that involves many genes. PNPase is necessary for the expression of the late competence genes, possibly functioning at a posttranscriptional step. A *B. subtilis* pnpA deletion strain also exhibits unusual morphological characteristics (97). PNPase is required to establish **bacteriophage** P4 immunity (124). PNPase is also involved in the maturation of chloroplast mRNA, which is an essential step in synthesizing stable chloroplast RNA in higher plants (17). Finally, it was shown that guanosine pentaphosphate synthetase I from *S. antibioticus* is a bifunctional enzyme capable of both pppGpp synthesis and PNPase activities (30). Many additional roles for PNPase have recently been observed and because it has such a complicated structure, it is quite possible that other important functions are yet to be discovered.

0.5. Regulation of Gene Expression

The gene encoding PNPase (*pnp*) starts with an unusual UUG triplet. It is situated at 69 minutes on the *E. coli* chromosome (125), downstream of the *rpsO* gene that codes for ribosomal protein S15. The *pnp* operons of *B. subtilis* and *Photorhabdus* (70) are organized similarly (68). In *E. coli*, each

gene has its own **promoter**, but there is also co-expression of *rpsO* and *pnp* from the P1 promoter, located 108 nucleotides upstream from *rpsO* (126). The P1 transcripts are attenuated by a **rho**-independent terminator located 38 nucleotides downstream from the termination codon of *rpsO*. A second promoter, P2, is located between the *rpsO* and the *pnp* genes, 158 nucleotides upstream of *pnp*. The P1 polycistronic transcript and the P2 transcript are both processed by RNase III at two sites located 81 and 119 nucleotides upstream of the *pnp* initiation codon (63). The expression of *pnp* is under translational control, and the first step of this control is cleavage of the *pnp* message by RNase III (63, 127). Several partially deregulated mutants map in a region that overlaps the ribosome loading site, located between nucleotides –40 and +87. This indicates that the translational initiation region and the beginning of the *pnp* coding region are important for regulation. Accordingly, the stability of the message strongly depends on translation (128). One explanation for these observations is that PNPase also binds specifically to the newly formed 5′-region of the message generated by RNase III cleavage. This binding interferes with the translation process and thereby allows the enhanced degradation of its mRNA. Indeed, scanning transmission electron microscopy supports the idea that both the 5′- and 3′-ends of RNA are bound by PNPase (55). What is the role of RNase III in generating 5′-ends that are specifically recognized by PNPase? Because PNPase does not recognize specific sequences, one may suggest that the distance between the 5′-end of the mRNA and the ribosome loading site is critical in determining the capacity of PNPase to inhibit the translation of its message. In addition, expression of RNase II and PNPase might be interregulated (129). *E. coli, B. subtilis* and *Photorhabdus* PNPases are cold shock proteins (70, 97, 130). In *Photorhabdus* the increase in the level of *pnp* mRNA may be a result of a cold-inducible promoter, P2, in the intergenic region between *rspO* and *pnp* (70). It was found that *pnp* mutants of *B. subtilis* and *E. coli* do not grow at low temperatures of 15°C and 23°C (97); C. Portier, personal communication) indicating that, under these conditions, the 3′ → 5′ exonuclease activity of PNPase cannot be compensated for by other nucleases.

0.6. Research Applications

PNPase is a useful tool for the synthesizing of homopolymers, heteropolymers, and oligonucleotides that have defined sequences. The enzyme is also employed to probe the structural conformational aspects of duplex polynucleotides involved in interferon induction (131, 132). Additional applications of the enzyme involve the synthesizing **radiolabeled** polynucleotides, the **radiolabeling** of NDPs and NTPs at their b-position (133-135), and sequence analysis of short oligonucleotides (84). The 3′-exonucleolytic activity of PNPase was used to analyze the size and composition of the 3′-terminal sequence of RNA molecules and their functions. With a molar excess of PNPase over the substrate, a synchronous mode of phosphorolysis is established, in which NDP molecules are sequentially released from the 3′-terminus of the RNA chains (80, 136-140). At 0°C the poly(A) tails of mRNA molecules are readily phosphorolyzed, whereas the rest of the RNA chains remain intact. Under these conditions, it was possible to determine the length of the poly(A) tails from various mRNAs and to establish their function (80, 114).

The enzyme displays low specificity for the side chains on the purine or pyrimidine moieties, whereas it shows high specificity for the number of phosphate groups on the nucleoside and the nature of the sugar moiety on the NDP substrate. The slow polymerization rate observed with some modified NDPs is enhanced by replacing Mg^{2+} with Mn^{2+}, raising the temperature, and by the adding organic solvents, such as methanol or dimethylsulfoxide [see (2)]. Blocking of NDPs at the 3′-position yields “monofunctional“ substrates, of which only one residue may be added to an oligonucleotide primer, thus serving as chain terminators. The blocking group can be subsequently removed chemically from the oligonucleotide product, permitting a succession of single addition reactions. This procedure has been utilized for the stepwise synthesis of polynucleotides of defined sequence (87, 141-144).

Combining these reactions and using T4 RNA ligase to ligate the synthesized oligonucleotides permits synthesizing appreciably long oligonucleotides (145, 146). PNPase cannot phosphorolyze DNA (9). However, the enzyme can direct the reversible addition of a single deoxynucleotidyl

residue to ribooligonucleotide primers. Further addition of oligodeoxynucleotide residues to the resulting product is very sluggish (147-152). In the presence of Mn^{2+}, *E. coli* PNPase catalyzes the transfer of deoyribonucleotide residues from the deoxyribonucleoside diphosphates to the 3′-OH end of an oligodeoxyribonucleotide primer that has a minimal length of three nucleoside residues. The repeated addition of single residues allows synthesizing oligodeoxyribonucleotides of defined sequence (153, 154).

We thank Drs. Claude Portier, Herald Putzer, and Philippe Regnier for their helpful suggestions.

Polyomavirus

Polyomaviruses include BKV, JCV, SV40, LPV, murine polyomaviruses, hamster polyomavirus, and others. BKV and JCV grow permissively in human cells, while SV40 and LPV grow permissively in monkey cells. The murine polyomavirus will here be simply referred to as polyomavirus. Because polyomavirus produces no detectable diseases when it multiplies in adult mice, it is regarded as a harmless passenger. However, polyomavirus inoculated into newborn mice induces parotid gland carcinoma, epidermal carcinoma, hemangioma, mammary carcinoma, thymic epithelioma, and many others, although productive virus infection does not establish in the mice. Polyomavirus replicates well in both primary cultures and established murine cell lines and produces progeny viruses (permissive infection). Primary cultured cells from other rodent origins are abortively infected with polyomavirus (nonpermissive infection). Some, but not all, of the infected cells are immortalized. Some immortalized cells are released from the tightly controlled cellular growth-regulatory system and become transformed. In contrast to SV40-transformed cells, polyomavirus-transformed cells are highly **oncogenic** in animals because of the function of the polyomavirus-encoded middle T Antigen.

The virion of polyomavirus has a diameter of about 45 nm and a sedimentation coefficient of 240S (see Papovavirus). The genome of polyomavirus is double-stranded circular DNA, 5292 base pairs in length, and encodes early and late genes. Three proteins with molecular weights of 100 kDa, 56 kDa, and 22 kDa, which are named large, middle, and small T antigens, respectively, are translated from the early messenger RNA that are transcribed before the onset of viral DNA replication . The large and middle T antigens are localized exclusively in nuclei and on the inner and plasma membranes, respectively. The small T antigen exists in all fractions as a soluble form. Viral capsid proteins VP1, VP2, and VP3 are encoded by the late gene.

Considerably less is known about the molecular basis of polyomavirus DNA replication than SV40. The large T antigen can bind to **retinoblastoma** family proteins but, unlike SV40 large T antigen, fails to associate with p53. Inactivation of p53 might not be necessary for making murine cells enter S phase. The large T antigen binds to the origin of DNA replication and unwinds the adjacent region by its ATPase and DNA helicase activities (preinitiation complex). Formation of the initiation complex and the chain elongation reaction are considered to occur in a similar mode as described in the SV40 system (see SV40 (Simian Virus 40)). The phosphorylation at Thr278 of the large T

antigen by **cyclin**-dependent kinase is required for viral DNA replication.

The small T antigen forms a complex with protein **phosphatase** 2A and inhibits its enzymatic activity. Thereby, the enhanced mitogen-activated protein (MAP) kinase pathways stimulate cell proliferation. This function is dispensable for viral DNA replication, however, because a mutant lacking the small T antigen still produces progeny viruses at the same efficiency as wild type.

Transfection experiments using complementary DNAs encoding the large, middle, and small T antigens separately have produced the following results. First, the large T antigen alone can immortalize primary-cultured cells from both permissive and nonpermissive animals. Second, the middle T antigen alone can malignantly transform established cells, but not primary-cultured cells. Third, in addition to the middle T antigen, coexpression of the large or small T antigen is necessary for both transformation of primary-cultured cells and induction of tumors in newborn animals.

The oncoproteins c-src, c-yes, and c-fyn are associated with the region from residues 185 to 210 of the middle T antigen. The middle T antigen activates c-src by repressing **phosphorylation** at Tyr527 of c-src or by making the phosphorylated Tyr527 accessible to protein **phosphatase**. The middle T antigen can similarly activate c-yes, but not c-fyn. Once the activated c-src kinase phosphorylates Tyr250, 315, and 322 of the middle T antigen, the SH2 domains of SHC, the regulatory subunit of PI3 kinase, and **phospholipase C**-g1 recognize the amino acid sequence containing the respective phosphotyrosine residues. Then, the tyrosine residues of the three proteins are phosphorylated by the activated c-src associated with the middle T antigen. The other SH2 domain-containing proteins, such as Grb2 and IRS-1, form complexes with the SHC, phosphoinositide-3-kinase subunit, and phospholipase C-g1 through the phosphotyrosine residues. The subsequent unusual activation of the signal transduction pathways mediated by the Raf and/or S6 kinase cascade is considered to be the molecular basis of the transformation by the middle T antigen.

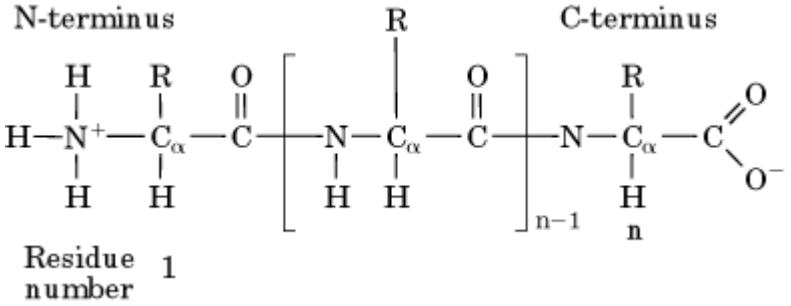
Polypeptide Chain

Polypeptide chain is a term that describes the basic covalent structure of proteins. That is, proteins are **polymers** comprising peptide bond units (hence, *polypeptide*) that connect together a large number of amino acids into a linear chain. The polypeptide chain thus consists of a regularly repeating part, the backbone or main chain, and a variable part, the side chains, corresponding to the functional groups of the amino acids. The term is most often used for proteins, which can consist of one or more polypeptide chains, but can also be used more generally for all amino acid polymers including **peptides**, polyamino acids, and chemically synthesized polymers of amino acids.

The linear polypeptide chain is formed from amino acids by a condensation reaction between the acidic or carboxyl group of one amino acid and the amino group of another. Amino acid units within the polypeptide chain are referred to as *residues*. The backbone of a polypeptide chain is a repeating

sequence of three atoms corresponding to the amide nitrogen (N) of the peptide bond, the central tetrahedral carbon (C_a;), and the peptide carbonyl carbon (C) (Fig. 1). The variable side chains or functional groups (R) are covalently linked to C_a;. The amino acid sequence defines the order of the side chains throughout the polypeptide chain.

Figure 1. Schematic representation of the polypeptide chain of a protein, showing in square brackets the atoms of the peptide repeating unit (N, C_a; and C) that form the backbone. The functional group or side chain, R, of each residue varies, depending on the type of the amino acid residue. By convention, numbering of amino acid residues in the polypeptide chain is from the *N*-terminus (residue 1) to the *C*-terminus (residue *n*).



The two ends of the polypeptide chain differ from each other. At one end there is an uncondensed or free amino group, and at the other end there is a free carboxyl group. The ends of the chain are therefore referred to as the amino terminus or ***N*-terminus** and the carboxyl terminus or ***C*-terminus**. By convention, numbering of the amino acid residues in the polypeptide chain is from the *N*-terminus to the *C*-terminus (Fig. 1).

The chemical nature of the peptide bond in the polypeptide chain allows hydrogen bond formation between peptide bond units. The propensity of the polypeptide chain to form these intrachain interactions gives rise to the several types of regular backbone structure, or **secondary structure**, observed in protein structures including **a-helices**, **b-strands**, and turns .

Polyploid

Cells with more than the normal complement of DNA in their **genomes**, usually with increased numbers of the standard chromosomes, are called polyploid. In many plants, but more rarely in animals, mutations occur that increase the normal number of chromosomes. For example, if the haploid set of chromosomes of a given plant is 7, the diploid set is 14. Mutants appear that contain 3, 4, 5, 6, 7, 8, etc. genomes. There are polyploid forms called **triploid** (three genomes), tetraploid (four genomes), pentaploid (five genomes), etc. Each of the chromosomes is repeated by the same

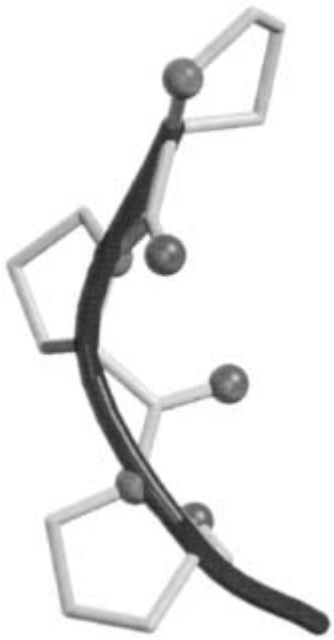
integer. During meiosis, polyploidy is maintained in subsequent generations if there is an even number of genomes.

Polyproline

Polyproline is the **polyamino acid** formed from proline residues. Like proteins and other **polypeptide chains**, the polyproline polymer is formed by condensation of the amino group of one amino acid and the carboxyl group of another amino acid. Proteins, however, have a defined and complex sequence that usually includes all 20 of the amino acids, but polyproline is formed from proline residues only. Polyproline adopts an unusual protein structure that is often used in **molecular recognition**.

Unlike the polypeptide chain formed from other amino acid residues, the peptide bond of the proline backbone cannot take part in hydrogen bond interactions because there is no hydrogen atom on the backbone nitrogen. Furthermore, the cyclic side chain of proline restricts the backbone conformation of polyproline. Therefore, the **secondary structure** elements observed in most protein structures, such as **a-helices** or **b-strands**, are not observed in the structure of polyproline. Instead, the polyproline backbone adopts one of two possible conformations, called poly(Pro) I (backbone f and y angles of –83° and 158°, respectively) and polyProII (backbone f and y angles of –78° and 149°, respectively) (see Ramachandran Plot). The difference between the two is that poly(Pro) I has all its peptide bonds in the ***cis*** configuration (backbone w angle 0°) and poly(Pro) II (Fig. 1) has the all ***trans*** configuration (backbone w angle 180°).

Figure 1. Schematic representation of the polyPro(II) helix for a three-residue sequence of polyproline. The first residue is at the top of the figure, and the third residue is at the bottom. The cyclic side chains of the proline residues are shown in light gray. The backbone nitrogen atoms, and backbone oxygen atoms are shown as dark spheres. The curve of the helix is shown by the dark line that traces the backbone of the polyproline sequence. This figure is generated using Molscript and Raster3D .



The polyamino acid formed from glycine (polyglycine) adopts a conformation called poly(Gly) II, which is similar to the poly(Pro) II conformation. Similarly, the backbone of each polypeptide chain of collagen, a structural protein that has a distinctive repeating unit in its polypeptide sequence corresponding to Gly–X–Y, where X is often proline, also adopts a conformation like that of poly (Pro) II.

Regions of protein sequence that are rich in proline residues can also adopt the poly(Pro) II conformation. These proline-rich regions are important recognition elements for protein–protein interactions. For example, **SH3 domains** of proteins recognize proline-rich regions in other proteins.

Polyproteins

Large precursor proteins encoding one or more active **peptides** or **polypeptide chains** are referred to as polyproteins. Polyproteins are synthesized on ribosomes in the normal method of **protein biosynthesis**, transported into the lumen of the rough endoplasmic reticulum (ER) and then transported to the Golgi apparatus, where they are sorted into secretory vesicles. In this process, the proteins undergo a series of **posttranslational modifications** and are processed into multiple copies of the same peptide or into different polypeptides or proteins. Thus many peptide growth hormones (see Peptide Hormones) and signaling peptides are cleaved proteolytically from their precursor pro-hormones by endoproteinases at basic residues or pairs of basic residues at the recognition sequence. This often occurs in the secretory granules or vesicles, prior to exocytosis. Furthermore, the differential processing of the polyprotein in various tissues often leads to different sets of products (1).

For example, pro-opiomelanocortin (POMC) is a 32-kDa polyprotein that is processed to adrenocorticotropic hormone (ACTH) and b-lipotropin (b-LPH) in the corticotrophic cells of the anterior pituitary under the control of corticotropin -releasing hormone (CRH). However, alpha-melanocyte-stimulating hormone (a-MSH), corticotropin-like intermediary peptide (CLIP), g-lipotropin, and b-endorphin are the products generated in the intermediary pituitary under the control of dopamine (2) (see Fig. 1 of Peptide Hormones). Like many translation products, polyproteins also contain a signal peptide for transport into the ER that is cleaved before processing. In another type of polypeptide processing, multiple copies of enkephalin are contained within the enkephalin precursor

(3).

Other examples of polyproteins are found in the translation products of **viruses**. Production of the infectious human immunodeficiency virus (HIV), for example, requires proper polyprotein processing by the dimeric HIV viral proteinase to activate it. Other viral polyproteins include those of the hepatitis A, C, and G, rubella, dengue, poliovirus, foot and mouth disease, and yellow fever viruses. These polyproteins not only play a role in infection and disease, but they may be of use in gene therapy. Viral **vectors** are now being investigated as a means of expressing and delivering peptide drugs to patients with deficiencies or genetic mutations (4).

Likewise, hybrid genes in **transgenic** animals can control synthesis of human polyproteins that can be isolated from milk, subsequently processed into human proteins, and used as therapeutic drugs (5).

Polyribosome, Polysome

The ribosome binds to one end of a messenger RNA and initiates protein biosynthesis, moving along the mRNA. mRNAs that are being translated actively are associated with multiple ribosomes, forming polysomes. Because the length of mRNA covered by one ribosome is 30 to 35 nucleotides, the size of the polyribosome varies, depending on the length of the mRNA as well as on its translatability.

In prokaryotic cells, where translation and transcription are coupled in the same cellular compartment, mRNA is bound with ribosomes to start translation even before the transcript is complete, forming polysomes. The eukaryotic translation machinery has been found to be localized near the nuclear pore complex and to bind to the Cap signal of mRNA when translocated from the nucleus to the cytoplasm. During translation of eukaryotic secretary or membrane-associated proteins, ribosomes are bound to the endoplasmic reticulum (ER) through the signal peptide of the nascent polypeptide. The polysomes are visible there, giving this part of the endoplasmic reticulum the name *rough endoplasmic reticulum*.

Polysomy

In cases of *polysomy* , in contrast to **polyploidy**, there is only one kind of chromosome in the triple

or quadruple state in the genome, whereas all others have the normal diploid number. Many cases of polysomy have been described in the **plants** *Datura stramonium*, *Oenothera lamarckiana*, *Matthiola incana*, *Nicotiana tabacum*, *Lycopersicum esculentum*, and in the fly **Drosophila** *melanogaster*. Polysomy is generally constant over generations. A case worth mentioning is that of **trisomies** in man.

1. Klinefelter's Syndrome in Humans

Klinefelter's syndrome is characterized by the karyotype 47,XXY, in other words by the presence of an additional X-chromosome in the male genome. It is associated with high stature, hypogonadism (small firm testes), azoospermy and infertility, gynecomastia, bilateral cryptorchidism, obesity and in some cases, by minor mental retardation. Testicular biopsy has revealed hyperplasia of the Leydig cells, which contain microcrystalline formations, absence of annular lamellae in the Sertoli cells, and hyalinization of the seminiferous tubular membrane. A certain number of patients are diagnosed only by their sterility. Prolonged testosterone therapy is beneficial. Secondary sex characteristics increase and gynecomastia generally disappears.

In addition to the pure 47,XXY karyotype, patients having 48,XXXY and 49,XXXXY have been described. Hormonal examination of the patients of these two groups reveals hypoandrogenia and a relative hyperestrogenuria. The occurrence of Klinefelter's syndrome occurs in one of every 600 live births.

XX-males have also been encountered, without a Y-chromosome in the karyotype. From a study using restriction fragment length polymorphisms (**RFLP**), these XX-males seem to have inherited an X-chromosome from each parent. The results argue that this is not a genetic **mosaic** involving a Y-containing cell line in males, but they do not exclude an X-Y (or Y-autosome) chromosomal translocation during paternal **meiosis** (1).

Polytene

In certain types of secretory cells of fly larvae, all copies of homologous chromosomes remain side by side, creating a single, giant *polytene* chromosome. In some cases, large cells undergo a polytene to polyploid conversion, in which the chromosomes separate. This demonstrates that the basic structure of a polytene chromosome is similar to that of a normal chromosome.

Polytene Chromosome

Polytene chromosomes result from the duplication of **DNA** during the cell cycle without a following **mitosis**, so that the **chromatids** do not separate. Each **chromosomal** homologue (see Homologous Chromosomes) contains as many as 1,024 chromatids in *Drosophila melanogaster*. The process of

repeated rounds of DNA replication in a single **S-phase** is called Endoreduplication. If the chromatids separate and remain in the same nucleus, the cells are called Endopolyploid . Giant polytene chromosomes result when the chromatids do not separate. Polytene chromosomes are immense compared to the normal chromosomes found in a **diploid** somatic nucleus. All of the homologous pairs of chromosomes remain side by side, forming a single giant chromosome. Like lampbrush chromosomes, it is possible to isolate polytene chromosomes under physiological ionic conditions with their higher order chromatin structure preserved.

This integrity of structure has facilitated a great deal of informative cytological and **immunofluorescent** analysis of chromosomal structure. Immunologic staining has revealed the specific distribution of several non-histone proteins, including **RNA polymerase** II and proteins apparently responsible for the generation of inactive heterochromatin. Grossbach and colleagues used **antibodies** against variants of histone H1 to demonstrate that the localization of particular linker histones can be highly specific for individual chromosomal **domains** within polytene chromosomes (1). In contrast, a similar approach with antibodies raised against **HMG**14-related proteins leads to the general immunofluorescent staining of transcriptionally active domains. Turner found that individual chromosomal domains within polytene chromosomes are significantly enriched with forms of histone H4 that have particular states of **posttranslational modification** (2). In related experiments, it has been discovered that hyperacetylation of histone H4 on the male X-chromosome of *Drosophila* correlates with the increased transcriptional activity necessary for the phenomenon of **dosage compensation**. In this phenomenon, the transcriptional activity of all genes on the single male X-chromosome increases relative to genes on the other chromosomes, which are present in two copies per cell. These studies strongly suggest that chromosomes possess highly selective microheterogeneity in protein composition in which individual chromosomal domains contain particular histone variants or posttranslational modification states. Now important questions exist about how and why a particular protein or enzymatic activity leading to histone modification is targeted at an individual chromosomal domain. More detailed ultrastructural analysis, especially of the Balbiani ring genes in the polytene larval salivary glands of *Chironomus tentans*, has yielded much information concerning transcription, chromatin structure, and RNA processing.

Ponceau S

Ponceau S is a dye commonly used to stain proteins on blotting membranes (1). The formal nomenclature of Ponceau S [I] is 3-hydroxy-4-[2-sulfo-4-(4-sulfophenylazo)phenylazo]-2,7-naphthalenedisulfonic acid, tetrasodium salt. Its molecular weight is 760.58. Ponceau S is used primarily because it is simple and rapid. It is not very sensitive, however, requiring 200 ng of protein in a normal spot to be visible. Proteins appear red on a pink background. The staining is reversible, so the blot can be used after initial protein staining for a second detection method.

Pore Gradient Electrophoresis

It is often desirable to have a gradient of pore sizes for gel electrophoresis, to provide varying degrees of **molecular sieving** to mixtures of macromolecule differing in size. This can be accomplished by generating a gradient of gel concentrations while preparing the gel. During electrophoresis, the sample molecules will encounter varying pore sizes as they migrate in the gel, which will affect their electrophoretic mobilities to an extent depending on their sizes and shapes.

Gel concentration gradients are usually formed using polyacrylamide, but they can also be formed with agarose. Three kinds of gradient gels need to be distinguished, each serving a different purpose:

1. Pore gradients formed parallel to the direction of electrophoresis, using a gel concentration range that allows for the migration of the sample at all gel concentrations. The decreasing mobility of the faster-migrating species results in a compaction of the gel pattern of the sample, so that molecules differing drastically in their mobilities can be resolved on the same gel. This is especially important for **SDS–PAGE**, where a greater range of molecular weights can be resolved on a single gradient gel than on a normal gel.
2. Pore limit gels are similar to those in gradient gel 1, but the samples encounter gel concentrations high enough to virtually halt their migration (2). Such pore limit gels allow the particle size of the arrested species to be estimated by comparison of its "arrested" position with that of molecular size standards of the same shape.
3. The third variety has the gel gradient perpendicular to the direction of migration, for transverse gradient gel electrophoresis . A uniform sample applied across the top of the gel migrates at continually varying gel concentrations and pore sizes; a single gel can give an entire Ferguson plot of the electrophoretic mobility as a function of gel concentration.

The reproducibility of polyacrylamide gel gradients depends critically on the control of the polymerization reaction over the entire range of gel concentrations; such control may require more than the usual type of gradient maker. Suitable gradient makers and computer programs predicting pore gradient profiles of any shape and any slope are available (3).

Porin

Porins are membrane proteins of the outer membrane of Gram-negative bacteria, with an b-barrel architecture (1, 2). Although much more is known about bacterial porins, there are functionally and structurally similar proteins, known as voltage-dependent anion channels (VDACs), that are believed to be present in the outer membrane of mitochondria (3). Known porins are composed of 250 to 450 amino acid residues. Their function is to facilitate diffusion of small molecules across the membrane by allowing solutes to pass through an aqueous channel in the middle of the transmembrane b-barrel. Some porins are nonspecific and permeable to any solutes smaller than 600 Da, but they can be cation- or anion-selective, favor polar solutes over nonpolar ones, or have specific substrates, such as maltodextrins (a1–4-polyglucose) or sucrose. The rate of transport in the nonspecific porins is a linear function of the concentration gradient of the solute. In contrast, the specific porins follow Michaelis–Menten kinetics, indicating initial binding of the solute.

The porins for which three-dimensional protein structures have been determined are homotrimers containing three identical transmembrane channels. The OmpA protein of *Escherichia coli* is thought to be a monomeric porin with a barrel comprised of eight **b-strands**. The membrane-bound form of a-hemolysin, a bacterial toxin, belongs to the same structural class, because its transmembrane region comprises a 14-stranded antiparallel b-barrel (4). A similar structure has been predicted for the channel assembled by the bacterial toxin aerolysin in its heptameric membrane-bound form.

The size of the pore is determined by one or more extracellular surface loops of polypeptide chain that fold back into the channel. Although the 18-stranded b-barrel of glycoporins is clearly wider than the 16-stranded barrel of general porins, the latter have a wider channel because their intrachannel loop structures are less extensive. The width of the channel mouth (the eyelet) of the general porins is determined by one long and structured loop between adjacent b-strands, which controls access to the channel. In some porins, additional control is provided by a transverse electric field, which is generated by an uneven distribution of positively and negatively charged residues inside the channel mouth. In maltoporins and sucrose porin, the channel mouth is constricted by three surface loops. For this reason, it is much narrower than the eyelet in the nonspecific porins. There is an extensive binding site or an aromatic path for the sugar rings to be translocated (5-8). Suitably positioned partners for hydrogen bonds to the sugar hydroxyl groups assist the translocation process.

Porins have a number of peculiar properties. First, their sequences are at least as hydrophilic as are those of soluble proteins. Yet, the lipid-exposed surface of the b-barrel is highly **hydrophobic**, and the proteins are only soluble in the presence of a detergent. Second, the primary structures of porins form at least 10 families that show no clear sequence homology with each other. It appears that highly diverse primary structures can fold into very similar three-dimensional structures, as shown by the eleven porin structures presently known at atomic resolution (see Table 1 of Membrane Proteins). The sequences of the mutually homologous nonspecific porins of *E. coli* (OmpF and PhoE) are not related to those of the general diffusion porins from the phototrophic bacteria *Rhodobacter capsulatus* and *Rhodopseudomonas blastica*, or from *Paracoccus denitrificans*, despite the fact that all five fold into 16-stranded b-barrels. The maltoporin family has an 18-stranded topology and is not related to the nonspecific porins. Third, porins are unusually stable, forming trimers that are resistant toward **denaturation** by SDS, even at elevated temperatures. Perhaps owing to this high stability, porins appear to be relatively easy to crystallize, as shown by the existence of a number of high-resolution structures.

In fact, the first well-ordered crystals of a membrane protein were those of the *E. coli* OmpF porin grown in the late 1970s in Jürg Rosenbusch's laboratory in Basel. Owing to an unfavorable crystal symmetry, however, this crystal structure was not determined until 1995.

The diverse nature of porin primary structures, along with their hydrophilic nature, makes the assignment of a novel sequence as a porin problematic (see **Homology modeling**). The hydrophobic transmembrane b-barrel is composed of b-strands whose lengths range from 6 to 17 residues. Moreover, only every second residue of each strand faces the lipid core of the membrane and is consistently hydrophobic. Owing to the fluid nature of the bilayer core, only the hydrophobic nature of the lipid-facing residues needs to be conserved. The rest of the residues in the barrel can be either hydrophilic or hydrophobic, depending on whether they are exposed to the aqueous pore or buried in the protein structure. As with helical and monotopic membrane proteins, the strands are rich in aromatic residues in the region that interacts with the lipid headgroups (see a-Helix). A protein structure prediction method based on the detection of these interfacial aromatic residues and on the "every second residue hydrophobic" pattern correctly assigned 16 out of the 18 strands in maltoporin (9).

Because porins reside in the outer bacterial membrane, they must first be translocated through the bacterial inner membrane to the **periplasm**. To this end, the porin sequences carry an *N*-terminal **signal sequence**. The subsequent folding pathway is not known with certainty, but it has been proposed that the folding of porins begins in the aqueous periplasm by the formation of the trimer interface (2). The interface resembles the hydrophobic core of soluble proteins and could, therefore, form spontaneously before insertion into the membrane. The lipid phase would then induce the formation of the three b-barrels, because the barrel both satisfies the hydrogen-bonding requirement of the peptide groups and uses the hydrophobic effect in the interaction with the oily core of the bilayer. A trimeric porin that is indistinguishable from the natural molecules has been produced by heterologous expression by protein engineering, followed by protein folding in vitro from inclusion bodies in the presence of detergents.

Much of the biological interest in porins stems from the observation that in pathogens porins often are the **antigens** against which the host's **antibodies** are directed. Thus, porins from pathogenic bacteria could be used to raise antibodies and make vaccines. Maltoporin of *E. coli* is also called LamB, because it is the receptor for lambda phage.

Position Effect

Early studies by cytologists led to the realization that some **chromosomal** regions have properties distinct from the rest of the chromosome. Large segments of chromatin are highly condensed and replicate late in **S-phase**. Geneticists determined that these chromosomal regions, which they called heterochromatin, did not participate in meiotic recombination . However, heterochromatin does have significant genetic effects. The most common observed consequence of heterochromatin formation is repression of transcription in the heterochromatin itself and in regions of chromatin adjacent to the heterochromatin domain. The variability in **gene expression** at the border of the heterochromatin is described as "position effect variegation". The functional organization of the chromosome into discrete **domains** has been increasingly recognized through experiments in *Drosophila* that use the phenomenon of position effect. These experiments employ a powerful combination of techniques including genetic analysis and cytological observation of the large polytene chromosomes. The introduction of a normally active gene into a chromosome at a position adjacent to a transcriptionally inactive, condensed heterochromatin domain leads to significant repression of the transcription process. This is believed to occur through spreading of the heterochromatin structure into the normally active gene (see Heterochromatin). Thus, the expression of a gene depends on its chromosomal position, and hence the term position effect . This phenomenon provides a useful screen for genes and their products that suppress or enhance the repression of transcription because of position effects on a suitable reporter gene, often one influencing *Drosophila* eye coloration. Many of the genes modifying the position effect have been characterized and encode structural components of chromatin itself or are capable of modifying the organization of chromatin through enzymatic mechanisms.

The general properties of "modifier" genes that enhance or suppress position effect variegation provide some insight into how particular proteins might work to change chromosomal structure. The **phenotypes** of modifier mutations strongly depend on the number of gene copies within the cell. This has led to the proposal that the modifier proteins that assemble heterochromatin act through simple mass action. The more modifier protein in the nucleus, the more repressive heterochromatin is assembled. It is probable that certain modifier proteins cooperate to assemble multimeric complexes that alter the structure of entire chromosomal domains (1). The distribution of Polycomb along the chromosomal domain including the bithorax complex, which encodes three homeotic genes, supports this hypothesis. Orlando and Paro (2) found that the Polycomb protein is associated with transcriptionally inactive chromatin over more than 200 kbp of DNA, whereas it is absent from regions of genetic activity. The boundaries of Polycomb-associated chromatin and Polycomb-free chromatin are very distinct, which implies that regulatory elements exist that initiate and terminate Polycomb binding (2).

An important aspect of the functional role of the Polycomb proteins is that they are not involved in establishing the expression state of a particular gene but maintain the repressed state through DNA replication and chromosomal duplication. Because they act through large multicomponent complexes, it is possible that they might subdivide through a replicative event, thereby maintaining a repressive chromatin structure. Specialized mechanisms exist within the chromosome to enable the removal of Polycomb from chromatin and the resetting of chromatin to a transcriptionally competent state (3). The molecular machines involved in this process include the Brahma protein, which is structurally related to a component of the yeast general activator complex SNF2/SWI2. Evidence for competition between transcriptional activators and repressors, such as Polycomb, comes from experiments in which Polycomb-mediated transcriptional silencing is overcome by the expression of high levels of the transcriptional activator Gal4. **Immunostaining** of polytene chromosomes revealed that the Polycomb complex is removed from the vicinity of the Gal4 binding site without

the need for DNA replication and **cell division**.

Gottschling and colleagues (4) successfully established that position effect variegation also occurs in the chromosomes of *S. cerevisiae*. When a gene is located near a telomere, its transcriptional activity is reduced (4). Transcriptional repression at yeast telomeres is caused by the assembly of a distinct chromatin structure that initiates at the telomere. The sequence of the DNA is important, because internal tracts of telomeric DNA also act as silencers of transcription in *S. cerevisiae* . Mutations in the amino-terminal tails of histones H3 and H4 relieve transcriptional silencing. Histone H4 at the telomeres is hypoacetylated, and mutations in the acetyltransferases that **acetylate** the amino terminus also relieve silencing. DNA **methyltransferases** expressed in yeast have more restricted access to telomeric chromatin than to most of the chromosome. This implies that telomeric chromatin either is more compacted or is sequestered away from freely diffusible ***trans*-acting** factors in the nucleoplasm. Several other similarities also exist between yeast and *Drosophila* heterochromatin. In both cases, genes within heterochromatin are normally maintained in a stably repressed state but occasionally escape repression (5).

The efficiency of transcriptional repression decreases when a gene is placed further from the *S. cerevisiae* telomere (over a 10- to 20-kbp range). This result supports the idea that a repressive chromatin structure originates at the telomere and spreads along the chromosome. The expression of protein SIR3 influences the extent of silencing at the telomeres, suggesting that it is essential for assembling repressive chromatin (6). SIR3 and the histone tails are also involved in sequestering yeast chromosomal telomeres at the periphery of the nucleus. Thus telomeric silencing could be related to the sequestration of this portion of the chromosome within a transcriptionally incompetent compartment of the nucleus adjacent to the nuclear envelope (7).

Many of the modifiers of the position effect in yeast chromosomes are shared between the telomeres of the chromosomes and the silent **mating-type** cassettes in yeast. Mutations in four *s*ilent *i*nformation *r*egulator genes, SIR1, 2, 3, and 4, cause derepression of the silent mating-type cassettes. Mutations in three of these, SIR2, 3, and 4, influence telomeric repression. The assembly of specialized chromosomal domains at the silent mating-type cassettes is reflected in the more limited access of restriction enzymes to DNA at these sites than at bulk chromatin. The silencers at the mating-type cassettes are required to reestablish the transcriptionally repressed state after each round of replication. This indicates that repressive chromatin structures do not self-template the reassembly of a repressive structure. It is possible that both the telomeres and the mating-type cassettes are sequestered in specialized nuclear structures or compartments in which the transcriptional machinery does not function efficiently.

Recent results also implicate heterochromatin-mediated silencing mechanisms in the nucleolus, the site of ribosomal RNA transcription. SIR2, SIR4, H2A, and H2B influence the transcription of genes requiring RNA polymerase II that are integrated into ribosomal DNA. Remarkably, silencing also controls aging in yeast. Interference with the targeting of silencing complexes by expression of mutant forms of SIR4 allows yeast to live longer (8). Nucleolar organization is implicated in this phenomenon, because mutant SIR4 proteins localize to the nucleolus. In the fission yeast *Schizosaccharomyces pombe*, the determinants of gene silencing and heterochromatin assembly at the silent mating-type cassettes are shared with the centromeres (9).

The existence of these diverse sites of heterochromatin-mediated silencing has led to the idea that competition exists to limit components and that the telomere might act as a molecular sink to form a reservoir of silencing factors. Alternatively, individual targeting factors, such as SIR1 at the mating-type loci, might modulate the stability of heterochromatin assembly.

Position effects in mammalian chromosomes have been a recurrent problem for **transgenic** research, because highly variable levels of transcriptional activity follow from the random introduction of reporter genes into the genome (10, 11). These effects are relieved by introducing a **locus control region** (LCR) that exerts a dominant transcriptional activation function over a chromatin domain (10

to 100 kbp). The mechanism of this activation function remains to be determined. Communication between LCRs, **enhancers** and **promoters**, however, either directly or through modifications of chromatin structural components, are favored hypotheses. Recent evidence suggests that both the locus control regions and enhancers act in cis to suppress position-effect variegation actively. In this regard, locus control regions function as operationally defined "powerful" enhancers. The coexistence of heterochromatin domains that transmit repressive effects and the definition of the extensive long-range activation function of LCRs emphasize the necessary compartmentalization of the chromosome into discrete functional units. These discrete functional units are prevented from influencing each other in a natural chromosomal context because of, in part, the existence of special chromosomal regions that prevent the transmission of chromatin structural features associated with the boundaries of repressive or active domains. These specialized chromosomal regions are known as insulators (see Domain, Chromosomal).

The original evidence for an insulator function within the chromosome came from genetic experiments in *Drosophila*. Each boundary of the 87A7 **heat-shock** locus is defined by a pair of nuclease **hypersensitive** sites bordering a 250- to 300-bp segment of DNA. These specialized chromatin structures (scs) are located at the junctions between the decondensed chromatin of the transcriptionally active 87A7 heat-shock locus and adjacent condensed chromatin. The scs elements have three functional properties: (1) they establish a domain of independent genetic activity at many distinct chromosomal positions; (2) scs elements are necessary at each edge of the domain; and (3) independently the elements are neither inhibitory nor stimulatory to transcriptional activity within the domain (12). Subsequent work found that introducing an scs element between an enhancer and a promoter blocks communication between the two regulatory DNA sequences. Thus, the scs elements prevent both the transmission of repressive effects on transcription from proximity to heterochromatin and the transmission of stimulatory effects on transcription from an enhancer. How this insulation is achieved is unknown. Moreover, the nature of the nucleoprotein complex assembled on the scs elements has yet to be defined. Fortunately, similar phenomena have been described that are associated with a well-defined nucleoprotein complex between the *Drosophila* suppressor of hairy-wing protein [su(Hw)] and the gypsy retrotransposon (13).

Insertion of a gypsy element as far as 10 to 30 kbp away from a promoter causes a mutant phenotype. The mutant phenotype requires the su(Hw) protein to interact with the inserted gypsy element at a 350-bp region containing 12 copies of a 10-bp sequence separated by AT-rich sequences. The su(Hw) protein has a molecular weight of 100 kDa, and its sequence includes several motifs characteristic of eukaryotic transcription factors, including 12 **zinc fingers**, a leucine zipper and two acidic **domains**. The complex of the su(Hw) protein with a gypsy element has many of the properties of an insulator element. The complex blocks enhancer activity when placed between an enhancer and a promoter, and when the complex is placed at the boundaries of a gene-containing fragment, the gene is protected from the repressive effects of heterochromatin on transcription (14).

Although in certain circumstances the su(Hw) protein does not independently stimulate or repress transcription of a reporter gene, the su(Hw) protein occasionally functions as a transcriptional activator. This suggests that the function of an insulator may be conferred on sequences by DNA-binding proteins that under other circumstances might have more conventional roles in the transcription process. Although it is clear that the su(Hw) protein does not bind to scs elements, it seems likely that these elements form large nucleoprotein complexes with a similar composition.

How might insulators function? Any models must explain how characteristics of both repressive or active chromatin are restricted to particular chromosomal domains. Several models have been suggested to explain the activities of LCRs and enhancers (Fig. 1). These elements might function as entry points for transcription factors, RNA polymerase, or other components of the transcription machinery, which then might track along the DNA until reaching the promoter. Alternatively, the LCR or enhancer complex might associate with the promoter complex by stable looping of the intervening DNA or chromatin, forming a complex that increases the efficiency with which RNA polymerase is recruited and used. Another possibility is that the LCR or enhancer complex might

cause the gene to assemble into a chromatin structure capable of being transcribed through its association with nuclear compartments (or **organelles**) that act as transcription factories or associate with proteins that modify repressive chromatin structure by disrupting nucleosomes. Similar models can explain the repressive effects of heterochromatin. Repressive chromatin proteins, such as the *Drosophila* HP1 protein or histone deacetylases, may undergo local diffusion to adjacent DNA sequences, enlarging the heterochromatin domain. Alternatively, heterochromatin may be sequestered in a transcriptionally incompetent region of the nucleus.

Figure 1. Models to explain the actions of insulators on the activities of locus control regions/enhancers and heterochromatin. (a) Enhancers could communicate with promoters by acting as entry sites for processive enzymes that track along DNA (entry), they could make direct contact with the promoter to enhance function by looping out intervenii DNA (looping), or they could direct the chromatin domain containing the promoter to a compartment of the nucleus competent for transcription (nuclear localization). Insulators could block each of these functions as indicated. (b) Proximity to heterochromatin leads to position effect variegation on adjacent genes. This could be caused by simple diffusion of repressive heterochromatin proteins to otherwise active genes in euchromatin (diffusion), or it could be caused by inappropriate nuclear localization in an environment that is not competent for transcription (nuclear localization). Insulators could block each of these functions as indicated.

In considering these models, it is important to recognize that the eukaryotic nucleus is a highly organized structure in which DNA is compacted into nucleosomes and the chromatin fiber by its association with histone proteins. Although it is possible that insulators prevent protein tracking or diffusion between active and repressive domains, it is difficult to envisage how this might occur in the nucleus—where DNA segments separated linearly by many kilobases can be juxtaposed by the folding of the DNA helical axis in three dimensions-without invoking some specific attachment of inactive chromatin domains, insulators, and active chromatin domains to a nuclear framework. Similar attachments might be required to prevent the juxtaposition, of LCRs, enhancers, and promoters as a result of DNA looping. Perhaps the most economical suggestion is that insulators are nucleoprotein complexes that associate neither with regions nor structures in the nucleus where "transcription factories" load on to DNA nor with regions or structures from which the transcriptional machinery is excluded (15, 16). Instead, the insulators might associate with distinct "neutral" nuclear structures. The "neutral" nuclear structures would tether promoter elements where the transmissible activating effects of enhancers or silencing effects of heterochromatin could not occur. This absence of transmissible effects could be accounted for by the exclusion of particular transcriptional coactivators or corepressor from the "neutral" nuclear structures.

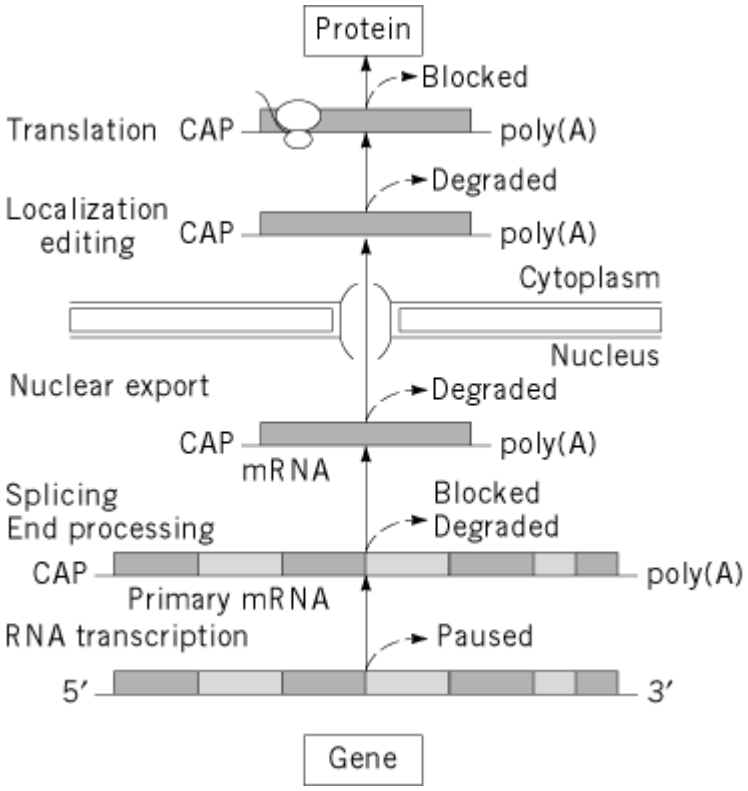
Post-Transcriptional Regulation

The synthesis of RNA in transcription is a selective process. Eukaryotic cells contain three types of **RNA polymerase** that transcribe DNA into RNA, whereas bacteria contain only one. The **enzyme** RNA polymerase II converts about 1% of eukaryotic cell DNA into messenger RNA (mRNA), the

template that codes for translation of new proteins in **protein biosynthesis**. Cells adopt many strategies to decide how and when a given **gene** should be expressed. Within eukaryotic cells there are numerous post-transcriptional steps available for regulating protein production, commencing with transcription of the primary mRNA in the nucleus and culminating with its eventual translation into protein in the cytoplasm (see Fig. 1). Newly synthesized precursor mRNAs, or primary mRNA transcripts, are usually quite large (10–20 kb), due to the presence of **intron** sequences, which are subsequently removed by RNA splicing. The 5′ and 3′ ends of the primary transcript require modification in the nucleus, and only then is the mature mRNA transported to the cytoplasm, where it is directed to the desired location and translated into protein. Therefore, several steps are involved in the conversion of a primary mRNA transcript into a polypeptide chain, and each level provides a locus for cellular fine-tuning (see Fig. 1).

Figure 1. The cellular pathway of protein synthesis: from gene transcription to mRNA translation. The major processes in this pathway are shown on the left side of the figure. Some of the potential effects of regulating these events are indicated by broken arrows. The gene-coding exons (dark gray) and introns (light gray) are as shown.



1. In the Nucleus

The process of protein biosynthesis comprises several discrete steps, some of which are likely to be integrated. The nucleus is a dynamic cellular structure, and the transcription of genes into mRNA occurs at specific sites in the nucleus, during which the growing mRNA chain becomes complexed with many different proteins.

1.1. Transcriptional Attenuation

Some genes in bacteria and eukaryotes are blocked at the level of transcriptional **attenuation**, where the transcribing polymerase pauses at a specific site on the DNA template. This event can regulate the rate of expression of certain genes, such as the c-myc oncogene in differentiated leukemia cells (1).

1.2. Capping

Primary mRNA transcripts (but not other RNAs) are modified at the 5′ end by the addition of a 7-methylguanosine cap . This “capping” reaction occurs almost immediately after the RNA chain is initiated, and the modification is required for subsequent events, which include the splicing, nuclear export, stability, and translation of each mRNA. The cap structure forms a stable complex with nuclear proteins that mediate some of these nuclear processes (2). Once the mature mRNA reaches the cytoplasm, the mRNA cap is bound by a different set of proteins that help facilitate translation.

1.3. 3′-End Processing and Polyadenylation

The primary mRNA transcripts of eukaryotes undergo more complex and regulatable processing at the 3′ end than in bacteria, and they contain two types of cleavage signal (AAUAAA and a less well-conserved GU-rich element nearby). This cleavage/polyadenylation sequence is located in the 3′-untranslated region (UTR), the noncoding end of the mRNA that follows the translation **stop codon** . Once the newly formed primary transcript is cleaved, a poly(A) polymerase enzyme adds a polyadenylate tail of about 100–200 A residues to the 3′ terminus of the RNA (3). Specific binding proteins associate with the poly(A) tail and are capable of enhancing the stability, translation, and nuclear export of the mature mRNA (4). The degree of polyadenylation can be regulated in the nucleus by splicing factors, such as U1A snRNP (3). Many genes contain multiple cleavage/polyadenylation sites, giving rise to different length transcripts in certain types of cell or tissue.

The combination of 5′ cap and 3′ poly-A tail identify the mature mRNA as a complete coding unit, and these end modifications are required for later translation of the mRNA template in the cytoplasm. The **histone** genes represent the only known exception. Histone mRNAs are synthesized without introns and are not polyadenylated; they contain a 3′-end stem-loop structure that mediates an alternate processing pathway for this mRNA (5).

1.4. Splicing

In higher eukaryotic cells, the growing primary transcript forms large complexes with different proteins, many of which include the abundant heterogeneous nuclear **ribonucleoprotein** particle (hnRNP) proteins. At the junctions between intron and exon, a spliceosome (RNA splicing complex) develops on the pre-mRNA and is responsible for removal of intron sequences from the immature transcript (6). The spliceosome machinery comprises many proteins, often complexed with small stable RNAs (6). Completion of the splicing process is required for continued processing of the primary transcript, and eventual export of the mature mRNA to the cytoplasm.

1.5. Alternative RNA Splicing

The process of pre-mRNA splicing involves not only distinguishing the junctions between exon-coding sequences and the intervening introns but also excising unwanted introns and religating the correct exon termini. The detailed orchestration of this procedure also provides a means for altering the gene product, essentially by religating different exons together. This is known as alternative splicing, and it provides a potent mechanism for generating not only different mRNAs but also different polypeptide chains, from a single gene. Some genes contain ambiguous splice sites, and as a result generate several alternative gene products in most cell types and tissues. The regulation of alternative splicing is observed more frequently during the tissue-specific expression of genes, and during development of higher eukaryotes (7). Alternative splicing can be effected by specific exon or intron sequences, examples of which occur in the genes for human growth hormone, cardiac troponin T, fibronectin, and the nerve-cell-specific form of the c-***src*** **oncogene**. The sex-determination genes of *Drosophila melanogaster* (sex-lethal, transformer and doublesex) currently represent the best characterized regulatory system of alternative splicing. In this example, both the pre-mRNA target sequences and the regulatory **RNA-binding** factors that block or activate splice site selection are well defined (6, 7).

1.6. Pre-mRNA Stability

Most RNA synthesized in the nucleus is degraded, and inappropriate splicing or end modification may sentence a primary mRNA to the same fate (see RNA Degradation In Vitro). The RNA-degrading enzymes are **ribonucleases**, and they operate in both bacterial and eukaryotic cells. The expression of many genes is, in fact, determined by regulated degradation of the primary nuclear transcript. This type of regulation can sometimes correlate with disease. For example, the gene encoding a cancer-associated proteinase, urokinase, is efficiently transcribed in both malignant and benign cancer cells derived from rat mammary tumors, but the **proteinase** is not well expressed in the nonmalignant cells, due largely to nuclear degradation of the primary transcript (8). Certain examples of **nonsense codon**–mediated mRNA decay, signaled by the presence of a premature stop codon, also occur in the nucleus. Although progress in this area has been slow, it seems likely that regulated nuclear RNA degradation, like the constitutive breakdown of excised intronic RNA, is somehow linked to RNA splicing and modulated by RNA-binding proteins, such as the hnRNPs (9).

1.7. RNA Export

Once spliced and processed, the mature mRNA transcript travels to the cytoplasm through the nuclear pore complex. The mRNA molecules do not exit the nucleus unescorted; they are chaperoned by proteins, some of which contain nuclear export signals (see Nuclear Import, Export). The mRNA translocates through the pores as part of a large ribonucleoprotein complex, of which some nuclear proteins are later replaced by cytoplasmic factors, to facilitate further movement of the mRNA or its translation into protein. The most common proteins to accompany exported mRNAs include the cap-binding complex proteins CBP20 and CBP80 and the hnRNPA1 shuttling protein (10). The cap-binding complex proteins also mediate U **small nuclear RNA** (snRNA) export in mammals and yeast. Different types of RNA, such as transfer RNA and **ribosomal** RNA, lack a cap structure, and their export requires interaction with specific carrier proteins. TFIIIA and **La** proteins are implicated in export of 5 S rRNA. The tRNA export receptor (termed exportin-t) was recently identified (11).

There is growing evidence that different types of mRNAs interact with very specific regulatory proteins, which either impede or enhance the rate of nuclear export. **Viruses** provide the best studied examples of regulated mRNA export. For example, unspliced intron-containing **HIV**-1 pre-mRNA is effectively exported, while cellular host pre-mRNAs remain anchored in the nucleus by the spliceosome. The HIV-1 pre-mRNA contains specific signals that redirect its nuclear location and target binding of the HIV Rev protein, which facilitates rapid nuclear export of the viral pre-mRNA. It is anticipated that several cellular mRNA-binding carrier proteins, containing export signals analogous to that of the Rev protein, will soon be identified. One potential candidate is HuR, a nuclear-cytoplasmic shuttling protein that binds to AU-rich mRNA instability elements, which may possibly enhance both the nuclear transport and stability of specific mRNAs (12). There is, in addition, evidence for vectorial transport of RNAs from the nucleus. The transcripts of the *Drosophila* **pair-rule gene** family (eg, even-skipped, hairy, and runt) exit from the apical side of the nucleus, and this directionality is dependent on sequences in the 3′-untranslated region of the RNAs (13).

2. In the Cytoplasm

2.1. mRNA Localization

In the cytoplasm, eukaryotic mRNAs interact with ribosomes that continuously translate the mRNA sequence into specific polypeptide chains. Genes that encode secreted proteins contain a unique sequence that, when translated at the amino terminus of the growing polypeptide chain, directs the translation complex to the endoplasmic reticulum, a **polyribosome**-coated organelle that surrounds the nuclear envelope. Some processed mRNAs contain sequences at the 3′ end that signal movement of the RNA, prior to translation, to defined locations in the cytoplasm. In this way, simply by relocalizing the mRNA, the cell is able to direct efficiently the site-specific accumulation of certain proteins.

Some mRNAs appear to be routed throughout the cell, not by passive diffusion, but through

association with proteins that interact with the cell's cytoskeleton. There is evidence in *D. melanogaster* oocytes that the mRNAs encoding the developmental proteins bicoid and **oskar** are transported in association with Staufen protein along microtubules to the anterior and posterior poles of the oocyte (13). Again, microtubule association is inferred for movement to the vegetal pole of Vg1 mRNA in *Xenopus laevis* oocytes. While the muscle b-actin mRNA appears to travel along microtubules in nerve cells, it associates only with actin filaments in fibroblast cells (13). Interestingly, the localization of b-actin is responsive to growth factors, and b-actin mRNA in chicken fibroblasts moves rapidly to the leading edge of the cell, where it is translated into actin filaments that influence cell motility. The proteins that bind to the actin and Vg1 mRNAs contain potential nuclear export signals, and they possibly chaperone the transcripts from the site of transcription/splicing in the nucleus, to that of translation in the cytoplasm. Other examples of localized mRNAs have been identified, and current study is focused on understanding the molecular mechanisms responsible for cytoplasmic mRNA movement.

2.2. mRNA Translation

The translation process itself can be influenced, most often by mRNA-binding proteins. The mRNA signal sequences that define the AUG initiation codon differ between bacteria and eukaryotic cells, although in all cases the mRNA is scanned by ribosomes in a 5′–3′ direction, and then translated into protein. In eukaryotes, translation initiation is dependent on the 5′-cap structure, and the translation process is subject to several levels of cellular control. mRNAs are translated in the cytoplasm by free or membrane-bound **polyribosomes**. The 5′ cap is recognized by the **initiation factor** eIF-4E, which recruits other proteins to form a functional cap-binding complex. The cap-binding complex, in turn, targets binding of the small 40 S ribosomal subunit (as part of a 43 S complex with additional factors). The resulting pre-initiation complex then scans along the mRNA, and following recognition of the initiation codon and binding of the 60 S ribosomal subunit, the mRNA open reading frame is translated (14). The cell may control translation by modifying some of the general initiation factors, or by shifting the balance of these factors in the cytoplasm.

Translation initiation of specific mRNAs can be regulated by RNA stem-loop structures near the 5′ cap. There are a few examples both in eukaryotes and bacteria, but the best studied case is the post-transcriptional regulation of vertebrate iron homeostasis. This is mediated by specific RNA stem loops near the 5′ cap of **ferritin** mRNAs and some other transcripts. When iron levels are low, iron regulatory proteins 1 and 2 bind the stem-loops and inhibit translation, presumably by interfering sterically with formation of the 43 S pre-initiation complex (14). High levels of intracellular iron relieve the translational block. Translation control signals can also occur at the 3′ end of mRNA. While all mRNAs undergo constitutive polyadenylation in the nucleus, the poly(A) tails of certain mRNAs are modified in the cytoplasm during early development in vertebrates, amphibians, and insects. Specific enzymes lengthen or shorten the poly(A) tail in the cytoplasm; a longer poly(A) tail (150–200 nucleotides) generally enhances translation of maternal messages during oocyte maturation and fertilization, whereas shorter poly(A) tails of less than 50 nucleotides block translation (14).

mRNA translation control signals have also been identified between the 5′ cap and 3′ poly(A) tail. Such elements were observed in the 3′ UTR of the 15-lipoxygenase mRNA and the mouse protamine 2 gene; both RNA signals bind to proteins that regulate translation. Other mRNAs contain similar regulatory elements within the actual protein coding sequence. An interesting example of this type is thymidylate synthase, which also represents the best defined case of translational autoregulation. Thymidylate synthase is an enzyme involved in DNA precursor biosynthesis, and it doubles in function as an RNA regulator, capable of binding and regulating translation of its own mRNA, in addition to mRNAs encoded by other genes (15). These examples are likely to represent a form of cross-talk between the 5′-bound pre-initiation complex and the distant site of regulation, but the mechanisms involved are not yet defined.

Finally, additional methods of translation control include signal-mediated pausing or stalling of the ribosomes, and ribosomal frameshifting, in which ribosome translocation is shifted one base out of

frame, thus producing a protein of different sequence. There are only a few examples of pausing and frameshifting, and the latter event is used primarily by eukaryotic and bacterial viruses.

2.3. mRNA Stability

Bacterial cells divide much faster than eukaryotic cells, and bacterial mRNAs are degraded at correspondingly faster rates. Most bacterial mRNAs are stable only for a matter of minutes, while some eukaryote mRNAs are stable for many hours. The mRNAs encoding **stress-response** or growth-responsive proteins, such as transcription factors and growth factors, are often degraded with minutes. Cellular stresses such as viral infection, growth-factor signaling, hypoxia, and other environmental changes can decrease, or extend, the rate of mRNA degradation.

In eukaryotes, the rate of cytoplasmic mRNA decay is regulated by mRNA-binding proteins. In addition to the poly(A) tail, control elements have been identified in the mRNA coding sequence and in the 3′ UTR. The interaction of specific proteins can protect the mRNA against attack from ribonucleases. Deadenylation, or shortening of the poly(A) tail, is an initial step in the decay of many mRNAs. The formation of a complex between the poly(A)-binding protein and the poly(A) tail stabilizes mammalian mRNAs, but it displays the opposite effect in yeast (16).

The 3′-untranslated region of many unstable growth factor and **oncogene** mRNAs contain instability signals, sequences rich in adenosine and uridine. These AU-rich elements fall into distinct classes, bind a variety of cellular proteins, and vary in their ability to modulate mRNA stability *in vitro*. Some of the AU-rich element binding proteins, such as the HuR protein, shuttle between nucleus and cytoplasm, and thereby they might associate with mRNAs soon after synthesis in the nucleus, acting as mRNA chaperone, as well as guardian against degradation. In other instances, the RNA stability signal is a hairpin or stem-loop structure, such as that occurring at the 3′ end of histone mRNA, or the cluster of five iron-response elements (IREs) in the 3′ UTR of transferrin receptor mRNA. When iron levels are low, the iron regulatory proteins bind to the IRE stem loops and protect transferrin receptor mRNA from degradation. This model for regulated mRNA stability is critical for maintaining iron homeostasis in the cell, and many other examples of such control are likely to occur.

There are several candidate ribonucleases specific for mRNA, but none has yet proved to play a major role in cytoplasmic mRNA degradation. General degradation of mRNAs occurs in a 3′–5′ direction and often is preceded by deadenylation. Some mRNAs, like transferrin receptor, are instead cleaved at specific sites by endonucleases, thereby generating an unprotected 3′ end susceptible to rapid exonuclease activity (16). Bound regulatory proteins are likely to modulate degradation by either specific endonucleases or general exonucleases.

2.4. mRNA Editing

Finally, various examples of RNA Editing (ie, specific nucleotide sequence alterations) have been identified in several organisms. One of the more intricate and extensive types of editing involves insertion and/or deletion of uridine residues in the mitochondrial RNAs of the trypanosome parasites. This type of editing is directed by a small class of RNA, termed **guide RNAs**, and results in a range of RNAs of varied sequence and reading frame. Additional types of editing have been observed in plants and higher eukaryotes. Several examples of single base alterations mediated by specific enzymes have been reported, leading to gene-specific changes in mRNA reading frame, or creation of new stop codons. As in the case of alternative splicing, a cell can use RNA editing to diversify the end products derived from a single gene.

Post-Translational Modifications

All naturally occurring proteins and polypeptide chains are primarily made up of the 20 amino acids, 21 including selenocysteine, dictated by the genetic code. To achieve the myriad of detailed functions required to support life in its varied forms, including the essential processes of translocation, regulation, activation, and turnover, a large number of additional modifications are required. These changes are introduced into both the polypeptide backbone and the majority of the amino acid side chains. For the most part, these occur either during the formation of the polypeptide chain during translation or at some point following chain termination. Thus, these alterations are labeled as either co- or post-translational. In some cases, however, reactions may occur at both stages, or at a time when that distinction is not clear. There are also a limited number of amino acid modifications that can occur after the formation of the charged transfer RNA species, but before

incorporation of the amino acid during translation, and it has been suggested that these be referred to as “pre-translational” to distinguish them from the co-/post-translational changes. The extent to which co-/post-translational modifications occur must await the complete characterization of all the proteins specified by the genome of any organism. Even excluding the actual **proteolysis** associated with **protein degradation**, it can be safely concluded that they will be very widespread, affecting nearly all proteins.

1. Function and Reversibility of Protein Modifications

Protein synthesis is predominantly a cytoplasmic process. A very small amount of synthesis occurs in organelles such as the **mitochondrion**, which reflects its endosymbiotic origin from prokaryotes, and hence can actually be thought of as being similar to cytosolic synthesis in these organisms. This is also manifested in many of the distinguishing characteristics of this process in mitochondria. Proteins must function in other cellular locations as well, however, and in these cases they must be translocated in an efficient fashion. Inability of the cell to place a protein correctly in its proper environment, despite the fact that it may otherwise be functional, is generally equivalent to a mutation or deletion that results in loss of function. Proteolytic events direct these translocation processes, as well as several additional changes that occur as a result of the transfer. In the case of both the endoplasmic reticulum (ER) and the mitochondrion, the translocation is accompanied by the transfer of the protein molecule across active membranes in an energy-dependent fashion, requiring the protein molecules to be in an unfolded state. Molecular chaperones, proteins that assist in the folding/unfolding process, are essential to complete these transfers, although they themselves do not introduce any modifications directly. Transport of proteins out of the cytoplasm into other organelles, **vesicles**, or eventually to the extracellular milieu, is a vectorial process, requiring essentially irreversible covalent changes (1).

In addition to the modifications that can occur on proteins during and after translocation, numerous covalent changes also occur on proteins that remain in the cytoplasm, or that are eventually transferred to the nucleoplasm. This group of reactions is designed primarily to induce the formation of active structures or to modulate or regulate these activities, and they involve almost exclusively the modification of amino acid side chains. In contrast, proteins that function in the compartments of the endoplasmic reticulum, Golgi apparatus and *trans*-Golgi networks, including the extracellular space, are frequently subject to additional backbone processing to generate active molecules.

The distinction between reversible and irreversible modification is of major significance, because these two forms of modification are used to achieve distinct cellular goals. Covalent modifications that are designed to drive a process in a single direction, such as the transfer of a protein from the cytoplasm to the extracellular environment, are almost always accompanied by irreversible change. Similarly, covalent modifications that are meant to contribute to the destruction of the cell and its components are usually of a similar nature. In addition, modifications that induce constitutive activity also tend to be permanent modifications, and generally require protein turnover and new synthesis to regulate their levels of activity. In contrast, changes that fine-tune the activity of enzymes, but are seldom actually involved in the catalytic process, are often reversible in nature. These tend to be associated with rapid, short-range responses, while the former are related more to long-range effects. Since most chemical modifications of proteins are formed through enzymatic catalysis, it follows that modification of a reversible type will have specific enzymes that catalyze both the addition and removal of the modifying group.

It should be emphasized that the reversibility of a chemical modification must be defined in a biological, not chemical, context. Thus, for example, the introduction of disulfide bonds into proteins is fundamentally irreversible under most physiological conditions, even though their cleavage by reduction or oxidation can be readily achieved, and often is, in the laboratory. *N*-Terminal acetylation, as a cotranslational event, is also basically an irreversible change because there are no deacetylase enzymes for removing this modification on peptides larger than two or three amino acids, despite the fact that the amide bond is readily hydrolyzed under a number of conditions.

Clearly, the irreversible nature of many structural modifications results from the lack of appropriate enzymes to catalyze the opposite reaction, rather than from an unfavorable thermodynamic situation.

It is also important to distinguish the controlled or regulated modifications that occur as the result of cellular function from those that happen in an uncontrolled manner. These can be both enzymatic and nonenzymatic in nature. Intracellular random proteolysis is an excellent example. Although it is unclear to what extent such reactions occur, the recent identification of a number of intracellular proteinases (eg, caspases) suggests that this may be a more extensive phenomenon than has been previously recognized. Even inactive forms of these enzymes can have some latent activity, albeit considerably less than the mature enzyme. It must be presumed that there are viable scavenger pathways for removing the fragments that are generated by these cleavages. Nonenzymatic modifications also result from the generation of various species, such as free radicals, that can arise from a variety of environmental conditions. These reagents can induce a host of chemical modifications, some of which are deleterious, particularly in biological macromolecules. This is particularly true of proteins and nucleic acids, and certainly a significant amount of cellular and genetic damage, which may be a major contributor to many pathologies such as cancer and aging, results from these modifications. Although there are appropriate mechanisms for removing or reversing inappropriately generated derivatives of both proteins and nucleic acids, the principal means for removing altered protein molecules is degradation and resynthesis.

2. Non-Enzymatic Modifications

Although apparently nonenzymatic modifications of proteins may be relatively common, it is often difficult to verify that any given modification is truly nonenzymatic under physiological conditions. For example, cyclization of amino-terminal glutamine residues to pyrrolidone carboxylic acid is well known to occur readily in solution under mild conditions. Thus, it might be logically concluded that this modification would occur and be found to a significant extent in all proteins with this sequence. There is, however, substantial evidence that there is a cyclase enzyme for carrying out this modification, at least with some substrates.

Many of the nonenzymatic modifications involve cleavage of the polypeptide backbone, including transpeptidation (see text below) and the modification of the a-**amino group** by reducing compounds, most commonly, sugars. Other modifications that occur nonenzymatically include the deamidation of asparagine and glutamine residues; the introduction of side-chain **crosslinks** to stabilize large multicomponent complexes, such as **blood clots**; the oxidation of certain amino acid side chains; and the conversion of serine and cysteine residues, usually in substituted form, to dehydroalanine, which, in turn, can readily react with lysine and histidine residues nonenzymatically, to form a new amino acid that can serve as an inter- or intramolecular crosslink.

The physiological relevance of these changes is for the most part difficult to determine. For example, it has been suggested that the deamidation of asparagine and glutamine in proteins, which varies in rate according to the surrounding amino acid sequence and the local conformation, may act as a biological clock, controlling turnover in at least some protein molecules. This hypothesis remains unsubstantiated. Some of the changes that occur, such as the formation of glycosylated derivatives of the a-amino group of long-term stable proteins, can be useful markers for monitoring pathological events, for example, the levels of the sugar-modified hemoglobin A1c are useful for monitoring diabetes. As noted above, random modifications by highly reactive species that may effectively inactivate the function of a molecule cannot be easily characterized, but they clearly contribute to some pathologies.

3. Enzymatic Modifications

3.1. Peptide Bond Hydrolysis

The cleavage of peptide bonds, formed during protein biosynthesis, is a major form of post-translational modification and can occur throughout the lifetime of a protein molecule. In functional

terms, such reactions can be grouped into three categories: (1) stabilization/translocation, (2) activation, and (3) degradation. The enzymes that catalyze all of these modifications act by removing single amino acids from either termini (exopeptidases) or by cleaving internal peptide bonds (endopeptidases). They can generally be sorted into several large families that are characterized by the reaction mechanism utilized (2).

Stabilization–translocation modifications occur primarily at the amino terminus, usually during protein biosynthesis; that is, they are co-translational. Virtually all protein synthesis is initiated with methionine or *N*-formyl-methionine in prokaryotes. The formyl group is added to the methionine as a "pre" modification. The formyl group is first removed by a deformylase in prokaryotes, and the methionine can be removed subsequently by a highly specific aminopeptidase. The specificity of this enzyme is well conserved and is defined primarily by the residue adjacent to the methionine (3). The 7 smallest amino acid side chains (as defined by the radius of gyration) are substrates, while the remaining 13 are generally not. This specificity matches well to that of the ***N*-end rule**, a mechanism that defines the rate of degradation of proteins and depends on recognition of amino-terminal residues (4). Thus, the retention of methionine by the proteins with the 13 largest amino acids protects them from premature degradation. In most organisms, it appears that proteins with the smaller amino acids at the *N*-terminus represent the largest class of proteins, as well as the largest amount of proteins on a mass basis. Thus, the majority of proteins are degraded, presumably to release methionine to allow for more protein synthesis initiation, as well as for other purposes.

As noted above, translocational reactions also involve protein hydrolysis, but usually at an internal site. Proteins to be transferred into the ER or mitochondrion have an *N*-terminal **signal sequence** that is first removed by specific enzymes appropriately located on the lumen side of the membrane to be transversed and subsequently degraded. The efficient removal of this entity prevents the protein from returning to the cytosolic compartment. The sequences defining the cleavage sites are well defined in both cases (5, 6).

The peptide bond cleavages that produce active proteins from a prohormone or proenzyme are of a more diverse nature. For the most part, these reactions occur in the ER continuum. However, other molecules can also be activated with entirely different functions, such as the structural protein collagen. The processing of these precursors is well defined in many cases and involves a variety of proteinases (2, 7). Activation reactions occur primarily as internal cleavages, but they often involve more than one hydrolyzable bond. In contrast, this activation mechanism is not common for proteins that remain in the cytoplasm or localize to the nucleoplasm. When activation of proteins in these latter compartments is required, it is usually achieved by reversible modification of one or more side chains.

The degradation and turnover of proteins is considerably less well understood than either of the two processes described above. Significant amounts of protein turnover are associated with lysosomes and the hydrolytic enzymes found in this organelle, following both endocytosis and intracellular vesicle fusion. Another major entity involved in degradation is the proteasome, a very complex structure in the cytoplasm and ER. Additional molecules associate with this core structure to provide it with the specificity for recognizing entities marked for degradation. This usually involves the formation of poly-ubiquitin "tags" that have been added to proteins ready for turnover. There would appear to be a variety of signals that generate these modifications, one of which is the *N*-terminus (*N*-end rule) noted above. However, the nature of the other signals is not well understood. It is noteworthy that ubiquitinylation of proteins for purposes other than signaling degradation is widespread. A number of cytosolic proteinases that may also be involved in protein turnover have been identified. Of particular note are the calpains—enzymes that are activated by increased levels of calcium—and the caspases, some of which are associated with intracellular hormone activation and appear to be widely involved in instituting cell death, or apoptosis.

A specific set of reactions involving the cleavage of peptide bonds, which can be viewed as a subset of the activation group, are found in proteins that undergo cleavages (either enzymatically or

nonenzymatically) leading to an eventual reorientation of internal protein sequences through protein splicing events that resemble those seen with messenger RNA. Concanavalin A is a case in point, although other examples, not involving cyclization, have also been defined. The concanavalin A reaction involves multiple backbone cleavages, presumably catalyzed by a specific proteinase, although this is still an area of controversy, and the resynthesis of peptide bonds in an autocatalyic fashion. Such transpeptidation reactions are highly unfavorable in an aqueous environment and presumably occur in a "compartment" in which water has been substantially eliminated, analogous to the nonaqueous conditions used to carry out these reactions in the laboratory.

3.2. Amino and Carboxyl Termini

In addition to the removal of the methionine or *N*-formyl methionine *N*-terminal residue and the nonenzymatic formation of glycosylated derivatives, a number of other *N*-terminal modifications occur, mostly as a result of post-translational modifications. The most prevalent of these is acetylation catalyzed by a series of N^{a}-acetyltransferases (3). The proteins with the four smallest amino acids (glycine, alanine, serine, and threonine), exposed after the initiator methionine has been removed, and those retaining methionine followed by aspartate, glutamate, or asparagine residues, represent the largest set of substrates for this modification. Other acylations can also occur, however, including by fatty acids ranging up to **myristoyl** moieties. Unsaturated fatty acids and pyruvyl groups (ketoacyl) as additional substituents have also been reported. These entities are all added post-translationally to the same residues that are usually acetylated. It is not known how this distinction is accomplished at a cellular level.

These various substitutions fulfill a variety of functional needs. N^{a}-Acetylation probably prevents the loss of reducing sugars by reaction with a-amino groups, which may be important for the energy metabolism of the cell. It has also been suggested that this modification stabilizes these proteins, presumably from attack by other aminopeptidases, although there is little evidence to support this theory. The appearance of this modification during evolution with the development of eukaryotes is more in keeping with the former view. The longer fatty acid derivatives are usually related to association with membranes. Such modifications allow a more transient interaction than do transmembrane segments within a polypeptide chain, but still allow sufficient contact to permit other modifications, reactions, and molecular interactions to take place. Although the occurrence of these modifications is limited, they are generally of marked significance.

Modifications of the a-carboxyl group include the formation of both amide and methyl esters, and are usually found on small bioactive peptides that have been formed from larger precursor molecules. *C*-Terminal amide groups result from the unusual cleavage of a *C*-terminal glycine residue between the a-amino nitrogen and the a-carbon, to produce the amidated derivative of the adjacent residue. a-Carboxyl groups can also be activated with ATP by the formation of mixed anhydrides, and this mechanism can be used to add individual amino acids or, in the case of ubiquitin, to transfer the entire protein onto the side chain of lysine residues to form a polyubiquitin derivative. (Amino acids can also be added to the a-amino group using charged tRNA.) The a-carboxyl group is also the site of the formation of *N*-ethanolamineglycanphosphoinositides.

3.3. Side-Chain Modifications

Only five of the amino acids (glycine, alanine, valine, isoleucine, leucine) do not appear to have significant side-chain modifications in proteins. All the other 15 residues contain moieties that can be modified, in some cases extensively, to produce 150–200 different derivatives. These are briefly summarized, by side chain, in Table 1 . For a more detailed treatment of these individual modifications, the reader is referred to the chapter by Krishna and Wold (see Suggestions for further Reading).

3.4. Oxidation

One of the most common side-chain modifications that occurs in proteins is the oxidation of cysteine to cystine to produce disulfide bonds. All proteins that are extruded into the lumen of the ER are exposed to the machinery for inserting these crosslinks, and nearly all such cysteines are so

converted. The cystine residues formed are found as both intra- and intermolecular bridges. The mechanism for forming these bonds clearly involves thiol–disulfide exchange between the cysteine thiol groups of the protein and oxidized molecules containing disulfide bonds that have been previously formed (see Hydrophilic). For the most part, these protein disulfide bonds are considered to impart greater rigidity and stability to proteins that exist and function in the extracellular milieu. Disulfides do occur in a few intracellular proteins, when the residues involved generally cycle between the reduced and oxidized states. Higher levels of oxidation of cysteine or cystine can also occur, producing progressively the sulfenic, sulfinic, and sulfonic acids, but these have not been detected in natural proteins, except under more extreme conditions or in laboratory experiments. However, they may form as products of environmental insults.

Methionine residues can also be oxidized to the corresponding sulfoxide, as an example of a common environmental "insult" that can lead to inactivation. The existence of a reductase to convert it back to methionine supports the view that this is the principal situation producing this alteration. As with cysteine, there is a higher oxidation state (sulfone), but this is seldom found except under severe oxidizing conditions. The sulfoxide modification renders the methionine residue more polar, and hence more hydrophilic, which has been suggested to be important in molluscan ligament proteins, where this modification has been found.

3.5. Glycosylation

Carbohydrate molecules are added to protein side chains in both the ER/Golgi compartment and the cytoplasm. In the former, two types of residues serve as attachment sites: asparagine (***N*-glycosylation**) and serine/threonine (***O*-glycosylation**). The *N*-linked class is quite large and very complex. In brief, a core oligosaccharide, attached to the lipid carrier dolichol, is donated to the protein acceptor in the ER, probably primarily as a cotranslational event. This structure can then be further processed by both excision and addition reactions. The array of different carbohydrate structures so produced depends on the cell and the organ, reflecting the complement of enzymes present. The attachment sites occur only in ═Asn–X–Ser/Thr sequences, but there are certainly also conformational requirements and restrictions that further limit the residues that are modified. Nonetheless, extracellular proteins, in particular the extracellular **domains** of transmembrane proteins, are heavily modified. *O*-Linked sugars are also added in the ER continuum, but they are rarer in occurrence. Four main classes are defined by the monosaccharide (mannose, *N*-acetylgalactosamine, galactose, and fucose) attached to the serine hydroxyl group, and they are variously distributed in different organisms.

There are many functions associated with such a varied group of modifications. The heavy glycosylation of the transmembrane proteins may be important in aiding their flow through the ER continuum and contribute to the buffy coat of eukaryotic cells. These moieties are also apparently important for regulating the surface lifetime of these proteins and may contribute, in individual cases, to their function. The glycosyl groups are also clearly important in maintaining the circulating levels of serum proteins and can be involved in targeting their turnover.

O-Linked *N*-acetylglucosamine is also found on certain intracellular proteins as a monomeric addition. In contrast to the extracellular modifications, this entity is readily removed, and it has been suggested that they may act in a similar fashion as phosphoryl groups in reversibly regulating diverse functions.

3.6. Phosphorylation

The addition of phosphoryl groups to the side chains of serine, threonine, and tyrosine, and to a much lesser extent several other amino acids (see Table 1), is certainly the most prevalent cytoplasmic modification aside from *N*-terminal alterations. The reactions are catalyzed by an extensive family of **kinases** using nucleoside triphosphates, usually ATP, as phosphate donors. For the most part, the protein kinases are specific for either serine/threonine or tyrosine residues, since the former represent esters and the latter, mixed anhydrides. A similar situation exists for the protein **phosphatases** that remove these groups. These modifications control the activity of key enzymes in

most metabolic pathways and are the primary basis for signal transduction pathways for hormones and growth factors. The role of this modification for the other amino acids, such as histidine, lysine and arginine, is less well defined but is probably not as important to metabolic regulation or signal transduction.

Table 1. Major Post-translational Modifications of Amino Acid Side Chains in Proteins

Arginine	Lysine
N^{w}-ADP-ribosylation	N^{e}-Acetylation
N^{w}-Methylation	d-Hydroxylation
N^{w}-Phosphorylation	N^{e}-Methylation
Asparagine	N^{e}-Ubiquitinylation
N-Glycosylation	N^{e}-Phosphorylation
Deamidation (*N*-terminal)	N^{e}-Retinylation
N-Methylation	*N′*-Lipoylation
b-Hydroxylation	N^{e}-Biotinylation
Aspartate	Crosslinking to (multiple entities)
b-Carboxylation	
erythro-b-Hydroxylation	Methionine
O-Phosphorylation	Oxidation
Methylation	Phenylalanine
Cysteine	Glycosylation (via oxidation)
Oxidation (to cystine)	Proline
Thioacylation	Hydroxylation
Dehydration (to dehydroalanine)	Serine
Thioether formation	*O*-Phosphorylation
Thioester formation	*O*-Acetylation
Thioglycerol formation	*O*-Glycosylation
ADP ribosylation	*O*-Acylation
Glutamate	Selenocysteine formation
b-Carboxylation	Threonine
Methylation	*O*-Phosphorylation
O-ADP ribosylation	*O*-Acylation
Glutamine	*O*-Glycosylation
N-Methylation	*O*-Methylation
Transamidation (crosslinking)	Tryptophan
Histidine	Interindolic crosslinking
N-Phosphorylation	Glycosylation
N^{p}-Methylation	Bromination
Iodination	Tyrosine
Dipthamide formation	Iodination (halogenation)
	Hydroxylation

O-Phosphorylation
O-Sulfation
O-Adenylation
(esterification)
Interphenolic crosslinking

3.7. Acetylation
In addition to the acetylation of the a-amino group, acetyl derivatives of both lysine and serine residues have been reported, although the latter is not common. As with the *N*-terminus, the acetyl group is derived from acetyl-CoA. The role of these modifications is largely unknown.

3.8. Acylation
In addition to acetylation, there are a large number of acyl-group additions to the side chains of serine, threonine, cysteine, and lysine residues. These are generally formed by various fatty acid or other **hydrophobic** moieties, such as isoprenoid compounds derived from the synthesis of cholesterol. As with acetylation, the carboxyl group of the donors is usually activated by CoA esterification prior to transfer. The function of these derivatives is varied but often is associated with membrane interactions, as is the case for the fatty acylation of the a-amino group.

3.9. Methylation
Methylation is a widespread modification and occurs on the basic, acidic, and hydroxyl-containing amino acids. Mono-, di-, and tri- (when possible) derivatives of the basic residues are known. The methyl esters of aspartate and glutamate are also common, while the methyl ethers of serine and threonine have not been conclusively demonstrated and have been inferred only from the acid stability of some protein-bound methyl groups. The formation of methyl aspartate actually uses either D-aspartate or L-isoaspartate as acceptor and may be important in tagging these residues for further modification or turnover. The functional significance of the methylation of the basic residues is largely unknown (see Hydroxylation (Lysine, Proline)).

3.10. Carboxylation
Additional carboxyl groups can be added to aspartate and glutamate in a vitamin K–dependent manner. This modification adds a strong calcium binding site to these residues and is commonly found in ribosomal proteins (Asp) and in blood clotting and calcification reactions (Glu).

3.11. Hydroxylation
Lysine and proline residues, as well as aspartate and asparagine, can be hydroxylated, usually to produce sites suitable for further additions. With lysine and proline, these modifications are very important in establishing or stabilizing crosslinks in various structural proteins (see Mass Spectrometry). The hydroxylation of aspartate and asparagine appears to be functionally related to the g-carboxylation of glutamate, as it occurs in many of the same proteins.

4. Analysis

The technology for determining the type, number, and sites of post-translational modifications in proteins has improved in precision and accuracy, to the point that direct identification on even small amounts of polypeptides is now possible. Advances in mass spectrometry and **chromatographic** separation techniques have not only increased the experimental capabilities but also raised the criteria for establishing these structural modifications. The success of these determinations depends, however, on the quantity and purity of the protein sample and on the instrumentation available (8).

The principal tools used to detect post-translational modifications are incorporation of

radiolabeling, Mass Spectrometry, and mass spectrometry. These approaches vary in their ability to detect, verify, or quantify alterations in protein structure, and they are often used in combination. Additional experimental tools can aid in both the detection and enrichment of modified proteins or peptides derived from proteolytic digests of complex mixtures, such as **affinity columns** (eg, antibody-conjugated, nickel-chelate) or **antibodies** specific for defined protein sequences or the modification (eg, antibodies to phosphotyrosine).

4.1. Radioactivity

Radioactive precursors are frequently used to identify modifications such as acylation or phosphorylation with intact cells, subcellular fractions, or purified proteins and enzymes. After incubation with a specific precursor molecule, the cellular proteins are typically separated by one- or two-dimensional gel electrophoresis, and then analyzed by both autoradiography and protein staining, so that the incorporation of the precursor molecule into a particular band or spot can be identified. Knowledge of the migration behavior of a protein in the electrophoretic system helps connect the protein with the modification. Use of a specific antibody to **immunoprecipitate** or immunolocalize the protein of interest provides further evidence.

For modifications such as phosphorylation, which are most commonly found on serine, threonine, or tyrosine residues, the protein(s) is (are) usually hydrolyzed and subjected to amino acid analysis by two-dimensional thin-layer electrophoresis and chromatography to determine which residues are modified. If radioactive methods are also used for the identification of the site(s) of modification, the labeled protein can be digested with proteinases followed by high-performance liquid chromatographic (**HPLC**) separation or another chromatographic method. Direct identification by Edman sequencing, and counting a fraction of the product of each cycle, can help identify the position of the modification. Some radioactive products are not stable or otherwise amenable to the chemistries used, and they often yield ambiguous results. They are also rarely used with more precise localization by mass spectrometry analysis because of the resulting contamination of the instrument. In some cases, the identity of the labeled peptide has been deduced by its properties and by the comigration of synthetic compounds used to “prove” the site of the modification.

4.2. Edman Degradation

Edman degradation techniques have been productively used to identify many modified amino acids and their positions within a protein or peptide sequence. Edman sequencers employ controlled reaction and reagent delivery systems, coupled to automated HPLC separation of the PTH amino acids. The Edman reaction is specific for peptide bonds, and the elution positions of many natural and modified PTH–amino acids are well documented (9). While these chromatographic characteristics have been used as proof of modification in the past, a mass measurement of the modified peptide is now an important confirmation. Detection of an unusual peak in a PTH–amino acid chromatogram can lead to an unexpected observation of a protein modification, which can then be followed through by other methods. Since the sequencers now available can analyze proteins in the low picomole/high femtomole range, this remains a valuable analytical tool for determining protein modifications. It is important to note that not all modified amino acids are stable under the conditions of Edman chemistry, and some modifications may elute outside the defined chromatographic separations, or they may be missed because of poor resolution. In addition, if specific efforts are not expended to purify modified peptides, detection of a modification by Edman sequencing can easily be overlooked because of the greater abundance of the unmodified amino acid.

4.3. Mass Spectrometry

Innovations in mass spectrometry, particularly in ionization techniques and in coupling to separation devices such as HPLC, have substantially advanced protein analyses. With careful technique and/or instrument modifications, many of the newer instruments are able to reach the subpicomole range. Analysis in the 25–200-fmol range is possible, but not common. Even routine analysis of small amounts of protein may, however, require repetition of experiments and experimental redesign, either because of the nature of the protein or because of contamination with other natural proteins or with experimentally derived materials. Both Edman degradation and mass spectrometry, but

particularly the latter technology, are very susceptible to problems developed during sample preparation. Nonetheless, given the constraints and the potential, it is now possible to undertake identification of proteins and protein modifications in bands from one-dimensional electrophoretic gels or single spots from two-dimensional gel electrophoresis.

A careful measurement of the mass of the intact natural protein can be very informative about the extent of its processing and modification. Tables now exist to help in preliminary identification of the types of modifications possible (10). In a relatively simple situation, it is possible to obtain data consistent with the presence of a polypeptide chain with a mass equal to that predicted by its gene sequence, plus the *N*-acetylated form and/or that lacking the initiator methionine residue (if these modifications occur), and such measurements, with an analysis of the differences between predicted and expected masses, represent a useful first step in determining the type of modification. Some modifications, such as formation of *N*-terminal pyrrolidone carboxylic acid from glutamine, result in the difference of a single Dalton, and these are difficult to detect directly and unambiguously without combined analysis by Edman degradation or mass spectrometry analysis of the blocked peptide. Importantly, the measurement of a single mass of a phosphorylated polypeptide, as an example, could represent a population of polypeptides phosphorylated to the same extent, but at different sites. It is well known that different sites may be phosphorylated or dephosphorylated at different stages of signal transduction. Thus, this analysis is only the first step in determining the full range of post-translational modifications in a given protein

Proteins in solution are most amenable to direct mass measurement, although methods are being developed for analysis of intact proteins from unstained polyacrylamide gels or blotting matrices . As yet, these measurements are more problematic and not as accurate. Methods have been developed to measure accurately the mass of immunoprecipitated proteins, providing an improved signal by enriching the target protein. Membrane proteins are still more of a challenge, but advances have been made in analyzing both intact proteins and hydrophobic peptides in unusual solvent mixtures or in the presence of certain nonionic [Error: anchor with id emb1184-anc-0054 not found in linking document].

4.4. Applications

To determine the location of a modification within a polypeptide sequence by mass spectrometry, digests are prepared using special preparations of proteolytic enzymes. Differences between observed and predicted masses usually locate the desired modified peptides. Depending on the instrumentation available, combining offline HPLC with mass measurement, or online HPLC coupled to mass spectrometry, can improve the “coverage” of the protein sequence and the identification of all predicted and modified peptides. Sequence analysis, to verify both the sequence of the peptide and the position of the modification within the sequence, can be accomplished by mass spectrometry analysis, which can often be usefully supplemented by Edman sequencing, not only to provide an orthogonal analytical approach but also in cases where fragmentation patterns may be challenging to interpret.

Techniques have been developed to take advantage of the properties of an individual group to aid in its identification. This is particularly true for phosphate groups, which can be monitored not only for added mass, or for fragility of the bond, but also by performing precursor ion scans. Chelating resins or antibodies, such as to phosphotyrosine, are tools that can be very helpful in enriching the desired species in the peptide mixture. Glycosyl groups are also notoriously difficult to analyze. In these cases, it is often useful to couple experiments with use of purified glycosidases to aid in verifying the presence of the carbohydrate, or to determine its location. Structural characterization of the carbohydrate moiety itself is often the most difficult part of the determination.

The strategy for identifying the partners in disulfide linkages, although relatively unchanged from the first such analyses, has been substantially augmented by mass spectrometry, which has added speed, precision, and sensitivity. Proteins are digested under conditions that minimize disulfide exchange, in the absence of thiol groups or at low pH. Mass measurements are made before and after

reduction. The differences in mass and the appearance of peptides with new masses identify the peptides involved. When more than one disulfide is present in a protein, and the peptide pairs are similar in mass and cannot be determined by mass measurement alone, it is necessary to purify the disulfide peptides first. The larger the protein, the more likely this is to be the case. Difficulties also arise when half-cystine residues are adjacent or near each other in sequence, since few proteolytic enzymes will cleave at these sites. Similar protocols can be used to analyze other types of protein crosslinks.

5. Conclusion

Post-translational modifications provide essential extensions of the structures produced by the 20 genetically coded amino acids (including the backbone itself). These alterations govern the protein's translocation, function, and turnover. For the most part, they cannot be accurately predicted from the sequence alone and must be determined by direct measurements. These analyses are complicated by the fact that many modifications, particularly those involved in intracellular functions, represent only a small percentage of the actual population of the mature molecule, indicative of the transient events that they control. Others are unstable and may be partially or completely lost during experimental manipulations. Finally, it is also important to avoid preconceived notions in analyzing for post-translational modifications, since new derivatives are still being discovered.

Potential Functions (Force Fields)

Computer simulation of macromolecules is based on a mathematical description of the dependence of their energy on their structure. Such a dependence is called the *potential surface*. Molecular potential surfaces can be evaluated in principle by using quantum mechanical approaches, but such approaches are too expensive for effective modeling of large molecules. Alternatively, one can use the fact that macromolecules are assembled by the same type of bonds that connect the atoms in small molecules. Thus one can describe large molecules as a collection of small molecular fragments, where the overall potential surface is expressed as a sum of contributions from bonded atoms and interactions between nonbonded atoms. Such a representation is usually done by sets of analytical function that present an approximation to the true potential surface and are called *potential functions* or *force fields*. The functional forms and parameters of molecular force fields are taken from studies of small molecules with the implicit assumption that these functions are transferable from small to large molecules.

Molecule potential functions are usually given in the form

$$U(\mathbf{s}) = U_{b,\theta}(\mathbf{b},\theta) + U_{\phi}(\phi) + U_{\mathrm{nb}}(\mathbf{r}) \tag{1}$$

where **s** is the vector of internal coordinates composed of **b**, q, f, and **r**, which are, respectively, the vectors of bond lengths, bond angles, torsional angles, and nonbonded distances. The first two terms define a very deep potential well; and because the molecule stays in most cases inside this well (except in extreme cases of bond dissociation), it is reasonable to approximate this part of the potential surface by its quadratic expansion, which is given by

$$U_{b,\theta}(\mathbf{b},\theta) = \frac{1}{2}\sum_i K_{b,i}(b_i - b_{0,i})^2 + \frac{1}{2}\sum_i K_{\theta,i}(\theta_i - \theta_{0,i})^2 + \text{cross terms} \tag{2}$$

where U is usually given in kcal/mol, b in Å and q in radians. The torsional potential U(f) is a periodic function, which can be described by the leading terms in the Fourier expansion of the potential

$$U_{\phi}(\phi) = \frac{1}{2}\sum_i K_{\phi,i}(1 - \cos n\phi_i) \tag{3}$$

The nonbonded potential, U_{nb}, can be described by an atom–atom interaction potential of the form

$$U_{nb} = \sum_{ij} A_{ij}r_{ij}^{12} - B_{ij}r_{ij}^{6} + Cq_iq_j/r_{ij} + U_{\mathrm{ind}}(\mathbf{r}) \tag{4}$$

where r_{ij} is the distance between the indicated atoms, the q_i are the residual atomic charges, and U_{ind} is the many-body inductive effect of the electronic polarizabilities. The constant C is 332 kcal/mol Å when the q's are given in atomic units. The introduction of potential functions opened the way for the use of computers in conformational analysis (eg, Refs. (1-3)). The earliest use of potential functions in modeling proteins was reported by Levitt and Lifson (4).

The accuracy of the given set of potential functions depends, of course, on the specific set of parameters (the K_b, K_{q}, A, B, etc.). These parameters can be optimized by using them to calculate different independent molecular properties (eg, energies, structures, and vibrations) and then fitting the calculated properties to the corresponding observed properties by a systematic change of the

potential parameters in a least-squares procedure. In general, the parameters b_0 and q_0 are sensitive to structural information and the parameters K_b and K_q are sensitive to molecular vibrations, while the K_f are determined by information about torsional barriers (which can also be obtained effectively by quantum mechanical calculations). The parameters A and B of the nonbonded potential are obtained by fitting properties of molecular crystals (3) (eg, sublimation energies, crystal structures, and lattice vibrations). Nevertheless, all properties depend in one way or another on all parameters; thus it is important to perform the fitting procedure simultaneously for different properties. Such a simultaneous fitting is the basis of the so-called consistent force field (CFF) approach (3) (for related methods see, for example, Refs. (2) and (5)).

The advent of powerful quantum mechanical approaches and the increase in availability of computer time allows one to start refining potential functions by fitting them to *ab initio* calculations (eg, Ref. 6). Such approaches should, however, involve careful attention to experimental facts. For example, charge distributions obtained from *ab initio* calculations with small basis sets are very unreliable, and, in general, studies that were based on empirical fitting have been much more reliable than those based on *ab initio* calculations until the late 1980s.

Simulation of macromolecules must reflect solvent effects, which are not just small perturbations but major contributors to the overall energetics and force. In fact, modeling of macromolecules in a vacuum is quite irrelevant to the behavior of such molecules in solution and to proteins. Here, one can use all-atom solvent models (5, 7, 8) or simplified solvent models (9, 10) as a part of the overall potential function. One can also use implicit solvent models (11, 12). The selection of proper representation of the solvent should involve special attention to the proper boundary conditions, because it is impossible to include an infinite system in the simulation. Periodic boundary conditions (7) and spherical boundary conditions (8, 9, 13) involve advantages and limitations, and improper treatment of the surface region in spherical systems might lead to incorrect polarization (8, 14).

In modeling complex processes such as **protein folding** or protein–protein interactions, it is frequently advantageous to use simplified protein models (15, 16) where the potential of groups of atoms or of an entire amino acid residue is represented by a single interaction center.

POU Domain

The POU "domain" is a conserved sequence motif defining a family of eukaryotic transcription factors that contains two structurally independent **DNA-binding** domains connected by a flexible linker of variable length and sequence. Both **domains** make sequence-specific contacts with DNA and together bind with high affinity to a conserved octameric binding site, ATGCAAAT. The N-terminal domain, POUS, is a **four-helix bundle** similar in structure to the bacterial **helix-turn-helix** domain, while the distal domain, POUH, is structurally homologous to the **homeobox** domain.

Prebiotic Evolution

The origin of life on Earth comprised a long series of steps: from the synthesis of small molecules within the primordial atmosphere or near hydrothermal vents, through the formation of biomonomers and biopolymers, culminating in the emergence of a self-replicating, autonomous organism. This philosophical outlook, if not the intimate details, began with the Russian biochemist Alexander Oparin and the British biologist J. B. S. Haldane, who, in the 1920s independently proposed a sequential model for the origin of life (1). Although the process of Darwinian selection may have modulated the populations of genetic macromolecules once the stage of an RNA (or "pre-RNA") world developed, the term "prebiotic evolution" is used here to describe the presumed earlier era of synthesis and degradation that preceded self-replication. A common theme is that the ingredients for life were generated by the flow of energy (sunlight, lightning, or thermal radiation) through the primordial hydrosphere so that the putative mechanisms for the origin of life should be compatible with the conditions that would have prevailed in the early atmosphere and oceans.

The time frame for the emergence of life must be constrained by the physical and biological history of the Earth, but firm dates are difficult to establish. The age of our planet is approximately 4.5 billion years, and life cannot be more ancient unless it came from an extraterrestrial environment. The latter possibility should not be dismissed and may gain credence if the existence of past (or current) life on other planets is confirmed (2). Regardless of the source, organisms would not have survived until the Earth cooled and meteoritic bombardment subsided sufficiently such that the oceans remained in a liquid state. The conditions necessary for sustainable life may not have persisted until about four billion years ago. However, evidence of extant organisms appears in fossilized stromatolites in Western Australia from 3.5 billion years ago, and possibly in apatite inclusions from rocks in Greenland dated at almost 3.9 billion years, suggesting that the appearance of life occurred quite rapidly on a geologic time scale once the conditions were favorable (3).

A historic demonstration of the feasibility of prebiotic simulations was performed by Stanley Miller (4) during the fall of 1952 in the laboratory of Harold Urey at the University of Chicago. Based on Urey's cold-accretion theory for the origin of the planets, Miller subjected a gaseous mixture of methane, ammonia, hydrogen, and water to an electrical discharge, analogous to the effect of lightning in the atmosphere of the young Earth. Chromatographic analysis revealed the presence of three biological amino acids (glycine, alanine, and aspartic acid) along with other products. Further work by Miller and by many other research groups extended the suite of presumed prebiotic amino acids to include glutamic acid, leucine, isoleucine, serine, and threonine. All of the chiral amino acids were obtained as a racemic mixture of left- and right-handed forms, as expected from the achiral starting materials.

The apparent success of these early experiments, which depended on the accessibility and sensitivity of assays specific for amino acids, heightened interest in the nascent discipline of origins-of-life studies. However, prescient objections to the reducing atmosphere of the Miller-Urey simulations were raised first by Philip Abelson, a geochemist at the Carnegie Institution, who argued that the hydrogen-rich gases would have been rapidly replaced by a secondary atmosphere in which carbon was present as carbon dioxide or carbon monoxide, while nitrogen was probably present as molecular dinitrogen (5). By the early 1980s, a growing body of computational and experimental evidence slowly led to a revised view of the dominant atmosphere during the era before life began. Unfortunately, as shown by Miller and others, these non-reducing gas mixtures ($CO_2/N_2/H_2O$ or $CO/N_2/H_2O$) give dramatically lower yields and less variety in amino acids produced by electric discharge (6). If gas-phase syntheses of the Miller-Urey design were important in the origin of life, they must either have proceeded during a brief period when the Earth was very rich in hydrogen, or there may have been another unidentified source of reducing equivalents that maintained a source of hydrogen over a longer stretch of geologic time. Alternatively, the formation of amino acids and other organic molecules may have been favored near submarine hydrothermal vents, where reducing equivalents would have been present in the extruded gases; the technical challenges inherent in high pressures and temperatures have necessarily restricted the number of such simulations, but compounds as complex as pyruvic acid have been detected using formic acid as the carbon source (7). Nevertheless, the existence of both thermodynamic and kinetic barriers to the reduction of CO_2 (the preferred starting point for any prebiotic synthesis) raises many questions about the availability of the organic precursors in hydrothermal models (8).

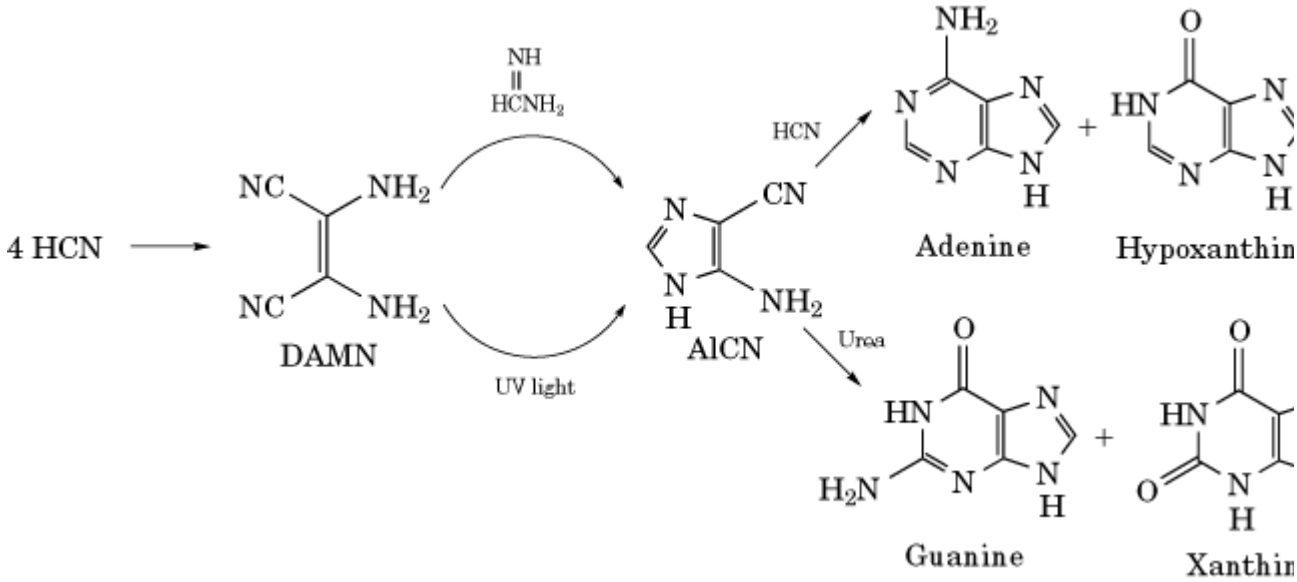
A very different source of the vital ingredients may exist beyond the Earth, in the form of comets, interplanetary dust, and asteroidal debris (9). These materials are believed to contain carbon compounds, some of which can survive passage through the atmosphere when such objects approach our planet. An intriguing possibility is that their cargo could already be enriched in the left-handed form of amino acids that are required to make modern proteins (10). While much remains to be understood about the chemical processing of these extraterrestrial bodies, there is great interest in their possible contribution to the primordial soup.

1. The Cyanide Paradigm

John Oró at the University of Houston in 1960 made a startling observation: adenine, a constituent of RNA as well as the nicotinamide and flavin cofactors, was formed after acid hydrolysis of ammonium cyanide solutions, which were deemed prebiotic starting materials based on the prior detection of HCN in the Miller-Urey electric discharge reactions (11). Although the conditions involved high concentrations of both cyanide and ammonia, James Ferris and his coworkers (12) at Rensselaer Polytechnic Institute obtained a yield of 0.03% after acid hydrolysis of a six-month reaction at room temperature of 0.1 M HCN, adjusted to pH 9.2 with ammonia and kept in the dark; adenine was also detected after hydrolysis at pH 8.5 (12). Ferris, working with Leslie Orgel (13) at the Salk Institute, demonstrated that adenine could be synthesized photochemically using near-UV light, via an intermediate known as 4-amino-5-cyanoimidazole (AICN, Fig. 1). This imidazole

derivative can be prepared through a dark reaction by combining diaminomaleonitrile (DAMN) with formamidine (14). Urea, widely regarded as a prebiotic compound formed (among other ways) by the hydrolysis of HCN oligomers, reacts with AICN to give another important purine, guanine (15).

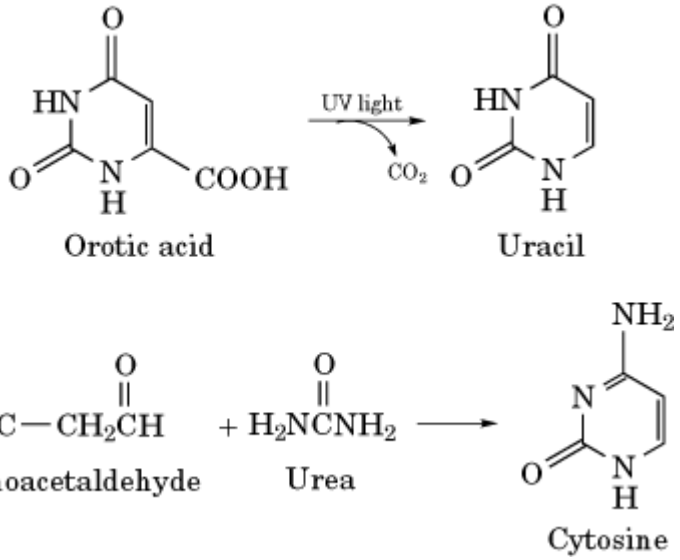
Figure 1. Synthesis of purines from HCN, showing two possible routes to the intermediate 4-amino-5-cyanoimidazole (AICN) from the HCN tetramer, DAMN.



The adenine that is released upon alkaline hydrolysis of the HCN oligomers is probably formed by a separate pathway (not shown in Fig. 1) that does not require light. The initial products in the oligomerization are now well-characterized, proceeding through a stepwise self-addition to give the tetramer, DAMN, which is a precursor to the imidazole derivatives (Fig. 1). The higher oligomers constitute a heterogenous mixture that is poorly defined, but their composition probably does not correspond to any known biopolymers (12).

HCN oligomerization also provides a source of the RNA component, uracil, which was first identified in such a mixture by Alan Schwartz and Andries Voet (16) at the University of Nijmegen. Ferris and Joshi (17) showed the presence of orotic acid after alkaline hydrolysis of HCN oligomers and further demonstrated that this pyrimidine undergoes a photochemical decarboxylation (Fig. 2) to yield uracil. Cytosine is more difficult to synthesize, but Miller and Robertson (18) have published an efficient pathway based on urea and cyanoacetaldehyde as starting materials; cyanoacetaldehyde is formed by hydrolysis of cyanoacetylene (a product of methane and dinitrogen atmospheres subjected to an electrical discharge, which thus requires a source of reduced carbon). Hydrolysis of cytosine yields uracil so that these syntheses provide an indirect route to this pyrimidine.

Figure 2. Possible steps in the prebiotic synthesis of pyrimidines.



Finally, HCN also provides a route to amino acids, notably glycine, alanine (alpha and beta isomers) and aspartic acid (12). Thus, an especially attractive feature of cyanide as a precursor to biomolecules is that it yields constituents of proteins and nucleic acids by a common reaction system. Moreover, Leslie Orgel and his colleagues (14) proposed an innovative mechanism for concentrating HCN by eutective freezing: at –23.4°C, a solution of 74.5 mole percent HCN (25 M) is obtained. Despite the low temperature, oligomerization is quite rapid under such conditions, which might have occurred in glacial climates.

An unresolved dilemma is how HCN itself might have been made on the early Earth (19). As Miller and others have shown, cyanide is readily formed when reducing gas mixtures of methane and ammonia are subjected to an electrical discharge, and this species was proposed as an important intermediate in the Miller-Urey syntheses of amino acids. By the same token, HCN is not formed from more oxidized atmospheres of $CO_2/N_2/H_2O$ or $CO/N_2/H_2O$. One possibility proposed by Fujio Egami (20) at the Mitsubishi-Kasei Institute of Life Sciences is that HCN resulted from the reaction of formaldehyde with hydroxylamine. Formaldehyde is a plausible photoproduct of oxidized atmospheres (CO_2 and H_2O), but the source of NH_2OH remains to be elucidated (21). If the synthesis of HCN can ultimately be reconciled with a non-reducing environment on the primordial Earth, this achievement would greatly strengthen the paradigm that cyanide played an important role in the synthesis of amino acids, purines, and pyrimidines.

2. Activation Processes

Modern biochemistry exploits the unique properties of phosphate as an activating group to drive unfavorable reactions, and the earliest biosynthetic processes may have used phosphate in an analogous fashion. A striking illustration of the activating power of this group is found in glycolaldehyde phosphate, which Albert Eschenmoser (22) of the Federal Technical Institute (FTH) in Zurich has proposed as a precursor of the RNA sugar, ribose. Under strongly alkaline conditions, glycolaldehyde phosphate reacts with formaldehyde to give ribose 2,4-diphosphate as the major product, with glyceraldehyde 2-phosphate serving the role of intermediate; by contrast, formaldehyde alone gives a complex mixture with only a trace of ribose. More recently, Gustaf Arrhenius and his colleagues (23) at the Scripps Institution of Oceanography have shown that certain mineral catalysts (known as layered double hydroxides) can effect the formation of ribose 2,4-diphosphate from glyeraldehyde 2-phosphate and glycolaldehyde phosphate at near-neutral pH. While the subsequent steps from this derivative to nucleotides have yet to be elucidated, the work of Eschenmoser represents a significant advance in stereoselective synthesis.

A formidable challenge in prebiotic research has been the demonstration of possible condensation mechanisms by which the elements of water (H_2O) could be removed in order to couple two molecules. One approach has involved the heating of the ingredients in the dry state to drive off the water. This method yields nucleosides in 2% to 10% yield when purines (adenine or guanine) are heated in the presence of ribose, but the reaction fails when the pyrimidines cytosine or uracil are substituted (24). Repeated wet-dry cycles, which simulate the periodic flooding and evaporation of a tidal lagoon, effect the self-condensation of amino acids to form modest amounts of oligopeptides up to the pentamer in a process that is catalyzed by a common clay mineral called kaolinite (25). While such a reaction system is relatively inefficient, with total yields near 1% after 2 months, it represents a more natural model than studies carried out with transient condensing agents as the activating species (26).

Phosphorylation of nucleosides and other substrates represents another step that has met with limited success. Organic condensing agents such as cyanamide and cyanoacetylene are effective but not under the low micromolar concentrations of phosphate that likely prevailed in the primordial ocean (26). Inorganic polyphosphates including the trimer, which has been detected in volcanic fumaroles, can convert adenosine into a mixture of mono-, di-, and triphosphates, but the high temperatures associated with volcanic environments render them unsuitable for complex organic synthesis (27). A structurally related compound, cyclotriphosphate or "trimetaphosphate," has been employed in the preparation of glycolaldehyde phosphate and other phosphate esters (28); however, trimetaphosphate concentrations would be limited by the geothermal formation of longer polymers from which it is derived. Mixtures of urea and inorganic phosphate give high yields of phosphorylated products under mild heating, but this approach requires high concentrations of urea that may not have been available on the early Earth (29). Further work must be done to elucidate plausible prebiotic pathways to phosphate esters.

In summary, a significant body of literature (see Suggestions for Further Reading) has emerged that demonstrates the feasibility of prebiotic syntheses of specific compounds under particular conditions. The efficacy of cyanide as a precursor to purines, amino acids, and, to a lesser extent, pyrimidines suggests that HCN likely had a role in the formation of the first biomolecules. However, much work remains to reconcile such pathways with geochemical conditions that might have prevailed on the early Earth and to elucidate how a genetic macromolecule might have formed from a dilute primordial soup. Despite the many problems in nucleotide assembly, the postulate of a so-called RNA world has provided remarkable insights into the interrelated roles of replication and catalysis in the origins of life.

Precession Photograph

Precession cameras were widely used in protein X-ray crystallography in earlier days. Their advantage is that they give an undistorted image of the reciprocal space of lattice planes (Fig. 1). Moreover, the symmetry in the crystal and its space group can easily be determined and the crystal quality checked. The precession camera is not suitable for efficient three-dimensional data collection because it records only one lattice plane in each exposure. Therefore, it is no longer a popular instrument in protein X-ray crystallography.

Precipitation

The solubility of a macromolecule is a complex function of a number of factors, such as pH, temperature, the chemical and physical nature of the macromolecular surface, and the nature of the precipitant (or solubilizer) used. The purposes of precipitating proteins out of solution may be varied.

1. During the purification, preparation of a particular protein out of a tissue extract or cell homogenate, the approach can be that of partial precipitation, or fractionation by precipitation using mild nondenaturing precipitants. This uses the solubility properties of the various components of the mixture to remove those that are less soluble than the desired product, or to separate the product in precipitated form from more soluble impurities. Once the more soluble and less soluble components of the original mixture have been removed, the desired protein can be purified further by cutting sharper fractions, based on solubility in a given agent, say, Na_2SO_4, until only a single component is left that precipitates very sharply at a constant very narrow concentration range of the precipitant. This represents pure protein by the criterion on solubility (1).

2. Proteins may be precipitated out of solution in the form of crystals for the purpose of X-ray crystallography structural studies. This involves very special techniques (see Crystallization).

3. At times, when it is necessary to obtain a protein-free solution for the purpose of analysis for other

components, in which proteins may interfere, proteins are precipitated in a denatured, generally coagulated state. This is done by the addition of general strong precipitants, with *trichloroacetic acid* being an additive of choice.

Precipitation of proteins during purification or crystallization is usually accomplished by the gradual addition at high concentration (0.3 to 10*M*) of small molecules that interact weakly, and gently, with the proteins. All these are known to be preferentially excluded from the protein accessible surface at the environmental conditions (such as temperature) used (2) (see Preferential Hydration). Many of them are structure stabilizers (see Stabilization And Destabilization By Co-Solvents). The most common precipitants are sulfate salts (ammonium sulfate, sodium sulfate, magnesium sulfate); ammonium sulfate is the most commonly used precipitant because of its high solubility in water and strong salting out properties (see Salting In, Salting Out).

Some organic solvents can also be used as precipitants (3). These include ethanol, acetone, and butanol. They must be used, however, at low concentration (about 5 to 10%) since they tend to induce protein **denaturation**. Two organic compounds, 2-*methyl-2,4-pentanediol* (MPD) and *polyethylene glycol* (PEG), have been found to be excellent protein precipitants and good crystallizing agents. They may be used at a high concentration (eg, 50% MPD), but their use is limited to room temperature at which they are preferentially excluded from proteins. At higher temperatures, however, both become good protein denaturing agents.

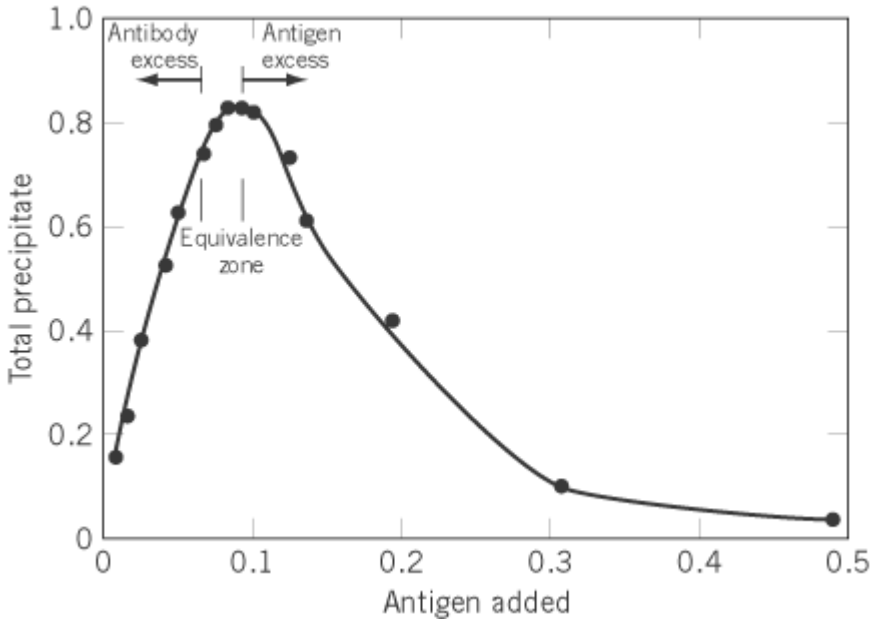
Precipitin Reaction

The precipitin reaction is a phase-change phenomenon observed in **antibody-antigen reactions**. Kraus (1), its discoverer, demonstrated formation of a precipitate when spent bacterial culture broth was mixed with a specific antiserum. Marrack and Smith (2) showed that recovery of precipitate was largely independent of solution conditions or the presence of nonspecific proteins, so the precipitin reaction was not a simple phase change. Marrack (3) proposed correctly that the precipitate was an extended lattice in which multivalent antibody molecules form links with two or more antigen molecules, which, in turn, can form multiple links with other antibody molecules.

Since lattice formation requires multiple intermolecular links per monomer, the precipitin reaction is very sensitive to the ratio of antibody and antigen. A precipitin curve, shown in Figure 1, refers to the rise, peak, and fall in amount of precipitate recovered as a fixed amount of serum is titrated with antigen. The maximum amount of precipitate forms when antigen and antibody are present in similar molar amounts (the equivalence zone). At a low antigen:antibody ratio, few antibody molecules will bind more than one antigen molecule, hence the multiple intermolecular links necessary for a lattice again do not form (antibody excess zone). At a high antigen:antibody ratio, all antibody combining

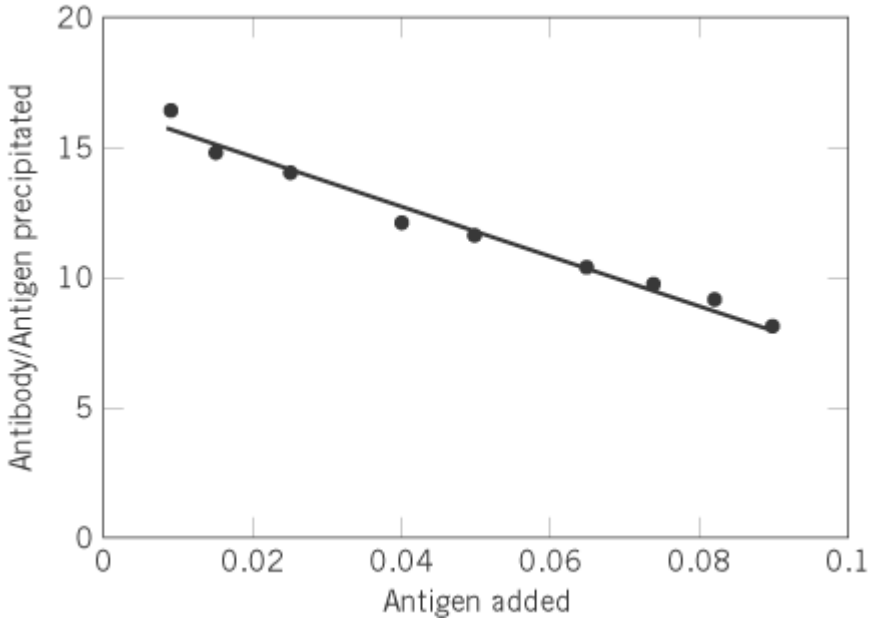
sites will be saturated with antigen, and few antigen molecules will be shared between two antibodies (antigen excess zone). The zones are defined empirically as those sets of reactions whose supernatants give additional precipitate upon adding a small increment of antibody (in the antigen excess zone) or antigen (in the antibody excess zone). In the equivalence zone, little antibody or antigen remains in the supernatant, and no additional precipitate can be induced. With some antigens and antisera, complete antibody precipitation occurs over an extended range of antigen additions, while excess antigen is still observed in the supernatant. In such cases, the term "inhibition zone" refers to the region of the antigen excess zone in which the absolute recovery of precipitate declines.

Figure 1. Precipitin curve. An antibody is titrated with antigen, and the resulting precipitates are isolated and quantitated. (Data are from Ref. 5.)



Heidelberger and Kendall (4, 5) analyzed the composition of precipitates and discerned a general relation that formed the basis of a quantitative assay of antigen or antibody preparations of unknown concentration. In this method, a precipitin curve is obtained, and the experimental points in the equivalence and antibody excess zones are identified as described above. (Points in the antigen excess zone are not used.) These authors found for many antibody–antigen systems that a straight line results if the ratio of antibody to antigen in the precipitate is plotted against the amount of antigen added, illustrated in Figure 2. (A frequent simplifying assumption is that all antigen added is precipitated.) The linearity of the relation allowed easy interpolation; hence the antigen content of an unknown could be determined by comparing the antibody:antigen ratio in the precipitate from the unknown to the results of precipitin reactions from standards of known concentration.

Figure 2. Precipitin curve analyzed by the method of Heidelberger and Kendall (4). Data from the equivalence and antibody excess zones in Figure 1 are replotted as the ratio of antibody to antigen found in each precipitate versus the quantity of antigen added to initiate the precipitation.



Although the precipitin curve technique illustrated in the figures is no longer used for analysis, the precipitin reaction itself has been incorporated into many immunological techniques (see Immunoelectrophoresis). One of the most visually elegant applications is the Ouchterlony double-diffusion assay (see Immunoassays), in which one can infer properties such as molecular weight and cross-reactivity of an antigen or antiserum preparation from the shape of a precipitin line on an agar plate (6). A turbidimetric assay based on the precipitin reaction is widely used in clinical laboratories. In this type of immunoassay, antibody that is free in solution reacts with microscopic antigen-coated latex beads (or free antigen reacts with antibody-coated beads) to farm large cross-linked aggregates that are easily and sensitively detected by light scattering (7).

Preferential Binding

The equilibrium binding of ligands to proteins (nucleic acids) is classically measured by equilibrium dialysis, or related techniques, such as gel **gel filtration**. The binding can be expressed by a simple mass action equation

$$P + L \underset{}{\overset{K_b}{\rightleftharpoons}} PL$$

where P is protein and L the ligand, with a binding equilibrium constant

$$K_b = \frac{[PL]}{[P][L]}$$

The binding isotherm is expressed by

$$\overline{\nu} = \frac{nK_b[L]}{1 + K_b[L]}$$

where n is the extent of binding (moles ligand per mole protein) at a concentration of free ligand $[L]$ and n the number of sites.

In the case of extremely weakly interacting ligands, which is the case with agents that stabilize (eg, sugar, glycerol) or destabilize (urea, **guanidinium chloride**) the folded structures of protein or nucleic acids, they are required at high concentrations ($\cong 1\ M$). Consequently, they are more properly considered to be cosolvents, and displacement of water from the binding sites must be taken into account explicitly (1). The binding process is depicted in Figure 1, and the equilibrium equation that expresses the water–ligand exchanges at a site is

$$P \cdot q\mathrm{H_2O} + L \underset{}{\overset{K_b}{\rightleftharpoons}} PL + q\mathrm{H_2O}$$

The binding equilibrium constant becomes an exchange constant

$$K_b = K_{ex} = \frac{[PL][\mathrm{H_2O}]}{[P \cdot \mathrm{H_2O}][L]}$$

For the simple case where one ligand molecule displaces one water molecule, the binding isotherm becomes

$$\overline{\nu} = \frac{n(K_{ex} - 1/m_w)m_L}{1 + K_{ex}m_L}$$

where m_1 and m_3 are the molal (moles per 1000 g H_2O) concentrations of water and ligand (cosolvent), respectively. Since M_1 = 55.56 moles H_2O per 1000 g H_2O, $(1/m_1) = 0.018\mathrm{m}^{-1}$. This means that the actual experimental result of a binding measurement by, say, equilibrium dialysis can yield *negative*, as well as positive, values of the extent of binding, n. When $K_{ex} > 0.018\mathrm{m}^{-1}$, the measured binding is positive. When $K_{ex} < 0.018\mathrm{m}^{-1}$, the value of n is negative. Operationally, the magnitude of preferential binding (in fact, the extent of any binding, weak or strong) is obtained from the measurements of the ligand concentration inside and outside the dialysis bag (in terms of

equilibrium dialysis):

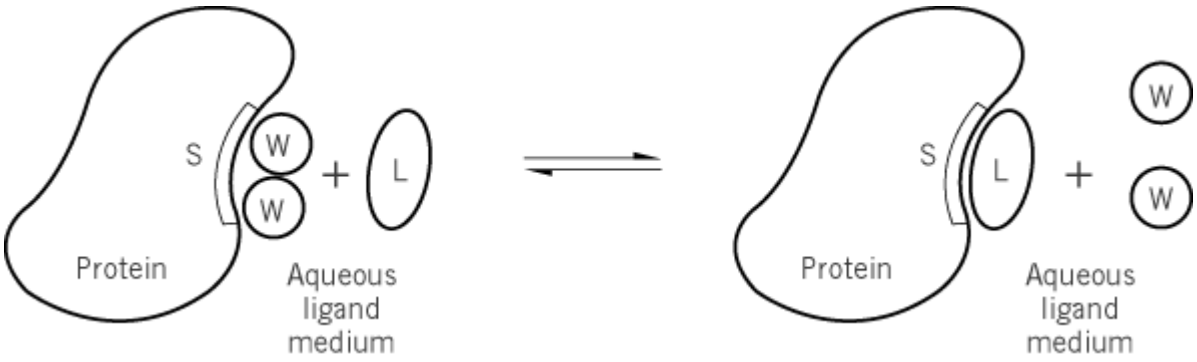
$$\bar{\nu}\left(\frac{\text{Moles ligand}}{\text{Mole protein}}\right) = \frac{(\text{Conc. ligand inside bag} - \text{Conc. ligand outside bag})}{\text{Conc. protein}}$$

It is clear, therefore, that the magnitude and *sign* of n are simply the expression of the difference between two measured concentrations. In more rigorous notation, this can be stated as

$$\bar{\nu} = \left(\frac{\partial m_L}{\partial m_{pr}}\right)_{T,\mu_w,\mu_L}$$

ie, variation of the ligand concentration induced by the presence of protein at a given temperature T and at dialysis equilibrium (this is indicated in the notation by the chemical potentials of water m_w and ligand m_L being identical inside and outside the bag). In this way, it has been found that many substances which stabilize protein structure give negative values of binding. For example, equilibrium dialysis of **ribonuclease A** (RNase A) in 1 *M* sucrose at pH 7 yields the following result: n = -7.6 moles sugar bound per mole RNase A. In other words, there is a deficiency of sugar molecules on the protein surface relative to the sugar concentration in the bulk solvent. This is referred to as **preferential exclusion**. Since an insufficiency of sugar exists, there must be an excess of water. This excess of water is referred to as preferential hydration .

Figure 1. Schematic representation of the replacement of water W molecules by a ligand L molecule at a binding site S on a protein. [Reprinted with permission from S. N. Timasheff (1992) *Biochemistry* **31**, 9857–9864. Copyright 1997 American Chemical Society.]



Total binding is the number of molecules of a solvent component (water or cosolvent) that form contacts with the protein (or nucleic acid) surface. Binding measured by the usual techniques is *preferential binding*. It is related to total binding by

$$\bar{\nu} = \left(\frac{\partial m_L}{\partial m_{pr}}\right) T, \mu_w, \mu_L = B_L - \frac{m_L}{m_w} B_w \qquad (1)$$

where B_L is the total binding of the ligand to the protein and B_w is that of water. In other words, B_L and B_w are the numbers of molecules of ligand and water that at any moment occupy sites on the surface of the protein molecule (are in contact with the protein surface). It is clear, therefore, that equilibrium dialysis result do not necessarily give the total number of ligand molecules that occupy sites on (are bound to) a protein molecule. Whether this is true or not depends on the magnitude of the second term on the right-hand side of Eq. (1). If binding of the ligand is strong (as is the case

with enzyme substrates, cofactors, various effectors, etc.), it is measured at a low concentration of the ligand, typically $<10^{-5}M$. This renders the second term of Eq. (1) negligibly small, with the consequence that equilibrium dialysis does yield the actual number of ligand molecules bound to the protein. This permits use of the classical binding equations, as expressed by various standard plots, such as the **Scatchard**, double reciprocal or **Hill plots** [(2)]. In the case of weakly interacting cosolvents that must be used at high concentration (>1 *M*, eg, 8 *M* urea), the second term becomes significant and $n \neq B_L$, so that equilibrium dialysis does not give total binding, ie, the true number of ligand molecules in contact with (occupying sites on) the protein.

Preferential Hydration

Preferential hydration is the excess of water in the immediate domain of a protein relative to the water concentration in the bulk solvent (eg, in 3 *M* glycerol). It is related to the preferential binding of a ligand by a simple reciprocal relation (see Binding):

$$\left(\frac{\partial m_w}{\partial m_{pr}}\right)_{T,\mu_w,\mu_L} = -\frac{m_w}{m_L}\left(\frac{\partial m_L}{\partial m_{pr}}\right)_{T,\mu_w,\mu_L} \qquad (1)$$

The term on the left-hand side is the excess of water molecules on the surface of the protein relative to the concentration of water in the bulk mixed solvent. As we see, this expression tells us that there is an excess of water on the protein surface if there is a deficiency of ligand, and vice versa. Understanding this and similar relations (see Binding) is of major importance in the stabilization and destabilization of protein structure by the addition of cosolvents, such as urea or sucrose. Preferential hydration must not be confused with total hydration.

Prenylation

Prenylation or isoprenylation is a post-translational modification process in which cysteine residues close to the C-terminal regions of some eukaryotic proteins are biosynthetically modified with an isoprenoid lipid: the 15-carbon farnesyl group or the 20-carbon geranylgeranyl group (see Fig. 1 and Table 1). Prenylation provides some proteins with a hydrophobic membrane anchor, and is important

for their correct localization within the cell. Prenylation is one of several processes that attach lipid membrane anchors to proteins (see Membrane Anchors).

Figure 1. Modification of C-terminal cysteine residues by prenyl groups. The C-terminal cysteine residue of the protein is outlined by the dotted line. The thiol group is thioether-linked to either a farnesyl or a geranylgeranyl group, and the exposed carboxyl group is methylated.

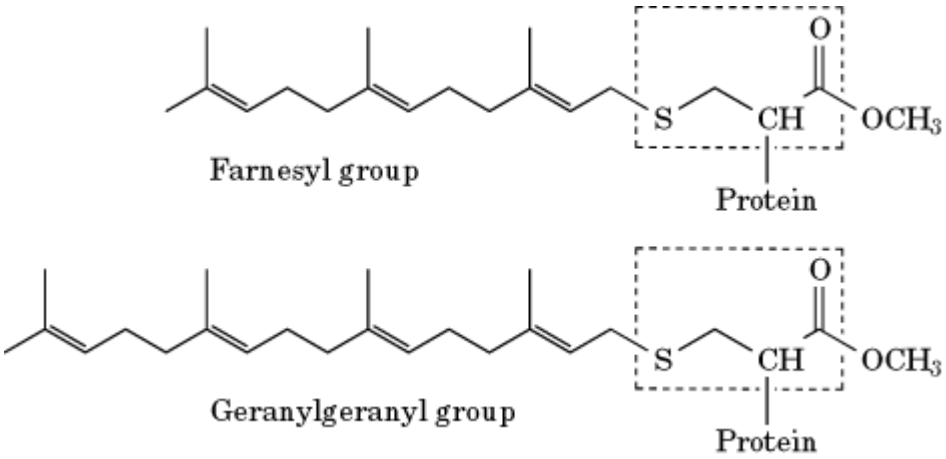

Table 1. Examples of Prenylated Proteins

Farnesylated
Ras proteins
Transducin g subunit
Rhodopsin kinase
Nuclear lamins A and B
Fungal mating pheromones[a]
Geranylgeranylated
g subunits of heterotrimeric G-proteins
Ras-related G-proteins (Rho/Rac/Rap/Ral/Rab)

[a] Peptides.

Isoprenoids are branched unsaturated hydrocarbons that are synthesized in eukaryotic cells from acetyl Coenzyme A by the first part of the metabolic pathway that is used to synthesize cholesterol and other sterols. Attachment of isoprenoids to proteins is a post-translational process with four main steps: 1) recognition of the C-terminal sequence by one of three distinct prenyltransferases (1); 2) prenylation of a cysteine residue(s) located at or close to the C-terminus using farnesylpyrophosphate or geranylgeranylpyrophosphate as the substrate; 3) proteolysis of the C-terminal residues exposes the carboxyl group on the prenylated cysteine; and 4) the isoprenylated cysteine is recognized by a methyltransferase, which methylates the carboxyl group using S-adenosyl methionine as the methyl donor. Steps 1) to 3) take place in the cytosol, whereas step 4)

occurs on the cytoplasmic surface of the endoplasmic reticulum or the plasma membrane. Thus efficient methylation requires prior isoprenylation to localize the protein at the membrane surface. The thioether linkage between the cysteine and the prenyl group is chemically very stable and probably not subject to metabolic turnover. However, the carboxylic ester linkage to the methyl group is relatively labile, and may be removed after attachment. These steps differ substantially between proteins, depending on the sequence motif at the C-terminus:

1. *Cys-a-a-X*. If X is **serine, methionine**, or glutamine, it is recognized by farnesyl transferase, and the cysteine residue will be farnesylated. If X is leucine, it is recognized by geranylgeranyltransferase I, and the cysteine residue will be geranylgeranylated. The identity of the "a" residues (usually aliphatic) is less important, but can influence whether isoprenylation takes place or not. Farnesyl transferase and geranylgeranyltransferase I are both heterodimers; they have identical a subunits, whereas the a subunits have only 30% identify. Farnesylation can also occur at the C-terminus of a variety of fungal mating pheromone peptides, and in yeast the same enzyme is used for farnesylating both proteins and peptides. Although farnesyl groups have relatively low affinity for membranes themselves, they can enhance the membrane association due to other lipid groups. Farnesyl groups, because of their small size, may also play an important role in protein–protein interactions by binding directly to specific sites on other proteins (2, 3).
2. *Cys-Cys, Cys-X-Cys* or *Cys-Cys-X-X*. These double cysteine motifs are restricted to the Rab subgroup of Ras-related small **G-proteins**. The Rab protein first forms a complex with Rab escort protein (REP). The Rab–REP complex is then recognized by geranylgeranyltransferase II. After prenylation, REP remains bound to Rab until it is delivered to the membrane. REP probably has a dual role: recognition of Rab and masking the two geranylgeranyl groups until they can be inserted into the appropriate membrane. Both cysteines are geranylgeranylated, and consequently proteolysis cannot occur. The C-terminus is not methylated in those Rab proteins ending with the sequence Cys-Cys (4).

Many of the prenylated proteins are involved in signal transduction or **vesicle** traffic, and the prenyl group, by facilitating rapid and reverible binding to membranes, plays an essential role in these functions (5, 6). The membrane affinity of the prenylated proteins can be influenced by four different mechanisms (for a general discussion of factors which can affect membrane affinity of lipid anchored proteins, see Membrane Anchors):

1. The attachment of a palmitate residue (see Palmitoylation) to a cysteine close to the C-terminus reinforces the binding (eg, as in H- or N-Ras). Palmitoylation only occurs in membranes, however, so prenylation is required for it to take place (7).
2. The presence of basic residues close to the C-terminus will result in electrostatic attraction to the negatively charged bilayer surface (as in K-Ras) and increase membrane affinity (8).
3. Methylation converts the C-terminal residue from a negatively charged, hydrophilic group to an uncharged, hydrophobic group and increases membrane affinity approximately 10-fold (5, 6)). The increase in affinity is due to the hydrophobicity of the methyl group, rather than a reduction in electrostatic repulsion, because methylation gives comparable increases in binding to uncharged membranes. Methylation can have a profound influence on the cellular distribution of farnesylated proteins, because the farnesyl group is too short to provide an effective anchor by itself. Turnover of the methyl group has also been observed, and it is possible that repeated cycles of methylation and demethylation are used to regulate protein function.
4. The membrane affinity will be reduced by soluble carrier proteins, which are able to bind to the isoprenyl group(s) and mask them from the aqueous environment. This mechanism is important for the repeated releasing and recycling of Rab proteins during membrane vesicular traffic processes (9, 10)).

Pre-Protein, Pre-Pro-Protein

Many proteins are synthesized as precursors in the form of pre-proteins or pre-pro-proteins that carry pre-sequences and or pro-sequences (see Pro-Sequence). Pre-sequences usually function as signal **peptides** for **protein targeting**, while pro-sequences play a crucial role in the folding of pro-proteins, whose examples are increasing.

Most proteins destined for protein secretion are synthesized in the cytoplasm as protein precursors (pre-proteins) containing an additional *N*-terminal sequence called the signal peptide, which plays a crucial role in protein recognition of the cell secretory machinery and in initiation of protein membrane translocation (1). The signal peptides vary between 18 and 35 amino acids and have no extensive sequence homology, but share similarities in their amino acid properties. The canonical signal peptide contains three characteristic regions: an *N*-terminal domain positively charged with one or two basic residues, a hydrophobic core, and a polar *C*-terminal domain containing the signal peptide cleavage site (2). Introduction of negatively charged and **hydrophobic** amino acids into the *N*-terminal basic region reduces the efficiency of secretion (3), which probably interact with anionic phospholipids of the membrane (4). Substitutions of hydrophilic amino acids for hydrophobic core residues abolish protein membrane translocation, suggesting that this region is involved in the interaction with components of secretory machinery.

Upon translocation, the signal peptide is cleaved by a membrane bound signal peptidase (5), and the pre-protein precursors are converted into mature proteins. Signal peptide cleavage sites are rather

regular and described by the "–3, –1 rule" (6) or "A-X-B" model (7) originally proposed by statistical evaluation of primary structures of known signal peptides. This model predicts the presence of small neutral residues at positions –3 and –1, whose structural regularity may be necessary for recognition of the signal peptide cleavage site by signal peptidase, although not essential for protein translocation itself (8). Consistently, amino acid substitutions at these positions of precursors prevent the processing.

Pre-pro-proteins have additional amino acid stretches (pro-peptides or pro-sequences) located between the signal peptide and the mature part of the protein (see Pro-Protein).

Pre-Replicative Complexes

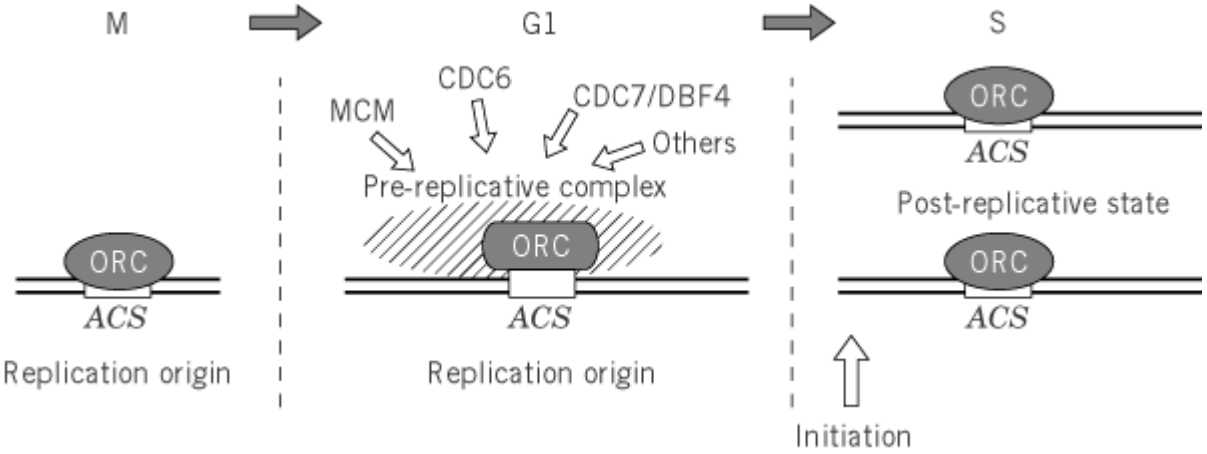
Prior to initiation of DNA replication, the replication origins must be prepared by forming DNA–protein complexes at the sites during the pre-replication period. The concept of a pre-replication stage arose from reconstitution studies of replication reactions *in vitro* using the replication origins of *Escherichia coli* (oriC), **bacteriophage** lambda and SV40 virus (1, 2). Dissection of these replication reactions revealed that they are composed of multiple steps and in the first step the initiator protein assembles at the origin DNA and activates it in an ATP-dependent manner. Formation of this protein–DNA complex induces a change in the structure of the DNA around the origin and directs it to accept several proteins necessary for DNA synthesis: DNA helicases, **primases**, and **DNA polymerases**. The initial active-complex state is relatively stable and retained for a certain period if the later DNA synthesis proteins are absent. Consequently, this initial complex can be isolated and is called a *pre-initiation* or *pre-priming* complex.

In eukaryotic chromosomes, preparation for triggering of the replication origins involves a long period and complicated procedures, since DNA synthesis from a replication origin has to occur within a narrow window of time during one cell cycle. Furthermore, the initiation site has to be distinguished clearly throughout the cell cycle from other regular chromosomal regions where stable

chromatin structures are formed. Actually, the predicted licensing mechanism that restricts the firing of each replication origin to once a cell cycle (see Licensing Factor) proposes a marking mechanism of potential origin sites at the end of mitosis to initiate DNA synthesis in the next **S phase**. Therefore, eukaryotic cells seem to start the preparation much earlier than the actual initiation time by establishing the competency for the initiation in parallel with the progression of cell-cycle events during the **G1 phase**. The molecular features of DNA–protein complexes at replication origins during the pre-replication period have been elucidated only in the **yeast** *Saccharomyces cerevisiae* (for a review, see (3)). A protein complex that binds specifically to the yeast replication origin (autonomously replicating sequence, ARS), the ARS conserved sequence (ACS) has been isolated and called the origin recognition complex (ORC). It binds to the origin throughout the cell cycle in an ATP-dependent manner and has an ATPase activity that is regulated by the ACS DNA. Thus, it is thought that ORC functions as a landmark for replication origins in the huge chromosomal structure and also has some active role in activating the replication origins. ORC is necessary to initiate DNA synthesis from the origins but is not sufficient for activation. Additional factors, MCM proteins (licensing factor), CDC6, and CDC7/DBF4 kinase (activators), interact with ORC and will be directly involved in the activation step.

The DNA–protein complex at the ARS was characterized by *in vivo* DNase I footprinting, which observed both an ORC-specific protection pattern and a second protection covering a wider region. The second protection pattern appeared at the end of mitosis, persisted throughout the G1 phase, and disappeared right after entry into the S phase. The wider nature of the protection pattern seemed to correspond to the formation of a larger protein complex on the ACS-bound ORC in the pre-replication stage. Further analysis demonstrated that the factors interacting with ORC, as indicated above, are all required for the formation and maintenance of the wider protection in the G1 phase and that the same factors are essential for the initiation of DNA replication from the origin (4). Therefore, it is most likely that these ORC-interacting factors form a large complex with ORC at the ACS, and the assumed complex built up on ORC early in the G1 phase is considered the pre-replicative complex competent to initiate DNA replication. During progression from the G1 to S phase, some highly programmed signaling mechanism transduces the final signal to each origin to initiate at the right time (Fig. 1). Then the pre-replicative complex will be disrupted and shifted to the post-replicative complex, simultaneously with the initiation of the origin.

Figure 1. Assembly of a pre-replicative complex at the yeast replication origin in G1 phase.



Knowledge about the actual assembly of the pre-replicative complexes in nuclei is limited. It was previously reported that replicating DNA and several replication proteins colocalize in nuclei and form replication foci in the S phase. It might be expected that pre-replicative complexes will

assemble at the same sites prior to the formation of replication foci. However, no components in the pre-replicative complexes reported in yeast have been demonstrated to be involved in such foci prior to the initiation of the S phase. Exceptionally, a eukaryotic single-stranded DNA-binding protein, RPA, exhibits punctuated assembly in nuclei prior to DNA replication in the Xenopus egg extract reaction (5). RPA is an essential component for SV40 virus DNA replication in *vitro*, and it facilitates the formation of unwound DNA at the SV40 replication origin in the pre-initiation stage. These RPA foci were formed at the end of mitosis, colocalized with some early replication foci upon the initiation of the S phase, and were linked with replication-associated unwinding of the DNA. Thus, they are called *pre-replication foci* (or *pre-replication centers*), which serve as the precursors for replication foci and will be one reflection of the formation of the pre-replicative complex or its closelyrelated protein assembly, although there is no direct evidence to connect them.

Pribnow Box

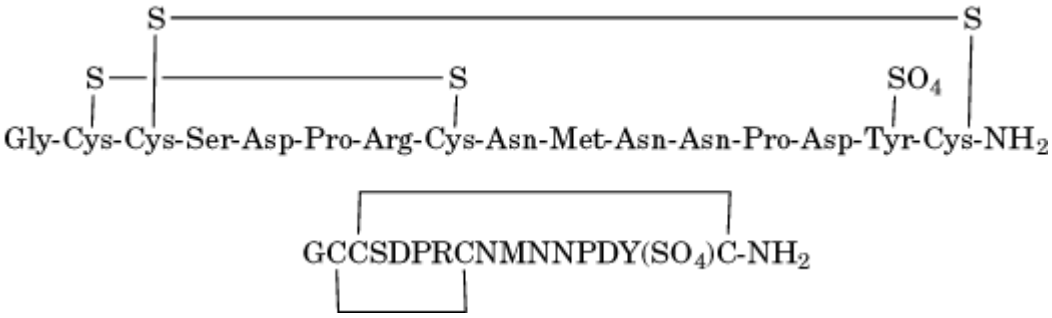
The Pribnow box is a conserved promoter element that is recognized by the main form of *E. coli*RNA polymerase holoenzyme (see TATA Box, Bacterial promoters). It is also called the -10 region to indicate its distance from the start site of transcription. This element was independently recognized as a region of sequence conservation in the mid-1970s by Drs. David Pribnow and Heinz Schaller when they visually inspected the first available sequences. Computer analysis of several hundred promoter sequences has established the sequence TATAAT (on the nontemplate strand) as the consensus sequence of the Pribnow box. Many eukaryotic and archaeal promoters have a sequence similar to that of the Pribnow box at approximately -30, with consensus sequence TATAAA.

Primary Structure

Protein structure is classified in a hierarchical manner into primary structure, **secondary structure**, tertiary structure, and quaternary structure. The primary structure of a protein is the sequence, or order, of amino acid residues in the polypeptide chain and can be represented in a variety of ways (two examples are given in Fig. 1). By convention, the sequence is numbered from the N-terminus to the C-terminus of the polypeptide chain. The primary structure also includes information about the number of polypeptide chains in a protein and any covalent modifications, such as disulfide bond formation, **phosphorylation**, sulfation, or **glycosylation** (see N-Glycosylation and O-Glycosylation). In addition, nonprotein groups, or **prosthetic groups**, such as heme, metal ions, or pigments, form

part of the primary structure of a protein. The significance of a protein's primary structure is that it determines both the three-dimensional structure and the function of that protein.

Figure 1. Alternative representations of the primary structure of the 16 residue peptide a-**conotoxin** EpI (1). The upper representation gives the amino acid sequence using the three-letter code, the lower representation uses the one-letter code for different amino acid residues. Both representations show the presence of two disulfide bonds, sulfation of the tyrosine residue, and amidation of the *C*-terminus (see Post-Translational Modifications).



Determination of a protein's primary structure can be done either directly using a combination of biochemical and chemical techniques (see Protein Sequencing) or, more often, indirectly by identifying the nucleotide sequence of the corresponding **gene** or complementary DNA. If two different proteins have similar primary structures, they are said to be **homologous** and are likely to have similar tertiary structures and functions. Sequence databases such as SWISS-PROT (1) hold information about the primary structures of many thousands of proteins and can be searched to identify homologous proteins.

In vivo, the primary structure of each protein is genetically encoded. Mutations in the genetic code, or errors in reading it, can lead to changes in the protein primary structure. Such variations from the normal or **wild-type** sequence can result in changes to both the structure and function of a protein and can affect the viability of the cell and/or the organism. On the other hand, changes may be engineered into the primary structure of a protein *in vitro* by site-directed mutagenesis to investigate the role of specific residues.

Theoretically, it is possible to predict the tertiary structure of a protein directly from knowledge of its primary structure (see Protein Structure Prediction). In practice, however, this so-called **protein folding** problem is not yet solved, except in those instances where protein structures can be predicted by **homology modeling** .

Primase

Initiation Of DNA Replication by **DNA polymerases** requires **primers** that provide a 3′-OH terminus on the template DNA. In some particular systems, long RNA **transcripts**, DNA fragments, or proteins covalently linked with nucleotides function as primers for DNA synthesis, but in general this function is performed by short RNA fragments newly synthesized on the template. During DNA replication, the two antiparallel DNA strands in double-stranded DNA have two different modes of synthesis, in which one strand is synthesized continuously (**leading strand**) and another discontinuously (**lagging strand**; see also Okazaki Fragments). Since the latter mechanism requires frequent priming in certain intervals on a DNA strand, an enzyme that is able to produce short RNA primers repeatedly is an essential component of most DNA replication systems. Indeed, all cells have an essential specialized enzyme, called the *primase*, that synthesizes short RNA primers for DNA replication. Originally, this enzyme was discovered through studies on the initiation of replication of *E. coli* single-stranded DNA **bacteriophages**. Among more than 10 replication proteins needed for the replication of these phages, the DnaG protein was identified as a factor essential for the initiation stage. Subsequent reconstitution of the reaction with purified proteins demonstrated that the role of this protein is the production of short RNA segments on a single-stranded DNA, which is subsequently used for DNA synthesis by DNA polymerase (1).

DnaG primase is inert on its own, and additional proteins cooperate in the priming process. Reconstitution experiments revealed that a mobile protein complex called the *primosome* is assembled and migrates along the template (2). One major member of primosome is the DnaB DNA helicase, which interacts functionally with primase and activates the enzyme. A *primosome assembly site* (PAS) was isolated from the *E. coli* fX174 phage genome as a characteristic stem-loop structure. An ATPase named PriA recognizes the PAS and forms a complex with two other primosome assembly proteins (PriB, C). Subsequently, DnaB helicase and DnaG primase are recruited to the complex. In the case of replication origins, complexes of initiator proteins also assemble the DnaB-DnaG primosome, as reported for *E. coli* oriC or the lambda phage origin (for a review, see (3)). The assembled primosome migrates on the template strand in a 5′ to 3′ direction, hydrolyzing ATP and synthesizing many primers. The direction of migration is opposite to that of DNA synthesis, which explains the mechanism of priming for the discontinuous, lagging strand. During DNA synthesis, the primosome will be a part of the replication fork complex and will manage the synthesis of primer RNA by the interval corresponding to the Okazaki fragment length. A similar tight link of primases and DNA helicases, and their involvement in the replication fork complexes, has also been reported in bacteriophage T4 and T7 replication (4, 5).

Eukaryotic primases have slightly different features from those of prokaryotic systems. They were detected as a component of DNA polymerase a, which is an essential DNA polymerase for chromosomal replication. This polymerase has a large subunit of about 180 kDa, a middle subunit of about 70 kDa, and two small subunits of 60 to 50 kDa (6). The primase activity is detected in the subcomplex of two small subunits, and maintenance of the complex is necessary for this activity. The primase catalytic activity is harbored in the 50-kDa subunit, and the 60-kDa one functions as its accessory subunit. Studies of the DNA elongation process using an *in vitro* SV40 replication reaction revealed that eukaryotes have multiple DNA polymerases and the DNA polymerase a complex is specialized for the synthesis of Okazaki fragments (7). Thus, the association of primase with DNA polymerase a would be an adapted feature of eukaryotes to synthesize Okazaki fragments efficiently by specializing one of many DNA polymerases for the priming process, although the mechanism of switching from the priming reaction to DNA synthesis in one protein complex is still unclear.

The nature of the sequence specificity of the primer RNA to initiate primer synthesis, and its ultimate length, have been studied with several *E. coli* replicons. The results indicate that the preferred sequence for DnaG priming is GTC, and most of the primers have pppApG at their 5′ end, which initiated from base pairing with the middle T. RNA–DNA junctions are observed at fixed sites from the primer start, and the primer length is predominantly 11 ± 1 nucleotides. Priming by T4 or T7 phage primers also has a sequence preference, but the sequences are slightly different from those of DnaG. The nature of the preferred sequence for eukaryotic primase has not been elucidated well, but the length of the primer is 12 to 14 nucleotides for Drosophila primase and 8 to 12 nucleotides for mouse or yeast primases (1).

Primer

DNA polymerase plays a primary role in DNA replication, catalyzing the synthesis of a DNA chain complementary to the template DNA strand as follows:

$$(\mathrm{dNMP})_n + \mathrm{dNTP} \rightarrow (\mathrm{dNMP})_{n+1} + PP_i$$

The reaction absolutely requires three components: (1) a deoxynucleosidetriphosphate (dNTP) as a substrate, (2) single-stranded DNA as a template, and (3) a short RNA or DNA as a *primer* (1). No known DNA polymerase is able to initiate DNA synthesis without a primer. The primer must be annealed to the template by base-pairing, and its 3′-terminus must possess a free 3′-OH group. Chain growth is exclusively 5′ → 3′ since the polymerization mechanism is a nucleophilic attack by the 3′-OH group of the primer on the a-phosphate of the incoming dNTP. The products are a new primer, longer by one nucleotide, and one inorganic pyrophosphate. A 2′,3′-dideoxyNTP can be incorporated by some DNA polymerases, but it blocks chain elongation because it lacks a free 3′-OH group. This chain termination property is utilized in some DNA sequencing methods (2) (see **Sanger method** and **Sequencing, DNA**).

Why does DNA polymerase require the primer for chain elongation? It has been thought that chain growth by the covalent extension of primer makes it possible for DNA polymerase to copy DNA very accurately. All the replicative DNA polymerases possess proofreading capacity, which allows for removal of nucleotides incorrectly inserted by the polymerase and increases the fidelity of DNA synthesis. The proofreading process involves melting the primer terminus to translocate it from the polymerase active site to the 3′ → 5′ exonuclease active site (3). Since the distance between both active sites is about four nucleotides in length, the elongating DNA in the molecule of DNA polymerase must be longer than four residues. If not, the short piece of DNA would not be set back properly on the template sequence. It is also known that the 3′-end of RNA annealed to template

DNA is not subjected to proofreading by DNA polymerase. Thus, the DNA polymerase can start DNA synthesis from primer RNA without an abortive proofreading process occurring. It should be noted that the primer RNA, which is made with a much higher error rate than DNA, is removed upon completion of Okazaki Fragments.

A common primer for the DNA replication of **chromosomal** DNA is a short RNA transcript synthesized *de novo* by a primase in both prokaryotic and eukaryotic cells (pp. 279–297 (1)). Numerous **bacteriophage** and **plasmids**, as well as some animal **viruses**, possess their own primase for DNA replication. This is probably due to the **replicon**-specific replicative apparatus. In prokaryote cells, primase is usually a single polypeptide chain, and its priming function requires other factors, forming a multiprotein complex called the *primosome* on single-stranded template DNA (4). A transient and functional interaction between primase and replicative DNA helicase is important for the priming reaction. In eukaryotes, however, primase is associated with DNA polymerase activity, as an integral part of DNA polymerase a (5). Since no eukaryotic DNA helicase has been assigned as the replicative helicase, the interaction between primase and helicase is not known. In contrast, a tight complex of primase and helicase, and even a single polypeptide chain carrying both primase and helicase activities, has been found to be a priming enzyme for bacteriophages (6).

Primases can start a new chain when copying a duplex DNA but, like DNA polymerases, they require single-stranded DNA as the template (7). Primases absolutely require an rNTP (ATP in most cases) to initiate the primer, but they can utilize dNTPs in place of rNTPs. Under physiological concentrations, rNTPs are preferentially used during primer synthesis. In prokaryotes, primer synthesis is initiated at preferred sequences on the template: 3′-GTC for *E. coli* primase (DnaG), 3′-CTG(G/T) for T7 phage primase (gp4), and 3′-TTG for T4 phage primase (gp61). The sequence preference of the initiation of primer synthesis by eukaryotic primases is uncertain. All primases found in various organisms extend the primer chain in the 5′ → 3′ direction to a particular length: 10 to 12 nucleotides by DnaG protein, 4 nucleotides by T7 gp4, 5 nucleotides by T4 gp61, and 8 to 12 nucleotides by eukaryotic primases (8-11).

There are several ways to make primer other than the priming process by primase. It has been shown that **RNA polymerase** can act as a priming enzyme, producing a special kind of RNA primer for the initiation of replication of some bacteriophage and plasmid DNA (12, 13). In the DNA replication of particular types of bacteriophage (such as *Bacillus subtilis* phage f29) and animal viruses (such as Adenovirus), protein priming promotes the initiation step, in which the 3′-OH group of an amino acid residue within the termination protein is recognized as a primer end by DNA polymerase (14). The end of a preexisting DNA strand can also serve as the primer. The 3′-OH terminus generated in nicks or gaps of DNA is a common primer for DNA synthesis to complete DNA repair or the recombination processes.

Primer Extension

Primer extension is a technique that can be used for a variety of purposes, such as mapping the 5′ ends of messenger RNA and the ribonuclease cleavage sites in RNA. A DNA oligonucleotide complementary to the RNA is synthesized and radiolabeled at the 5′ end with g^{32}P ATP and **polynucleotide kinase** (Fig. 1). The primer is then annealed to the RNA, followed by the addition of nucleoside triphosphates and **reverse transcriptase** (RT). The reverse transcriptase synthesizes the complementary strand until it falls off the template RNA at its 5′ end. The primer-extended product is then purified and subjected to electrophoresis on a denaturing polyacrylamide gel to determine its length. In the case of mRNA, a DNA **sequencing** reaction is carried out in parallel on the genomic sequences encoding the mRNA, which permits the site at which the reverse transcriptase stopped, that is, the site of initiation of transcription, to be mapped to the exact nucleotide (1, 2).

Figure 1. The primer extension reaction. A small DNA oligonucleotide, labeled at the 5′ end (*) with a 5′ radioactive phosphate, is annealed to the RNA. The primer is extended using reverse transcriptase and nucleoside triphosphate. The extended products are resolved by denaturing polyacrylamide gel electrophoresis (PAGE) and visualized by autoradiography. The exact size of the product can be judged by reference to a sequencing ladder generated from a corresponding fragment of the gene. For example, see reference (2), where this technique was used to map cleavage sites in ribosomal RNA precursors.

Prion

The term “prion” was coined by Prusiner (1) as a shortened form of “proteinaceous infective agent”, to describe the agent he thought responsible for the transmissibility of certain spongiform encephalopathies such as scrapie, BSE, or “Mad Cow” disease and Creutzfeldt Jakob disease (CJD) (see Scrapie). What makes the prion concept so interesting and controversial is that it breaks with current orthodoxy that nucleic acids are necessary for the process of disease infection. Prusiner has long maintained that the evidence of scrapie infection ruled out involvement of nucleic acids, leaving a self-replicating proteinaceous agent as the only other possibility, however heterodox that might seem. The threat that these diseases present to the human population, their insidious nature involving very long incubation periods, the uncertain routes of infection, and their particularly unpleasant symptoms has heightened general public concern in their study and the parallel search for therapies. For his persistence in exploring the prion hypothesis and demonstrating its apparent correctness, Prusiner was awarded a Nobel Prize in 1997.

The scrapie agent was first discovered in the brains of the Syrian hamster and identified by antibody-labelling with the prion protein in both infected and uninfected brains. This suggested that the agent was a single protein that exists in a different isoform from that in healthy tissue. Subsequent studies have shown that the prion protein is responsible for both toxicity and infectivity of scrapie. The prion protein appears to occur in two distinct forms: PrP^{C}, the normal cellular form and PrP^{Sc}, the infective scrapie form. The two forms can be readily distinguished by their different sensitivities to proteases: PrP^{C} is a 33–35 kDa protein rapidly degraded by protease K, while PrP^{Sc} is more stable to this protease forming a 27–30 kDa proteinase-resistant core, known as PrP27–30. In the presence of detergents, PrP^{C} remains soluble, while PrP27–30 polymerizes into amyloid fibrils (2, 3) (see Amyloid). As the PrP is a single copy gene encoded on a single exon, these different forms do not derive from differential splicing. The difference between the PrP^{C} and PrP^{Sc} forms appears to reside in the three-dimensional, rather than the covalent, structures of the proteins. Spectroscopic examination of PrP^{C} and PrP^{Sc}, using Fourier transform infra-red spectroscopy (FTIR) and circular dichroism, shows that PrP^{C} contains around 42% a-helix but only about 3% b-sheet (4), while in PrP^{Sc} the helix content declines to 20% to 30%, and the b-sheet rises to about 43% and even further to 47% to 54% in the PrP27-30 proteolytic product (5-7). The high a-helical content of PrP^{C} form has been confirmed by an NMR determination of its largest folding domain, residues 121–231 (8), which shows a globular structure with three a-helices and a small two-stranded b-sheet. Solid-state NMR of the adjacent peptide, residues 109–122, suggests it has a b-structure under some conditions and an a-helix under others (9). This supports the proposal that the change associated with infectivity has the character of an a- to b-structural conversion. It is interesting to note that these studies have not uncovered any unusual structural feature in the prion protein that might explain the structural conversion.

In Prusiner’s view, infectivity of the prion occurs because PrP^{Sc} molecules can convert normal PrP^{C} molecules into the PrP^{Sc} form, which, in turn, may convert further cellular prions into the scrapie form, as in some kind of chain reaction. How this process occurs *in vivo* is not absolutely certain, but it has been found possible in the presence of guanidinium to slightly destabilize the proteins and generate a proteinase-resistant form of the prion protein from a simple mixture of PrP^{C} and PrP^{Sc} *in vitro* (10). One possible mechanism for the conversion of PrP^{C} to the PrP^{Sc} form by PrP^{Sc} is through the formation of a mixed dimer (11) (see Scheme A in Table 1). Alternatively, a hypothesis of nucleated, or seeded, polymerization has been proposed (13) in which the structural conversion involves the recruitment of PrP^{C} molecules into a growing PrP^{Sc} polymer (see Scheme B in Table 1). Evidence is increasing that the PrP^{Sc} form is not dimeric but at least tetrameric or oligomeric (14,

15). As PrP27–30 is known to form amyloid and amyloid formation from a-helical proteins is known to involve a- to b- structural conversion (see Amyloid), an amyloid fibril may function as the prion-converting agent. This view is given support by sedimentation and ultrafiltration studies, which suggest that converting acitivity is associated with heterogeneous particles that are several times larger than the solubilized PrP molecule (16). On the other hand, a number of observations (17) do not correlate infectivity with the presence of visible or high molecular weight prion amyloid. However, it is not certain that the involvement of small amyloid fragments or templates that might act as initiators of prion amyloid can be entirely ruled out.

Table 1. Proposed Mechanisms of Prion Structural Conversion

A. Dimer formation(11)

$$PrP^{C} + PrP^{Sc} \rightarrow PrP^{C}.PrP^{Sc} \rightarrow PrP^{Sc}.PrP^{Sc}$$

B. Aggregation (13)

$$PrP^{C} + [PrP^{Sc}]_{n} \longrightarrow [PrP^{Sc}]_{n+1}$$

Other studies have suggested alternative mechanisms for the structural conversion of PrP^{C} and have implicated another molecule, designated "protein X," in the process of formation of PrP^{Sc} from PrP^{C} (18). It is proposed that protein X may bind to PrP^{C} in such a way that subsequent binding of PrP^{Sc} to produce a ternary complex, and conversion of the cellular to the scrapie form, is facilitated (19). Another proposal (20) suggests that the single disulfide bond in the prion may be destabilized and reforms as an intermolecular bond linking PrP^{Sc} units in an amyloid fibril. This model has the additional advantage of adding yet greater stability to the already very stable amyloid fibril, thereby providing an explanation of the extreme thermal and chemical stability of the scrapie agent.

About 10% of the incidence of CJD is familial and, thus, inherited. PrP is encoded by a single gene on chromosome 20 in man, consisting of a single exon. Some 20 different mutations in the human prion gene segregate with dominantly inherited disease, and five of these have been genetically linked to human familial prion diseases (Table 2). Plotting these mutations on the known structure of the 121–231 domain of the PrP^{C} molecule (8) shows a tendency to cluster within, or close to, a-helices, possibly stabilizing their conversion to b-structures (10). Alternatively, the placement of many variant residues in the hydrophobic core of the prion domain may result in a large-scale unfolding and refolding of the prion protein, as indicated experimentally in the a- to b-conversion in lysozyme (21), whose proportions of a-helix and b-sheet broadly match those of PrP^{C} (see Amyloid Precursor Protein). This is supported by the proposal that molten globule prion intermediates (22) may be involved in the a- to b-conversion PrP^{C} to PrP^{Sc} conversion, as they are in lysozyme.

It has also proved possible to establish transgenic animal models of the disease (18, 23), which have been used to test a number of important avenues of investigation. One of these is the most puzzling aspect of prion diseases: the question of strains (24, 25). The scrapie diseases, like many other infectious diseases, exist in a number of sub-forms or phenotypes, which implies that differences in the prion protein molecule are capable of being passed on. Because no nucleic acids are present in the scrapie diseases to replicate amino acid variation, how can the representation of different disease phenotypes occur in the protein-only prion system? This question needs to be considered against a clear experimental background that scrapie strains can be transmitted. In a crucial experiment (25), mice expressing a chimeric mouse-human PrP gene were inoculated with prions from two different subtypes of CJD and from Fatal Familial Insomnia (FFI). The different mutations in the PrP molecules from CJD and FFI (Table 2) result in slight differences in chain conformation, which are expressed as different fragmentation patterns when treated with proteinase K; the CJD proteins yield a 21 kDa proteinase-resistant fragment, whereas in the FFI protein it is 19 kDa. Innoculation of the mice with FFI brain extracts induced the formation of the 19 kDa PrP^{Sc} fragment, whereas inoculation with CJD extracts induced formation of the 21 kDa fragment. The only reasonable conclusion is that this experiment demonstrates that the probably subtle structural differences in variant PrP^{Sc} molecules can be "imprinted" on the same set of PrP^{C} molecules in their conversion to the PrP^{Sc} form, leading to prions carrying specific information of their strain of origin. As the resultant PrP^{Sc} molecules are covalently identical, the differences representing the strains must reside in differences in the folding of the polypeptide chains or possibly in their pattern of glycosylation. One possible model is analogous to crystallization; crystals can replicate themselves in the presence of monomers by the process of seeding or nucleation. Different PrP^{Sc} molecules could give rise to structurally slightly different amyloid fibrils (fibril formation can be considered as one-dimensional crystallization); fragments of these, in turn, could act as nuclei recruiting into a growing fibril only those prions of the same kind, thereby replicating themselves. Experimental evidence seems now to support this mode (26, 27).

The study of the prion has challenged the two long-held fundamental dogmas. First, that the amino acid sequence is the sole determinant of the native protein fold (28) and, second, that protein structural information can only be transmitted through the mediation of DNA or RNA. It has also indicated how protein-protein information transmission might occur. All of this is in the context of identifying protein misfolding as a hitherto unsuspected cause of certain widespread inherited and infectious diseases.

Probe Hybridization

The ability of complementary nucleic acids to form hybrid duplexes has been exploited in a large number of powerful techniques for identification and manipulation of the genetic information stored in DNA and used by the cell via RNA. Most of these **hybridization** techniques rely on the use of a labeled probe nucleic acid to hybridize with a target nucleic acid. After removal of any unreacted probe, detection of the remaining labeled probe identifies and quantifies the hybrid duplex and, consequently, the regions of complementarity between the probe and the target.

If the target is one strand of a duplex, **denaturation** must precede hybridization. Usually, denaturation is accomplished by heat or by exposure to alkaline conditions. Often the number of targets is quite low, perhaps only a few copies. There are a number of amplification techniques that will produce large numbers of copies of the target and thus increase the amount of hybrid duplex produced with a concomitant increase in the observed signal. Solid-phase hybridization requires an addition preparative step, namely, immobilization of the target.

The length of a hybridization probe can vary from about 15 bases to several hundred or more, with the appropriate choice depending on the specific experiment. Long probes provide greater specificity. They can incorporate many detectable groups per probe, thereby increasing the signal intensity. Long probes typically are generated by random-primed labeling, nick translation, or **PCR** (1), and require more work to prepare than do short chemically synthesized probes.

Short probes (15–30 bases) can be synthesized in large quantities. Incorporation of nonisotopic reporter groups is easily accomplished. Short probes bind less tightly to the target than do long probes. In many circumstances weaker binding is advantageous. The hybridization experiment can then be sensitive to single defects of complementarity, including mismatches, deletions, bulges, and small internal loops.

Detection and quantification of the hybrid duplex is provided via the labeled probe. Labeling, whether isotopic or nonisotopic, is an essential feature of the probe. All the early work in hybridization was performed with isotopic labels. More recently, sensitive **chemiluminescent** and bioluminescent detection schemes have come into common use. The nonisotopic techniques have advantages in speed, cost, and safety, and are approaching isotopic techniques in sensitivity.

Immobilization of the target on a surface is the most powerful method for avoidance of the competitive equilibrium problem. Because the target and its original partner strand are immobilized, the original duplex cannot reform. The target is immobilized on a nitrocellulose or nylon filter, although there are many other solid-phase formats. In most techniques, the probe is delivered to the target; however, in DNA chip technology the target is delivered to a microarray of immobilized oligonucleotides.

Blotting techniques provide a means for quantifying and identifying specific target nucleic acids. In dot blots or slot blots, the target is deposited on a small area of a **blotting matrix** . A series of targets, each deposited in a discrete spot on the filter, can be hybridized simultaneously to a single probe. In **Southern** and **Northern blots** and related techniques, target nucleic acids are distributed into discrete bands on a gel by electrophoresis. The target nucleic acids are then transferred to a filter membrane, on which a conventional hybridization procedure is performed. The extend of hybridization is detected and quantified for each band on the original gel.

When the spatial distribution of target is sought, in situ hybridization techniques are employed. Tissue, cell, or chromosome samples are prepared and fixed. The nucleic acids are denatured. The hybridization reaction is performed by placing a probe-containing solution directly onto the sample. Visualization involves one of several microscopy techniques.

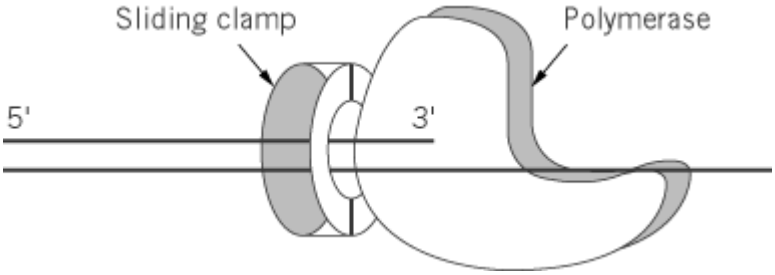
DNA Polymerase Sliding Clamps

Chromosomal replicases are multiprotein assemblies composed of a DNA polymerase and several accessory proteins and are characterized by remarkable speed and processivity. The term "processivity" refers to the fact that the polymerase is capable of polymerizing thousand of nucleotides without dissociating from the DNA. In several well-characterized systems (bacteria, archaea, eukarya, and bacteriophage-T4), the replicases have been shown to be similar in function, structure, and overall organization (see Clamp Loaders of DNA Polymerases), and in all these systems the remarkable processivity is achieved, in party, by the DNA polymerase accessory proteins. The polymerase accessory proteins can be divided into two group: a complex of proteins known as the "clamp loader," and a processivity factor called the "sliding clamp" (1). The sliding clamp is a ring-shaped protein (Fig. 1) that encircles DNA and anchors the polymerase to the DNA template (Fig. 2). The sliding clamp cannot assemble itself around DNA but is loaded onto DNA by the clamp loader (see Clamp Loaders of DNA Polymerases). The arrangement of the polymerase and sliding clamp allows for rapid and processive DNA synthesis (Fig. 2). The sliding clamps have also been shown to play a role in DNA repair and gene transcription and to interact with cellular components involved in progression and control of the cell cycle.

Figure 1. Computer generated images of *E. coli*, b subunit, and yeast PCNA. Ribbon representation of polypeptide backbones of trimer of yeast PCNA (**right**) and a dimer of the *E. coli* b subunit (**left**). Strands of b sheets are shown as fl ribbons, and a helices are shown as spirals. The subunits within each ring are distinguished by different colors. A hypothetical model of DNA is placed in the center of each ring. Adapted from (8).

Figure 2. A model for the action of a sliding clamp as a processivity factor. The sliding clamp encircles the DNA and bi
the polymerase, thus tethering it to the DNA for processive DNA synthesis.



1. Structure and Biochemical Properties of the Sliding Clamp

The sliding clamps of bacteria, archaea, eukaryotes and phage-T4 are similar in both structure and function (2-4). In *Escherichia coli*, the sliding clamp is the b subunit; in archaea and eukaryotes, it is the product of the proliferating cell nuclear antigen (PCNA) gene, and in phage-T4, it the product of gene-45 (gp45). The b subunit is active as a homo-dimer, whereas PCNA and gp45 are active as home-trimers (Fig. 1) (3, 5). The molecular mass of the dimer of the b subunit is 81 kDa (40.5 kDa as monomer), the PCNA trimer is 87 kDa (27 kDa as monomer), and gp45 trimer is 74 kDa (24.5 kDa as monomer) (6). Thus, the molecular mass of these oligomers are similar, and it would be shown that the b subunit, PCNA, and gp45 have similar structures.

1.1. The Three-Dimensional Structure

The processivity factors are ring-shaped proteins that encircle DNA. The overall structure of these sliding clamps are very similar; the PCNA and the b subunit rings are superimposable (Fig. 1) (5, 7-12). Each ring has similar dimensions and a central cavity large enough to accommodate a double-stranded DNA (dsDNA) molecule (Fig. 1) ((7-12); reviewed in: (3-5)). Although PCNA and gp45 are trimers and the b protein is a dimer, they each have sixfold symmetry. The symmetry derives from the two (PCNA and gp45) or three (the b subunit) globular domains, each within each monomer that have the same chain fold. Although the domains in each monomer do not have

significant sequence similarity, they are superimposable in three dimensions (7). Each domain contains two a-helices that line the central cavity and are perpendicular to the DNA. The a-helices are supported by a continuous layer of b-sheet structures all around the outside that also form the intermolecular boundaries (7-12).

The sliding clamps are quite acidic proteins and would be repelled by DNA. The charge distribution on the ring, however, is asymmetric. The outer surface has strong negative electrostatic potential, which may prevent the clamp from nonspecific interactions with DNA. On the other hand, the inside of the central cavity, where the DNA is located, has a net positive electrostatic potential and, thus, may strengthen the interaction with DNA upon proper assembly of the ring around by the clamp loader (see Clamp Loaders of DNA Polymerases).

Although the three prototypic clamps have a similar structure, they differ in their relative stability, in solution and on DNA. The b subunit forms a stable dimer in solution and is also stable on DNA while PCNA is not as stable. On the other hand, gp45 is much less stable in solution and on DNA (6).

2. The Biochemical Properties

The first indication for the toroidal shape of the sliding clamps came from the study of the b subunit of the *E. coli* replicase. The b subunit was shown to bind tightly to circular DNA but dissociate readily upon linearization of the plasmid by sliding off the ends (6, 13). This dissociation of b from linear DNA could be prevented if the DNA ends were blocked (6, 13). Because the affinity of b to DNA depended on the geometry of the DNA molecule, these observations suggested a toroidal shaped structure for the sliding clamp and a topological mode of binding.

Evidence for the topological binding of PCNA to DNA came from the observation that PCNA alone can support processive replication by the polymerase in the absence of clamp loader (see Clamp loaders of DNA Polymerases) only when the DNA is linear and has a double-stranded end (14). These results demonstrated that PCNA could thread itself onto the end of the dsDNA and slide along the duplex until it reaches the 3′terminus where it interacts with the polymerase to initiate processive DNA synthesis (Fig. 2). Photocrosslinking experiments also demonstrated the sliding property of PCNA. PCNA can be crosslinked to DNA after its assembly around circular DNA. This crosslinking did not occur if the DNA was linearized, suggesting that the PCNA had dissociated from the DNA via sliding over the ends (15).

Cryoelectron microscopy was used to observe gp45, which appeared to encircle DNA; the results also indicated that it might slide along the duplex (16). The ability of gp45 to slide along DNA was confirmed using photochemical cross-linking analysis. gp45 could be cross-linked to circular, but not linear, DNA, suggesting that the protein could slide offer linear DNA (15).

3. Functions of the Processivity Factors

3.1. Processivity Factors and DNA Replication

To data, the best understood function for the sliding clamps is their essential role in chromosomal DNA replication. The processivity factors endows its cognate polymerase with the ability to polymerize thousands of nucleotides without dissociating from the DNA template. The b subunit is the processivity factor of DNA polymerase (pol) III holoenzyme; PCNA is a part of the pold holoenzyme, and gp45 binds the product of gene-43 (phage-T4 polymerase).

In bacteria the processivity factor is essential for DNA replication. *dnaN* is the gene that encodes the *E. coli* b subunit (17). *E. coli* cells harboring a temperature-sensitive mutation in the *dnaN* gene stop DNA synthesis when shifted to the restrictive temperature (18). This observation, together with early biochemical analysis (19), indicated a role for the b subunit in DNA replication. Further studies demonstrated that the b subunit is responsible for the processivity of both DNA polII and polIII

(Table 1). The polymerase of the *E. coli* polIII holoenzyme incorporates approximately 20 nucleotides/s and is processive for only 11 nucleotides before dissociating from the DNA template. Upon binding of the b subunit, polIII becomes a very rapid (750 nucleotides/s) and highly processive (>50,000 nucleotides) enzyme (20). Upon the assembly of the b subunit around the DNA template by the accessory complex (see Clamp Loaders of DNA Polymerases), the clamp loader can be removed, leaving the clamp around the DNA. Then, the b ring can associate with the polymerase (Fig 2) to initiate rapid and processive DNA synthesis (21). Thus, at least in prokaryotes, the formation of a processive holoenzyme can be seen as a two step process. In the first step, a b clamp is assembled around the DNA primer by the clamp loader to form the "preinitiation complex." In the second step, the polymerase assembles with the preinitiation complex to form the "initiation complex" capable of rapid and processive DNA synthesis (see Clamp Loaders of DNA Polymerases). Therefore, the mechanism by which a b ring confers processivity to polymerase is by direct contact with it, tethering the polymerase to the DNA (Fig. 2). The polymerase would then pull b along during polymerization.

Table 1. Partial List of Sliding Clamp Interacting Proteins

Clamp	Interacts With:	Role of Interaction
PCNA	DNA polymerase d	Processive DNA synethesis
	DNA polymerase ε	Processive DNA synthesis
	RFC	Loading/unloading of PCNA
	Fen-1	Stimulation of Fen-1
	DNA ligase I	Okazaki fragment maturation
	D-type cyclins	Inhibits DNA replication
	p21	Inhibits processive DNA replication
	Gadd45	DNA repair
	MSH	DNA repair
b subunit	DNA polymerase II	Processive DNA synthesis
	DNA polymerase III	Processive DNA synthesis
	g-complex	Loading/unloading of b
	DNA ligase	Okazaki fragment maturation
	MutS	DNA repair
gp45	gp43	Processive DNA synthesis

gp44/62 complex Loading of gp45

E. coli RNA polymerase Activation of transcription

In eukaryotes, the early indication of a role for PCNA in DNA synthesis came from the pattern of expression during the cell cycle. PCNA is a nuclear protein with elevated expression during the S-phase (DNA synthesis) of the cell cycle (22, 23) whereas in quiescent and senescent cells there are very low levels of the protein.

Several *in vivo* and *vitro* studies determined the important role played by PCNA in DNA replication. Expression of anti-sense RNA in exponentially growing cells caused a suppression of DNA replication and cell-cycle progression (24). Deletion of the PCNA gene in both the budding yeast (25) and the fission yeast (26) demonstrated that PCNA is an essential protein that is important for DNA replication. *In vitro* replication assays have been employed to establish the role of PCNA as the processivity factor of Pold (Table 1), the replicase of eukaryotic cells. PCNA enables pold to replicate a template with long single-stranded stretches (27) and is required for Simian virus 40 (SV-40) *in vitro* replication (28), while antibodies generated against PCNA inhibit pold-dependent *in vitro* replication (29). PCNA also plays an important role in coordinating leading and lagging strand synthesis (30).

PCNA also stimulates the activity of polε (Table 1) (31). The precise role of polε in chromosomal DNA synthesis, however, is not yet clear; it may play a role in Okazaki fragment maturation. Polε was shown to be important for DNA repair (23, 32), and its stimulation by PCNA might be important in this process.

The role of PCNA in chromosomal DNA synthesis might not be limited to its effect on the polymerase. PCNA was shown to stimulate the activity of Fen-1 and DNA ligase I (Table 1), proteins that are important for Okazaki fragment maturation on the lagging strand (33). Thus, not only does the processivity factor play an important role in DNA synthesis but also in the final steps leading to the formation of a mature duplex DNA. PCNA may also interact with other members of the replication machinery, although these interactions have not yet been elucidated.

Early studies using temperature-sensitive mutants of gp45 (and gp44/62, its clamp loader) demonstrated its importance for DNA replication (34). Further studies using purified protein in *in vitro* replication assays have been used to establish the role of gp45 as the processivity factor for phage-T4 polymerase (gp43) (35).

3.2. Processivity Factors and DNA Repair

Both b and PCNA are also involved in DNA repair, at least in part, via the stimulation of their respective polymerases (32, 36). As discussed above, the b subunit forms a dimeric ring that functions as the processivity factor of polII and PolIII, both of which are involved in DNA repair processes (36, 37). It was also shown that the protein interacts with mutS, a protein needed for mismatch repair (36-38). It was also demonstrated that exposure of *E. coli* cells to UV-irradiation induces a shorter form of b, called b* (39). b*, comprised of the C-terminal 2/3 of normal b, was shown to behave as a trimer, presumably forming a trimeric ring, and was found to stimulate DNA synthesis by polIII. Thus, b* might serve as an alternative clamp in DNA repair processes. In eukaryotes, PCNA is the processivity factor of polε, an enzyme that has been implicated in DNA repair (23, 32). PCNA becomes localized in the cell nucleus after UV-irradiation of cells not in S-phase (40); PCNA transcription is stimulated upon UV-irradiation (41), and several mutant forms of

PCNA have been shown to be defective in DNA repair processes (42). These *in vivo* observations are consistent with *in vitro* repair assays that demonstrated a role for PCNA in DNA excision-repair (43, 44 reviewed in: 32, 36).

PCNA may also be involved in DNA repair in mechanisms that do not involve the polymerase (23). Upon DNA damage, there is an elevation in the level of several genes. Two of these genes, p21 and Gadd45, have been shown to bind PCNA (Table 1) (33). The role of the interactions between PCNA and these proteins in DNA repair is not yet fully understood. It was shown, however, that p21-PCNA interaction inhibits DNA replication, thus linking cell-cycle control processes to the DNA replication machinery (23).

3.3. Transcription and Other Processes

Several well characterized examples suggest a role for viral-encoded sliding clamps in RNA transcription. It was demonstrated that gp45 serves as a transcriptional activator of phage-T4 late genes (45, 46). Two other viral-encoded proteins are also involved in this mechanism: the gene-33 product (gp33) is a transcriptional coactivator, and the gene-55 product (gp55) recognizes the late promoter. The gp45 protein, in association with gp33 and gp55, binds to the *E. coli* RNA polymerase and directs it to the promoters of the phage genes expressed in late stages of infection (45-47) (Table 1). The clamp loader is also involved in this process as it was demonstrated that gp45 has to be assembled around DNA in order to activate transcription (46).

At least one eukaryotic virus has been shown to utilize a sliding clamp for the regulation of gene transcription. A PCNA homologue from an insect virus has been shown to be important for the expression of several viral genes. This PCNA, however, is not essential for viral DNA replication (48).

These two examples imply that cellular-encoded sliding clamps (b and PCNA) may have a similar function and may play a role in gene transcription. Upon completion of DNA replication, some rings may be left around the duplex DNA (49). These rings perhaps then bind to RNA polymerase, directly or indirectly, and regulate gene expression.

PCNA may also play a role in chromatin remodeling. Studies conducted in starfish and *Drosophila* have indicated a function for PCNA in the assembly of chromatin (50, 51).

4. Concluding Remarks

The DNA polymerase sliding clamp encircles DNA and endows the polymerase with its high processivity by tethering the polymerase to the DNA. In the last several years, however, it has become apparent that the sliding clamps play diverse roles in nucleic acid metabolism (e.g., DNA repair and transcription). The proteins were also shown to be involved in cell-cycle progression via their interaction with diverse cellular proteins (23). The list of proteins that interact with the clamp is not complete. Future studies will elucidate the scope of processes in which the sliding clamps are involved.

The first proteins found to have a ring-shaped structure and encircle DNA were the DNA polymerase sliding clamps. Since that structure was demonstrated for the sliding clamps, other ring-shaped protein complexes that encircle DNA have been shown to play a role in DNA metabolism (52, 53). It will be interesting to know how general this structure is, how many other proteins have a similar structure, and how many other cellular processes utilize these proteins.

Prochiral

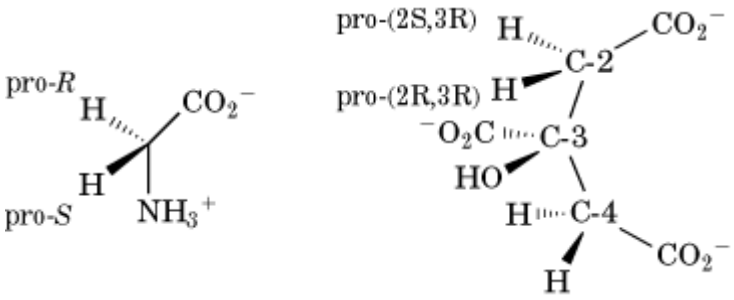
Atoms, substituents, or whole molecules can be described as prochiral . When describing an atom, prochiral indicates that the substitution of that atom with a heavier isotope will alter the **chirality** of the molecule. The phrase prochiral center is employed to describe an atom with two identical substituents such that the substitution of either one with a different isotope would make that atom a

chiral center (see **Chiral**). If the isotopic substitution of the substituents would generate **enantiomers**, the groups are enantiotopic, whereas if the substitution would produce **diastereomers**, the groups are diastereotopic (1, 2). The concept of enantiotopic and diastereotopic groups is important in biochemistry and molecular biology because these groups interact differently with chiral molecules. The classic example of the difficulties presented by prochiral chemistry was interpreting the isotopic labeling of citrate during its biosynthesis (3).

As an example of prochirality, the a-carbon in glycine is a prochiral center because the substitution of either of the two identical substituents (for glycine, the H^a atoms) with a heavier isotope would generate a chiral molecule. The two H^a atoms are enantiotopic because their replacement would generate different enantiomers of glycine. To differentiate the enantiotopic groups, they are preceded with the prefix "pro-" preceding the specification of the configuration generated. In chemical structures, the prochirality of an atom can be identified by the subscript *R* or *S* (1), which indicates the configuration of the chiral center as determined by the Cahn, Ingold, and Prelog rules (4) (see Configuration). In the peptide glycyl-L-alanine, the glycine H^a atoms are diastereotopic because the substitution of either glycine H would generate diastereomers.

In citrate, the carboxy methyl groups are enantiotopic and C-3 is a prochiral center, because the substitution of any of the atoms in either carboxymethyl group will generate chirality at C-3 (Fig. 1). The upper carboxymethyl group in Figure 1 is the pro-*R* group because isotopic substitution anywhere in the functional group would generate (3*R*)-citrate. C2 and C4 are also prochiral centers, because the substitution of the methylene hydrogen atoms would generate a chiral center at the substituted carbon. Both hydrogen atoms on C-2 of citrate are diastereotopic, because the substitution of deuterium at either of these two positions would generate diastereomers. They are diastereomers because two new chiral centers (C2 and C3) would be generated, and the chirality at C3 is the same for both hydrogens, whereas the chirality at C2 would differ.

Figure 1. The stereochemistry of glycine and citrate. The enantiotopic hydrogen atoms of glycine are labeled (left). The forward H is pro- *S* because substitution with ^2H at this H would generate (*S*)-[2- ^2H]glycine, as suggested by the counterclockwise arc connecting the atoms in order of priority. In citrate (right), the hydrogen atoms at C2 are diastereotopic; C2 and C3 are prochiral centers because the substitution of ^2H at either of these hydrogen atoms would generate the labeled diastereomers.



Planar double-bonded carbon and nitrogen atoms have the potential to be prochiral if they have three different substituents, because the two faces of the molecule are nonequivalent (2). The faces of the molecule are differentiated by the designation of *Re* or *Si* based on the Cahn, Ingold, and Prelog priority (4) of the three substituents. As shown in Figure 2, the two faces of pyruvate are enantiotopic because addition to opposite faces would generate enantiomers. If the addition to opposite faces would generate diastereomers, the faces are diastereotopic.

Figure 2. The stereochemistry of pyruvate. The two faces of pyruvate are different. When viewed from the left, the circle connecting the three different substituents in their Cahn/Ingold/Prelog priority order describes a clockwise motion, whereas when viewed from the right, the circle describes a counterclockwise motion. The faces are enantiotopic because the addition of an identical group to each face would generate enantiomers.

Product Inhibition

It would be expected that the addition of a reaction product will inhibit the rate of the forward reaction catalyzed by an enzyme. As a substrate for the reaction in the reverse direction, it must give rise to the same enzyme forms as that from which it was released in the forward reaction. In practice, however, it may be difficult to demonstrate the inhibition if the inhibition constant for the product is relatively high.

Product inhibition occurs either by partly reversing the reaction or by competing with a substrate for a particular form of the enzyme. The inhibition patterns produced by a product can be very

informative in the case of enzyme reactions that produce multiple products. Rules for the qualitative prediction of product inhibition patterns have been developed by Cleland (1, 2); they can be summarized as:

1. A product inhibitor affects the *slope* of a double-reciprocal plot (see Lineweaver–Burk Plot) when
    1. the product inhibitor and the variable substrate combine reversibly with the same enzyme form, or
    2. the product inhibitor and the variable substrate combine reversibly with different enzyme forms that are connected by a series of reversible steps along which interaction can occur. The release of product at zero concentration or the addition of substrate at a saturating concentration are considered to be irreversible steps that break reversible connections.
2. A product inhibitor affects the intercept of a double-reciprocal plot when it combines reversibly with an enzyme form other than the one with which the variable substrate combines and saturation with the variable substrate does not overcome the inhibition.

Application of these rules permits analysis of product inhibition patterns that make it possible to distinguish between different **kinetic mechanisms**. Product inhibition patterns for Bi—Bi reaction mechanisms, with two substrates and two products, are illustrated in Table 1.

Table 1. Product Inhibition Patterns for Bi–Bi Reaction Mechanisms

		Variable Substrate	
Mechanism[a]	**Product Inhibitor**	**A**	**B**
Ordered	P	NC[b]	NC[c]
	Q	C	NC
Equilibrium, ordered	P	NC	NC
	Q	C	C
RER[d] plus dead-end EBQ	P	C	C
	Q	C	NC
RER plus dead-end EBQ and EAP	P	NC	C
	Q	C	NC
Ping-Pong	P	NC	C
	Q	C	NC

[a] Mechanisms are illustrated under **Kinetic mechanisms**.

[b] C, linear competitive; NC, linear noncompetitive; UC, linear uncompetitive.

[c] Inhibition becomes UC if B is present at a saturating concentration.

[d] RER, rapid-equilibrium, random.

Product inhibition patterns can also be predicted by using the complete rate equation for a particular mechanism, setting to zero the concentration of the product that is not to be added, and then rearranging the equation in double-reciprocal form, with each of the two substrates as the variable one (2, 3). The resulting equations are also of importance with respect to the quantitative analysis of product inhibition data. It is only when the quantitative relationship between true and apparent constants is in hand that it becomes possible to determine true values for the kinetic constants associated with a particular mechanism.

Proenzyme

Proenzymes are enzymes that are synthesized in cells as inactive precursors that must undergo modification before they are catalytically active. They often function as proteinases, when they are also known as **zymogens**, and they are produced in this latent form because of their destructive potential. An additional protective measure that applies to some of the activated proenzymes is their inactivation through the formation of tight complexes with specific proteins (see Proteinase Inhibitors). The activation of proenzymes often occurs by **proteolysis**, a process in which peptide bonds are irreversibly cleaved and peptides may be liberated from the molecule (1). Proteolysis may occur autocatalytically or by the action of another proteinase or as a result of the combination of the two activities. Most of the proenzymes are proteinases responsible for digestion, but thrombin plays an important role in blood clotting. A list of proenzymes and the reactions involved in their conversion to active enzyme forms are given in Table 1. (See top of next page)

Table 1. Activation of Proenzymes (see Proenzyme article, previous page)

Proenzyme	Active form	Chemistry of activation
Chymotrypsinogen	**Chymotrypsin**	Cleavage of Arg-Ile bond by **trypsin** and autocatalysis
Pepsinogen	**Pepsin**	Cleavage of Leu-Ile bond, removal of residuesfrom N-terminus at lower pH, and by autocatalysis
Procarboxypeptidase	Carboxypeptidase	Removal of peptide from N-terminus by trypsin
Proeleastase	Elastase	Removal of residues from N-terminus by trypsin
Prothrombin		Removal of peptide from N-terminus

	Thrombin[a]	by cleavageof Arg-Thr bond by serine endopeptidase and then cleavage of Arg-Ile bondby same enzyme
Trypsinogen	**Trypsin**[b]	Cleavage of Lys-Ile bond by enterokinase and autocatalysis[a]

[a] Inactivated by interaction with antithrombin III.

[b] Inactivated by interaction with trypsin inhibitors.

Profilin

Profilin (mw 12 000–15 000) is an abundant actin monomer-binding protein in eukaryotic cells (see Actin-Binding Proteins) ((1); review). Particularly high concentrations of profilin are found in lymphoid cells and brain cells. In lymphoid tissues the concentration of unpolymerized actin is about 100 mM and in platelets it may be as high as 200 µM. In both cases about 50% of the unpolymerized actin can be accounted for by profilin:b-actin and profilin:g-actin isoforms. The remaining unpolymerized actin appears to be sequestered by b-thymosins (see below). In tissue cultured cells, profilin is concentrated in regions of high motile activity (2), where it is thought to bring actin monomers to growing (+)-ends of filaments exposed through transmembrane signalling events. It binds to a number of cell cortex-associated proteins participating in the control of actin filament formation, eg the VASP family of proteins (3), the WASP-binding protein WIP (4), the formins (5-7) and the Arp2 protein (8).

Sacharomyces cerevisiae has one essential profilin gene (9), *Dictyostelium discoideum* has two (10), and plants contain multiple isoforms of profilin (10). *Acanthamoeba castellani* also contains two isoforms of profilin (11), as do mammalian cells (12).

Genetic studies suggest that profilin plays a key role in the establishment of actin-dependent cell polarity in *Saccharomyces cerevisiae*, in the formation of the fruiting body in *Dichtyostelium discoideum*, and during early development in *Drosophila* (10, 13). In transgenic mice, homozygous profilin “knock-outs” are lethal emphasizing the physiological importance of profilin in mammalian cells (14).

The structure and ligand-binding by different isoforms of profilins have been elucidated by mutagenesis (15), crystallography (16-19) and NMR (20). All isoforms of profilin have similar folds even though the amino acid sequence is highly divergent. In *Arabidopsis* profilin, the residues involved in the actin interaction have diverged, but the general character of involved residues are conserved. In the profilin:b-actin crystal, profilin makes two contacts with actin. The largest contact involves 2260 $Å^2$ of buried surface area, and is the contact between profilin and actin in solution. It engages subdomains 1 and 3 of actin at the (+)-end of the actin monomer (16). This leaves the (–)-

end of the monomer free to bind to the fast growing (+)-end of an actin filament in the polymerization process. The less extensive profilin:actin interaction site (1187 Å ^{2} b.s.a.) seen in the crystal is formed by the N-terminal helix of profilin binding to subdomain 4 of a different actin monomer (16). So far, this contact has not been observed in solution.

In vitro, profilin inhibits the polymerization of actin with varying efficiency depending on the ionic conditions, and on whether the homologous nonmuscle actin or heterologous muscle a-actin is used (21-23). In the presence of physiological concentrations of Mg^{2+} ions, profilin is a relatively poor actin sequesterer. Apparently, the conformation of the (–)-end is not disturbed by profilin, and the profilin:actin complex can add onto the (+)-end of filaments. Thus both actin and the profilin:actin complex can support growth of actin filaments at the fast growing (+)-end (22, 24). The characteristics of the association/dissociation of actin monomers at the (–)-end of actin filaments are such that profilin effectively prevents the addition of actin at that end.

Beta thymosins, which inhibit growth at both ends and occur at high concentrations in cells, are thought to be the primary actin-sequestering proteins, and profilin, with its higher affinity for actin, serves to deliver actin to the barbed end (24). In the presence of proteins that cap the (+)-end of actin filaments, profilin is an efficient actin sequestering protein, since it effectively prevents polymerization at the (–)-end under all conditions (25, 26). This implies that the control of actin polymerization in cells may depend primarily on regulating the association/dissociation of proteins that cap the (+)-end of preexisting filaments, or by regulating the nucleation of new filaments.

Profilin increases the rate of **nucleotide** exchange on actin more than 1 000-fold (27, 28), and stabilizes the actin in the nucleotide-free state. Since actin with ATP bound polymerizes faster than ADP-actin, profilin might promote repolymerization of actin.ADP monomers coming off of filaments during depolymerization, by rapidly converting them to ATP-actin monomers.

In a search for proline hydroxylase, Tanaka and Shibata found that affinity columns of poly(L-proline) (PLP), in addition to the hydroxylase, also bound profilin and actin. This allowed the development of a simple procedure to obtain a mixture of profilin and the two isoforms of profilin:nonmuscle actin (29, 30), from which the profilin:b-actin and profilin:g-actin isoforms can be isolated (31). The poly(L-proline) binding site on profilin has been identified. It is comprised of highly invariant hydrophobic and aromatic amino acids involving the N- and the C-terminal helices of profilin (15). Mutagenesis, modelling and direct structure determination has shown a bonding pattern in the profilin:polyproline interaction that is analogous to that of SH3 domains in signal transduction proteins (15, 18, 19). The VASP family of proteins, the WIP protein, and the formins all contain proline rich sequences with capacity to bind profilin. Profilin has also been found to bind to Arp2/Arp3 complex which is a multiprotein complex implicated in the mechanism of actin polymerization (see below).

In vitro, profilin alone or in complex with nonmuscle actins binds the phospholipid PtdIns 4.5-bisphosphate in micellar form, as well as in vesicles together with other phospholipids. Profilin:b/g-actin complexes also bind to PtdIns 4,5-bisphosphate *in vitro*, something which results in dissociation of the complexs with release of polymerization-competent actin. This would seem to indicate that the appearance of PtdIns 4,5-bisphosphate in the plasma membrane could recruit profilin:actin for polymerization in the advancing cell edge. However, that this is an oversimplification is indicated by the observations that the hydrolysis of PtdIns 4,5-bisphosphate by phospholipase Cg-1 is inhibited when profilin is associated with the PtdIns 4,5-bisphosphate substrate, and that phosphorylation of the enzyme with an activated tyrosine kinase receptor overrides this inhibition. This points at profilin also playing a role in the control of the metabolism of the polyphosphoinositides. Furthermore, profilin binds to the regulatory subunit of PtdIns 4,5-bisphosphate kinase and stimulates the formation of PtdIns 3,4,5-trisphosphate ((1)-for refs).

These observations point at profilin being an important factor also in the control of the release of

inositol trisphosphate and thus of the generation of Ca^{2+} pulses in the cell. The primary targets for Ca^{2+} regulation in cells is the actomyosin system with global changes in structure and activity as the result. It is now known that many of the microfilament-associated proteins interact with components formed in the phosphatidylinositol-cycle as a result of receptor-mediated activation of the cell, and that these interactions modulate the activity of these proteins vis-à-vis actin. Although the exact physiological roles of these interactions remain to be elucidated, it suggests that the phosphatidylinositol-cycle is directly involved in controlling the microfilament-based motility cycle.

Progenote

The current literature uses the term progenote in two different ways: 1) it signifies an organizational level in evolution when prokaryotic organization preceded cells; or 2) it is used to denote the last common ancestor of all extant life. In some scenarios that describe early cellular evolution, it was assumed that the last common ancestor was at a preprokaryotic level of organization; however, subsequent analyses of the molecular evolution of different cellular components suggest that the last common ancestor was a prokaryote. Based on this realization, the term progenote should be more properly used to denote a hypothetical preprokaryotic stage in cellular evolution, distinct from the last common ancestor.

In 1977 Woese and Fox (1) defined progenote as a hypothetical stage in the evolution of cells where typical prokaryotic cellular organization preceded organisms:

Eucaryotes did arise from procaryotes, but only in the sense that the procaryotic is an organizational, not a phylogenetic distinction. In analogous fashion procaryotes arose from simpler entities. The latter are properly called progenotes, because they are still in the process of evolving the relationship between genotype and phenotype.

Woese and Fox intended to define an organizational level simpler than, and preceding, the prokaryotic level. At the progenotic level, genes and encoded proteins were smaller, and the accuracy of transcription and translation was lower than at the prokaryotic level. As a result, sequence evolution occurred more rapidly.

At the prokaryotic level, organisms contain a genome that encodes a multitude of biochemical and structural functions. Among the genome-encoded functions at the prokaryotic level are genome replication, translation of genomic information into functioning molecules, and formation of a semipermeable barrier between the organism and its environment. Prokaryotic organization is so complex that the likelihood is close to zero that a prokaryote spontaneously assembled from activated **nucleotide** and amino acid precursors in a primordial soup (see Prebiotic Evolution). A solution to this problem is to assume intermediate steps that successively evolve into more complex structures. An intermediate step usually assumed in the origin of life is self-replicating RNA-like molecules (see RNA World). However, because of the limited accuracy of these early replicators, the size and information contained in these self-replicating molecules is limited (2).

How a self-propagating network of biochemical reactions that maintains a boundary with the environment, that is, an autopoietic network (3), might have evolved from simple self-replicating

molecules is a major puzzle in the evolution of life. Most scenarios that describe the evolution of cellular life include progenote-like organisms that are intermediate between the RNA world and the first prokaryotes [e.g., ((4); see Fig. 1**b**). However, the progenote concept that postulates an organism without strict coupling between **genotype** and **phenotype**, partially negates the major conceptual breakthrough associated with the RNA world, that Darwinian natural selection already acted on simple self-replicating RNA molecules. Several questions remain open regarding the evolution of progenotes: How does natural selection act on an organism without strict coupling between genotype and phenotype? Can progenotes evolve by natural selection without a phenotype encoded by their genes? Is it feasible that selection took place only (or mainly) at the level of individual molecules, not at the organismal level? Are alternative scenarios reasonable that assume tight coupling between genotype and phenotype at the level of self-replicating molecules that maintain this coupling throughout the transition stages from the RNA world to the prokaryotic level (2)

Figure 1. Comparison of two scenarios of the early evolution of cellular life: **(a)** the scenario envisioned when the term progenote was first defined (5, 6, 8); **(b)** the view that the last common ancestor was a prokaryote and that the progenote represents an earlier stage in the evolution of life (4, 10, 13).

(b)

At the same time that the term progenote was introduced to describe a pre-prokaryotic stage of cellular organization, an alternative meaning of the term progenote originated. Woese and Fox (1) argued that the last common ancestor of bacteria and the eukaryotic nucleocytoplasmic component was a progenote. Later, this argument was extended to also include a third line of descent, the archea or archebacteria ((5)–(7)). Woese and collaborators suggested that the three domains or Urkingdoms might have evolved independently from the progenote, that the optimization of the transcriptional and translational machinery occurred in parallel in the three lines of descent, and that the last common ancestor might be equally related to each of the three domains ((5)–(8)) (see Fig. 1**a**). Unfortunately, the initial definitions were ambiguous and potentially contradictory. Describing the evolution of bacteria and the eukaryotic nucleocytoplasmic component, Woese and Fox (1) summarize,

The two lines of descent, nevertheless shared a common ancestor, that was far simpler than the procaryote. This primitive entity is called a progenote, to denote the possibility that it had not yet completed evolving the link between geno and phenotype.

Taken literally, this paragraph labels the ancestor of bacteria and eukaryotic nucleocytoplasm a progenote and justifies the choice of name by stating that the last common ancestor might have been at a preprokaryotic level of organization. As a result, the term progenote is often used in the sense of progenitor to denote the last common ancestor of archea, bacteria, and eukaryotes, not in the intended sense as a contrast to genote or eugenote, that is, organisms that have a "precise, accurate link between genotype and phenotype" (7).

Determining the properties of the last common ancestor is an important matter. Horizontal Gene Transferand the fusion of formerly independent lineages have turned the tree of life into a net of life (9). Characters found in all three cellular lineages might have been present in the last common ancestor, but these shared characters also might have evolved much later in one of the lineages and spread into the other two domains by horizontal transfer (10-12). The congruence of many molecular phylogenies supports the scenario depicted in Figure1**b**, and suggests that the last common ancestor had DNA and RNA polymerases, complex ribosomes made of both rRNA and proteins, and membranes already used for chemiosmotic coupling (13). However, if molecular phylogenies reflect horizontal gene transfer more than shared ancestry, recurring patterns might result from frequent gene transfers between some organisms and make the nature of the last common ancestor hard to discern. The use of ancient duplicated genes allows resolving the deep tripartite division of life into two successive bifurcations (14, 15). The current majority consensus considers that the archea is a sister group of the eukaryotes ((4, 13, 16); see Fig. 1**b**). According to this view (4, 13), the last common ancestor was a prokaryote that had a DNA genome, elaborate transcriptional and translational machinery, and strong coupling between geno- and phenotype. Although DNA replication and transcription appear to have been further optimized independently in the three domains (17), the last common ancestor appears to have been a prokaryote, not a progenote. Therefore, to avoid confusion, the last common ancestor of all extant life should be denoted the universal ancestor (8) or cenancestor (18), and the term progenote should be reserved to denote a hypothetical preprokaryotic stage in cellular evolution (1).

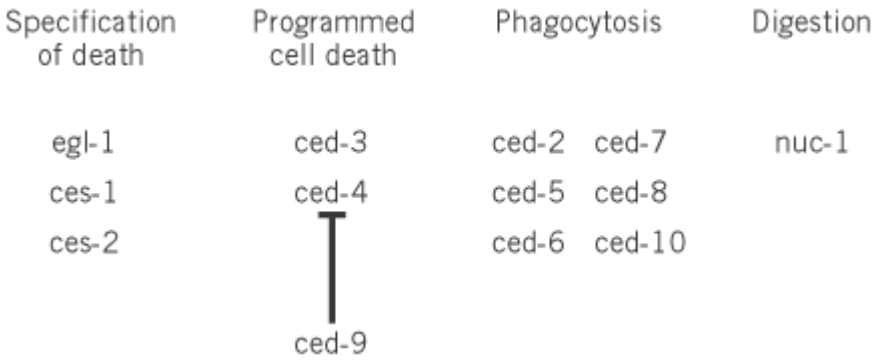
Programmed Cell Death

Programmed cell death (PCD) is the term used to describe an active form of cell death that occurs during invertebrate and vertebrate development. PCD shares all the attributes of apoptosis, but the term apoptosis is generally restricted to the description of active mammalian cell death, whereas PCD describes all other active cell deaths. PCD pathways have been characterized in several invertebrate systems (1), but none so clearly as that occurring in the nematode worm *Caenorhabditis elegans*.

A definitive plan of **gene expression** during cell development and death is seen in *C. elegans* (2-4). The cell lineage development pattern within this animal has been extensively investigated, which established that exactly 131 cells of the 1090 within the developing nematode die. Some of the genes involved in these deaths are shown in Fig. 1. Of the genes involved in nematode PCD, three have been investigated extensively. **C**ell **d**eath gene 3 (*ced-3*) and *ced-4* are directly responsible for the death of specific cells during development. Loss-of-function mutants of *ced-3* or *ced-4* result in an

animal where cells that normally die during development do not, but instead take up the same differentiated form as their sister cells (2). Ced-3 and Ced-4 gene products act within the cells that die and not as killer signals produced by neighboring or surrounding cells (5). Ced-3 and Ced-4 killing is suppressed by another gene product, Ced-9. Although *ced-9* gain-of-function mutants exhibit no cell death, cell death does occur in *ced-9* loss-of-function mutants. Moreover, this death occurs not only in the 131 cells that normally die, but also in other cells within the nematode (6). These observations suggest that ced-9 is a general genetic suppressor of cell death within these animals.

Figure 1. The genetic control and pathway of programmed cell death in *C. elegans*. The 'killing' of the cell is carried out by the products of two genes, *ced*-3 and *ced*-4, whose activities are regulated by *ced*-9. Many of the genes that act within this pathway have been conserved throughout the evolution of multicellular organisms, demonstrating the importance of regulated cell death (2, 7, 9)



The notion that cell death is essential for the development of the organism is verified by the conservation of death genes throughout multicellular evolution. For example, mammalian homologues of two of the nematode *ced* genes have been identified. Gene *ced-9* is a homologue of the mammalian anti-apoptotic proto-oncogene *bcl-2* (7), the **B-cell** leukemia/lymphoma gene (8) that suppresses apoptotic cell death, and a host of other *bcl-2*-like genes that define a gene family involved in cell death regulation (9, 10). **Transgenic** expression of *bcl-2* in *ced-9* loss-of-function nematode mutants suppresses cell death, demonstrating the conservation of function between these two homologues (11). This conservation of function suggests that genes with functions similar to those of *ced-3* and *ced-4* should exist in mammalian cells. This hypothesis was borne out by the discovery of a *ced-3* mammalian homologue, the *interleukin-1b-converting enzyme* (ICE) (12). ICE is a thiol proteinase that activates pro-interleukin-1b by **proteolytic** cleavage to its active form during an inflammatory response (13). Expression of ICE in fibroblasts results in apoptosis, as does expression of Ced-3, demonstrating the conservation of function between these two homologues (12). There are currently 14 members of the Ced-3/ICE gene family in mammals (14-16) (more recently termed caspases for **c**ysteine **asp**artate protein**ases** (17)) and two in *Drosophila* . A mammalian homologue of *ced-4* has been identified, and its function is slowly being deciphered (18-21). Ced-4 binds both Ced-9 and Ced-3, resulting in a protein complex that somehow acts to regulate PCD (see Apoptosis). Although the exact role of Ced-4 in this complex is unclear, Ced-4 induces death in both mammalian and yeast cells, suggesting some intrinsic death capacity (19, 21).

Other genes within the *C. elegans* PCD pathway are involved in the phagocytosis of dead cells. Mutant worms that lack one or more of these genes do not phagocytose dead cells; instead, the cells are left within the cellular tissues with no apparent deleterious effects (22), unlike unphagocytosed cells in mammalian tissues. Once again, some of these genes are also conserved in higher organisms, demonstrating the conservation of the PCD pathway as a whole throughout evolution (23).

The fruit fly ***Drosophila*** also has conserved PCD pathways. *Drosophila* **embryos** exhibit PCD at approximately 7 hours after egg laying (stage 11 embryos), with cell death becoming widespread throughout the embryo at stages 12 and 13. More specific regions of cell death are also seen during dorsal closure (stage 14) and advanced head involution (stage 15) (24). PCD in *Drosophila* climaxes with prominent cell death throughout the central nervous system as the ventral nerve cord condenses. As in *C. elegans*, the genes required for PCD in *Drosophila* are being sought and characterized. One such gene, *reaper* (*rpr*), is required for virtually all PCD in the developing embryo. *rpr*-deficient embryos have many extra cells and fail to hatch, demonstrating the requirement for *rpr*-regulated cell death during development (25). These embryos are also resistant to X-irradiation-induced death at low doses. That cell death occurs at higher radiation doses suggests that the death pathway is intact but less sensitive in the absence of *rpr* (26). Two other genes, Grim (27) and Head Involution Defective (*hid*) (28), are also required for some of the PCD occurring during development. Acting downstream of these genes are the Ced-3-like caspase homologues. Two of these genes have so far been identified, *Drosophila* cell death proteinase-1 (DCP-1) (29) and *Drosophila* ICE (DrICE) (30). Like their mammalian counterparts, these caspase homologues cleave specific protein substrates during PCD. However, unlike the hierarchical arrangement of the caspases in mammalian cells, DrICE appears to be able to autoactivate and carry out PCD in *Drosophila* cells without requiring DCP-1 activity [Fraser, personal communication].

Other insect models have been successfully used to document genes regulating PCD. Following metamorphosis, the intersegmental muscles of the tobacco hawk moth, *Manduca sexta*, are no longer required and undergo degeneration, a process triggered by a reduction in the levels of an ecdysone hormone (31-33). This type of PCD involves the activation of several genes, plus the process of attachment of multiple ubiquitin molecules to other proteins**,** which is probably required for tagging them for **protein degradation**. Additionally, several genes are downregulated during the commitment of these cells to PCD, and over 30 new polypeptides are translated during muscle degeneration (34).

Examples of PCD are found in all multicellular organisms so far studied, and many of the genes that regulate these deaths have been conserved throughout evolution. This makes the study of invertebrate cell death invaluable in identifying how PCD is regulated in more complex organisms such as mammals.

Prokaryotic Genetics

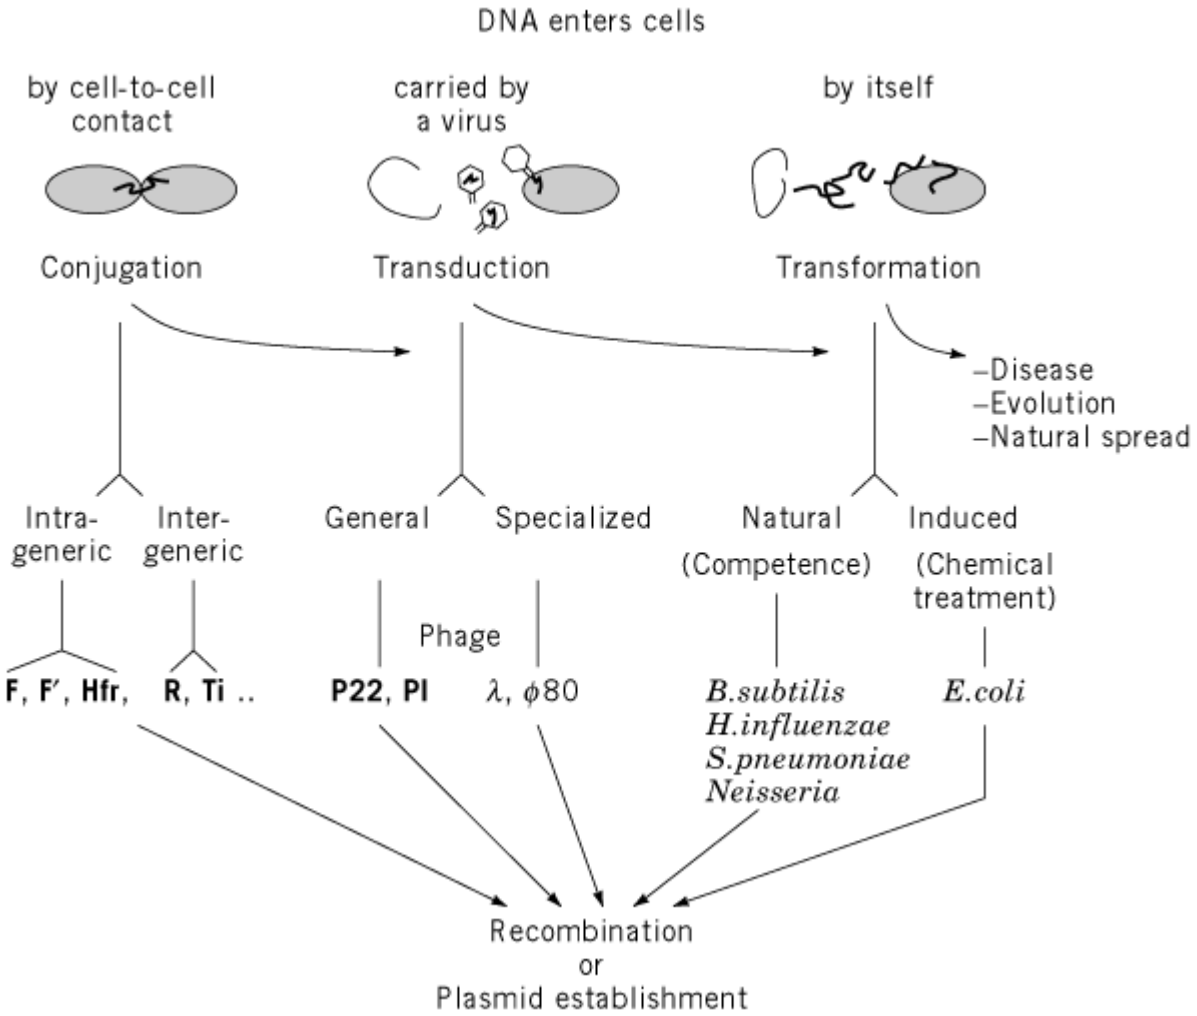
Prokaryotic genetics took biology's center stage for about 30 years, transforming the classic genetic study of abstract factors of inheritance into the assertively molecular style of genetics that we know today. The impact of prokaryotic genetics on biology has been succinctly described by Thomas Brock:

> Almost every area of modern biology under active research study today owes a major debt to bacterial genetics. Molecular biology, immunology, cancer research, medical virology, epidemiology, genetics of higher organisms, evolution, taxonomy, cell biology, and developmental biology all depend on concepts that arose first from studies in bacterial genetics.

To this must now be added whole-genome sequencing, scarcely underway in 1990, when the above words were written, but now usurping the function of genetic crosses in the mapping and definition of genes.

The purpose of this section is to highlight some of the key phenomena on which prokaryotic genetics is based. In practice, genetics is based on exploiting natural modes of gene transfer from one cell to another (Fig. 1). Individual entries are devoted to each of the known methods of transfer—transformation, **transduction**, and **conjugation**—as well as to certain devices that that played a central role in putting gene transfer to work: **replica plating**, development of competence for transformation, **merodiploidy**, **Hfr's and F-primes**, and the **F-plasmid**. While the heyday of this traditional prokaryotic genetics is over, an appreciation of its essentials, as represented by the topics presented here, remains important as genetic investigations spread to the wider reaches of the microbial world.

Figure 1. The primary methods of transfer of genetic information in prokaryotes. Aspects for which there are individual entries are in bold.



Proliferating Cell Nuclear Antigen (PCNA)

Proliferating cell nuclear antigen (PCNA) was originally identified as an antigen of the autoimmune disease systemic lupus erythematosis (1). This protein localizes in **nuclei** in a **cell-cycle**-dependent manner and was also called *cyclin*, due to its periodic appearance in **S-phase** cells. The name of PCNA is now used for this protein so as to avoid confusion with the cyclin family of proteins that bind to cyclin-dependent protein **kinases** (cdk). Staining of growing cells with an antibody against PCNA showed a punctuated pattern in S-phase nuclei that colocalized with bromodeoxyuridine foci, or replication foci (2). This observation suggested that this protein was closely involved in DNA replication. This speculation was confirmed by the second discovery of PCNA as the essential replication factor in **SV40 virus** replication *in vitro* (3). Concomitantly, PCNA was identified as an accessory protein of **DNA polymerase** d (pol d) (4).

Without PCNA, pol d has limited activity and synthesizes only several tens of nucleotides into DNA, but the addition of PCNA greatly stimulates the activity and makes the polymerase very processive, to synthesize long DNA strands. These characteristics implied that PCNA might function as a **eukaryotic** processivity factor as the b-subunit (b-clamp) of *Escherichia coli* DNA polymerase III.

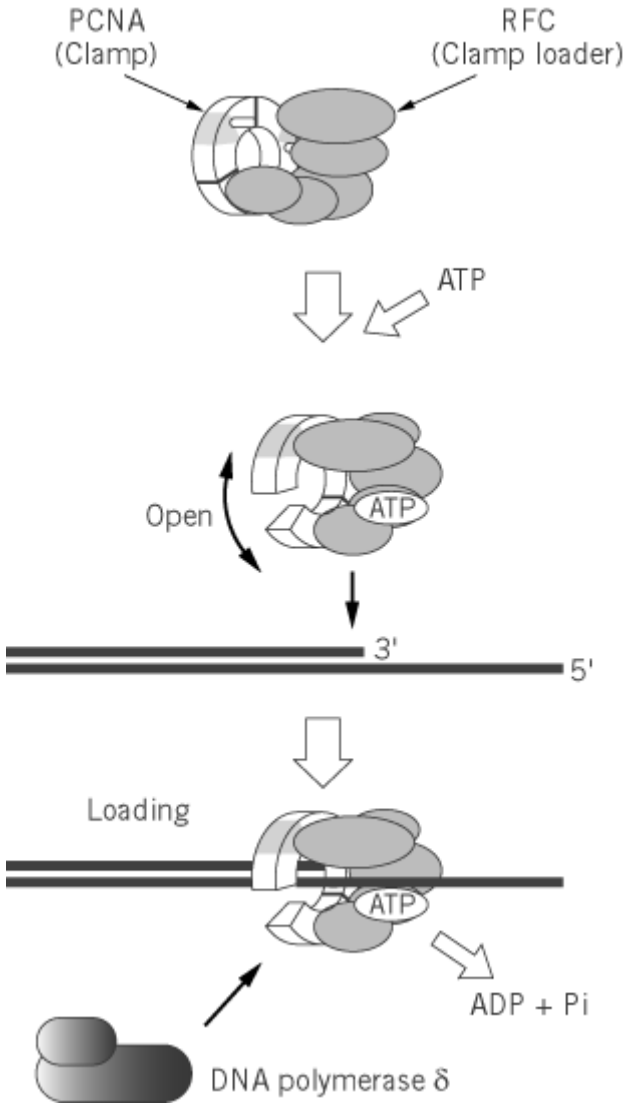
The omission of PCNA from the complete SV40 replication reaction results in an accumulation of short Okazaki Fragments, rather than the full-length products, indicating that PCNA is essential to coordinate the elongation of leading and lagging strands (5). Another newly identified replication factor, RFC (replication factor C), was also required at the same elongation stage and to coordinate two-strand synthesis, suggesting that RFC, PCNA, and pol d function at the same DNA elongation stage of eukaryotic DNA replication (6).

Comparable studies of the elongation process of *E. coli*, **bacteriophage**, and eukaryotic systems have revealed that there is a striking functional conservation in their replication apparatus. Factors called DNA **sliding clamps** were commonly identified in all of them, such as PCNA in eukaryotes, DNA polymerase III (pol III) b-subunit in *E. coli* and gene45 protein in T4 phage. The name DNA sliding clamp came from the experimental observation that once the clamp molecule binds on circular DNA, it stably associates with the DNA, but dissociates quickly upon linearization of the DNA (7). This property suggests the protein has a ring structure that binds the DNA topologically and can slide freely along the DNA. Comparison of the predicted **secondary structures** of clamp molecules demonstrated striking conserved alignments, although there are almost no similarities in their primary structures. The monomer sizes of b-clamp, PCNA, and gene45 are 41, 29, and 25 kDa, respectively, but their native molecular weights are similar. This is because PCNA and gene45 have homotrimer structures, whereas, in contrast, the b-clamp has a homodimer structure.

The structures determined by X-ray crystallography of the b-clamp and PCNA demonstrated that they have very similar ring structures composed of monomers joined head to tail (8). The monomers of b-clamp and PCNA have three and two internal repeating structures, respectively, so both rings are composed of six repeating domains that generate a hexagonal shape. Each domain unit has a stable triangular structure comprising nine antiparallel beta strands facing outward and two **alpha-helices** facing the center of the ring. The inside surfaces are strongly positively charged, and the hole has a size sufficient to accommodate double-stranded DNA. Thus, this class of proteins has a new sequence-nonspecific, topological type of DNA binding, which permits these proteins to slide along a duplex DNA stably but freely in either direction.

A crucial process for PCNA function is its loading onto DNA prior to its association with pol d. However, loading of the ring molecule onto DNA without the free ends will be topologically difficult. Another accessory protein, RFC, has the activity of loading PCNA at the 3′-end of a primer on circular DNA in the presence of ATP. During this process, ATP-bound RFC interacts with PCNA and may induce the opening of its ring to pass template DNA through it. Since further ATP hydrolysis by RFC is necessary to load pol d on the DNA, the second structural change of the RFC–PCNA complex will occur by ATP hydrolysis and induce the association of pol d with PCNA (Fig. 1) (see also Clamp Loaders, Processivity Complex).

Figure 1. Loading of PCNA onto a template DNA and formation of pol d complex.



Besides its function as a replication factor, PCNA also plays crucial roles in DNA repair processes. Studies with *in vitro* nucleotide excision repair and mismatch repair reactions indicated that PCNA functions as a component of the DNA polymerase complex for repair DNA synthesis. In addition, if a cell is irradiated by UV light, PCNA accumulates in nuclei, where the DNA repair reaction occurs, although the cell is not in **S phase** (9). PCNA also interacts with various proteins involved in **cell-cycle** regulation, including CDK/cyclin, p21(Cip1/Waf1), and GADD45 (for a review, see (10)). The binding of p21 to PCNA resulted in inhibition of the elongation reaction by pol d, suggesting a mechanism to regulate the functions of the replication apparatus by these cell-cycle regulators. The importance of these secondary function of PCNA is still ambiguous, but suggest a novel mechanism to directly connect cell-cycle control and the DNA replication apparatus.

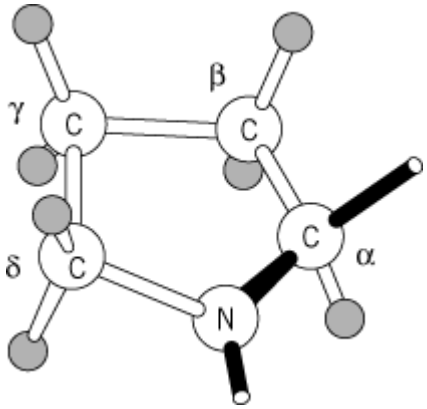
Proline (Pro, P)

The imino acid proline is incorporated into the nascent polypeptide chain during **protein biosynthesis** in response to four **codons**—CCU, CCC, CCA, and CCG—and represents approximately 5.1% of the residues of the proteins that have been characterized. The prolyl residue incorporated has a mass of 97.12 Da, a **van der Waals volume** of 90 Å ^{3}, and an accessible surface area of 143 Å^2. Pro residues are changed infrequently during divergent evolution; they are interchanged in **homologous** proteins most frequently with alanine and serine residues.

The side chain of Pro is unique in that it is bonded covalently to the nitrogen atom of the peptide backbone, which is indicated by the solid bonds:



Therefore, the peptide backbone at Pro residues has no amide hydrogen for use as a donor in **hydrogen bonding** or in resonance stabilization of the peptide bond of which it is part. The cyclic five-membered ring is invariably puckered, with the C^a, C^g, C^d, and N atoms approximately coplanar, but with the C^g atom displaced about 0.5 Å from the plane. This ring imposes rigid constraints on rotation about the N–C ^{a} bond of the backbone; the value of the torsion angle f is restricted to approximately –60° (see Ramachandran Plot). The peptide bond preceding Pro residues also has an intrinsic tendency to adopt the cis configuration approximately 10% of the time in model peptides (1). This configuration is also found frequently at certain Pro peptide bonds in folded protein structures. The synthetic polypeptide Poly(Pro) adopts one of two regular conformations, depending on the conditions, known as Poly(Pro)I and II. Form I has all *cis* peptide bonds, whereas form II has all *trans*. The values of f and y are very similar for both, but form I is a right-handed helix with 3.3 residues per turn, whereas form II is a left-handed helix with 3.0 residues per turn (2). The two forms can be interconverted by changing the solvent; the interconversion occurs by a "zipper" mechanism in which the intrinsically slow *cis–trans* isomerization of each peptide bond starts at one end and progresses sequentially along the polypeptide chain. The $I \rightarrow II$ interconversion starts at the amino end of the chain, whereas the reverse interconversion starts at the other end (3).

The side-chain atoms of Pro residues are nonpolar and chemically inert, but only about 18% of Pro residues are fully buried in protein structures. Instead, they often occur at the protein surface, because they are frequently used in reverse turns. In contrast, the geometry of the Pro residue is incompatible with the a-**helix** and b-**sheet** types of **secondary structure**, and the Pro residue destabilizes an a-helix by about 3 kcal/mol in model peptides. Nevertheless, Pro residues fit well at the *N*-terminus of an a-helix, and single Pro residues can be accommodated in long a-helices by distorting the helical geometry locally. Pro residues have special roles in the triple helix of **collagens**, where they are often modified by hydroxylation at the g carbon when in the sequence–Xaa–Pro–Gly– or at the b carbon when in the sequence –Gly–Pro–.

Promiscuous Dna

Interactions between the nucleus and **organelles** of **cytoplasm** have a major role in eukaryotic cellular metabolism. **ATPases**, some cytochromes, for example, the yeast cytochrome *c* oxidase complex, are assembled posttranslationally in mitochondria and **chloroplasts** from some polypeptide subunits synthesized in the nucleus, others in the organelle. The genetic materials of the nucleus, mitochondrion, and chloroplast are usually maintained discretely in each organelle without duplication elsewhere. Exceptions are known as *promiscuous DNA*, defined as a nucleotide sequence that occurs in more than one of these three membrane-bound organelles. This should be distinguished from the DNA of promiscuous **plasmids,** which can be transferred to a wide range of prokaryotic cells.

Promiscuous DNA was first reported upon the discovery that the genomes of mitochondria and chloroplasts of **maize** have a 12-kb DNA sequence in common. The most attractive conclusion is that the chloroplast DNA became incorporated in the mitochondrial genome after gene duplication and transposition (1).

A similar phenomenon was found in **Saccharomyces** *cerevisiae*. A piece of DNA is common to the mitochondrial and nuclear genomes. There is good evidence that the "jumping" occurred in the direction nucleus → mitochondrion (2).

A third example comes from the sea urchin, *Strongylocentrotus purpuratus*, whose sections of mitochondrial DNA, coding for cytochrome oxidase subunit 1 and the 3′ 16 S RNA of ribosomes, are found in the nuclear genome. This is probably a result of a **chromosomal** transposition about 25 million years ago, followed by chromosomal rearrangements and single nucleotide substitutions (3).

Pronase

The K-1 strain of *Streptomyces griseus* synthesizes and secretes a mixture of proteinases that for many years has been commercially available under the proprietary name of "Pronase." Initially offered as a purified proteinase of broad specificity and widely adopted for this purpose, it became clear that pronase is composed of a variety of exo- and **endopeptidases** (1), thus accounting for its remarkable ability to catalyze the hydrolysis of many types of peptide bonds. Among the different constituents are more than a dozen separate enzymes having the specificities of **trypsin, chymotrypsin**, elastase, subtilisin, carboxypeptidase, and aminopeptidase . Many of these have been isolated in pure form, starting with the crude mixture, and subsequently characterized both structurally and kinetically. The commercial product is still referred to as "an unusually nonspecific proteinase," although it is now well known to be a mixture of proteinases. It is free of **nuclease** activity and hence is convenient for removing proteins in the course of procedures for the isolation of **nucleic acids**.

Pro-Protein

Many proteins destined for protein secretion undergo a fast maturation process during translocation through membranes by cleavage of signal peptides. Some secretory proteins, however, go through an intermediate stage of the relatively long-lived intracellular form termed pro-protein (See Pre-Protein, Pre-Pro-Protein and Pro-Sequence). Some serum proteins (eg, Albumin) or hormones (eg, insulin and glucagon) are synthesized as longer inactive precursors, from which specific polypeptides (or pro-sequences) are cleaved to generate mature active molecules (1, 2). In general, proteolytic conversion of the pro-protein to the mature form involves endoproteolytic cleavage at the site after an amino acid recognition sequence, such as Arg–Arg or Lys–Arg. Additional sequences can be cleaved at the *N*-terminus (eg, in the case of proalbumin) or at both ends of the pro-protein (eg, proglucagon). In proinsulin, the extra sequence, named the C peptide, is located internally in the pro-protein.

Pro-Sequence

A pro-sequence is part of a protein and is required for protein folding or its maintenance in an inactive form (see Pre-Protein, Pre-Pro-Protein and Pro-Protein). Pro-sequences are removed from exported protein after their translocation across a membrane. Several of these pro-peptides are composed of long polypeptide chains. For example, the propeptide in pro-a-lytic proteinase has 174 amino acid residues; there are 91 in pro-carboxypeptidase Y, and 77 in pro-subtilisin. Long pro-peptides are typical for proteinases. The pro-sequence is usually attached to the *N*-terminus of the proteinase (although pro-sequences are sometimes also found to be *C*-terminal extensions, or a combination of the two). There is evidence that some pro-sequences are necessary for proper folding of the proteins. The concept of pro-sequence-assisted protein folding was originally demonstrated for serine proteinases. The best-studied examples include the proteinases subtilisin BPN′, which is secreted from *Bacillus amyloliquefaciens*, a-lytic protease from *Lysobacter enzymogenes*, and the vacuolar carboxypeptidase Y from *Saccharomyces cerevisiae*. The pro-sequence in all three cases is important for mediating proper folding of the corresponding proteinase domain *in vivo* and *in vitro*. In the absence of pro-sequences, these enzymes fail to form an active proteinase conformation. After pro-proteins are folded properly, their pro-sequences are cleaved off in an intramolecular (via autocatalysis) or intermolecular (via a second proteinase) reaction. Pro-sequences of a-lytic protease and subtilisin are known to accelerate proper folding of the proteinase domain by lowering a high-energy barrier on the folding pathway; that is, the pro-sequence directly catalyzes the folding reaction. Therefore, the pro-sequence can been classified as an intra-**molecular chaperone**.

Protamine

The classic protamines are small basic proteins, originally defined in teleosts, that are rich in arginine residues, but deficient in lysine and cysteine. Their length is about 30 amino acid residues, and clusters of arginine residues are distributed throughout the sequence. Protamine–**DNA** complexes often represent the final state of chromatin compaction in fish sperm. The organization of sperm chromatin containing protamines does not include **nucleosomes** (1). Protamines fold up into a-helical structures when they bind to double-stranded **nucleic acid** .

Mammalian protamines are more complex than those in fish. They are arginine-rich and contain cysteine residues, but remain deficient in lysine. Three distinct regions exist within the approximately 50-residue mammalian protamine sequence, an N-terminal segment of 15 residues that always begins with the same four amino acids, a central region of 25 residues that is arginine-rich, with 3 to 4 clusters of arginine clusters separated by neutral amino acids, and a variable C-terminus. The cysteine residues are distributed throughout the protein at relatively conserved positions. Protamine genes are generally specific to the male germ line in their expression (2).

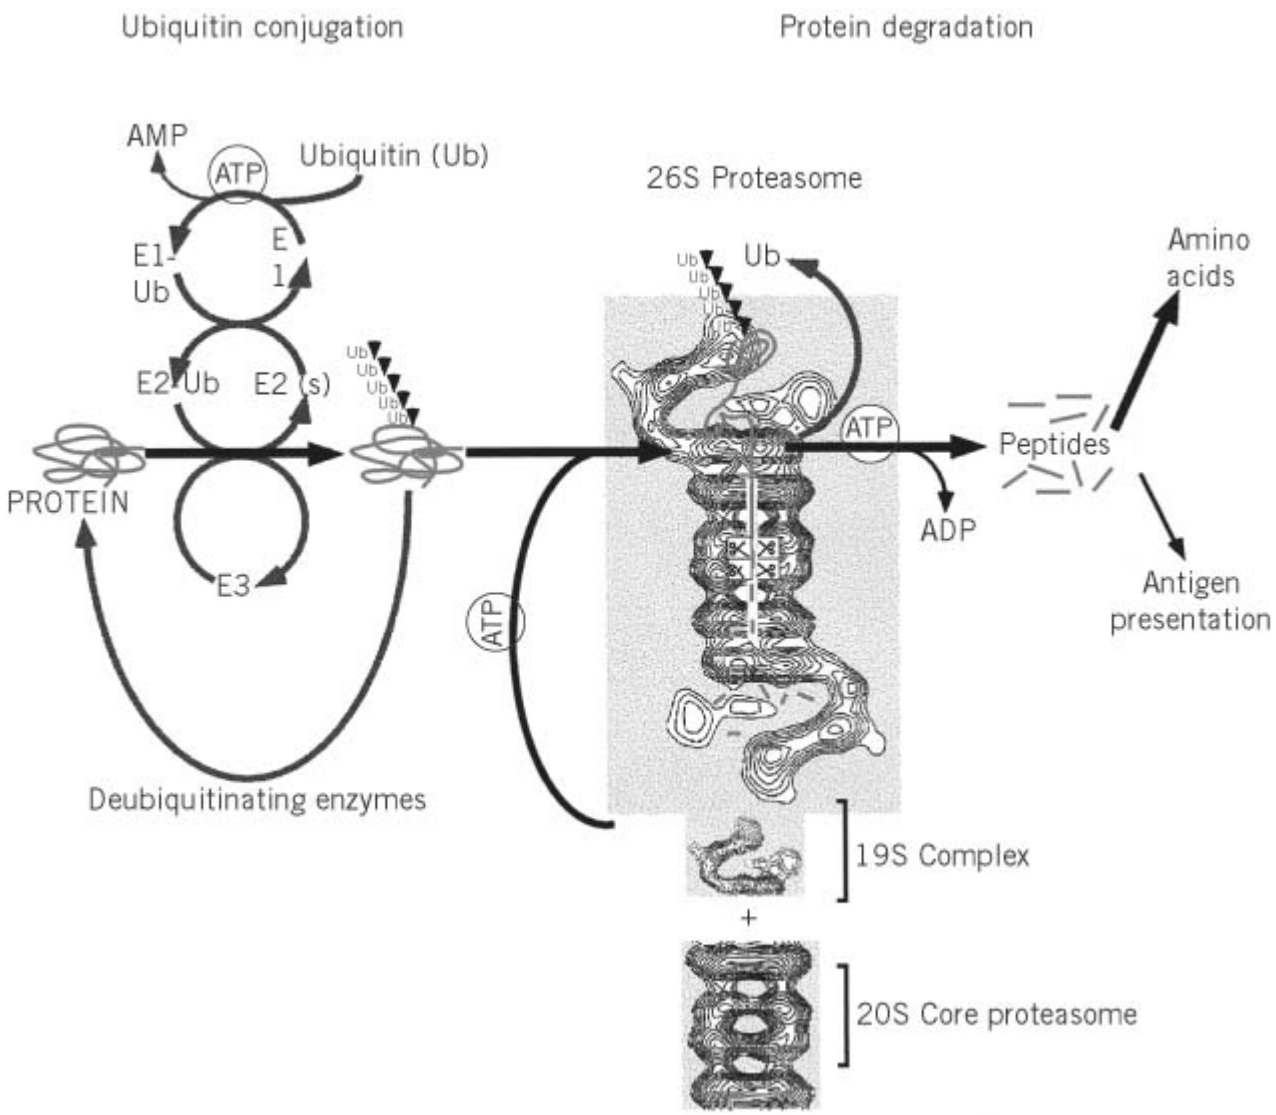
Proteasome

Individual proteins in eukaryotes are marked for **protein degradation** by being covalently linked to ubiquitin (Ub). They are then digested **proteolytically** into small **peptides** by the 26 S proteasome particle (Fig. 1). The key proteolytic component of this large complex is the 600-kDa 20 S particle. It is a major cell constituent, comprising up to 1% of the cellular protein. It has a barrel-shaped **structure** composed of four stacked rings, each containing seven subunits surrounding a central cavity. The two inner b rings enclose a large central chamber containing the sites where proteins are degraded, and the two outer a rings surround a small opening through which protein substrates enter. Because of the opening's small diameter, polypeptides must first be unfolded to enter it.

Figure 1. Mechanism of ubiquitin-conjugated protein degradation by the proteasome. Key: E1, ubiguitin-activating protein; E2, ubiguitin carrier protein; E3, ubiquitin-protein ligase; Ub, ubiquitin.



Unlike traditional proteinases, the proteasome does not simply cleave a protein and release the fragments; on the contrary, a protein substrate, once bound, is cut multiple times into small peptides ranging from 3–25 residues in length before the next protein molecule is attacked. This highly processive mechanism ensures that partially digested proteins do not accumulate within cells. Peptides released by the proteasome are rapidly hydrolyzed to amino acids in the cytosol, although some peptides are used in **major histocompatibility** class (MHC) I **antigen presentation** .

The presence of a powerful proteolytic enzyme system within the cell requires the evolution of mechanisms to safeguard against the nonspecific digestion of essential proteins. The first safeguard is the requirement for conjugation with ubiquitin before degradation of the protein. Second, the active sites of the proteasome are geographically isolated within the central chamber and away from the cytosolic milieu. Third, only unfolded proteins can enter the narrow opening in the a rings on either end of the 20S proteasome.

On either end of the 20S proteasome, there is a large 19S (700 kDa) regulatory particle. This structure provides specificity to proteolysis by binding ubiquitinated substrates and catalyzing the entry of the polypeptide into the 20S particle. Interestingly, the 19S regulatory complex also contains at least six different **ATPases**. It is likely that the consumption of ATP by the 19S complex enables it to unfold protein substrates, to inject them into the 20S proteasome, and to activate the proteolytic activity of the particle. Thus, the marking of substrates by Ub conjugation, the organization of the

26S complex, and the energy requirement for proteolysis all appear to have evolved to provide a remarkable degree of selectivity and regulation to the degradative process.

The mechanism by which peptide bonds are cleaved in the proteasome is also unique. Proteasomes do not fit into the standard classification of proteolytic enzymes according to their active sites (eg, serine proteinases, thiol proteinases, carboxyl proteinases, or metalloproteinases). The sequences of their b subunits are not **homologous** to those of known proteolytic enzymes, and the pattern of sensitivity to various inhibitors differs from that of any known proteinase family. The recent X-ray crystallography studies and site-directed mutagenesis of different amino acid residues in the proteasome have uncovered a new type of proteolytic mechanism. The active-site nucleophile of the proteasome is the hydroxyl group of a threonine residue at the amino terminus of the b subunit. This novel mechanism has permitted selective inhibitors of the proteasome to be synthesized.

The mammalian proteasome contains three types of active sites that differ in their specificity for different types of bonds. One site cleaves preferentially after basic amino acid residues, the others after large **hydrophobic** residues, small neutral residues, or acidic residues. These activities, which function together to catalyze the complete digestion of proteins, are associated with different b subunits. Intriguing adaptations exist in proteasome subunit composition that can aid in the generation of diverse antigenic peptides. For example, in disease states, the cytokine g-**interferon**, which enhances antigen presentation in most cells, induces the expression of three novel b subunits that are incorporated into the 20S proteasome in place of the b subunits normally present. These components alter the way in which peptide bonds are cleaved to favor the production of the kinds of peptides that are used preferentially for MHC class I antigen presentation.

1. 20 S Proteasomes of Prokaryotes

Many Gram-Positive Bacteria, like archaebacteria, contain a 20S proteasome, resembling in size and shape that in eukaryotes but composed of only one type of a subunit and one type of b subunit. These 20 S proteasomes appear *in vivo* to function in protein breakdown in association with ATPase complexes called PAN, or Proteasome-Activating nucleotidase. This hexameric-ring structure is a member of the AAA family of ATPases and is homologous to the six ATPases found in the 19S regulator of the eukaryotic proteasome. Addition of ATP and PAN to the 20S proteasome allows the ATP-dependent degradation of proteins but does not influence peptide hydrolysis. Many features suggest that this PAN complex was the evolutionary precursor of the 19S component of the eukaryotic 26S proteasome that degrades ubiquitinated proteins in an ATP-dependent fashion.

Protein A

Protein A is a cell-surface protein isolated from *Staphylococcus aureus* that binds mammalian **immunoglobulins** . The reactivity of an extract of *S. aureus* cells with all human sera was initially thought to reflect an innate human anti-staphylococcal immune specificity (1). Later studies showed that the binding reaction could be competed with Fc fragments of human IgG, rather than Fab fragments (see Immunoglobulin Structure). This finding pointed to a non-specific interaction of Protein A with the heavy-chain constant region of IgG, present in Fc, rather than a normal antibody–antigen recognition reaction mediated through the variable region that is present in Fab (2). A distinct immunoglobulin binding mode was subsequently discovered in which Protein A bound to antibody variable domains (3, 4).

Native protein A consists of a single polypeptide chain with five homologous ~60-residue **domains**, arranged from the *N* terminus in the order EDABC (5-7). An additional region following the C domain is used for covalent linkage to the peptidoglycan cell wall of *S. aureus* (8-11). The E domain has less homology to A, B, C, and D than the other four domains have with each other, and it was not identified in the initial protein sequence determination (7). Soluble protein A is released as an intact fragment by digestion of the peptidoglycan with the staphylolytic endopeptidase lysostaphin (12). Each domain is capable of binding Fc regions (6, 13). Structural studies of domain B and of Protein A showed that domain B is a three-helix bundle that binds near the junction of the immunoglobulin C_{H2} and C_{H3} domains and makes contacts with both immunoglobulin domains (14, 15).

The role of Protein A in staphylococcal infection remains speculative. The primary importance of Protein A in molecular biology is as an extremely versatile reagent for immunological studies. Protein A crosslinked to Sepharose or other supports is used as an affinity adsorbent for immunoglobulins (16). The serum of virtually all mammalian species has immunoglobulin classes that will bind Protein A, and other classes that do not, allowing rapid fractionation (17, 18). Within a species, the heavy-chain **isotypes** that bind protein A often do so with differential sensitivity to pH and may be separated quantitatively by pH step or gradient elution (19, 20).

A second use of Protein A is as an immunosorbent. To prepare this immunosorbent, *S. aureus* cells expressing surface Protein A are fixed with formalin, then heat-killed. Following this treatment, the Protein A remains attached to the cell wall and functional in Fc binding. Treated cells added to an antibody solution rapidly adsorb antibodies and immune complexes, and they retain these adsorbed molecules while the cells are repeatedly washed and pelleted by centrifugation . This stability makes the fixed cells ideal for capture of antibody and antibody–antigen complexes in immunoassays (21). Little nonspecific adsorption of other assay components to the cells is observed; hence uncomplexed antigen is free in solution. Fixed staphylococci have also been used as an immunosorbent for isolating surface antigens from animal cells or cell lines (22). Cells expressing the antigen to be isolated are first **radiolabeled** biosynthetically or chemically. Cells are then lysed, usually concomitant with detergent solubilization of the antigen. A specific antiserum or monoclonal antibody is added, and time is allowed for antigen binding to occur. The Protein A immunosorbent is then added to trap antibody–antigen complexes, from which antigen can be isolated by denaturing gel electrophoresis. The advantage of this technique over using a second antibody for immunoprecipitation of antibody–antigen complexes is that in the latter case precipitate formation is slow, seldom quantitative, and highly dependent on the ratio of the first and second antibodies.

Recombinant fusion proteins incorporating one or more domains from Protein A or one of the other receptors take advantage of their high-affinity interaction with immunoglobulins and have become

widely used in biotechnology (23). Such proteins are easily detected with immunological reagents and can be purified in a single step by affinity chromatography on immobilized IgG media.

Protein A is the most extensively used and studied **Gram-positive** bacterial immunoglobulin receptor, but it is not the only one. Other proteins with similar functions have been identified (24), and they often have complementary specificities. Protein G from staphylococci binds to all human IgG **isotypes**, interacting with both the Fc region and the heavy-chain C_{H1} constant domain (25, 26). Protein G overlaps the protein A binding site on Fc, yet it has a very different three-dimensional structure. Protein L from *Peptococcus magnus* is structurally homologous to protein G (27), but it binds to conserved regions in a subset of kappa light-chain variable domains (28, 29).

Protein Blots (Western Blots)

SDS–Polyacrylamide gel electrophoresis (SDS–PAGE) is one of the most versatile and important separation methods for analyzing proteins. Hundreds of polypeptides can be resolved on a single gel by this process, and **two-dimensional electrophoresis** expands the possibility of separation to thousands and more. These techniques separate the components on the basis of their physical properties, not on their activity or ability to interact with a given probe, eg, immunoglobulin, lectin or **ligand**. Western blotting (also called protein blotting) extends gel electrophoresis of proteins to provide such information (1, 2).

The production of a protein blot involves transferring the protein pattern from the gel onto a blotting matrix (see Blotting). This is commonly achieved by electroelution, subjecting the slab gel to a second electric field perpendicular to the surface of the gel, so that the polypeptides are eluted onto a blotting matrix, such as a nitrocellulose membrane filter. Numerous factors affect the quality of the transfer, such as the molecular mass of the peptides, the type of gel, the composition of the transfer buffer, the type of matrix, and the transfer conditions (e.g., voltage/current and time) (1-4). The transfer apparatus also affects the quality of the blot. Generally, systems that produce uniform or regulated gradient electric fields should be employed (5, 6).

Before a blot is probed, it is stained for protein to reveal the pattern of all transferred proteins. Stains, such as Ponceau S or Amido black are useful. Then the blot must be quenched, i.e., all available unoccupied surface of the matrix must be blocked with an inert blocking agent . Commonly, bovine serum albumin, gelatin, or milk (casein) have been used, and nonionic detergents, such as Tween-20 or Triton X-100 are often included in the quenching, washing, and incubation solutions. Quenching minimizes nonspecific adsorption of the probe to the blot and reduces the irrelevant background to a minimum. Then the quenched blot is incubated with a probe to identify any protein with which it associates specifically (see Blot Overlays). For example, when **antibodies**, lectins, **ligands**, or even cells are used as probes, immunoblots , lectin blots, ligand blots, and cell blots, respectively are carried out. After probing, the blot undergoes extensive washes to remove nonbound probe.

Identifying the complex between the probe and the protein bound to the surface of the blot achieved is by autoradiography when the probe is **radiolabeled**. Alternatively, a second probe can be used to identify the complex. For example, an enzyme conjugate of goat antimouse IgG might be used to reveal a murine monoclonal antibody bound to its corresponding antigen. Avidin or streptavidin enzyme conjugates are often required when biotinylated probes are used (see Avidin-Biotin System). Nonradioactive detection systems routinely employ the typical **ELISA** reagents that produce precipitating colored products. However, **luminescent** and **chemiluminescent** procedures are also sensitive and easy to use (7, 8).

In addition to detecting bimolecular interactions, protein blots have gained importance as an essential step in peptide sequence analysis. In such cases, a protein is transferred a gel by using a blotting

matrix that withstands the reactions of the Edman Degradation. Polyvinyl difluoride (PVDF) membrane filter is the blotting matrix most commonly used for this application. (9, 10).

DNA Degradation *In Vivo*

Low levels of DNA degradation occur continuously in all cells from bacteria to man in conjunction with DNA repair processes (see DNA Repair). Probably 90% of this degradation can be attributed to excision repair during which only a few nucleotides are released from each damaged site by the actions of repair endo- and exonucleases and recycled in the overall process. High levels of DNA degradation occur within a population of cells in individual cells that need elimination from that population. This need occurs either because their DNA has become too heavily damaged to be successfully repaired, because the cells have been infected with bacteriophages or viruses, or, during development and tissue remodeling in multicellular organisms, because these cells have received signals instructing them to commit suicide. In higher eukaryotes, this cell suicide is known as apoptosis (see Apoptosis). In this case, the chromatin DNA is fragmented and packaged with other cellular materials into apoptotic bodies that are engulfed by adjacent healthy cells in the tissue and digested in their lysosomes.

Except for a small body of work on *Escherichia coli,* little is known about cell suicide in bacteria. When DNA bacteriophages that have not adapted to growth in *E. coli* are cleaved by host restriction nucleases, the resulting ds-DNA fragments are degraded to small oligo-nucleotides by a nuclease with Mg^{++}- and ATP-dependent endo- and exonuclease activities encoded by the recB, recC, and recD genes. This nuclease acts normally in recombination and in recombinational ds-break repair, a minor DNA repair pathway (1). Some bacteriophages that have adapted to *E. coli* contain genes that encode specific inhibitors of the recBCD nuclease. This nuclease is also responsible for degrading genomic DNA damaged beyond repair by UV light or ionizing radiation (1), but the details of the process are not known. The enzyme has homologs in many other species of bacteria.

Most chromatin DNA fragmentation in eukaryotic cells follow an ordered path that yields first

300 kbp double strand (ds) fragments, then 50 kbp ds-fragments, and, last, a range of small ds-fragments that are multiples of mononuclesome-sized DNA, 180 to 200 bp (2). This fragmentation pattern reflects the different levels of packing of the DNA in the chromatin. Six 50 kbp loops form 300 kbp rosettes that are stacked together. Cleavage between rosettes releases the 300 kbp fragments, and cleavage at the bases of the loops releases 50 kbp linear ds-DNA that is readily cleaved between nucleosomes to small fragments that have 3′-OH and 5′-P termini. When electrophoresed in agarose, the latter appear as a characteristic "ladder" of DNA. All stages of the fragmentation are Mg^{++}-dependent, but the subsequent cleavage to small fragments is also activated by Ca^{++}. This may indicate that there is more than one nuclease involved in chromatin DNA cleavage (2). In a few cases, the earlier stages of fragmentation are sufficient for apoptosis to proceed to completion.

Random DNA degradation occurs during cell necrosis as a result of very heavy damage to the cell or tissue injury and is accompanied by lysosome disruption and cytolysis. DNase II, an acid DNase normally sequestered in the lysosomes, will generate a ladder of ds-DNA fragments when incubated *in vitro* with isolated nuclei at acidic pH. However, only a small decrease in intracellular pH (0.3 pH U) occurs during apoptosis (3), not enough to result in appreciable activation of DNase II even if it had a nuclear location. DNase II is not metal ion-dependent and makes ds-breaks with 3′-P and 5′-OH groups, termini not found on the apoptotic ds-DNA fragments. The corresponding acid DNase of the flatworm, *Caenorhabditis elegans,* plays a role in apoptosis, namely in helping to digest the DNA in the apoptotic bodies engulfed by healthy cells. A loss of function of this nuclease caused by mutation of the *nuc 1* gene leads to accumulation of the apoptotic bodies in the lysosomes (4).

At least three nucleases have been identified as responsible for DNA degradation during apoptosis in higher eukaryotes: endo-exonuclease (EE), caspase-activated DNase (CAD), and the mitochondrial nuclease (mitNuc). These are present in cells either in inactive forms (EE and CAD) that are activated by proteases or sequestered (mitNuc). EE was first purified from *Neurospora crassa* (5). It is a Mg^{++}-dependent enzyme with homologs in other fungi and yeast, where it acts in recombination and in recombinational ds-break repair (5). It may be the eukaryotic counterpart of the bacterial recBCD nuclease. It has endonuclease activity with both DNA and RNA and exonuclease activity with DNA. EE is the major degradative nuclease in nuclei of human leukemia cells, present entirely in inactive form, mainly bound to the nuclear matrix (6). A nearly equal amount of inactive EE is also bound to the membranes of the endoplasmic reticulum. Proteolysis of EE has been detected in response to different apoptotic agents and yielded polypeptides identical in sizes to the various Ca^{++}-, Mg^{++}-endonucleases isolated previously from apoptotic cells by others (6). EE is activated *in vitro* by treatment with the serine protease trypsin or with caspase-3 (7). A mammalian EE, synergistically activated by Ca^{++}, has been isolated from monkey CV-1 cells (8). Genetic evidence is needed to further delineate the precise role of EE in apoptosis.

CAD is present in the cytosol and in nuclei of mammalian cells (9) in the form of a single inactive polypeptide called DNA fragmentation factor (DFF). Activation of CAD takes place when DFF is cleaved by one of the specialized and highly regulated proteases called caspases. This occurs *in vitro* with caspase-3 or caspase-7. CAD is a Mg^{++}-dependent specific DNase that cleaves the DNA of isolated nuclei to nucleosome-sized fragments. However, CAD is not present in some lower organisms such as yeast or the flatworm (10). In addition, DNA degradation occurs during apoptosis in cells from DFF-knockout mice (10). This indicates that CAD is not essential and that other nucleases also play a role in the process.

In cells of DFF-knockout mice, tumor necrosis factor causes high levels of nuclear DNA degradation. In this case, it is due to the release of the mitNuc from the inter-membrane space of the mitochondri (10). Yeast mitNuc was previously shown to be an endo-exonuclease and is closely related to the mammalian mitNucs (5). The release of mouse mitNuc is mediated by the activation of caspase-8. This protease cleaves a protein called Bid to a truncated form (tBid) that induces the release of several apoptotic factors including mitNuc (10). However, mitNuc is not released from

mitochondria in HL-60 cells during apoptosis induced by two other agents, the chemotherapeutic drug etoposide (VP-16) or the anti-rheumatic drug hydroxychloroquine (11). Thus, it is unlikely that mitNuc is involved in the DNA degradation caused by these apoptotic agents.

Protein Detection

Many methods for detecting or measuring proteins in solution or on a blotting membrane have been developed. The Kjeldahl method detects all of the nitrogen atoms of proteins as ammonia after heating them with sulfuric acid. It is used only with very complex samples. The Lowry (see later), **biuret**, and ninhydrin assays are more widely used colorimetric methods. The UV method utilizes the **absorbance** of tryptophan and tyrosine residues at 280 nm and is a very convenient method for determining protein content (1). Detecting or determining proteins by the binding of dyes (see Coomassie Brilliant Blue and Ponceau S) and after reaction with a dye that becomes fluorescent (see Fluorescamine) are sensitive and convenient methods. Many of the methods mentioned previously can be employed to detect proteins on a membrane or in a polyacrylamide gel. The most sensitive detection method is silver staining, which detects 2 to 5 ng of protein/band. For most of these assays, the responses of different proteins vary quantitatively, depending upon their amino acid compositions, which makes quantification difficult.

To determinate or detect a particular protein, its biological function can be utilized (see Overlay Assay: Enzyme Zymography of Plasminogen Activators and Inhibitors). **Immunoblotting** is one of the most widely used methods of this type.

1. Lowry Assay

The Lowry method (2) is a sensitive, colorimetric, protein determination method that measures 1 to 20 μg of protein. It is a combination of the phenol method and the biuret method. The Folin and

Ciocalteu phenol reagent contains sodium molybdate(VI), sodium tungstate(VI), and phosphoric acid, and it reacts with phenols. Phenol reagent is added to the protein sample after the **biuret** reaction, and the absorance at 750 nm is measured.

Protein Disulfide Isomerase

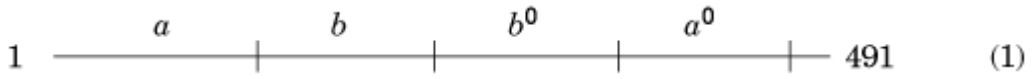
Protein disulfide isomerase (PDI) is the major catalyst in the endoplasmic reticulum of **eukaryotes** of **protein folding** that involves disulfide bond formation. It catalyzes the formation of protein disulfide bonds, their reduction, and their rearrangement, using domains that are **homologous** to thioredoxin. Its catalytic activity results primarily from the somewhat unusual thiol–disulfide exchange properties of its thioredoxin-like active sites, plus a tendency to bind unfolded and misfolded polypeptide chains. In Gram-Negative Bacteria, such as *Escherichia coli*, its multiple activities are catalyzed by several simpler proteins.

1. Eukaryotic PDI

PDI was the first catalyst of protein folding to be discovered, being detected independently by two groups in 1963 (1, 2) as part of the classic studies of C. B. Anfinsen and colleagues on the refolding of reduced **ribonuclease A** that accompanies disulfide bond formation. It was apparent that the oxidation of reduced ribonuclease was much too slow to account for its rate of biosynthesis *in vivo*, so a catalyst was sought; it was named PDI when it appeared that its prime function was to catalyze protein disulfide rearrangements, or isomerization. The importance of PDI in catalyzing disulfide formation and breakage was overlooked because those studies were using air oxidation to generate protein disulfide bonds. When a more physiological procedure was used, using reduced and oxidized glutathione, GSH and GSSG, respectively, it became apparent that PDI catalyzes every step in the disulfide-linked folding of a protein (3). Glutathione is the primary sulfur reagent present within the endoplasmic reticulum, occurring in the millimolar concentration range. There the ratio of GSSG to GSH is between 1:1 to 1:3 (4), more oxidizing than the cytosol, where the ratio is closer to 1:100 (see Disulfide Bonds).

PDI occurs at high concentrations in the ER, approximately 10^3M, where it comprises about 12% by weight of the total protein. At these concentrations, it is believed to be a dimer. It is a calcium-binding protein, as are many proteins of the ER, although this has no known effect on its functional properties (5). The PDI polypeptide chain is also used as the b-subunit of prolyl-4-hydroxylase (6)

and as one subunit of the heterodimeric microsomal triglyceride transfer protein (7); in both cases, it appears to play primarily a structural role. The primary structure of the mammalian PDI polypeptide chain (8) suggested that it is comprised of four domains, or modules, plus an acidic C-terminus that is believed to be involved in binding Ca^{2+} ions, and this has been confirmed by dissection studies (9):



(1)

The *a* and *a*′ domains are clearly **homologous** to thioredoxin, with the typical pair of cysteine residues at the active site, and they have the same fold (10); surprisingly, the *b* domain also has the thioredoxin fold, but with the active-site cysteine residues deleted (11); the *b*′ domain is homologous to *b* and therefore probably also has the thioredoxin fold.

Disulfide bond formation, breakage, and rearrangement in proteins are believed to occur by PDI reacting with their disulfide or thiol groups ($\mathbf{P}^{\mathbf{S}}_{\mathbf{S}}$ or $\mathbf{P}^{\mathbf{SH}}_{\mathbf{SH}}$, respectively) using the pair of cysteine residues at the thioredoxin-like active sites of the PDI *a* and *a*′ domains, $A^{SH}{}_{SH}$ and $A^{S}{}_{S}$, through an intermediate mixed disulfide between the two:

$$\mathbf{P}^{\mathbf{S}}_{\mathbf{S}} + \mathbf{A}^{\mathbf{SH}}_{\mathbf{SH}} \leftrightarrow \mathbf{P}^{\mathbf{S-S}}_{\mathbf{SH}}{}_{\mathbf{HS}}\mathbf{A} \leftrightarrow \mathbf{P}^{\mathbf{SH}}_{\mathbf{SH}} + \mathbf{A}^{\mathbf{S}}_{\mathbf{S}} \downarrow \text{Disulfide rearrangements} \qquad (2)$$

The activities of the individual *a* and *a*′ domains account quantitatively for the activity of PDI in inserting disulfide bonds into protein by the mechanism of Eq. 2 (12). The interconversion between the dithiol and disulfide forms of PDI might be accomplished by its reaction with the high concentrations of GSSG and GSH in the endoplasmic reticulum, or it could be enzyme-catalyzed (13). Protein disulfide isomerizations would occur if a different protein cysteine residue reacted with the mixed disulfide bond between protein and PDI to generate a new disulfide bond. Nevertheless, the individual *a* and *a*′ domains have incomplete disulfide isomerization activity, which requires the presence of the *b* and *b*′ domains.

The disulfide bonds at the PDI active sites are relatively unstable, so they are readily transferred to a substrate protein that can readily form disulfide bonds (12). The instability of the PDI disulfide bonds is an indirect effect that arises primarily because the accessible active site thiol groups of the *a* and *a*′ domains have very low p K_a values; that for the *a* domain is 4.5 (14). Relative to a normal Cys residue thiol group, this thiolate anion is stabilized by 5.7 kcal/mol; most of this is believed to be due to interaction with the partial positive charges at the N-terminus of the a-helix where it is located, with 1.1 kcal/mol being due to electrostatic interaction with a nearby His residue (14). The thiolate anion is the reactive form of a thiol group, so its stabilization in PDI is undoubtedly at least part of the reason why this thiol group is so reactive. Stabilization of the thiolate anion also stabilizes the reduced dithiol form of the protein over the disulfide form, so it indirectly destabilizes the disulfide bond.

In addition to the intrinsic reactivities of the thiol and disulfide groups at the active sites of PDI, weak binding interactions between the catalyst and a substrate protein are also believed to contribute to catalysis. The details of these phenomena are best understood in the analogous catalysts from *E. coli*.

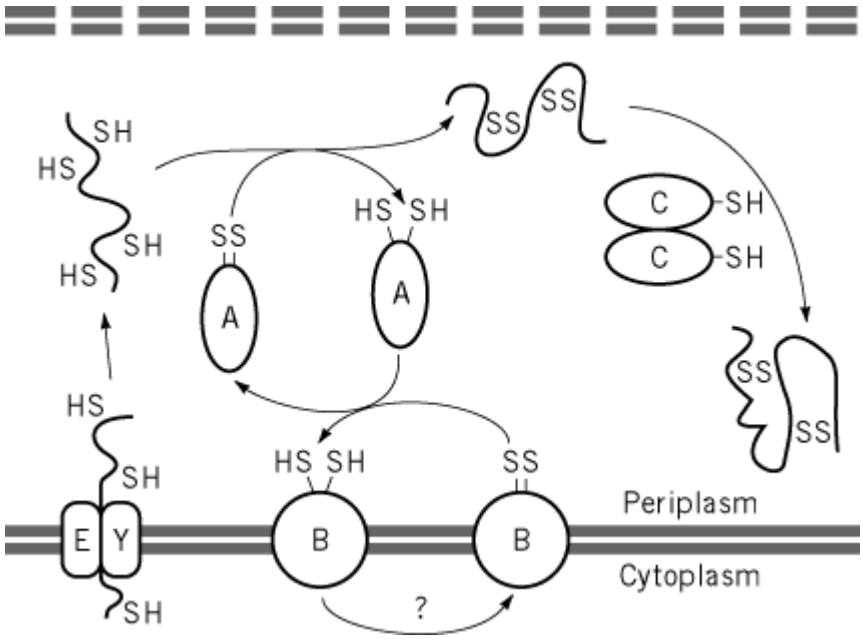
2. Gram-negative bacteria

Gram-negative bacteria have a **periplasmic** compartment between the inner and outer membranes,

where **secreted proteins** fold and incorporate disulfide bonds. Genetic analysis has identified a number of proteins that are required for this process (15-17).

Disulfide bonds are believed to be generated in newly secreted proteins by reaction with the unstable disulfide bond of DsbA, as in Eq. 2 (Fig. 1). This protein has an active site and a fold like that of thioredoxin, but with another domain inserted into the polypeptide chain (18). DsbA has a disulfide bond that is one of the least stable known (19), due to its reduced form being stabilized by electrostatic interactions with the thiolate anion form of the accessible cysteine thiol group, which has a greatly reduced pK_a of 3.5 (20). This disulfide bond is less stable than when the protein is unfolded, so it actually destabilizes the folded conformation of DsbA (19). Upon transfer to a newly synthesized protein (21), the DsbA disulfide bond is regenerated by the plasma membrane-bound DsbB protein, and may be coupled to the redox potential of the cytosol (17) (Fig. 1).

Figure 1. Present model for folding and disulfide formation in a newly secreted protein in the periplasm of Gram-negative bacteria. At lower left, a newly synthesized protein with four cysteine residues is being secreted through the plasma membrane using the *Sec* system. This protein incorporates two disulfide bonds by reacting with the disulfide form of two molecules of protein DsbA (labeled A). The disulfide form of DsbA is regenerated by the membrane protein DsbB. These disulfide bonds are isomerized by the dimeric DsbC to generate the native protein.



DsbA has very little protein disulfide isomerase activity, but this function appears to be catalyzed by a separate protein, DsbC. About half the polypeptide chain of this homodimeric protein is likely to have a folded conformation like thioredoxin (22). Its properties are very similar to those of DsbA, and why it is a better isomerase is not clear. It is likely that binding interactions with the substrate are crucial, and they are known to occur in both DsbA and DsbC (23).

Further genes involved in disulfide bond formation in the *E. coli* periplasm are being discovered and await characterization (24). In addition to the thioredoxin motif in all of these proteins, the additional domains are likely to be present to restrict the interactions between these various proteins and for their interaction with substrate proteins.

Protein Engineering

Protein engineering is a multidisciplinary technology for the design and production of new proteins

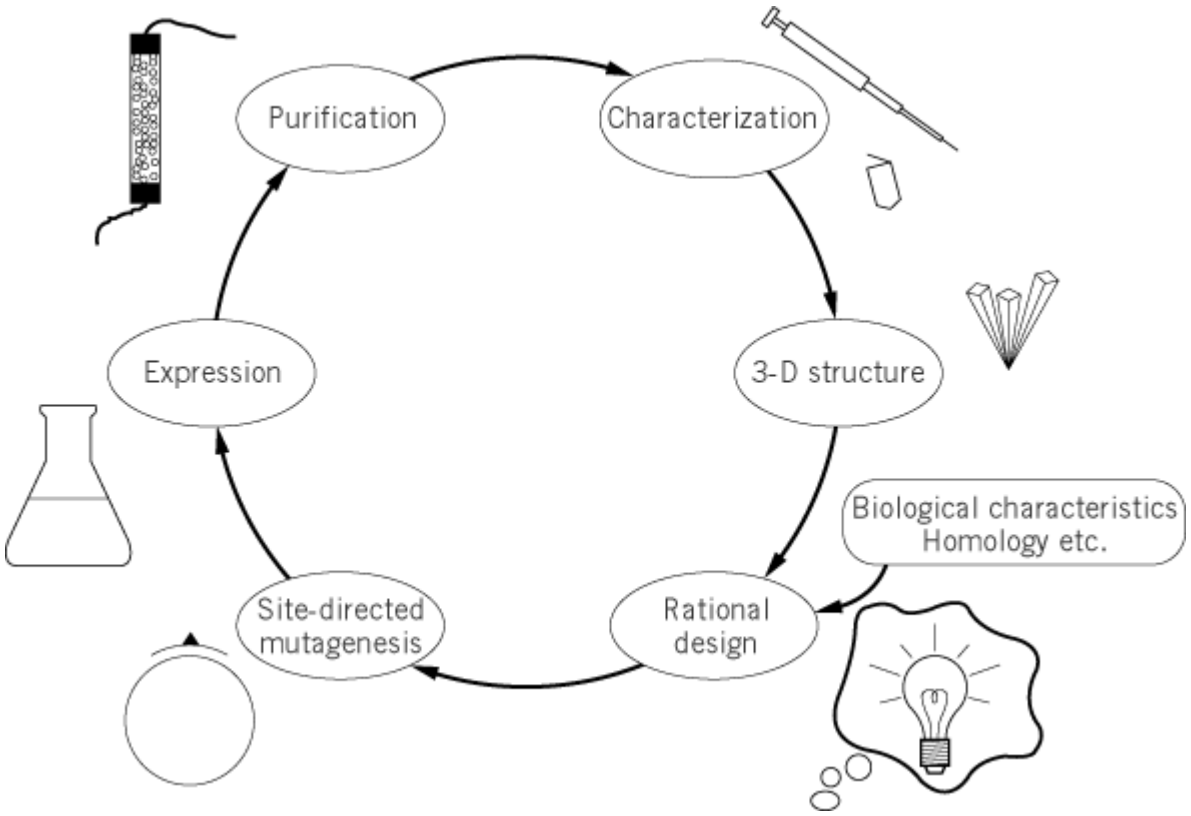
with predetermined properties. There are two basic motivations for pursuing protein design. The first is academic, aimed at increasing our knowledge about the fundamental properties of natural proteins, such as their folding pathways, stability (see Protein Stability) and catalytic properties (see Enzymes). Studies of the first type are often referred to as structure-function studies because they aim at establishing the relationship between how local parts of a protein's structure (individual amino acid residues or specific segments) contribute to its net functional behavior. The second is a practical motivation to be able to construct "tailor-made" proteins with improved properties to fulfill specific tasks in industry, medicine, agriculture, and so forth. Because the conditions under which industrially important proteins are used often differ from those of their natural environment, stability is a necessary consideration for most engineered proteins. An increase in catalytic activity is another goal of great interest. The ultimate ambition of the protein engineer is to be able to create a protein with any desired structure and function.

Three strategies for design dominate the field. The oldest strategy, "classical" protein engineering, is based on the reengineering of already existing proteins, whereas the second, *de novo* design, uses nature's rules to design entirely new proteins. These two are rational approaches by which the scientist tries to predict which sequence is needed to obtain a certain structure and function of interest. The third category of methods encompasses strategies mimicking natural evolution, making these approaches more "irrational."

1. Classical Protein Engineering

Classical protein engineering follows a cyclic diagram (Fig. 1), which is reiterative and can, in principle, be repeated infinitely. It is desirable to have considerable information about both the structural and functional aspects of the system to be studied. Structural information derives from **X-ray crystallographic** or NMR (nuclear magnetic resonance) studies, two techniques that complement each other. Functional information can derive from biochemical analysis, such as enzymatic assays, affinity labeling, chemical modification, and crosslinking and includes knowledge about any sites of post-translational modifications . This structural and functional knowledge of the protein forms the basis for deciding which amino acid substitutions should be introduced by site-directed mutagenesis in order to solve the present problem.

Figure 1. The classical protein engineering cycle uses the structure of the protein of interest as the starting point for designing mutants to explore a given problem. The mutations are introduced into the protein's gene using site-directed mutagenesis, and the mutant protein is expressed in a suitable expression system. Thereafter, the resulting protein is purified and characterized with respect to alterations in its function. The functionality profile is interpreted in structural terms and, ultimately, the structure of the mutant protein is determined in order to obtain a complete understanding of its functional behavior.



Gradually, computer tools are being developed to assist the protein engineer. These range from **homology modeling** to predict the structure of a related protein and the expected impact of a mutation on its structure or function to programs that will dress a structure of interest with the optimized sequence. There are two fundamentally different ways of computer modeling: a subjective, intuitive, and interactive approach and an objective, analytic approach based on energetic criteria and other mathematically formulated biophysical concepts.

The design of point mutants should focus on which amino acid residue to mutate and what to replace it with. A guideline for the identification of important residues is found in alignments of the protein of interest with related proteins (1) (see Sequence Analysis). Residues that are directly involved in a common function, such as catalysis, will be among the most conserved; and residues that are important for structural reasons will also show a high degree of conservation. Consequently, mutations in residues that are required for structure formation or stability can also have dramatic effects on activity, leading to misinterpretations of the role of these residues. Conversely, the nonconserved residues are likely to be involved in functions unique to each protein, such as substrate binding and specificity, or these residues may have resulted from neutral mutations and may be dispensable for function.

Two sources of information can be used in attempts to determine which new amino acid should be introduced. Natural evolution has used *in vivo* mutations to engineer stable protein structures for specific functions. A similar overall folding pattern is maintained for functionally related molecules, irrespective of the accumulation of natural amino acid substitutions. Considerable variation can be tolerated in external loops, while the protein cores are maintained as well-packed regions with topologically equivalent side chains in each of the species. Evolutionary studies suggest that the interior of a protein can tolerate a volume change of no more than one methyl group without a change in the polar/nonpolar nature of the mutated residue. In contrast, residues near the surface can be permitted drastic substitutions, providing there is enough exposed surface for the side chain to reach the aqueous solvent (see Accessible Surface). Overall, however, the surface should appear

hydrophilic whereas the core is stabilized by **hydrophobic interactions** (2). Another source of information comes from other protein engineering studies, but the rules for "safe" mutations deduced from these two types of studies are more or less the same.

Two possible kinds of alterations can be introduced into a protein (3): (1) substitution of one amino acid by an isosteric residue of different function (eg, Glu by Gln), or (2) replacement of one amino acid by another of the same nature but different structure (eg, Glu by Asp). The first kind of substitution attempts to probe function while keeping structure constant, whereas the second kind enables the study of how function depends on structure. It is generally advisable to refrain from the mutation and introduction of glycine and **proline residues**, because these residues often have a great impact on the structure of the protein.

One should be very cautious when designing mutants because a badly designed mutant will produce more questions than answers. Mutations are easy to make, but the results of the subsequent functional characterization can turn out to be laborious, or even impossible, to evaluate in a sensible manner.

Apart from point mutations, the introduction of insertions or deletions (**indels**) can turn out to be a valuable tool for the engineering of proteins (4). Indels often give rise to structural alterations that could not have been obtained using substitutions alone. Nature seems to have used indels as a way of optimizing the position of side chains for a specific biological function. So far, protein engineers have used indels mainly for the mapping of protein structure and function, but the introduction of indels should provide a new tool for engineering changes in protein activity. The consequences of this type of mutation are very difficult to predict, making a random approach combined with a screening/selection strategy the most feasible procedure (see below). Another mutagenesis strategy that is also being used for the identification of functionally important regions is the "charged-to-alanine scanning mutagenesis." This technique involves the progressive replacement of each of the charged amino acids in the protein, ie, Asp, Glu, Arg, Lys, and His, with Ala. This primary screen should be followed by the creation of additional mutations to assess the contributions of the neighboring polar and neutral amino acids in the relevant regions (5).

The mutations used in classical protein engineering are most often introduced into the corresponding **gene** using **site-directed mutagenesis**, and an extensive number of methods are available for introducing mutations *in vitro* (6). **PCR** has also proved to be a powerful technique for the generation of both site-specific and random mutations.

The engineered gene must be expressed using an expression system. Most often, a simple and fast expression system will be the first choice for the exploration of the effects of a series of point mutations. The use of a homologous expression system can be an advantage because the mutant proteins have a better chance of being processed correctly in their native environment, leading to easier folding and more stable expression. It is beneficial to choose a generally applicable expression strategy, such as a **fusion gene** approach, to avoid the need for individual optimization for each mutant. Often, a few milligrams of the mutant protein will provide enough material for the subsequent functional characterization. If a more thorough structural analysis is desired, larger amounts will be needed, and the generation of microheterogeneity in terms of folding or addition of post-translational modifications will be a concern. Finally, if the mutant turns out to be of practical/commercial value, more work needs to be put into the development of the most stable, efficient, and safe expression system, taking into account the intended use of the engineered protein.

After expression, the mutant protein must be purified. Once again, a fusion gene approach will minimize the need for time-consuming optimizations and, often, the protein of interest can be obtained in pure form in one chromatography step. One further advantage is that the mutant protein is easy to separate from the **wild-type** protein, which may be a problem if a homologous expression strategy is applied. For some applications, the fusion partner needs to be cleaved off in a subsequent step but, frequently, it will not affect the function of the mutant seriously, enabling the functional

characterization to be carried out directly on the fusion protein. The wild-type protein should be expressed and purified in exactly the same manner as the mutant protein, to serve as a reference in the functional characterization.

The purified protein can be characterized in various ways to determine if it meets one's requirements. First of all, one should make certain that the protein actually contains the mutation. This can be done by mass spectrometry analysis or peptide sequencing. It is most often assumed, however, that the mutant gene remains unaltered in the expression host. The use of a **recombination**-deficient host increases the likelihood of this. The next task is to ensure that the overall structure of the mutant protein is preserved. In some cases, the solubility and stable expression of a mutant protein may be taken as evidence of its structural integrity, given that mutations disturbing the overall structure of a protein often result in **denaturation**, insolubility, and **proteolytic** degradation. The most exact and detailed methods for obtaining structural information are, of course, X-ray crystallography and NMR, but both methods are time-consuming, and faster methods are available that usually will supply sufficient information about the preservation of structure, such as measurement of the thermostability of the mutant protein using, for example, **calorimetry** or the application of various kinds of spectroscopy (see Circular Dichroism; Vibrational Spectroscopy). If no global or long-range structural distortions are apparent, one can proceed to the functional assays that will investigate the role of the substituted amino acid in terms of catalytic activity, involvement in **ligand binding**, and so forth. The ultimate characterization of a mutant will be the determination of its three-dimensional structure, which allows a complete evaluation of the functional characterization in structural terms. Furthermore, it is the starting point for a new round of improvements in the protein engineering cycle.

Traditional site-directed mutagenesis provides the possibility of substituting one amino acid residue with each of the other 19 natural amino acids. This is a fairly limited selection, and the range narrows when one considers that some of these substitutions will obviously give rise to unplanned structural changes. Methods are available, however, that permit the insertion of unnatural amino acids into a protein. The principle is that a purified and chemically mischarged suppressor tRNA is added to an *in vitro* transcription/translation system containing the gene of interest with the cognate **nonsense codon** at the position to be mutated (7, 8).

As an example, the engineering of increased stability is often a requirement for proteins with industrial applications. One of the most obvious sources of information is a comparison of sequences and structures of proteins from a **thermophilic** origin with those of their **mesophilic** counterparts (9). A number of "rules" for achieving thermostability can be set up on this basis: (1) certain residues tend to be circumvented (eg, Cys, Asn, and Gln); (2) thermostable proteins often have compact structures, and internal cavities are avoided; (3) the sizes of loops connecting **secondary structure** elements are reduced; and (4) interfaces are designed to be hydrophobic. Most often, several mutations need to be introduced into a thermolabile protein in order to increase its stability, which is a rather tedious task. Protein minimization (10), in which proteins are decreased in size via a combination of design, selection, and screening, is another approach to increasing the stability of a protein.

The engineering of proteins using site-directed mutagenesis can be rather complicated. The simplest approach for building new proteins has been transferring entire **domains** from one protein to another (11). Functional sites can also be transferred from one protein to another, with conservation of structural integrity and gain in function. The maintenance of structure, however, requires that the three-dimensional structure of the protein used as a scaffold be consulted.

2. Strategies for Design of Structure *de Novo*

The problem to be solved when designing a novel protein structure is to create an amino acid sequence that will fold into a stable and unique three-dimensional structure. A polypeptide chain can, in principle, take up an astronomically large number of conformations. Therefore, the **entropic** cost

of fixing the chain in a unique conformation is rather high. The task is to design a fold with a number of favorable interactions whose formations are associated with a gain in **free energy** that exceeds the decrease in conformational entropy.

The design process often occurs in a series of steps representing the hierarchy of forces required for stabilizing tertiary structures, starting with hydrophobic forces and adding more specific interactions as required to obtain a unique functional protein (12). The simplest strategy of *de novo* design is the modular approach, in which fragments forming units of **secondary structure** are assembled into oligomeric structures. The driving force for this process is most often the burial of hydrophobic side chains in the center of the assembly. The modules are easy to synthesize, but the practical applicability of the approach is limited. The modular approach has been most successful for the assembly of **alpha-helices** into bundles, because a-helices are stabilized by intramolecular hydrogen bonds that make them rather stable as single units. In contrast, **beta-strands** need to be linked together by interstrand hydrogen bonds to form stable assemblies; a b-strand is not stable individually. There are some general rules for the design of secondary structure building blocks for the construction of protein bodies. The modules need to be amphiphilic, and the presence of hydrophobic and hydrophilic residues needs to follow the regular pattern of the secondary structure elements in question. The assembly of modules can be facilitated by decreasing the entropic freedom of the system by linking its individual elements covalently. Several kinds of linkers, such as peptide loops, ligand-binding sites, covalent crosslinking, or synthetic templates have been used successfully.

The next step in *de novo* design is to create single polypeptide chains that fold into a defined three-dimensional structure without the need for any linkers. The structure of interest needs to be stabilized by the introduction of appropriate interactions. Yet one also needs to design against unwanted, alternative structures by destabilizing such structures. Interactions stabilizing a protein structure are of many types, eg, van der Waals interactions, hydrogen bonds, salt bridges, and **hydrophobic interactions**. Furthermore, the amino acids have certain propensities for existing in different kinds of secondary structure elements. Nevertheless, two rules that govern protein design in nature seem sufficient when proteins are designed *de novo*: (1) soluble proteins fold to maximize the burial of hydrophobic residues and exposure of hydrophilic residues, and (2) proteins are composed of building blocks of secondary structure elements, which are stabilized by a repeated hydrogen bonding pattern.

The ultimate ambition in *de novo* design is, of course, to design proteins that not only take up a predetermined structure but are also equipped with a specified function. The *de novo* design of function has led to proteins and peptides with specified properties for binding and catalysis. Synthetic membrane proteins, **ion channels**, and new polypeptide materials are other examples of *de novo* design of function.

3. “Irrational Design” of Proteins via Directed Evolution

Rational design of proteins is hampered by how little we understand how precisely the secondary and tertiary structures of a protein are related to the amino acid sequence and how structure and function are related; but we are now learning how to mimic nature's way of designing new proteins. In nature, proteins are built in an “irrational” manner by the force of evolution driving the process by mutation and natural selection. A library of the protein of interest containing randomly introduced mutations is subjected to screening or selection to find variants with new biological functions (examples can be found in references (13-15)). Directed evolution (also known as *in vitro* evolution) has an advantage over rational design in that it bypasses the need for understanding structure–function relations. This approach will also benefit from structural knowledge, however, as only a very small fraction of all possible protein sequences are available to analysis because of the practical limits of libraries. A library containing 10^{12} different random peptide motifs enables the display of only ten residues in all possible combinations of the 20 amino acids. It is therefore very important to

be able to target the sequence randomization to critical areas. The terms *screening* and *selection* are often confused in the literature, even though they are fundamentally different techniques. Screening conditions apply if all members of a library are present when one chooses clones for further analysis. Screening methods include simple visual inspection and calorimetric assays (16). Under selection conditions, in contrast, only those clones of potential interest appear, which aids the sampling of much larger libraries. Selection techniques include genetic selection, **phage display**, the peptide-on-plasmid-technique, **polysome** display, and the two-hybrid system (17). The first and last methods represent *in vivo* techniques, whereas the selections of the others take place *in vitro*.

The generation of catalytic antibodies is a special way of mimicking nature, and the process can be carried out both *in vitro*, as described above, or *in vivo*, taking advantage of the immune system of the immunized animal, which possesses tremendous powers of randomization. A catalytic antibody is an antibody that has been raised against a transition state analog (18). The resulting antibody will therefore have a much stronger affinity for the transition state than for the substrate or product, which is how an enzyme provides a more favorable energetic route from substrate to product. The difficulty lies in choosing the best analogue of the transition state because the transition state itself cannot be synthesized.

Protein engineering is a multidisciplinary technology involving computer technologists, X-ray crystallographers, molecular biologists, fermentation experts, biochemists, and other specialists. Protein engineering will face many challenges before the ultimate goal of designing a protein purposely endowed with a specific structure and function is reached. One of the most serious challenges is probably to induce these scientists representing different disciplines to cooperate effectively.

Protein Evolution

The of can be studied at the levels of **nucleotide sequences, primary structures, secondary structures**, and . A nucleotide substitution within a **gene** coding for a protein can be classified as either synonymous substitution or nonsynonymous substitution (1). A synonymous substitution is the so-called silent substitution that never causes amino acid changes. On the other hand, nonsynonymous substitutions alter the amino acid sequence. The ratio (f) of the number of nonsynonymous substitutions (K_A) over that of synonymous substitutions (K_S) can be used as a measure of the functional constraints on a protein. It has constantly been found that the rate of amino acid substitution in the functionally more important parts of the protein is slower than in the less important parts. With the assumption that K_s is a more direct reflection of the mutation rate, because there are no changes of amino acids (although this assumption is not always valid), f is an indicator of the degree of functional constraints for the whole, as well as parts of a protein.

For amino acid sequences, the rate of amino acid substitution is estimated as a measure of an evolutionary rate of change of proteins (for more details, see). Regarding secondary structures, most functional protein **domains** are composed of a certain combination of **alpha-helix, beta-sheet** structures, , and irregular parts. One of the strong driving forces of protein evolution should be , in which those secondary structures may play an important role. and have elucidated a large number of three-dimensional . Moreover, methods for the prediction of tertiary structures of proteins from the amino acid sequences have improved tremendously (2). This provides a unique opportunity for us to make throughout comparisons of tertiary structures among different proteins, possibly leading to the elucidation of the ancient evolution of proteins and genes.

Protein Folding *In Vitro*

Proteins are biologically active only after they have adopted their native, three-dimensional folded **conformations** (see Protein Structure). Yet the genetic information used in **protein biosynthesis** specifies only the linear sequence of amino acids residues, the primary structure. Natural proteins can often be **denatured**, or unfolded, and then **renatured**, or refolded, to the original conformation. When they cannot, it is usually because the unfolded protein has precipitated, aggregated, or been subjected to covalent modification. Therefore, the information for the **secondary structure** and the tertiary structure resides in the primary structure. Consequently, it should be possible to predict the three-dimensional structure of a protein from just its primary structure, if the process of protein folding were understood. Moreover, many proteins produced for pharmaceutical or industrial uses are generated initially in insoluble, unfolded, and inactive forms in inclusion bodies, and they must be folded before they can be used.

Protein folding is simply a conformational change, an isomerization (unless disulfide bonds are formed), but its unusual aspect is the enormous number of conformations that an unfolded protein can adopt. If each amino acid residue adopts an average of j conformations, a polypeptide chain with (N+1) residues (N peptide units between them to define the conformation) could adopt up to j^N different conformations. The value of j is believed to be approximately 8, so a relatively small polypeptide chain of 100 amino acid residues should be able to sample some 10^{89} different conformations. If the rate constant for an unfolded conformation to change is k_v, the average time to sample all of these conformations is given by

$$\tau = (Nk_v)^{-1} j^N \qquad (1)$$

Unfolded conformations cannot change more rapidly than 10^{13} times per second (and probably do so some 10^9 to 10^{10} times per second), so it would require, on average, more than 10^{66} years to sample 10^{89} conformations. Even if there were only two conformations possible per residue, there would still be 10^{30} conformations for $N = 100$, and 10^7 years would be required for random searching. Nevertheless, many proteins refold *in vitro* within seconds or minutes, some within a millisecond. Clearly, protein folding does not occur by a random searching of all possible conformations to find the unique native conformation, and there are likely to be pathways of folding.

A further complication is that unfolded proteins under denaturing conditions (eg, 8 *M* urea or 6 *M* **guanidinium chloride** (GdmCl)) approximate random coils, so that each of the 10^{15} to 10^{18} molecules in a typical experimental sample would be expected to have a different conformation at each instant (and a slightly different one some 10^{-10} seconds later). Therefore, each molecule is initiating folding from a different starting point.

1. Refolding of Small, Single-Domain Proteins

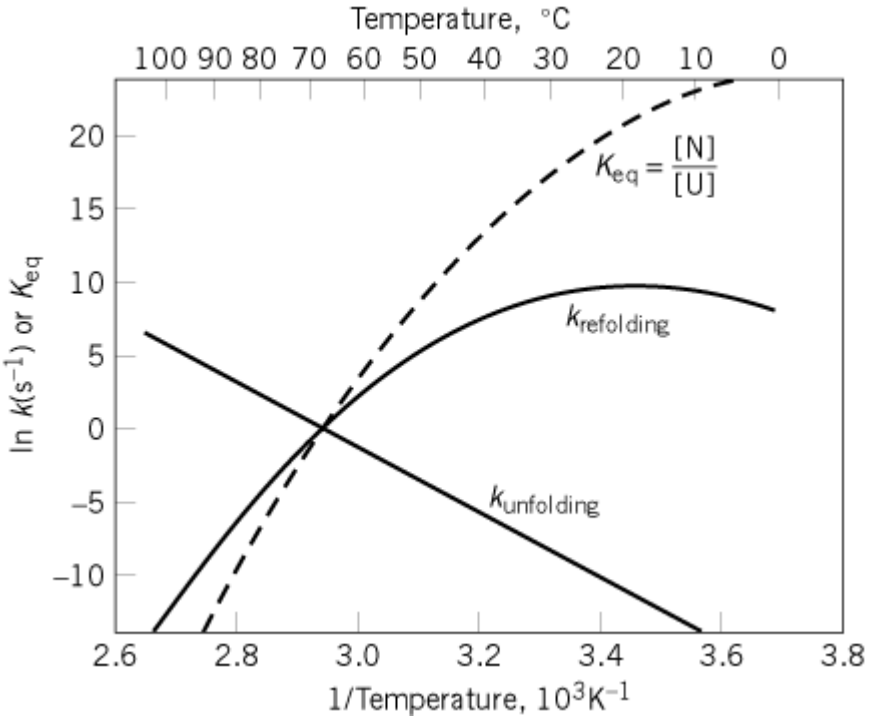
The native conformational states of proteins may often be unfolded reversibly by adding **denaturants**, increasing or decreasing the temperature, varying the pH, applying high pressures, or cleaving disulfide bonds (see Denaturation, Protein). At equilibrium, the unfolding transitions of single-domain proteins are usually two-state, and only the fully folded, native (N) and unfolded (U) states are populated. In this case, unfolding of the native conformation is cooperative, and partly folded molecules are unstable relative to the U or N states under all conditions. The most common

exception is the molten globule conformation, which predominates under intermediate denaturing conditions with some proteins.

Experimental *in vitro* studies of protein refolding kinetics generally start with the fully unfolded protein under unfolding conditions and, to initiate refolding, change the conditions abruptly to favor the folded state. Then changes in the conformational properties of the protein molecule population are monitored as a function of time. Studies of a number of small, model proteins have given the following general picture of how proteins fold (although there are always exceptions, and there is no generally accepted view of the protein folding mechanism.)

Generally, the fully folded state N begins to appear immediately without a detectable lag period and at a rate depending on both the identity of the protein and the refolding conditions. The rate is independent of the unfolding conditions used. The more physiological the refolding conditions, the greater the rate of folding (Fig. 1). Unfolding is observed by the reverse process of abruptly changing conditions from folding to those favoring unfolding, for example, by rapidly adding a denaturant or by changing the pH or temperature. The more denaturing the conditions, the more rapid the rate of unfolding.

Figure 1. Typical temperature dependence of the rates and equilibria of protein folding transitions not involving intrinsically slow isomerizations. The natural logarithms of the rate constants for unfolding and refolding are plotted as a function of (temperature)$^{-1}$ in an Arrhenius plot. A similar plot of the equilibrium constant K_{eq} between the folding (N) and unfolded (U) states is a van't Hoff plot. The curvature of the van't Hoff plot results from the greater apparent **heat capacity** of U than N. The linear Arrhenius plot for the rate of unfolding indicates that the folding transition state has the same heat capacity as N. The greater heat capacity of U is reflected entirely in the curvature of the Arrhenius plot for the rate of refolding because $\ln K_{eq} = \ln k_{refolding} - \ln k_{unfolding}$. The data used to construct this diagram are for hen egg-white lysozyme at pH 3 (2, 3), extrapolated to the absence of GdmCl. Although $k_{refolding} = k_{unfolding}$ at $K_{eq} = 1$, it is a coincidence that the rate constants also have the value $1 s^{-1}$ at this temperature, so that all three curves intersect at a common point.

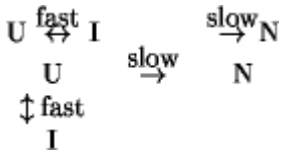


In both unfolding and refolding, all of the molecules have the same probability of undergoing the

transition, and a single rate constant is observed for the population, unless the molecules differ covalently or conformationally in a way that is only slowly interconverted. The most apparent instances of the latter are when there are both *cis* and *trans* isomers of peptide bond residues.(see Cis/Trans Isomerization). The *trans* form is intrinsically more stable, and the *cis* form is usually not present substantially, except when adjacent to proline residues. This *cis* form can occur in a folded protein, which usually has such a peptide bond *cis* in all of the molecules. In the unfolded state, however, there is an equilibrium mixture of both isomers. Consequently, some unfolded molecules have one or more incorrect isomers. Such isomerization is intrinsically slow, and the folding of these molecules is slowed or prevented by the incorrect isomer. The isomerization can be rate-limiting for their folding. The following discussion is limited to those small model proteins that show no such intrinsically slow process in folding.

The ratio of the rate constants for unfolding and refolding generally agrees with the equilibrium constant for the transition, so microscopic reversibility applies. There appears to be a classical transition state for the unfolding/refolding transition. That all of the many conformationally diverse molecules of a population of unfolded protein refold with the same rate constant, independent of how the protein was unfolded, indicates that all of the molecules must equilibrate rapidly and reversibly before undergoing the same **rate-limiting step**.

Upon transferring the unfolded protein to refolding conditions, some proteins adopt partly folded or molten globule conformations very rapidly, more rapidly than the native conformation appears. Such partly unfolded species are often considered responsible for the rapidity of folding, and much effort has gone into characterizing them. This is difficult because they are populated only transiently and are converted to N. These intermediate species, however, are usually in rapid equilibrium with the unfolded state, and it is generally not possible to distinguish between the two possible kinetic models, in which they are either on- or off-pathway intermediates I:



(2)

Many proteins do not adopt such partly folded species but remain unfolded until converting to N in an apparently all-or-nothing transition. These proteins also refold more rapidly than those that adopt partly folded conformations, although they are also the smaller proteins. Therefore, the presence of stable, partly folded intermediates is not necessary for rapid protein folding.

Such partly folded species are generally not detected as intermediates during unfolding, which is almost always an all-or-nothing transition, even with proteins that adopt partly folded intermediates in refolding. Some exceptions have, however, been reported (1).

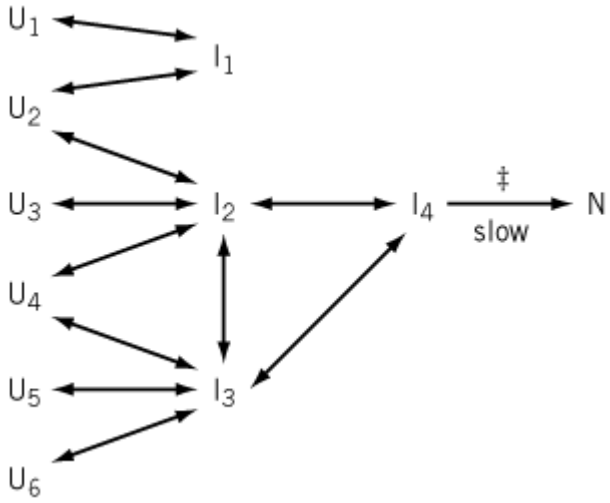
The transition state for the folding transition is characterized indirectly by measuring the rate of unfolding or refolding as a function of changing the conditions (Fig. 1) or by altering the covalent structure of the protein. Plots of the logarithm of the rate constant versus the denaturant concentration are generally closely linear, which suggests that the nature of the transition state and the pathway remains constant. The particular data of Figure 1 indicate that the transition state in that case has the same **heat capacity** as the native state but somewhat lower **enthalpy** (estimated by the slopes of the Arrhenius plots). Similar observations are found with other proteins, usually by varying the denaturant concentration rather than the temperature. Studies using protein engineering to alter the structure of the protein systematically indicate that many, if not all, of the stabilizing interactions of the native state have been disrupted in the transition state. The transition state is close to the final conformation structurally but lacks the cooperativity that gives net stability to the fully folded conformation.

Ligands that bind tightly to the native protein generally do not increase the refolding rate of small proteins. Instead, they usually decrease the unfolding rate, and this is why they increase the stability of the folded conformation. These observations indicate that the transition state does not bind the ligand tightly.

Folded proteins are often cleaved by proteinases at specific sites on their surfaces, and the folded conformation is maintained. Such cleaved proteins can be unfolded and dissociated into two or three polypeptide fragments. Very often these fragments recombine and regenerate the folded conformation.

The general kinetic scheme suggested by the experimental observations for folding a single protein domain is illustrated in Figure 2.

Figure 2. A general kinetic model for protein folding indicated by the experimental observations, in the absence of intrinsically slow conformational isomerizations. U_i are various unfolded molecules with different conformations at the start of folding, I_i are partially folded molecules, and N is the fully folded protein. All kinetic steps indicated by arrows are rapid, except for that labeled "slow." "‡" indicates the occurrence of the overall transition state. All steps are reversible, except for that indicated with a single-headed arrow, which occurs only in the indicated direction under conditions strongly favoring the folded state. As indicated, all of the unfolded molecules rapidly equilibrate under refolding conditions with a few partly folded species, which are also in rapid equilibrium. All of the molecules pass through a common slow step, which involves going through a transition state that is a distorted form of the native-like conformation. The intermediates I_i might be stable or unstable and therefore populated transiently or not, but all intermediates that occur after the rate-determining step are very unstable relative to N.



2. Kinetic Determination of Folding

If proteins cannot fold randomly and nonrandom folding pathways are crucial, the resulting folded state may not be the most stable conformation possible, but could be instead the form most kinetically accessible. If a kinetic pathway of folding is so vital, it should be possible to block folding by interfering with that pathway, and a protein might fold normally, solely for kinetic reasons, to a metastable state that is not the most stable thermodynamically. Examples are known, but only relatively few.

A number of bacterial proteinases, such as subtilisin and a-**lytic protease**, are synthesized as inactive precursors that have amino-terminal prosegments which are subsequently removed proteolytically to generate the active, native proteinase. These proproteinases unfold and refold *in vitro*, but the mature

forms do not refold. They refold only when the pro segment is added. The negligible rate of refolding of the mature protein, when the native protein is very stable, indicates a kinetic block to folding that is alleviated by the pro segment.

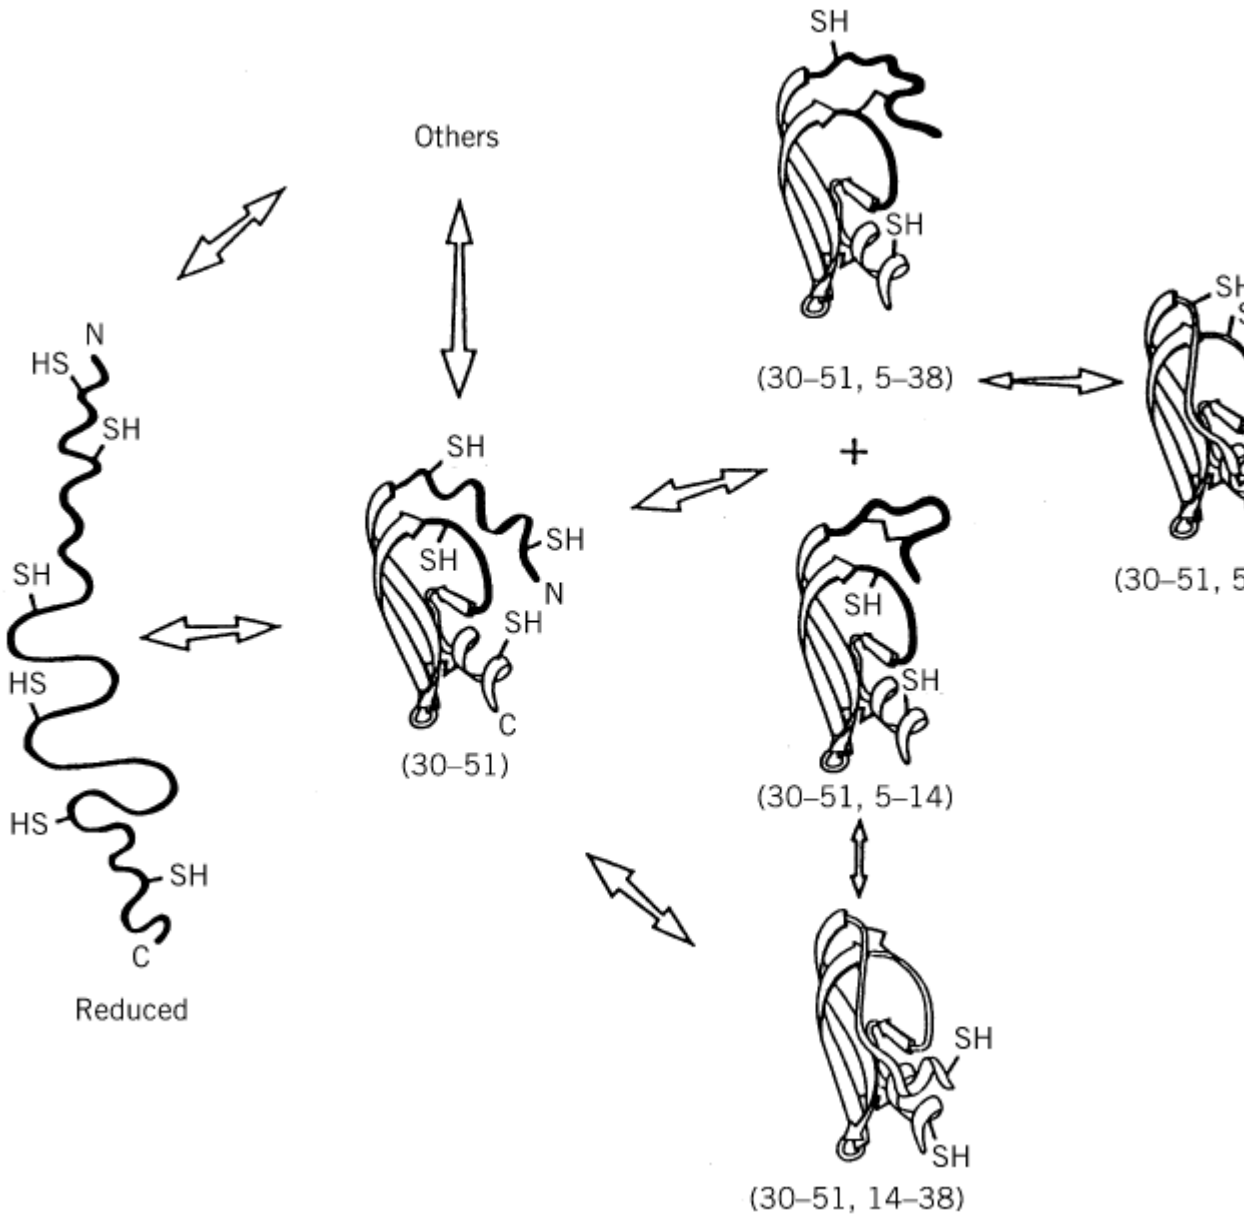
Within the serpin proteinase inhibitor family, plasminogen activator inhibitor –1 is synthesized in a form that is active as an inhibitor but relatively unstable. The active form slowly converts to a more stable form but is inactive as an inhibitor and known as the latent form. If this latent form is unfolded and then refolded, the active metastable form is regenerated before again undergoing the slow conversion to the inactive but stable form. Therefore, folding does not produce the most stable folded conformation directly but only through a metastable intermediate. The difference between the two forms involves a large change in a b**-sheet** of the protein.

2.1. Folding Coupled to Disulfide Formation

Many proteins that contain disulfide bonds between the thiol groups of **cysteine residues** become unfolded if these bonds are reduced, even in the absence of denaturants. The reduced protein remains unfolded even under physiological conditions. If the disulfides are permitted to form again, the protein can regenerate the native disulfide bonds and conformation. Then folding is coupled to disulfide formation. The great advantages of this are that disulfide bond formation and breakage can be controlled experimentally (using **thiol-disulfide exchange** with a disulfide reagent) and that any disulfide bonds in a protein can be trapped in a form that can be stable indefinitely. Cysteine residues can also be replaced or their thiol groups blocked irreversibly to decrease the number of disulfide possibilities, and the effect on the folding process can be used to dissect the pathway. Therefore, all the disulfide intermediates can be identified and characterized, and their roles in the folding process can be determined, usually unambiguously.

The best characterized disulfide folding pathway is that of BPTI (Fig. 3). Reduced BPTI is a very unfolded polypeptide chain, approximating a random coil, but with weak local interactions between residues close in the primary structure. Consequently, the initial formation of disulfide bonds is approximately random (after correcting for any differences in thiol group reactivity). The one-disulfide intermediates are not random, however, because that with the Cys30–Cys51 disulfide bond adopts a stable, partly folded conformation: this restricts which disulfide bonds can be formed subsequently. There is a kinetic block in forming either the 30–51 or 5–55 disulfide bonds, if the other is already present, which would generate the native-like (30–51,5–55) intermediate. Instead, this intermediate is normally formed most readily by intramolecular disulfide rearrangements of two intermediates with nonnative second disulfide bonds (Fig. 3).

Figure 3. The productive disulfide folding pathway of BPTI. R is the fully reduced protein. Intermediates are indicated b
paired. The major disulfide intermediates are depicted, and their conformations determined by NMR analysis are indicat
backbone are unfolded or very flexible. The relative rates of the intramolecular step in forming each disulfide bond are ir
appropriate arrowhead. The wider the arrowhead, the greater the rate in that direction. The brackets indicate that the one-
equilibrium. The "+" between two species indicates that they have the same kinetic roles. The nonproductive quasi-nativ



The disulfide pathways elucidated to varying extents with a few other small proteins show similar properties but have variations. Initial disulfide formation in the reduced protein is approximately random until a stable folded conformation is adopted, which can either favor or disfavor formation of further disulfide bonds. Some proteins, such as BPTI (Fig. 3), adopt partly folded conformations. Some, such as a-**lactalbumin**, adopt the molten globule conformation, and others remain unfolded until the entire folded conformation appears, such as **ribonuclease A**. In the absence of a folded conformation, further disulfide bonds are formed more slowly and are less stable. There is a kinetic block in forming a disulfide bond if that bond will become buried in a resulting stable folded conformation. Such kinetic blocks are caused by the high energy barrier that is most apparent in the reverse direction, upon reducing a buried disulfide bond. This kinetic barrier is usually overcome most readily in disulfide formation by intramolecular protein disulfide rearrangements in place of the intermolecular process of direct protein disulfide formation. The two processes involve, however, the same energy barrier and the same conformational transitions.

When the protein has all but one or two of the native disulfide bonds, it can adopt the stable native

conformation. For example, the very same native conformation is observed with BPTI in which any one of the three native disulfide bonds is missing. These quasi-native species indicate that disulfide bonds merely stabilize the native conformation and do not determine it. The stability of the quasi-native conformation varies, depending on which disulfide bond is missing. The quasi-native conformation inhibits formation of native disulfide bonds that will be buried but favors formation of those on the surface.

3. Multiple Domains

Large proteins are divided into **domains**, each of which is usually comparable to a small single-domain protein, although they vary in the extent to which the domains interact with and stabilize each other. When such interactions are not very great, a single domain excised from such a protein usually maintains the same conformation and refolds to it after being unfolded. The same principles are expected to apply to the folding of a single domain within a multidomain protein, and it is believed that multidomain proteins fold modularly by their individual domains folding and then associating. The final step, in which the domains interact, is often rate-limiting. Very often, the isolated domain folds more rapidly than when in the intact protein, suggesting that the unfolded domains interact and interfere with each other during folding.

The folded domains and subunits present during refolding of these complex proteins often recognize and bind their specific ligands. Consequently, the presence of such a ligand in this instance increases the rate of refolding and assembly.

Multidomain proteins are also appear to be especially susceptible to aggregation during refolding. This is thought to be caused by specific complementary interactions between the domains of different molecules, similar to those that should occur between the domains of the same polypeptide chain.

3.1. Multiple Subunits

Proteins with quaternary structure, consisting of multiple polypeptide chains, are often dissociated and unfolded under denaturing conditions. Upon transfer to folding conditions, they can refold and reassemble to regenerate the original tertiary and quaternary structures. The folding of the individual domains and their reassembly is often observed as separate transitions. Assembly can be followed by covalent **cross-linking** at different times. Whether folding or assembly is rate-limiting depends on the protein concentration, because assembly is more rapid at higher protein concentrations. Kinetic results with a number of proteins are consistent with individual subunits folding and then reassembling, but the assembly process also involves some changes in the tertiary structure of the individual subunits. The large size and complexity of multisubunit proteins makes it difficult to elucidate the details. It is usually further complicated by the tendency of the protein to aggregate during refolding, especially at high protein concentrations. The interactions responsible for the aggregation are specific, because other proteins do not usually have an effect, unless very closely related.

In some dimeric proteins, the two polypeptide chains are highly entwined in their native conformations, and it is impossible for the same conformation to be stable with a single chain in the absence of the other subunit. Nevertheless, such proteins refold and reassemble. This process is probably similar to that in which proteolytic fragments of a single polypeptide chain reassociate and refold (see previous discussion). The two processes of folding and assembly must be coordinated and occur in a single, concerted step.

3.2. Differences with Folding *in Vivo*

Protein folding ***in vivo***, during or after biosynthesis of the polypeptide chain, differs most fundamentally from refolding *in vitro* in that domains can fold sequentially as the polypeptide chain is synthesized. It also involves the concerted action of **chaperones** and catalysts of *cis-trans* isomerization (eg, cyclophilin) and disulfide bond formation, breakage, and rearrangement (eg,

protein disulfide isomerase).

Protein Folding *In Vivo*

Protein folding is the process by which the linear information contained in the amino acid sequence of a polypeptide chain gives rise to the unique three-dimensional conformation of the functional protein structure. How folding is achieved with high efficiency constitutes one of the basic problems in biology. The discovery that unfolded polypeptides can refold spontaneously *in vitro* (1) (see Protein Folding In Vitro) suggested that the folding (acquisition of tertiary structure) and assembly (formation of quaternary structure) of newly-synthesized polypeptides *in vivo* also occur spontaneously, without the involvement of further components. It is now clear, however, that in many cases efficient folding in the cell depends on a machinery of preexisting proteins, the **molecular chaperones**, whose primary task, often in an energy-dependent manner, is to prevent protein misfolding and aggregation (2, 3). Thus *in vivo* the principle of self-assembly of proteins is replaced by a process of assisted self-assembly. Another important difference between protein folding *in vitro* and *in vivo* relates to the fact that in the cell folding occurs in the context of translation during **protein biosynthesis**. As a result, folding can initiate cotranslationally, and this mechanism is important for the successful folding of large modular polypeptides with multiple **domains**.

1. Protein Aggregation

Many proteins refold via compact globular intermediates that contain varying amounts of **secondary structure** but lack the stable tertiary structure that defines the native state (see Molten Globule). These intermediates expose to solvent some **hydrophobic** amino acid residues (which mostly will be buried upon correct folding) and via these residues tend to associate with one another to form aggregates. Aggregate formation is usually an irreversible off-pathway step. *In vitro*, the extent of aggregation can often be controlled by lowering the protein concentration and the temperature of the refolding mixture and by adjusting other physical parameters of the reaction, such as pH and ionic strength. In contrast, cellular conditions dictate that, without the intervention of molecular chaperones, aggregation would outcompete correct folding, at least for a significant fraction of newly synthesized polypeptides. The concentration of unfolded polypeptides emerging from ribosomes (ie, “nascent” polypeptide chains) in the cytosol is very high; it reaches ~35 μM (~1mg/ml for a 30-kDa chain) in *Escherichia coli*, assuming a uniform distribution of ribosomes. The local concentration of nascent chains is significantly greater, however, because of macromolecular crowding (see Excluded Volume) and because translating ribosomes are organized in

polyribosomes. *Macromolecular crowding* refers to the fact that a large fraction of the cellular volume is occupied by proteins and other **macromolecules** at a total concentration of ~300 g/L and is therefore not available to other macromolecules (4, 5). Crowding is predicted to result in an increase by several orders of magnitude in **association constants** for unfolded polypeptides over those in dilute solution.

The risk of newly synthesized polypeptides aggregating is enhanced by the inability of nascent chains to fold into stable tertiary structures, at least during the early phase of translation. Stable folding requires the presence of a complete protein domain (usually ~100–300 amino acid residues in length) that can fold independently (see Protein Structure). As the *C*-terminal ~30 amino acid residues of a translating polypeptide are tethered to the ribosome, and are thus topologically restricted, nascent chains remain unfolded until an entire domain has emerged from the ribosome. Aggregation of these nascent chains is thought to be prevented by the co-translational binding of molecular chaperones, including members of the **heat-shock** proteins 70 (Hsp70) and Hsp40 (DnaJ) families (3).

2. Molecular Chaperones

Molecular chaperones were originally defined as proteins that mediate the correct assembly of other proteins, but are not themselves components of the final functional structures (2). Chaperones occur ubiquitously, and many of them are classified as **stress response** proteins, although their functions are essential under normal growth conditions (3, 6-9). Most chaperones function by stabilizing an otherwise unstable conformer of another protein—and by controlled binding and release, may facilitate its correct fate *in vivo*, whether this is folding, oligomeric assembly, transport to a particular subcellular compartment, or disposal by degradation (9). Molecular chaperones do not contribute steric information for correct folding, but rather prevent incorrect interactions between (and perhaps also within) nonnative polypeptides, thus typically increasing the yield, but not the rate, of folding reactions. These properties distinguish the chaperones from so-called folding catalysts, protein disulfide isomerases, and peptidylprolyl ***cis–trans*** **isomerases**, which accelerate intrinsically slow steps in the folding of some proteins, namely, the rearrangement of disulfide bonds in secretory proteins (see Protein Secretion) and the *cis–trans* isomerization of peptide bonds preceding proline residues, respectively (10, 11).

Molecular chaperones fall into several structurally unrelated families of proteins, including the members of the Hsp70, Hsp40 (DnaJ), and Hsp90 families, as well as the **chaperonins** (Hsp60) and the so-called small heat-shock proteins. Most of these proteins are soluble, but **membrane**-bound chaperones, such as **calnexin** in the endoplasmic reticulum (ER), exist as well. A table summarizing the main classes of molecular chaperones is found in the entry **Molecular chaperone**. Chaperones may be expressed constitutively or on exposure of cells to stresses, such as high temperature. Those chaperones with a broad spectrum of protein substrates generally suppress protein aggregation by recognizing hydrophobic amino acid residues or accessible surfaces that are exposed by unfolded proteins or incompletely folded polypeptide chains. The need for an increase in cellular chaperone capacity at elevated growth temperatures (or upon exposure of cells to other stresses) is explained by the tendency of preexisting proteins to unfold under these conditions. Proper folding is usually achieved by the controlled dissociation of the complexes between unfolded polypeptides and chaperones, which often occurs in an ATP- and cofactor-dependent mechanism.

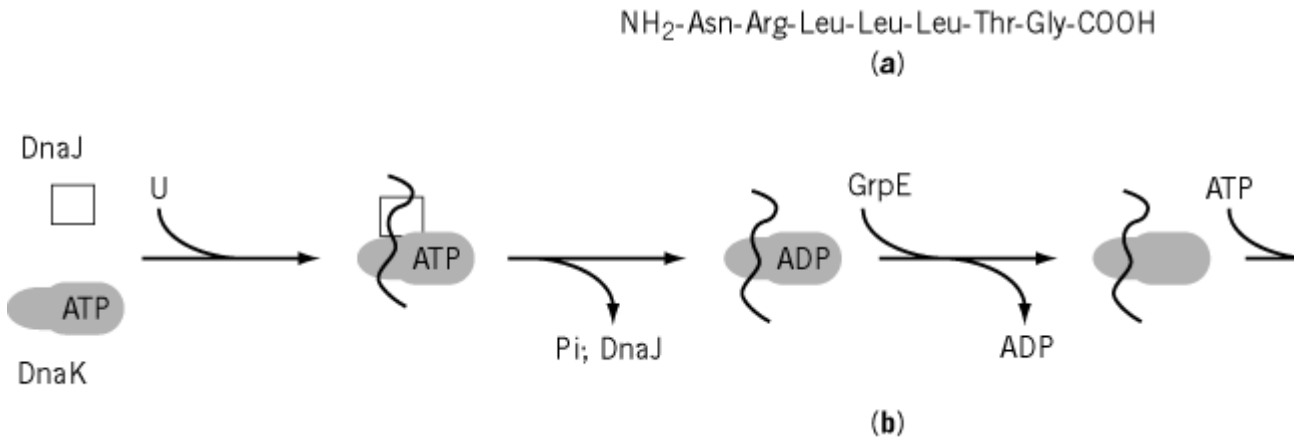
Of the chaperones with a well-documented role in assisting the folding of newly synthesized polypeptides (*de novo* folding), the members of the Hsp70 and chaperonin classes have been studied most extensively. They represent two basic paradigms of ATP-dependent chaperone action.

3. Hsp70s

The Hsp70s are a family of highly conserved **ATPases** of relative molecular mass ~70,000 found in **prokaryotes** (see DnaK/DnaJ Proteins) as well as in eukaryotes, where they occur in the **cytosol**,

mitochondria, **chloroplasts**, and the ER (12) (see BiP (Hsp70)). Protection of nascent chains from aggregation is thought to be the main role of Hsp70 in de novo protein folding (13-15). In addition, Hsp70s have other important functions in protein metabolism under both stress- and nonstress conditions, including functions in membrane translocation of proteins and the degradation of misfolded proteins. This versatility of the Hsp70s results from their basic function, which is to bind and release hydrophobic peptide segments that are generally exposed in unfolded polypeptides. These peptide segments are on average seven amino acid residues in length and must be enriched in hydrophobic amino acids, such as leucine (Fig. 1a) (16-18). These segments are bound in an extended conformation within a binding cleft of the ~18 – kDa *C*-terminal domain of Hsp70, whose high resolution X-ray crystallography structure is known (19). Peptide binding and release by the *C*-terminal domain is regulated via ATP-dependent conformational changes in an *N*-terminal ATPase domain of ~45 kDa, which has the three-dimensional structure of actin (20). Peptide binds to the ATP-state of Hsp70 in which the peptide binding cleft in the *C*-terminal domain is open (Fig. 1b). In the ADP state, the peptide cleft is closed, preventing the peptide from dissociating. Efficient peptide binding depends on essential cofactors of the Hsp40 (DnaJ) family. *E. coli* DnaJ and several of its eukaryotic homologues are chaperones in their own right, as well as activators of the Hsp70 ATPase (21-23). DnaJ can present an unfolded polypeptide to ATP-bound Hsp70 (DnaK in *E. coli*). DnaJ-catalyzed hydrolysis of ATP results in stable peptide binding. In *E. coli* (and in mitochondria) an additional cofactor, GrpE, catalyzes the exchange of Hsp70-bound ADP for ATP and thereby facilitates polypeptide release (21, 24). It is noteworthy that the Hsp70 reaction cycle resembles the regulation of certain GTP-binding proteins (3, 23) (Fig. 1b).

Figure 1. The Hsp70 chaperone system. (**a**) Example of a peptide with high affinity for Hsp70. This peptide was cocryst peptide binding domain of DnaK (19). Peptide segments with similar properties occur on average at a distance of 50–10(Mechanism of the *E. coli* Hsp70 system DnaK (Hsp70), DnaJ, and GrpE. Note that *E. coli* DnaJ binds to the unfolded pc chaperones, but this may not be the case for other Hsp40 homologs, such as mammalian Hsp40. Whenever U is released, provided all structural elements necessary for folding are available (eg, on release of a nascent chain from the ribosome). of interaction with the Hsp70 system.



Hsp70 functions essentially as a buffer for unfolded and incompletely folded polypeptides, thus reducing the concentration of aggregation-sensitive folding intermediates. The net result of Hsp70 action is the binding and release of the polypeptide chain in an unfolded conformation. On release, the unfolded polypeptide may fold spontaneously to the native state, provided all structural elements necessary for folding are available, or it may be transferred to another chaperone (see text below) or rebind to Hsp70. On the basis of these properties, the Hsp70 chaperone system is ideally suited to protect nascent polypeptide chains against aggregation and to assist in their folding. As long as a polypeptide chain (or a domain) is not yet completely synthesized, release of nascent polypeptide from Hsp70 will not result in folding but in rebinding to Hsp70 as the chain continues to expose

hydrophobic residues (see Fig. 1). Indeed, a large fraction of nascent polypeptide chains interact with Hsp70 *in vivo* (15), but whether this interaction is generally required for folding remains to be demonstrated.

4. Chaperonins

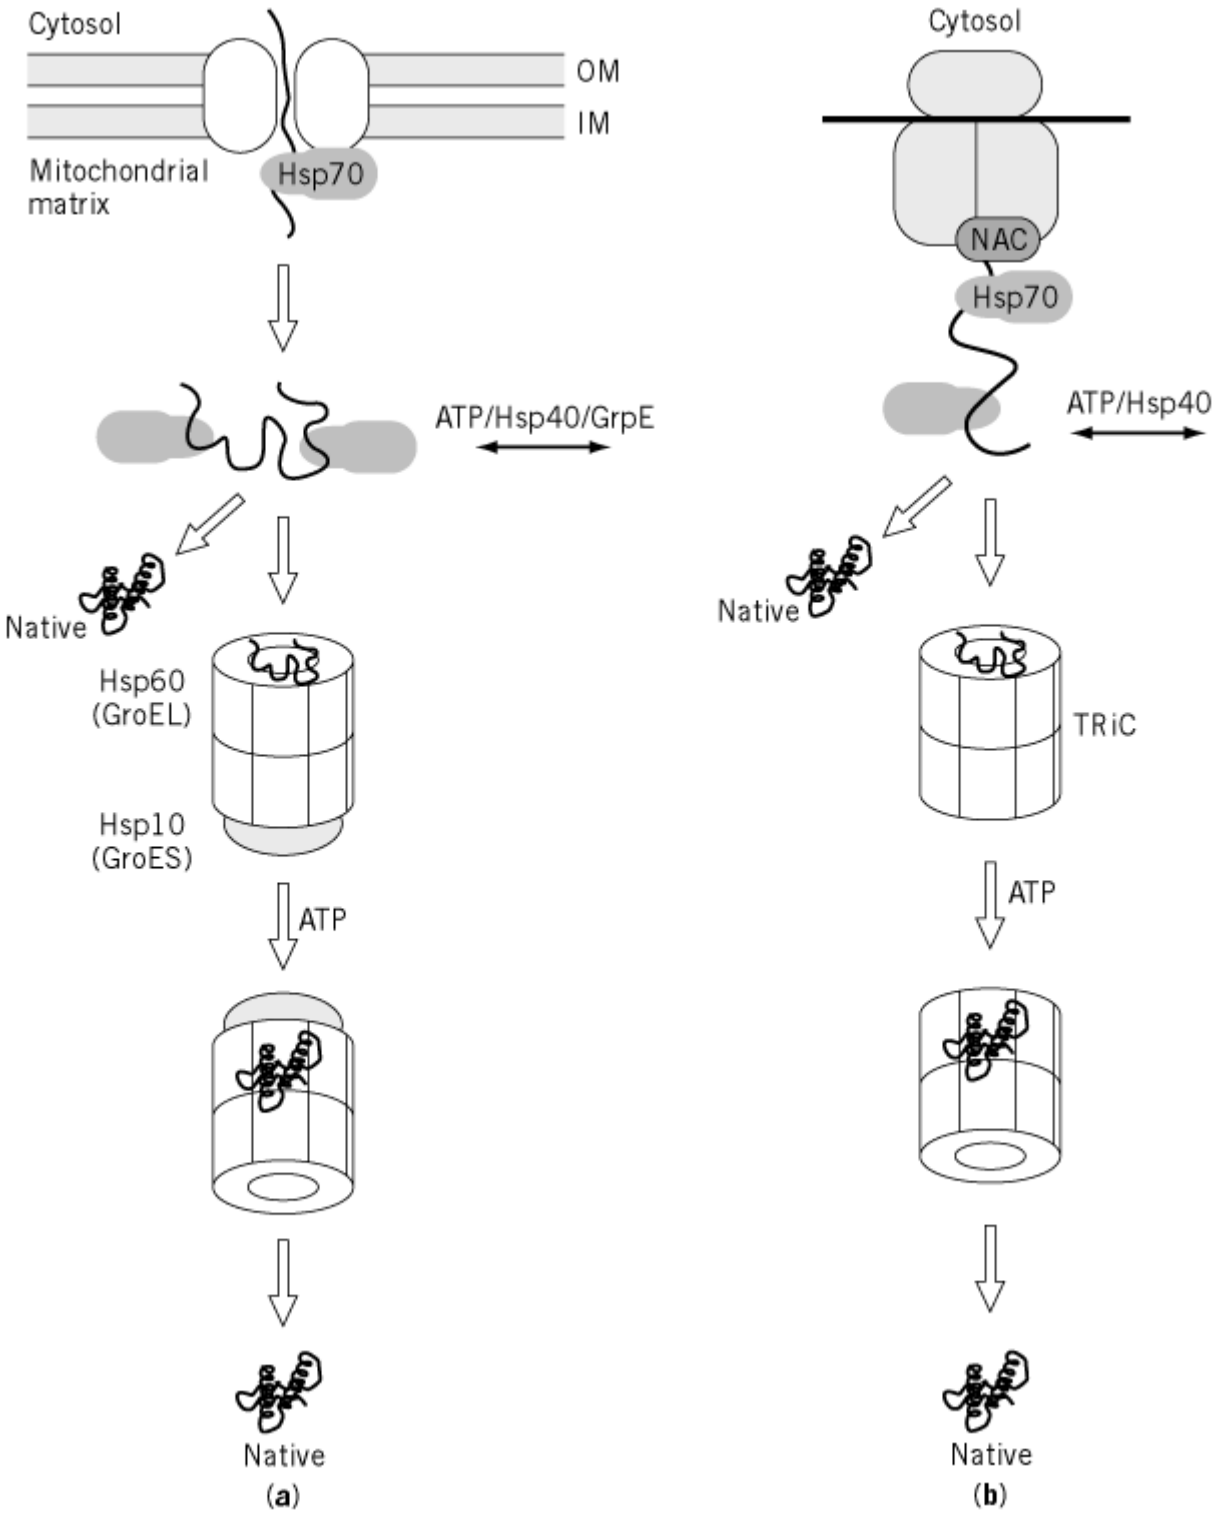
In contrast to the Hsp70s, the chaperonins (also classified as Hsp60s) are large cylindrical protein complexes consisting of two rings of ~60 – kDa subunits that are stacked back to back. In the case of eubacterial chaperonins, such as GroEL of *E. coli*, there are seven identical subunits per ring, whereas the chaperonins of **archaebacteria** and the eukaryotic cytosol are heterooligomeric and may contain up to eight different subunits (3, 25). The salient structural feature of these ~800 – kDa complexes is a central cavity in which a single polypeptide molecule can fold and avoid aggregation with other unfolded polypeptides. Unfolded polypeptide chain binds to hydrophobic patches at the inner wall of the chaperonin cavity. In the case of GroEL, binding of the ring-shaped cofactor GroES to the opening of the GroEL cylinder then displaces the polypeptide from these binding sites into an enclosed folding cage (26-29). The ATPase activity of the chaperonin regulates the closing and opening of the cage. Binding to chaperonin may also unfold polypeptides that have been kinetically trapped in misfolded states, thereby giving them another chance to fold upon release into the cavity. (See also Chaperonin.)

Chaperonins are essential for cell viability under all growth conditions (30-32), because they are required for the folding of a subset of newly synthesized polypeptides. In *E. coli*, GroEL interacts with approximately 15% of total newly synthesized cytosolic proteins at growth temperatures of 30–37°C, and with up to 30% or more under heat stress at 42°C (33). In addition to chaperonin-dependent proteins that interact more or less quantitatively with GroEL, other proteins transit GroEL with only a few percent of the total population of molecules. These latter proteins do not depend on GroEL for folding, at least under nonstress conditions. GroEL acts predominantly post-translationally, and most of its substrates fall into the size range of 10 to 55 kDa, the upper size limit of the folding cage (33). According to *in vitro* studies, GroEL-dependent proteins have relatively slow folding rates and therefore are highly aggregation-sensitive. When expressed in cells containing insufficient or dysfunctional chaperonin, these proteins aggregate or are degraded proteolytically. The mechanisms of folding for polypeptides larger than ~55 kDa will be discussed below.

5. Chaperone Pathways in Folding

The Hsp70 and chaperonin systems can act sequentially. This sequential action has been demonstrated for protein folding in the cytosolic compartment and in mitochondria and chloroplasts (3). Considering the origin of mitochondria from endosymbiotic bacteria, the matrix of mitochondria—specifically, the space surrounded by the inner mitochondrial membrane—is evolutionarily related to the bacterial cytosol. This compartment contains homologues of all the major bacterial chaperones, DnaK (Hsp70), DnaJ, GrpE, GroEL, and GroES. Although mitochondria still synthesize a small number of proteins in the matrix, most mitochondrial proteins are imported from the cytosol (34). A prerequisite for effective membrane translocation is that these polypeptides be maintained in an unfolded state by cytosolic chaperones (see Translocation). On import, they interact first with mitochondrial Hsp70 that is bound to the inner surface of the inner membrane and then with soluble Hsp70 in the matrix (Fig. 2a). Membrane-bound Hsp70 participates actively in the translocation process itself, whereas soluble Hsp70 assists in folding. A subset of imported proteins has to be transferred from Hsp70 to the mitochondrial GroEL homologue, Hsp60, for successful folding (35, 36). *In vitro* reconstitution experiments using the *E. coli* chaperones established the mechanistic significance of this chaperone relay (22). The Hsp70 system prevents aggregation of unfolded polypeptides, preserving their folding competence, whereas the chaperonin mediates folding to the native state. This pathway is not necessarily unidirectional; polypeptides that cannot fold on the chaperonin may be transferred back to Hsp70 and may eventually be degraded (3).

Figure 2. Sequential action of the Hsp70 and chaperonin systems in folding. (**a**) Protein folding in mitochondria. OM and IM, outer and inner mitochondrial membranes, respectively. Hsp60, mitochondrial GroEL; Hsp10, mitochondrial GroES. Mitochondrial Hsp70 interacts first with the incoming polypeptide because of its ability to recognize extended peptide motifs and its specific association with the translocation machinery of the inner mitochondrial membrane. Release of newly translocated polypeptide from Hsp70 is dependent on ATP and the action of mitochondrial Hsp40 (DnaJ) and GrpE (see Fig. 1). The Hsp70 and Hsp60 (chaperonin) systems are functionally distinct in that only Hsp60 can release the substrate protein in a fully folded state. Small, rapidly folding proteins will either not interact with Hsp60 or will do so only with low efficiency. (**b**) Folding of newly synthesized polypeptides in the eukaryotic cytosol. TRiC, the cytosolic chaperonin. Cytosolic Hsp70 interacts with the nascent polypeptide because of its ability to recognize extended peptide motifs. Binding of NAC very close to the peptidyl-transferase center may precede that of Hsp70 for most cytosolic proteins. Release of newly translated polypeptide from Hsp70 is dependent on ATP and the action of Hsp40 (DnaJ). This step is probably GrpE-independent in eukaryotes. Most proteins fold upon release from Hsp70, but a subset of proteins needs assistance by the chaperonin for folding. Although folding of these proteins occurs in the central cavity of TRiC (as in the case of GroEL), TRiC is independent of a GroES cofactor. The function of GroES to form a lid on the opening of the chaperonin cylinder appears to be integrated into the structure of the TRiC subunits (50).



There is increasing evidence from *in vivo* studies that the Hsp70/chaperonin pathway plays an important role in the prokaryotic and eukaryotic cytosol, both for the folding of newly synthesized polypeptides and during the refolding of stress-denatured polypeptides (3, 37-41). Hsp70 interacts with a wide array of nascent chains in eukaryotes (15). While the majority of proteins probably do not have to transit further chaperones to complete folding, a subset of proteins, presumably those that fold slowly, must be transferred from Hsp70 to chaperonin to reach their native state (39, 40) (Fig. 2b). The major substrate proteins in eukaryotes that follow such a pathway are the cytoskeletal proteins actin and tubulin, which are critically dependent on the cytosolic chaperonin (CCT, or

TRiC) for folding (32, 40, 42, 43). The situation is similar in bacteria in that only a fraction of all newly formed polypeptide chains bind to chaperonin (33). For example, folding of certain bacterial forms of **ribulose bisphosphate carboxylase** expressed in *E. coli* requires interaction with DnaK (Hsp70) and with GroEL, whereby the two systems must act sequentially and not in parallel (41).

Although the basic mechanistic principles of chaperone action are now well understood, the complexity of chaperone-assisted folding pathways *in vivo* is only beginning to be appreciated. For example, in *E. coli* cytosol a significant fraction of nascent chains interact with trigger factor, a 48-kDa chaperone that has an affinity for ribosomes and possesses both chaperone and peptidylprolyl *cis–trans* isomerase activities (44). In eukaryotes many nascent chains interact first with nascent-chain-associated complex (NAC) before they form a complex with Hsp70 (45) (Fig. 2b). NAC is a heterodimer of 33-kDa and 21-kDa subunits. NAC binds also to ribosomes and prevents their association with the membrane of the endoplasmic reticulum, except when a secretory precursor polypeptide is synthesized. For cytosolic proteins, NAC binding may help to recruit Hsp70.

A multiplicity of chaperone components cooperate in mediating proper folding, disulfide bond formation, and **glycosylation** of secretory proteins in the lumen of the endoplasmic reticulum (ER) (see Protein Secretion). Correct folding and assembly is a prerequisite for the packaging of proteins into **vesicles** that travel from the ER via the Golgi apparatus to the cell surface, and the ER lumen is effectively a highly concentrated solution of chaperones and protein folding catalysts. These include, among others, the Hsp70 homologue **BiP**, various Hsp40s, the Hsp90 homologue Grp94, protein disulfide isomerase, **calnexin**, and **calreticulin**. The latter two chaperones recognize certain carbohydrate modifications that are typical of incompletely folded polypeptides and retain these polypeptides in the ER until folding is completed (46). It is noteworthy that the ER does not contain a chaperonin homologue.

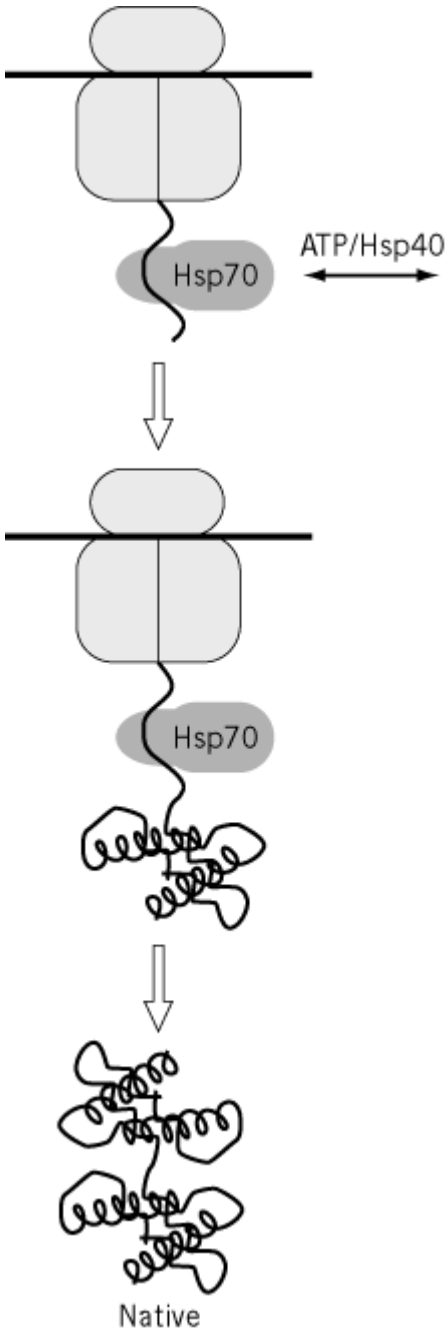
6. Cotranslational Folding of Multidomain Proteins

Analysis of the size distribution of proteins in several completely sequenced genomes indicates that eukaryotes have a proportionally larger number of modular polypeptides consisting of multiple protein domains, than do bacteria (47, 48). For example, in the yeast *Saccharomyces cerevisiae* the average protein has a length of 496 amino acids (~55 kDa), and ~38% of all yeast proteins are larger than 55 kDa, including ~1450 soluble proteins (48). In contrast, the average length of an *E. coli* protein is only 317 residues (~35 kDa), and only 13% of all *E. coli* proteins exceed 55 kDa, the size cutoff of the GroEL/GroES folding cage. The size distribution of protein domains (the "folding units") is uniform across all three kingdoms of life (bacteria, archaea, eukarya) in the range of 100–300 residues. Thus a genome encoding proportionally longer polypeptides must encode more and/or longer multidomain polypeptides. Since these proteins frequently do not refold efficiently *in vitro*, it would be expected that their folding *in vivo* is particularly chaperonin-dependent. However, the volume capacity of the central cavity of the eukaryotic cytosolic chaperonin, TRiC, is probably not much greater than that of GroEL. Moreover, TRiC is of low abundance in many eukaryotic cells and is thought to interact with only a restricted subset of polypeptides (see text above). Neither do other abundant chaperone proteins, including the Hsp90 system (49), play a general role in de novo protein folding. How do large modular polypeptides manage to fold efficiently *in vivo*?

In modular polypeptides, domains are often joined by flexible linker segments. Such proteins are able to fold cotranslationally as their domains emerge sequentially from the ribosome (3, 47). This mechanism allows a high efficiency of folding by reducing unproductive intramolecular interactions between concurrently folding domains. Such interactions may occur during the collapse of the unfolded chain into a disorganized globule and may explain the tendency of multidomain proteins to misfold *in vitro* (see Protein Folding In Vitro). Mechanistically, cotranslational folding reduces the problem of folding a large polypeptide to the folding of its independent modules or domains, those structural units most able to fold spontaneously. Sequential domain folding probably relies predominantly on the protection of nascent chains by Hsp70 until a complete domain has been synthesized and emerged from the ribosome (Fig. 3). ATP-dependent release of Hsp70 may then

allow domain folding. The ATPase activity of Hsp70 in the eukaryotic cytosol (~1ATP hydrolyzed per molecule per minute) seems to be adjusted to the speed of translation (about two to three amino acids per second) such that Hsp70 would bind and release the nascent chain once during the synthesis of a polypeptide domain of average length. Transfer from Hsp70 to the chaperonin may be necessary only for proteins that are unable to fold into stable structures during translation. This transfer is the case for some multidomain proteins in which the domains are constructed of discontinuous sequence segments of the polypeptide chain. Here a continuous chain forms part of a domain, then leaves the compact region to form part or all of another domain, after which it returns to complete the previous domain. Actin, one of the main substrate proteins of the eukaryotic cytosolic chaperonin, is composed of discontinuous domains and forms stable tertiary structure only post-translationally. Similarly, proteins whose domains are structurally unstable in isolation (and are ultimately stabilized by interactions with other domains or subunits) may also require sequestration in the chaperonin folding cage for post-translational folding. Thus a combination of chaperonin-independent (cotranslational) and chaperonin-dependent (post-translational) mechanisms is operative in the eukaryotic cytosol (48).

Figure 3. Protein folding pathways in the eukaryotic cytosol. Model for the cotranslational folding of a multidomain protein in the eukaryotic cytosol. Folding is assisted by the Hsp70 system independently of the chaperonin. Folding of a completed domain occurs as Hsp70 dissociates from the nascent chain in an ATP-dependent manner.



Evidence has been presented that the bacterial translation–folding machinery has a reduced capacity to support the cotranslational and sequential folding of multidomain proteins, when domain folding is slow compared to the rapid speed of bacterial translation (15–20 amino acids per second) (47). It has been proposed that bacterial proteins are generally selected for efficient post-translational folding. Inefficiency of cotranslational folding in bacteria would help to explain not only why many eukaryotic multidomain proteins misfold upon bacterial expression, but also perhaps why the bacterial protein complement is structurally less complex than that of eukaryotic cells. Modular polypeptides are believed to have evolved by random gene fusion events. Thus, if cotranslational folding in bacteria were even partially constrained, the evolution of multidomain proteins by domain shuffling would be less frequent than in organisms more generally able to support sequential domain folding. Future research will have to explore to what extent differences in folding mechanism between bacterial and eukaryotic cells may be responsible for the explosive evolution of modular polypeptides in eukaryotes.

Protein Kinase A (Cyclic Amp-Dependent Protein Kinase)

The effects of cyclic AMP (cAMP) as a second messenger are mediated by the activation of cAMP-dependent protein kinase, also known as protein kinase A (PKA). PKA exists as a tetramer, with two catalytic (C) subunits, and two regulatory (R) subunits. The binding of cAMP to the R subunits results in their dissociation from C, releasing the catalytic subunit from the inhibitory effect of R, and activating it for phosphorylation of acceptor proteins. Because the binding of cAMP to R is **cooperative**, small changes in cAMP levels can produce a large increase in protein phosphorylation in cells (1).

The physiological substrates for PKA are many and varied. This enzyme participates in the regulation of secretion, metabolism, transcription, and almost every regulatory process known in signal transduction. The importance of PKA as a physiological effector has been studied pharmacologically, with peptide and organic inhibitors. There have also been a number of transgenic mice made lacking **alleles** containing different components of the PKA family of proteins.

Protein Kinase C

Hormone-stimulated hydrolysis of phospholipids by phospholipases gives rise to two potential second messengers, calcium and diacylglycerol. Both of these molecules are directed to the activation of another family of protein kinases, protein kinase C (PKC). PKC is a family of enzymes, presently known to comprise up to nine members, with different patterns of expression and sensitivity to phospholipids, diacylglycerol, and calcium. In resting cells, these enzymes are largely cytoplasmic, but they translocate to the plasma membrane upon the generation of diacylglycerol by phospholipase C.

PKC is a multidomain protein. The family members contain a conserved catalytic domain, along with additional calcium-, phospholipid-, and substrate-binding sites that vary considerably. In general, PKC a and g are completely dependent on calcium, while b is less calcium-sensitive. Other forms of the enzyme are calcium-insensitive (1).

The activation of PKC in different cells results in a large number of biological effects. PKC can **phosphorylate** a variety of substrates, regulating processes in metabolism, differentiation, and growth. Its substrates include transcription factors, other enzymes, receptors, and **ion channels**, to name a few. Moreover, PKC is involved in several examples of cross-talk and feedback regulation in signal transduction (1).

Protein Motif

A protein motif, sometimes referred to as a supersecondary structure, is the term used to describe certain common combinations of **secondary structure** elements that are observed frequently in protein structures. Protein motifs provide a useful way of categorizing distinctive and recurring components of protein structure. In the hierarchy of protein structure classification, the protein motif falls between that of secondary structure and tertiary structure. Classification of these preferred patterns of packing secondary structure elements is somewhat arbitrary, and there is sometimes overlap between the structural terms of protein motifs and protein **domains**. However, unlike domains, protein motifs do not necessarily fold independently of the rest of the polypeptide chain, and they may not always have an intrinsic function.

Proteins having structurally similar motifs can share significant sequence identity in the equivalent regions of the polypeptide chain, even if there is very low sequence identity overall. The identification of regions of conserved sequence within proteins means that novel protein motifs can be predicted using sequence information only, in the absence of any three-dimensional structural data. The Kringle domain is an example of such a sequence motif, in that it is easily identified from

protein sequences based on three characteristic disulfide bonds. Other protein motifs are purely structural and have little or no sequence conservation; examples include the **b-meander**, the **Greek key**, and the **jelly roll**.

Protein Secretion

Most of the proteins made by a cell are retained intracellularly; only a specialized subset is secreted outside the cell. Proteins secreted by cells have several major functions, including signaling to other cells, formation of an insoluble extracellular matrix surrounding the cell, and degradation of extracellular material. Molecular biology has helped explain how newly synthesized proteins are selected for secretion and transportation across the **hydrophobic** barrier of the plasma membrane (see **Protein biosynthesis**).

The mechanism for transporting newly synthesized proteins is highly conserved from bacteria to mammals. A key difference, however, is that bacteria translocate the proteins directly across the plasma membrane to the outside world, whereas eukaryotic cells translocate them into a specialized intracellular organelle, the endoplasmic reticulum. Newly synthesized proteins are conveyed from the endoplasmic reticulum to the cell surface via a series of carrier **vesicles**. It is therefore useful to consider prokaryotic and eukaryotic protein secretion separately.

1. Protein Export from Bacteria

Bacteria are extremely simple from a cell biological point of view. **Gram-positive** bacteria have only a single membrane, the plasma membrane, separating their cytoplasm from the outside world. Gram-negative bacteria have a second outer membrane, separated from the inner membrane by periplasmic space. In this case, the newly synthesized protein that is to be exported must cross the outer membrane in addition to the inner plasma membrane.

The basic elements of translocation across the membrane appear to be universal (1). A small pore or hole through which unfolded proteins can pass traverses the membrane. Energy is used to push unfolded protein through the hole. **Molecular chaperone** proteins exist on the cytoplasmic side of the pore to maintain a protein in an unfolded state, which allows it to be threaded through the pore. The chaperones distinguish proteins that are to be exported from cytoplasmic proteins because the exported proteins have **signal sequences**, regions of contiguous amino acids that are usually at the amino terminus of the protein. Once the protein has crossed the membrane, additional chaperones can facilitate correct **protein folding**.

Much of the research on protein export by bacteria has utilized *Escherichia coli*, a gram-negative bacterium. In *E. coli* there are at least two different ATP-driven transport systems, one that uses the

*sec*A system (see Sec Mutants/Proteins) to pump proteins into the periplasmic space (2), and a second that uses a member of the ABC (ATP-binding cassette) family of proteins to export proteins across both *E. coli* membranes simultaneously (3).

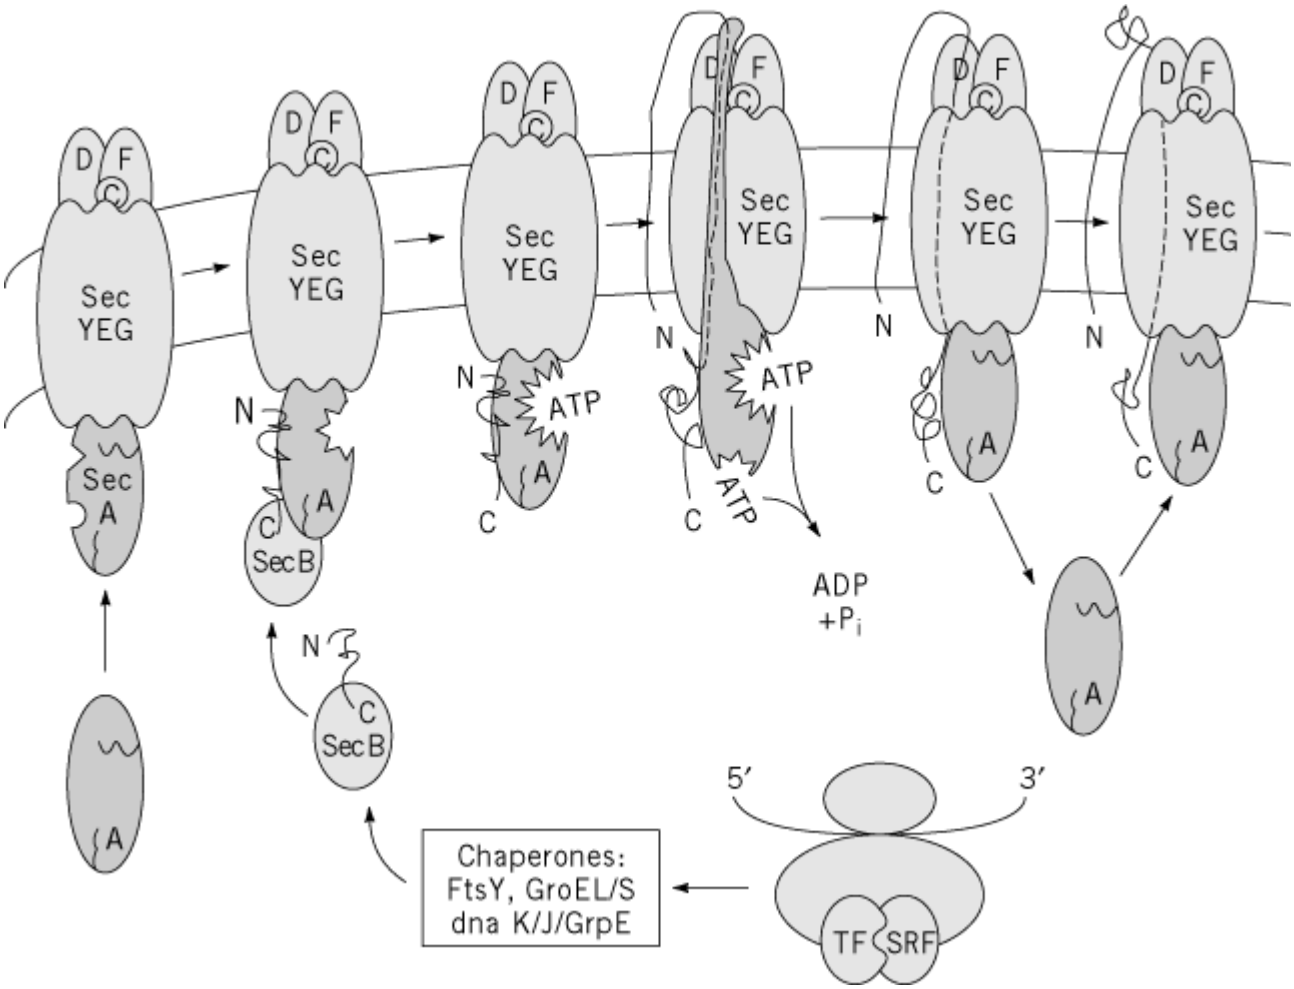
1.1. The secA System of Protein Transport

When *E. coli* makes a protein that is destined for export, it is made as a preprotein containing a signal sequence (4). In most proteins, these signal sequences are a stretch of contiguous amino acids at the amino terminus of a protein, with a positively charged amino terminus, at least six sequential hydrophobic amino acids, and a cleavage site for the signal peptidase that removes the signal after translocation. The presence of the signal sequence in a newly synthesized protein causes a protein chaperone to bind to it, retarding its folding. There appear to be at least two major chaperone systems in *E. coli*. One involves the tetrameric cytosolic protein secB, which binds to newly synthesized proteins that contain a signal sequence. It binds throughout the length of the newly synthesized polypeptide chain, keeping it from adopting its native conformation (2). A different class of chaperones binds to the nascent chain as the secreted protein is being synthesized on the ribosome. An example of such a chaperone is a ribonucleoprotein, the **signal recognition protein** (SRP). In *E. coli* SRP consists of a 4.5 S RNA molecule and a single protein, Ffh, which is a GTPase; that is, it hydrolyzes guanosine triphosphate (5).

The proteins destined for export, complexed with chaperones that keep them from folding, interact with receptors on the bacterial plasma membrane to initiate translocation across the membrane. The *sec*B receptor is *sec*A, and the SRP receptor is another GTPase, FTsY (5). The signal sequence has therefore two functions: (1) attracting a chaperone and (2) helping to target the complex to plasma membrane receptors.

The actual translocation event is through a transmembrane pore. In *E. coli* the pore is made up of the *sec* YEG complex, consisting of three major membrane proteins (*sec*Y, *sec*E, and *sec*G) with several accessory proteins. The sec YEG complex forms the pore through which unfolded proteins pass on their way out of the cell. Translocation involves pushing the unfolded peptide through the pore by a mechanism that resembles a sewing machine needle or a piston (6). A peripheral membrane protein (*sec*A) takes a 25-residue loop, formed by the amino-terminal signal peptide and the contiguous amino acids, and pushes the loop through the membrane. The amino-terminal amino acids remain cytoplasmic. To do this, the *sec*A protein goes through a remarkable, ATP-driven, conformational change, which causes an arm of the *sec*A protein to be inserted transiently into and partially across the membrane. After the pushing step, ATP is hydrolyzed and *sec*A is returned to a cytoplasmic location, ready for a second translocation pumping cycle. The signal peptide is cleaved off by a "signal peptidase" located in the periplasmic space. Further translocation in 25-residue steps can be driven by additional cycles of protein activity. After the initial step, however, further translocation is facilitated by a transmembrane proton motive force (Fig. 1).

Figure 1. The SecA system of protein transport. Chaperones bind to a nascent protein in order to keep it an unfolded stat it to receptor SecA at the membrane. SecA translocates the protein across the membrane through the protein pore (SecYI conformational changes. [Figure 1B from F. Duong, J. Eichler, A. Price, M. R. Leonard, and W. Wickner (1997) *Cell* **91**



Bacteria may push protein across the translocation channel, rather than pull it, because the source of energy, ATP, is exclusively cytoplasmic. Once in the periplasmic space, secreted proteins form disulfide bonds and fold into **proteinase**-resistant conformations. Such folding is necessary before the proteins are transported through holes, poorly described, in the outer membrane.

1.2. ABC Protein-Mediated Export

Some proteins destined for export are recognized in the cytoplasm of *E. coli* by an entirely different class of signal sequences. In these cases, the sequence is at the **C-terminus** and is not cleaved off by a signal peptidase after transport. Proteins with this type of signal sequence are closely related to each other and include such proteins as toxins, proteinases, and lipases. The signal sequence is recognized by a different class of plasma membrane protein, ATP-driven protein translocators of the ATP-binding cassette (ABC) family (3, 7). ABC proteins have two cytoplasmic ATP-binding **domains** and two hydrophobic domains, with six transmembrane sequences. They can be either a single polypeptide or be made up of several polypeptides. A complex of a bacterial ABC export with two accessory proteins allows it to export a cytoplasmic protein across both the inner and outer bacterial membrane at the same time. Assembly of the transporting complex is triggered by substrate binding (8).

2. Protein Export from Eukaryotes

Unlike bacteria, eukaryotic cells are packed with intracellular membranes. A considerable fraction of those membranes is involved in protein export. Thus protein export in eukaryotes involves translocation across membranes but also transport of the newly synthesized protein through

intracellular compartments (9). Protein export in eukaryotes is thus a much more complex process than in bacteria. It becomes necessary to know the intracellular pathway taken by a newly synthesized protein before it reaches the eukaryotic cell surface (see also **Protein targeting**).

2.1. Intracellular Trafficking of Exported Protein

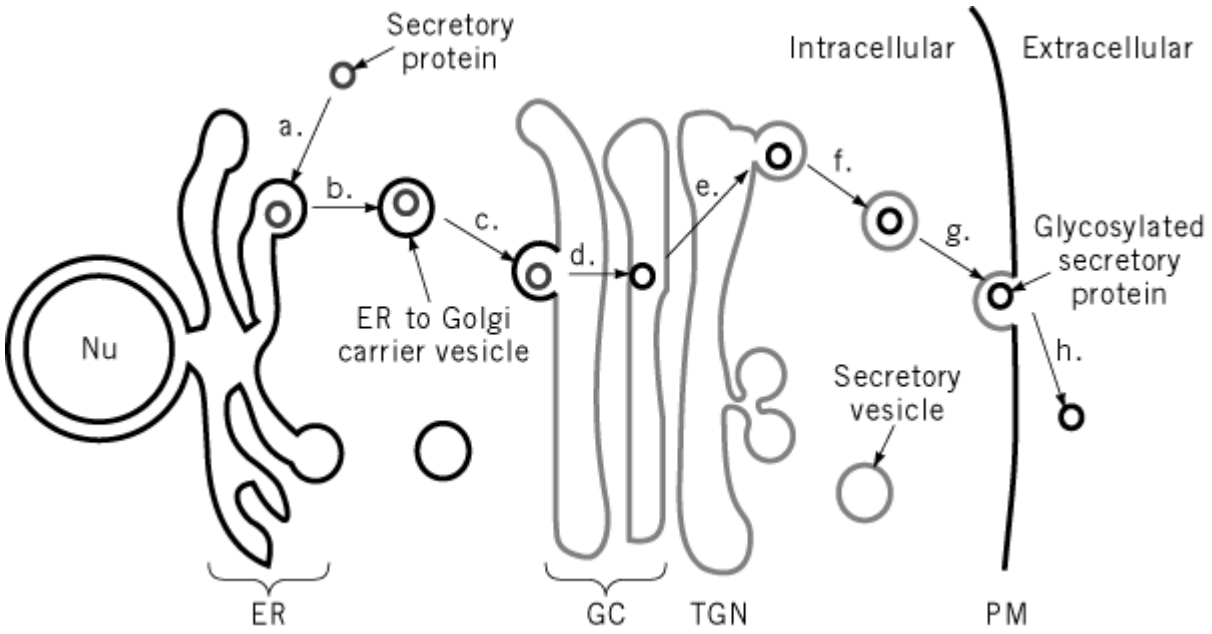
For the most part, eukaryotes do not secrete proteins directly across the plasma membrane. Instead, the newly synthesized proteins are translocated from the cytoplasm into an intracellular organelle, the endoplasmic reticulum (ER). The ER is a series of membranous cisternae and tubules that spread throughout the cytoplasm and is continuous with nuclear membrane. As we shall see, the mechanisms for translocating proteins across ER membranes and bacterial membranes both involve a transmembrane pore. Why have an ER? A common speculation on the evolutionary advantage of the ER is that it provides a controlled milieu in which exported proteins can fold and oligomerize, without being exposed to the rigors of the extracellular world. In this regard, the lumen of the ER resembles the **periplasmic** space in gram-negative bacteria.

A protein, correctly folded and oligomerized in the ER, must be transported to the outside of the cell. The initial step in transport from the ER is the formation of small membrane vesicles, usually called carrier vesicles, that contain the exported proteins as cargo (10, 11). Formation of carrier vesicles occurs at specialized ER regions called transitional zones, and it requires a cytoplasmic coat, to impart curvature to the vesicle membrane and to pinch it off from the donor ER (12).

After a carrier vesicle is formed, it must recognize and fuse with its target. Recognition and fusion (see Exocytosis) involve proteins on the vesicle (v-SNARE) and on the target membrane (t-SNARE) (13). When a carrier vesicle leaves the ER, it does not go directly to the plasma membrane but instead fuses with an organelle, the **Golgi complex**, which is a mandatory way station on the secretory pathway of eukaryotes. The Golgi complex is a stack of membranous cisternae, similar morphologically to a stack of pancakes. The carrier vesicles enter the *cis* end of a Golgi stack and exit from the *trans* side. A protein to be exported goes through a series of glycosylation steps in which six- or nine-carbon sugars are added to or removed from oligosaccharide chains attached to serine, threonine (O-glycosylation), or asparagine residues (**N-glycosylation**). The added sugars can often protect the exported protein from rapid **proteolytic** degradation after it is secreted into the extracellular world. A unique class of oligosaccharides is added to newly synthesized lysosomal enzymes that allows them to be diverted out of the secretory pathway to primary **lysosomes**.

A second budding event takes place from the *trans* region of the Golgi complex. A second coating mechanism causes the formation of a **secretory vesicle** containing glycosylated proteins for export. The post-Golgi secretory vesicles move to the plasma membrane, either by diffusion or by transport along microtubules. When the secretory vesicles reach the plasma membrane, their membranes and the plasma membrane fuse to form one continuous bilayer, a process known as exocytosis. The fusion step results in the release of the exported protein into the extracellular medium (Fig. 2).

Figure 2. The eukaryotic secretory pathway. Secretory proteins enter the membrane trafficking system by (a) translocation from the cytoplasm into the endoplasmic reticulum (ER) (b) In the ER, proteins are packaged into ER to Golgi complex (GC) carrier vesicles that (c) deliver proteins to the GC. As proteins progress through the GC they become (d) glycosylated. Once the (e) reach the *trans*-Golgi network (TGN), they (f) are sorted into secretory vesicles in which proteins are (g) transported to the plasma membrane (PM). At the cell surface secretory proteins are (h) released into the extracellular environment.



This pathway of protein export or secretion is the one followed in most organisms, including yeast, protozoa, and mammalian cells such as muscle cells and fibroblasts. It is commonly referred to as the constitutive pathway, to distinguish it from a specialized pathway found in specialized cells, such as endocrine and exocrine cells, and in cells of the **hematopoietic** system, such as neutrophils or cytotoxic T lymphocytes . In such cells, newly synthesized proteins are diverted out of the normal biosynthetic pathway to be stored in secretory granules (14). Fusion of the secretory granule with the plasma membrane is usually triggered by an external stimulus. Because export of this class of secreted proteins is controlled by a stimulus, the triggered release of protein from a storage pathway has been called regulated release.

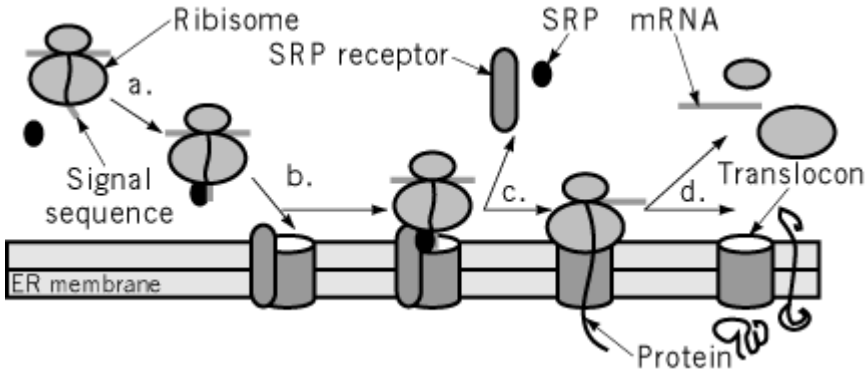
The protein export pathway of eukaryotes is highly conserved. Protozoa, yeast, and mammalian cells use essentially the same mechanisms to translocate proteins into an ER, to glycosylate and sort them in the Golgi, and to export them across the plasma membrane by exocytosis.

2.2. Translocation Across the ER Membrane

Translocation of newly synthesized proteins across the ER membrane shows many similarities to translocation across the plasma membrane protein of bacteria (1, 15, 16). Proteins are prevented from folding in the cytoplasm. They are fed across the plasma membrane through a translocon, a proteinaceous pore, which has three subunits very similar to the bacterial proteins made by the *sec*Y, E, and G genes. By electron microscopy, these pores are rings about 8 to 10 nm in diameter, with a central pore of 2 nm, sufficient to allow the passage of an extended, hydrated peptide of 1.1 nm in diameter. These pores can now be recognized (17). In yeast, proteins traverse pores in the ER by two different types of translocation mechanisms. One is an ATP-driven process that translocates proteins whose synthesis is complete. The other couples translation to the translocation process. In this transport mode, the ribosome is attached to the proteinaceous transport pore, the translocon, and feeds the nascent train through the pore as it is being synthesized. Mammalian cells only have the co-translation made of translocation. When translocation is co-translational, the nascent chain is recognized in the cytoplasm by a signal recognition particle, which stops further protein synthesis until the complex of ribosome, nascent chain, and signal recognition particle reaches the endoplasmic reticulum (Fig. 3).

Figure 3. Translocation across the ER membrane. (a) Signal recognition particle (SRP) binds to a signal sequence on a

nascent protein and halts the protein's synthesis by the ribosome. (b) SRP brings the protein and ribosome to the translocon on the ER membrane by binding to its receptor. (c) Protein synthesis restarts when the ribosome is correctly positioned and the protein has been threaded into the translocon. (d) Proteins can either be translocated completely into the lumen of the ER to become secretory proteins or translocated partially through the membrane to become integral membrane proteins.



As the nascent chain enters the cytoplasm, it is glycosylated on suitable asparagine residues and forms disulfide bonds. Folding is completed by association with accessory proteins such as BiP, **calnexin**, **peptidyl prolyl *cis/trans*** isomerases, and protein disulfide isomerase (18). Proteins also oligomerize in the lumen of the ER. For example, protocollagens trimerize with an extended coiled-coil configuration, accompanied by cross linking between hydroxyproline and hydroxylysine residues (see Hydroxylation (Lysine, Proline)). If cross linking of collagen protofibrils is inhibited, the improperly folded collagen cannot leave the ER and is quickly degraded. A similar observation is made with the secreted protein **a1-antitrypsin**. In the disease, a-antitrypsin deficiency, a mutation in the protein can prevent its correct folding. These two examples demonstrate that there is a quality-control system that surveys the proteins leaving the ER and prevents the export of improperly folded proteins. Recent data suggest that improperly folded ER proteins are exported from the ER back to the cytoplasm, where they are degraded by proteasomes (19).

2.3. Traffic of Secretory Proteins from the ER

To take correctly folded and oligomerized proteins from the ER, a vesicle forms in the transitional elements and includes proteins to be exported, but excludes resident proteins of the ER lumen, such as BiP (20). The coat that causes the vesicle to form is now known as COPII. Yeast COPII contains four subunits, *sec*31p, *sec*13p, *sec*23p, and *sec*24p (see **sec mutants**). Assembly of a COPII coat requires a small GTPase, *Sar*1, and a guanine nucleotide exchange factor, *Sec*12p, in the ER membrane (12) (Fig. 4). The coated vesicle leaving the Golgi carries with it a complement of v-SNARE molecules (see Exocytosis) to allow it to fuse with the *cis*-Golgi network. In yeast, these are *Sec*22p, *Bos*1p, and *Bet*1p. Resident proteins such as BiP may be excluded from the lumen of the coated vesicle because they are oligomerized into complexes that are too big to enter the small vesicle. To some extent, exported proteins are those that lack a retention signal and so are not retained in the ER. Export of secreted proteins would then be by default, because they lack information to go anywhere else. There is evidence, however, that positive sorting occurs (21) (Fig. 5). In yeast, the secreted protein invertase is recognized by a membrane-bound ER protein (*Emp*24p) that is required for its transport to the Golgi (22). Furthermore, cargo proteins are concentrated as they leave the ER (23, 24). Since most soluble resident proteins in the ER lumen are not glycosylated, an attractive hypothesis is that exported proteins are recognized by a lectin, which concentrates them in budding vesicles. A protein, ERGIC-53, recycles between the ER and the Golgi and is a lectin with the capacity to bind the mannose residues found on newly synthesized secretory proteins (25). Proteins such as ERGIC-53 might bind secreted proteins and actively carry them to the Golgi complex, in the same way that the **mannose phosphate receptor** carries newly formed lysosomal enzymes to the prelysosomal compartment.

Figure 4. Formation of ER to GC carrier vesicles. ER to GC carrier vesicles are formed with the COPII coat (Sar1, Sec 13/31p, and Sec 23/24p). Components are thought to bind sequentially with (a) the GTPase Sar1 (in its GTP state), binding to v-SNARE and cargo molecules. (b) Sec 13/31p binds to Sar1 and then (c) Sec 23/24p binds to the whole complex. By unknown mechanisms the COPII coat (d) causes a vesicle to bud off from the ER membrane, and (e) uncoating leads to the (f) mature carrier vesicle, which can then go on to fuse with the Golgi complex. Formation of other types of vesicles is likely to involve similar steps using different coating proteins.

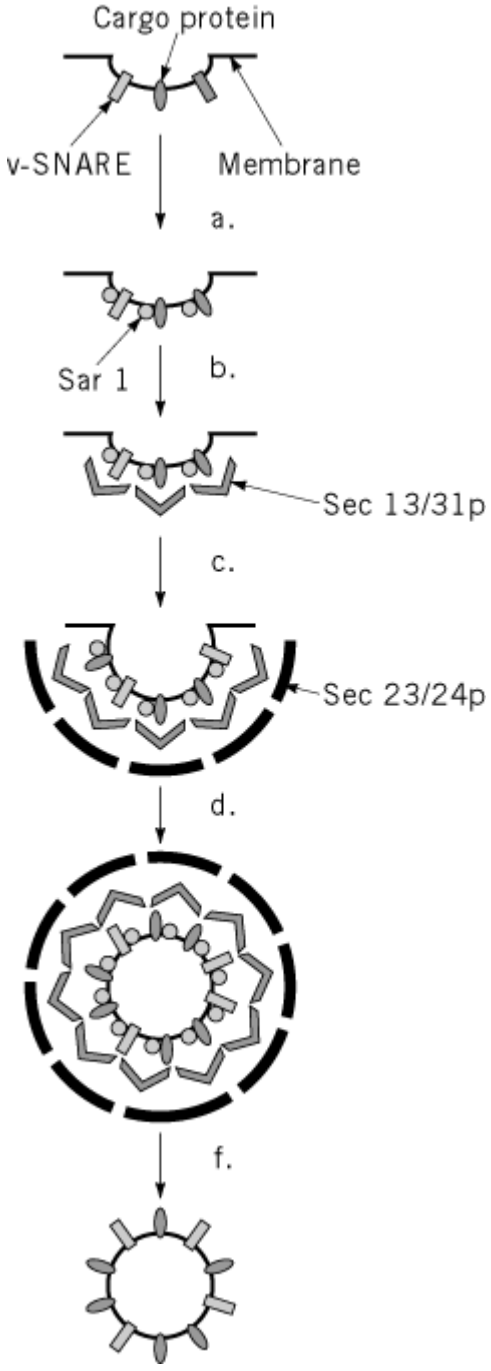


Figure 5. Sorting of proteins between the ER and GC. (a) Cargo proteins destined for secretion and v-SNAREs needed for carrier vesicle fusion to the GC are sorted away from the ER resident proteins into COPII coated vesicles. After delivery to the GC, the cargo proteins continue through the secretory pathway. (b) However, v-SNARES needed for the ER to GC trafficking step and ER resident proteins that have been mistakenly transported to the GC can be

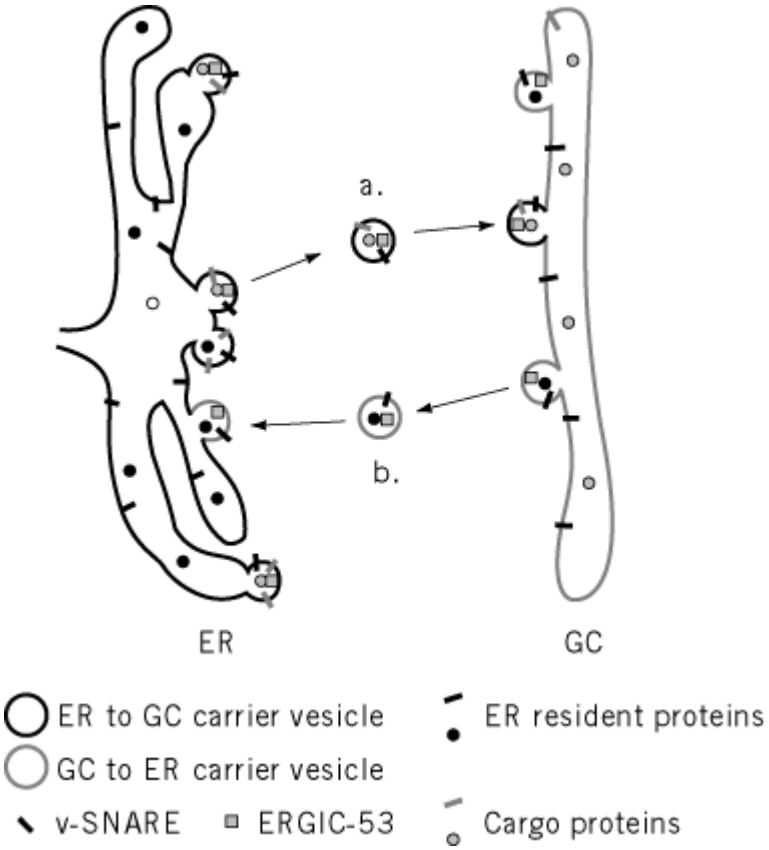
retrieved from the secretory pathway through retrograde transport back to the ER by COPI-coated carrier vesicle. ERGIC-53, a likely carrier protein, cycles between the ER and GC and may assist in sorting the secretory proteins from proteins that are retained in the ER.



Proteins such as ERGIC-53 and the v-SNARE proteins can recycle back to the ER from the Golgi. The vesicle for Golgi to ER flow is made up of coatomers, referred to as COPI coatomers. Coatomers consist of seven subunits. The small GTPase active during coatomer coat formation is an **ADP ribosylation** factor (ARF1).

Fusion of the ER-derived carrier vesicle with the Golgi membranes requires the v-SNAREs *Sec*22p, *Bos*1p, and *Bet*1p in the vesicle membrane, and the cognate *cis*-Golgi t-SNARE, the *sed*5 protein. In addition, a second class of small GTPases are required that are members of the *rab* family (26). The *rab* GTPases are *ras*-like proteins that are specific to a certain organelle or a certain trafficking step. In yeast, mutations in the *rab* protein *ypt*1 inhibit fusion with the Golgi and cause the accumulation of carrier vesicles. The *ypt*1 protein appears to play a role in v-SNARE/t-SNARE interactions (see Exocytosis) involved in *cis*-Golgi targeting. Two of the v-SNAREs in yeast, *Bos*1p and *Sec*22p, normally form a complex. The complex does not form if ypt1 is absent, nor is a v-SNARE/t-SNARE complex formed, suggesting that *ypt*1 plays a role in activating the v-SNAREs, allowing a v-SNARE/t-SNARE complex to form. It is also possible, however, that *ypt*1 is also activating the t-SNARE complex on the target membrane, by removing its chaperone, *Sly*1p. This chaperone is a member of the *Sec*1p family of syntaxin-family Chaperones (see Exocytosis).

2.4. Modification of Secreted Proteins in the Golgi

As secreted proteins pass through the Golgi complex, they can be modified by glycosylation, sulfation, or **proteolysis**. Three major types of glycosylation occur, N-linked, O-linked, and glycosaminoglycan addition. In mammalian cells, the mannose-rich, asparagine-linked oligosaccharides that had been added in the ER are first trimmed in the Golgi complex and then rebuilt. Mannoses are first removed and then replaced by other sugars. On a stump of the original

mannose tree, a multichain oligosaccharide is generated by the orderly addition of the sugars *N*-acetylglucosamine, galactose, and sialic acid (*N*-acetylneuraminic acid). The previous form of glycosylation is referred to as **N-glycosylation**, since the sugars are added to an asparagine residue. If a sugar chain is added to a serine or threonine residue, it is referred to as O-glycosylation. The first sugar added is usually *N*-acetylgalactosamine. The oligosaccharide chains are branched but are usually shorter and more variable than N-linked oligosaccharides.

The third type of glycosylation results in the formation of proteoglycans. Proteoglycans are formed by the addition of xylose to serine residues as the protein moves from the ER to the Golgi (27), followed by the addition of a long, highly charged, unbranched oligosaccharide called a glycosaminoglycan. Glycosaminoglycans are polymers of a disaccharide unit, one of which is usually uronic acid. The other member of the oligosaccharide pair varies, depending on the type of glycosaminoglycan. Part of the strong negative charge on the proteoglycans is due to the addition of sulfate groups to the glycosaminoglycans. Sulfate can also be added directly to tyrosine residues on secreted proteins. Sulfation of proteins only takes place in the late Golgi. Radioactive sulfate is thus commonly used to label exported proteins selectively and to identify a set of proteins at a late Golgi step of transport. Glycosaminoglycan chain synthesis can be initiated in the late Golgi by growing cells in the presence of a membrane-permeable derivation of xylose (28). This technique has also been used to identify membrane traffic from the late Golgi to the surface of the cell.

Several proteins, membrane associated and secreted, are subject to proteolytic processing as they pass through the Golgi complex. The proteolysis is highly specific, occurring usually to the carboxyl side of a four-residue consensus sequence: Arg–X–(Lys/Arg)–Arg (29). The Golgi enzyme that carries out this proteolysis is a membrane-attached form of the subtilisin family, called furin. Secreted proteins cleaved by furin include the hepatocyte and **nerve growth factors** and pro-**albumin**.

Exported proteins can take one of two pathways to leave the Golgi complex, the constitutive and the regulated [Fig. 4 in (14)]. In the regulated pathway, newly synthesized proteins are stored in specialized secretory granules until cells receive a signal to secrete. Storage does not occur in the constitutive pathway; nascent proteins go directly from the Golgi to the cell surface. Little is known about sorting into constitutive carrier vesicles, the coat required to generate a carrier vesicle, or the v-SNAREs and t-SNAREs required for fusion with the cell membrane. Much more is known about the regulated secretory pathway, which packages newly synthesized proteins into secretory granules (qv). Similarly, study of the regulated secretory pathways has revealed a great deal about the final step, fusion with the plasma membrane, exocytosis.

2.5. Nonclassical Protein Secretion

The secA-mediated pathway of bacterial protein export uses a translocon or transmembrane pore that is closely similar to the ER translocon in eukaryotes. There is also a eukaryote equivalent of the ABC transporter system in bacteria. The yeast protein, Ste6p, is an ABC protein that exports a-factor, a small yeast mating-type peptide, from the cells. There is no evidence, however, that eukaryotic ABC proteins can translocate full-length proteins across the plasma membrane.

Yeast can export proteins without using the classical, ER to Golgi pathway. Mutations in the classical pathway that block invertase secretion have no effect on this pathway, called the nonclassical pathway. The gene for a transmembrane protein, nce2, that is important for nonclassical secretion has been **cloned** and sequenced, but its role in protein export remains unclear (30).

Mammalian cells export proteins, such as **interleukin**-1b, basic **fibroblast growth factor**, and thioredoxin, that do not have a classical signal sequence (31). In addition, drugs such as **monensin** and **brefeldin** A that normally block classical secretion are without effect on these proteins. Their secretion has been linked to the **heat-shock** response. Little is currently known about the molecular mechanisms that are involved.

Protein Sequencing

The introduction of protein sequence determination started the era of macromolecular

characterization. It established the homogeneity of proteins, permitted analytical automation, initiated the path to increasing speed and sensitivity, and was instrumental also in the interpretation of three-dimensional protein structure analysis and, later, DNA sequence analysis. Both the speed and sensitivity of chemical protein sequence determination have increased enormously. Initially, each analytical step required days or more in time and millimoles in amounts, but now only minutes and picomoles or less are necessary. At the same time, the major chemical method, the Edman Degradation, has stayed more or less unchanged. It now constitutes one of the oldest molecular methods that is still much in use. Recently, however, even this method has been challenged by other approaches, mass spectrometry in particular, but further chemical sequencers are also still being launched. Probably, both chemical and mass spectrometric protein sequence analysis will remain for a considerable time. However, protein sequence determination is not just a question of the degradative analysis; it also involves sample preparation, correlation with DNA sequences, including genome sequencing projects, the screening of **databases, NMR** and X-ray crystallography, as well as epitope analysis and protein structure predictions, all of which constitute different aspects of integrated, modern molecular biology. In short, sequence determination is part of the era of the proteome that is now emerging at the protein identification stage of the genomic sequencing breakthrough. The various stages of protein analysis using chemical degradation and mass spectrometry are presented here, together with the current stage and perspectives of future methodology.

1. Development of sequence determination

Sequence determination of proteins has been possible for about 50 years (1-5). During the second half of the twentieth century, development has been rapid, bringing structural analysis from something requiring the effort of a whole department, a small protein, large amounts, several years of work, and still some uncertainty, to something requiring just a single person, any size of protein, minute amounts, a limited time, and great reliability. This progress has been paralleled by methodological and instrumental developments in essentially nine steps (Table 1).

Table 1. Important Steps in the Development of Methods and Instruments in Protein Sequence Analysis

1. The first analysis and recognition of defined structures (1940s to 1950s)
2. The Edman reaction (~1950)
3. Manual methods: “Dansyl-Edman”and later follow-ups (DABITC) (from ~1960 on)
4. Automation: the protein sequenator or sequencer (1967 on)
5. Development of HPLC (~1977)
6. Polybrene, membranes, valves, conversion,on-line HPLC: 2nd generation sequencers (end of 1970s)
7. Mass spectrometry (1970s)
8. Third-generation sequencers, including C-terminal degradation (end of 1990s)
9. Electrospray, nanospray, present-generation “Protein mass spectrometers” (end of 1990s)

Each one of these steps has meant a corresponding leap in analytical speed, reproducibility,

sensitivity, and ease of analysis. The successive development is clearly traceable in the scientific literature, and in this case especially in the Proceedings volumes of the series of the special methods conferences, MPSA (for Methods in Protein Sequence Analysis, 1975–1992, and Methods in Protein Structure Analysis from 1994 to the present) that originated from still earlier meetings that roughly coincided with the introduction of automatic sequencers (6, 7). MPSA continued for a long time as the leading methodological meeting, but other conferences also covering the subject now compete in progress reports, in particular the Protein Society (which started in 1986) and its journal, *Protein Science* (started in 1992), and the ABRF (Association of Biomolecular Resource Facilities, from 1988; *The Journal of Biomolecular Techniques*, electronic since 1997). ABRF and MPSA still concentrate on the methodological developments, with ABRF being the larger source. Details of the MPSA meetings and their proceedings are given in Table 2. In retrospect, most of the major advances can be followed in these proceedings.

Table 2. MPSA Proceedings

MPSA Number,	Proceedings Volume	
	Year	Publisher (editor), Year of Publication
I,	1975	Pierce (Laursen), 1975
II,	1977	Elsevier (Previero and Coletti-Previero), 1977
III,	1979	Elsevier (Birr), 1980
IV,	1981	Humana (Elzinga), 1982
V,	1984	(Not Published) (Walker)
VI,	1986	Humana (Walsh), 1987
VII,	1988	Springer (Wittmann-Liebold), 1989
VIII,	1990	Birkhäuser (Jörnvall et al.), 1991
IX,	1992	Plenum (Imahori and Sakiyama), 1993
X,	1994	Plenum (Atassi and Appella), 1995

XII,	1998	To be held (Kyriakidis and Choli-Papadopoulou)

2. Methodology and instrumentation

2.1. Initial Analysis of a Protein Sequence and Definition of the Concept

During the end of the 19th century and early parts of the 20th century, proteins were gradually purified, giving insight into the fact that they constitute defined molecules of exact structure. During the same time, the constituent amino acids were characterized, culminating with threonine in the mid-1930s (8). By the use of many methods, including partial acid hydrolysis, and reaction with a labeling reagent that is stable during hydrolysis and specific for the protein amino group, fluorodinitrobenzene (FDNB) (9), the first protein primary structure, that of insulin, was determined in the late 1940s and early 1950s (1, 2), for which Frederick Sanger received the 1958 Nobel Prize in Chemistry. With this sequence determination, proteins were recognized as defined molecules, marking the start of the modern era of structural analysis.

2.2. Edman Degradation and Protein Sequencers

The Edman degradation and its use in automatic protein sequencers is described in the entry Edman Degradation.

2.3. Mass Spectrometry

The nonvolatility of peptides was the prime limitation to the use of mass spectrometry (MS) with proteins. Many advances changed this recently. One especially important step was the introduction of triple quadrupole instruments (10), essentially tandem mass spectrometers (MS/MS), where a first quadrupole, the first "mass spectrometer" or MS_1, performs peptide mass selection; a second quadrupole acts as a collision gas cell where peptide fragmentation can occur; and the third quadrupole, the second mass spectrometer, or MS_2, analyzes the peptide fragments generated in the collision cell by their mass, thus allowing peptide sequence analysis by collision-induced dissociation or collision-activated dissociation mass spectrometry (11).

Another crucial step in the MS sequencing approach was the introduction of novel ion-producing techniques, to make MS accessible to proteins in general (see Mass Spectrometry). Desorption methods of ionization such as fast atom bombardment (12), plasma desorption (13), and matrix-assisted laser desorption ionization (MALDI) (14), made it possible to transfer peptides and proteins into the gas phase, making them available to mass spectrometry. MALDI, coupled to time-of-flight (TOF) instruments (14), made mass spectrometers easy to handle and brought the technique within the economic means of many protein laboratories. Hence, MALDI-TOF instruments are now used in many laboratories, but mostly for peptide mass measurements, for peptide identification and screening, rather than sequence analysis. With further developments, however, such as the introduction of reflectrons (15), delayed extraction (16), and post-source decay (17), these instruments can also give some sequence information via peptide cleavages. However, more important for sequence analysis, and the real breakthrough via MS/MS instruments, was the introduction of electrospray ionization (ESI) (18). This opened the way to sample introduction via solvents, and hence to on-line applications, with the MS analysis immediately following a chromatography separation. Similarly, further mass analysis systems, including ion traps (19), made additional progress in some MS/MS techniques. Finally, full-scale computerization and on-line databank screenings allowed further speed and interpretations (20). It is possible that MS may become the method that eventually replaces the Edman method.

2.4. Present-Generation Chemical Sequencers

Recent chemical developments of automatic protein sequencers have involved primarily further miniaturization. The most novel type of chemical sequencers now have phenylthiohydantoin (PTH) detection columns in the sub-millimeter diameter range, UV detectors with volumes in the nanoliter range, application possibilities in the sub-picomole range, and overall sensitivities at that level. An important complement has also been developed on the side of sample preparation, with instruments now blotting proteins and peptides in nanoliter volumes from chromatography separations directly onto blotting matrices for subsequent sequencer analysis (21).

2.5. C-Terminal Sequencing

Other chemical advancements have involved development of sequence determination from the C-terminus. The principle has long been known, using isothiocyanate degradation (22). The conditions were harsh, however, using strong acids, acetic anhydride, and repeated activation of the C-terminal carboxyl group in each step. Consequently, the yields were low, side-reactions plentiful, and erroneous peptide bond cleavages frequent. In addition, the secondary amine of proline residues could not react at all, and yields for carboxyl and hydroxyl residues were especially poor. Hence, degradative methods from the C-terminus have not been used much, and commercial C-terminal sequencers did not exist, in spite of all the progress with the N-terminal (see Edman Degradation). Instead, C-terminal analysis long relied on hydrazinolysis (now outdated) (23), reductive methods to get the corresponding alcohol (also outdated) (24), and, in particular, enzymatic approaches, utilizing carboxypeptidases (25). Initially, the available carboxypeptidases had too strict substrate specificities

to be useful for protein analysis in general. Lately, however, carboxypeptidases have appeared with wide specificities, and hence good applicability to proteins in general (26-28). In conjunction with mass spectrometric analysis in MALDI-TOF instruments, this has opened a new route to small-scale C-terminal analysis in the "ladder sequencing mode" (see below); (29, 30).

Progress has also been substantial in chemical aspects of C-terminal degradations of proteins. Several adjustments allowed the method to work for a few cycles in most cases (31). Recently, further modifications allow, in one step, simultaneous cleavage of the C-terminal residue and activation of the next, by the use of an additional chemical modification involving S-alkylation of the thiohydantoin. This has now made it possible to degrade several proteins in reasonable yield, and in several cases to follow the C-terminal sequence for up to 10 cycles (32). This new approach has just become available in commercial instruments. Although C-terminal degradation is still less sensitive than N-terminal degradation and less reliable, does not reach as far, has difficulties with some residues (carboxylic and hydroxylic), and is still not feasible at all with proline residues, C-terminal analysis is now becoming practical. Just a few cycles of C-terminal sequence information are sometimes sufficient, especially for identification of the correct recombinant proteins and corresponding gene constructs; for this purpose, there are now both C- and N-terminal instruments.

In conclusion, present-day chemical sequencers have reached the sub-picomole range for N-terminal analyses, and degradations from both ends on a larger scale. The chemistry for C-terminal degradations has started to develop. For N-terminal degradations, miniaturization has progressed substantially, with sensitivity increased about 10^8-fold and speed about 10^2-fold in ~50 years, using the same basic chemistry of Edman degradation.

2.6. Present-Generation "Protein Mass Spectrometers"

Substantial progress has also been made in mass spectrometry. Electrospray ionization has been miniaturized. The use of small capillaries in the "microspray" mode (33) or "nanospray" mode (34) transfersions into the gas phase more efficiently and increases the sensitivity, as do the infusion of small volumes at low flow rates (10 nL/min), and signal averaging (33, 34).

Similarly, introduction of ion traps has allowed the more efficient collection of ions, increasing the sensitivity. Furthermore, use of TOF mass analyzers as the second MS of MS/MS instruments (35) has increased both the speed and the accuracy (mass accuracy of 0.1 Da and sensitivity at the attomole scale) to new levels in instruments just released. Such instruments for sequence analysis, coordinated with MALDI-TOF instruments for peptide mass determination and screening, are easy to run and require less work than ordinary mass spectrometers. Together, they bring MS to a stage beyond that of chemical protein sequencers, and will perhaps one day overtake the whole sequencing market at a future step. For the moment, TOF combination instruments on the mass spectrometry side, plus the current chemical sequencers, have brought protein sequence determination to a new stage of perfection, speed, and sensitivity.

3. Perspectives and further methodology

Three levels of future protein sequencing may be predicted: "conventional approaches, tissue characterizations, and further correlations.

3.1. "Conventional" Approaches, with Protein Purification and a Column End-Step

For this approach, MS/MS mass spectrometers are now in routine use at the femtomole scale, and miniaturized modern chemical sequencers work in the sub- or low picomole range. Regarding mass spectrometry, the nanospray approach to electrospray ionization has made it routine to analyze proteins in solution. Similar approaches with chemical sequencers and with sample preparation using capillary zone electrophoresis (36) or micro-HPLC (18) mean that sample preparation will continue to make progress along with both MS and chemical sequencer instrumentation. This combination makes it possible to analyze virtually any protein prepared by column chromatography. This development is expected to continue, with further miniaturization, plus on-line shortcuts. Regarding

sensitivity, however, we may just have passed half or even more of the major leaps in this "conventional" mode of analysis! Half a century of progress has seen a sensitivity increase of about 10^8, down to about ~10^{-14} moles, which is about half-way down through the magnitudes to one atom (the inverse of Avogadro's number, 0.16×10^{-23}). In other words, we might expect to reach the ultimate one-molecule sensitivity level before or just after another similarly large leap. Also, in some special approaches of protein detection and analysis, using fluorescence correlation spectroscopy, science can already approach the one-molecule level of analysis (37). Although much still remains to make it all routine, to increase speed, and to lower the cost, it is possible that something like half of the major leaps have already been seen in the "conventional" approach of sequence analysis via column preparations of individually purified proteins.

3.2. Tissue Characterizations Using Two-Dimensional Gel Separations for Sample Preparation

This is one of two other types of analysis that offer great possibilities. With proper care, two-dimensional gel electrophoresis can now separate almost thousands of proteins into distinct positions (38). The patterns obtained can be stored, compared, and analyzed for both relative and absolute changes. In this manner, all major proteins of any tissue can be rapidly screened. Comparisons between patterns from normal or diseased organs allow direct detection of tumor markers, signal proteins, and other special forms. Similarly, gene expression in different tissues, and at different ages, allows conclusions to be drawn about developmental and differentiation patterns. In all cases, the corresponding protein spots, including all those that can be detected by ordinary or silver-staining methods (see Silver Stain), can be recovered and identified by sequence analysis.

The present procedure involves recovery of the corresponding gel piece, proper washing to allow subsequent analysis, drying, addition and penetration of a **proteinase** (usually **trypsin**), digestion of the protein in the gel (39), and recovery of the fragments, most conveniently via subsequent mass spectrometry. The MS can be performed simply by accurate mass determination of all the peptide fragments obtained from the action of the proteinase; this is usually sufficient to identify a known protein from a sequence database. If this tryptic fragment mass analysis is not sufficient for identification, the MS/MS instrument can simply be set instead to analyze directly for sequence (via use of the collision cell) of all those fragments that are not identified by just their masses. Notably, this entire analysis is theoretically possible from just one spot recovered from a two-dimensional gel. Several such approaches are listed in the latest MPSA proceedings volumes (eg (40, 41)), and are within reach of most protein analysis centers (42). It is to be expected that all major proteins in most tissues will soon have been identified as to their nature and function.

3.3. Further Correlations of Databank Technology, Protein Analyses, and Separation Modes

The great variety of post-translational modifications can also be identified through protein sequencing methods. Two-dimensional gel separations are excellent also for separation of multiple forms of the same protein, independent of whether the multiplicity is derived from additions/deletions (size differences, noticeable in one of the two directions) or from changes in charge (the other direction). It should also be noted that mass spectrometry can be used to detect also noncovalent associations, simply by using proper energy levels in the ionization steps of ion production.

4. Summary

In short, much of the proteome era to come will use the separation, analysis, and computer methods now available to characterize all cellular proteins functionally through sequence analysis. Because of the large equipment involved, much of this era may be expected to occur in "protein analysis centers" rather than in individual laboratories or groups. Still, continuous miniaturization and small-scale approaches like the "ladder" modes mentioned above (28, 29) may also keep individual laboratories and groups genuinely in-scale and fully contributing.

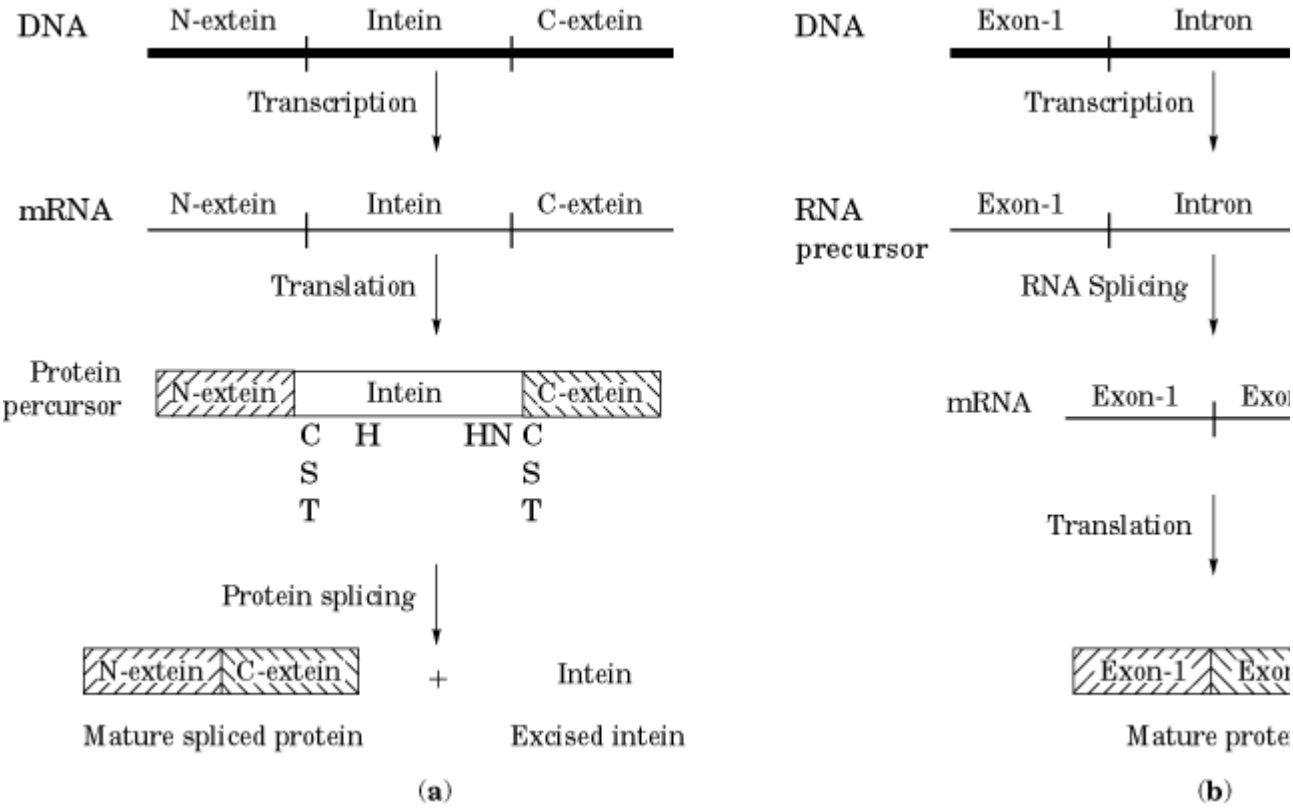
Protein Splicing

Two types of **intervening sequences** within **genes**, **introns** (RNA splicing elements) and *inteins* (protein splicing elements) are not present in the mature protein (1). Introns are spliced out of a precursor RNA before translation of the messenger RNA, whereas inteins are posttranslationally excised from precursor proteins by a process termed protein splicing (Fig. 1). The discovery of protein splicing in 1990 (2, 3) fundamentally changed our view of genetic information flow from DNA to RNA to protein. Protein splicing results in the expression of two proteins from a single gene and thereby is an exception to the rule of one gene, one protein. Protein splicing is defined as the synthesis of a precursor protein followed by the excision of an internal intein domain and the simultaneous ligation of the external protein domains (termed exteins) to form the excised intein and the mature protein product of the extein gene (1). The ligation of the flanking extein domains to form a mature protein differentiates protein splicing from other types of **posttranslational** processing of precursor proteins or polyproteins (4). Protein splicing requires proteolytic cleavage of the precursor protein at both splice junctions and formation of a native peptide bond between the exteins. This complex pathway is mediated by a highly coordinated series of simple chemical reactions (four nucleophilic attacks). The elements that direct these chemical reactions are contained within the intein plus the first C-extein residue, which are capable of splicing if cloned in foreign protein contexts. However, splicing in foreign proteins is generally not as efficient as splicing in the native context, suggesting that the exteins may play a role in the splicing reaction by helping to align the splice junctions or by enabling proper folding of the intein catalytic core.

Figure 1. Comparison of protein (**a**) and RNA (**b**) splicing. Genes that contain protein splicing elements (inteins) are tra translated normally. After synthesizing a precursor protein, however, the intein is precisely excised, and the flanking ext ligated together to form two stable protein products. The five conserved residues that actively participate in the splicing p below the protein precursor (in one-letter code). They are a Ser (S), Thr (T), or Cys (C) immediately following both splic His (H) about 100 residues from the intein N-terminus, and the dipeptide His-Asn (HN) at the intein C-terminus (immed the downstream splice junction). RNA splicing differs from protein splicing in that the precursor RNA is spliced before t forming the mature mRNA, which is then translated into a single mature protein product.



The intein, often a bifunctional protein, is also a site-specific **endonuclease** capable of cleaving DNA at the intein insertion site in genes that lack the intein (also termed the intein "homing site") (1, 5, 6). This type of endonuclease is called a homing endonuclease (7). Homing endonucleases were originally described as **open reading frames** in mobile self-splicing introns in which homing endonuclease activity is required for intron mobility via the double-strand, break-repair pathway (8, 9). Many inteins are members of the dodecapeptide class of homing endonucleases and are thus potential genetic mobile elements (7-10). Inteins and self-splicing introns also have similar phylogenetic distributions in **Archaebacteria**, **eubacteria**, and lower **eukaryotes**. Inteins and self-splicing introns have not been found in higher eukaryotes.

In early papers, inteins were called spacers, protein introns, protozymes, or intervening protein sequences (IVPS), among other names (2-4, 6, 11-15)). In 1994, however, the majority of workers in the protein splicing field established a standard nomenclature for protein splicing elements consisting of the terms intein and extein, as defined previously (1). The name of each intein (gene or protein) consists of a three-letter genus and species designation, followed by the name of the extein in which the intein resides. If multiple inteins are present in the same protein, they are given a numerical suffix. For example, the second intein in the *Thermococcus litoralis* DNA polymerase gene is called *Tli* pol intein-2. If endonuclease activity has been demonstrated, the intein is also given an endonuclease designation following the restriction enzyme nomenclature convention with the addition of the prefix "PI-" (eg, PI-*Tli*I).

Protein precursors that contain inteins are synthesized just like any other protein (Fig. 1) (see

Protein biosynthesis). The gene is first **transcribed** into mRNA, and then the entire mRNA that contains the intein sequence is **translated** to produce a precursor protein. The RNA is not spliced. Silent substitutions at the extein/intein junction that change the RNA sequence, but not the protein sequence, do not affect protein splicing as they would RNA splicing. Then, the precursor protein is spliced to yield the free intein and the ligated exteins. Splicing of many inteins, including the *Tli* pol inteins, *Psp* pol intein-1, *Sce* VMA intein, and *Mtu* recA intein, does not depend on host cell factors because these inteins splice when expressed in many different heterologous systems, such as *Escherichia coli*, eukaryotic *in vitro* translation systems, or **baculovirus** (4, 6, 12, 16). However, the *Mle* recA intein does not splice when expressed in *E. coli* (13), suggesting that either some inteins may require host factors for splicing or that some expression systems do not provide a suitable environment for properly folding or splicing inteins.

Irrespective of the expression system, splicing is so rapid in the native protein that the precursor is rarely observed in cell extracts after staining of **SDS–PAGE** or **Western blotting** . The inability to demonstrate splicing of a purified precursor protein was a major obstacle to proving that inteins splice as proteins and not as RNA. A major breakthrough in understanding protein splicing was the establishment of the MIP *in vitro* protein splicing system, consisting of the *Psp* pol intein-1 cloned in-frame with the *E. coli* **maltose-binding protein** (MBP) at its N-terminus and a fragment of *Dirofilaria immitis* paramyosin at its C-terminus (16-18). Because MIP contains the maltose-binding protein, it can be rapidly purified by affinity chromatography over amylose resin. Splicing of MIP is blocked by inducing the fusion protein at low temperatures (12° to 20°C) and purifying it at pH 8.5 or above (MIP splicing is slowed at pH 8.5 and totally inhibited at pH 10). Then, splicing of the purified precursor protein is induced by raising the reaction temperature to 30° to 65°C and lowering the pH to 6 to 7.5. Splicing of the *Psp* pol intein-1 in its native DNA polymerase context is not temperature-dependent in *E. coli*, even though it was derived from an extreme thermophile (*Pyrococcus spp*., strain GB-D) that normally grows at 95°C. This suggests that the foreign protein environment in MIP is responsible for the observed temperature-dependent splicing of this fusion protein.

The MIP *in vitro* splicing reaction was followed by examining the size of the proteins present on **Coomassie Brilliant Blue**-stained SDS-PAGE or by probing Western blots with antisera specific for each of the three domains. When purified MIP precursor is incubated *in vitro* over time, the full-length fusion protein gradually disappears, and a concomitant increase occurs in a larger, slowly migrating protein, instead of the expected splicing products. This larger protein still contains all three MIP domains. The expected spliced products do not appear until the slowly migrating protein begins to disappear. These data suggested that the slowly migrating protein is a splicing intermediate. Formation of the slowly migrating intermediate is reversible. At pH 10, the slowly migrating species reverts back to the full-length precursor. N-terminal amino acid sequencing indicates that the slowly migrating protein is a branched protein that has two N-termini comprising the MBP N-terminus (the N-extein) and the intein N-terminus. The N-extein (MBP) is linked to the remainder of the precursor (IP) by an alkali-labile bond. The formation of stable branched proteins is very rare in biology.

0.1. Identification of Inteins and Conserved Intein Motifs

Because inteins are in-frame insertions that are absent from homologous extein genes, intein junctions were initially determined by comparison with sequenced extein homologues. In many cases, pairwise comparisons with extein homologues or insertion of the intein in a conserved extein motif clearly indicated the intein boundaries. These predictions were confirmed when the N-termini of the free *Sce* VMA, *Tli* pol-2, and *Psp* pol-1 inteins were sequenced by Edman degradation (4, 6, 16). Characterization of many inteins indicates that they are moderately sized proteins (300 to 550 residues) with two known exceptions, *Ppu* dnaB intein (150 residues) and *Mxe* gyrA intein (198 residues) (19). However, these small inteins have yet to be analyzed for splicing or endonuclease activity.

Analysis of 36 intein sequences revealed four conserved splice junction residues (see the precursor protein in Fig. 1) and eight conserved intein motifs (Blocks A to H) that are considered important for

splicing or endonuclease activity (19, 20). Known inteins begin with either Ser or Cys, although it should also be possible for Thr to occur at this position. These amino acids contain side-chain hydroxyl (Ser or Thr) or **thiol** (Cys) groups. Inteins end in Asn, and 33 of 36 sequenced inteins have a His preceding the C-terminal Asn. C-exteins begin with Ser, Thr, or Cys. Thus, the amino acid at the downstream side of both splice junctions is limited to Ser, Thr, or Cys. As discussed later, these residues participate in the chemical reactions required in protein splicing. The four conserved amino acids at the two splice junctions reside in larger conserved intein terminal motifs, Blocks A and G. Another conserved intein motif, called Block B, is usually approximately 100 residues from the intein N-terminus and contains a second conserved His, which, it is thought, is involved in N-terminal splice junction cleavage. Two of the intein motifs are also the homing endonuclease dodecapeptide motifs (Blocks C and E) that catalyze DNA cleavage. It has been suggested by many researchers that the region between and including the dodecapeptide motifs functions as the homing endonuclease and that the regions flanking these motifs direct splicing. Further study, especially structural analysis, is required to support this hypothesis.

0.2. Inteins, Endonuclease Activity, and Mobility

The dodecapeptide motifs in the dodecapeptide class of homing endonucleases are also found in many inteins. However, these motifs are absent or mutated in many inteins, suggesting that not all inteins are active homing endonucleases. Endonuclease activity is not required for protein splicing (21). Endonuclease activity has been demonstrated in inteins from yeast [PI-*Sce* I, (5)], *T. litoralis* [PI- *Tli* I and II, (6)] and *Pyrococcus spp*., strain GB-D (PI- *Psp* I). Homing endonuclease activity in self-splicing introns is a prerequisite for intron mobility. *Sce* VMA intein mobility has been demonstrated during **meiosis** in yeast (10). Homing endonucleases have large (15 to 40 nucleotide) recognition sequences that correspond to the intein or intron homing site and are absent in the indigenous genome when the intein or intron is present (7). The homing site is composed of the intein or intron sequences that flank the insertion site in genes that lack the intein or intron. When an intein or intron is present in the gene, the homing site is disrupted, and the endonuclease cannot cleave the DNA. Therefore, homing endonucleases can only cut DNA of alleles that do not contain the intein or intron. Mutational analysis indicates that homing endonucleases will still cleave target DNA containing one or more mutations. In fact, very few specific positions within the recognition sequence are strictly required for DNA cleavage. This lack of complete sequence specificity is advantageous for enzymes that initiate mobility because individual, species, or genus variation would otherwise limit cleavage activity and mobility.

Inteins that encode PI-*Tli* II and PI- *Psp* I are inserted in the same position in their respective DNA polymerase genes. These enzymes are isoschizomers (different endonucleases that have the same recognition site). Inteins in the same site in extein homologues are intein **alleles** (19). Intein alleles can be transmitted horizontally as mobile genetic elements and are more closely related to each other than to nonallelic inteins. Not every individual in a species necessarily contains an intein identified in one member of that species (13, 22).

Although the mechanism of intein mobility has not been determined, it is considered analogous to intron mobility mediated by the dodecapeptide class of homing endonucleases (8, 9). Intein mobility is initiated when an extein allele that lacks the intein enters the cell during sexual **reproduction**, **conjugation**, **transduction**, **bacteriophage infection**, or **plasmid** transfer. The intein endonuclease activity cleaves the extein gene at the intein homing site, making a double-strand break. This double-strand break initiates very efficient **gene conversion** by the double-strand, break-repair pathway, and most extein genes acquire the intein.

0.3. The Mechanism of Protein Splicing

The mechanism of protein splicing in the *Psp* pol intein-1 was determined by using a combination of genetic, chemical, and biophysical techniques (16-18, 23, 24). Analysis of the *Sce* VMA intein confirmed this splicing pathway (25). The protein splicing pathway requires four nucleophilic attacks to complete the splicing reaction. The chemically important amino acids are the intein N-terminal residue, the intein C-terminal residue, and the downstream extein N-terminal residue (see

precursor protein in Fig. 1). The intein catalytic core is formed by bringing the conserved amino acids at the two splice junctions into proximity by properly folding the intein. Although the protein splicing mechanism was initially defined in the *Psp* pol intein-1 system with serine residues following both splice junctions, the mechanism applies equally well to inteins that have either Thr or Cys in these positions. The *Sce* VMA intein has cysteine after each splice junction. Ser, Thr, or Cys have similar side-chain groups (hydroxyl or thiol) and chemical properties. However, because of the differences in their nucleophilic properties and pK_a, there are slight differences in the reactions involving each of these residues.

The mechanism of protein splicing is presented in Fig. 2. The first step in the protein splicing pathway is a chemical rearrangement involving the intein N-terminal residue. This reaction is called an acyl or N-O shift (or rearrangement). If the residue is a Cys, it is called an acyl or N-S shift. The side-chain hydroxyl (or thiol) attacks the carbonyl (C=O) of the adjacent upstream amino acid. This nucleophilic attack results in cleavage of the peptide bond at the N-terminal splice junction and shifting of the N-extein onto the side chain of the intein N-terminus. Thus, the N-extein is connected to the remainder of the precursor by an ester (or thioester) bond. Acyl shifts involving Ser, Thr, or Cys are reversible, and the equilibrium strongly favors the peptide bond, not the ester form. However, the environment created by the intein catalytic core enhances formation of the ester. The second step in the splicing pathway is a transesterification reaction. The side-chain hydroxyl (or thiol) of the Ser (or Thr/Cys) at the downstream splice junction attacks the carbonyl at the upstream splice junction, resulting in cleavage of the upstream splice site and transfer of the N-extein to the side chain of the Ser (or Thr/Cys) at the downstream splice junction, forming the previously described slowly migrating branched protein intermediate. The third step in the splicing pathway is resolution of the branched intermediate by cyclization of the intein C-terminal Asn residue to form a succinimide ring, which results in cleavage of the downstream splice junction. This occurs when the side-chain amide nitrogen of Asn attacks the Asn main-chain carbonyl (C=O). The succinimide ring at the intein C-terminus is susceptible to hydrolysis to form Asn or isoasparagine (aspartic acid amide) (see also Deamidation). After removal of the intein, the N-extein is still linked to the side chain of the Ser (or Thr/Cys) at the downstream splice junction. This structure is identical to the ester form of Ser (or Thr/Cys) after an acyl shift. Once the intein is removed, this ester is no longer stabilized and, in Step 4, the Ser (or Thr/Cys) spontaneously undergoes an O-N (or S-N) acyl shift to form a native peptide bond between the exteins.

Figure 2. The chemical mechanism of protein splicing. The intein is depicted with a Ser residue following both splice junctions. It should be understood that the mechanism is essentially unchanged when a Thr or Cys is at either or both of these positions. Protein splicing involves four nucleophilic attacks. The first step is an N-O acyl shift at the intein N-terminus, followed by a transesterification reaction that results in forming the branched intermediate. The intein is cleaved from the branched intermediate by cyclization of the intein C-terminal Asn. The native peptide bond is formed between the two exteins after a spontaneous O-N shift. See text for further details. The residues involved in protonation and deprotonation reactions are not shown.

Mutagenetic data indicate that the penultimate His residue of the intein is required for branch resolution (succinimide formation) and thus may be involved in deprotonating the intein C-terminal Asn, directly or via a charge relay system. A few inteins lack this intein penultimate His (19, 26). Other residues in these inteins must assist the cyclization of the intein Asn. However, these residues do not necessarily have to be adjacent to the Asn in primary amino acid sequence, but they need only be correctly positioned in the three-dimensional structure of the enzyme. It has been proposed that the conserved His in Block B assists in the acyl shift at the N-terminal splice junction (20). The identification of all the residues involved in these nucleophilic attacks awaits further mutagenetic experiments and the determination of the crystal structure of a splicing precursor.

The splicing pathway is finely tuned and highly coordinated. Even conservative substitutions of the splice junction Ser, Thr, or Cys residues result in reduced or blocked splicing. When the splicing reaction is perturbed by conservative mutation or expression of the intein in unacceptable foreign protein contexts, the most commonly observed phenomenon is cleavage at one or both splice junctions in the absence of extein ligation. Extein ligation is the most sensitive step in the protein splicing pathway. C-terminal cleavage occurs when Asn cyclization predominates or precedes branch formation. N-terminal cleavage occurs when the upstream ester bond is hydrolyzed or attacked by other nucleophiles before branch formation. Intein N-terminal cleavage and autocleavage of several proteins, including glycosylasparaginase (27) and the hedgehog protein (28), proceed essentially by the same pathway and have an acyl shift resulting in ester (thioester) formation at a Ser, Thr, or Cys, followed by cleavage via nucleophilic attack on the resultant ester (or thioester).

0.4. Protein Splicing and Protein Engineering

Understanding the protein splicing pathway opens up avenues for protein engineering. For example, mutating the C-terminal splice junction Asn and Ser (or Thr/Cys) results in inteins that fail to splice but instead cleave the N-terminal splice junction. Likewise, mutating the intein N-terminus (Ser, Thr, or Cys) results in inteins that cleave only at their C-terminal splice junctions. A controllable N-terminal cleavage system for protein purification has been developed using the *Sce* VMA intein (25, 29). Furthermore, inteins may provide a new method for controlling expression of active proteins. The target protein is inactivated when an intein is present, but it can be activated by splicing the intein. One can imagine numerous methods for controlling splicing. For example, cold-sensitive mutants of the thermostable *Psp* pol intein-1 splice at temperatures over 30°C, but not below 30°C. Temperature-sensitive mutants of inteins from **mesophiles** splice at low temperatures but not higher. Removable blocking agents incorporated into essential junction residues prevent splicing until they are removed (30). Controllable splicing elements provide a means of expressing toxic proteins or making controllable knockouts. Finally, modified inteins provide a means of introducing electrophilic esters and thioesters into proteins, which then can be exploited to tag proteins with nucleophilic reagents (**fluorescent** labels, radioactive Cys residue, peptides) at their C-termini or as substrates for protein semisynthesis (31).

For proteins from
Protein Stability

Protein stability involves the ability of the native, folded protein structure to withstand the disruptive, denaturing influence of the external environment, its resistance to unfolding (see Proteins). This depends on the type of disruptive influence (eg, extremes of temperature, pressure, pH, or concentration of **denaturants**) and on the criteria for judging the nativeness of the folded conformation. The criteria might be a specific functional property of a given protein (eg, catalysis, **ligand binding**, etc.), a structural property (eg, light **absorption**, circular dichroism, NMR spectra, hydrodynamic volume), or a thermodynamic property (eg, **heat capacity**, **enthalpy**). However, when protein denaturation (unfolding) is a highly **cooperative** process (see Proteins), all of these changes occur simultaneously with variation of the denaturing conditions. In that case, the stability of a protein against any external factor can be specified by the value of the factor that induces 50% of the maximal change in the protein properties. These semiquantitative measures of protein tolerance to various factors have practical importance for specifying the range of external conditions in which that protein preserves its native structure and functions. However, it is not straightforward to compare tolerances against different denaturing factors. They must be correlated. For example, denaturation by temperature depends on the solvent conditions, particularly pH, and denaturation by pH depends on the temperature at which the experiment is carried out. Consequently, these half-denaturation values are not very informative in themselves for understanding the physical and energetic basis of the native protein structure.

With regard to energetics, it is much more useful to specify protein stability by the amount of work required to disrupt its native structure by any means, that is, to specify it as the Gibbs **free energy** difference between the unfolded (denatured) and the native states of the protein. This Gibbs free energy difference is a multidimensional function that depends on all the parameters which specify the external conditions. It can be determined through thermodynamic analysis of the processes of protein denaturation by varying one of the parameters and keeping the others fixed. It can be determined quantitatively, however, only if the unfolding process is reversible, complete, and highly **cooperative**, close to a two-state transition. Therefore, it can be used only for small globular proteins for which denaturation can be approximated by a two-state transition.

For large proteins, denaturation is usually not a two-state transition but proceeds in discrete steps corresponding to the unfolding of the individual structural **domains** present. Therefore, one has to specify thermodynamically the stability of each of the domains individually, plus any interactions between them. The latter might be stabilizing (positive cooperation) or destabilizing (negative cooperation) (1-3). Estimating of the mutual influence between domains requires determining of the stability of each domain with and without its neighboring domains or reversing of the sequence of domain unfolding by changing the environmental conditions.

Estimation of the Gibbs free energy difference between the native and denatured (unfolded) states is usually based on measuring the equilibrium constant K_{eq} between these states in the unfolding transition zone where both are populated, using any observable parameter sensitive to the state of the

protein, $Y(x)$, that depends on the variable parameter x that specifies the environmental condition, (eg, temperature, pressure, concentration of denaturant, etc.). For a two-state monomolecular transition

$$\Delta G(x) = -RT \ln K_{eq} = -RT \ln \left\{ \frac{Y(x) - Y_n}{Y_d - Y(x)} \right\}$$

where Y_n and Y_d are values of the parameter that characterizes the pure native and the pure denatured states, respectively (see Proteins). However, the main interest is not the value of D$G(x)$ in the denaturation transition zone, but the value under some standard conditions. Extrapolation of this function to the chosen standard condition is the main problem in measuring of protein stability. When protein stability is probed by varying the concentration of a denaturant (eg, urea or **guanidinium** chloride, GDMCl), the values of the DG function determined in the presence of rather high concentrations of denaturant have to be extrapolated to zero concentration (4). This is usually done by assuming that this function is linear, although this has no clear basis (see Proteins). When pressure is used to probe the stability of a protein, the values of D G obtained at the very high pressure at which the protein denatures have to be extrapolated to normal pressure. Again this is usually done by assuming that this functional dependence is linear (5) because not much is known about protein volume depending on pressure, which determines this function. Only in thermal denaturation and denaturation by pH can extrapolation to standard conditions be done reliably because the functional dependence of DG values on temperature and pH can be determined experimentally.

In thermal denaturation by a monomolecular, two-state transition, we can determine **calorimetrically** the **enthalpy** and the **entropy** of the transition over the entire temperature range in which the difference between the partial **heat capacities** of protein in the unfolded (denatured) and native states, $DC_p(T) = DC_p(T)^U - DC_p(T)^N$, is known (see Eqs. (10) and (11) in Proteins). Using these functions, we can determine the Gibbs free energy difference between the unfolded (denatured) and folded (native) states of protein at any temperature T in the temperature range considered (6-8):

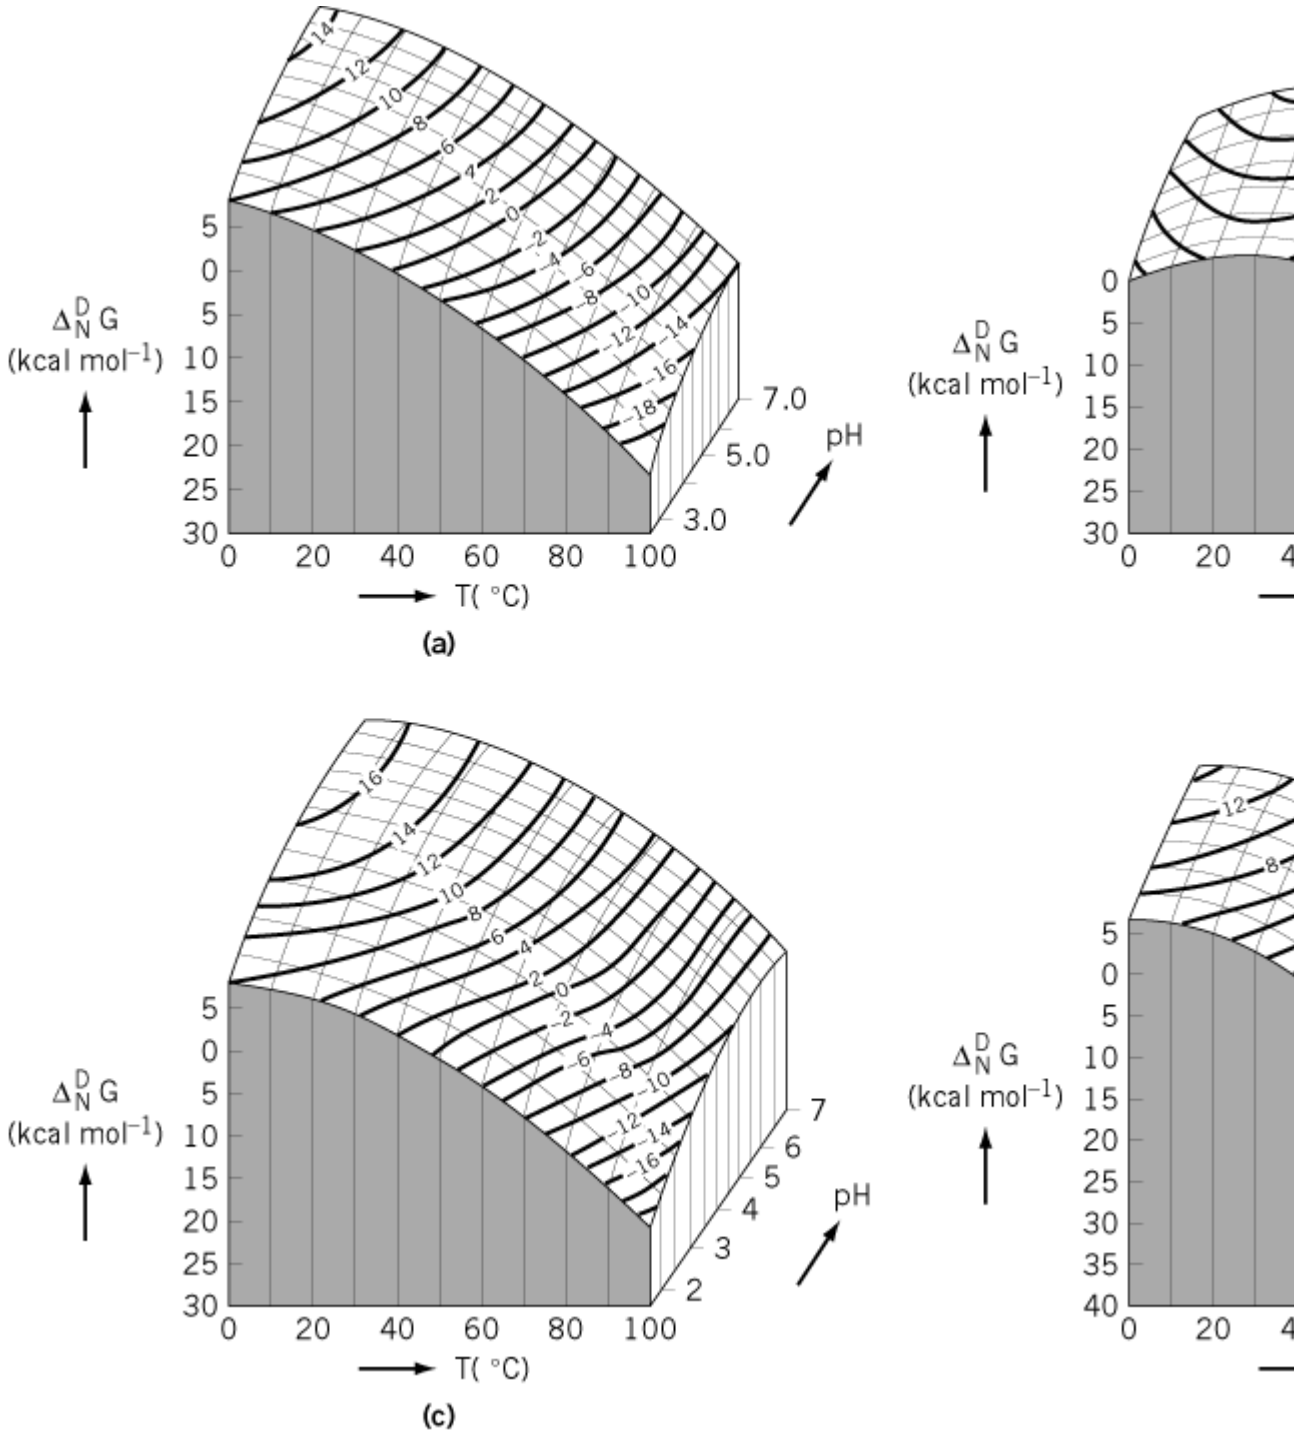
$$\Delta G(T)_{pH} = \Delta H(T)_{pH} - T\Delta S(T)_{pH} = \Delta H(T_t)_{pH} \frac{T_t - T}{T_t} + \int_{T_t}^{T} \Delta C_p(T) dT - T \int_{T_t}^{T} \frac{\Delta C_p(T)}{T} dT$$

In of pH denaturation, potentiometric titration of a protein at some fixed temperature T can be used to determine the difference between the Gibbs free energies of the unfolded and folded states as a function of pH (9):

$$\Delta G(pH)_T = 2.3RT \int_{pH_t}^{pH} \Delta\nu(pH) dpH$$

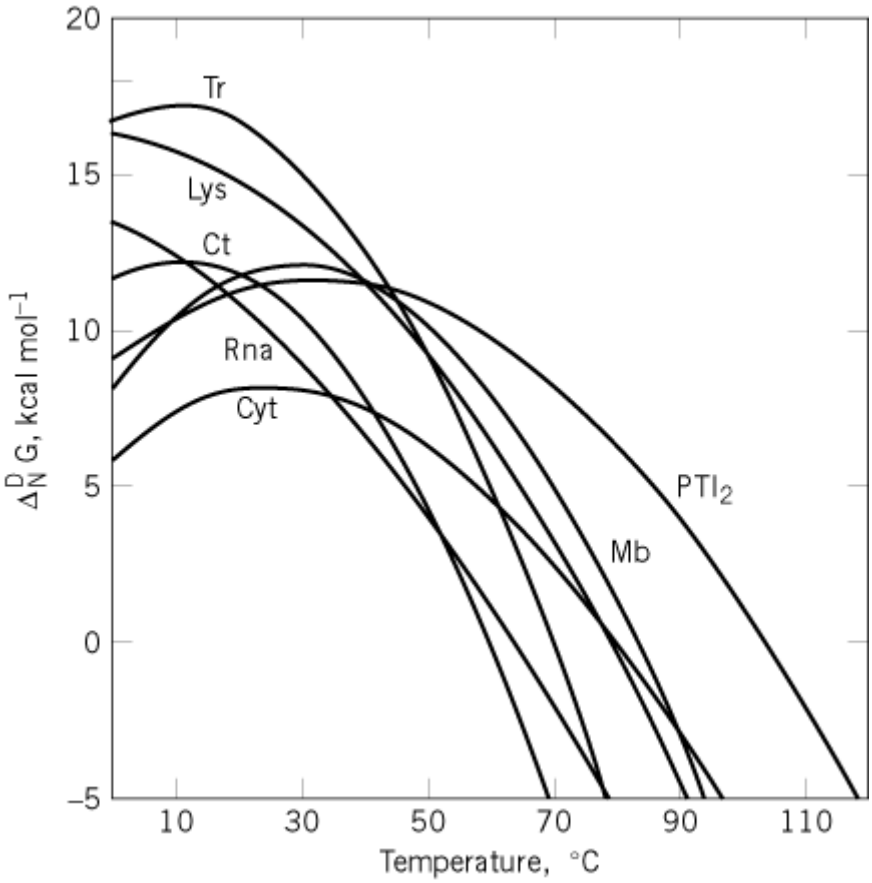
Combining both types of information (10), one can construct D$G(T, pH)$ functions for the protein (Fig. 1).

Figure 1. The Gibbs free energy difference between the unfolded and folded states of **(a) ribonuclease A**, **(b)** met-myog **chymotrypsin**, describing protein stability as a function of temperature and pH. Reproduced from Ref. 10.



The Gibbs free energy difference between the unfolded and the native states of a protein usually decreases in magnitude at acidic and alkaline pH values. It decreases at high temperatures because of the increased dissipative thermal motion, and it also decreases at low temperatures because of hydration effects (11-14). Because $(dDG/dT)T_{max} = -DS(T_{max}) = 0$ at T_{max}, the maximum stability of a protein is achieved at the temperature at which the entropy of unfolding is zero, and therefore the structure is stabilized enthalpically. For most **mesophilic** proteins this maximum takes place at temperatures close to physiological or lower (Fig. 2).

Figure 2. Temperature dependence of the molar unfolding Gibbs free energies of various single-domain globular proteins. Tr: bovine **trypsinogen**; Lys, hen lysozyme; Ct, bovine **chymotrypsinogen**; Rna, **ribonuclease A**; Cyt, cytochrome ***c***; Mb, met-myoglobin; PTI $_2$, BPTI, assumed to be dimeric. Reproduced from Ref. 11.



For proteins from **thermophiles**, which function at much higher temperatures (15), one can expect either a shift of the maximum of the Gibbs free energy of protein stabilization to the higher temperatures or a flattening of the Gibbs free energy function, that is spreading of its positive values over a broader temperature range, including those at which thermophiles function. The first requires increasing the enthalpic interactions that stabilize the native state. This is achieved by improved packing of the nonpolar groups in the protein interior or by a decrease of the configurational entropy of protein unfolding, which is achieved by **disulfide** cross-linking of the polypeptide chain. Flattening of the Gibbs free energy function requires decreasing the heat capacity increment of protein unfolding. This can be achieved by increased hydration of polar and charged groups upon protein unfolding, at the expense of nonpolar groups. Comparison of the structures of homologous proteins from mesophiles and thermophiles does not reveal significant differences in their packing densities (16-20). Because of the steep dependence of **van der Waals** interactions on distance, however, even the smallest change in packing density, beyond what can be resolved by X-ray crystallography could result in a significant increase of the van der Waals contribution to the stabilization of protein structure. Indirect evidence of a higher packing density of thermophiles is their lower rates of hydrogen exchange (17). On the other hand, comparative analysis of structures shows that proteins from thermophiles have more internal salt bridges (charged pairs) and hydrogen bonds than their mesophilic homologues (21-24). If so, hydration of the charged and polar groups upon protein unfolding should decrease the heat capacity increment of unfolding and thus flatten the Gibbs energy function that describes the temperature dependence of protein stability. Unfortunately we do not know much about the real Gibbs free energy function of proteins from thermophiles because these proteins unfold at too high temperatures, where the covalent structure becomes

modified. Consequently, the unfolding of these proteins is usually irreversible.

Determining of the contribution of the various factors to the stabilization of native protein structure is complicated by the fact that many factors contribute with opposite signs and with different dependence on temperature. The details of this balance and the contributions of various factors to the energetics of protein structure are still some of the most disputable subjects in protein science. The lack of experimental information on the magnitude of various contributions to protein energetics has led to a wide variety of opinions. During the past several decades, attention has swung between complete concentration on hydrogen bonding (25) and complete neglect of its role in stabilizing of compact native states. According to a current widely accepted point of view, the main driving force in polypeptide chain folding is the **hydrophobic** interaction, which is responsible for the low solubility of nonpolar liquids in water (26). However, the protein interior can hardly be regarded as a liquid phase, although if one considers it a crystal-like phase, it is more appropriate to describe its energetics by van der Waals interactions between tightly packed groups and by the hydration effects upon exposure of these groups to water (27). Estimates of these effects come from the data obtained by studying the transfer of model compounds from the gaseous phase into water. More recent analysis has led to the conclusion that the main contributors to the stabilizing of compact native protein structures are, first, hydrogen bonding and secondly, van der Waals interactions, and the hydration effects on nonpolar groups. These stabilizing interactions are opposed by the hydration of aromatic and polar groups and by the dissipative force of thermal motion, which is proportional to the increase in configurational entropy upon unfolding, $T\Delta S^{conf}$ (14). However, if the energy of hydrogen bonding between polar groups is combined with the hydration effects of these groups and the energy of van der Waals interactions between nonpolar groups is combined with the hydration effect on these groups, the overall contributions stabilizing the protein structure of polar groups (ie, hydrogen bonding) and of nonpolar groups (ie, hydrophobic effect) are almost of the same order of magnitude, and the stabilizing effects of both of them decrease with decreasing temperature (14). Therefore, both of these factors are responsible for the decrease of protein stability at low temperatures (cold denaturation ; see Proteins). As the charged groups are commonly exposed to the aqueous solvent and are surrounded by counterions, the electrostatic interactions between them cannot be of major importance for protein stabilization (26). However, internal salt bridges might play a role in protein stabilization because hydration of the individual groups upon unfolding should decrease the heat capacity increment of unfolding and thus flatten the Gibbs energy function. This might be the reason that more salt bridges are found in extremely thermostable proteins from thermophilic microorganisms (21-24). An essential factor stabilizing the native state of protein is also **disulfide** cross-linking, which significantly decreases the configurational entropy gain upon protein unfolding (28).

The maximum stability under conditions close to physiological does not differ much for different mesophilic proteins and is on the order of 30 to 60 kJ/mol for small globular proteins and for the cooperative structural units (**domains**) of multidomain proteins (14, 29, 30). Small proteins consist of about 100 amino acid residues, so it appears that each amino acid residue contributes on average about 0.5 kJ/mol to stabilizing the native state. This value is five times smaller than the energy of thermal motion at room temperature, $RT = 2.5$kJ/mol. This raises two questions: (1) why the native structure is stable at room temperature, and even higher; and (2) why protein stability is so low.

The formal answer to the first question is obvious. A native protein structure is stable only because all of its elements cooperate and it can unfold only cooperatively, that is its stability is determined by the combined contributions of all of the residues. Not much is known, however, about the mechanism of cooperativity. It is supposed only that specific tight packing of groups in the protein interior plays a significant role. As for the low contribution of each residue to the stabilizing the native structure and the low overall stability of this structure, perhaps they are needed because otherwise the polypeptide chain could not search for the proper native conformation during **protein folding** but would collapse into a compact aggregate, the molten globule (31).

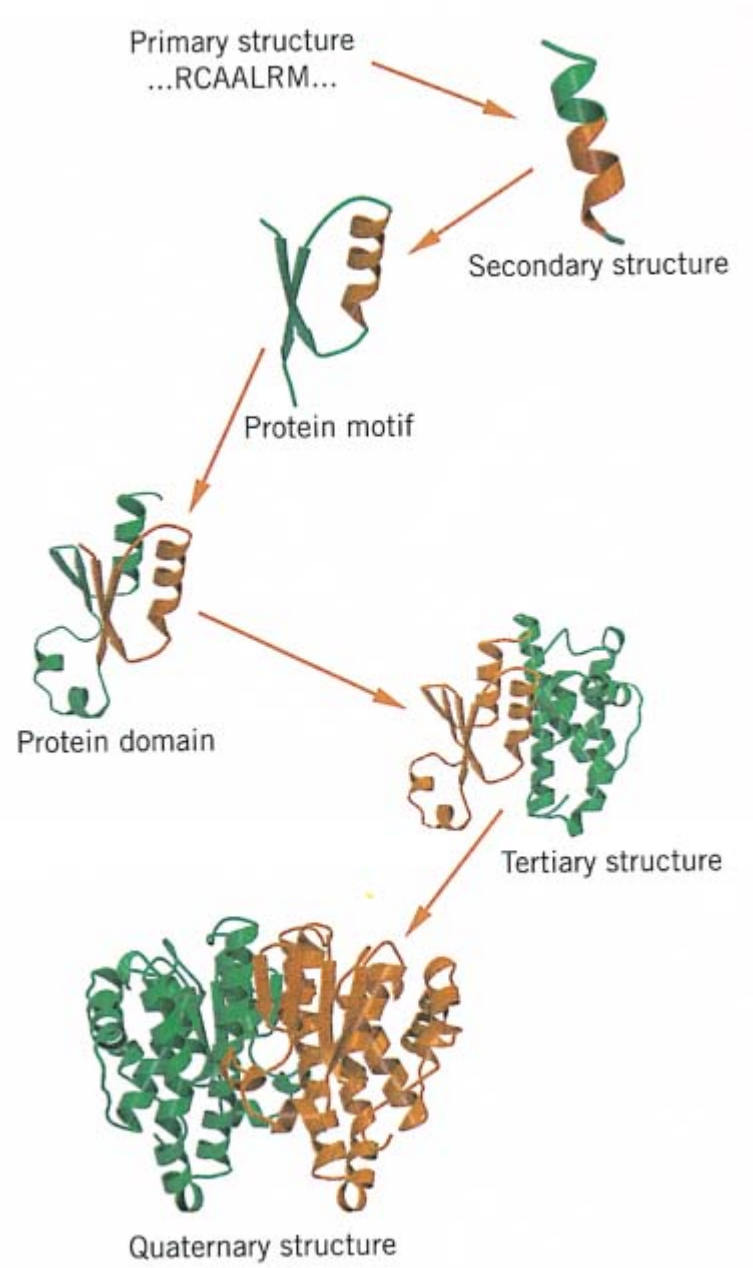
Protein Structure

The structures of proteins are the key to understanding both their function and evolution. Determination and analysis of the stable folded three-dimensional structures of proteins also provides the foundation for protein structure prediction from amino acid sequences, design of novel proteins with desirable catalytic functions, and design of new medicines with specific and selective therapeutic activities.

Proteins are biopolymers formed from amino acids linked together by peptide bonds into a polypeptide chain. They can consist of many thousands of atoms, and their structures are extremely complex. Protein structure has therefore been classified into different levels, beginning at the simplest level of primary structure on through **secondary structure**, **protein motifs**, **domains**, tertiary structure, and quaternary structure (Fig. 1).

Figure 1. Different levels of protein structure, from primary to quaternary, are shown using the structure of human p-class glutathione ***S*-transferase** as an example (6). In each succeeding level of protein structure, that portion corresponding to the preceding level is shown in orange. Helices are depicted as coils, and b-strands are depicted as arrows. The secondary structure example shown is an a-helix, and the protein motif is a bab motif (where b is a b-strand, a is an a-helix, and the motif produces a parallel b-sheet). The highlighted protein domain is a thioredoxin domain, and the green domain is an all-helical domain. The active enzyme is a homodimer, as shown in the quaternary structure. This figure was generated using Molscript (7) and Raster3D (8, 9).



The primary structure is the sequence, or order, of amino acid residues in the polypeptide chain. By convention, the sequence is numbered from the N-terminus to the C-terminus. The primary structure also includes information about the number of polypeptide chains in a protein and covalent modifications such as disulfide bond formation, **phosphorylation**, sulfation, N-glycosylation, and O-glycosylation.

The secondary structure of a protein refers to the **backbone conformation** of the polypeptide chain. There are several different types of secondary structure elements found in proteins including the a-helix, b-sheet, and loops and turns that reverse the direction of the polypeptide chain. In protein structures, linked secondary structure elements have preferred modes of packing together. These preferred packing arrangements of secondary structure units are called protein motifs or supersecondary structure. Examples of different types of protein motifs include the Greek key motif and the jelly roll motif.

The next level of protein structure is the protein domain, although there is some overlap between the structural levels of protein motif and protein domain. The protein domain (also referred to as a *protein fold* or *module*) usually consists of 50 to 150 amino acid residues and is considered to be the building block of protein structure, function, and evolution. In general, it is defined as that part of a protein's structure that can fold independently of the remainder of the protein. Individual domains within a protein structure usually have distinct functions, including catalytic, regulatory, binding, recognition or oligomerization roles. Examples of protein domains include the EGF motif and the Kringle domain.

The polypeptide chain of a protein folds into one or more domains; the tertiary structure describes the three-dimensional arrangement of these protein domains. Proteins can also incorporate one or more polypeptide chains, called *subunits*. The three-dimensional arrangement of these individual subunits, which may or may not have equivalent sequences and tertiary structures, is described by the quaternary structure of the protein.

Certain rules govern the structures adopted by proteins. For example, the side chains of most globular proteins are distributed in a nonrandom manner. Most **hydrophobic** residues are located in the inner core of the structure, and charged side chains are generally found on the surface. In addition, over 90% of amino acid residues are involved in secondary structure elements such as a-helices, b-strands, and turns. These rules can be used to assess the quality of experimentally determined structures and to assist and validate protein structure prediction. Three-dimensional structures of proteins can be determined experimentally by protein X-ray crystallography, **nuclear magnetic resonance** (NMR), or cryoelectron microscopy. Coordinates that describe the atomic structures of all published protein structures are deposited with the Brookhaven Protein Data Bank (PDB) (1) (see Structure Databases). The PDB is an extremely useful resource for searching, analyzing, and retrieving protein structure information. Databases that define different structural types of protein domains have also been developed (2-5).

Protein Structure Prediction

The goal of protein structure prediction is to infer the unique three-dimensional protein structure of any **protein** simply from its amino acid sequence, or primary structure. There are sufficient data available of known protein structures and sequences to test any prediction method, but the problem has not been solved in spite of many approaches attempted over the past thirty years.

The difficulty arises from two sources. The first is the extremely large number of conformations that a polypeptide chain may adopt, often called Levinthal's paradox (1). The ideal way to accomplish structural prediction would be to simulate the entire **protein folding** process on the computer. This is possible, in principle, because no unknown factors are involved in the *in vitro* folding process. Calculations to minimize the **free energy** of the conformation should be applicable, taking into consideration the various kinds of interactions within a protein molecule and between the protein and the surrounding medium, water. In fact, this type of computer simulation is effective for small-sized polypeptide chains, such as a peptide of 10 amino acid residues, but not for a protein of 100 residues. The difference between the calculations for a 10-residue peptide and a 100-residue protein is not a factor of 10 in magnitude, because it increases exponentially. The magnitudes of the two situations may be 2^{10} (about 10^3) versus 2^{100} (about 10^{30}), based on the very conservative assumption that every residue, on average, has two different choices of conformation. This vast increase in computational time makes the prediction impractical.

The second difficulty arises from the intrinsic nature of protein folding. Folding is a **cooperative** transition between the **denatured** and the folded states. Folding and unfolding are so cooperative that individual protein molecules remain in one of the two states at any instant without adopting intermediate conformations to any substantial extent. In forming the cooperatively folded structure, each part of the protein molecule is influenced by the entire structure and vice versa. Because of this complexity, there is no simple logical one-to-one correspondence between the sequence and the structure. A segment of polypeptide with a certain sequence may adopt an **alpha-helical** conformation in one protein, but a beta-strand in another. Therefore, the sequence/structure relationship is only probabilistic, rather than deterministic, making prediction difficult.

Several lines of approach to protein structural prediction have been developed thus far. The folding simulation approach has encountered the problem of the size effect described previuosly. This approach is important, however, because its success would also explain the mechanism of protein folding, which is one of the greatest enigmas of basic molecular biology. Another type of approach uses rules relating sequence and structure that are derived empirically from the known protein structures. After use for several decades, this approach is successful with **secondary structure prediction**, but it has not been able to address tertiary structures. Another, more recent approach is known as threading protein sequences. This approach is quite different in logic from the others. It assumes that the folded conformation is known and present in the structure databases and simply examines whether the new sequence is likely to fit any of these known structures. This threading method is an extension of the methods that search for homology between protein sequences (see Sequence Analysis) and therefore is more practical than the other methods (see Homological Modeling). In fact, several proteins of unknown structure have been successfully predicted by the threading method, which is an epoch-making event in the field of protein structure prediction. On the other hand, there is an inherent limitation to the method. It is impossible to predict any truly novel structures because it assumes that the structure is already known. Also, it would not be able to reveal the mechanism of protein folding because the logic behind the algorithm skips the entire process of folding and assumes the final structure in advance.

1. Ab initio Predictions

All of the approaches of structural prediction that do not require a known protein structure are lumped together as ***ab initio* methods** (from the Latin "from the beginning", or from the sequence). Considering the limitations of the threading procedure, it is still worth pursuing the development of *ab initio* methods, which would be applicable to any protein, including those of novel structure. Although this is a very difficult task, success of *ab initio* methods would also provide understanding of the mechanism of protein folding because any successful algorithm would have to incorporate the key factors of protein folding in it.

One of the earliest *ab initio* approaches to simulate the folding of a protein was that of Levitt (2), using BPTI. To reduce the computation time required even for this very small protein (58 residues), the geometry of the polypeptide chain was simplified, as were the atomic force fields employed to estimate the energy. Energy minimization drove the conformation of BPTI from an initial open structure to a folded, globular structure with the lowest energy. The final structure had some resemblance to the known native structure of BPTI. There was a root mean square (rms) deviation of 6 Å between the computed and known structures. Another line of approach is to attempt to pack the secondary structure elements, a-helices and b-sheets, into a globule using empirical rules (3) or posing general constraints (4). In these cases, it is assumed that the locations of all secondary structural elements along the chain are known in advance. If the algorithm works well, the combination with secondary structural prediction could provide a complete prediction scheme starting simply from the amino acid sequence.

More recently, a series of folding simulations on a lattice was intensively studied by Skolnick et al. (5). Lattice models require that each residue occupy only a point intersection on the lattice and adjacent residues in the sequence must be on adjacent lattice points. They have the advantage of dramatically reducing the number of possible conformations, actually digitizing them into countable objects. Lattice models mimic quite well the overall shape of a protein, but they are poor at mimicking the local structure properly. It is not difficult to imagine the difficulty of representing an a-helix on a cubic lattice. Using lattices more sophisticated and better suited for realistic protein models, however, the interactions between the various residues occupying neighboring lattice points can be defined to approximate the energy of the conformation. A method that simulates the entire folding process of large proteins, including one with a TIM barrel fold, has been developed (5, 6). This achievement was not claimed as a prediction because for some interactions specific to the native protein being studied were built in to the computations to guide the folding process in the right direction. If those few guiding potentials can be replaced by general potentials, such results could be called predictions.

After the advent of the threading approach, it should be possible to incorporate the fundamental idea of threading into an *ab initio* method. The difference between the two is not so great. If the backbone conformation were no longer fixed but were allowed to vary, the procedure would be converted from threading to *ab initio*. The trial by Jones (7) is one such example, in which partial, supersecondary structures are first threaded by a query sequence and then the threaded structures are combined into one as the starting conformation for refinement to a final, novel structure. A combination of the threading algorithm and the *ab initio* energy calculation seems to be a promising direction to be pursued because the efficiency of threading protein sequences has been verified. When *ab initio* predictions open the door to success, a new era of protein science will begin.

Protein Targeting, Intracellular

A central feature of the cell is the spatial separation of various biochemical reactions, due to the existence of separate areas containing specific sets of proteins. However, the protein composition of those areas may change due to import or export of proteins in response to extracellular or intracellular signals (eg, the binding of a soluble kinase to a membrane-bound receptor during signal transduction); some proteins may be directed to **proteolysis** [eg, targeting of cytoplasmic proteins for in lysosomes degradation (1)]; and new proteins must be translocated from their site of synthesis into the correct area in order to maintain its protein composition. Therefore, cells need a controlled exchange of proteins between the different areas. This entry will concentrate on one aspect, the intracellular protein transport between cellular compartments, emphasizing the fate of newly synthesized proteins that are exported from the cytoplasm.

Cellular compartmentalization is achieved by the separation of hydrophilic areas with the help of **hydrophobic** membranes. Typical compartments are (a) the cytoplasm, (b) the extracellular space, (c) organelles, like the nucleus or the peroxisome, or (d) parts of organelles, like the different stacks of the Golgi apparatus . The most simple form of compartmentalization is found in many prokaryotes, where the only membrane present is the plasma membrane, which constitutes the borderline between the interior and the exterior of the cell. In eukaryotes, this compartmentalization is more complex, due to the existence of the various membrane-surrounded cellular organelles. Moreover, the surface of several eukaryotic cell types may also be subdivided. In epithelial cells, for example, the plasma membrane and the adjoining extracellular space of the apical and basolateral surfaces differ considerably in their protein composition.

Because **protein biosynthesis** is restricted to only very few compartments—the cytoplasm of prokaryotes and eukaryotes, the matrix of mitochondria, and the stroma of plastids (see Chloroplast)—all proteins that perform their function in other compartments must be transported into them. In addition, proteins may get relocalized from one compartment to another one in order to regulate their function—for example, the shuttling of transcription factors between nucleoplasm and cytoplasm, or the internalization of receptor proteins from the plasma membrane into endosomes. Proteins synthesized in the cytoplasm are targeted to all other compartments of the cell or leave the cell completely (protein secretion). Often the proteins do not enter their final compartment directly from the cytoplasm but have to cross other compartments to reach their destination (see text below). Therefore, the transport of proteins synthesized in the cytoplasm may be divided into the following major steps: the targeting of the protein from the cytoplasm to the correct translocation sites of an adjoining compartment; the direct transfer of the protein from the cytoplasm into this compartment; and, if desired, the sorting to the final compartment.

The signals determining the intracellular transport pathway of proteins are encoded in their primary structures. Proteins that reach their final compartment *in transit* have usually two types of transport signals: One encodes for the translocation site that is used to leave the cytoplasm, and a second one triggers further sorting to the final compartment. Moreover, membrane proteins need additional signals triggering their integration into the lipid bilayer (2) and determining their orientation within the membrane (3, 4). The same region of one protein may bear two signals. For example, several

membrane proteins have signal-anchor sequences that function as a signal sequence and as a membrane anchor (5).

Signals may be short defined clusters of amino acids, like the peroxisomal targeting signal 1 (PTS1) (6). Other signals may cover longer regions of the protein, containing more variable sequences that are characterized by more general features—for example, the signal peptide involved in transport to the endoplasmic reticulum (ER), the leader peptide of prokaryotic secretory proteins, the mitochondrial targeting sequences, or the plastid targeting sequences (7, 8). But a modification of a protein may also serve as a signal. For example, lysosomal proteins bear special sugar modifications as sorting signals (9), and some plasma membrane proteins are directed to the apical plasma membrane due to the presence of a post-translational lipid modification, the GPI anchor (10). In the end, even here the primary structure of the protein is decisive, because it determines if this modification may occur (11, 12).

1. Targeting

The synthesis of proteins exported from the cytoplasm starts on free ribosomes, regardless of whether the transport occurs post-translationally or co-translationally. Therefore, the first step during the export of a newly synthesized protein from the cytoplasm is directing it to the correct translocation site. Although this is always triggered by specific protein-coded signals, there may be signals within the messenger RNA of exported proteins, leading to concentration of the mRNA near the appropriate translocation sites and facilitating the targeting process (13).

With the exception of cyanobacteria, prokaryotic cells have only the plasma membrane in contact with the cytoplasm. Nevertheless, these cells may have several protein export pathways that use different types of translocation sites and targeting signals (14-18) (see Table 1). Although eukaryotic cells contain many compartments adjoining the cytoplasm, the bulk of protein export occurs across membranes of only a few organelles—the ER membrane, the outer membrane of mitochondria (or plastids), the nuclear envelope, and perhaps the peroxisomal membrane (see Table 1). Secretory proteins, plasma membrane proteins, and proteins destined to compartments of organelles forming the so-called secretory pathway (Golgi apparatus, endosomes, transport and storage vesicles or lysosomes/vacuoles) are usually first translocated into the ER. However, a few secretory proteins and some proteins of the yeast vacuole are transported directly across the plasma membrane (19) or the vacuolar membrane (20), respectively.

Table 1. Pathways of the Intracellular Protein Transport of Newly Synthesized Proteins[a]

Synthesizing Compartment	Exit Membrane	Type of Translocation Site	Targets
Prokaryotic cytoplasm	Plasma membrane	SecY-complex	Inner membrane space, plasma membrane, outermembrane extracellular space
		ABC-type transporter (Type I secretion) (eg,secretion of hemolysin)	Inner membrane space, extracellular space

		Contact-dependent secretion system (Type IIIsecretion), (eg, transport of YpkA Ser/Thr kinase)	Extracellular space (plasma membrane and cytoplasmof eukaryotic host)
		Unknown (Sec-independent secretion of TMAO reductase)	Inner membrane, inner membrane space, extracellularspace
	Thylakoid membrane of cyanobacteria	SecY complex	Lumen and membrane
Eukaryotic cytoplasm	Nuclear membrane	Nuclear pore	Compartments of the nucleus
	ER membrane	Sec61 complex	Extracellular space, plasma membrane, compartmentsof the secretory pathway (Golgi apparatus, lysosomes/vacuoles, endosomes,transport vesicle, storage vesicles)
	Outer mitochondrial membrane	TOM complex and TIM complex	Outer membrane, inner membrane, inner membranespace and matrix of mitochondria
	Outer plastid membrane	TOC complex and TIC complex	Outer envelope, inner envelope, inner membranespace, stroma, and thylakoids of plastids
	Peroxisomal membrane?	Unknown	Peroxisome
	Plasma membrane	ABC-type transporter (eg, secretion of a-factor)	Extracellular space
		Unknown (eg, secretion of basic fibroblast growthfactor)	Extracellular space

	Unknown	Unknown (eg, aminopeptidase I transport)	Vacuolar lumen (yeast)
Mitochondrial matrix	Inner membrane	Unknown	Inner membrane
Stroma of plastids	Inner envelope	Unknown	Inner envelope
	Thylakoid membrane	SecY	Thylakoids
		Unknown (eg, pH-dependent import of 23-kDa proteinof PSII)	Thylakoids

[a] ABC, ATP-binding cassette; TOM, translocase-of-the-outer-membrane; TIM, translocase-of-the-inner-membrane; TOC, translocase of the outer chloroplast envelope; TIC, translocase of the inner chloroplast envelope; PSII, photosystem II. For some pathways, typical substrates are included. The table does not cover pathways exclusively involved in the insertion of membrane anchors.

In some pathways, correct targeting requires recognition of the protein-coded signal by a specific cytoplasmic receptor. One example is the co-translational transport of proteins across the ER membrane. In this case, targeting starts as soon as the signal sequence that is responsible for the targeting of the nascent chain has left the ribosome. Briefly, the signal sequence is recognized by its cytoplasmic receptor, the signal recognition particle or SRP, which also binds to the ribosome (21, 22). The SRP-ribosome-nascent chain complex is then transported to the translocation sites in the ER. Here the interaction between SRP and its membrane-bound receptor triggers release of the signal sequence (23), which is then recognized by its membrane receptor, a step which is essential for the following transport across the membrane (24). Another example is the post-translational import of nuclear proteins. Specific cytoplasmic factors have been discovered that bind the targeting signals of distinct proteins and carry them through the nuclear pores, finally releasing those proteins into the nucleoplasm. Examples are the importin complex, which recognizes the “classical” basic nuclear localization sequence (25), and transportin, which interacts with nuclear import signals of the M9-type (26). Some mitochondrial proteins are also imported using a specific targeting factor: the mitochondrial import stimulating factor (MSF), which recognizes the respective targeting signal (27) and triggers the binding of the substrate to the Tom70/Tom37 receptors at the translocation sites of the outer membrane (28). For most of the targeting pathways, however, specific cytoplasmic factors are still missing. It may be that in these cases the signals are recognized only directly at the membranes by their corresponding receptors at the translocation sites [eg, Sec61 at the ER (24), the Tom20/Tom22 (29) at the mitochondria, or the various peroxisomal targeting sequence receptors at the peroxisomes (30)]. This recognition might be supported by general molecular chaperones, like cytosolic Hsp70 (31-33), keeping the proteins in a loosely folded state and helping to present the targeting signal to the environment (see BiP (Hsp70)).

2. Transport at the Translocation Site

In the co-translational mode of translocation, the nascent chain is crossing the membrane in an extended conformation due to the tight binding of the ribosome to the ER translocation site (34). But in many post-translational pathways also, translocation of proteins across the membrane requires the substrate to adopt a more or less unfolded conformation. This is observed during mitochondrial

import (35), transport across the ER (36), SecA-dependent transport across bacterial membranes (37), and the import into plastids (38) (39). It should be noted that some proteins may be transported across the plastid envelope in a nonextended conformation (40). As far as is presently known, these translocation sites consist of membrane–protein complexes (translocases) that often form channel-like structures (39) (41-44). These translocases allow the transport of hydrophilic proteins across the hydrophobic membrane bilayer and may also trigger the integration of hydrophobic membrane anchors of membrane-spanning proteins into the bilayer (45, 46). For this purpose, their structures must be very dynamic. For example, in the case of the ER translocation site, it was found that the channel opens both perpendicularly to the membrane, to allow the transfer between cytoplasm and lumen (47), and laterally, to allow the transfer of membrane anchors from the channel into the bilayer (48). Moreover, although these channels allow the signal-dependent transport of relatively large hydrophilic molecules, they are tight enough to prevent uncontrolled ion fluxes between the compartments. In mitochondria and plastids, the translocation sites may even traverse both the outer and inner membranes of the organelle, allowing a direct delivery of cytoplasmic proteins to the inner membrane and the matrix or stroma of the organelle. In mitochondria, these two membrane-spanning structures are formed due to the dynamic interaction of the translocase-of-the-outer-membrane (TOM) complex with the translocase-of-the-inner-membrane (TIM) complex (49, 50) (see Table 1). Nevertheless, the TOM complex may also function independently from the TIM complex during protein transport to the outer membrane or the inner membrane space (51). A similar situation may exist within the two membranes of the chloroplast envelope (52). During or shortly after translocation, the proteins are folded. In the ER, in mitochondria, in plastids, and in the periplasmic space of certain bacteria, various chaperones exist that assist the folding of proteins that traversed the membrane in an extended conformation and. Some of these chaperons also are involved in the directionality of the post-translational transport across the membrane. Examples are Kar2p, which is involved in protein import into the ER lumen (36, 53) (see Disulfide Bonds), and mitochondrial Hsp70, which is essential for the import into the mitochondrial matrix (54). Folding is accompanied by **post-translational** modifications, like the removal of amino-terminal targeting signals (55, 56), the formation of disulfide bonds, or N-glycosylation. In the case of the transport into the ER, the modifying enzymes may be part of the translocation site (OST, signal peptidase).

Correct functioning of the folding and modification machinery is in many cases a prerequisite for further transport of proteins. In mitochondria and plastids, the chaperones present in the matrix and the stroma, respectively, have to guarantee that proteins that must cross further membranes (see below) are kept in a translocation-competent form (57). Incorrect folding/modification of proteins leaving the ER may lead to their retention in the ER, often followed by their **protein degradation** (58). Correct modification in the ER may also be essential to create the signals for further sorting (eg, GPI anchor, or mannose 6-phosphate modification).

In various pathways, proteins leave the cytoplasm in a more or less completely folded state. The translocation site used for the transport of proteins into the nucleus is also a hydrophilic proteinaceous channel, the **nuclear pore**. However, it is far larger than the channels mentioned above, and it allows the unregulated exchange of molecules of up to 60 kDa between nucleoplasm and cytoplasm (59). For other export pathways that probably also transport folded proteins (the transport into peroxisomes, the direct transport of proteins into yeast vacuoles, and the **Sec**-independent transport of bacterial proteins across the plasma membrane) the translocation site is unknown. Delivery of proteins to the yeast vacuole may not rely on the transport across a hydrophobic bilayer through channel-like structures, but on vesicle-mediated processes similar to those found during autophagy (61). In the case of import into peroxisomes, very complex pathways are presently being discussed, including ER-dependent steps and vesicle-mediated processes (62).

3. Sorting to the Final Compartment

Sorting of proteins from the ER to their final compartment employs a system of vesicular budding and fusion, without any further membrane-crossing steps (63). This vesicular flow mediates a specific and controlled transport of substances between the different organelles, including the plasma

membrane. Proteins that end up in the compartments of other organelles of the secretory pathway, as well as proteins that stay in the ER, need a sorting signal. Secretory proteins and plasma membrane proteins may reach their destination by default (64), but many of them rely on specific sorting signals too (eg, proteins of the apical plasma membrane or secretory proteins that are subject of regulated secretion) (65). The signals may code for a true retention in the target compartment (eg, signals involved in the so-called kin-recognition of the membrane proteins of the Golgi apparatus), or they may trigger the packaging of proteins into specific transport vesicles. Sorting may result in forward transport along the secretory pathway, or it may lead to a retrieval of proteins that left their "final" compartment accidentally. For example, a carboxy-terminal located KDEL sequence (-Lys-Asp-Glu-Leu) guides soluble proteins back from the *cis*-Golgi to the ER (66). There is still not much known about how the packaging into the transport vesicles occurs. Well-studied examples are membrane proteins containing signals in the cytoplasmic portion of the protein—for example, the KKXX-motif (Lys-Lys-X-X) of ER-proteins (67) or the di-leucine-containting motif of endosomal proteins (68). These signals may be recognized by components of the cytoplasmic coat of transport vesicles (69, 70). Since the assembly of the coat is essential for the budding of these vesicles, this interaction triggers the inclusion of the membrane proteins into these vesicles (see Membrane Anchors). Soluble proteins or membrane proteins that have the sorting signal located in the lumen of the organelle may be recognized by membrane receptors [eg, the KDEL receptor (71) or the **mannose 6-phosphate receptors** (72)]. These receptors in turn contain signals that trigger their sorting, together with the bound ligand, into the correct transport vesicle (73). In some cases, the membrane anchors of proteins define the final compartment [eg, some membrane proteins of the Golgi apparatus (74, 75) (see GPI Anchor)], probably due to their tendency to partition preferentially into a specific lipid environment. Similar mechanisms are discussed for the sorting of membrane proteins with GPI anchors.

Some mitochondrial and plastid proteins that left the translocation sites and reached the matrix or stroma, respectively, are also subject to sorting events, such as proteins destined for the chloroplast thylakoids, the inner envelope membrane of chloroplasts (76), or the mitochondrial inner membrane (57) (conservative sorting). In contrast to what is known about the secretory pathway, this additional sorting includes a second step of crossing a membrane. Both mitochondria and chloroplasts are descendants of formerly free-living bacteria according to the endosymbiont hypothesis. Therefore, matrix and stroma are homologous to the bacterial cytoplasm, and the inner membranes and thylakoid membrane are homologous to the plasma membrane, respectively. Signals triggering the export of proteins from the mitochondrial matrix or the plastid stroma are similar to the bacterial leader sequences that trigger the secretion of prokaryotic proteins (77, 78). They are removed by a **proteinase** that is **homologous** to the bacterial leader peptidase (79, 80). Even more striking, translocation of proteins from the stroma into the thylakoids occurs via translocation sites, containing membrane proteins homologous to those engaged in the protein export from the bacterial cytoplasm (81, 82) (see Table 1).

Protein-DNA Recognition

The binding of a protein to a specific DNA sequence is largely dependent on two types of interaction. The principal basis for sequence selectivity is direct contact between the polypeptide chain and the exposed edges of the base pairs, primarily in the major groove of B-DNA. These contacts may involve either hydrogen bonds or van der Waals interactions. Small molecules, such as water molecules, which are tightly and rigidly bound to a protein and are thus integral components of

the **macromolecular** structure, may also participate in these interactions and so provide binding specificity to the protein by proxy. These direct interactions are supplemented by the sequence-dependent bendability or deformability of DNA which limits the energetically favorable conformations of a particular binding site, and thereby, imposes additional sequence-dependent constraints on the binding affinity. Relative to direct contacts to the base pairs, this is a second-order effect which modulates the affinity for the whole binding site.

The binding energy available from direct interactions with the base pairs, although significant, is not in general sufficient by itself to allow the formation of a stably bound complex for binding sites of average length (6–15 bp). The required additional binding energy may be provided by direct electrostatic interactions between basic amino acid residues and the negatively charged sugar-phosphate backbone. The spatial constraints imposed by this type of interaction may also serve to constrain the configuration of the DNA when bound to protein. It is the difference between the binding energies for the sequence-dependent and sequence-independent components of the interaction that is the measure of the sequence selectivity of a DNA-binding protein.

In many DNA-protein complexes, the DNA is substantially bent. This is achieved by a variety of mechanisms, notably the induction of bends by spatial constraint on a rigid protein surface (the histone octamer, FIS), the insertion of hydrophobic residues between adjacent bases in the DNA duplex (HMG domain proteins, TBP, lac repressor) and charge neutralization on one face of the double helix (histone octamer, CAP).

Typically a DNA sequence recognition motif recognizes a sequence of 3–4 bp. This is insufficient to allow highly selective discrimination among all sequences in a genome. In practice the effective site size for recognition can be increased by use of a larger protein assembly. This assembly is often a stable dimer (as in helix-turn-helix and bZip proteins). However, in other cases cooperative interactions between proteins bound at contiguous or distant DNA sites are required for the formation of an assembly. One example of such interactions is the cooperative binding of l C_I repressor dimers to the leftward and rightward operators in l DNA, each of which contains three C_I binding sites. Because stable binding to any two of these sites is dependent on interaction between separate dimers, occupation is sensitive to small changes in concentration of repressor molecules over a certain range. Interactions can also occur between distant binding sites on the DNA such that simultaneous occupation generates a loop of intervening DNA. Loop formation of this type need only require a single stable protein assembly (as in the case of the tetramer of the *lac* repressor containing four helix-loop-helix motifs) or may require cooperative interactions between proteins bound at the separate sites (as have been postulated for interactions between eukaryotic enhancer and promoter elements).

Protein–Protein Interactions

Noncovalent protein-protein interactions are ubiquitous in cells and living organisms. They are the basis for building every biological structure, from the nanometer scale of the molecule to the micrometer scale of the whole cell, and above. In the nucleus, the nucleosome that holds eukaryotic **DNA** in a compact form, and the machinery that **replicates** and **transcribes** it, are noncovalent protein-protein complexes. In the cell membrane, the **channels**, **pumps** and energy-producing systems are assemblies of proteins held together by noncovalent forces. So are the coats of **viruses** and the fibers of muscles. These particular assemblies are permanent and made of **polypeptide chains** that, under normal conditions, are found only as complexes. Such permanent interactions often occur concomitantly with folding of the individual subunits. Other protein–protein interactions

are readily reversible and require preformed partners to meet and recognize each other. The quaternary structure of oligomeric proteins is an example of a permanent interaction, whereas antibody recognition of a native protein antigen is an example of folding and association as two separate steps. The noncovalent forces involved are the same in the two cases, and the many intermediate situations of all kinds make the distinction between permanent and nonpermanent assembly somewhat arbitrary. Nevertheless, oligomeric proteins are dealt with in a separate entry, and here we concentrate on the pairwise and reversible recognition of preformed proteins in solution, a simple example of a protein–protein interaction. In this particular case, the crucial concepts of **affinity** and specificity can be given a structural and a **thermodynamic** basis, and we may trust that the rules that apply here will also apply to more elaborate multi-component assemblies.

1. Detecting Protein–Protein Interactions

It is often possible to detect the interaction of two proteins initially by genetic methods. Suppressor mutations are indicators of a protein–protein interaction. If a suppressor mutation occurs in a gene other than that containing the original defect, it may be that the two gene products form a functional complex. The first mutation destabilizes the interaction; the second compensates and restores it. Dominant-negative mutations are another indicator; in heterozygous cells in which normal and mutant polypeptide chains are expressed, the two **alleles** can interact—if the mutant chains form an inactive assembly with the wild type chains, this will lead to a negative **phenotype**. On the other hand, there are alternative explanations for both suppressor and dominant-negative mutations, and neither interpretation is general. In contrast, the very popular yeast two-hybrid system was specifically designed for detecting *in vivo* partner proteins. The test relies on the observation that transcriptional activator proteins in **eukaryotes** often consist of two independent folding units, a DNA-binding domain and a transcription-activation domain, that must be part of the same molecular assembly but need not be covalently bonded. To detect an interaction between proteins A and B, a genetic construction is prepared in which A is linked to the DNA-binding domain and B, to the activation domain. If A and B form a stable complex in the cell, the two transcriptional activator domains will be brought together, and transcriptional activation of a reporter gene will be detected. In a commonly used construction, the A gene fused to the sequence coding for the DNA-binding domain of the *Escherichia coli* LexA repressor. Then, a gene library is used to fuse a large number of unknown B proteins to the activation domain of the yeast Gal4 activator. Yeast colonies that express the reporter gene under LexA regulation contain hybrid genes for proteins that interact with A *in vivo*, and they can be isolated and characterized further. The method requires the two hybrid genes to be expressed, produce proteins that fold and enter the nucleus, and interact in a way that brings the DNA-binding domains and activation domains into the appropriate proximity; thus it has a high incidence of false negatives. Nevertheless, it is so simple and powerful that it is possible in principle to search for pairwise interactions between all proteins encoded in the *Saccharomyces cerevisiae* genome.

In contrast to the genetic approach, biochemical methods require the purification of at least one of the partners of the putative complex. Once purified, partner A can be chemically coupled to activated agarose or another matrix support. The derivatized matrix is then used to isolate interacting proteins from cell extracts by affinity chromatography. Alternatively, antibodies prepared against the purified protein, preferably monoclonal antibodies, can be used to precipitate it, together with any protein it binds to. Such coimmunoprecipitation has many successes to its credit, for example, isolation of the **retinoblastoma** protein from precipitates obtained with antibodies against a protein from adenovirus. In this case, false positives are common, and an interaction that is detected may involve several partners, rather than being direct. Further characterization requires the identification of all the major components in the coprecipitate, and eventually their purification to homogeneity, opening the way to a detailed structural and functional analysis.

2. Affinity and Stoichiometry of Protein–Protein Complexes

Two parameters characterize protein–protein interaction at equilibrium: the stoichiometry and the

affinity of the partners for each other. The one-to-one association reaction of two components A and B may be written as follows:

$$A + B \underset{k_d}{\overset{k_a}{\rightleftharpoons}} AB \tag{1}$$

where k_a is the rate constant for the bimolecular association reaction and k_d is that for the monomolecular dissociation. Their ratio is equal to either K_a, the **association constant**, or K_d, the **dissociation constant**. This is related to the concentrations of A, B, and AB at thermodynamic equilibrium by the law of mass action:

$$\frac{[A][B]}{[AB]} = \frac{1}{K_a} = K_d = \frac{k_d}{k_a} \tag{2}$$

where K_d has the dimension of concentration. Its value determines the stability of the complex AB at equilibrium; therefore, it is a measure of the affinity of the two components for each other. If x = [A], the equilibrium concentration of free A, and y = [AB], the concentration of bound A, Equation (2) can be written

$$\frac{y}{x} = \frac{[B]}{K_d}$$

Assuming B to be in excess over A, a high affinity implies that most of A is in the bound state. In other words, the y/x ratio is large, and therefore K_d must be small relative to [B]. Affinity is essentially a relative concept, not an intrinsic property, as is often assumed. For a hormone receptor, a ligand with a K_d of 1 μM can be considered to have low affinity and unlikely to be physiologically relevant, because hormone concentrations are usually much less than micromolar. Yet, this is approximately the K_d value for the dissociation of human hemoglobin into ab dimers when oxygen is bound, which is usually considered a stable complex. In red blood cells, the hemoglobin concentration is well above millimolar, and oxyhemoglobin remains a tetramer, whereas it would readily dissociate in a dilute solution.

Determination of the dissociation constant and of the stoichiometry of reaction is an important step in the study of protein–protein interaction. It relies on measuring the equilibrium concentrations of the complex and its components. This generally requires having pure proteins and a means to detect their association at concentrations of the order of the dissociation constant. When K_d is micromolar or greater, a wide range of physical and chemical methods are available, among which fluorescence quenching, sedimentation equilibrium centrifugation, and **microcalorimetry** may be cited. The data may be obtained by titrating a fixed concentration of component B with increasing concentrations of component A. They are analyzed by drawing the binding isotherm, which relates the concentration y of bound A to that of the free species x:

$$y = [B_0]\frac{x}{x + K_d} \tag{3}$$

Here, $[B_0]$ is the total concentration of B, or more appropriately, the total concentration of binding sites on B. Equation 3 is derived from the law of mass action (Eq. 2) by noting that $[B_0] = [B]+[AB]$. It can be rearranged to yield a linear Scatchard Plotin which y/x is plotted against y:

$$\frac{y}{x} = \frac{1}{K_d}([B_0] - y) \tag{4}$$

The Scatchard plot has slope $-1/K_d$ and intersects the horizontal axis at $y = [B_0]$, from which the stoichiometry may be derived.

When K_d is much less than micromolar, more sensitive detection methods are needed. Binding isotherms may be obtained by **radiolabeling** one of the components, or by indirect titration with antibodies. However, these methods are also inadequate when K_d is in the subnanomolar range. For such very tight complexes, kinetic measurements are a useful alternative to equilibrium methods; the two rate constants in Equation (2) are measured directly, and the dissociation constant is derived as their ratio. This particular relationship between rate and equilibrium constants is valid only if the reaction mechanism is that of Equation (1). More elaborate mechanisms are possible, including mono-molecular steps that precede or follow the bimolecular association step. These may in principle be detected in kinetic experiments by exploring the concentration dependence of the rate of the reaction and analyzing its departure from second-order kinetics.

Assuming Equation (1) to be a valid approximation, the two rate constants can be measured in the same or in separate experiments. Mixing experiments yield k_a: B is added in excess to A, and pseudo-first-order association kinetics are measured. They should follow a single exponential curve with a concentration-dependent relaxation rate $1/q_a$:

$$\frac{1}{\tau_a} = k_a[B] + k_d$$

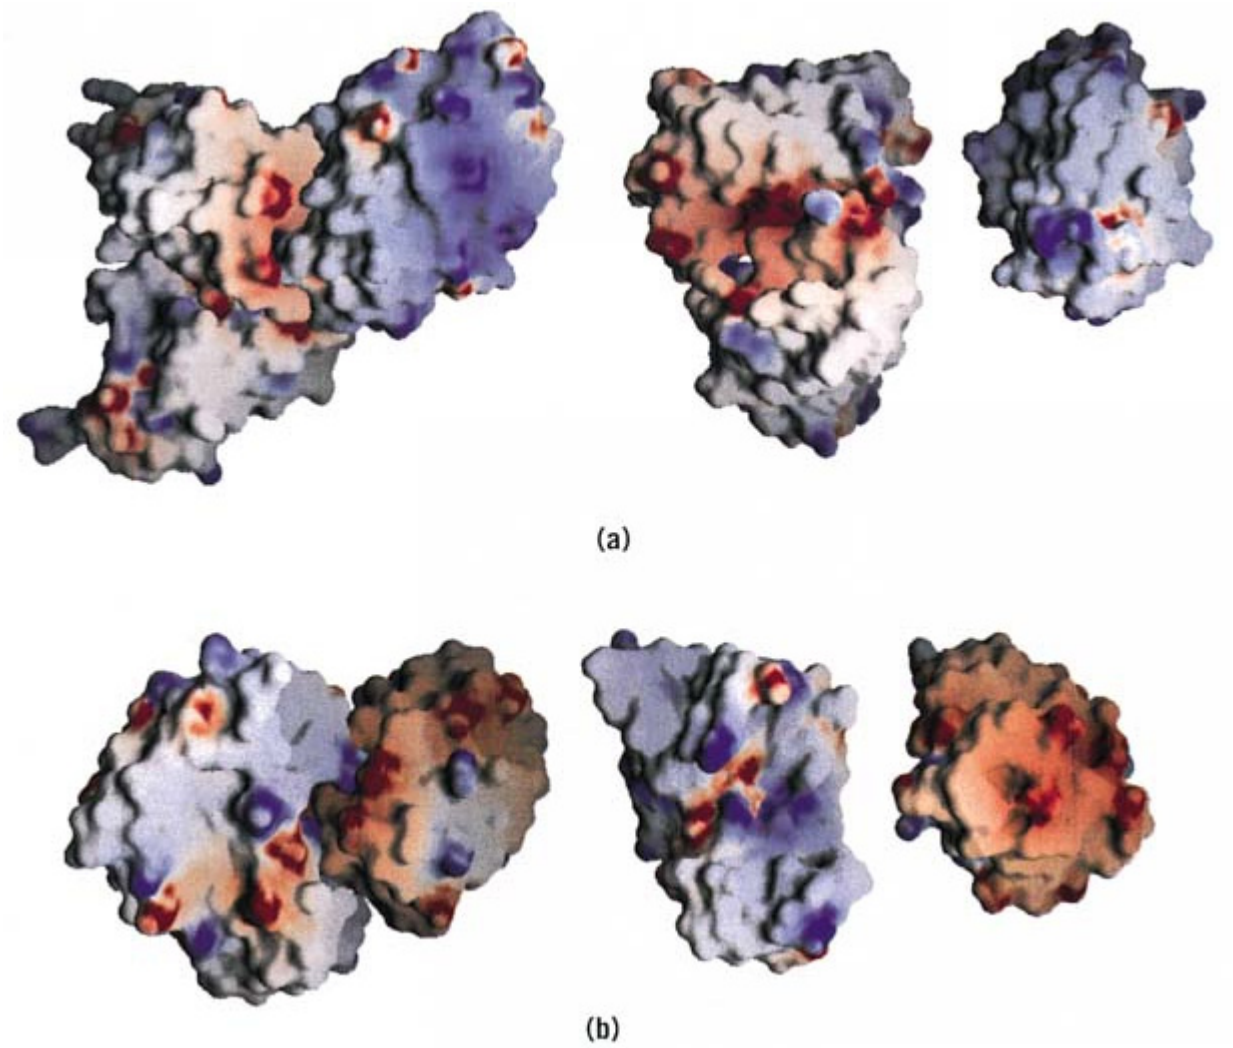
A plot of $1/t_a$ versus $[B]$ should be linear and yield k_a as the slope and k_d by extrapolation to $[B] = 0$, although such an extrapolation is often unreliable. Most observed k_a values for association of two protein molecules are in the range $10^5 - 10^9\ M^{-1}\ s^{-1}$. This implies that t_a is less than a second when $[B]$ is greater than micromolar, so the experiment must be performed in a rapid-mixing device, such as a stopped-flow apparatus. To determine k_d properly, the dissociation kinetics could in principle be followed by diluting the complex below K_d, but this is not practical even when the required sensitivity can be achieved, because measuring subnanomolar protein concentrations is not reliable. Thus, the experiment is usually performed by chasing a radioactive ligand bound to the complex with an excess of cold ligand. The rate of release of the radioactivity yields k_d. Values observed in protein–protein complexes cover a wide range: $10^{-6} - 10^3\ s^{-1}$, which implies that dissociation is completed in milliseconds for the weaker complexes, whereas it takes days or months for the tighter ones.

Deriving the value of K_d from kinetics instead of equilibrium studies can be convenient in other circumstances. **Surface plasmon resonance** measurements are well suited to kinetic studies of association–dissociation reactions. This technique uses a very sensitive optical method to detect changes of the refractive index at the surface of a gold chip placed in a continuous flow of buffer. First, purified partner A is chemically immobilized on the surface of the chip. Then partner B is added to the buffer, and its binding to the immobilized component is detected by recording the optical signal due to the change in refractive index of the chip. Partner B needs not to be pure so long as no other component of the solution binds to A, but in all cases estimates of the stoichiometry must take into account possible artifacts of the immobilization procedure. After binding is completed, pure buffer is used, and the dissociation of partner B from the complex on the chip yields a signal of opposite sign. As a result of the continuous flow of material or buffer, the system cannot reach true equilibrium, only a steady state. Still, provided the buffer flow rate is low compared to the reaction rate, the steady state should be sufficiently close to equilibrium for the measurement to yield approximately correct kinetic and equilibrium parameters.

3. The structural basis for recognition

Many noncovalent protein–protein complexes have been analyzed by X-ray crystallography and some by high-resolution NMR. Data sets of atomic coordinates, available through the Brookhaven Protein Data Bank (PDB), provide a structural basis for understanding protein association 1, 2. Other than oligomeric proteins, the best-represented examples of protein–protein interactions in the PDB are the complexes between antibodies and protein antigens and between proteinases and protein proteinase inhibitors. There are also examples of enzymes other than proteinases that form complexes with protein substrates or inhibitors. Figure 1**a** shows hen egg lysozyme bound to the Fab fragment of monoclonal antibody HyHEL5, a typical example of an antibody–antigen complex (3); in Figure 1**b**, the bacterial ribonuclease **barnase** is bound to the protein inhibitor barstar (4). The dissociation constants are of the order of $10^{-10}M$ for lysozyme-HyHEL5 and $10^{-13}M$ for barnase-barstar. Both X-ray crystallography structures illustrate the tight and highly specific association of two proteins that fold independently of each other and, for lysozyme and barnase, at least, perform their biological functions in the unbound state.

Figure 1. Examples of antibody–antigen and enzyme–inhibitor complexes. On the left, the complexes are shown as they are in the X-ray structure; on the right, the components are separated by opening the complex like a book and exposing the two protein surfaces that form the interface. The surface is colored according to its electric charge—red is negative; blue, positive; white, neutral. (**a**) Hen egg lysozyme complexed to the Fv part of monoclonal antibody HyHEL5 (file 3hfl in the Protein Data Bank). The combining site of the antibody (middle panel) forms a cleft lined with negative charges, in which part of the positively charged lysozyme surface (right panel) fits (3). (**b**) Complex of the bacterial ribonuclease barnase with its natural inhibitor barstar (PDB file 1brs). The inhibitor (right panel) is negatively charged and covers the active site of the enzyme (middle panel), which carries several positive charges (4). (Figure made with GRASP, K. Sharp and B. Honig, Columbia University, New York). See color insert.



The individual structures of lysozyme, barnase, and barstar are known. They differ from those seen in the complexes by only small changes, typically no greater than 1 Å (1 Å = 10^{-10} m) in amplitude, in the polypeptide main-chain fold and in the conformations of a number of amino acid side chains. Thus, the partner molecules of the complexes shown in Figure 1 associate to a good approximation as rigid bodies. Their interface involves two complementary surfaces that are largely preformed. Quasi rigid-body association of this type is frequent in protein–protein recognition, but is definitely not general. The PDB shows examples where significant or major conformational changes accompany association. A case in point is the complex formed between **trypsinogen** and bovine pancreatic trypsin inhibitor (BPTI). Its X-ray structure is essentially identical to that of the trypsin-BPTI complex, a very high affinity complex in which the two components undergo little conformation change. Yet free trypsinogen is not like free trypsin; it contains disordered loops of polypeptide chain that constitute its activation domain. These loops are fully ordered in the mature enzyme, trypsin, and in the trypsinogen–BPTI complex (5). Thus, BPTI binding induces a disorder-to-order transition in trypsinogen that converts it to the mature enzyme conformation, and this change is reflected in its lower affinity than trypsin for BPTI.

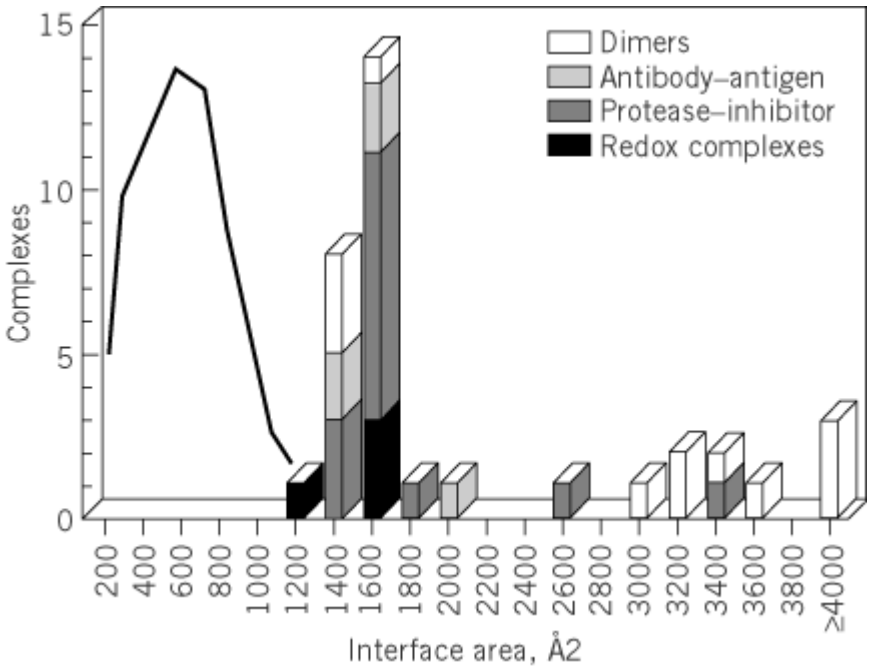
In addition to specific complexes of the kind just discussed, the PDB contains many examples of weaker, nonspecific protein–protein interactions: those that build protein crystals. Their physicochemical basis is the same as that for antibody–antigen or enzyme–inhibitor association, but crystal contacts are not subjected to natural selection by evolution or by the immune system. From a structural point of view, the obvious difference is that crystal contacts are less extensive than in

specific complexes. On the basis of their atomic coordinates, the extent of the contact between molecules A and B can be measured from their interface area:

$$B = A_A + A_B - A_{AB} \quad (5)$$

where A_{AB} is the solvent-accessible surface area of the complex, A_A and A_B are those of the dissociated components, and B represents the area of the protein surface that becomes buried at their interface when the two proteins associate. Its value is proportional to the number of pairs of atoms from the two components that are in contact in the complex. Figure 2 (6) is a histogram of interface areas observed in the PDB. For crystal packing contacts, the distribution is broad and centered at $B \approx 500$ Å^2. For protein-protein complexes, there is a well-defined peak centered at $B \approx 1500$ Å^2. No interface area is less than 1000 Å^2, yet there are interfaces burying 2000 Å^2 and more. The most plausible interpretation of the histogram is that any stable, specific protein–protein association requires removing approximately 1500 Å^2 from contact with water, 750 Å^2 per partner molecule, whereas the random contacts illustrated by crystal packing bury much less. A 1500-Å^2 interface typically involves 15–20 residues from each partner, with widely varying contributions of individual residues. A single arginine or tryptophan residue can lose more than 150 Å^2 of accessible surface area. Arginine is almost never buried inside protein monomers, yet buried arginine residues are not uncommon at protein–protein interfaces, and they are major contributors to both the interface area and the polar interactions. Arginine and the nonpolar residue leucine are actually the two most abundant residues in protein–protein interfaces, a finding that indicates that polar interactions (illustrated by arginine) and the hydrophobic effect (by leucine) are nearly equally important in protein-protein interactions, as they are in protein stability.

Figure 2. Histogram of interface areas in protein–protein complexes. The data are for 5 antigen–antibody, 15 proteinase–inhibitor and 3 redox–protein complexes, one of which is the cytochrome c-cytochrome c peroxidase complex. The interface areas observed in 12 homodimeric proteins are included, to show that most homodimers have larger interfaces than do protein–protein complexes. The thin line is a similar histogram for the 1320 pairwise interface areas of crystal contacts in a sample of monomeric protein crystals. These small interfaces illustrate weak and more nonspecific protein-protein interactions (6).



A few protein–protein complexes have small interface areas near 1200 Å^2; **cytochrome c**-cytochrome c peroxidase is an example. This is a redox enzyme–substrate complex that must be stable transiently for the electron transfer reaction to occur; the affinity cannot be very high in such a case. Yet beyond that qualitative statement, there is no simple correlation between the value of B and the affinity, for the major peak at $B \approx 1500$ Å^2 includes complexes with K_d values ranging from 10^{-7} to 10^{-13} M. On the other hand, there is a relation between interface area, affinity, and the occurrence of conformation changes. The lysozyme-HyHEL5, barnase–barstar, and trypsin–BPTI complexes, all of which associate as quasi-rigid bodies, have interface areas near 1500 Å^2. The trypsinogen–BPTI complex is similar, yet its dissociation constant is six orders of magnitude greater than that for trypsin. This can be safely attributed to the conformation change in trypsinogen. Components of the complexes that have very large interfaces often undergo major conformation changes. An example is hirudin, from the medicinal leech, binding to the blood proteinase thrombin. The complex has an interface area of 3300 Å^2, half of which is due to the C-terminal tail of hirudin filling a fibrinogen-binding site on the proteinase that is distinct from its active site (7). This tail is disordered in free hirudin. Like the trypsinogen–BPTI association mentioned above, association of hirudin–thrombin causes a disorder-to-order transition in hirudin. From that point of view, it resembles the assembly of subunits in oligomeric proteins, where the subunits generally form large interfaces and subunit folding is tightly coupled with oligomer assembly.

Interfaces in the lysozyme–HyHEL5, barnase–barstar, and trypsin–BPTI complexes comprise a nonpolar component, mostly from amino acid side chains, and a polar component, originating from both the main chain and the side chains. The nonpolar component contributes to stabilizing the complexes through the hydrophobic effect, the polar component through hydrogen bonds. The relative proportion of the nonpolar and polar components of the interface area is about the same in the three examples, and it is also very close to that on the average protein surface, which is 55% nonpolar and 45% polar. In other complexes, there are indications that nonpolar patches of protein surface serve as a binding site. Still, the polar fraction of the interface area is always significant and in the range 30–50%. With very few exceptions, the many polar groups that are buried form hydrogen bonds. The number of hydrogen bonds per unit buried surface area is similar in all complexes, about one per 150 Å^2. Thus, the complexes forming the major peak at $B \approx 1500$ Å^2 have 10±4 hydrogen bonds bridging their components. In addition to direct hydrogen bonds between protein groups, one finds water molecules bridging polar groups of the two proteins, usually at the periphery of the contact region. In the lysozyme-HyHEL5, barnase–barstar and trypsin–BPTI examples, a majority of both the direct and indirect hydrogen bonds are salt bridges or charged bonds; that is, hydrogen bonds where either the donor group, the acceptor group, or both in a salt bridge, is an anion or a cation. These features are observed in many other protein–protein complexes (8).

4. Thermodynamics of association

Thermodynamic state functions for the dissociation reaction are related to the equilibrium constant K_d and its temperature derivative (Table 1). The equilibrium constant yields the standard-state **free enthalpy** of dissociation, ΔG_d, whereas the temperature derivative gives the **enthalpy** of dissociation, ΔH_d, by the van't Hoff law. Note that the standard-state concentration of 1 M is a convention and that the values of the free energy and **entropy** changes depend on it. The temperature dependence of the affinity yields ΔH_d from the slope of a van't Hoff plot (plot of ln K_d vs $1/T$). The van't Hoff plot need not be linear, because ΔH_d can be temperature-dependent. This dependence is expressed in the **heat capacity** of dissociation at constant pressure, ΔC_d. In recent years, the development of isothermal titration calorimetry (ITC) has made it possible to measure the enthalpy change directly. Sensitive microcalorimeters measure the heat of mixing of the two components,

which is equal to $-D H_d$ per mole of complex. Provided the reaction mechanism is that of Equation (1), the bimolecular association of two free subunits, the calorimetric enthalpy value should be the same as the one derived by applying the van't Hoff law to the temperature dependence of K_d.

Table 1. Thermodynamical State Functions

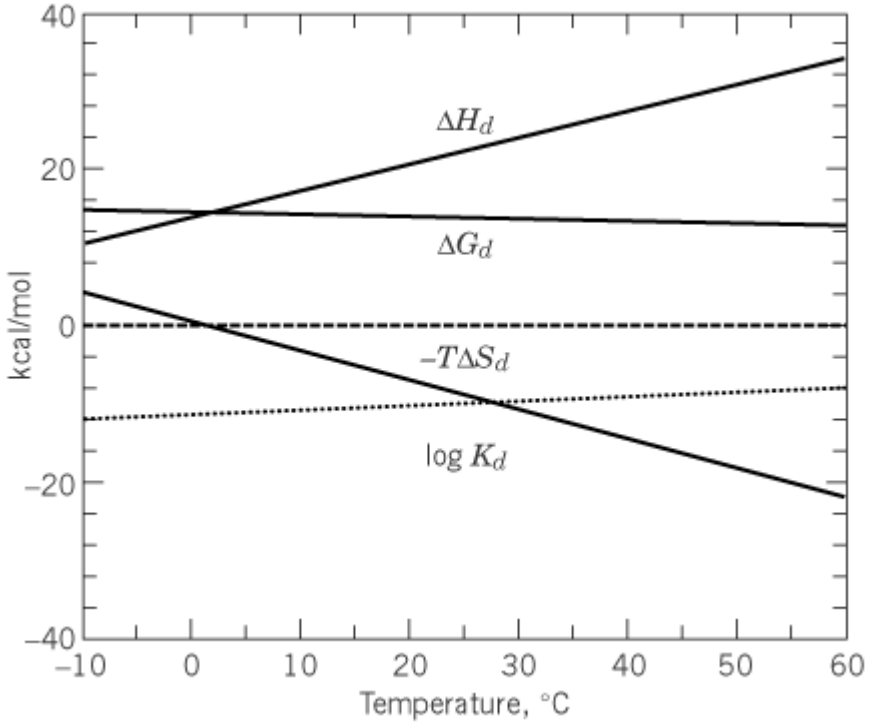
Standard-state[a] free-energychange	$D G_d = D H_d - T D S_d$
	$= -RT \ln \frac{K_d}{c_0}$
Enthalpy change (van't Hoff)	$\Delta H_d = R \frac{d(\ln K_d)}{d(1/T)}$
Entropy change	$\Delta S_d = -\frac{d(\Delta G_d)}{dT}$
Heat-capacity change	$\Delta C_d = \frac{d(\Delta H_d)}{dT} = T \frac{d(\Delta S_d)}{dT}$
Gas constant	$R \approx 2$ cal·mol^{-1}·K^{-1}[b]

[a] Standard state: pressure $p_0 = 1$ bar, concentration $c_0 = 1\ M$ (1 mol/L).

[b] 1 cal = 4.19 J.

Biologically relevant protein–protein interactions may have extremely different stabilities. The value of K_d ranges from at least millimolar to less than picomolar concentrations, and therefore the value of $D G_d$ varies from 4 to 17 kcal/mol. The relative contributions of $D H_d$, the enthalpic contribution to $D G_d$, and of $-T D S_d$, the entropic contribution, depend greatly on the system. This also depends strongly on the temperature, for calorimetric data indicate that $D C_d$ is usually positive and large. This is illustrated by Figure 3 (9) for the lysozyme-HyHel5 monoclonal antibody complex. At 25°C, K_d is less than 1 nM, a value rather typical of such complexes. ITC measurements demonstrate $D H_d$ to be large and positive at 25°C, sufficient to explain the stability of the complex. Thus, lysozyme-HyHEL5 association is enthalpy-driven: a favorable enthalpy change overcomes the destabilizing effect of the positive entropy change. On the other hand, calorimetric analysis of the lysozyme–HyHEL5 complex also yields a large positive value of the heat capacity change, $D C_d$. As a consequence, both $D H_d$ and $D S_d$ become smaller at lower temperatures. These variations compensate each other in $D G_d$, which undergoes a much smaller change; $D S_d$ even changes sign near 0°C, so that at lower temperatures, lysozyme–HyHEL5 association would be entropy-driven. The change of sign does not imply a different mechanism; it is simply a consequence of the temperature dependence of the state functions. Protein–protein complexes with negative (destabilizing) dissociation enthalpies and negative (stabilizing) dissociation entropies at 25°C also exist. They do not differ in any fundamental way from enthalpy-driven complexes, such as lysozyme-HyHEL5. The large positive $D C_d$, which leads to a strong temperature dependence of the enthalpy and entropy, is attributable largely to the hydrophobic effect. When a complex dissociates, many nonpolar chemical groups that were buried at the interface become **hydrated** . Nonpolar group hydration has a large positive heat capacity and is the dominant term in $D C_d$. Other components of $D H_d$ may be greater in absolute value than nonpolar group hydration, yet they are much less temperature-sensitive and therefore contribute less to the heat-capacity change. For example, polar groups at the interface also become hydrated on dissociation, but polar-group hydration has very little heat capacity, even though its enthalpy is large.

Figure 3. Thermodynamics of an antibody–antigen complex, that of lysozyme and antibody HyHEL5 (9). The dependences on temperature of the DH_d and DC_d state functions were derived from calorimetric measurements, whereas DG_d and -TD S_d were measured by the temperature dependence of the dissociation constant, K_d. (1 cal = 4.19 J).



5. Site-Directed Mutagenesis of Protein–Protein Interactions

In many protein-protein complexes, only 15–20 amino acid residues of each partner contribute directly to the interface, and if the structure is known, it is feasible to substitute each one by site-directed mutagenesis and to test how this affects the stability of the complex. Such measurements have been made on several systems, including antigen–antibody complexes, the human growth hormone–growth hormone **receptor** complex, and the barnase–barstar complex (10-12). The effect of a mutation on the stability of the complex can be evaluated as the ratio of the dissociation constants or, equivalently, as DDG_d, the change in free energy of dissociation from the wild type to the mutant:

$$\Delta\Delta G_d = \Delta G_d^{\text{wt}} - \Delta G_d^{\text{mut}} = RT\ln\frac{K_d^{\text{mut}}}{K_d^{\text{wt}}} \qquad (6)$$

The accompanying change in the enthalpy and the entropy of dissociation can be measured by microcalorimetry. Substitution of an amino acid by alanine effectively deletes a side chain and all its interactions, hopefully without introducing major perturbations in the structure. It is often the best choice when testing side-chain contributions. Deleting a polar side chain that makes hydrogen bonds across the interface can have a dramatic effect, the K_d of the complex increasing by up to five orders of magnitude, equivalent to DDG_d = 7 kcal/mol. This is more free energy than expected for breaking a hydrogen bond in aqueous solution, but the hydrogen bond partner of the mutated residue is left buried in an unfavorable environment at the interface, unless water molecules replace the missing

side chain. Thus, when deleting in partner A an arginine side chain that forms a salt bridge with an aspartic acid residue of partner B, the observed DDG_d value may represent the cost of dehydrating the carboxylate rather than the salt bridge energy. The latter may be recovered by also mutating the aspartate residue, measuring dissociation constants for all four complexes AB, $A^{mut}B$, AB^{mut}, and $A^{mut}B^{mut}$, and calculating:

$$\Delta G_d^{inter} = \Delta\Delta G_d^{AmutB} + \Delta\Delta G_d^{ABmut} - \Delta\Delta G_d^{AmutBmut} \quad (7)$$

Through Equation (6), this relates to the ratio of the dissociation constants:

$$\Delta G_d^{inter} = RT \ln \frac{(K_d^{AmutB})(K_d^{ABmut})}{(K_d^{AB})(K_d^{AmutBmut})}$$

If there is no interaction between the two mutated residues, the effect of the two substitutions should be additive and $DG^{inter}_d \approx 0$. If they form a salt bridge, its energy is lost in all three mutant complexes. Equation (7) indicates that it contributes directly to DG^{inter}_d, whereas the cost of dehydrating the two side chains cancels out. Mutagenesis data collected in several systems reveal that a single pairwise interaction may account for as much as 6 kcal/mol of the free energy of dissociation. Residue pairs that form salt bridges and charged hydrogen bonds yield the largest values; pairs making neutral hydrogen bonds or nonpolar interactions rarely exceed 3 kcal/mol. It should be kept in mind that polar interactions also include a **van der Waals** component and that the mutagenesis method cannot assess the contribution of the main chain. In complexes of known three-dimensional structure, peptide groups are involved in at least half of the hydrogen bonds at protein–protein interfaces; side chain-to main chain bonds are very common, and main chain–main chain bonds also occur.

6. Complementarity and specificity

Complementarity is an essential feature of both stability and specificity. Figure 1 illustrates how it is expressed in both the shape of the surface and its chemical composition. In the lysozyme–HyHEL5 and barnase–barstar complexes, the interacting surfaces are bumpy, yet fairly flat in their general appearance. There is a global fit that exists prior to their association, supplemented with a knob-into-hole type of fit, which may result largely from side-chain adjustments. Two extreme models of shape complementarity are (1) the lock-and-key fit of two rigid pre-formed shapes, and (2) the hand-into-glove fit, where one partner adapts to the shape of the other. Whereas neither model is a satisfactory description of reality, the two systems of Figure 1 are closer to the first than the second. The overall shape complementarity is not only apparent visually but is also sufficient for a computer search to be able to select the right mode of association. This can be performed by **docking** lysozyme onto the combining site of the antibody, or barstar onto barnase. The search usually succeeds when docking is performed using protein structures from a dissociated complex or the free protein structures, when their conformations are not optimized for association (13). The chemical and electrostatic complementarities of the interacting surfaces are equally obvious in Figure 1. Barnase is positively charged around its active site, which binds **RNA** substrates, and barstar has a very negatively charged surface to interact with it. In lysozyme–HyHEL5, **electrostatic** effects are more subtle, but in both complexes buried polar groups on one surface find hydrogen-bonding partners on the other.

When interface residues are changed by mutation, the complementarity is perturbed. Deleting a large side chain creates a hole that water may or may not fill, depending on the size of the hole; removing (or adding) a polar group leaves a hydrogen bond donor or acceptor unsatisfied. This is achieved experimentally by site-directed mutagenesis or by using natural evolutionary variants, such as bird lysozymes that are closely related to hen lysozyme and bind to the same monoclonal antibody, but with different affinities. Specificity is often evaluated from the effect of such single-residue

substitutions on affinity. Because a mutation on partner A can, in principle, be compensated by modifying the surface of partner B, the double mutant complex $A^{mut}B^{mut}$ may be more stable than either single mutant species $A^{mut}B$ and AB^{mut}, demonstrating that a point mutation can alter specificity. However, point mutants are not appropriate tests of the specificity required for function *in vivo* or in immunochemical experiments for antibodies. In these cases, specificity is the capacity to identify a given molecular species among many others, not to discriminate between closely related molecules such as two bird lysozymes. When an immunological test is performed, the lysozyme epitope competes with others for interaction with the antibody-combining site. The competition is not with a mutant version of the epitope, but with features on the molecular surface of all the other chemical species present in the sample. How many show sufficient complementarity with the combining site to compete with the cognate epitope? The answer to this question obviously depends on the composition of the solution, and it determines the response to the test. To visualize nonspecific protein–protein interactions associated with random contacts in such mixtures, we may assume that they create transient interfaces comparable to crystal contacts. These interfaces are small, and very few of them have surface areas that can compare with the cognate interface. Because the number of polar interactions increases with the area of the interface, this remark also applies to hydrogen bonds and salt bridges. Thus, the presence on the surfaces of two proteins of regions covering a sufficient area (on the order of 750 $Å^2$ each), and having complementary shapes and chemical compositions, appears to be both necessary and sufficient for specific recognition (1).

7. Conclusion

A combination of structural, biochemical, and thermodynamic studies has increased our understanding of protein–protein interactions in recent years. Site-directed mutagenesis, guided by a known three-dimensional structure, has proved to be a powerful tool in elucidating the roles of individual amino acid residues and of pairwise interactions. In systems that assemble as approximately rigid bodies, general rules have been established. They may help in designing protein surfaces that show sufficient complementarity to form stable complexes. Much less can be said at present of those systems where major conformation changes occur or where, as in trypsinogen–BPTI and thrombin–hirudin, association is coupled with folding of the components. In these systems, the bimolecular step becomes part of the folding process, underlining the close relationship between the two and recalling that protein-protein interaction is as essential to structure as it is to function.

Proteinase Inhibitors

Inhibitors of **proteolytic enzymes**, *proteinases*, encompass a wide variety of molecules, ranging from protein inhibitors (see Proteinase Inhibitors, Proteins) to naturally occurring, low-molecular-weight inhibitors; and from broad-specificity, synthetic inhibitors to highly specific, low-molecular-weight inhibitors. Among the latter (Table 1), there are group-specific reagents that are effective against most of the members of each of the four major types of proteinase (**carboxyl**, **thiol**, serine, and metalloproteinase), and these can be reversible or irreversible. Thus, pepstatin reversibly inhibits pepsin, renin, cathepsin D, and other carboxyl proteinases. Isolated from the culture filtrate of **Streptomyces** species, it is a transition state analogue that forms a tight binding complex with the enzyme. Highly specific inhibitors have been synthesized that are directed against renin, the human immunodeficiency virus (HIV) proteinase, and numerous other pathogen-related carboxyl proteinases. **Iodoacetate** and *p*-mercuribenzoate are irreversible inhibitors of thiol proteinases because they are general alkylating agents for thiol groups. Metals such as Hg^{2+} or Ag^{+} are relatively nonspecific reagents for thiol groups and also inhibit thiol proteinases. Another more specific, irreversible inhibitor of this class of proteinases is E-64 [*trans*-epoxysuccinyl-L-leucylamido (4-guanidino) butane] isolated from culture filtrates of *Aspergillus japonicus*. While it covalently modifies thiol groups in thiol proteinases, it does not modify them in other enzymes.

Table 1. Proteinase Inhibitors [a]

Type	Proteinases Inhibited

Amastatin	Peptidic	Metallo (aminopeptidases)
Antipain	Peptidic	Serine/thiol (trypsin-like)
a_1-Antitrypsin	Protein	Serine
Aprotinin	Protein	Serine
Bestatin	Peptidic	Metallo (aminopeptidases)
Cystatin	Protein	Thiol
Chymostatin	Peptidic	Serine/thiol (chymotrypsin-like)
3,4-Dichloroisocoumarin	Heterocyclic	Serine
E-64	Epoxide	Thiol
Elastatinal	Peptidic	Serine (elastase-like)
EDTA	Chelator	Metallo
Leupeptin	Peptidic	Serine/thiol (trypsin-like)
b_2-Macroglobulin	Protein	Many
Pepstatin A	Peptidic	Carboxyl (some)
PMSF	Sulfonyl	Serine
Phosphoramidon	Peptidic	Metallo (some)
TLCK	Alkylating	Serine (trypsin-like)
TPCK	Alkylating	Serine (chymotrypsin-like)
Trypsin inhibitors	Proteins	Serine

[a] This is a representative list of the many proteinase inhibitors that are known. The ones listed are active against particular classes of proteinases, although in several cases inhibitory activity is limited. There is a very large number of proteinase inhibitors that have been designed or found to be specific for just one proteinase such as angiotensin converting enzyme inhibitors or AIDS proteinase inhibitors. A listing of these is beyond the scope of this table. Those interested in the structures and/or mechanism of action of any of the above inhibitors are referred to specific listings.

There are many irreversible inhibitors of serine proteinases, some of which are described elsewhere in this volume, such as DIFP (diisopropylfluorophosphate), **PMSF** (phenylmethylsulfonyl fluoride), TLCK, and TPCK. A slowly reversible inhibitor of a wide range of serine proteinases is 3,4-*dichloroisocoumarin* . Some reversible inhibitors that inhibit serine as well as thiol proteinases are leupeptin, *antipain*, and *chymostatin*, all of which are aldehyde derivatives of amino acids.

Metalloproteinases are inhibited by reagents that remove the active site metal ion, most notably EDTA (ethylenediaminetetraacetic acid) and 1,10-phenanthroline (orthophenanthroline). A naturally occurring fungal product, *phosphoramidon*, is a potent but reversible inhibitor of thermolysin and similar bacterial metalloendoproteinases. It has served as a model for the synthesis of many more-specific metalloproteinase inhibitors.

There are naturally occurring inhibitors, such as *amastatin* and *bestatin*, that are specific for aminopeptidases. A particularly effective inhibitor of carboxypeptidase A is L-benzylsuccinate. Carboxypeptidase Y, which is useful in protein analysis, is inactivated by serine proteinase inhibitors and by thiol reagents.

Proteinase Inhibitors, Protein

Proteinase inhibitors, protein are proteins that form tight complexes with proteolytic enzymes. Such complexes are commonly totally devoid of enzymatic activity but some, especially those with macroglobulins [see Macroglobulins], retain activity against small but not large substrates. In view of the very large number of biological functions of proteinases, the spatial and temporal control of their activity is essential. Nature appears to employ two major mechanisms for this control. Many proteinases are synthesized as zymogens, where the removal of a propeptide is required for the expression of maximal activity. Once activated, proteinases are controlled by protein inhibitors. These are extremely abundant, as each organism contains many kinds of protein proteinase inhibitors, some of them at very high molar concentrations. The two mechanisms of control of proteolysis often, but not always, overlap. In many, but not all, zymogens, the propeptide is a protein inhibitor covalently tethered to the enzyme.

Although overall function of protein proteinase inhibitors—the control of unwanted proteolysis—is obvious for most inhibitors, their target enzymes are not. The presumed biological purpose of an inhibitor is to inhibit its target enzymes. *In vitro*, most inhibitors are capable of inhibiting a much greater number of enzymes, called the cognate enzymes. There seems to be little likelihood of the ovomucoid from the egg white of laughing kookaburra coming in contact with bovine chymotrypsin outside a biochemical laboratory. In some cases, the target enzymes seem obvious. The worm *Ascaris lumbricoides* contains large amounts of inhibitors of digestive enzymes—trypsin, chymotrypsin, elastase, and pepsin. As the worm spends a large fraction of its lifetime in the digestive tract of its mammalian host, it seems intuitive to presume that the host's digestive enzymes are the targets. Similarly, the saliva of a large number of blood-sucking animals contains inhibitors for thrombin or for enzymes preceding thrombin in the blood-clotting cascade. It seems natural to assume that the targets are the blood-clotting enzymes of the prey. Humans with genetic deficiency of a serpin–a_1 proteinase inhibitor are often subject to emphysema. Emphysema is a consequence of excessive proteolysis of the lungs by leukocytic enzymes. As these enzymes are inhibited by a_1 proteinase inhibitor, they are among the target enzymes for this inhibitor. In several other cases, genetic diseases provided a clue for the target.

For most protein proteinase inhibitors, however, the targets are unknown. One reason for this is that the targets are not limited to cognate, endogenous enzymes of the organism. As already shown, inhibitors are often involved in interorganismic interaction. In particular, defensive function is often postulated for inhibitors, and the list of potential predators—vertebrates, insects, and bacteria—is huge. Historically, the first protein proteinase inhibitors known were trypsin inhibitors. A custom developed of screening numerous plant, animal, and bacterial tissues with bovine cationic trypsin. A very large number of proteins that inhibit bovine trypsin were found and frequently named as tissue X trypsin inhibitors without regard to the likelihood that any trypsin in general or bovine trypsin in particular was the target. The a_1 proteinase inhibitor discussed above was first isolated as a bovine trypsin inhibitor and named a_1 antitrypsin. The name diverted many researchers into the detailed study of bovine trypsin–a_1 proteinase inhibitor interaction, even though later it was shown that trypsin is not among the targets and is not an especially efficient cognate enzyme. Similar histories occurred for many other inhibitors, and it must be expected that many of the substances called trypsin inhibitors do not have trypsin as their primary target.

Some protein proteinase inhibitors appear to have been recruited to perform functions other than inhibition of proteinases. Such is the case with the serpin, ovalbumin, and with several members of

the Kunitz bovine pancreatic trypsin inhibitor family, which function as dendrotoxins and as Ca^{++} channel blockers. In such proteins, the inhibitory activity has either disappeared, as in ovalbumin, or remain in vestigial form. An alternate possibility is that inhibitory activity of some proteins is accidental. The inhibitory activity arose without any biological pressure to inhibit. The exquisitely good fit between enzymes and inhibitors in many enzyme-inhibitor complexes appears to belie such an accidental origin.

Protein proteinase inhibitors are a huge and highly diverse class of proteins. However, a classification based on the mechanistic class of proteinases they inhibit proved moderately successful. They can be conveniently divided into the following classes. [See separate entries for each class.]

Macroglobulins

Serine proteinase inhibitors

Cysteine proteinase inhibitors

Aspartyl proteinase inhibitors

Metalloproteinase inhibitors.

Macroglobulins trap proteinases belonging to all four mechanistic classes. The remaining four classes inhibit only some enzymes belonging to its mechanistic class. This classification lasted for 20 years. Some exceptions have been found. For example, the viral serpin CrmA, a serine proteinase inhibitor, inhibits the interleukin-converting enzyme, ICE, which is a cysteine proteinase.

In some proteinase inhibitors–proteinase associations, it is impossible or difficult to define an equilibrium constant for the interaction K_a or its inverse, the inhibition constant K_I. Such is the case for complexes with human a_2 macroglobulin, where the presence of covalent isopeptide bonds between the trapped enzyme and the inhibitor leads to effective irreversibility. Similarly, in many enzyme–serpin interactions [see Serpins], the main route of dissociation is to the enzyme and the reactive site hydrolyzed inhibitor. In contrast to standard-mechanism protein inhibitors of serine proteinases, such a reactive site hydrolyzed inhibitor is no longer effective. Therefore, instead of inappropriate K_a or K_I values, such systems are characterized by the second-order association rate constant k_{on}. The reported k_{on} values range from $10^3 M^{-1}s^{-1}$ to somewhat above $10^7 M^{-1}s^{-1}$ at optimal pH value. The same range is also reported for inhibitors for which enzyme-inhibitor equilibrium is established. The typical k_{on} value is $10^6 M^{-1}s^{-1}$.

Most inhibitors are characterized by enzyme inhibitor association equilibrium constants K_a or by their inverses, the inhibition constants K_I. The reported values for K_I range from 10^{-3} to $10^{-14} M$; these range limits are not a function of the system but rather of the ability of available measurement techniques. It is quite likely that both much weaker and much stronger enzyme-inhibitor pairs will be found as the range of measuring techniques widens. The association equilibrium constant K_a is given by

$$K_a = \frac{1}{K_I} = \frac{k_{on}}{k_{off}} \qquad (1)$$

where k_{off} is the first-order dissociation rate constant for the enzyme inhibitor complex. As the k_{on} value is typically $10^6 M^{-1}s^{-1}$ and varies relatively little, it is seen that, for K_I greater than 10^{-7} to 10^{-8}M, k_{off} is quite large and the dissociation half-life is fast on the laboratory time scale. At K_I, 10^{-8}M half-life is 70 s, and this rises to 7×10^7s (2 yr) for K_I of 10^{-14}M. These very slow dissociation half-lives tend to mislead many investigators who do not expect them. A great majority of protein

inhibitors of proteinases are strictly competitive as binding of the inhibitor to the active site completely prevents the binding of substrate to the active site. When concentrated substrate is added to an enzyme inhibitor complex, however, it competes for the enzyme so slowly that the phenomenon is often missed. Thus, many protein inhibitors are incorrectly labeled *noncompetitive*.

Two techniques of measuring K_a ($1/K_I$) are widely employed. In one, k_{on} and k_{off} are both determined, and the equilibrium constant is derived from the ratio. In the other, appropriate known concentrations of enzyme and inhibitor are preincubated together until they achieve equilibrium. Then the concentration of the components is determined. Both methods generally employ the determination of free enzyme by detection of the hydrolysis of highly sensitive synthetic substrates. Such substrates are well worked out for many proteinases.

Because we are still discussing all the protein proteinase inhibitors together, it is relatively hard to make strong and sweeping generalizations about their behavior. Some (a_2 macroglobulins, serpins) are moderately large and rather unstable proteins. Others are very small (marinostatins have only a dozen amino acid residues, whereas squash family inhibitors have about 30 residues). Some are exceptionally stable to heat, denaturing acids, and proteolysis. Some of these—such as bovine pancreatic trypsin inhibitor (Kunitz), Bowman-Birk family inhibitors, and avian ovomucoids—are isolated by denaturing most proteins in the sample so that only the native inhibitor remains. It is quite common to encounter single polypeptide chains that consist of more than one inhibitory domain. The phenomenon is well exemplified by the Kazal family of protein inhibitors of serine proteinases. Pancreatic secretory trypsin inhibitors and acrosin inhibitors in sperm consist of but a single domain. Submandibular inhibitors in carnivore mammals have two tandem domains on the same polypeptide chain. Avian ovomucoids have three tandem domains, and alligator ovomucoids have four. Ovoinhibitor, a protein present both in avian egg white and in avian blood, has seven such domains. There are 10 Kazal domains in addition to many other domains in agrin. Similar multiple tandem domains are present in the bovine pancreatic trypsin inhibitor (Kunitz). In that family, many such inhibitors are called bikunins, trikunins, and so forth. Most inhibitors in the plant inhibitor Bowman–Birk family consist of two homology regions each with its own reactive site. In the potato II family, multidomain and tandem domains are common.

Although serine proteinase inhibitors are the most studied, the presence of multiple tandem domains on the same polypeptide chain is not limited to them. High molecular weight kininogens, histidine-rich glycoproteins and fetuins consist of several tandem repeats of cystatin—a widely known cysteine proteinase inhibitor. An 85-kDa inhibitor with eight cysteine proteinase–inhibiting domains from potatoes has been described.

Multiple domains, each of which can combine with an enzyme, sometimes arise from strong and specific noncovalent association. All the members of *Streptomyces* subtilisin inhibitor family, SSI, are homodimers of this type. They form ternary complexes with enzymes. Similarly, a serine proteinase inhibitor from *E. coli*—ecotin—is a homodimer. A Kazal inhibitor from red sea turtle egg whites, testudin, is a disulfide bridged heterodimer of two Kazal inhibitory domains. Finally, human a_2 macroglobulin is a noncovalent homodimer of two disulfide bridged homodimers. The biological reasons for multiple inhibitory domains in the same molecule vary. Ovoinhibitor is present in the blood of birds. Its seven domains and glycosylation make it just large enough to avoid renal filtration. The SSI dimer strongly contributes to the stabilization of this otherwise fragile protein. The multidomain ornamental tobacco potato II family inhibitor appears to be an in vivo precursor of separate inhibitory domains.

Proteinase K

Proteinase K is a serine proteinase of the subtilisin family obtained from *Tritirachium album*. It catalyzes the hydrolysis of peptide bonds involving the carbonyl group of **hydrophobic** aliphatic and aromatic amino acid residues (1). It has quite broad specificity and is capable of degrading native proteins (2). As a consequence, it is often added to cell or nuclear extracts to inactivate **nucleases** during the isolation of DNA or RNA. It can also be used to release **nucleic acids** from protein–nucleic acid complexes and to modify proteins and **glycoproteins** on cell surfaces. It can also be used to examine the topological orientation of membrane-associated proteins (3). It is stable in solution at 4°C, pH 8.0 in the presence of 1 mM calcium for several months. Serine proteinase inhibitors such as **DIPF** or PMSF will inactivate it, but TLCK and TPCK do not.

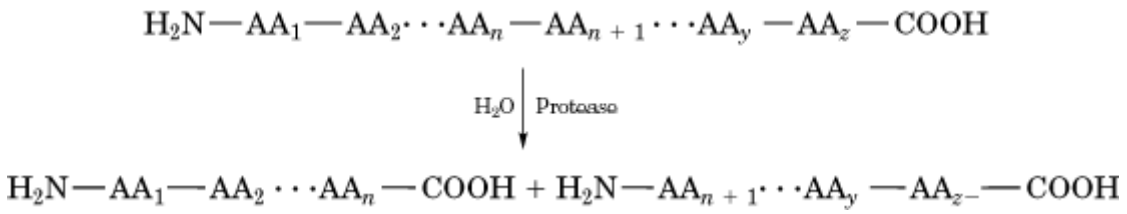
Proteinases

Proteinases are enzymes whose substrates are proteins and whose catalytic mechanism involves the hydrolysis of one or more of the peptide bonds that constitute the **polypeptide** backbone of the protein molecule (Fig. 1). Proteins are the functional molecules of cells. Some are the catalysts that facilitate essentially every chemical reaction that occurs in biology; others are inhibitors, activators, or modulators of these reactions; still others have a structural function; and some participate in various processes of cellular communication. Indeed every conceivable biological function relies directly or indirectly on one or more proteins. Some of these functions are required for very short periods of time (minutes to hours), whereas others are more persistent (days to weeks). The cell has developed elaborate schemes based on gene regulation (see **Gene expression**) to ensure that proteins are synthesized and are available when needed. Similarly, they have developed mechanisms to eliminate proteins when they are no longer needed and to recycle their constituent amino acids. These mechanisms involve hydrolysis of the peptide bonds that link the amino acids into polymeric chains, a process (known as proteolysis) that is catalyzed by enzymes known as proteinases (also referred to as proteases, proteolytic enzymes, peptide hydrolases, or peptidases). As one might imagine, the realm of proteinases is about as extensive as that of proteins in general; and because of the catastrophic havoc they could create if allowed to run rampant, they must be subject to tight control. Consequently, an intricate system of checks and balances has evolved to limit the location, duration, and specific target of proteinase activity. The Enzyme Commission of the International Union of Biochemistry and Molecular Biology has classified proteinases according to their

numerical system as E.C. 3.4.

Figure 1. Schematic depiction of the (endo)proteinase-catalyzed hydrolysis of a single peptide bond in a protein [here represented as a linear polymeric chain of z amino acids (AA)]. For simplicity, the amino (H_2N-) and carboxyl (-COOH) ends of the protein and its cleavage products are indicated in the nonionized state.



Four general classes of proteinases have been defined based on the particular hydrolytic mechanism that is used for peptide bond cleavage.

1. The carboxyl proteinases (E.C. 3.4.23) employ a pair of carboxyl groups, the side chains of two aspartic acid residues, to activate a water molecule so that it can lyse a peptide bond in a protein substrate.
2. The serine proteinases (E.C. 3.4.21) are characterized by a unique catalytic triad of amino acid side chains: an aspartyl carboxyl group, a histidyl imidazole group, and a seryl hydroxyl group.
3. The third class of proteinases has a cysteinyl thiol group that is required for activity, and hence these enzymes are called thiol proteinases (E.C. 3.4.22).
4. The fourth class of proteinases is unique in that it has a metal ion, zinc, as part of the active site (see Metalloproteinases) (E.C. 3.4.24).

Proteinases are also classified on the basis of where they act on a protein chain. Those that remove amino acids sequentially from the end of the chain are called *exoproteinases*. If they remove amino acids from the amino terminus, they are aminopeptidases (E.C. 3.4.11); and if they act at the carboxyl terminus, they are carboxypeptidases (E.C. 3.4.16–18). Proteinases that cleave bonds in the middle of the protein chain are *endoproteinases*.

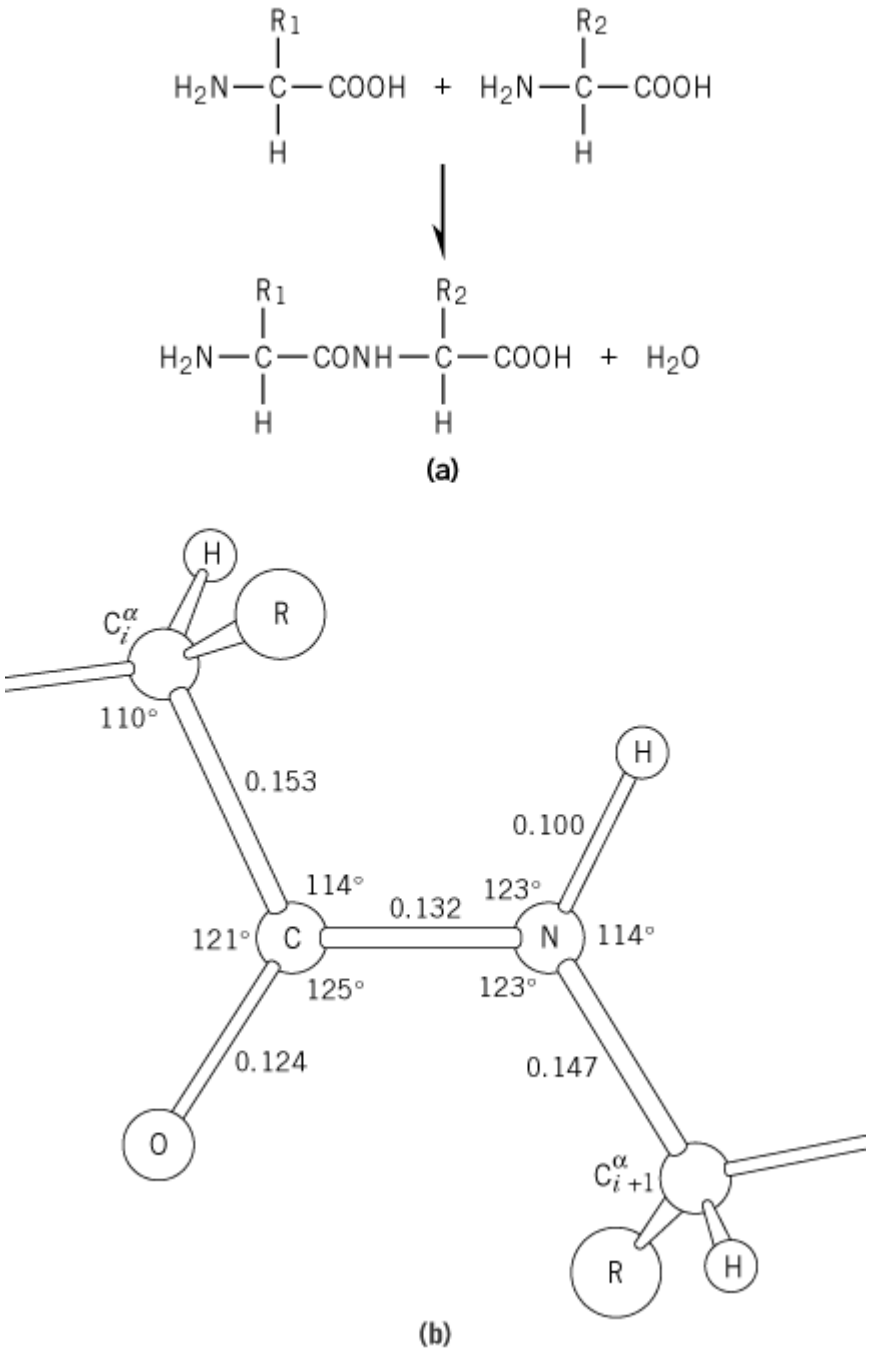
Proteinases often act collectively, as with the digestive proteinases of the pancreas, the compartmentalized proteinases of the **lysosome**, the cascading proteinases of blood clotting, or the sequentially acting proteinases of the renin–angiotensin–**kinin** system. A rather specialized group of proteinases constitutes what is known as the proteasome, a macromolecular assembly of numerous different proteinases that degrades cytosolic proteins that have been specifically marked for that purpose by covalent attachment of a small protein called ubiquitin (see **Protein degradation**). The proteasome also plays a role in processing antigens as part of the immune response and also functions critically in the control of the cell cycle.

Proteins

Proteins are **macromolecules** that support both the structural and functional aspects of life, along with other molecules such as nucleic acids, polysaccharides, lipids, vitamins, etc. The name derives

from the Greek “protos,” meaning “first,” as suggested by Berzelius in 1838. Proteins are most vividly recognized for their functions; eg, enzymes as **catalysts**, muscle and **flagella** as motor machines, growth factors and hormones as regulatory elements. In contrast, bones, tendons, nails, and hair are notable manifestations of structural proteins. Proteins are linear copolymers of 20 rather limited kinds of L-a-**amino acids** (plus selenocysteine), which are linked through condensation polymerization, with the loss of one H_2O unit from the a-**carboxyl group** of one amino acid and the a-**amino group** of another (see Fig. 1). The polypeptide backbone of a protein is thus a long repeat of amino acid residues in the form of —NH—CH(R_i)—CO—, R_i being one of 20 kinds of side chains. The group of atoms between two amino acid residues, —CO—NH—, contains the peptide bond. Hence, proteins are collectively polypeptide chains of biological origins. The N—C peptide bond has a partial double-bond character, through resonance with the carbonyl double bond, that prevents its free rotation. Thus, the geometry of a peptide bond is virtually fixed in a planar conformation, usually the *trans* isomer (see Cis/Trans Isomerization). This is a very important characteristic when one considers the conformational possibilities of proteins (1). One end of a linear polypeptide bearing H_2N is called the amino- or **N-terminus**, and the other with —COOH is called the carboxyl- or **C-terminus** (2).

Figure 1. (**a**) Structure of L-a-amino acids and polymerization mechanism by dehydration between the amino and carboxyl groups. (**b**) Structure of the peptide bond.



Each polypeptide chain is therefore distinguished by the number of different kinds of amino acid residues it contains (its amino acid composition) and the specific order of such residues, aligned from the N- to C-terminus (its amino acid sequence, or the primary structure). The chemical nature of the side chains and their distribution along the main chain determine the **conformational** state of a polypeptide chain under any particular conditions. The side chains of the 20 amino acids are therefore classified according to their most notable chemical properties, such as (1) ionizable (hydrophilic), (2) polar but not ionizable (hydrophilic), (3) aliphatic (**hydrophobic**), (4) aromatic (hydrophobic), (5) crosslinker, and (6) others, as in Table 1. (More details are found under Amino acids and entries on the individual residues.)

Table 1. Classification of the 20 Natural Amino acids That Constitute Proteins

Ionizable	**Asp, Glu, Lys, Arg, His, Tyr, Cys**
Polar but nonionizable	Ser, Thr, Asn, Gln
Aliphatic-containing	Ala, Val, Leu, Ile, Pro (ring), Met (S)
Aromatic	Phe, Tyr, Trp
Crosslinker	Cys
Others	Gly

Unlike synthetic **polymers**, the arrangement of amino acid residues in the primary structure of a protein is not random, but is precisely determined by the genetic information stored in the chromosomal DNA or RNA. In humans, there are more than 100,000 proteins with various activities. Although a human has the capacity to synthesize the majority of the amino acids from carbohydrates and other nutrients, proteins are formed in most part from recycled amino acids, both from the daily intake of food stuff and from the degradation products of proteins in the body. So long as they recover their original chemical structures, recycled amino acids from any protein may be used for the resynthesis of any other protein by linking them in different orders according to the genetic instruction. One of the most unifying views of biochemistry is that the fundamental metabolism is common among all the organisms, eg, the energy-yielding metabolic cycle called the glycolysis pathway is one of the bases of life, for *Escherichia coli* as well as humans. Enzymes participating in the corresponding steps in the glycolysis pathway in various organisms have virtually the same functions and the same name, but when looked at more closely, their amino acid sequences differ from species to species, thus defining each enzyme as species-specific. The same muscle protein we take as beef must, therefore, be hydrolyzed (digested) to individual amino acids in the digestive organs and transported via the bloodstream to the liver and other tissues to be repolymerized into muscle and other proteins, all of which are specific to the human body. Hydrolysis of proteins into amino acids is effected by a class of proteins known as **proteolytic** enzymes, or proteinases, such as **pepsin** in the stomach, and **trypsin** and **chymotrypsin** in the small intestine. Proteins are also constantly synthesized and degraded in the cell for the regulation of cellular activities and for recycling amino acids. Intracellular protein degradation is carried out in acidic vesicles called lysosomes. They contain a group of enzymes called cathepsins for the hydrolysis of proteins, along with many other enzymes for the degradation of nucleic acids, polysaccharides, glycolipids, etc. Both in the stomach and lysosomes, an acidic condition is effective to loosen the three-dimensional structure of proteins and to expose their peptide bonds for hydrolysis (2).

Proteins are synthesized inside living cells on a supra-molecular machinery called the ribosome. After receiving genetic information prescribing an amino acid sequence from the nucleus in the form of messenger RNA (mRNA), ribosomes interpret the base sequence of mRNA into the expected amino acid sequence with the help of transfer RNAs (tRNA) and enzymes called aminoacyl tRNA synthetases. Once each tRNA carrying a specific anticodon is conjugated on the enzyme with a corresponding amino acid, it will bind to the mRNA on ribosomes. As tRNAs are aligned along the mRNA, amino acids at the other end of the tRNA are polymerized into a nascent polypeptide chain.

The polypeptide chains formed in this way are not biologically active without going through the processes called post-translational modification and **protein folding**. These are, respectively, the covalent modifications and the formation of a specific three-dimensional structure that are needed for their full biological activities. Polypeptide chains with unrelated primary structures usually form different three-dimensional structures having different activities. Thus, one **gene** dictates one particular amino acid sequence and a corresponding activity through the unique three-dimensional structure of the protein. During the folding process, disulfide bonds between pairs of **cysteine**

residues may be generated. Post-translational modifications include, among others, proteolytic cleavage of peptide bonds, O-glycosylation at specific serine and threonine residues, and **N-glycosylation** at asparagine, hydroxylation of proline and/or lysine residues, **methylation** of Lys residues, and covalent linkage of fatty acids (see Membrane Anchors).

Prosthetic groups can be added covalently or noncovalently. Post-translational modifications cannot yet be predicted always from the sequences of genes, so the chemical analysis of proteins must be conducted carefully to reveal every possible modification not directly prescribed by structural genes. After going through folding and post-translational modifications, a protein assumes its "native" conformation, complete with its biological activity. The three-dimensional structure of the native conformation is called the tertiary structure, which may be dissected into several **secondary structures** known as the alpha-helix, **beta-sheets**, turns, and various irregular structures. Secondary structures are generally those favored by the local sequence of residues, whereas the tertiary structure is built up by the long-range interactions between residues distant in the primary structure.

1. Molecular Weight

The molecular weights of protein range from relatively small values, such as 5,807 for insulin (51 amino acid residues) or 6,380 for rubredoxin, up to many millions. If we limit our scope to a single polypeptide chain, rather than including multichain complexes, the largest thus far known is the muscle titin (connectin), which acts as a structural support of myofibrils in muscle, with $Mw = 3.5 \times 10^6$. Many polypeptide chains smaller than insulin are found as enzyme inhibitors, hormones or growth factors, toxins, etc. and are usually referred to as **oligopeptides** or polypeptides, rather than proteins.

2. Subunit or Quaternary Structure

Protein molecules are often composed of multiple polypeptide chains, termed subunits, within the arrangement called the quaternary structure . Subunits may be identical (homo) or different (hetero) from each other, and they are held together primarily by noncovalent forces, such as hydrophobic and/or electrostatic interactions and hydrogen bonds; sometimes, disulfide bonds are also found either within or between subunits. Two (dimer), four (tetramer), and even-numbered subunit structures predominate, whereas three (trimer) or odd-numbered ones are less common (see Quaternary Structure).

3. Origin and Evolution of Proteins

The **evolutionary** origin of proteins is not yet known, but it is certain that life on the Earth as we know it is not possible without proteins. DNA carries the genetic information, but proteins implement the machinery of life. Nevertheless, RNA molecules may have initially played the roles of proteins in an early stage of evolution, known as the RNA world. Yet proteins are more efficient than RNA molecules, so they gradually replaced them, except in ribosomes, tRNA, and ribozymes. The most important events in protein evolution since then are considered to be the enlargement of protein structures through gene duplication phenomena, where the structural genes for proteins were repeatedly duplicated, producing larger and larger proteins. During biological evolution, it was imperative that at least one active site in an enzyme must retain its activity to keep the life process going. Gene duplication is a convenient strategy to satisfy that condition, while allowing the rest of the multiple active sites free to change their functions from generation to generation. Many mutations can, therefore, be accumulated in a protein that went through gene duplication events without totally abolishing the biological activity of the resulting protein, and that protein can be reborn one day as a remodeled protein with a newly acquired function. Today, it is possible to trace the **phylogenetic** relations between proteins based mainly on a statistical comparison of their primary structures and to estimate the structure of their common ancestor and how many years have

elapsed since they branched off. Such divergent evolution is the most frequent, but occasionally there are pairs of proteins with similar activities, but without an obvious sequence or structural similarity except in the active site regions. These cases are referred to as convergent evolution, meaning that the two proteins have come a long way during their evolution from different ancestors, to express similar activities from necessity.

4. Methods in Protein Chemistry

Proteins are biological macromolecules, so they are usually discovered and purified on the basis of a specified activity. Occasionally, a protein is purified without knowledge of its activity or, most recently, amino acid sequences of many putative proteins are deduced solely from the **nucleotide sequences** of their genes, using the genetic code. In such cases, researchers are forced to speculate on the biological activities of unknown proteins by analogy.

4.1. Purification

Purification of proteins from various biological sources has been a major concern of protein biochemistry since the early days of its history. Enzymes are purified using (1) **chromatographic** methods (**size exclusion**, **affinity**, and **ion exchange**), (2) electrophoresis, (3) differential and density gradient centrifugation, (4) **salting out** methods using, eg, ammonium **sulfate** as precipitant, (5) macromolecular phase separation using, eg, polyethylene glycol, etc. In purification procedures, the activity of the targeted sample is used to follow the direction of fractionation at each step. Because a finite amount of actual protein must be recovered, it has been extremely difficult to purify proteins that exist in very small amounts. The recent development of molecular biology cloning techniques has, however, changed protein purification quite dramatically by enabling the researchers to produce rare proteins of, eg, human origin easily and in abundance from *E. coli* using recombinant DNA technology, provided the degree of post-translational modifications is not extensive. For example, glycosylation cannot be achieved unless eukaryotic cells are used instead of *E. coli* for the expression of recombinant DNA (3) (see Protein Engineering).

4.2. Chemical Structure

The chemical structure of a protein is studied, first, from the quantitative analysis of its amino acid composition, by amino acid analysis . Classically, proteins are hydrolyzed into their constituent amino acids by heating them under evacuated conditions at 110°C in 6 *M* HCl for 24 hours. To protect tryptophan from oxidative degradation, a small amount of thioglycol is added. Separation and quantification of each amino acid are completed with an automated ion-exchange chromatography system known as an automatic amino acid analyzer. Cysteine residues in both the thiol and disulfide forms are oxidized to cysteic acid and cannot be differentiated, and glutamine and asparagine are converted to glutamic acid and aspartic acid, respectively, and cannot be distinguished from their acid counterparts. Despite such ambiguities, a quantitative amino acid analysis must be done before the next step of the determination of amino acid sequences.

The primary structure, or the amino acid sequence, of a protein is usually elucidated by a chemical procedure known as the Edman Degradation, which uses PITH (phenylisothiohydantoin) as the starting reagent to modify the N-terminal amino acid residue. After release and identification of the N-terminal residue as a PTH (phenylthiohydantoin) amino acid, the process is repeated on the shortened polypeptide chain, to identify the next amino acid residue, and so forth. This is still the most efficient and reliable way to determine the primary structure (see Protein Sequencing), provided the amino terminal is not blocked, eg, by acetylation or formylation.

4.3. Mass Spectrometry

Proteins are not normally volatile, but mass spectrometry has become a powerful tool in the sequence determination of peptides and of the oligo-saccharide structures of **glycoproteins** . The extraordinary sensitivity of modern mass spectrometry enables researchers to distinguish a difference of one atomic mass unit from a total of 10,000 units.

4.4. X-ray Crystallography
The three-dimensional structures of proteins are usually determined by X-ray crystallography. The first protein to be crystallized was albumin, the first enzyme was urease, and the first structure to be determined was that of myoglobin. The procedure of structure determination is, in brief, as follows. First, the protein is crystallized out of aqueous solution by, eg, adjusting the pH closer to the isoelectric point (pI) of the protein, where its solubility is the lowest, or by changing the ionic strength and/or the activity of water by adding polymeric substances such as polyethylene glycol. Once a single crystal is obtained, it is usually irradiated with a monochromatic X-ray beam, and as many so-called "reflections" as possible are collected. This defines the crystal parameters. Each reflection is the Bragg reflection from a particular crystal plane with three integer indexes; when enough of them are collected, and their phases estimated (see Phase Problem), the reflections can be recombined to reconstruct inside a unit cell of the crystal the distribution of electron density and, therefore, that of the atoms. A unit cell contains at least one molecule of the protein, so the result will give the 3D distribution of all the protein atoms, except for the hydrogens, and consequently the structure of a protein molecule.

Neutron diffraction can also be used to determine the structures of proteins, but it is usually more consuming of time and money and is used primarily for special cases where the location of the hydrogen atoms is important. Electron crystallography can be used to determine the structure of membrane proteins in two-dimensional crystalline arrays. **Single-particle reconstruction** of individual protein molecules with different orientations from electron microscopy has also been used to determine the structures of noncrystalline proteins, especially those of tubular or fibrous bacteriophages and of muscle origins.

4.5. Nuclear Magnetic Resonance (NMR)
NMR has increasingly come to be used to determine the structure of small proteins in solution. It has the advantage over X-ray crystallography that proteins do not have to be crystallized. However, the accuracy of the resulting structure is somewhat less than those obtained from the X-ray diffraction method, and only smallish proteins can be studied; the upper limit in molecular weight is of the order of 50,000 at the present time.

4.6. Chemical Modification
The reaction of proteins with chemical reagents has been the classical method to study the contribution of particular side chains to their activities, or to change their physical and chemical properties. For example, polyethylene glycol groups can be linked to lysine side chains of proteins, to alter its solubility properties, particularly in organic solvents, change the immunological properties, in some cases to increase the stability, and so forth. The e- amino group of Lys residues is often targeted as the site of chemical modification, using reagents such as anhydrides and succinimide, whereas the thiol groups of cysteine residues react readily with many reagents, such as **iodoacetamide** . Chemical modification has, however, been largely superseded of late by site-directed mutagenesis and protein engineering.

5. Other Methods Frequently used in Protein Chemistry

5.1. Circular Dichroism (CD)
CD is conveniently used to estimate the **secondary structure** content of a protein, by comparing the CD spectrum of a protein with those of the alpha-helix, beta-sheet, and turns. It is based on the chiral interaction of circularly polarized light with optically active molecules. A helical structure itself is chiral and interacts with left- and right-polarized light in different ways, as do nonhelical structures. A b-sheet, being another type of helix, is also chiral and shows a different spectrum from that of the a-helix. Consequently, the CD spectrum of a protein can be used to estimate the percentage of its residues in helical, b-sheet, and turn secondary structures.

5.2. Electron Microscopy (EM)
Large protein molecules can be observed by **EM**, either after staining them with a chemical

containing heavy atoms such as tungsten or uranium, or unstained by cryoelectron microscopy . The staining method called “negative staining” is frequently used to visualize proteins “negatively” as empty regions after staining with the heavy-metal reagent. Three-dimensional reconstruction of protein images taken from different angles is increasingly used for the structural determination of noncrystallizable proteins. The arrangement of subunits within an oligomeric protein molecule is often deduced from electron micrographs of negatively stained protein molecules. Observation is made in a high vacuum, which is far from the native condition for biomolecules, and the stain can perturb the structure. The recent inventions of cryoelectron microscopy and atomic force microscopy (AFM) have greatly increased the possibility to visualize individual protein molecules under near-native conditions.

5.3. Chromatography

Most classical types of chromatography are now available as **HPLC**, for improved performance when working with small samples. Prepacked columns with uniform-sized gel particles having a small size and high mechanical stability guarantee a superior performance over manually operated systems. Ion-exchange, gel permeation, and affinity chromatography are most frequently used for the purification of proteins. Reversed phase chromatography is particularly suitable for separating oligopeptides.

5.4. Polyacrylamide Gel Electrophoresis (PAGE)

PAGE is a mainstay in protein chemistry, with a variety of modifications suited to different purposes. Among them, disc electrophoresis and SDS-PAGE under reducing conditions are the two most frequently used variations, with great resolving power for the former, and as a convenient method for the estimation of the molecular weight for the latter. Electrophoretic mobility measurements made at several pH values provide the isoelectric points of proteins, as does isoelectric focusing. Capillary zone electrophoresis is a new development for all types of electrophoresis for analytical purposes, using very small amounts of sample.

5.5. Centrifugation

It was by ultracentrifugation that proteins were first shown to be homogeneous macromolecules, each of which had a definite molecular weight. Today, ultracentrifuges are widely used for preparative purposes to separate proteins and other biological macromolecules on the basis of their sedimentation coefficients. The analytical ultracentrifuge is specifically built for the determination of the molecular weights and hydrodynamic volumes of proteins by running a **sedimentation equilibrium** and **sedimentation velocity** experiments. The sedimentation equilibrium method was one of a few last resorts for determining the absolute molecular weight, until the development of mass spectrometry techniques. Other methods of determination of protein molecular weights include, in the order of specialization, light scattering, X-ray scattering, and neutron scattering.

5.6. UV and Visible Spectroscopy

The **absorbance spectroscopy** of proteins detects absorption bands in the visible and UV regions. The characteristic absorption of many proteins around 280 nm is due to the presence of Trp and Tyr residues. It is used to determine the concentration of a protein in solution, if its extinction coefficient is known. Proteins with a low content of Trp and/or Tyr (eg, collagen) have a very low absorption at 280 nm. Proteins with chromophores as prosthetic groups have visible colors. The red color of hemoglobin or cytochrome solutions is a good example. Some of the copper-containing proteins have an intense blue color. Flavin-containing proteins are often yellow in solution.

The backbone structure of a protein gives characteristic infrared and Raman spectra, due to its peptide groups (see Vibrational Spectroscopy). The absorption bands called amide I and II appear at specific wavelengths for a-helix and b-sheet structures. The relative intensities of these bands can be used to estimate the secondary structure of a protein.

5.7. Fluorescence Spectroscopy

Fluorescence is a sensitive and versatile technique for the study of various conformational aspects of

proteins. When irradiated with UV light, many proteins give a fluorescence emission spectrum in the wavelength region of 300 to 400 nm. The wavelength of maximum emission (l_{em}) is highly variable and depends on the physical environment of Trp and Tyr residues, which are solely responsible for the protein fluorescence. The emission from Tyr residues has l_{em} around 304 nm when no Trp residues are present, but if the protein has both Trp and Tyr, the emission spectrum is usually that of Trp alone, because of the resonance **energy transfer** from Tyr to Trp. Fluorescence spectroscopy is a very sensitive tool to monitor any structural change of protein molecules.

5.8. Rapid Kinetics

Methods such as stopped-flow and temperature-jump methods have been applied extensively to the study of the rates of enzyme catalysis or structural changes in proteins. Many valuable kinetic parameters have been obtained, and important intermediate species in such reactions have been proposed and identified. The time-scales of typical structural changes of proteins, and therefore of many biochemical reactions, including enzyme catalysis, range from microseconds to milliseconds.

6. Physical Properties of Proteins

6.1. Stability

Protein molecules, unlike synthetic polymers, normally have specific three-dimensional protein structures with unique thermodynamic and kinetic stabilities. The native three-dimensional structure of a protein is thermodynamically stabilized by the **cooperative** effects of hydrogen bonds, **hydrophobic**, **electrostatic**, and van der Waals interactions, plus in some cases covalent disulfide bonds (4, 5). This folded conformation can be destabilized by extremes of temperature, pH, and pressure and by **denaturants** (see Protein Stability). It can be unfolded reversibly, when the unfolded protein refolds upon changing the conditions, or irreversibly, when it is prevented from refolding, usually by covalent modification or by aggregation. Unfolding can be monitored by changes in either the physical or functional properties of the protein, as **denaturation** usually inactivates the protein.

6.2. Folding

Protein folding is the process of forming a specific three-dimensional structure of the protein from its newly synthesized state or after being unfolded. After C. B. Anfinsen showed that denatured and reduced **ribonuclease A** can be refolded into the correct native structure with full specific activity (6), the *in vitro* refolding of many proteins has been studied, and many have been shown to occur spontaneously. Subsequently, it has been recognized that the resulting "Anfinsen's dogma" applies primarily to small proteins without complicated **domain** or quaternary structures. The pathway of folding has been investigated extensively with a hope to isolate and characterize the intermediate state(s) that are important in determining the rate and direction of folding. Many unexpected and exciting details in the folding process of proteins have been steadily unraveled, but the molecular mechanism of protein folding still remains one of the most outstanding unresolved problems in science (6, 7). Recent developments on the role of proteins called **molecular chaperones**, which seem to help other proteins fold to their native conformations, are giving insight into how proteins gain their functional structures *in vivo*. (see Protein Folding In Vivo).

7. Classification of Proteins

Proteins are traditionally classified as either *globular* or fibrous proteins. The individual domains or subunits of globular proteins are approximately spherical (see Protein Structure), whereas fibrous proteins usually have elongated structures. The classification is useful because of the lack of simple and visual words to describe complex structures of proteins. When approximated as ellipsoids of revolution, typical enzymes have an axial ratio of the long and short semiaxes of no more than five and thus are called "globular," whereas proteins like silk fibroin, **collagens** in bones and tendons, keratins, and muscle myosin are examples of fibrous proteins with greater axial ratios.

Another classical way of classifying proteins is based on their solubility properties in aqueous salt solutions. Historically, the fractionation of blood proteins was one of the most important contributions of protein chemistry to practical clinical applications. It was based on their solubilities in solutions with different concentrations of ammonium **sulfate**, at different pH's, or with different ionic strengths. Globulins were thus defined as those proteins that precipitated in 50% saturated ammonium sulfate and were insoluble in pure water. Proteins that were not precipitated in 50% saturated ammonium sulfate and were soluble in pure water were called albumins. Such names still persist, but today proteins are named after their functions as much as possible.

Yet another way of classifying proteins is based on whether a protein is functionally complete by itself or needs extra nonamino acid molecules other than polypeptide chain(s). Those that function alone are called *simple* proteins, and those that need other molecules are *conjugated* proteins. The polypeptide part of a conjugated protein is termed the **apoprotein**, and the other part is called the **prosthetic group**. The fully active complex is the **holoprotein**. Examples of conjugated proteins are (1) **glycoproteins** and mucoproteins (mucoids), where the former contain smaller amounts of carbohydrates than the latter; (2) nucleoproteins; (3) **lipoproteins**; (4) proteins, mostly enzymes, with small molecules, such as pyridoxal phosphate (PLP) and related compounds, biotin, flavins, NAD and NADP, folate, various metal ions in metalloproteins, retinal, vitamin $\mathbf{B_{12}}$, thiamine, fatty acids, etc.

Proteins are also classified according to their functions or by the major sites of their presence or synthesis. Thus, functional groupings are recognized, such as (1) enzymes (bio-catalysts); (2) enzyme inhibitors like proteinase inhibitors; (3) hormones; (4) **channel** proteins; (5) transport proteins; (6) structural proteins; (7) DNA-binding proteins; (8) **antibodies** (immunoglobulins); (9) growth factors; (10) lens proteins; (11) **ribosomal** proteins; (12) storage proteins, etc. According to their origins, proteins are often grouped as (1) blood (or plasma or serum) proteins; (2) egg proteins (egg yolk and egg white proteins); (3) milk proteins; (4) membrane proteins; (5) plant seed proteins, etc. Historically, different groups of proteins have been studied by researchers in different fields; eg, blood proteins by medical biochemists, milk and egg proteins by agricultural chemists, with specific purposes peculiar to their respective fields.

Proteolysis, Proteolytic

Proteolysis, or *proteolytic cleavage*, is the enzymatically catalyzed hydrolysis of peptide bonds in proteins [from *proteo*, the combining form for protein (from the Greek, meaning of primary importance) and lysis (from the Greek meaning dissolution)]. A large number of enzymes can catalyze peptide bond hydrolysis (see Proteinases). Some enzymes only act on one particular protein, others act on almost all proteins. Some may hydrolyze a single peptide bond in a protein (a process known as limited proteolysis, most commonly seen in zymogen activation), others may act only at selective peptide bonds in proteins (eg, those involving one particular type of residue, such as arginine), and yet others may have very broad specificity and cleave many types of peptide bonds.

Proteolysis is essential for an enormous range of biological phenomena ranging from digestion of dietary protein in the gastrointestinal tract, to blood clotting, hormone production, and blood pressure regulation. It also has numerous commercial applications. Proteolysis can be inhibited by naturally occurring anti-proteinases, which are either proteins, peptide analogues, or nonpeptide organic or inorganic molecules (see Proteinase Inhibitors). Synthetic proteinase inhibitors are being developed as important drugs by the pharmaceutical industry.

Proteome

The word “proteome” was created at the 1994 Conference on Genome and Protein Maps in Siena, Italy (1) and appeared in the literature for the first time in 1995 (2-5). Since then, the word has been widely adopted and within two years appeared in more than fifty publications (6-8).

Proteome means PROTEin complement expressed by a genOME. The proteome is all the expressed **genes** or proteins of a genome. A cell type may display numerous subproteomes under different growing conditions, nutrition status, health, or disease. “Proteomics” is the use of quantitative measurements of the level of a protein or gene expression to characterize biological processes and to decipher the mechanism and control of **gene expression** . Proteome research or proteomics is the best path between genome and function studies.

The word proteome is not synonymous with two-dimensional electrophoresis (2D-PAGE), but 2D-PAGE is currently the most powerful method to separate thousands of proteins in parallel and to display many of them. This parallel process is necessary, as discussed below, because of the tremendous complexity of nature and the proteome.

1. Nature's Complexity

In the past, we were taught that one gene expresses one protein or enzyme, but this statement is no longer strictly tenable. First, RNA **splicing** can produce several species of messenger RNA (mRNA), and the mRNA can be edited and modified before its translation. So, a single gene may give rise to several mRNAs. Second, most, if not all, **eukaryotic** proteins are modified covalently during or after translation (see Post-Translational Modifications); for example, more than 30% of eukaryote proteins are **phosphorylated** (9). Therefore, a single gene sequence might provide one or several polypeptide chains, each of which may then be modified in various ways, leading to many versions of the final protein.

Based on a study of more than a hundred proteins identified by 2D-PAGE, one gene in *Escherichia*

coli produces on average 1.3 different polypeptides, in *Saccharomyces cerevisiae* 3 variant proteins, and in humans 3 cellular proteins and more than 20 proteins secreted into fluid (5). If the human genome contains 100,000 genes, which seems a reasonable estimate, between 300,000 and 500,000 protein variants might be expressed at different times; they will represent the full human proteome.

Interestingly, pigeons have 80 pairs of chromosomes; we have only 23. Frog and salamander cells contain between 1.5 and 20 times the amount of nucleic acid we have (see C-Value). Nature might have increased the complexity at the protein level of humans, in part, to keep the size of the genome within bounds while preventing a growing number of errors during replication.

Full genomes of several organisms have been sequenced recently. However, the life of these organisms is understood only at the level of the information content. Such information dictates how the amino acid residues are assembled to form the polypeptide chain (see Translation), the precursor of the mature co-and/or post-translationally modified proteins. We need to characterize most of these proteins, the proteome, before we can understand the structure and/or function of complex biological systems.

Each cell or tissue has different subproteomes, depending on their differentiation state, nutrition status, health, or disease. Proteins from many cell or tissue subproteomes can be detected in body fluids. It is indeed well known that dying cells release their contents into the lymph and blood. As an example, myocyte cytosolic proteins such as creatine phosphokinase or troponin are released into the circulation in myocardial infarction. One therefore could anticipate that most soluble human proteins from any cell or tissue could be found sometimes in the bloodstream, even if only in minute amounts. At least 100,000 different proteins could probably be found in plasma at certain times.

It is then quite obvious that the study of cell, tissue, or even body fluid subproteomes requires massively parallel and rapid protein analysis and identification techniques. The selected methodologies should be very sensitive over a large dynamic range. The speed of all processes should be maximized by automation and size reduction.

2. Parallel Concentration and Separation of Protein Samples

Most biological samples are highly complex, and the range of protein concentrations encountered is tremendous, exceeding a factor of 10^6 for cell subproteomes and 10^{12} for body fluids. Consequently, concentration and separation steps are necessary today for most proteome analyses. Filtration, centrifugation, or recycling electrophoresis provides means to concentrate proteins that are present only in minute amounts. Liquid chromatography and/or electrophoretic techniques allow the powerful separation of proteome content, especially when they are linked to mass spectrometry.

Currently, high-resolution 2D-PAGE techniques are still the most powerful for concentrating and separating in parallel thousands of proteins (10-15). The two dimensions are, first, an isoelectric focusing separation, where the proteins are separated along a pH gradient by charge or isoelectric point, and, second, an SDS-PAGE separation done orthogonally to the first one, where the proteins are separated by size. For the first dimension, the pH gradient can be generated by carrier ampholytes (10, 11, 16) or immobilized pH gradients (17-20) (see **Isoelectric focusing)**. Immobilized pH gradients allow high loading capacity (21, 22), by reswelling precast dry IPG strips with sample solution (13, 23-25), and give highly reproducible separations even between laboratories, since the gradient is covalently attached to the gel matrix (26). Alkaline immobilized gradients have been designed that extend from pH 6 to 12 (27, 28). The second dimension SDS PAGE separation may be replaced by mass spectrometers, which give very precise protein mass measurements (29-34).

After an SDS-PAGE second dimension, the protein can be **blotted** or eluted from the gel for further chemical analysis, such as Edman Degradation amino acid microsequencing (34, 35). Several gel, or

membrane, punching machines have been designed to transfer gel or membrane spots automatically to robotized chemical stations and mass spectrometers. The parallel 2D-PAGE process then becomes sequential. The blotted membrane can also be scanned by matrix-assisted laser desorption ionization (MALDI) mass spectrometry (33). The mass spectrometry techniques can identify proteins, as well as simply detect them (30-32, 36-44).

3. Protein Detection and Identification

Numerous protocols for staining proteins have been designed (see Coomassie Brilliant Blue, Gel Electrophoresis, Ponceau S). The most sensitive until recently has been **silver staining** (45-56), although fluorescent dyes now provide similar sensitivity. If further protein identification and characterization are desired, however, no staining methods that modify the protein should be used (57, 58). The limit of detection varies from protein to protein, but at least 0.1 ng/mm^2 is generally required. Most of the colloidal stains provide a linear correlation over several factors of 10 between the protein concentration and the staining intensity. The slope of this correlation varies from protein to protein, however, with the staining properties being influenced by the amino acid composition, and even the amino acid sequence, of the polypeptide chain (59).

Proteins can also be detected if they are **radiolabeled** . ^{35}S-methionine labeling is most frequently used. In some cases, proteins are ^{14}C-labeled sequentially with each amino acid to obtain in parallel the amino acid composition of each spot (60, 61). This provides a massively parallel way to detect, and also to identify, many 2D-PAGE spots. Derivatization with Fmoc (9-fluorenylmethyl chloroformate) after acidic hydrolysis provides information about the amino acid composition at high detection sensitivity (pmol), but such analyses are sequential, not parallel (62, 63). The amino acid composition can be used to identify a protein and is successful on average 50% of the time when the genome is known. It is useful also for cross-species comparison when a genome is unknown (64). The identification of a few residues of amino acid sequence from the N-terminal, C-terminal, or even internal regions of the polypeptide chain is very powerful and discriminating: this has been called *sequence tagging* (65-68).

For small genomes, such as that of *E. coli*, a 3-residue sequence tag from the C-terminus, or 4-residues from the N-terminus, are usually sufficient for unambiguous protein identification. Once the full human genome is known, a 6-residue tag from either end will probably suffice. In addition, comparisons between the predicted and measured isoelectric points (pI) and the mass further refine the protein identification process. Indeed, the pI of a polypeptide chain that has not been post-translationally modified can be predicted, and it corresponds with very high accuracy to the value measured in immobilized pH gradients under denaturing conditions (69, 70). Prediction of the mass by SDS-PAGE is rather unreliable, but developments in mass spectrometry fortunately circumvent this problem.

Peptide **fingerprinting** and partial sequencing are certainly the most attractive tools to identify a protein rapidly when the corresponding genome is known (64, 71-73). In addition, peptide mapping allows the detection and identification of numerous post-translational modifications. Proteins are cleaved either chemically (by cyanogen bromide, CNBr) or enzymatically (**trypsin**, Lys C, etc.) in the gel, in the eluted spot solution, or on the membrane. The masses of the peptide fragments produced are then compared to the theoretical masses calculated from the known proteins of that species. When the masses of four or five fragments correspond to expected masses, the protein is identified with confidence. Any differences between the remaining unmatched peptide masses and the expected ones are often the result of one or more post-translational modifications, which then can be deduced from the difference. Table 1lists several cyber tools available on the World Wide Web in 1997 for protein identification and characterization.

Table 1. Several Sequence Analysis Tools Available on ExPASy Server [a], [b]

Protein identification	
Swiss-Shop *(L)*	A sequence alerting system for SWISS-PROT that allows one to obtain automatically (by e-mail) new sequence entries relevantto one's field(s) of interest.
AACompIdent *(L)*	Identify a protein by its amino acid composition.
AACompSim *(L)*	Compare the amino acid composition of a SWISS-PROTentry with all other entries.
MultiIdent *(L)*	Identify proteins with pI, MW, amino acid composition,sequence tag, and peptide mass fingerprinting data.
TagIdent *(L)*	Get the SWISS-PROT proteins closest to a givenpI and Mw and identify proteins with a sequence tag.
PeptideMass *(L)*	Calculate masses of peptides and their post-translationalmodifications for a SWISS-PROT or TREMBL entry or user sequence.
Compute pI/Mw *(L)*	Compute the theoretical pI and Mw from a SWISS-PROTor TREMBL entry or for a user sequence.
ProteinProspector	A variety of tools from UCSF (MS-Fit, MS-Tag,MS-Digest, etc) for mining sequence databases in conjunction with mass proteometryexperiments (see also the mirror in UCL-Ludwig in the UK).
PROWL	Protein information Retrieval On-line WWW Lab from the MS groups at Rockefeller and New York Universities.
PeptideSearch	Peptide mass fingerprint tool from EMBL Heidelberg.
MOWSE	From Daresbury Laboratory.
Pattern and profile searches	
ScanProsite *(L)*	Scan a sequence against PROSITE or a pattern against SWISS-PROT and TREMBL.
ProfileScan	Scan a sequence against the profile entries in PROSITE.
Pfam	Scan a sequence against the PFAM HMM proteinfamilies db. A HMM search at Washington University/Sanger Centre (Hinxton,UK).
FPAT	Regular expression searches in protein databases.
PRATT	Interactively generates conserved patterns froma series of unaligned proteins.
Primary structure analysis	
ProtParam *(L)*	Physico-chemical parameters of a protein sequence (composition, extinction coefficient, etc).
ProtScale *(L)*	Amino acid scale representation (hydrophobicity,other conformational parameters, etc).
SAPS	Statistical analysis of protein sequences at ISREC (also available at EBI).

PSORT	Prediction of protein sorting signals and localizationsites.
SignalP	Prediction of signal peptide cleavage sites.
NetOGlyc	Prediction of type O-glycosylation sites in mammalian proteins.
NetPicoRNA	Prediction of proteinase cleavage sites in picornavial proteins.
Coils	Prediction of coiled coil regions in proteins (Lupas's method).
Paircoil	Prediction of coiled coil regions in proteins (Berger's method).
REPRO	Recognition of protein sequence repeats at EMBL.
Protein Colourer	Tool for coloring your amino acid sequence.
RandSeq *(L)*	Random protein sequence generator.
Secondary structure prediction	
AntheProt	Institute of Biology and Chemistry of Proteins (IBCP)/Lyon.
BCM PSSP	Baylor College of Medicine.
DSC	Discrimination of protein secondary structure at BMM (ICRF/London).
GOR	Garnier, Osgoodthorpe, and Robson (GOR) secondary structure prediction method (at SBDS).
nnPredict	University of California at San Francisco (UCSF).
PredictProtein	PHDsec, PHDacc, PHDhtm, PHDtopology, PHDthreader, MaxHom, EvalSec from EMBL.
PREDATOR	Protein secondary structure prediction from single sequence at EMBL (Argos' group).
PSA	BioMolecular Engineering Research Center (BMERC)/Boston.
SSPRED	Protein secondary structure prediction from aligned sequences at EMBL (Argos' group).
Tertiary structure	
Swiss-Model *(L)*	An automated knowledge-based protein modeling server.
Swiss-PdbViewer *(L)*	A program to analyze and superimpose protein three-dimensional structures.

[a] The tools marked by (*L*) are local to the ExPASy server. The remaining tools are pointers to other servers.

4. Protein Characterization, Modeling, and Function Prediction

First, any covalent modifications of the protein need to be identified. Many dozens of different types of modification have been reported, and many influence the protein's charge, hydrophobicity, conformation, and **half-life** (see Post-Translational Modifications). Numerous methods have been used to identify specific post-translational modifications: (1) blotting with lectins to detect specific

sugars (74, 75) (2) detecting phosphoamino acids by immunoblotting or ^{32}P radiolabeling, (3) Edman degradation sequencing, and (4) mass spectrometry.

Then, characterizing the protein and modeling its three-dimensional structure can be used to predict its function. The shape of the protein and how it interacts with other molecules provide functional information. Often, a protein structure can be predicted directly from its amino acid sequence when the structures of **homologous** proteins belonging to the same family have already been determined (see **Homology modeling)** (76, 77).

From separating the proteins to their identification and characterization, or to the final modeling and prediction of function, the extensive use of databases and computers is required. An up-to-date repository of genome and proteome information is absolutely essential in proteomic research, and a set of related cyber tools greatly enhances the potential to make significant discoveries.

5. Proteome Databases and Related Cyber Tools

Annotated protein databases (78-82) serve as a platform to link any virtual or real experiment with genome and biomedical information. Virtual protein chemistry tools can be applied to the protein database to predict results (Table 1). Comparison between experimental and computer data permit the identification and characterization of numerous proteins, as mentioned above.

2D-PAGE image analysis provides qualitative and quantitative information on changes in protein or gene expression and can display epigenetic regulation (Fig. 1). Principle component analysis (83, 84), heuristic clustering tools (85), neuronal networks (86-90), and wavelet decomposition algorithms (91, 92) cluster gel images in meaningful groups and highlight the most significant proteome alteration or modification in a wide variety of experiments, in toxicology, health, or disease states. Protein databases establish a link between 2D-PAGE image databases (93) and genome and biomedical information (site currently unavailable) (Fig. 2). Many other databases should be linked to the protein structure database, such as those for protein motifs, three-dimensional structures, mass spectra data, etc (see Databases). Protein physicochemical parameters should be used to display and link the result of all experiments in proteome research such as the precise protein size, charge, composition, amino acid sequence, etc. Artificial two-dimensional protein maps can be reconstructed to display the expected results of any proteome analysis.

6. Present and Future Frontiers

The behavior of proteins is difficult to predict (Table 2). Their building blocks are far more complex than those of nucleic acids. Their solubility is often poor in water and even sometimes in the presence of **chaotropic** agents and strong detergents. Many proteins are unstable or quite reactive and have a short half-life. Their concentrations in a very complex biological fluid can vary tremendously. There is no necessary correlation between mRNA level and protein concentration (94). Indeed, expressed sequence tag (EST) databases are derived from mRNA abundance and not from the amount of protein. Therefore, we cannot predict protein abundance from genome or mRNA studies. Today, separation techniques such as 2D-PAGE or capillary zone electrophoresis and mass spectrometry show only the tip of the iceberg as far as the complexity of organisms goes, but they will undoubtedly progress. Even when the technological problems are solved, real physiological experiments will be required in many cases to study further epigenetic regulation in the entire

organism and to measure the effects of external influences (95-97). At that point, proteome research will bring a new dimension to combinatorial chemistry and genome studies and will hasten new therapeutic developments.

Table 2. Differences between Proteins and Nucleic Acids

Chemical Family	Nucleic Acids	Proteins/Peptides
Belongs to	Genomes	Proteomes
Level	Information	Product
Number of building blocks	4+	≥20
Solubility in water	High	Often very low
Natural or artificial blockage when sequencing	No, but sometimes problems with GC rich stretches	Yes, very often
Prediction of behavior	Easy	Difficult
Number of specific cleavage enzymes	Very many (>300)	Few (<12)
Possible propagation or amplification	Easy	No (except prions orenzymes that catalyze their formation from pro-enzyme?)
Number of residues sequenced/day (1997)	>10,000	<50

Proton Gradient

The term “proton gradient” is a somewhat inappropriate name for the transmembrane electrochemical proton potential that is involved in chemiosmotic coupling. This term obscures the fact that the gradient is actually composed of two terms: the difference between the proton activity (concentration) or pH, and the membrane potential. See Chemiosmotic Coupling for further details.

Proton Motive Force

The *proton motive force*, abbreviated D*p*, is the electrochemical proton potential across a membrane expressed in terms of volts, which is the energy available to drive ATP formation, metabolite transport, or motility. At 25°C, the value of D*p* in millivolts is approximately equal to 59 (DpH) + DY, where DY is the membrane potential in millivolts. See Chemiosmotic Coupling for

further details.

Protoplast Fusion

The cells of bacteria, fungi, and plants may be converted to protoplasts (or *spheroplasts*) by the enzymatic degradation of their cell walls. This opens up a range of new possibilities for the investigation of cells. Protoplasts may be fused with other protoplasts from strains of the same or different species or even with animal cells (1) or liposomes (2). The motivations for carrying out such protoplast fusions are diverse and include genetic investigations of species that are not amenable to normal genetic study, the improvement of strains of organisms of agronomic or biotechnological importance, the study of nucleo-cytoplasmic interactions and the introduction of foreign materials into cells (see Transfection).

The spontaneous fusion of protoplasts is usually quite rare, and the event must be induced in some way. The fusion technique itself involves two processes: 1) bringing the two protoplasts into close membrane contact; and 2) limited, localized disruption of adjacent membranes, permitting the formation of cytoplasmic continuities between the cells. The presence of residual cell wall material on the surface of spheroplasts may interfere with the formation of close contacts between the cytoplasmic membranes, but the fusion of spheroplasts is quite often possible although it occurs at a lower frequency than protoplast fusion (3, 4).

Two basic techniques have been employed for inducing fusion. The first, and currently most widely used, technique involves chemical induction. Polyethylene glycol (PEG) causes a non-specific aggregation of protoplasts and also causes protoplasts to shrink by withdrawing water. This serves to bring cytoplasmic membranes into close contact and, of itself, is adequate to bring about a small number of protoplast fusions. For efficient protoplast fusion, PEG treatment must be accompanied by calcium-ion treatment that results in local disturbances in the membrane, leading to fusion. The optimal molecular mass and concentration of PEG should be investigated as a preliminary step to any previously untried fusion. For plant and fungal protoplasts, it is often desirable to use re-crystallized PEG, as degradation products or other impurities may interfere with fusion yields (5, 6). Degradation products formed during the autoclaving of PEG are similarly toxic and, when good yields are critical, it is necessary to sterilize by filtration. Calcium chloride is the usual source of calcium ions, but improved fusion yields have been achieved for *Candida albicans* and *Saccharomyces cereuisiae* (7) when calcium acetate or propionate is used.

The alternative to the chemical induction of protoplast fusion is *electrofusion.* This was first achieved by Senda et al (8), who used a DC pulse to fuse pairs of plant protoplasts micro-manipulated into contact. The process has been refined and applied to bacterial (9), fungal (10), and plant protoplasts (11). Contact is established between protoplasts by exposing them to an alternating, weakly inhomogeneous field that leads to polarization of the cells and their migration to regions of higher field density in a process known as *dielectrophoresis.* Because they form dipoles, the protoplasts line up on meeting, parallel to the field lines, in what have been termed “pearl chains.” The AC field also causes the lateral diffusion of membrane proteins and formation of protein-free regions at points of close contact (12). The fusion of adjacent cells is induced by a DC-field pulse of short duration and high intensity. This leads to electrical breakdown at the area of membrane contact causing pore formation and cytoplasmic continuity. The technique has a number of advantages over chemical fusion. It permits controlled observation of the fusion, limits the possibility for multiple cell fusion, and results in fusion products that have not been subjected to prolonged toxic effects of the fusogenic agent. The major disadvantage is that relatively small numbers of protoplasts may be processed compared with chemical fusion. It is possible to combine the PEG-induced aggregation of

protoplasts with electrical-field-induced fusion.

Whichever technique is chosen for protoplast fusion, it is necessary to have some means of selecting the fused cells (fusants) and a suitable regimen for the regeneration of a cell wall and reversion to dividing cells. Complementary auxotrophic mutations in the parent protoplasts are most commonly used to select fusants that should grow on a minimal medium. Other selection techniques may be based on (1) the complementation of resistances to antibiotics or other inhibitors (2), in the case of yeasts, the restoration of respiratory competence in a respiration-deficient mutant and (3), in plants, the complementation of an albino mutation. The use of mutant parent strains may not always be desirable, particularly in fusions aimed at producing new strains with agronomically or biotechnologically improved characteristics, where the presence of such mutations, even in a complemented situation, may be deleterious. In such situations, it may be advantageous to fuse protoplasts that have been differentially labelled, eg, with contrasting fluorescence signals.

Fusant cells with hybrid fluorescence may be selected either visually or using a *fluorescence-activated cell sorter* (FACS) (see Flow Cytometry). It is not always necessary that partners in a fusion should be individually viable. Protoplasts from cells killed by chemical, irradiation, or heat treatments may be fused with viable protoplasts. In some situations, this may improve the chances of obtaining hybrids; in others, it can be used to bias the genetic input of the parents. The heat killing of one partner in a bacterial fusion may inactivate restriction systems that could interfere with the success of the fusion. Regeneration and reversion conditions for hybrids may need to be investigated, as it is not necessary that hybrid protoplasts will behave similarly to the parents. It is not always possible to regenerate hybrids under direct conditions of selection. When bacterial protoplasts are fused, a wider variety of hybrid types can be isolated if they are initially grown on rich medium. Plant hybrids may need to be grown alongside nurse cells that provide growth factors for the protoplasts. The general requirements for the regeneration of protoplasts are discussed in Protoplasts.

Natural genetic systems in bacteria have three characteristics (13): 1) Genetic transfer is unidirectional; 2) DNA alone, and no cytoplasm, is transferred; and 3) It is an unusual event for the full genome to be transferred. Protoplast fusion seemed to offer great potential for studying genetic recombination between whole genomes and interactions between the nucleus and cytoplasm. Much work has been done with the *Bacillus* species, as these are easy to convert to protoplasts. Attempts at genetic mapping by recombination analysis in protoplast fusion hybrids, however, have not always been very successful. When protoplasts of complementary auxotrophic strains of *B. subtilis* were fused and fusants selected on a minimal medium, complemented diploids were extremely hard to find (14). When fusants were regenerated on a complete medium and well-isolated colonies were examined, practically no prototrophs were found. A significant number of fusants that grew on minimal medium plus the nutritional requirements of either of the parents, but not on a minimal medium alone, were discovered. These were referred to as *noncomplementary diploids* (NCDs). The physical presence of chromosomes from each parent in NCDs was demonstrated, and it was postulated that only one of the two chromosomes was being expressed. The silence of the chromosome is not the result of methylation but rather of a total shutdown of transcription (15). The genomes of the NCDs can undergo recombination, and this is the probable origin of the small numbers of prototrophic fusants obtained. Gabor and Hotchkiss (16) examined the recombination patterns and found that recombination was frequent and multiple in some NCDs and reciprocal recombinants were frequently uncovered, often together within a single regenerated colony. Recombination occurred in all chromosomal regions, but the frequencies of recombination were considerably greater in the chromosomal replication origin and termination regions. The latter was attributed to structural characteristics at the origin and termination regions associated with membrane attachments. The genetic manipulation of organisms when the requisite genes are known and accessible is best performed by transformation. Protoplast fusion for genetic manipulation is most useful when target genes are not known or a polygenic trait is to be transferred (17). It is also of value for the manipulation of organellar genetic systems.

The use of protoplast fusion for genetic manipulation has perhaps its greatest success, and potential

with plants and has involved intraspecific, interspecific, intergeneric, and intertribal fusions. Intraspecific fusions are generally performed to effect the pooling of desirable characteristics from varieties within a species. Attempts at interspecies (and higher-order) hybrid production have aimed to increase the gene pool available for the improvement of a crop or ornamental plant. Particular objectives have been the acquisition of disease and pest resistance, characteristics often found in wild species but lost from cultivated species or the breeding of new types of ornamental plants. With respect to crop plants, it is generally important that hybrids are fertile and they maintain the advantageous characteristics of the cultivated parent. Somatic hybrids often display low fertility, in particular for pollen, but this may be improved and desirable crop plant genes maintained by using the hybrid as the female parent in a back-cross to the cultivated species. The last few years have seen a rapid growth in the range of species for which protoplast formation, fusion, and regeneration are possible. Notably, techniques have been developed for woody species and members of the Poaceae (grasses), many of which are of economic importance and had previously proved recalcitrant, particularly in protoplast regeneration.

Whatever the outcome of a fusion process with respect to the contributing nuclei, cytoplasmic union is an inevitable outcome. When this occurs without nuclear fusion or the exchange of genetic information between the nuclei, the product is a *cybrid* (cytoplasmic hybrid). Mixing of the cytoplasms may be a slow process, but the time taken for the regeneration of protoplasts ensures fairly thorough cytoplasmic mixing before cell division occurs. In the yeasts *Saccharomyces cerevisiae* (18) and *Kluyveromyces lactis* (19), cybrid formation is the most common outcome of the fusion of two protoplasts. When nuclear fusion does not take place, loss of one of the two nuclei is likely to occur during the early divisions of the regenerating protoplasts. Fusion of a respiratory deficient, mitochondrial DNA mutant strain of *Candida utilis* with a respiratory competent *S. cerevisiae* gave rise to fusants having *C. utilis* nuclear and mitochondrial genomes, the latter transformed to respiratory competence (20). In addition, respiratory competence has been restored in a respiratory deficient strain of *S. cerevisiae* by fusion of protoplasts with mini-protoplast-containing functional mitochondria. This demonstrates the possibility of selectively introducing organelles into specific cells via protoplast fusion. In fusions involving protoplasts of respiratory competent strains, the mitochondrial genomes may not be retained equally in the hybrids. In a fusion of *K. lactis* and *K. fragilis,* it was demonstrated that the mitochondrial genome of the latter was always preferentially retained. Protoplast fusion may also be used in fungi to demonstrate the mitochondrial DNA location of a mutation (21). The transfer of dsRNA viruses between *Aspergillus* species has been achieved by protoplast fusion, although the strains involved were mating incompatible, demonstrating the potential of this technique to overcome mating barriers (22).

After fusion, the nuclei exist in a common cytoplasm for some time before karyogamy, or the loss of one nucleus occurs. Stable heterokaryons are characteristic of a wide range of filamentous fungi but not of yeasts or plant cells. However, heterokaryosis can be maintained by the continued application of selection in fusants when karyogamy does not take place. In *Saccharomyces cerevisiae,* the incidence of karyogamy can be greatly increased if the nuclei of the parents are synchronized by treatment with either *a*- or a-mating pheromones before protoplast isolation (18, 23).

The fusion of haploid strains of *Saccharomyces cerevisiae* usually produces stable **diploids**. *Kluyveromyces lactis*, however, gives stable diploids only if haploids of similar mating type are fused; *ala* hybrids produced by protoplast fusion **sporulate** spontaneously. In some cases with filamentous fungi, protoplast fusion produces stable, vigorously growing heterokaryons. In a similar manner to a fungal parasexual cycle, karyogamy may occur, producing heterozygous diploids and recombinants on segregation. This is the case for *Aspergillus nidulans* (24), *Penicillium chrysogenum* (25), *Aspergillus oryzae* (26), and *Aspergillus niger* (27). In the case of *Paecilomyces fumosoroseus* (28) or *Aspergillus chrysogenum* (29), heterokaryons grow very slowly, and heterozygous diploids are rarely found. Recombinant haploids can usually be obtained, probably resulting from karyogamy followed by early haploidization. In a number of instances, heterokaryons stabilized by the apparent random loss of chromosomes from one parent and gave rise to a genome containing the chromosomes from one parent together with a few chromosomes from the other.

The products of interspecific fungal protoplast fusion are less predictable. As a general rule, interspecific heterokaryons formed from filamentous fungi grow badly. Sporulation gives spores characteristic of either parent, often with a predominance of one of them (30). When the selection of yeast protoplast fusants is based on auxotrophic complementation, a common outcome is that these contain the full genome of one of the parents plus a small number (often one) of the chromosomes of the other parent (31-33). Aneuploids and diploids have been formed as a result of interspecific fusions of yeast protoplasts, but the fusants display the characteristics associated with the dominant contributor of DNA. It is not clear whether the retention of a single chromosome of one partner in a hybrid results from: 1) karyogamy followed by chromosome loss, or 2) from chromosome transfer between nuclei in a transitory heterokaryon.

As for plant protoplasts, the most significant potential for protoplast fusion is for the transfer of polygenic traits between species. When a characteristic to be transferred is determined by a small number of known genes, a direct molecular genetic approach to transfer is the most useful. When protoplast fusion is used, the fusant progeny are likely to have acquired an uncontrolled number of unwanted genes, as well as those being sought. Nevertheless, there have been many attempts to produce fusion hybrids with biotechnological value. Many of these have sought to construct strains in which the ability to metabolize novel carbon sources has been transferred from a poorly fermenting species to the efficient ethanol producer *Saccharomyces cerevisiae.* These include the fermentation of lactose, from *Kluyveromyces lactis* (34) and *Kluyveromyces fragilis* (35); of xylose, from *Pachysolen tannophilus* (36); and of cellulose hydrolysates, from *Zygosaccharomyces fermentati* (37). These studies have met with mixed success. Typically, fermentation levels in the hybrids are better than those of the parent strain that metabolized the substrate but still somewhat inferior to *S. cerevisiae* in terms of general fermentation efficiency. The stability of the hybrids is often an additional problem. Hydrids produced as a result of the fusion of protoplasts of the yeast *Pichia stipitis* stabilized during culturing as a result of ploidy reduction. Attempts have been made to improve the fermentation characteristics of yeasts by raising the ploidy level using protoplast fusion. In the case of xylose fermentation, raising ploidy levels increased rates of ethanol formation with *P. tannophilus* (38) and *Candida shehetae* (39) but not with *Pichia stipitis* (40). For filamentous fungi, improvements in citric acid synthesis by *Aspergillus niger* (27) and cephalosporin production by *Aspergillus chrysogenum* (29) have been achieved by the fusion of different strains. In many other recorded cases, however, protoplast fusion did not give rise to improved performance (30, 41). There is clearly some potential for the improvement of biotechnological performance using protoplast fusion with fungi, but the approach is so empirical that more rational strategies are preferable wherever possible.

Protoplasts

The cells of most **bacteria**, plants and **fungi** are surrounded by a more or less rigid cell wall. This is a multifunctional structure separated from the protoplasmic contents of the cell by the plasma membrane. Cell walls provide protection for cells against mechanical damage and allow cells to survive in a medium of lower osmotic potential than that of its protoplasm. They may also provide a locus for enzymes, ligands, and receptors, and, in some cases, they represent a barrier to the penetration of exogenous materials. These cell walls may be removed from most bacterial, plant, and fungal cells, leaving protoplasm surrounded by a plasma or cytoplasmic membrane. Such cells are referred to as *protoplasts*.

Protoplasts are osmotically sensitive, as in a suspension medium hypotonic to that of its protoplasm, water enters the cells by osmosis. This inflow is prevented in walled cells by the rigidity of the cell wall. It has been calculated (1) that the hydrostatic pressure of the cytoplasm of bacterial cells suspended in a dilute aqueous medium may be as much as 30 atm. In intact cells, this is contained by the inward pressure of the wall. In contrast, protoplasts transferred to a hypotonic medium swell and burst. It is consequently necessary for them to be suspended in an iso-osmotic or hypertonic medium for the protoplasts to survive. In iso-osmotic conditions, protoplasts assume a spherical shape. It is often difficult to be certain that a cell wall has been totally removed because cells become osmotically sensitive and adopt a spherical shape before the cell wall is completely removed, so neither of these can be regarded as an adequate indicator of protoplast formation. Cells from which the cell wall has been incompletely removed are referred to as spheroplasts. When it is not certain whether protoplasts or spheroplasts are being used, these are often referred to as osmotically fragile cells.

1. Bacteria

Bacterial protoplasts or spheroplasts can be prepared by the treatment of cells with the enzyme lysozyme (murein hydrolyase) that digests the peptidoglycan murein component of their cell walls. This was first achieved using **Gram-positive** *Bacillus* cells (2, 3). In the case of Gram-negative bacteria (4), the situation is significantly more complicated, as the typical wall (or envelope) structure comprises a relatively mobile inner or cytoplasmic membrane, a thin layer of murein and an outer membrane rich in lipopolysaccharide and stabilized by divalent cations. Both lipopolysaccharide and murein contribute to the rigidity of the envelope. The outer membrane prevents access of lysozyme to the murein, so it is usual to include EDTA (ethylene diamine tetraacetic acid) in the isolation medium to remove divalent cations. This destabilizes the outer membrane, causing the loss of significant quantities of lipopolysaccharide, and permits access for lysozyme to the murein layer. This technique invariably leaves significant quantities of outer membrane in place, so the usual products are spheroplasts rather than protoplasts.

Regeneration of bacterial protoplasts or spheroplasts to normal cells is variable in its success. Removal of the induction regime (lysozyme/EDTA) may permit regeneration of the cell wall if a suitable medium is provided. Success may depend on the growth phase of the cells used initially or the temperature at which the cells were grown and the regeneration is attempted (5). The nature of the osmotic stabilizer used to prevent the lysis of bacterial protoplasts can be critical, especially if the regeneration and reversion of protoplasts are required. Those most commonly used are inorganic salts (KC1, NaCl, $MgSO_4$) or nonmetabolizable sugars or sugar derivatives (sucrose, mannitol, sorbitol), or combinations of these.

Most, and possibly all, species of bacteria are capable of converting to *L-forms*. These, named after the Lister Institute where they were first discovered (6), resemble normal protoplasts or spheroplasts in being spherical in shape and osmotically sensitive but differ in their replication capabilities. **Electron microscopic** (EM) examination of L-form cells shows that they can be either devoid of any obvious cell wall material (protoplast-type L-forms), or they may contain some cell wall material (spheroplast-type L-forms). Large-scale conversion of *Bacillus subtilis* and other species of bacilli was first achieved by the removal of cell walls with lysozyme and plating the resultant protoplasts (spheroplasts) onto hypertonic soft agar medium (7). L-forms are most effectively induced by treatment with inhibitors of cell wall biosynthesis, especially penicillin and other **b-lactam** antibiotics. It is not always clear what heritable change leads to the L-form transition. Although there have been reports of changes in DNA sequence associated with the transition (8, 9), the ways in which L-forms are induced and the abilities of most L-forms to revert fairly readily suggest that, in most cases, the transformation is likely to be epigenetic in character. It has been suggested that the transition from an unstable to a stable L-form in *Proteus mirabilis* may be the result of a genetic change (4).

L-forms may be stable or unstable. The latter readily revert to the normal bacterial growth pattern and must be maintained in the presence of penicillin; the former are more difficult to revert, and, in some cases, reversion has not been possible. They grow by a budding process and shed envelope components as vesicular fragments. Murein is present in normal quantities and fully cross-linked but lacks its normal organization. Stable L-forms are usually devoid of an outer membrane and murein layer (10, 11). The cytoplasmic membrane of stable L-forms of *Proteus mirabilis* has been shown (4) to be modified from its normal composition, containing significant quantities of lipopolysaccharide and with a shift toward shorter-length fatty acids. L-form bacteria exhibit several properties that distinguish them from normal cells, such as resistance to **bacteriophage** in protoplast but not in spheroplast types, resistance to **antibiotics**, whose primary mechanism is to inhibit cell wall assembly, and increased sensitivity to antibiotics that act intracellularly. Early work suggested that L-forms of pathogenic bacteria were not pathogenic unless they showed a significant tendency to revert spontaneously. More recently (12), L-forms of some pathogens have been shown to retain pathogenicity. Some other pathogens show a tendency to adopt the L-form when patients are treated with penicillin.

2. Filamentous Fungi and Yeasts

Protoplasts may be formed from both filamentous fungi and yeasts. The usual method for making fungal protoplasts is to treat a culture with an enzyme cocktail that digests the major polysaccharide components of the cell wall: b-glucan, mannan, and chitin. Digestion of the cell wall was first achieved for *Saccharomyces cerevisiae* by Giaja (13) using the gastric juices of the snail *Helix pomatia* as the digesting enzyme mixture, although no protoplasts were formed in the absence of an osmotic stabilizer. These were obtained by Eddy and Williamson (14) also using snail gut juice (Suc *d'Helix pomatia*). Emerson and Emerson (15) produced the first protoplasts in filamentous fungi. There are now several commercially available sources of snail gut juice (b-glucuronidase, glusulase, helicase), and these are known to be complex mixes of glucanases, mannanases, lipases, and proteinases. Subsequently, other enzyme preparations have become available—some from bacteria, principally *Bacillus* and *Streptomyces* spp., others from fungi. The most widely used fungal enzyme preparations are Novozyme 234 (from *Trichoderma harzianum*) and Funcelase (from *Trichoderma viride*), which contain chitinase as well as the other enzymes mentioned.

Enzymic release of protoplasts from yeasts follows one of two pathways. Either the cell wall is gradually eroded until a protoplast (or spheroplast) remains or, when a suitably sized portion of cell membrane is exposed, the protoplast may be extruded through what is left of the cell wall. In yeasts this often occurs through a bud scar. In the case of filamentous fungi, protoplasts are often smaller than individual fungal cells, particularly in the case of coenocytic fungi, and are variable in size and nuclear content. The growing tips of hyphae are generally more susceptible to enzymic digestion, so protoplasts tend to be released from these regions. In some species, however, the release of

protoplasts may occur at any position on the hyphal surface. Because of the method of release, the osmotically fragile products of filamentous fungi are usually protoplasts rather than spheroplasts. The rate at which fungal protoplasts are formed may be limited by the accessibility of digesting enzymes to the inner layers of the cell walls. In particular, the access of glucanases to the inner glucan component may be restricted by the outer mannoprotein layer. The inclusion of disulfide-reducing agents (e.g., b-mercaptoethanol, dithiothreitol) may open up the mannoprotein matrix and enhance the rate of protoplast release. This is most important for stationary phase cells, from which it is often quite difficult to release protoplasts. For some species, however, the release of protoplasts is not enhanced by the presence of reducing compounds, and their presence may be deleterious insofar as they may interfere with the reversion of the protoplasts.

Sorbitol or mannitol are mostly preferred as osmotic stabilizers for yeasts and inorganic salts for filamentous fungi. Optimal stabilizers and concentrations of these differ from species to species, from strain to strain, and with growth conditions. For any new species or strain, it is usually necessary to establish optimal conditions for protoplast formation and maintenance. The minimum condition is that the osmolality of the suspending medium be at least isotonic with that of the cytoplasm. Hypotonicity results in lysis; hypertonicity may be tolerated up to a point but can result in a reduction of the rate of protoplast release (16, 17). There is a cell wall-less mutant strain of *Neurospora crassa* (18) that grows on the surface of osmotically stabilized agar as a cluster of multinucleate protoplasts. This mutant, to an extent similar to bacterial L-forms, has been used as a source of protoplasts whose cell membranes have not been exposed to lytic enzymes.

Protoplasts from some fungal species (eg, *Schizosaccharomyces pombe*, *Nadsonia elongata*) can regenerate a cell wall in liquid suspension (19). In many species, however, regeneration requires embedding protoplasts in a solid or semisolid medium (20, 21). This is necessary to prevent the diffusion and loss of cell wall materials secreted from the protoplast. In some species, it has proved difficult to regenerate dividing cells from true protoplasts but relatively easy to regenerate from spheroplasts (22). The first polymer to appear on the surface of a regenerating protoplast of the yeast *Candida albicans* appears to be chitin, which is then followed by b (1, 3) and b (1, 6) glucan. Once these polymers have been deposited on the protoplast surface, mannans and mannoproteins are secreted and, if restrained by the presence of a physical barrier, aggregate to form a nascent cell wall. In the case of yeasts, the initial regenerated cells are spherical because the cell wall is assembled on the surface of a spherical protoplast. The typical shape of the yeast cell is reinstated only in cells arising during subsequent budding divisions. Protoplasts of filamentous fungi may also regenerate a spherical cell that subsequently produces either a germ tube or pseudohyphal structure before the establishment of true hyphae (23).

Once the cell wall has assembled around the protoplast, the process of reversion to the normal cellular state can take place. While in the protoplast state, nuclear division (karyokinesis) can proceed, but cytoplasmic division (cytokinesis) is impossible. Consequently, many protoplasts may be multi-nucleate by the time the cell wall has regenerated. During the first few generations, the "regenerated" cell reverts to the "normal" state, that is, the number of nuclei per cell is eventually reduced to one, the cell wall changes from one having a high amount of chitin to one with a relatively low amount and cellular metabolism re-commences.

3. Plants

Plant protoplasts have been prepared from plant types ranging from algae to flowering plants and from a variety of tissues. Many protoplasts are totipotent and, given suitable conditions, will regenerate cell walls, initiate and sustain cell division, and regenerate complete plants. The source of plant material for protoplast production is very important, particularly if good regeneration is required. Suspension cultures have been widely used, early exponential phase cultures giving the best yields (24). Sequential subculturing, however, leads to diminished protoplast yields, as well as to the accumulation of mutations and loss of totipotency (25). If regeneration is required, protoplasts isolated from leaf mesophyll cells of living plants grown under strictly controlled environmental

conditions are usually most consistent. Shoot culture under axenic conditions is finding increasing usage as a source of mesophyll and shoot apical protoplasts (26, 27). This is particularly useful for woody plants. Other sources of protoplasts include roots, petals, cotyledons, somatic embryos, and pollen.

The first-ever protoplast isolation was completed by Klercker (28), who cut onion scale epidermis using a sharp knife under 1 *M* sucrose. A small number of protoplasts were released from cells whose cell walls had been cut without damaging the protoplasts. Enzymic isolation of plant protoplasts in quantity was later achieved by Cocking (29). In intact tissues, plant cell walls are surrounded by a layer of pectin that must be removed before a tissue may be dis-aggregated. The major component of plant cell walls is cellulose; a minor component, particularly in aging cells, is hemicellulose. Various enzyme products are available for the removal of plant cell walls. When purified enzymes are used, a mixture of pectinase, cellulase, and hemicellulase may be required, but cruder preparations often contain sufficient amounts of all the enzymes necessary for cell wall removal. An empirical approach may be necessary in any new investigation, as preparations that give good protoplast yields in one system may be damaging to the protoplasts in another. Fowke and Cutler (30) give detailed protocols for the isolation of protoplasts from soybean suspension cultures, pea leaves, somatic embryos, and the filamentous green alga *Ulothrix*. Protoplast yields may be enhanced by adding, in addition to the necessary enzymes and osmotic stabilizer (usually a sugar alcohol): 1) Tween 80 to encourage protoplast release (31), 2) potassium dextran sulfate (32) or bovine serum albumin (33) to improve protoplast stability, or 3) antibiotics to prevent the growth of bacteria present from the source material (34). Protoplasts may be purified from residual plant material by flotation on either sucrose or Ficoll gradients (30). Healthy protoplasts appear spherical, and cytoplasmic streaming is apparent. Viable protoplasts, on treatment with fluorescein diacetate, produce **fluorescence** inside the plasma membrane.

The regeneration of plant protoplasts was first reported by Takebe et al. (35) for tobacco and has now been described for well over 300 species from at least 50 families. The process is very complex but can be considered to take place in three stages: 1) preparation for cell division involves the synthesis of a cell wall and the onset of DNA replication and **organelle** assembly; 2) cell division results in the establishment of a callus (undifferentiated cell mass); and 3) morphogenesis comprises differentiation to produce a somatic embryo. Establishment of cell division of protoplasts has been achieved by embedding in agar medium or overlaying a liquid protoplast suspension onto an agar surface. The accumulation of toxic compounds in the region of the regenerating cells may interfere with their recovery and, for this reason, it may be useful to include filter paper at the liquid agar interface or activated charcoal in the agar (34). Other problems stem from the presence of toxic materials in some agars or the temperature shock experienced by protoplasts on suspension in molten agar. Success has been achieved in many cases by the use of agarose or alginate as low-temperature gelling agents.

The nutritional requirements for protoplast culture are generally similar to those required for plant cell suspension cultures and are complex. Plant protoplasts are remarkably variable in their nutritional demands, and slight variations in the quality of the protoplast source or of medium constituents have given rise to difficulties in reproducing results between laboratories. The nature of the nitrogen source and the levels of growth regulators provided are particularly critical.

4. Applications

Probably the most important use of protoplasts, and the one that gave the impetus to the rapid developments in protoplast technology during the last 20 years, is genetic manipulation of species using protoplast fusion. However, protoplasts have also found many other uses. One of the most important has been the isolation of cell organelles undamaged by the mechanical fragmentation required for walled cells. This approach has been used for the preparation of intact nuclei, mitochondria, chloroplasts, and vacuoles, as well as for cytoplasmic and tonoplast membranes. Protoplasts have also been employed for the study of cytoplasmic membrane permeability and

transport properties, for the investigation of the biochemistry of cell wall synthesis, and to assist in the introduction of macromolecules into cells.

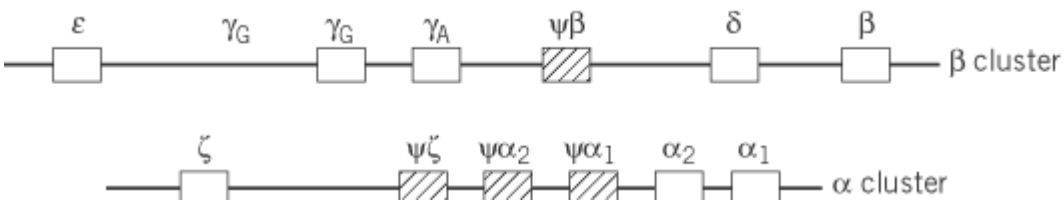
Pseudogenes

Pseudogenes are functionless **gene** variants that are present as a result of ancient historical accident. Two general types of origin of pseudogene are postulated: (1) duplication within tandemly repetitive gene clusters, most easily envisaged as due to **unequal crossing over**; and (2) **reverse transcription** of messenger RNA followed by reinsertion of the **DNA** into the chromosomes. In both cases the sequence of the newly generated gene copy can decay by mutation without adverse effects on fitness. The new tandem repeat of (1) will be functionally redundant, and the reinserted reverse transcript of (2) will generally be without function from the start because it will be separated from its **promoter** sequence.

Pseudogenes that apparently arose as additional, redundant, tandem repeats were first identified in the two globin gene clusters of mammals (Fig. 1). **Globin**-encoding genes are expressed at different stages of development to provide the polypeptide chains for the range of globin tetramers: z_2 e_2, z_2g_2, a_2e_2, and a_2g_2 in the embryo; a_2e_2 in the fetus; and a_2 d_2 and a $_2b_2$ in the adult. In mammals generally, the a and a-like genes are present in one cluster and the b and b-like genes in another on different chromosomes. Figure 1 shows the arrangement in humans. Pseudogenes are present in both human gene clusters and are designated by the prefix “y.” Almost exactly the same arrangement is found in chimpanzee, gorilla, orangutan, and baboon, so the pseudogenes must have originated more than 100 million years ago. During the intervening time they have presumably been free to decay by mutation. Their present inactivity is due to multiple mutations, some of which would have been inactivating individually (1).

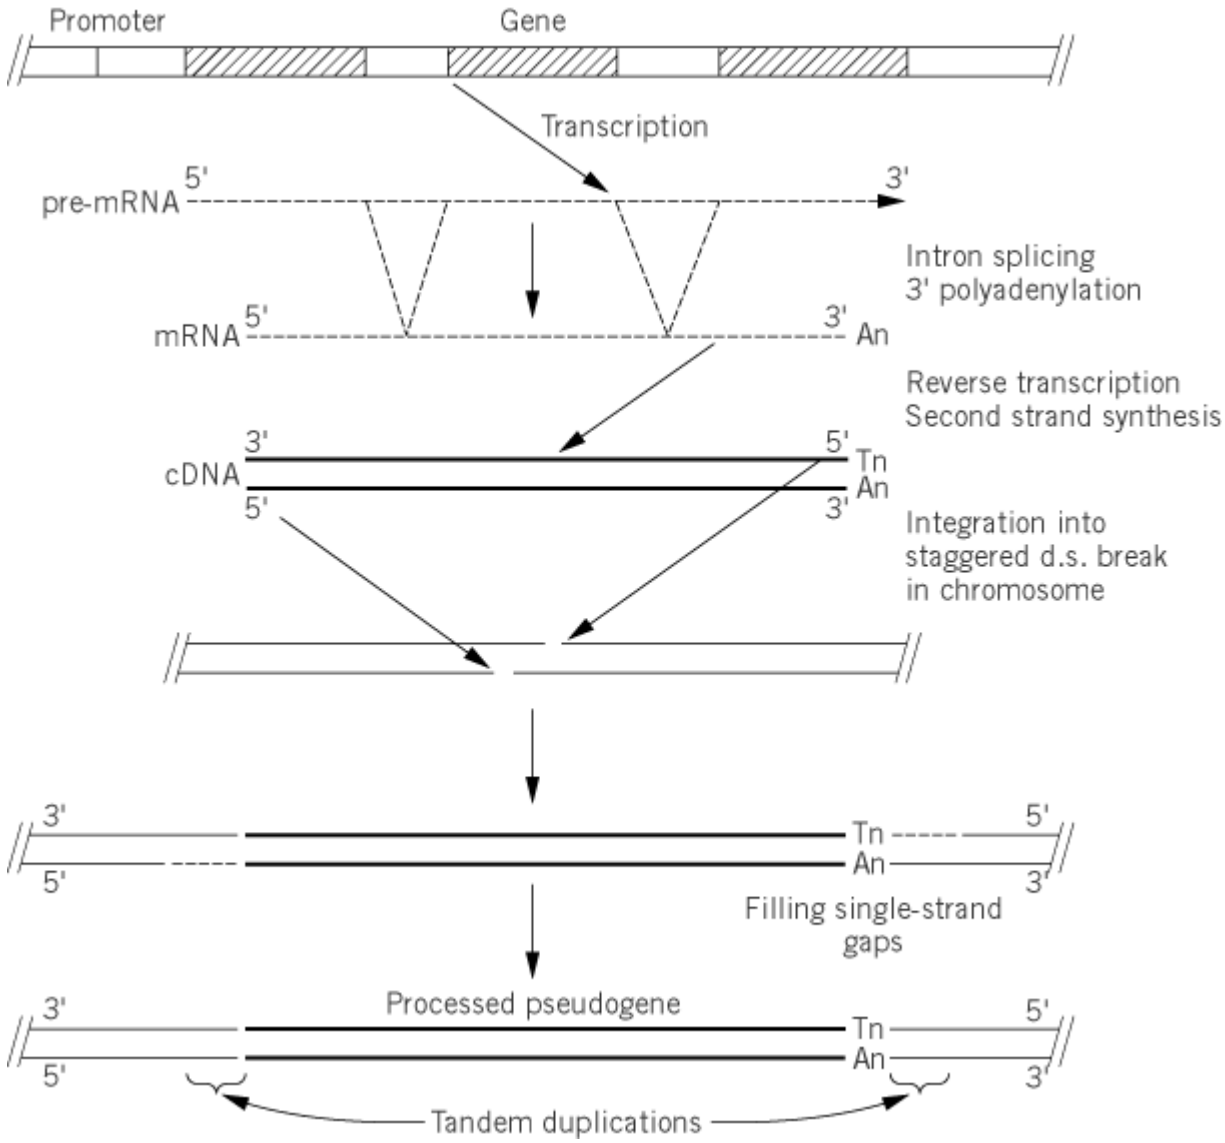
Figure 1. The arrangement of human globin genes. Pseudogenes are crosshatched and given the prefix y. They have undergone many disabling mutations, but retain recognizable similarity to their their functional progenitors, including intron sequences.



More remotely related mammals, for example, rabbit and mouse, have differently arranged a and b clusters, but these also include pseudogenes. This suggests that any tandemly repetitive arrangement of genes should be subject to the same generation of redundancy and decay. Indeed, several examples in support of this prediction are known, for example, in immunoglobulin and histocompatibility gene clusters and the repetitive 5 S **ribosomal** RNA genes.

Pseudogenes originating through reverse transcription of RNA differ most obviously from those arising from genomic DNA duplication in that they have lost any **introns** that may have been present in their progenitors. For this reason, they are often called processed pseudogenes. They may also show their mRNA origin through the presence of sequences of T residues at the 5′ end of their ancestrally transcribed sequence and an opposite sequence of A's at the 3′-end of the complementary strand, which is presumably a relic of the poly-A sequence at the 3′-terminus of mRNA. Processed pseudogenes may also be flanked by short direct repeats, a common feature of sequences that have been inserted into the genome in new positions (see Transposon, Retrotransposons) (Fig. 2).

Figure 2. The presumed mode of origin of a processed pseudogene by reverse transcription of mRNA and insertion of double-stranded cDNA into a double-strand break at some apparently arbitrary chromosomal locus. The flanking tandem repeats, which are present often but not always, are usually 10 to 20 base pairs long. They occur when the double-strand break is staggered, leaving single-strand gaps to be filled in by repair synthesis. The poly-A/T tracts (A_n/T_n) are on the order of 10 bp.



Because their sequences arise solely from RNA transcripts, processed pseudogenes lack any nontranscribed promoter sequences. Thus, if they are derived from messenger RNA, the product of **RNA polymerase** II, which depends on upstream promoters, they should not generally be capable of further transcription. Processed pseudogenes in this category should all be due to independent events. However, analysis of a total of 14 pseudogenes derived from the human gene that encodes argininosuccinate synthetase (2, 3) has shown that certain pairs have closely similar patterns of mutation, suggesting further replication following the initial reverse transcription. It remains true that processed pseudogene derivatives of protein-encoding genes, though collectively fairly numerous in mammalian genomes and a source of confusion in hunts for real genes, do not **amplify** individually to high copy number.

In contrast, the relatively small RNA molecules transcribed by RNA polymerase III can develop superabundant pseudogene clones. Examples are the transfer RNA-related elements in several mammalian genomes and, most famously, the **Alu elements** of humans, thought to be derived originally from the gene for the RNA component of the 7SL signal particle. This capacity for indefinite proliferation is attributed to the fact that polymerase III promoters are downstream of the transcription start point and hence within the transcribed region, so that reverse transcripts are capable of further rounds of transcription.

Psoralen

The psoralen family of compounds was originally discovered as natural products with the ability to cause intense photosensitization reactions (exacerbated sunburn) in human skin. Under controlled conditions, they became a major tool in the dermatologic armory for the treatment of several skin disorders. Simultaneously, it was found that they could also be used to unravel the details of molecular contacts between DNA and proteins, as well as between DNA strands. Among the wide variety of compounds that can be photoactivated, the photochemistry of psoralen is probably the most studied and the best understood.

1. Properties

Psoralens are members of the furocoumarin family. They are tricyclic structures (Fig. 1) with an extended aromatic system that gives rise to strong ultraviolet **absorption** bands near 220, 250 and 300 nm (Fig. 2) (1). Also shown in Figure 2 is the output of the ultraviolet lamps typically used to activate psoralen. The spectroscopic properties of representative psoralens are listed in Table 1. After absorption of a photon by a molecule in the ground state, an electron can be promoted to an excited singlet state. It may then return to the ground state by the emission of a photon or by the release of energy in the form of heat (radiationless collisional deactivation) or light (**fluorescence** or phosphorescence). Excited state forms of the molecule can react in different ways: photo-addition, photo-dimerization, and photo-oxidation of nearby moieties (nucleic acids, proteins, or membranes). Alternatively, energy may be transferred to molecular oxygen, leading to highly reactive singlet oxygen ($^1O_2$) (2). Although many molecules may absorb UV light, photochemistry rarely occurs. Furthermore, it has been shown that psoralen photochemistry in a solution can differ drastically from that within the confines of a cell.

Figure 1. The chemical structures of psoralen (**a**) and angelicin (**b**).

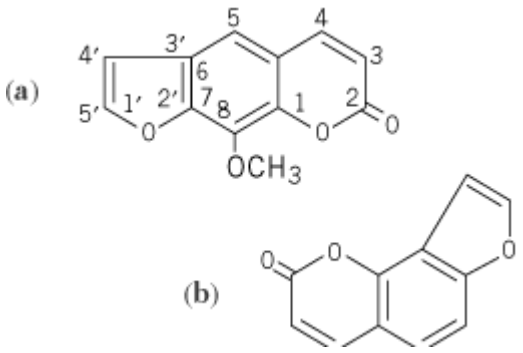

Figure 2. The UV absorption spectrum for 8-methoxypsoralen (8-MOP; inset) and the typical output of UVA lamps used to photoactivate psoralens.

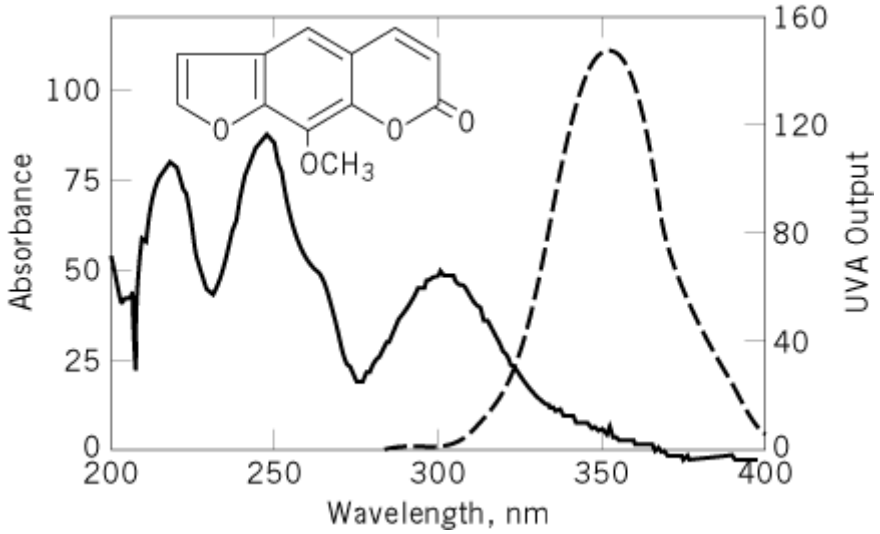

Table 1. Spectroscopic Properties of Psoralens(1)

	Absorbance		Fluorescence	
Compound	**l_{max} (nm)**	**Extinction Coefficient ($M^{-1}cm^{-1}$)**	**l_{max} (nm)**	**Quantum Yield**
Psoralen	295	10,600	450	0.019
8-methoxy	303	11,500	495	0.013
5-methoxy	308	14,500	-	-
3-carbethoxy	320	11,500	490	0.025
4,5′,8-Trimethylpsoralen	293	7,950	460	
4′-aminomethyl	298	10,000	450	
Angelicin	300	9,350		
3-methyl	300	10,900		
5-methyl	305	11,410		
4,5′-dimethyl	298	9,350		
4,6,4′-trimethyl	298	8,650		

2. Photoadduct Formation

2.1. Nucleic Acids

The best understood psoralen photochemistry is that which occurs when psoralen is intercalated between DNA base pairs. A 2 + 2 photocycloadditon product is formed between pyrimidine (primarily thymidine at 5′-TpA sites) when the intercalation complex absorbs UV radiation (3). Furan side monoadducts can absorb additional long-wavelength ultraviolet radiation (UVA, 320–400 nm) and, if located at a proper site, undergo a second photoaddition reaction, thereby forming an interstrand **crosslink**. The psoralen isomers (angelicins) are angular psoralens (Fig. 1) that have been studied because of their ability to form only mono-addition photoadducts on one DNA strand (4). Due to its angular structure, the angelicin 4′,5′-monoadduct cannot form crosslinks.

2.2. Proteins, Lipids

Although DNA psoralen photochemistry has attracted the most attention, psoralens also react with proteins as well as other cell constituents (5). In studies of subcellular fractions of rat epidermis after treatment with 8-methoxypsoralen (8-MOP) and UVA light, it was found that 17% of the 8-MOP was bound to DNA, whereas a substantial amount was bound to proteins (57%) and lipids (26%) (6). Proteins photomodification is known to alter the ability of endopeptidases to recognize the usual sites of incision (7). Much greater doses of 8-MOP and UVA are required to affect proteins than doses necessary to damage DNA. Even low levels of protein modifications, however, could participate in the concerted cellular events that lead to clinical effects. Recently, the first psoralen–amino acid photoadduct was described (8).

The ability of 8-MOP and trimethylpsoralen (TMP) to react in an oxygen-independent way with unsaturated fatty acids was first shown by Kittler et al. (9). Specht et al. (10, 11) and Caffieri et al. (12) independently isolated the lipid-psoralen adducts. NMR studies indicated that these adducts resulted from cyclo-additions of the 3,4-double bond of the psoralen to the central double bond of the fatty acid. Recently, Dall'Acqua et al. (13) suggested that these adducts have structures similar to **diacylglycerol** (DAG) and proposed that they could play a role in cell signal transduction events. In more recent studies, it has been observed that some photoactivated psoralens can crosslink DNA and proteins (14).

3. Impact on Cells

Over the nearly three decades that psoralen photochemotherapy has been employed by dermatologists, its efficacy has been explained on the basis of cytotoxicity, immune modulation, and/or apoptosis, somewhat depending on what has been in vogue. The initial observation of psoralen crosslinking led to the potent antiproliferative/cytotoxic paradigm that persisted until the evidence arose for gene induction and immune modulation.

The formation of psoralen–DNA adducts has been studied extensively in different cell types under *in vitro* conditions. [^{3}H]8-MOP has been used to quantify the number and type of adducts formed, using **HPLC** and radioactivity incorporation analysis (15). In Figure 3, the number of photoadducts induced in a variety of cells, and treated *in vitro* is shown as a function of the combined dose of psoralen and light (8-MOP concentration in ng/ml multiplied by UVA dose in J/cm^2). Adduct formation is directly proportional to the dose (r = 1.0). The effect of 8-MOP and UVA in response to mitogenic stimulation by phytohemagglutinin (PHA) and exclusion of trypan blue has been studied in human lymphocytes. The former response is abrogated at relatively low doses of 8-MOP and UVA, with a complete block at a combined dose greater than ~3050ng J/ml cm^2 (Fig. 4). Much greater doses are required to affect membrane integrity; hence, a distinctly different curve is seen for trypan blue exclusion (16). The antiproliferative effect of 8-MOP and UVA on murine keratinocytes was studied *in vitro* by Tokura et al. (17), who correlated the number of adducts with inhibition of [^{3}H]thymidine incorporation after PHA stimulation. A minimum number of 0.9 adducts per million bases was required to inhibit DNA synthesis. Moreover, it was shown that the photoadduct removal rate in keratinocytes was dependent on the extracellular calcium concentration, being reduced in low-calcium media (17).

Figure 3. Dose dependence for 8-MOP photoadduct formation in cells treated with 8-MOP and UVA light. Adduct numbers per megabase pair (mbp) are plotted vs combined dose of 8-MOP (ng/ml) and UVA light (J/cm^2). △, human lymphocytes; ○, murine keratinocytes; , bovine aorta smooth muscle cells; *f*, Jurkat cells.

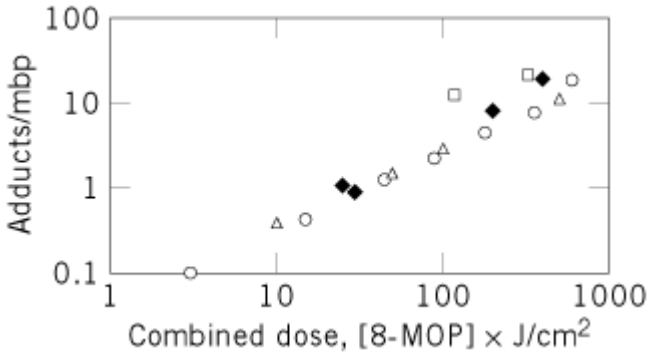

Figure 4. Dose dependence for cellular responses to psoralen and light. linear fit of the photoadduct data from Figure 3. The biological effects of these adducts are most significant at the lower modest doses (1 to 100), over which the response to PHA stimulation (, as measured by tritiated thymidine incorporation) is completely abrogated by a combined dose of 100. The impact on cell viability (as measured by trypan blue exclusion (heavy dash) measured three days after treatment) only occurs at much higher doses, reflecting the lower efficiency of 8-MOP photochemistry with proteins and lipids. Superimposed on these results are data (solid lines) illustrating the induction of class I MHC molecules on murine lymphoma cells, either total (*f*), (48), or surface-bound (○) ((49),(50)). Finally, the induction of apoptosis in human lymphocytes is shown (△) (22). Taken together, these data illustrate that any selected property is likely to have its own characteristic dose dependence. Furthermore, these different effects are likely to reflect the combined effects of 8-MOP/UVA at different cellular sites involving a range of biomolecules. The range of these dose-dependent effects may be represented by response to mitogen (perhaps best reflecting the impact of DNA photoadducts) and cell viability (reflecting the effects of photomodification of lipids and proteins). Regarding the latter, it is interesting to note that the impact on viability takes several days to develop. If viability is measured immediately following the 8-MOP/UVA treatment, there appears to be little difference between cell populations treated with different doses of 8-MOP and UVA.

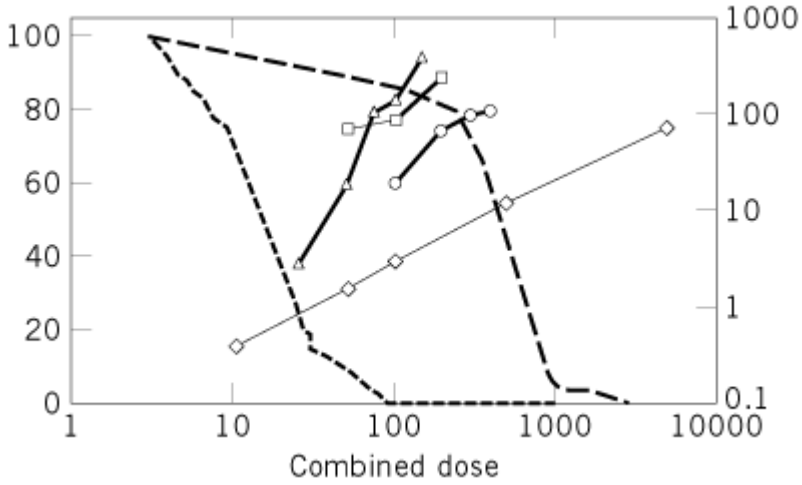

Extensive DNA repair studies have been carried out in bacterial systems as well as in mammalian cells. Several repair mechanisms have been described, including excision repair (the most common), postreplication repair, and photoreactivation (18). (See Photolyase/Photoreactivation.) It has often

been assumed that crosslinks would not be repaired, but an excision-recombination mechanism has been proposed to account for crosslink repair in bacteria and bacteriophage (19, 20).

Repair mechanisms in mammalian cells have not been described as completely, but it has been shown in various human and murine cells that DNA–psoralen adducts induced by 8-MOP and UVA can be removed (see Table 1). Freshly isolated human lymphocytes do not repair 8-MOP photoadducts when treated with 100 ng/ml 8-MOP and 1 J/cm^2 of light, but do remove photoadducts after treatment with only 10 ng/ml 8-MOP. In PHA–stimulated lymphocytes, relatively more adducts are formed, but more of these are repaired in 24 hours (16). Repair in murine keratinocytes seems to be more efficient than in lymphocytes, which may be due to the increased metabolic activity of keratinocytes.

4. Apoptosis

Although modest doses of 8-MOP and UVA are antiproliferative, higher doses can be toxic to cells. Thus, depending on the dose employed, the resulting effects can range from cytostatic to apoptotic to necrotic. Marks et al. (21) demonstrated the induction of apoptosis in human lymphocytes by using 300 ng/ml 8-MOP and 10 J/cm^2 UVA light (21). This dose is much greater, however, than the therapeutic dose used in patients (100–200 ng/ml 8-MOP and 1–2 J/cm^2 UVA). More recently, Vowels et al. (22) described the induction of apoptosis with more therapeutically relevant doses of 8-MOP and UVA (see Fig. 3).

5. PUVA Therapy for Psoriasis and Skin Cancer

If apoptosis fails, mutations may occur, which can lead to skin cancer. Thus, the therapeutic use of psoralens and UVA (PUVA) is not without drawbacks. PUVA therapy for psoriasis increases the incidence of squamous cell carcinoma (23). This is thought to be due to the formation of mutagenic psoralen photoadducts in the keratinocytes that are repaired incorrectly or not at all. Based on mutation frequencies in human fibroblasts treated with physiologic doses of 8-MOP and UVA, Burger and Simons (24) calculated the number of induced mutations in human *hprt* genes per phototherapeutic session (1.2×10^{-5}) and per 30 years of maintenance therapy (1.3×10^{-2} mutants per cell). This is two orders of magnitude greater than the spontaneous mutation rate. Petersheim et al. observed chromosomal aberrations and sister chromatid exchanges in treated lymphocytes immediately after photopheresis (25). Although the damage was repaired in 72 hours, no molecular information was presented to demonstrate the accuracy of the repair processes. The implications of these data are not clear, but close monitoring for mutations occurring in treated cells would appear to be prudent.

It has been thought that crosslinks would primarily lead to the observed mutations, because the mutations occur at crosslinkable sites (5′TpA). Recent evidence indicates that this is probably not the case. Chiou et al. (26) studied the induction of mutations in the *hprt* gene in human fibroblasts. Using 8-MOP plus low doses of UVA (0.0060 J/cm^2) to induce primarily monoadducts, mutations at 5′-TpA sites were observed. Fewer *hprt* mutations per 10^6 clonable cells were detected when a protocol favoring crosslinks (second irradiation of treated cells in the absence of any free psoralen) was employed. Because the numbers of adducts were not reported, drawing firm conclusions is difficult, but monoadducts might be at least as mutagenic as crosslinks.

Gunther et al. (27) studied the mutations induced by UVA and 8-MOP (producing both crosslinks and monoadducts) and those induced by UVA and 5-methylangelicin (5-MA; producing only monoadducts), related to adduct distribution. Mutagenesis was examined in a mouse fibroblast cell line carrying a recoverable, chromosomally integrated lambda phage shuttle vector, using the *supF* gene as a mutation reporter gene. Both psoralens generated predominantly T:A to A:T transition mutations with some T:A to G:C transversions. Most of the mutations occurred at TpA and ApT

sites, both of which are conducive to crosslink formation. However, 5-MA induces only monoadducts. In addition, it was shown by HPLC analysis that, under the 8-MOP/UVA conditions used, only 20% crosslinks and 80% monoadducts, were formed, strongly indicating that monoadducts, as well as crosslinks, are critical premutagenic lesions. Earlier, different studies concluded that crosslinks were more mutagenic than monoadducts, showing one mutation hot spot that correlated with crosslink formation (28, 29). These studies were performed by irradiating isolated vector DNA containing the *supF* gene with very high doses of 8-MOP and UVA. Gunther et al. (27) irradiated cells containing DNA with a chromosomally integrated *supF* transgene. Thus, the different results of these two kinds of studies could be attributed to the extra- and intracellular PUVA treatments used, which would be expected to lead to different adduct yields and distributions and, hence, to different mutation frequencies and spectra.

6. p53 Mutations in Murine vs Human Skin Cancer

Mice exclusively exposed to a regimen of psoralen and UVA radiation developed skin cancers over a 42-week period (30). Analysis of p53 mutations in the resulting tumors showed evidence of psoralen photochemistry at the expected 5′-TpA hot spots. In humans, however, the picture is significantly different. In two independent studies, a paucity of PUVA–type mutations at 5′TpA sites were found, and UVB–type mutations at dipyrimidine sites were more prevalent (31, 32). These data suggest that the incidence of skin cancers in PUVA patients may be traceable to some degree of immunosuppression in the PUVA–treated skin. In fact, these cancers may arise from previous solar damage. It may be possible to dissect the relative contribution of previous actinic damage and therapy-induced damage by analysis of p53 mutations in these patients.

Although it is common to think that DNA damage is mutagenic and cytotoxic, it has also been shown that it can lead to gene induction. In fact, many studies have illustrated how DNA damage can induce immune-modulating gene expression. An example of this was demonstrated by Bernstein et al. (33) in a transgenic murine system. Transgenic mice containing a chromosomally integrated reporter gene construct with the promoter for human elastin linked to the gene for chloramphenicol acetyl transferase (CAT) were used to demonstrate the dose-dependent induction of CAT activity (33). Events such as these link DNA damage to gene induction and can explain changes in cytokine production in phototreated cells (34, 35)

7. Therapeutic Applications

Psoralen photochemotherapy has been widely used for the treatment of the hyperproliferative skin disease psoriasis (36). 8-MOP is administered orally or topically and, after an appropriate time, the affected skin is exposed to UVA light. Clearing can be achieved after 8–12 weeks, with three treatments each week. The PUVA therapy can be gradually decreased, so that only maintenance therapy at monthly intervals is required. For vitiligo, a similar therapy can be followed, leading to repigmentation of the affected skin after 200–300 treatments (37)

It has long been thought that 8-MOP DNA photoadducts inhibit cell division and lead to the beneficial effects of PUVA therapy. However, immunosuppression due to PUVA also appears to play an important role (38). Although PUVA therapy has a high efficacy, it also exhibits some undesirable side effects, such as skin phototoxicity and increased risk of squamous cell cancer (see text above), both of which are thought to be due to the ability of psoralens to undergo photoreactions with DNA.

8. Other Applications

A completely different application of psoralens and UVA light is the sterilization of blood products, mainly platelet concentrates (38, 39). It has been shown that 8-MOP and 4′-aminomethyl-4,5′,8-trimethylpsoralen (AMT) are able to reduce the titers of enveloped viruses by factors of 10^5–10^6

while preserving platelet function. AMT has the advantage of being water soluble, and it is not harmful to the DNA-lacking platelets in the presence of scavengers of reactive oxygen species (40). AMT exerts some mutagenic effects in the dark, however, so it must be removed before transfusion. Other psoralens with undisclosed structures have reported to be very efficient for platelet concentrate sterilization (41), but the lack of published data makes evaluation of these claims very difficult.

9. A Tool for the Study of Macromolecular Structures

In studies employing adventitious interactions of proteins and nucleic acids, the ability of psoralen to be photoactivated *in situ* and to lock in structures has been used to identify molecular contact points between the interacting molecules (42). In other studies, psoralens have been chemically linked to oligonucleotides that recognize specific DNA sequences (including double helical structures) to deliver psoralen adducts either to specific nucleic acid base sequences or to proteins in contact with oligonucleotides (43). The internal structure of 16 S ribosomal RNA (rRNA) in the small ribosomal subunit has been studied using a site-directed crosslinking approach (44, 45). Psoralen derivatives were transferred into specific positions in the 16 S rRNA aided by complementary deoxyoligonucleotides, which were completely removed after the transfer reaction. Another photoreactive group, azidophenacyl, was then attached to the psoralen moiety before reconstitution of the 16 S rRNA into the 30 S subunit. Re-irradiation of the derivatized subunits with UV radiation produced intramolecular crosslinks in the 16 S rRNA, as evidenced by gel electrophoresis under denaturing conditions. Crosslinking points in the 16 S rRNA were determined after preparative separation of the products by gel electrophoresis, followed by reverse transcriptase analysis.

In another study by the same group, this technique was refined by pre-forming monoadducts in an oligonucleotide (46). Thus, monoadducts were targeted to specific nucleotides in the pre-mRNA, leading to the subsequent formation of intramolecular RNA-RNA crosslinks after another round of photoactivation. This decreased the number of crosslinked products in comparison to nonspecific psoralen crosslinking and confirmed the locations of previously determined free psoralen crosslinks in the human precursor mRNA. New crosslinks consistent with an alternative secondary structure were also observed, as were a small number of crosslinks representative of higher-order interactions. The use of psoralen isomers such as angelicins, and/or activation with other UV and visible wavelengths, could lead to more selective photochemical reactions that have the potential to reveal other binding modes and sites. The recent elucidation of a psoralen amino acid photoadduct is noteworthy in this context (see text above).

Table 2. Repair of 8-MOP Photoadducts in Different Cell Types[a]

Cell Type	8-MOP (ng/ml)/UVA (J/cm^2)	Adducts/mbp	% repaired (24 h)
Human lymphocytes (15)			
Resting	10/1	0.40	25
PHA stimulated	10/1	0.80	52
Murine keratinocytes (17)	15/1	0.48	54
Murine fibroblasts (27)	1080/0.1	4.4	ND
	1080+60′400nm light	2.9	66

10. Historical Acknowledgments

Five figures stand out for their contributions to the field of psoralen photochemistry, photobiology, and photomedicine. A half century ago, Aaron Lerner and Tom Fitzpatrick pioneered the application of psoralen photochemotherapy for vitiligo. In the 1970s, this was expanded by John Parrish to include therapy for psoriasis. It was in this same era that John Hearst developed techniques that led to a fuller development of psoralen photochemistry. In the 1980s, largely through the efforts of Margaret Kripke, we came to a better understanding of the immune-modulating effects of photoactivated psoralen.

Puff, Chromosomal

Puffs represent sites in polytene chromosomes that are active in gene transcription. The morphology of puffs is such that they contain chromosomal material that has become dramatically decondensed. The process of generating a puff has been likened to untwisting the strands of a rope (1). It is important to note, however, that transcription also occurs at nonpuffed bands in polytene chromosomes (2). Therefore it is probable that puffing represents a specialized adaptation of chromosomal structure or is a consequence of very high levels of transcriptional activity. Evidence for transcription at sites of puffing derives from the **immunofluorescent** staining of **RNA polymerase** II and the incorporation of **radioactive** uridine into RNA at puff sites, as revealed by autoradiography (3).

The appearance of puffs in polytene chromosomes is developmentally regulated. Analysis of puffing patterns has been very informative for studies of **gene expression**. In some organisms, like the midge *Chironomus*, puffs become enormous, thereby providing very valuable cytological insights into transcription and RNA processing (see Balbiani Ring). In *Drosophila melanogaster*, the study of puffing induced by the hormone ecdysone has been especially valuable. Ecdysone induces several puffs in salivary gland nuclei during the late third larval instar stage of development. These fall into two classes: (1) the early puffs, which appear within minutes of hormone addition and increase in size over a 1- to 4-hour period before diminishing; and (2) the late puffs, which appear after 3 hours, reach their maximal activity after 5 to 7 hours, and then regress. Inhibition of protein synthesis using drugs, such as cycloheximide, prevents the appearance of the late puffs but not the early puffs. This result indicates a requirement for protein synthesis to generate of late puffs, most probably using messenger RNA derived from the genes in the early puffs (4). Some of the early puffs fail to diminish if protein synthesis is inhibited, suggesting that autoregulatory circuits exist in which the early puffs are turned off by their own gene products. The early puffs encode several regulatory DNA-binding proteins that carry out both gene activation and repression (5). Interestingly, chromosomal duplications or deletions of sites of early puffing indicate that more copies lead to greater and more rapid activation of the late puffs, whereas fewer copies lead to a reduced level of late puffing activity (6). Genes within the puffs, activated by ecdysone, encode proteins, such as dopa decarboxylase, an enzyme involved in cuticle formation and pigment synthesis in hypodermal cells (7), and the glue proteins required to attach the pupa to its substrate (8).

Pulse-Chase Experiments

Radioisotopes provide one of the most sensitive methods of tracing the chemical pathway of a moiety in a biological system, especially in a complex milieu like that of an entire cell. Because a radioactive atom differs from its nonradioactive counterpart only in the weight of its atomic nucleus, the cell treats any compound containing a radiolabel virtually the same as an unlabeled one. The kinetics of a process can be followed by performing a pulse-chase experiment using radiolabeled material. The labeled material is added for only a brief period of time (the pulse). This is followed by adding a large excess of the unlabeled material (the chase), which effectively stops utilization of the labeled material. Then the fate of the radioactive material that entered the biological process during the brief pulse is followed as a function of time.

If the radiolabeled material is metabolized, the pathway followed by the radioactive atoms can be determined by fractionating the system as a function of time and determining into which other molecules they are transformed. Metabolic pathways have been determined in this way, as have the pathways of assembly of complex structures, such as **viruses**. If the radiolabeled material is not metabolized but transported within an organ or cell, its location can be determined by autoradiography . Such methods have assisted in elucidating the pathway taken by proteins secreted to the cell exterior (see Topogenesis) after their synthesis in the endoplasmic reticulum. Pulse-chase experiments using radiolabeled proteins also demonstrate that most of them are degraded and then replaced by new synthesis.(see **Protein degradation**)

Pulsed Field Gel Electrophoresis

During gel electrophoresis, long elastic polymers, such as **DNA** chains, and even large polystyrene spheres, become so entangled during their passage through the gel as ultimately to stop migrating. A change in the direction of the electric field can liberate these species from their entanglement. Net migration in one direction can be accomplished by alternating the field direction in pulses. The periodic change in the direction of the field also provides a mechanism for separation based on size; the longer chains are more sluggish in following the periodic changes of field direction than the shorter ones. Pulsed field gel electrophoresis (PFGE) of large DNA is based on the two mechanisms of liberation from entanglement and size separation (1).

Strictly, this is not a gel electrophoretic separation method because the separation is not directly related to the concentration of the gel; the gel acts as an anticonvection medium and, more importantly, as an array of obstacles entangling, stretching, and releasing the elastic, reptating DNA

chain (2).

A pulsed power supply can also be used to advantage in the electrophoresis of proteins to provide improved resolving capacity. This presumably functions by suppressing the band spreading that would occur as a result of effective heat dissipation during the off-power phase in cases of inadequate joule heat dissipation capacity of the apparatus.

Pumilio Gene

The *pumilio* is a **maternal effect** gene required for development of the fruit fly *Drosophila melanogaster*. *pumilio* is required during oogenesis for the development and maintenance of the germ-line stem cell lineage and in the embryo for patterning of the abdomen. *pumilio*, in concert with **nanos**, represses translation of maternally provided *hunchback* messenger RNA in the *Drosophila* embryo. Translational regulation is mediated by sequences in the 3′ untranslated region of *hunchback*, and Pumilio binds specifically to these regulatory sequences. Pumilio is a member of a conserved family of **RNA-binding** proteins with a novel RNA-binding motif. Ongoing studies seek to understand the interaction of the Pumilio protein with its RNA target.

0.1. Protein and RNA Structure

The *pumilio* gene spans over 160 kbp. The primary transcript contains **12 introns** (one over 120 kbp) and produces two mature mRNAs (6.8 kb and 6.7 kb) that encode identical proteins, but use different first exons. The *pumilio* mRNA is detected at high levels in ovaries, 0 to 8 hour embryos, and adult females (1, 2). Low levels of the transcript are also detected in 8- to 24-h embryos and pupae. The Pumilio protein is a 1533-amino-acid-residue polypeptide with a predicted molecular weight of 160 kDa. Analysis of Pumilio protein reveals eight imperfect repeats of 36 residues each (1). Recently it has been shown that these repeats constitute the *pumilio* RNA-binding domain (3, 4). This RNA-binding motif (known as the *pumilio* homology domain or PUM-HD) is conserved from yeast to humans (3, 5).

1. *pumilio* in Oogenesis

A *Drosophila melanogaster* ovary consists of approximately 16 ovarioles each representing an independent egg assembly line (for review see Ref. 6). Every ovariole is a linear array of developing egg chambers, beginning at the anterior with the germarium, where the progeny of the germ-line and somatic stem cells are organized into egg chambers. At the tip of the germarium, the germ-line stem cell produces a new stem cell and a cystoblast by asymmetric division. The cystoblast undergoes four rounds of division with incomplete cytokinesis, resulting in 16 cells connected by cytoplasmic bridges; one of these cells becomes the oocyte while the other 15 become nurse cells. Somatically derived follicle cells surround the egg chamber. As the egg chambers mature, the nurse cells synthesize and deposit factors into the oocyte that are required for the development of the oocyte and

early embryo. Late in oogenesis, the nurse cells contract and dump the contents of their cytoplasm into the oocyte.

Pumilio protein is expressed at high levels in the germ line stem cells and at lower levels in the dividing cystoblasts and the soma (7, 8). Females *trans*-heterozygous for strong *pumilio* alleles lay a few eggs, but rapidly become sterile due to a loss of germ-line stem cells from the ovary (7, 8). Analysis of *pumilio* mutant ovaries demonstrates that germ cells often fail to be incorporated into the ovarioles, suggesting that *pumilio*, like *nanos*, is required for germ-line cells to populate the ovary. Ovarioles with germ-line cells lack germ-line stem cells, and germline cells differentiate directly into egg chambers. This suggests that *pumilio* is required for establishment of the germ-line stem cell fate. Additionally, *pumilio* mutant ovaries from older flies often contain tumorous growths resulting from overproliferation of somatic cells, suggesting a role for *pumilio* in the soma as well.

2. *pumilio* in Embryonic Patterning

In the late oocyte and early embryo, *pumilio* mRNA and protein are distributed throughout the embryo (2). Pumilio activity is required for the **translational repression** of maternal *hunchback* RNA in the posterior half of the embryo. Hunchback is a zinc-finger transcription factor that controls transcription of the abdominal gap genes (9). In addition to Pumilio, repression of maternal *hunchback* translation is mediated by sequences within the *hunchback* 3′-untranslated region (known as *nanos* response elements or NREs) and the activity of the posterior determinant *nanos* (10). Pumilio protein binds to the *hunchback* NREs (3, 4, 11). Mutations that disrupt Pumilio binding *in vitro* have a strong effect on the regulation of *hunchback in vivo* (4). Together Pumilio and Nanos act through the *hunchback* NREs to direct removal of the maternal *hunchback* poly (A) tail in the posterior of the embryo, suggesting that deadenylation mediates translational repression (12). Ectopic expression of Nanos in the eye **imaginal** disc results in disruption of ommatidial development (4). Loss of Pumilio function suppresses the activity of ectopic Nanos, suggesting that *nanos* and *pumilio* are cooperating to regulate some gene product required for eye development. Additionally, ectopic *nanos* can repress the expression of reporter genes bearing the *hunchback* NREs and an internal ribosome entry site, suggesting that *nanos* and *pumilio* regulate translation independent of the **5′-cap** (4).

3. The Pumilio Homology RNA-Binding Domain

The pumilio homology domain has been identified in proteins or expressed sequence tags from human, mouse (*M. musculus*), rat (*R. norvegicus*), nematodes (*C. elegans*), yeast (*S. cerevisia* and *S. pombe*), plants (*A. thaliana*), rice (*O. sativa*), and corn (*Z. mays*) (3, 5). The high degree of sequence conservation among these very diverse species suggests that the PUM-HD is an ancient protein motif. Furthermore, a human PUM-HD can bind to the *hunchback* NREs, albeit with slightly altered sequence specificity (3). *fem-3* is a gene required to determine the sexual fate of *C. elegans* hermaphrodite germ line (13, 14). The regulation of *fem-3* is very analogous to that seen for *Drosophila hunchback*. *fem-3* contains a small *cis*-element within its 3′-untranslated region (known as the point-mutation element) that, when mutated, causes aberrant translation of *fem-3* (15, 16). Recently, FBF-1 and FBF-2 were cloned based on their ability to bind to the wild type, but not mutant, point-mutation element. FBF-1 and FBF-2 each contain a PUM-HD, suggesting that these proteins share not only a conserved protein motif with *pumilio*, but also a conserved function (5). Other PUM-HD family members have recently been shown to have a role in aging and recovery from stress, but their mechanism of action remains unclear (17).

Pure Line

A population of identical **homozygotes** constitutes a pure line. Pure lines "breed true"; that is, they maintain their phenotype indefinitely if genetic crosses are restricted to members of the pure line (see True Breeding).

The concept of pure line was introduced by Johannsen (1). Pure lines are obtained through repeated self-fertilization of heterozygous individuals or consanguineous crosses in heterozygous populations. Under Mendelian inheritance, the offspring of a single self-fertilization will be heterozygous for one-half as many genes as the parent. Repeated self-breeding approaches full homozygosity asymptotically. Several generations of self-fertilization are needed to obtain an acceptable pure line (97% of the genes that were originally heterozygous would have turned homozygous after five

generations). A population of an autogamous organism is a mixture of pure lines; and, if started from a single organism, the whole population is a single pure line.

Repeated crosses between close relatives also approach full homozygosity, but more slowly than self-fertilization. Thus, about 20 generations of crosses between a brother and a sister from each generation may be carried out to produce a pure line of mammals.

Populations of allogamic organisms, in which crosses occur at random or even with preference for distantly related partners (outbreeding), maintain a high level of heterozygosity. In these populations, rare recessive alleles that are deleterious when homozygous have little effect on the fitness of the population, because most of them are maintained in heterozygotes. The total number of such alleles may be high, because they may occur at many genes. The overall deleterious effect on the population (the *genetic load* of the population) may be considerable. Thus, human populations suffer on average a genetic load that is equivalent to that caused by the presence in each individual of four recessive lethal alleles (or a larger number of less disabling alleles). Inbreeding in allogamic organisms bring the deleterious recessive alleles to homozygosity; the immediate consequence is an increase in the frequency of defective offspring, or, in another words, an increase in the genetic load of the population. This phenomenon is called *inbreeding depression* or *inbreeding degeneration*. As inbreeding continues, the deleterious alleles are selected out and eventually disappear. The original heterozygous populations are often more fit than the resulting pure lines because they profit from heterosis and balanced polymorphisms; the main advantage of pure lines is the quick production of many individuals with the same well-adapted genotype, while the allogamy continuously generates new genotypes.

Purine Ribonucleotide Metabolism

1. Biosynthesis of the Purine Ring

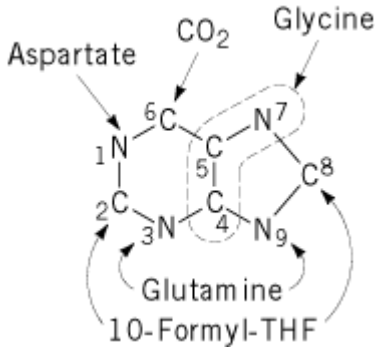
The biosynthetic pathway for the purine ring was described in the 1950s, in a classic series of experiments carried out in the laboratories of John Buchanan and G. Robert Greenberg. Birds excrete most of their nitrogen in the form of uric acid, an oxidized purine. Therefore, by feeding **radiolabeled** precursors to pigeons and then chemically degrading the uric acid crystallized from their droppings, it was possible to identify precursors to each position in the ring, and this led to identification of the reactions and isolation of the enzymes involved. This pathway is called the *de novo* pathway because it involves synthesis of the purine ring from low-molecular-weight precursors. A separate set of pathways is referred to as salvage pathways because they involve reutilization of preformed purine ring–containing compounds, usually nucleosides or nucleobases released by nucleic acid degradation (see Salvage Pathways To Nucleotide Biosynthesis).

2. *De Novo* Biosynthesis of Purine Nucleotides

2.1. Biosynthesis of Inosinic Acid

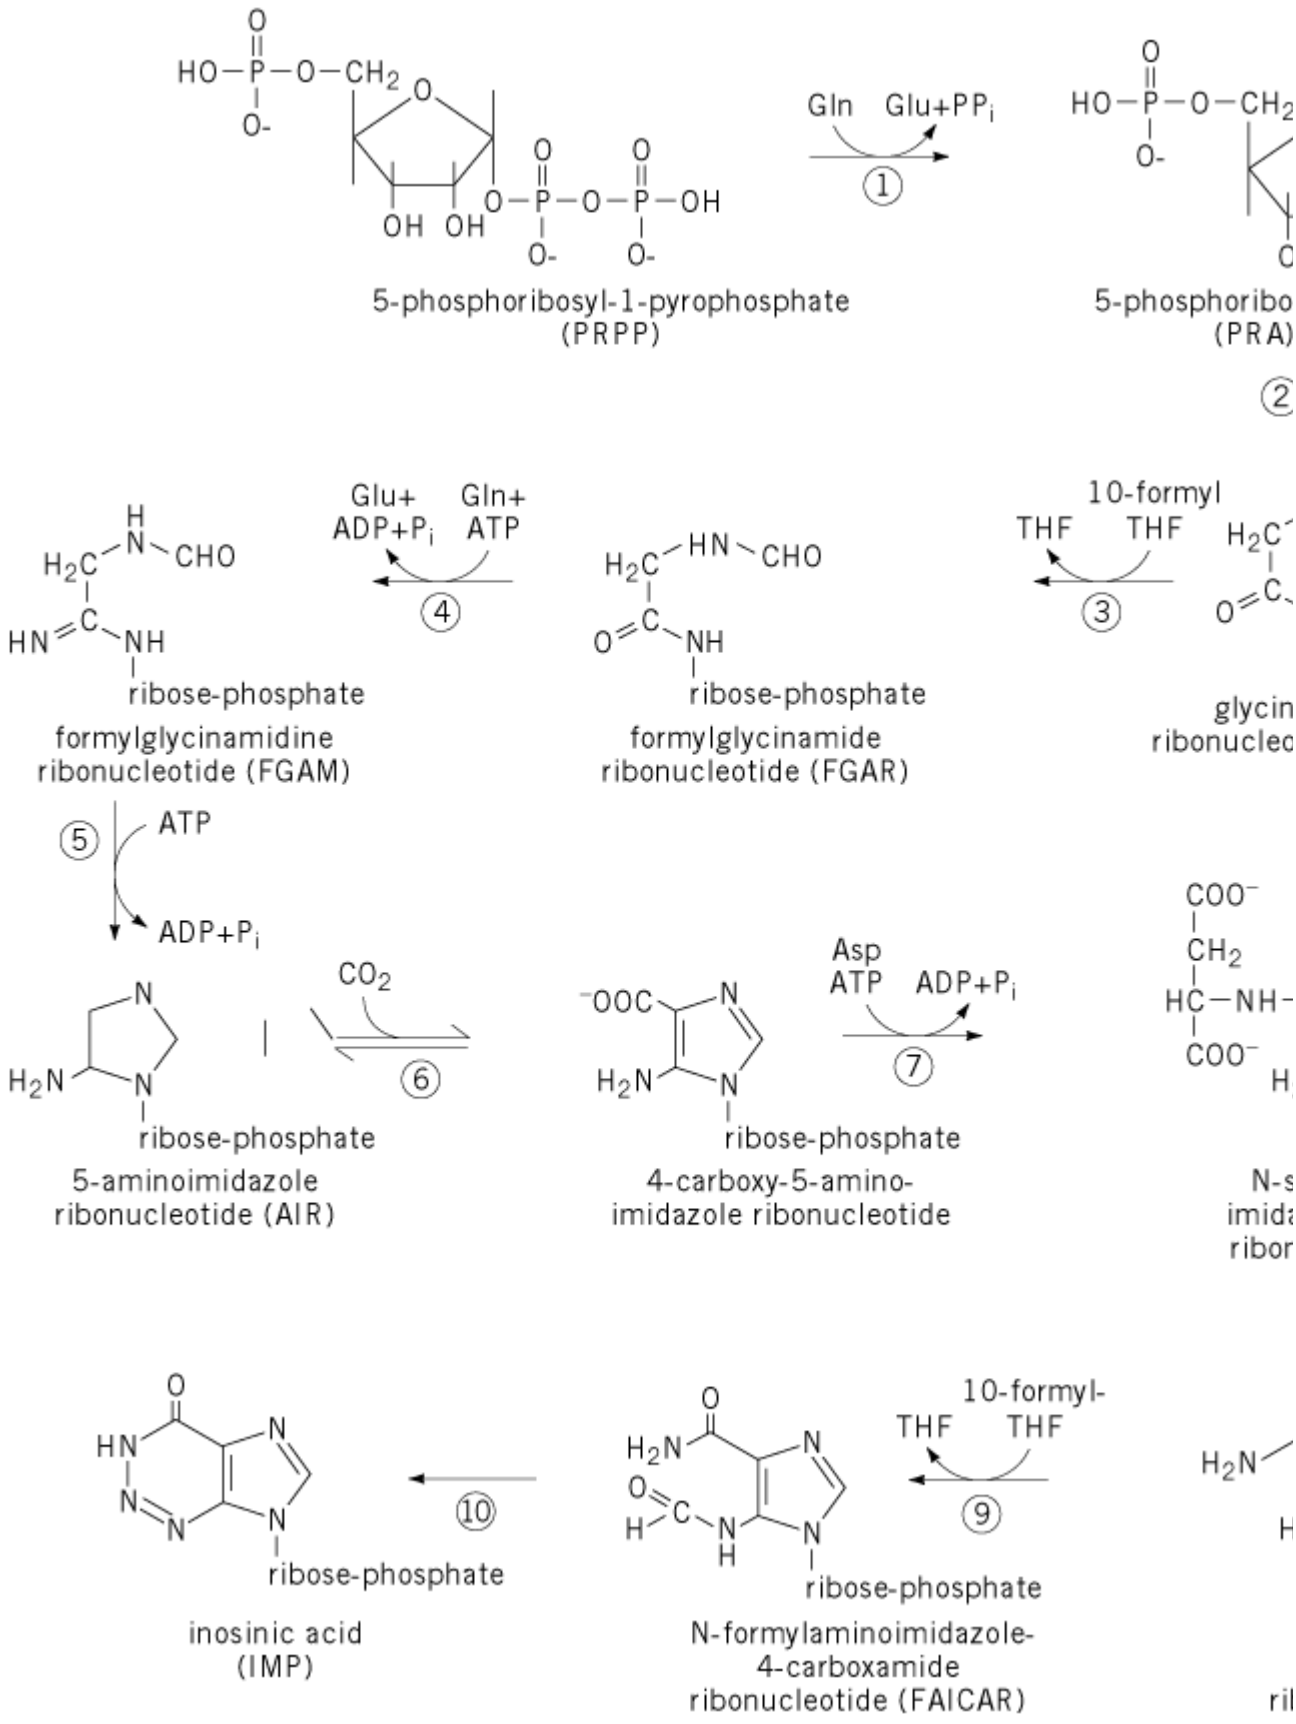
The early radiolabeling studies identified the precursors of the purine ring (Fig. 1) as glycine, glutamine amide nitrogen, CO_2, aspartate amino nitrogen, along with the "one-carbon pool," which included formate or the b-carbon of serine but which is now known to come directly from the formyl group of N^{10}-formyltetrahydrofolate (10-formyl-THF). The pathway is sensitive to inhibition by folate antagonists, such as methotrexate, and glutamine antagonists, such as azaserine, and this sensitivity largely explains the chemotherapeutic efficacy of these classes of antimetabolites. Aside from a number of parasitic protozoans, which lack the capacity for purine ring synthesis and depend on salvage pathways, the *de novo* purine synthetic pathway is virtually identical among all organisms examined to date.

Figure 1. Metabolic sources of the atoms of the purine ring, as determined by administration of labeled precursors.



That pathway, summarized in Figure 2, involves the stepwise assembly of the purine ring at the nucleotide level, on a ribose 5-phosphate backbone. In the first committed reaction (step 1), the glutamine amide group displaces the pyrophosphate at C-1 of 5-phosphoribosyl-1-pyrophosphate (PRPP), to give 5-phosphoribosylamine, the simplest possible nucleotide (its base is ammonia). The enzyme, PRPP amidotransferase , is the principal point for control of the overall pathway. There follows the ATP-dependent incorporation of glycine (step 2), the first of two formyltransferase reactions involving N^{10}-formyltetrahydrofolate (step 3), a second glutamine amidotransferase reaction (step 4), and a ring closure (step 5), yielding the imidazole portion of the bicyclic purine ring. The next reaction (step 6) is a CO_2-fixation reaction unusual in that it does not require biotin as a cofactor. Next (step 7), an ATP-dependent reaction links the aspartate amino nitrogen to the carboxyl group formed in the previous reaction. There follows an a,b-elimination reaction (step 8) in which the carbon skeleton of aspartate is released as fumarate, with its nitrogen becoming part of a carboxamide group. A second formyltransferase (step 9) creates a product that undergoes an intramolecular condensation (step 10), yielding inosinic acid (IMP), the first completed purine nucleotide. IMP has hypoxanthine as its purine base.

Figure 2. The *de novo* biosynthetic pathway to inosinic acid. Enzyme names: 1, PRPP amidotransferase; 2, GAR synthe FGAR amidotransferase; 5, FGAM cyclase; 6, AIR carboxylase; 7, SAICAR synthetase; 8, SAICAR lyase; 9, AICAR tr synthase.

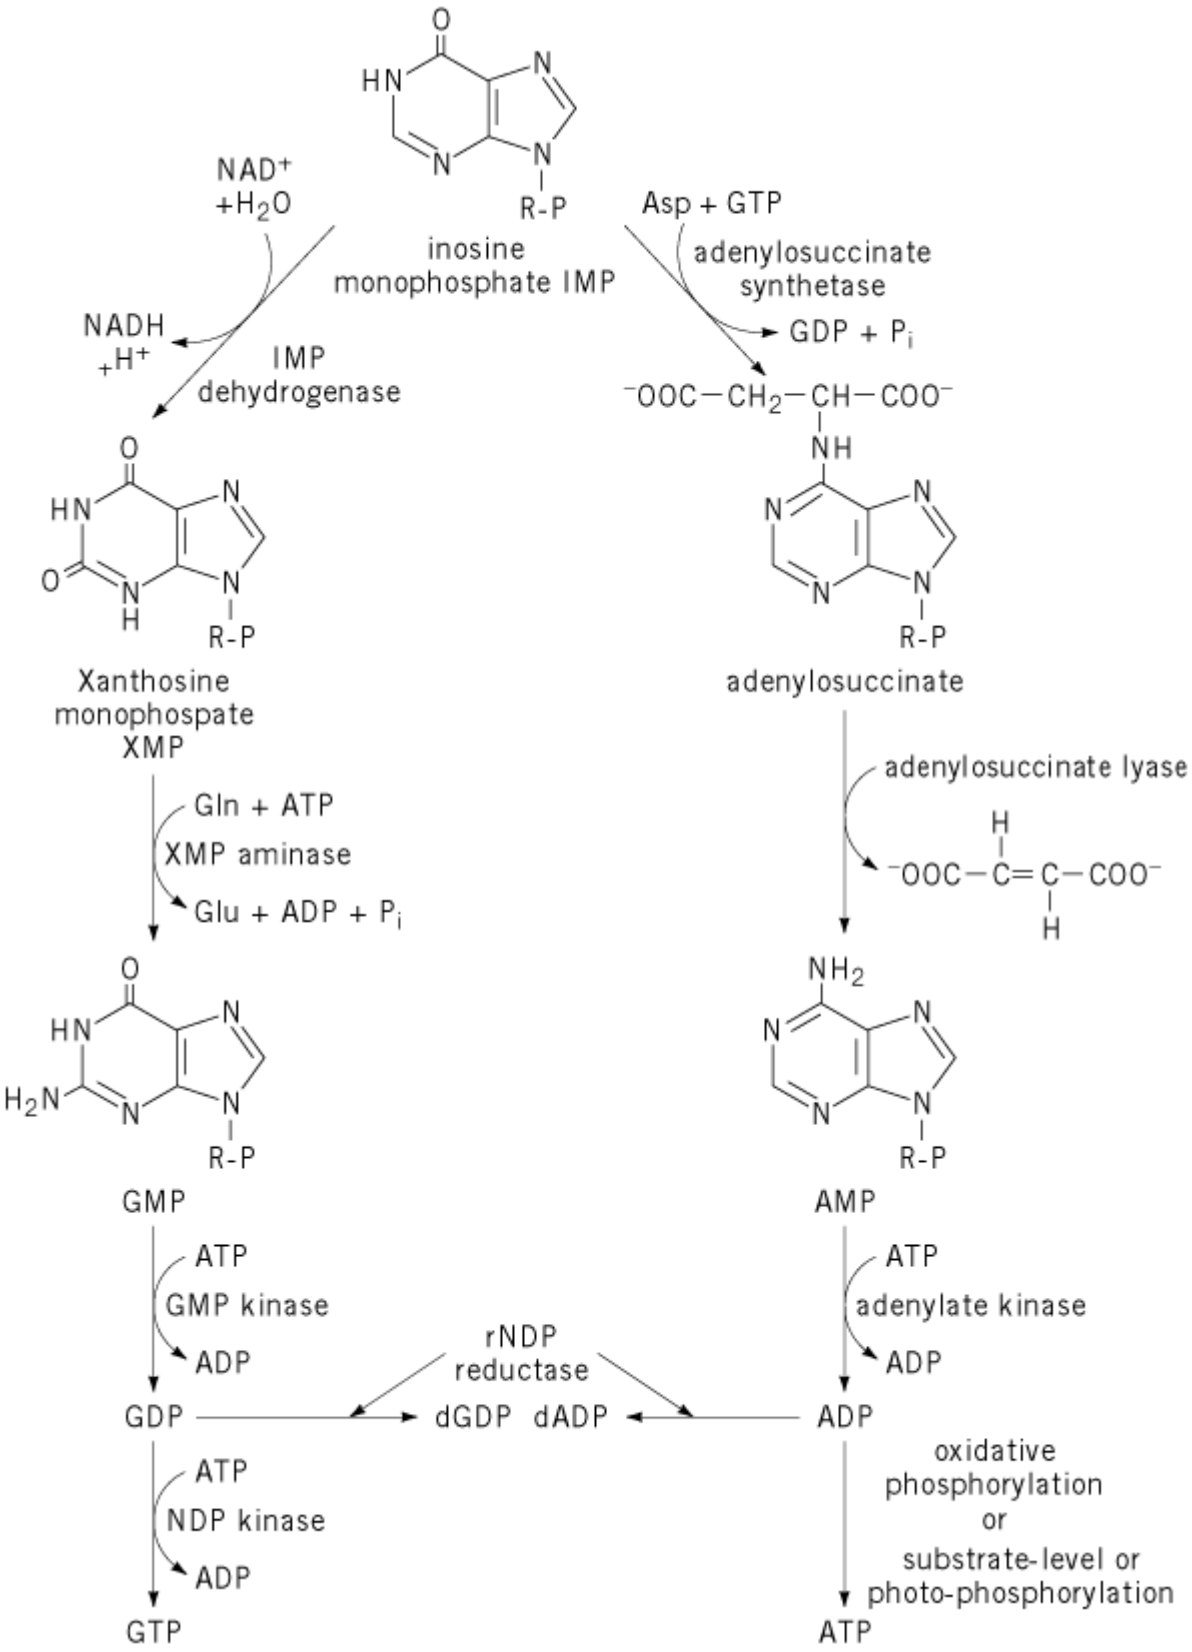


2.2. Conversion of IMP to Adenine and Guanine Nucleotides

IMP represents a branch point in the synthesis of adenine and guanine nucleotides, as shown in Figure 3. En route to GMP, IMP dehydrogenase oxidizes the hypoxanthine base of IMP to the

xanthine base of xanthosine monophosphate (XMP). An ATP-dependent glutamine amidotransferase converts XMP to GMP. En route to AMP, IMP undergoes a reaction sequence involving aspartate, which is very similar to reactions 7 and 8 of the IMP synthetic pathway, except that GTP, not ATP, is the energy cofactor. The release of fumarate is the last step in AMP synthesis.

Figure 3. Pathways from inosinic acid to ATP and GTP. R-P is a ribose 5-phosphate moiety. NDP kinase is nucleoside diphosphate kinase. A few organisms reduce ribonucleotides to deoxyribonucleotides at the triphosphate level rather than, as shown here, the diphosphate level.



AMP and GMP are converted to the respective 5′-diphosphates by specific nucleotide kinases. The resultant ADP and GDP are converted to the triphosphates by nucleoside diphosphate kinase, an active and nonspecific enzyme that transfers the g-(outermost) phosphate of any nucleoside 5′-triphosphate to any nucleoside 5′-diphosphate. Because the reaction has an equilibrium constant close to 1, the direction of the reaction is determined primarily by concentrations of substrates and products. Because ATP is by far the most abundant nucleotide in most aerobic cells, the principal

function of nucleoside diphosphate kinase is to catalyze the ATP-dependent conversion of nucleoside diphosphates to triphosphates, using ATP that was produced by oxidative phosphorylation.

In most organisms, the ribonucleoside diphosphates (purine and pyrimidine) serve as precursors for biosynthesis of deoxyribonucleotides (see Ribonucleotide Reductases and Deoxyribonucleotide Biosynthesis And Degradation). In some organisms, however, those precursors are the respective triphosphates.

2.3. Multifunctional Enzymes and Enzyme Complexes

Vertebrate cells contain a number of the various enzyme activities of IMP biosynthesis in the form of multifunctional enzymes. This was first suspected when **cloned** vertebrate **cDNAs** encoding purine synthetic enzymes were found to complement multiple genetic defects in purine synthesis after transformation into *Escherichia coli* (1). By this means, it was found that a single enzyme catalyzes the second, third, and fifth reactions shown in Figure 2. Similar evidence indicated that the sixth and seventh reactions are catalyzed by a bifunctional enzyme. Moreover, the two transformylase enzymes (reactions 3 and 9) in some animals constitute part of a tightly associated multienzyme complex that also contains several activities of tetrahydrofolate metabolism and single-carbon mobilization. The metabolic rationale for all these enzyme associations has not been established, but it may well involve the cell's attempt to utilize scarce or unstable intermediates more efficiently by facilitating their transfer from active site to active site within the same reaction sequence.

2.4. Regulation

Control of purine nucleotide synthesis involves both allosteric and genetic regulation. In most cells, PRPP synthetase, which synthesizes the first intermediate in IMP synthesis, is inhibited by AMP, ADP, and GDP, whereas PRPP amidotransferase (reaction 1), the primary control point for the overall reaction (2), is inhibited allosterically by AMP, ADP, GMP, and GDP. In *E. coli*, biosynthesis of the enzymes of IMP synthesis is inhibited by a **repressor** encoded by the *purR* gene. This protein binds either hypoxanthine or guanine, and the resultant protein-purine base complex binds to DNA sites upstream from **promoters** for several purine (and pyrimidine) biosynthetic enzymes. The crystal structure of the PurR repressor (3) shows it to be closely related to the well-known Lac repressor, which controls the lactose utilization operon by similar mechanisms.

Conversion of IMP to AMP and GMP is also regulated allosterically. GMP inhibits IMP dehydrogenase, the enzyme that converts IMP to GMP, whereas AMP controls its own formation by inhibiting the addition of aspartate to AMP to form adenylosuccinate (Fig. 3). Also, it may have regulatory significance that ATP is involved in the conversion of IMP to GMP, whereas GTP is required for one of the reactions leading from IMP to AMP.

3. Catabolism of purine nucleotides

Nucleotides released by enzymatic digestion of nucleic acids are rather efficiently reutilized for nucleic acid biosynthesis in most cells. However, pathways of nucleotide degradation are significant, as shown by sometimes unexpected and severe consequences of genetic deficiencies in humans of particular enzymes of purine degradation, as dealt with in the next section.

In primates, the end product of purine nucleotide catabolism is uric acid, which is excreted as such. Pathways leading to uric acid vary considerably in different tissues and cells. Most of the reactions involved are shown in Figure 4. Note, for example, that AMP degradation can begin either with deamination, to yield IMP, or with hydrolysis, to yield adenosine. In mammals, the deamination pathway is particularly active in muscle tissue. Both pathways lead to the nucleoside inosine, which is cleaved by inorganic phosphate and purine nucleoside phosphorylase , yielding ribose 1-

phosphate and hypoxanthine. Hypoxanthine is oxidized by the versatile molybdenum- and iron-containing enzyme, xanthine oxidase , to xanthine, which is also produced by guanine nucleotide catabolism. Xanthine is also acted on by xanthine oxidase, to give uric acid. As noted, the process ends here in primates. However, most animals further degrade uric acid to allantoin and then to allantoic acid. Some fishes excrete allantoic acid, but most aquatic animals further catabolize allantoic acid to urea and, in the case of marine invertebrates, to ammonia. These latter pathways are summarized in Figure 5.

Figure 4. Pathways of purine nucleotide catabolism to uric acid. R-1-P is ribose 1-phosphate.

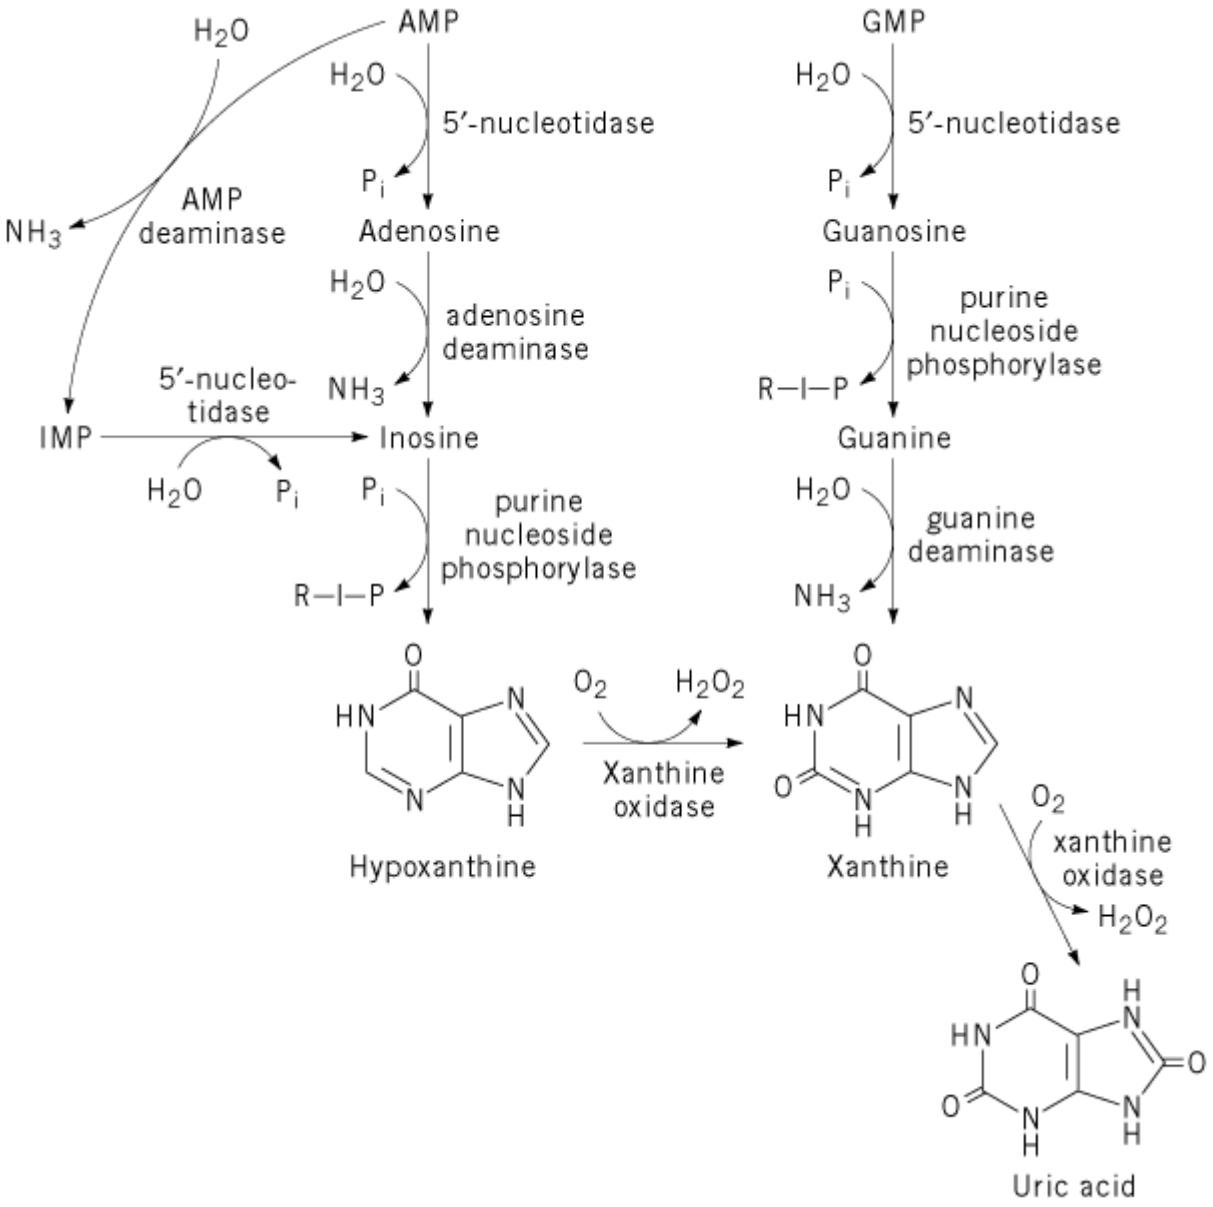


Figure 5. Metabolic degradation of uric acid.

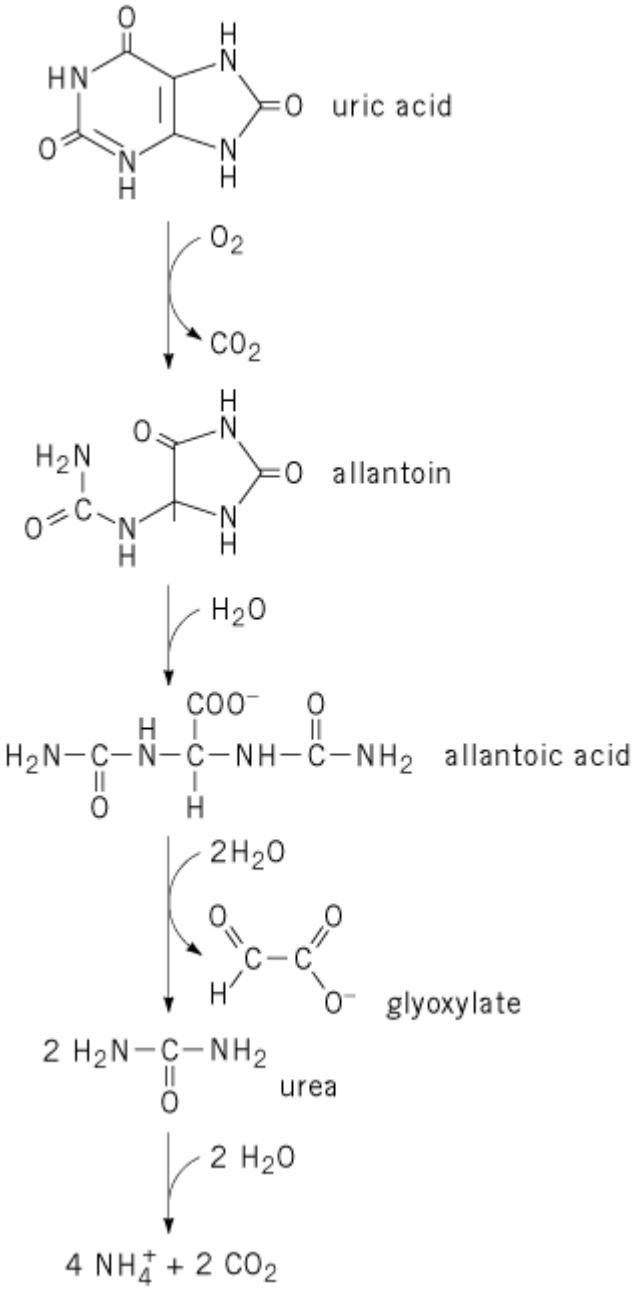


4. Clinical abnormalities of purine metabolism

Six classes of metabolic disorders involving purines have been described (4-9). Three of these conditions—adenine phosphoribosyltransferase deficiency (4), adenylate deaminase deficiency (5), and xanthine oxidase deficiency (6)—are quite rare and will not be discussed here. The three conditions that will be described either are relatively common or their study has revealed important metabolic principles and relationships, or both.

4.1. Hyperuricemia and Gout

Gout refers to a family of diseases in which prolonged elevation of uric acid levels in tissues and blood leads to its crystallization in the joints, causing intermittent attacks of an acute inflammatory arthritis (7). Prolonged hyperuricemia does not always lead to gout attacks; factors leading to the precipitation of urate salts are not thoroughly understood.

Normally, about two-thirds of the uric acid produced in purine catabolism is excreted through the kidneys; the remainder is further broken down by intestinal bacteria. Renal malfunction can lead to elevation of blood uric acid levels, which is a cause of gout. Gout also results from abnormally high purine nucleotide synthesis, which leads to degradation of the excess. Three specific biochemical changes are known to cause this condition. First, hyperactivity of PRPP synthetase elevates intracellular concentrations of PRPP, the substrate for PRPP amidotransferase, the first and rate-controlling step in the *de novo* pathway (reaction 1, Fig. 2), and this increases flux through the whole pathway.

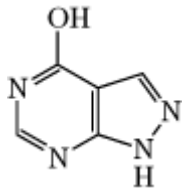
A second form of gout results from partial or complete deficiency of a purine salvage enzyme, hypoxanthine-guanine phosphoribosyltransferase (HGPRT). This enzyme catalyzes the following reactions:

$$\text{Hypoxanthine} + \text{PRPP} \rightleftharpoons \text{IMP} + \text{pyrophosphate}$$

$$\text{Guanine} + \text{PRPP} \rightleftharpoons \text{GMP} + \text{pyrophosphate}$$

It is not yet clear why this deficiency accelerates purine synthesis. One model states that in the absence of these salvage pathways, GMP levels decline which, in turn, modulates the feedback inhibition of PRPP amidotransferase by this nucleotide. Alternatively, it has been proposed that decreased flux through this salvage pathway causes PRPP to accumulate and this, in turn, accelerates flux through PRPP amidotransferase by substrate level control.

The third enzymatic deficiency leading to gout is a deficiency of glucose-6-phosphatase (glycogen storage disease type I). The relationship between this abnormality and uric acid accumulation is still obscure. Whatever the basis for hyperuricemia, the most effective drug for treating the condition is the xanthine oxidase inhibitor allopurinol.



Inhibition of xanthine oxidase causes hypoxanthine and xanthine—both of which are both more soluble and less toxic than uric acid—to accumulate, thereby preventing uric acid precipitation.

4.2. Lesch–Nyhan Syndrome

As noted, a partial HGPRT deficiency leads to gout. A total deficiency of this enzyme has far more serious consequences. Lesch–Nyhan syndrome (8) involves not only severe hypericemia and gout but, in addition, the nervous system develops abnormally, leading to spasticity and behavioral problems, including aggressive behavior toward others and self-mutilation. Because the gene for HGPRT lies on the X-chromosome, the Lesch–Nyhan syndrome is **sex-linked**, having been observed only in males. Although the gouty arthritis of Lesch–Nyhan syndrome usually responds well to allopurinol, there is no known cure for the developmental and neurological abnormalities, and afflicted individuals rarely live beyond age 20. Moreover, although it is clear that all symptoms of this condition arise from the HGPRT deficiency, the specific relationship between the enzyme deficiency and the neuropathology is not understood.

4.3. Immunodeficiencies Caused by Purine Abnormalities (9)

In 1972, a patient with an inheritable combined immunodeficiency involving both **B** and T cells was found to be deficient in the enzyme adenosine deaminase (ADA), which converts adenosine to inosine in purine nucleotide catabolism (see Fig. 4). This surprising finding was followed by the

discovery of other families in which the same enzyme deficiency was associated with severe combined immunodeficiency and, by now, several hundred such families have been described. In 1975, a second form of immunodeficiency was found to result from a different purine abnormality, namely, a deficiency of purine nucleoside phosphorylase, an enzyme whose primary function is to degrade guanosine to guanine in purine catabolism. Often, purine nucleoside phosphorylase deficiency involves only defective T-cell function in the immune system.

What is the relationship between deficiencies in two obscure purine catabolic enzymes and defective immune function? A clue came when it was found that erythrocytes of ADA-deficient patients contained high levels of deoxyadenosine and dATP. Since human erythrocytes are without nuclei, the presence of a DNA precursor seemed gratuitous. Subsequently, it was found that dATP accumulates in many tissues. It arises because ADA acts on deoxyadenosine as well as adenosine. Lymphoid tissues have very high activities of purine salvage enzymes, which reutilize products released in nucleic acid breakdown of cells undergoing apoptosis. Accumulation of deoxyadenosine, when its catabolism is blocked, leads to its conversion to dATP in these tissues, and it accumulates in both red and white blood cells. dATP is a potent allosteric inhibitor of ribonucleotide reductase, and its accumulation can block the white cell proliferative response that results from immunochallenge by inhibiting an essential step in replication of DNA—the synthesis of its precursors. There are also indications that excessive accumulation of dATP leads to an ATP deficiency in some cells. By contrast, in PNP-defective cells, the deoxyribonucleotide that accumulates is primarily dGTP, which is a less potent inhibitor of ribonucleotide reductase. This may explain the somewhat milder immune dysfunction associated with PNP deficiency. However, a completely different mechanism for the toxic effect has recently come to light from *in vitro* studies showing that dATP, in combination with cytochrome c, triggers a chain of protease activation steps leading ultimately to apoptosis (10).

Adenosine deaminase deficiency is the first condition to be treated by gene therapy.

York. Various chapters treat the biochemistry of folate coenzymes in detail, as well as their involvement in purine metabolism.

Puromycin

1. Introduction

Puromycin, first described in 1952, is a secondary metabolite of *Streptomyces alboniger* that blocks **protein biosynthesis**. Puromycin is a structural analogue of the 3′ end of aminoacyl-transfer RNA, but differs from tRNA insofar as the aminoacyl residue is linked to the ribose via an amide bond rather than an ester bond. Puromycin, like aminoacyl-tRNA, binds to the A site of the ribosome peptidyl-transferase center. When the A site is occupied by puromycin, peptidyl-transferase links the peptide residues of the peptidyl-tRNA in the ribosomal P site covalently to puromycin. Since the amide bond cannot be cleaved by the ribosome, no further peptidyl transfer takes place, and the peptidyl-puromycin complex falls off the ribosome.

Puromycin has facilitated the elucidation of ribosome structure and function, particularly the peptidyl-transferase reaction. The puromycin reaction provided the first demonstration that ribosomes can catalyze the formation of peptide bonds in the absence of cytoplasmic factors and without an added energy source, as well as the basis for distinguishing the A site from the P site (peptidyl-tRNA bound to the P site reacts with puromycin, whereas peptidyl-tRNA bound to the A site does not). The fragment reaction served to localize the peptidyl-transferase center on the 50S subunit of the bacterial ribosome.

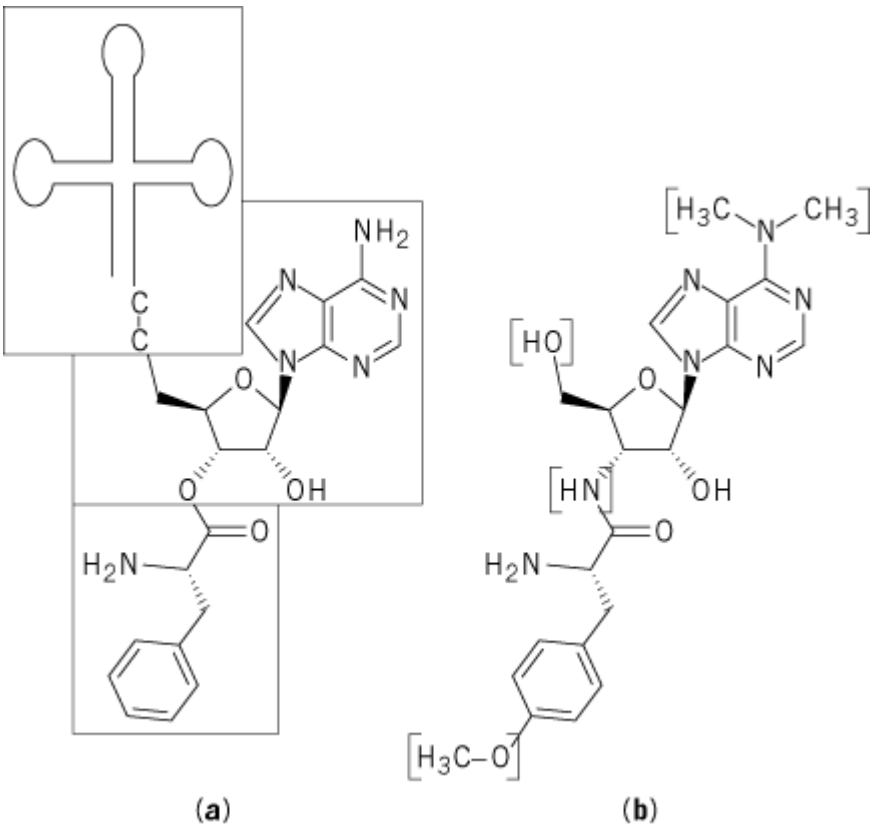
2. Antibacterial Spectrum

In light of the structural resemblance of puromycin to aminoacyl-tRNA, it is not surprising that the spectrum of activity of this antibiotic is broad (1). The spectrum includes not only eubacteria and archaebacteria but also eukaryotes; consequently, puromycin is too toxic to be used clinically.

3. Structure–Activity Relationships

Puromycin essentially mimics aminoacyl-tRNA, in particular, phenylalanyl-tRNA (Phe-tRNA). The chemical structure of puromycin, 3′-(a-amino-*p*-methoxyhydrocinnamamido)-3′-deoxy-*N*,*N*-dimethyladenosine, is shown in Figure 1. In order for puromycin to retain its activity, both the nucleoside and amino acid moieties are required, and the amino acid moieties must be in the L configuration and have an unsubstituted amino group (i.e., the same requirement as that for amino acids incorporated into protein) (2). Derivatives with aromatic side chains are more active than aliphatic ones (3), which suggests that the aromatic aminoacyl residues may enhance the ability of puromycin to bind to the ribosomes.

Figure 1. Comparison of the chemical structure of puromycin and Phe-tRNA. (**a**) Puromycin mimics the amino acid part of Phe-tRNA (bottom box) and its 3′-terminal A (middle box). The tRNA body itself (top box) is absent in the puromycin molecule. (**b**) The differences between the two molecules are bracketed.

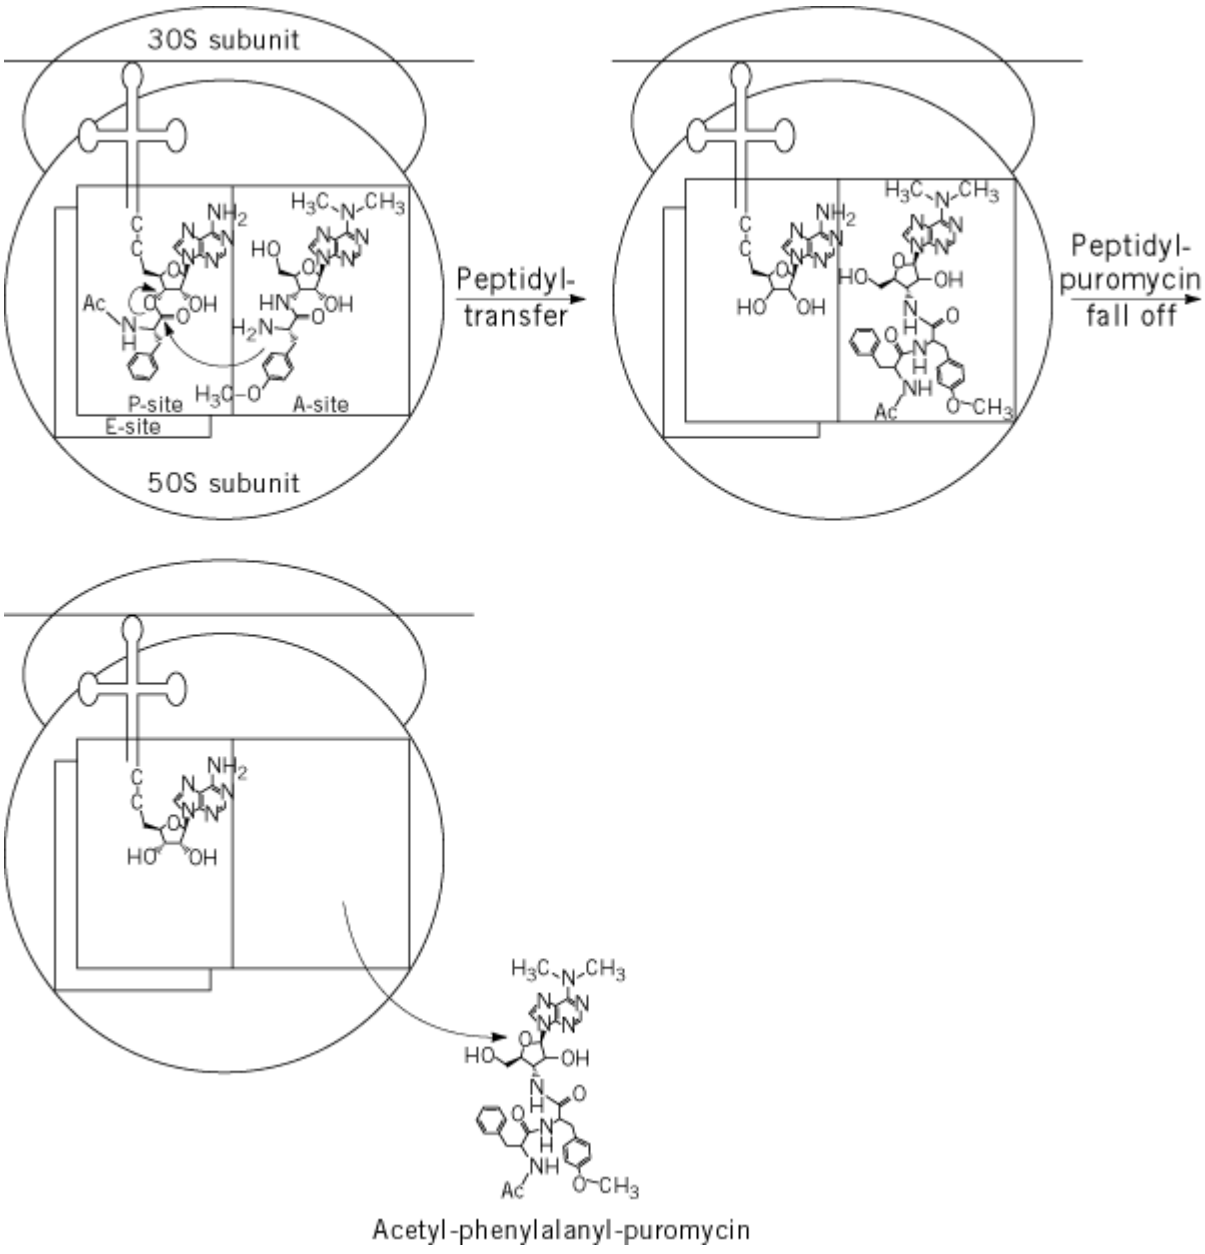


All tRNA molecules that are active in translation contain a conserved 3′-terminal sequence ending in an adenosine (A; see Transfer RNA). Similarly, puromycin retains the final A, although in a slightly modified form. Puromycin analogues having other nucleoside residues have little (I,C) or no (U,G) activity (4). The nucleoside and amino acid moieties of puromycin are linked by an amide bridge, rather than by an ester bridge as occurs in aminoacyl-tRNA. Since the amide bond is more stable than the ester bond, it cannot be cleaved by the ribosome.

4. Mechanism of Action

Puromycin blocks protein synthesis as follows (Fig. 2): first, puromycin binds to the A site of the peptidyl-transferase center of the ribosome in the pre-translocational state, where the P site is occupied by peptidyl-tRNA. Peptidyl-transferase then covalently links the antibiotic to the peptide residues of the peptidyl-tRNA in the P site. Because the ribosome cannot cleave the amide bond of puromycin and because peptidyl-puromycin, which lacks the whole tRNA body, has a lower affinity for the ribosome than peptidyl-tRNA, peptidyl-puromycin falls off the ribosome. High puromycin concentrations are needed to inhibit translation completely, because (*i*) the binding of puromycin to the ribosome is weak ($K_{diss} = 3 \times 10^{-4}$ *M*) (5), (*ii*) one ribosome can transfer several puromycin molecules to peptidyl-puromycin, and (*iii*) once peptidyl-puromycin has fallen off the ribosome, it does not bind again and has no further antibacterial activity. The degradation of **polysomes** observed with puromycin *in vivo* and *in vitro* is caused by the release of peptidyl-puromycin from the ribosome, followed by ribosome subunit dissociation.

Figure 2. Puromycin reaction with P-site bound peptidyl-tRNA, eg, Ac-Phe-tRNA as the peptidyl-tRNA. See text for details.



The puromycin reaction (6) is a classic *in vitro* experiment that has been used to explore ribosome function and to investigate the intrinsic peptidyl-transferase catalytic activity of the ribosome. This reaction, in which ribosomes are combined with puromycin and peptidyl-tRNA or its analogues (eg, Ac-Phe-tRNA), provided the first demonstration that ribosomes could catalyze the formation of peptide bonds in the absence of cytoplasmic factors and without an added energy source, such as GTP.

In the fragment reaction (7), 50S ribosomal subunits are combined with puromycin and a fragment of the tRNA molecule (CACCA-Leu-Ac) in the presence of 33% ethanol. Under these conditions, peptidyl-puromycin is still formed, demonstrating that the entire tRNA molecule is not necessary for peptidyl transfer. The fragment reaction also demonstrated for the first time that the entire ribosome is not required for peptidyl transfer and that the peptidyl-transferase center is located on the 50S subunit. Additionally, puromycin is used to investigate the inhibition mechanism of different translation inhibitors [eg, oxazolidinones (17) and azithromycin (18)].

The classic definitions of the tRNA binding sites on the ribosome are based on the ability of

peptidyl-tRNA to react with puromycin: peptidyl-tRNA bound to the P site reacts with puromycin, whereas peptidyl-tRNA bound to the A site does not. The third tRNA binding site, the E site, is specific for deacylated tRNA, which does not undergo the puromycin reaction. Consequently, puromycin cannot be used to characterize this tRNA-binding site.

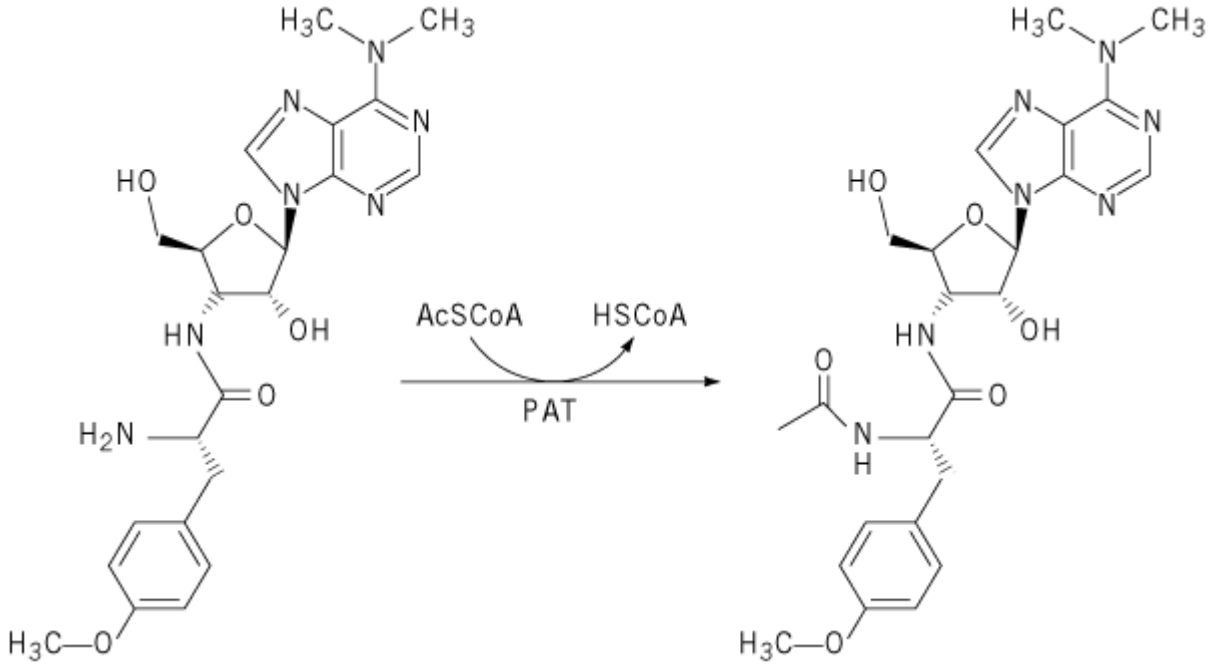
5. Ribosomal Binding Site

Our knowledge of the topography of the peptidyl-transferase center of the ribosome is largely derived from experiments with puromycin. In *E. coli* crosslinking experiments, a large number of proteins on the 50 ribosomal subunit, including L15, L18, L23, and L29, were labeled by puromycin and p-azidopuromycin (8-10). Most of these proteins are located in or next to the peptidyl-transferase center of the ribosome, and several can be **affinity-labeled** with other antibiotics that interact with this center (**erythromycin**, lincosamides, streptogramins, chloramphenicol). In contrast to the other peptidyl-transferase inhibitors, puromycin crosslinks proteins of both the large ribosomal subunit and the small subunit (eg, S7, S14, S18) (8-10). This indicates that the peptidyl-transferase center of the ribosome is located on the 50S subunit next to the 30S/50S subunit interface. P-azidopuromycin also cross-links nucleotides G2502 and G2504 of the central loop of 23 S rRNA (11) (see Peptidyl Transferase, Chloramphenicol); thus, this loop may be involved, directly or indirectly, in the peptidyl-transferase reaction (12).

6. Resistance

Puromycin can be inactivated by puromycin-*N*-acetyltransferase (PAT), which is found in the producing organism, *Streptomyces alboniger* (13). The resulting *N*-acetyl puromycin (Fig. 3) cannot bind to ribosomes and fails to inhibit translation. Puromycin- *N*-acetyltransferase is commonly used as a dominant selectable marker for genetic studies of mammalian cell lines (14); the gene encoding this enzyme is used as a reporter gene in gene expression experiments (15).

Figure 3. Inactivation of puromycin by puromycin-*N*-acetyltransferase (PAT).



In other organisms, efflux pumps have been identified that export puromycin from the bacterial cell.

The genes encoding such pumps (eg, *acr*AB and *env*CD in *E. coli* and *bmr* and *blt* in *Bacillus subtilis*) confer a multiple-drug resistance phenotype (16).

So far, no resistance mechanism has been discovered that operates by ribosomal modification. This is not surprising, in light of the similarity between puromycin and tRNA: ribosomes that could not bind puromycin would probably be unable to bind tRNA and therefore be unable to synthesize protein.

Pyridoxal Phosphate

Pyridoxal 5′-phosphate (PLP), a phosphate ester of the aldehyde form of vitamin B_6, is an essential **coenzyme** for numerous Enzymes (Table 1), many of which function in all living cells. PLP is a rather simple derivative of 3-hydroxypyridine. Its structure and that of related forms of vitamin B_6 are as follows: (Structure **1**) Within the human body, dietary vitamin B_6 is converted into the coenzyme forms PLP and pyridoxamine 5′-phosphate (PMP). For all these compounds, the dipolar ionic ring structure shown predominates in solution and is also found in most enzymes.

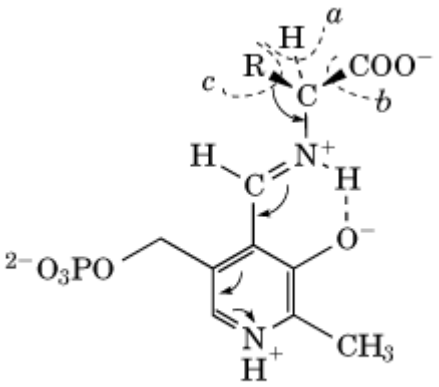
[a] Names of a few representative enzymes are also listed.

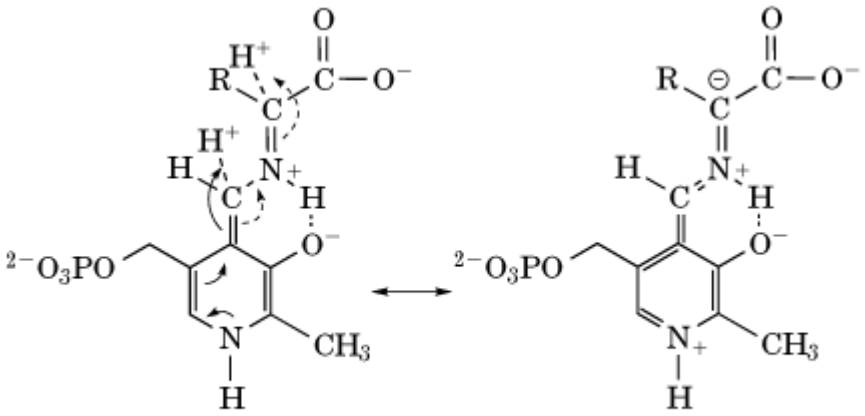
Within the active sites of most PLP-dependent enzymes, the carbonyl group of the coenzyme forms a Schiff Base with an amino group of a specific lysine side chain. This Schiff base is commonly called the *internal aldimine*. When an amino acid substrate binds into the active site, a series of rapid reactions occur, many of which have been characterized spectroscopically and kinetically (1-6). The amino group of the substrate is deprotonated and then adds to the carbon atom of the C=N Schiff base group of the internal aldimine, forming an intermediate geminal diamine . After another proton transfer, elimination of the lysyl side-chain amino group leads to a stable **hydrogen-bonded** Schiff base with the substrate, the external aldimine: (Structure **2**) In this structure, the protonated ring nitrogen provides a powerful electron-accepting center that can assist in breaking any one of the



Schiff base

three bonds marked *a*, *b*, and *c* on Structure **(2)**, as indicated by the curved arrows (7). Which type of reaction occurs is determined by the structure of the enzyme active site and the way in which the amino acid part of the Schiff base is held. The bond to be cleaved must be nearly perpendicular to the plane of the coenzyme ring and to the conjugated p-electron system of the Schiff base. (8) Side-chain cleavage (*c*) occurs only for b-hydroxyamino acids and related compounds.

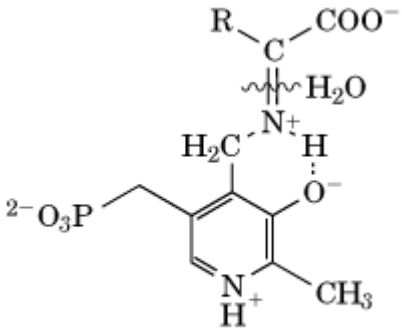
The product of the bond cleavage has been called the *quinonoid* or *carbanionic* intermediate, and the product of removal of H^+ by a catalytic base



Quinonoid-carbanionic structure

is illustrated with cleavage of bond a: (Structure **3**) The two resonance structures shown illustrate the quinonoid and carbanionic attributes. The carbanionic structure is stabilized by the adjacent positively charged hydrogen-bonded proton. Another resonance form has the negative charge on the 4′ carbon rather than the a carbon. It is possible that the proton on the Schiff base nitrogen may be shifted onto the phenolate oxygen of the ring in this intermediate (9). There are still uncertainties about the details of the reaction mechanism.

The quinonoid-carbanionic form shown in Structure **(3)** can undergo reprotonation at either Ca or C4′. Protonation at Ca, but without stereospecificity, leads to racemization of the amino acid (see Stereoisomers) and is observed for bacterial alanine and glutamic acid racemases. Transaminases (aminotransferases) catalyze protonation at either Ca (with retention of the configuration) or C4′. The initial product in the latter case is another Schiff base called the *ketimine*: (Structure **4**) Its hydrolysis produces pyridoxamine phosphate (PMP), the product of a half-reaction of a transaminase.



Ketimine

Removal of the a-hydrogen is also a first step in a number of other reactions, such as synthesis in plants of the ethylene precursor aminocyclohexane carboxylate and numerous reactions involving elimination of the b or g substituent. For example, the bacterial tryptophan indole-lyase releases indole from tryptophan, the remainder of the molecule being converted to pyruvate and ammonia. The g-elimination reactions are more complex and pass through a ketimine step before the elimination.

Removal of the a-carboxylate as carbon dioxide is characteristic of a large number of decarboxylases, including glutamate and dihydroxyphenylalanine (DOPA) decarboxylases of the brain. Cleavage of the side chains is of more limited occurrence but accomplishes another series of important metabolic reactions. Best known of these is cleavage of serine by serine hydroxymethylase to give glycine and formaldehyde. The latter does not leave the active site but is captured by

tetrahydrofolate as methylenetetrahydrofolate.

There are many medical and technological aspects to the study of PLP. Amino acid racemases are targets for antibacterial drugs, and several enzymes are targets for herbicides and pesticides. Enzyme deficiency diseases are known. Poor removal of homocysteine leads to homocysteinemia, which is linked to atherosclerosis (10, 11). PLP has some blocking effect on the virus HIV (12). PLP is widely used as a labeling reagent for amino groups in proteins by reduction of Schiff bases formed with borohydride (13), which may be **radiolabeled** with deuterium or tritium.

Pyrophosphatase

Inorganic pyrophosphatase (PPase) was first discovered in animal tissues in 1928 (1). It hydrolyzes pyrophosphate (PP_i) to two molecules of inorganic phosphate (P_i). Soluble cytoplasmic PPase (s-PPase) is believed to be both ubiquitous and essential (2-4), playing a central role in cell metabolism by hydrolyzing the truly staggering quantity of PP_i produced as a by-product of the biosyntheses of nucleic acids, proteins, lipids, and polysaccharides. Klemme (5) calculated that bacterial PP_i levels would rise to 3 M in an hour in the absence of PPase, and several kilograms of PP_i are generated in adult humans per day. The required high flux of PP_i hydrolysis results from the high specific activity of s-PPase [turnover numbers at 25°C and neutral pH of ~100500 s^{-1} (6, 7), 10^{10} faster than the uncatalyzed rate (8)] and its relative abundance, typically 0.1–0.5% of cell protein by weight.

PPase catalysis of PP_i hydrolysis drives biopolymer synthesis (9), but the high rate of PP_i production results in steady-state cellular PP_i concentrations that in some cells are well above equilibrium levels. Thus, at conditions close to physiological, the concentration of PP_i in equilibrium with 10 m*M* P_i is about 0.1 m*M* (10, 11), whereas in bacterial, plant, and yeast cells PP_i levels of the order of millimolar or greater are observed (5, 12, 13). Even in mammals, where the PP_i concentrations are generally much lower, millimolar levels have been found in blood platelets (14), starved hepatocytes (15), and hepatocytes metabolizing acetate in the presence of Ca^{2+} (16).

The steady-state levels of PP_i can be important for metabolic regulation. For example, there is a linear relationship between the PP_i concentration and the error rate in DNA polymerization (17) (see DNA Replication), and a model for PP_i regulation of the termination of transcription in *Escherichia coli* has been presented (18). A disorder of PP_i metabolism is suspected as a cause of calcium pyrophosphate dihydrate crystal deposition disease, a major arthropathy in the elderly that has also been linked to osteoarthritis (19, 20). Although as yet no linkage has been established between these diseases and a PPase abnormality, s-PPase has been shown to be effective in dissolving calcium pyrophosphate dihydrate crystals (21).

In addition to s-PPase, plants and certain bacteria have a membrane-bound PPase, structurally unrelated to s-PPase, which works as a reversible **proton pump**. In these organisms, the PP_i level is much higher, and PP_i is used as a phosphoryl and energy donor instead of, or in parallel with, ATP (22, 23). **Mitochondrial** PPase is a third kind of PPase, which, though structurally and functionally similar to s-PPase (3), contains noncatalytic subunits that anchor it to the inner mitochondrial membrane.

s-PPases have been studied from a large number of organisms (6, 22). Here we focus on the two best understood s-PPases, those of *Saccharomyces cerevisiae* (Y-PPase) and *E. coli* (E-PPase). Both of these enzymes have been **cloned** and expressed, and the structural and functional properties of wild-type enzyme, as well as many variants, have been characterized (7). Comprehensive recent reviews of E- and Y-PPases may be found in Refs. 6, 24, and 25.

1. Substrate Specificity

Isolated PPase requires added divalent metal ion for activity. Only four of many divalent ions tested

have been shown to confer PPase with appreciable (≥5% of maximal) PP_i hydrolysis activity, with relative activities in the order $Mg^{2+} > Zn^{2+} > Co^{2+} \approx Mn^{2+}$ (26). E-PPase shows similar specificity toward divalent metal ions (27). For Y-PPase, the lower effectiveness of Zn^{2+} and Co^{2+} as cofactors for PP_i hydrolysis than Mg^{2+} is due mainly to the slower rates of product P_i release from enzyme in the presence of each of these ions.

With Mg^{2+} as cofactor, the reaction is almost totally specific for PP_i as substrate; in contrast, with Zn^{2+} and/or Mn^{2+}, other pyrophosphates, such as ATP and serial pyrophosphate, are hydrolyzed at rates within a factor of 10 of that of PP_i itself (28-30). $CaPP_i$ is not a substrate, but is a potent competitive inhibitor of PPase, with a K_i considerably lower than the K_m (**Michaelis constant**) of Mg PP_i under corresponding conditions (31). In the presence of Mg^{2+}, high specificity is also evident for the back reaction from P_i to synthesize enzyme-bound PP_i. Thus, enzyme catalysis of thiophosphate, phosphoramidate, or fluorophosphate hydrolysis, which would be analogous to P_i–H_2O oxygen exchange (Eq. (1)), proceeds very slowly if at all**.** Fluoride shows very potent inhibition of Y-PPase (but not E-PPase), by formation of a stable, isolatable complex: $PPase{\cdot}(Mg^{2+})_2{\cdot}PP_i{\cdot}F^-$ (32).

Paralleling its substrate specificity, PPase displays a high binding specificity for its natural ligands, PP_i and P_i. The two P_i sites per PPase subunit differ in affinity. Both the higher-affinity (P1) and the lower-affinity (P2) sites bind P_i more tightly as a function of added metal ion (33). Some changes are tolerated for the atom bridging the phosphoryl groups. In the presence of Mg^{2+}, both $O_3PCHOHPO_3$ and O_3PNHPO_3 are reasonably good **competitive inhibitors**, although $O_3PCH_2PO_3$ is not. With Mn^{2+}, the specificity is somewhat relaxed: PPP_i has a K_m similar to that of PP_i, and $O_3PCHOHPO_3$ binds quite tightly. The binding of analogues of P_i has been examined only in the presence of Mn^{2+}. None of the analogues tested, methyl phosphonate, phosphoramidate, or thiophosphate, bind comparably to P_i in site P1, but methyl phosphonate binds comparably to P_i in site P2. Thus, site P1 appears the primary source of binding specificity (33).

2. Kinetic Mechanism

Y-PPase and E-PPase share a common mechanism for catalysis of PP_i hydrolysis, P_i–H_2O oxygen exchange, and PP_i:Pi exchange (34, 35). PP_i hydrolysis proceeds via single-step direct phosphoryl transfer to water, without formation of a phosphorylated enzyme intermediate (Eq. (1)):

$$Mg_jE + Mg_2PP_i \underset{k_2}{\overset{k_1}{\rightleftarrows}} Mg_jEMg_2PP_i \underset{k_4}{\overset{k_3(H_2O)}{\rightleftarrows}} Mg_jE(MgP_i)_2 \underset{k_6}{\overset{k_5}{\rightleftarrows}} Mg_jEMgP_i + MgP_i \underset{k_8}{\overset{k_7}{\rightleftarrows}} Mg_jE + MgP_i \qquad (1)$$

$$j = 1, 2 : K_1 = k_1/k_2; K_3 = k_3/k_4; K_5 = k_5/k_6; K_7 = k_7/k_8$$

The outstanding features of Equation 1 are as follows: (a) All three forward rate constants, k_3, k_5, and k_7, are partially rate-determining for PP_i hydrolysis; (b) synthesis of enzyme-bound PP_i from product P_i proceeds quite readily, but release of bound PP_i (step 2) is very slow; (c) the equilibrium

constant for hydrolysis of enzyme-bound PP_i, K_3, is only 4–5, in contrast to much higher value for the hydrolysis of PP_i in solution; and (d) the first P_i released (step 5) is the electrophilic P_i, containing an oxygen atom from the nucleophilic water (34). The value of k_{cat} goes through a maximum as a function of pH (at pH 8 for E-PPase, 7 for Y-PPase), implying that both acidic and basic groups are important for activity (7, 36). The value of k_{cat}/K_m also displays a pH optimum near neutrality for each enzyme.

3. Structural Studies on PPases

Y-PPase is a homodimer (286 amino acid residues per subunit), typical of eukaryotic PPases (37), and E-PPase is typical of prokaryotic PPases in being a homohexamer (175 residues each) (38). Although the enzymes have only about 27% sequence identity (6), they have a very similar protein structure, consisting of eight **beta-strands** and two **alpha-helices** (39) and belonging to the nucleotide-binding motif. The E-PPase subunit may be thought of as embedded in the Y-PPase subunit, and the common parts of the two molecules are best described as a distorted, highly twisted five-stranded b-barrel with four excursions, the latter creating a very large active site. About 14 polar active-site residues, highly conserved in s-PPases, are significant for catalysis (7), and 12 of them are in the excursions. In addition to E-PPase and Y-PPase, more than a dozen soluble PPases have been **cloned** and sequenced (6, 24).

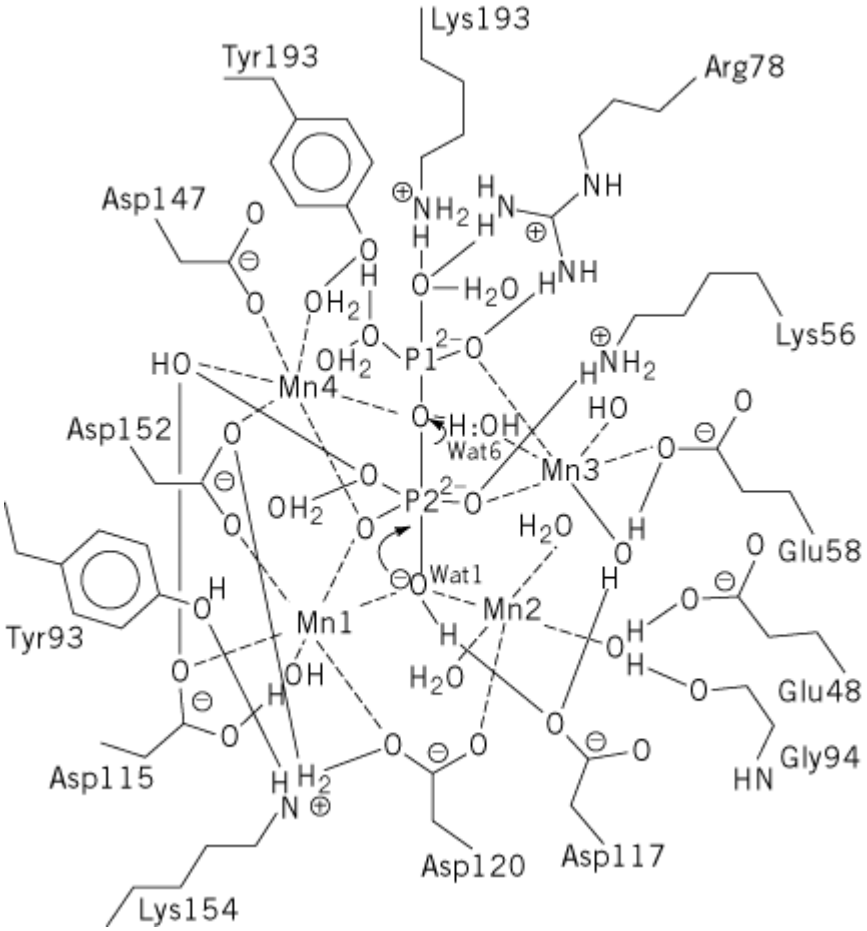
High-resolution structures have been determined for the $Mg_{1.5}$ (39) and $Mg_{2.5}$ (40) complexes of E-PPase and for the Mn_2 and $Mn_4(P_i)_2$ complexes of Y-PPase (25, 41), where the numbers refer to the stoichiometries of ligand per monomer. These ligands are all bound at the active site, with the exception of the half Mg^{2+} site in E-PPase. The latter reflects Mg^{2+} binding at the trimer:trimer interface, which stabilizes the enzyme but otherwise has little effect on enzyme activity (42). In these structures, the E-PPase active site residues are virtually superposable on those of Y-PPase, demonstrating the highly conserved nature of the PPase active site. The 2.2-Å resolution structure of the product $Mn_4(P_i)_2$ complex of Y-PPase (25) has been the most useful for considerations of mechanism (see text below).

4. Chemical Mechanism

PPase is presently unique among phosphoryl transfer enzymes in having four divalent metal ions at the active site, although it is probable that not more than three of these are required for hydrolysis (43). The structure of the $Mn_4(P_i)_2$ complex of Y-PPase, along with functional studies of wild-type and variant PPases, allows formulation of a detailed proposal for the catalytic mechanism (Fig. 1). In the proposed mechanism, PPase catalyzes PP_i hydrolysis by lowering the pK_a of the leaving group in site P1 (studies of phosphoryl transfer reactions in solution show that the rates of such reactions increase by 10- to 20-fold for each unit lowering of the leaving group pK_a), by forming an incipient hydroxide ion that functions as a stronger nucleophile than water, and by shielding the charge on the electrophilic phosphorus in site P2, thus permitting attack by the hydroxide anion. According to this mechanism, the leaving phosphoryl group is activated by coordination to Arg78, Tyr192, Lys193, Met3, Met4, and Water6, the pK_a of the nucleophilic water is lowered by coordination to Met1, Met2, and Asp117, and the charge on the electrophilic phosphoryl group is neutralized through coordination to Lys56, Tyr93, and Met1 to Met4. The extraordinary array of Lewis acids (four divalent metal ions; Lys, Arg, and Tyr side chains, bound waters) within the active site activate PP_i hydrolysis through coordination to almost all of the available electron pairs in the oxygens of bound PP_i. The essential base implicated by both steady-state and pre-steady-state pH-dependent studies is assigned to the presumptive nucleophilic water, Wat1, which has an abnormally low pK_a (~ 6) by virtue of its coordination to Met1, Met2, and Asp117. These same studies implicate the essential acid

in a step following PP_i hydrolysis, which is believed to be protonation of the phosphate in site P1 prior to its dissociation from enzyme (44).

Figure 1. Mechanism and active-site structure of Y-PPase as deduced from the crystal structure of the $Mn_4(P_i)_2$–Y–PPase complex. From Ref. 25, with permission.



Interestingly, the proposed PPase mechanism has much more in common with those proposed for inorganic phosphatase and **DNA polymerases** and exonucleases than with that proposed for ATPase, which catalyzes a chemically more analogous reaction (25). Studies of the crystal structures and functional properties of critical active-site variants, such as Arg78Lys and Asp117Glu, that test various aspects of the proposal in Figure 1, are underway.

Pyrimidine Ribonucleotide Metabolism

1. Biosynthesis of the Pyrimidine Ring

The biosynthesis of pyrimidine **nucleotides** is comparable to that of **purine nucleotides** in several important respects. Both rings are synthesized by *de novo* pathways that begin with amino acids and their metabolites as precursors. The *de novo* pathway to pyrimidines is universal among organisms studied thus far, as is the purine pathway. Like purines, pyrimidine bases and nucleosides can be used in **"salvage" pathways** that involve reutilization of components released in nucleic acid degradation. Salvage capacities vary considerably among organisms and among different cell types in a single organism.

There are also important differences between purines and pyrimidines in the nature of the *de novo* synthetic pathway. The purine ring is assembled at the nucleotide level whereas, in pyrimidine synthesis, the sugar and phosphate are incorporated near the end of the pathway. Also, purine synthesis is branched, with guanine and adenine nucleotides formed by separate pathways from a common intermediate, inosinic acid. In contrast, pyrimidine ribonucleotide synthesis is unbranched, with uridine nucleotides serving as precursors to cytidine nucleotides.

In bacteria, the principal regulated step, and the committed reaction for the pathway,

$$\text{Aspartate} + \text{carbamoyl phosphate} \rightarrow \text{Carbamoyl aspartate}$$

is catalyzed by aspartate transcarbamoylase (ATCase), the enzyme that has perhaps told us more than any other enzyme about **allosteric** mechanisms in **enzyme regulation**. The entire pathway is shown in Figure 1 . Control of ATCase involves allosteric inhibition by a pyrimidine end product, CTP, and “feedforward” activation by a purine nucleotide, ATP. The product, carbamoyl aspartate, contains all six of the carbon and nitrogen atoms that will eventually appear in the pyrimidine ring.

Figure 1. *De novo* biosynthetic pathway to pyrimidine nucleotides. Enzyme names are as follows: 1, carbamoyl phospha
2, aspartate transcarbamoylase; 3, dihydroorotase; 4, dihydroorotate dehydrogenase; 5, orotate phosphoribosyltransferas
orotidylate decarboxylase; 7, UMP kinase; 8, nucleoside diphosphate kinase; 9, CTP synthetase; 10, ribonucleoside diph
reductase. PRPP is 5-phosphoribosyl-1-pyrophosphate. The circle drawn around the letter P denotes organic phosphate,
triphosphate, as indicated. For the conversion of CTP to CDP by nucleoside diphosphate kinase, the preferred phosphate
any, has not been identified.

Carbamoyl phosphate synthetase (CPS), which provides one of the substrates for aspartate transcarbamoylase, is often considered the initial reaction in pyrimidine synthesis. Carbamoyl phosphate is a precursor to both pyrimidines and arginine. Bacterial cells contain a single carbamoyl phosphate synthetase, so that the reaction is not committed to pyrimidine synthesis, and control is exercised at the next reaction, catalyzed by ATCase. **Eukaryotic** cells, however, contain two carbamoyl phosphate synthetases in different compartments—one in the cytosol, specialized for pyrimidine synthesis, and one in mitochondria, used for the synthesis of arginine (and urea in those organisms possessing a urea cycle for amino acid degradation). Thus, one usually thinks of carbamoyl phosphate synthetase in eukaryotic cells as catalyzing the first step in pyrimidine synthesis (reaction 1 in Fig. 1), with ATCase as reaction 2.

In all cells, carbamoyl aspartate cyclizes (reaction 3) to give a ring compound, dihydroorotate, and this undergoes dehydrogenation (reaction 4) to give the first pyrimidine—orotate, which is 6-carboxyuracil. A phosphoribosyltransferase reaction with 5-phosphoribosyl-1-pyrophosphate (PRPP) gives a pyrimidine nucleotide, orotidine-5′-phosphate (reaction 5). Decarboxylation (reaction 6) yields uridine monophosphate, which undergoes two successive phosphorylations (reactions 7 and 8) to give uridine triphosphate, UTP. UTP is the substrate for an amidotransferase enzyme, CTP synthetase, which transfers the amide nitrogen of glutamine in the ATP-dependent conversion of UTP to CTP (reaction 9).

In most organisms, the synthesis of deoxyribonucleotides occurs at the nucleoside diphosphate level (reactions 10), with reduction of the ribose sugar to deoxyribose *in situ* (see Ribonucleotide Reductases). UDP is formed as an intermediate in UTP synthesis, whereas CDP is probably synthesized in a nucleoside diphosphate kinase–catalyzed reaction in which CTP serves as a phosphate donor. Because nucleoside diphosphate kinase has very low specificity for both phosphate donor and phosphate acceptor, this represents the most straightforward route for conversion of CTP to CDP. There is a report of a myokinase -type activity in mammalian cells that reversibly transfers phosphate from CTP to CMP, yielding two CDPs (1). If this enzyme plays a major role in CDP synthesis, much of the CMP probably comes from catabolism of cytidine-containing phospholipids, CDP-choline, or CDP-diacylglycerol. CMP is not an intermediate in pyrimidine synthesis *de novo*.

2. Regulation of Pyrimidine Synthesis

As noted earlier, bacterial ATCase presents a particularly well-understood example of allosteric regulation. Control of pyrimidine ring synthesis occurs also at the level of gene transcription, with an interesting **attenuation** process (2). Classic attenuation control involves operons of amino acid biosynthesis, where the rate of translation of a messenger RNA determines the folding pattern of a nascent mRNA which, in turn, determines whether the conformation adopted by that mRNA will lead to premature transcriptional termination. In the case of pyrimidine synthesis, the intracellular concentration of UTP inversely controls the transcription of the genes *pyrB1* and *pyrE*, which encode subunits of ATCase and orotate phosphoribosyltransferase, respectively; at high concentrations of UTP, the transcription rates are low. Low UTP levels limit the rate of transcriptional chain elongation because the K_m of **RNA polymerase** for this nucleotide is high. Under these conditions, ribosomes translating the nascent mRNA catch up to RNA polymerase, and the interaction interferes with formation of an RNA hairpin loop that acts as a transcription terminator. By contrast, high UTP levels allow RNA polymerase to move fast enough to prevent interference with formation of the transcription terminator.

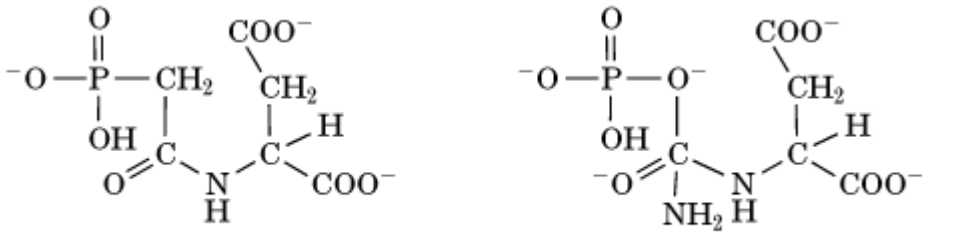
Another important control mechanism involves allosteric regulation of CTP synthetase . This enzyme is activated by GTP and inhibited by its product, CTP (3). The physiological importance of this regulation is seen in the dramatic effects in mammalian cells of mutations that abolish the

feedback inhibition by CTP. Cells bearing these mutations have grossly elevated pools of CTP and dCTP and abnormally small pools of uridine and thymidine nucleotides. The pool imbalance creates a **mutator** phenotype, and the dTTP deficiency creates a thymidine auxotrophy. Also, a recent report states that phosphorylation of CTP synthetase by protein kinase C decreases the enzyme's sensitivity to CTP inhibition (4).

3. Multifunctional Enzymes in Eukaryotic Pyrimidine Synthesis

In animal cells, the six enzymes of UMP biosynthesis are encoded by just three genes because of the existence of two multifunctional enzymes. This finding came to light with the synthesis of *N*-phosphonoacetyl-L-aspartate (PALA), which was produced as a bisubstrate analogue in the ATCase reaction and a potential inhibitor of pyrimidine biosynthesis (Fig. 2). PALA does inhibit pyrimidine synthesis. However, when cell lines resistant to PALA were developed, they were found to have greatly elevated levels not only of ATCase, the target enzyme, but also of carbamoyl phosphate synthetase and dihydroorotase. Analysis showed that the three activities are carried on one 220-kDa polypeptide chain and that three or six chains associate to form one enzyme molecule, called by the acronym the CAD protein (5). Through sequence analysis and limited **proteolysis**, it has been established that each chain of this multifunctional protein contains an N-terminal carbamoyl phosphate synthetase **domain**, a C-terminal ATCase domain, and an internal dihydroorotase domain. From the names of these three domains comes the term CAD. The ATCase domain displays significant homology to the catalytic subunit of bacterial ATCase. There is no regulatory subunit counterpart in the eukaryotic enzyme, and control of CAD activities and of the overall pathway is usually exerted at the level of carbamoyl phosphate synthetase.

Figure 2. Structures of *N*-phosphonoacetyl–L-aspartic acid and the presumed transition state in the aspartate transcarbamoylase reaction.



The fifth and sixth activities in the pathway—orotate phosphoribosyltransferase and OMP decarboxylase—also form a bifunctional enzyme, called UMP synthase. In mammals, these two activities are carried on a single polypeptide chain of about 52 kDa. The enzyme exists as either a monomer or a homodimer, with binding of **ligands**, particularly orotidine monophosphate, stimulating dimerization (6). Through sequence comparison with organisms containing separate forms of these enzymes, it has been established that the N-terminal part of the UMP synthase polypeptide is the orotidine phosphoribosyltransferase domain; the decarboxylase activity is carried in the C-terminal portion.

What is the biological significance of a protein design that carries either two or three activities in a single polypeptide chain? One likely answer is that it allows for coordinate control of enzymes involved in a single pathway. Another plausible answer is that it permits metabolic channeling—the facilitated transfer of a scarce or unstable metabolite from one active site to the next, so as to drive the overall pathway more efficiently. However, kinetic analysis has not established that either the CAD protein or UMP synthase displays significant channeling activity *in vitro*. Moreover, the

subcellular localization of pathway enzymes makes channeling *in vivo* seem improbable, at least so far as the overall pathway is concerned. The CAD protein, catalyzing reactions 1, 2, and 3, is located in the cytosol. The product of reaction 3, dihydroorotate, must then move to the outer surface of the inner mitochondrial membrane, where the fourth enzyme, dihydroorotate dehydrogenase, is located. The product, orotate, then moves back to the cytosol for the final two reactions catalyzed by UMP synthase. The necessary migration of an intermediate from one cell compartment to another clearly precludes channeling from steps 3 to 5.

4. Pyrimidine Nucleotide Degradation

Pathways of pyrimidine catabolism are shown in Figure 2. Nucleic acid breakdown usually generates nucleoside 5′-monophosphates, which are cleaved to the respective nucleosides by pyrimidine 5′-nucleotidase. Cytidine is converted to uridine by deamination (the same enzyme also converts deoxycytidine to deoxyuridine). Uridine phosphorylase cleaves uridine, giving uracil plus ribose-1-phosphate. Uracil is reduced to dihydrouracil, which then undergoes a hydrolytic ring opening to give b-ureidopropionate. A further hydrolysis gives b-alanine (a precursor to coenzyme A) plus CO_2 and NH_3. A parallel pathway, using mostly the same enzymes, acts on thymine nucleotides. The final product is b-aminoisobutyrate.

5. Disorders of Pyrimidine Metabolism

In contrast to purine metabolic disorders, hereditary deficiencies of pyrimidine metabolic enzymes are extremely rare (6). The most common such deficiency, hereditary orotic aciduria, has been described in just 15 cases. This condition arises from a deficiency of UMP synthase, the bifunctional enzyme that catalyzes reactions 5 and 6 in *de novo* pyrimidine synthesis. The condition involves excessive excretion of orotate, which usually crystallizes in the urine. A megaloblastic anemia is seen, presumably resulting from insufficient pyrimidine nucleotides to support the nucleic acid synthesis needed for blood cell division and maturation. In addition, some form of mental retardation is seen in orotic aciduria. In all cases tested thus far, the patient responds well to treatment with uridine, which can replete the pyrimidine nucleotide pools through salvage pathways.

Deficiencies of pyrimidine 5′-nucleotidase and dihydropyrimidine dehydrogenase have been described (reactions 1 and 4, respectively, in Fig. 3). The former condition involves a hemolytic anemia; also, the erythrocytes contain abnormally high levels of UTP and CTP. In the latter condition, high levels of uracil and thymine are seen in both blood and urine. Finally, two cases have been described involving deficiency of dihydropyrimidase (reaction 5, Fig. 3), the enzyme that converts dihydrouracil to b-ureidopropionate. The condition involves excessive excretion of dihydrouracil. Because of the rarity of these conditions, few metabolic or clinical details are available.

In addition, reference 6 above includes a complete presentation of pyrimidine nucleotide synthesis and degradation, as well as a description of clinical disorders and an exhaustive (353-entry) reference list.

Qb Replicase

The RNA-dependent **RNA polymerase** of **bacteriophage** Qb was first isolated in 1965 by Haruna and Spiegelman, who named it Qb replicase (1). Today, this enzyme still represents the prototype of RNA **virus**-replicating polymerases, and it has remained unique in that it allows the specific replication and amplification of an infectious viral RNA by a complex of soluble, stable, and defined protein components *in vitro*. Early studies had established that the viral RNA genome (the plus strand) was replicated by primer-independent end-to-end RNA synthesis in the 5′ to 3′ direction. A free, single-stranded complementary strand (minus strand) is synthesized as an intermediary product and serves as a template for the synthesis of single-stranded plus strands, whereas double-stranded RNA is devoid of any template activity (2). Investigations with Qb replicase have resulted over the years in a surprising number of novel concepts of more general relevance, such as: (1) specific template recognition by a polymerase (1); (2) recruitment of host proteins as subunits of a viral polymerase (3, 4); (3) role of a viral polymerase in the temporal control of **protein biosynthesis** (2); (4) an internal RNA binding site as an enhancer of synthesis initiation (5); (5) activation of an RNA template by a host factor acting as an RNA molecular chaperone (6); (6) secondary and tertiary structure as determinants of template recognition (7, 8); (7) role of secondary structure in elongation of RNA synthesis (9, 10); (8) sequence evolution *in vitro* (11) and the quasispecies concept (12); (9) *de novo* synthesis of replicatable RNA (13); (10) site-directed mutagenesis (14); (11) use of small RNA templates as **vectors** for foreign sequences (15); and (12) development of such systems for diagnostic purposes (16). Most of these aspects will be discussed here.

1. Protein components of the *in vitro* Qb RNA replication system

Qb replicase is isolated from Qb-infected *Escherichia coli* cells as an enzyme consisting of four different subunits, only one of which (subunit b, 65.5 kDa) is phage-specific. The other subunits are recruited from the host cell and were identified as the **ribosomal** protein S1 (subunit a, 61.2 kDa) and the protein synthesis elongation factors EF-Tu and EF-Ts (subunits g, 43.2 kDa, and d, 30.3 kDa). In addition to this holoenzyme form of replicase, a smaller core enzyme species, consisting of only subunits b, g, and d, was found to be equally active for all templates except the Qb plus strand. Of the three core subunits, b (phage-specific) represents the catalytic subunit, and EF-Tu/Ts (subunits g and d) appear to be important for the assembly and stabilization of the active enzyme complex. The role of protein S1 (subunit a) as an RNA-binding protein consists of mediating the recognition of the Qb plus-strand RNA as a template (see below). The template activity of the Qb plus strand, in contrast to the other known template RNAs, depends further on the presence of an additional host-derived RNA binding protein called the “host factor” (17), or Hfq protein (6×11kDa). Hfq protein was recently found to function in the cell as an “RNA chaperone” required to activate translation for the induction of the stationary phase and other functions (18).

Replicases of other RNA phages make use of the same host-derived subunits (19, 20), but their host factor requirements may be different, as shown for phage f2 (21) and its close relative MS2 (22).

2. Template Specificity

For an RNA to be replicated and amplified by replicase, both the RNA itself and its complementary strand must be efficient templates. This is the case for Qb RNA and the Qb minus strand in the presence of the holoenzyme and host factor. The core enzyme without the host factor is sufficient to copy the minus-strand RNA into a plus strand, but cannot by itself use the latter as an efficient template. However, the core enzyme is efficient for replicating and amplifying a family of small RNAs, collectively called 6 S RNA, that arise *in vitro* (and possibly also *in vivo*) in the absence of added template RNA, either by uninstructed *de novo* synthesis or through elongation and recombination of small RNA fragment contaminants (see below). RNAs of closely related phages (eg, SP) have partial activity (23), but more distant phage RNAs (eg, MS2), like other viral and cellular RNAs, are inactive. Synthetic templates like poly(C) and mixed polyribonucleotides rich in C function as templates for the synthesis of a complementary strand, which however remains paired with the template and is itself not active as a template.

3. Recognition of the Qb plus-strand template

Replicase holoenzyme forms tight complexes with the Qb plus strand by binding at two internal RNA regions called the S- and M-sites (24), mapping at positions 1247 to 1346 and 2545 to 2867 of the Qb genome (4217 nucleotides), respectively. **Electron microscopic** examination of such complexes revealed the formation of RNA loops between these sites, showing that the two interactions occurred simultaneously on one and the same strand (25). Similar looped complexes were observed by binding of S1 protein alone, which suggests that these internal interactions are mediated by the a subunit (26). Binding of replicase to the S-site, located at the start of the coat protein cistron, is not necessary for template recognition but is thought to represent a **translational repression** mechanism by which replicase prevents the attachment of ribosomes during the time it uses the plus strand as a template (2). This stands in contrast to the M-site, in which a branched secondary structure element (nucleotides 2696 to 2754) has an enhancer-like function essential for high template activity (5). Binding of the 3′-end, ie, the site of initiation of synthesis, is mediated by the host factor, which in addition binds to two internal sites adjacent to the M- and S-sites (26, 27). Qb phages adapted to growth in host factor-less *E. coli* strains contained mutations altering the 3′-terminal folding of the RNA and releasing the sequence at the immediate 3′-end from base-pairing (6). This is in agreement with the concept of the host factor as an RNA chaperone that modifies the secondary and tertiary structures of the 3′-end so as to make it accessible to replicase.

In summary, the recognition of the Qb plus strand by replicase occurs through contacts at three (or possibly even more) different RNA sites that map far apart on the genome but must be held in close vicinity by the tertiary structure of the RNA (8). Interestingly, it is the host proteins S1 and Hfq that are the mediators of these interactions, whereas the catalytic b subunit is very probably responsible for the direct contacts at the 3′-end of the template that allow synthesis to start. Initiation occurs with GTP, which is complementary to the template's essential 3′-terminal ¼ CCC motif; the additional A residue found at the 3′-end of most RNA chains is not essential.

4. The Qb minus strand and other RNAs as templates

The interactions of replicase with the Qb minus strand and the replicating 6 S RNAs are expected to be different from those with the plus strand, because the former RNAs are efficient templates for core replicase in the absence of proteins S1 and Hfq. Deletion analysis of the Qb minus strand identified two structural features required for template activity (7). One consists of a sequence that folds into an imperfectly base-paired stem-loop structure located near the 5′-terminus of the minus strand. A highly **homologous** sequence is found in MDV-1 RNA (a 6 S RNA) and was characterized as an element essential for recognition of this template (28). The other essential element is formed by two short complementary sequences forming a helical stem by long-range base-pairing near the 3′-end of the minus strand. On the basis of stability calculations, the 3′-terminal ¼ CCC(A) sequence, which represents another essential structure, appears in the minus strand to exist in an unpaired

conformation, in agreement with the fact that this template does not require a host factor.

Of the many short-chain RNAs characterized as templates, their only common features (29) consisted of a single stranded ¼ CCC(A) 3′-end, as well as sequences rich in secondary structure, as discussed below.

Recently, the SELEX technique was used to generate two families of short RNA ligands that bound strongly to replicase holoenzyme and were active templates (30). One contained a pseudoknot structure rich in A and C residues in the unpaired loops and was found to crosslink to S1 protein. The other contained a polypyrimidine tract and crosslinked to EF-Tu (the g subunit). At present, it appears difficult to integrate these findings into a common picture with those from the Qb plus and minus strand.

5. Secondary structure required for the release of single-stranded product RNA

Short-range intrastrand base-pairing in product and template RNAs appears to be necessary for the release of the product RNA in a single-stranded form, presumably by competitively inhibiting the formation of long product-template duplexes. In fact, longer tracts of template sequence unable to form local stem-loop structures resulted in the formation of duplexes between product and template strands that could not be replicated further (9). Moreover, RNA phage mutants carrying insertions of such tracts *in vivo* quickly evolved to revertants that had eliminated the inserts (10).

6. Evolution *in vitro* and *in vivo*, error rates, recombination, and the question of *de novo* synthesis

Spiegelman and coworkers recognized very early that their RNA amplification system provided a unique opportunity to study evolution *in vitro* by serial transfer experiments (11). Studies focusing on this aspect were instrumental in the development of the "quasi-species" concept by M. Eigen (12). Estimates of the phage Qb mutation rate (about 10^{-4}; (31)) and of the sequence heterogeneity of the Qb genome in phage populations determined by Weissmann and coworkers (32) were in full agreement with this notion.

The occurrence of RNA recombination in RNA phage replication was first experimentally demonstrated *in vivo* (33), but had been suspected before, because sequences homologous to cellular RNAs were found in several 6 S RNA species (34). Later *in vitro* studies confirmed the process, which was thought to take place via copy-choice (35) or by a novel type of mechanism (36).

The claim that rigorously purified replicase under specific conditions can be observed to synthesize small replicating RNAs *de novo* without template instruction (13) encountered opposition because of the difficulty of excluding contamination by traces of 6 S RNA in any laboratory engaged in *in vitro* work with replicase (37). The doubts have stimulated, however, a large amount of careful work, making today a convincing case for *de novo* synthesis, such as the demonstration that different incubation mixtures of identical ingredients result in entirely unrelated RNA sequences arising after widely fluctuating latency periods (29). The stochastically arising RNA species and their propagation and evolution to high-efficiency replication could be followed quantitatively by fluorescence techniques in a sophisticated capillary incubation apparatus (13).

7. Practical applications of replicase

Not surprisingly, the unique properties of replicase as a nucleic acid amplification system have raised interest in developing practical uses. Most efforts were directed toward using replicating RNAs as vectors for the amplification of foreign sequences (15). Success was achieved mostly with relatively short inserts, because of the high tendency of the system toward mutation and recombination and the requirement of a strong secondary structure, as outlined above. Nevertheless, a sensitive diagnostic assay using short inserts of ribosomal RNA sequences from several pathogenic

agents was developed and marketed as an alternative to **PCR** (16).

8. Outlook

Despite the described attempts to get "something useful" out of Qb replicase, it appears likely that the main fascination with this enzyme will remain within the realm of basic science. The most intriguing questions may concern the precise mechanics of the interplay of the macromolecular components that make the system behave in the way it does. No doubt, knowledge of the three-dimensional structures of these components would be a great step forward toward this understanding. Efforts toward determining a structure of replicase by **X-ray crystallography** have not been successful thus far, but should be continued and extended to substructures like the core enzyme, S1 protein, and host factor. As the crystallography of RNA is still in its infancy, large RNA structures like the Qb plus and minus strand may not be accessible very soon, but interesting information could come from specific and well-studied small RNAs like MDV-1, especially if co-crystals with replicase and its subassemblies could be analyzed. In the meantime, the recent rapid advances in computer modeling of RNA structures (38) will continue and, together with **phylogenetic** comparisons and chemical or biochemical probing techniques, should give us improved models of template RNAs and their complexes with replicase. Similarly, we can expect that functional studies with site-directed RNA mutants, and especially the elegant evolutionary approach in which deficient mutants are allowed to evolve back to high viability (8), will continue to advance our understanding of this exemplary RNA-protein recognition process.

Quaternary Structure

The *quaternary structure* describes the way two or more **polypeptide chains** are arranged within the same **protein** molecule. The term, suggested by J. D. Bernal, was used first by J. Kendrew in 1959 [(1)] to further develop the already classical hierarchy of K. Linderström-Lang. If (1) primary structure refers to the amino acid sequence, (2) **secondary structure** is **alpha-helices** or **beta-sheets**, and (3) tertiary structure is the fold of the polypeptide chain, quaternary structure refers to the assembly of several polypeptide chains, as in four-chain hemoglobin, or of many chains in **virus** capsids or muscle fibers. In 1959, Kendrew had just solved the crystal structure of the single-chain myoglobin, which illustrated secondary structure as the a-helix and produced the first image of a tertiary structure. Soon afterward, M. Perutz obtained the crystal structure of hemoglobin, making quaternary structure directly visible in atomic detail. We now have many more examples in proteins ranging from enzymes to transcription factors and membrane components.

Proteins with more than one polypeptide chain are *oligomeric* or *multimeric*, and their chains are also called *subunits*. Oligomeric proteins may be built of identical subunits, when they are called *homo-oligomers* and their quaternary structure can be coded in the formula a_n to indicate that they are made of *n* copies of an a subunit. Other oligomeric proteins are referred to as *hetero-oligomers*. The quaternary structure formula $a_n b_m$ describes a hetero-oligomer that contains two types of subunits a and b in *m* and *n* copies, respectively. Gtpases involved in cellular signal transduction are abg hetero-

trimers. Mammalian hemoglobins may be written as either a $_2b_2$ or (ab) $_2$. **Immunoglobulins** G also have this formula, but unlike the a and b chains of hemoglobin, the **heavy** and **light chains** of an immunoglobulin are covalently linked by disulfide bonds. a_2 dimers and a_4 or a_2b_2 tetramers are the most common formulae in globular oligomeric proteins. More complex quaternary structures do exist, however, especially in membrane proteins. Thus, the formula a_2bgd describes the quaternary structure of the nicotinic acetylcholine receptor of the neuromuscular junction, which comprises four different chains with unequal stoichiometries.

In order to write a formula such as a_2b_2, we need to know the number and type of the constituent polypeptide chains. This cannot be deduced from just the knowledge of the **gene** sequences, although genetic evidence may point to the presence of more than one type of chain. Determination of the formula usually requires expressing and purifying the protein. After purification, SDS-PAGE or mass spectrometry are commonly used to separate the individual polypeptide chains and estimate their apparent molecular weights. If a homogeneous protein yields more multiple species with different molecular weights, it is probably a hetero-oligomer, but quantitative peptide **sequencing** will be needed to determine the relative amounts of each chain type and to eliminate the possibility that they derive from **proteolysis** or post-translational modification of a single gene product.

Whether or not the constituent polypeptide chains are of one or several types, their actual number in the protein is ascertained by measuring the molecular weight of the native protein complex. The most commonly used methods are gel filtration and **sedimentation equilibrium** ultracentrifugation. However, neither is as easy and sensitive as SDS-PAGE, and both are much less accurate than mass spectrometry, two techniques that yield the molecular weights of the components, but not of the assembly. Moreover, the results from gel filtration and ultracentrifugation may be misinterpreted if the assembly is not fully stable, so that partial dissociation or aggregation takes place under conditions where the measurement is made. Chemical crosslinking followed by SDS-PAGE is an alternative to molecular weight determination. Covalent crosslinking an a_n protein can, in principle, yield *n* bands on the gel having apparent molecular weights corresponding to species a, a_2, ¼, a_n. However, not all the constituent chains may form crosslinks readily, and the conditions where a complete ladder of *n* bands can actually be observed may be difficult to obtain. When the quaternary structure does not dissociate spontaneously during a separation, the number of subunits can be determined by hybridizing two distinguishable forms of the subunit, say, *A* and *B*, and then separating the various oligomers on the basis of this difference. For a tetramer, this should yield five species: A_4, A_3B_1, A_2B_2, A_1B_3, and B_4. In practice, molecular weight determination is more difficult and less reliable for a native protein than for a **denatured** protein. Indeed, we lack that basic information for the vast majority of the proteins known only as putative gene products or bands on a gel. In addition, quaternary structures are sometimes revised, and tabulated values should be verified.

Beyond counting polypeptide chains, the quaternary structure is part of the three-dimensional structure as a whole. NMR and X-ray crystallography studies can determine the symmetry relationships between subunits, the location of their interfaces, and the nature of their atomic contacts, together with the fold of the polypeptide chains. In crystals, contacts between subunits coexist with intermolecular, crystal packing contacts. The subunit contacts can usually be recognized just on the basis of their greater extent, but ambiguities sometimes arise. They must be resolved by other methods, such as the site-directed mutagenesis of the proposed subunit contacts. To characterize the contacts by NMR, special isotope labeling techniques have been developed. In a dimer, one subunit is labeled with ^{13}C, the other with ^{15}N, and isotope-edited **NOE** signals are specifically detected between CH hydrogen atoms of the first subunit and NH hydrogen atoms of the other. However, the large sizes of oligomeric proteins generally make the NMR resonance lines broad, so the spectra are poorly resolved and difficult to assign. Indeed, neither NMR nor crystallography can dispense with the determination of the molecular weight of native protein.

The subunit contacts that make up the quaternary structure are generally noncovalent and form interesting examples of specific protein–protein interactions. They almost always make a major contribution to the stability of the native protein and often its function also. There are many oligomeric proteins in which a **ligand-binding** site exists at the interface between subunits. This is the case of the **antigen**-binding sites of immunoglobulins and of the DNA-binding sites in the great majority of DNA-binding proteins. Enzyme active sites at subunit interfaces are not uncommon, and **allosteric** mechanisms of regulation largely rely on properties of the quaternary structure. These aspects are discussed under Oligomeric proteins, together with the evolutionary aspects of quaternary structure.

R-Factor (Crystallographic)

The final result in X-ray crystallography is presenting a molecular model of the structure being determined. If this were an ideal model and if the packing of the models in the crystal structure were accurately known, the calculated the amplitude of the structure factor F_{calc} would be equal to the observed amplitude F_{obs} for each reflection. In practice this ideal situation does not exist, and the difference between the two values indicates model's inadequacies. This difference, averaged over all of the measured reflections, is expressed as the crystallographic R-factor or reliability or residual index R:

$$R = \frac{\sum_{hk\ell} |F_{obs}| - k|F_{calc.}|}{\sum_{hk\ell} |F_{obs}|}$$

or alternatively

$$R = \frac{\sum_{hk\ell} |F_{obs}| - k|F_{calc}|}{\sum_{hk\ell} |F_{obs}|} \times 100\%$$

where k is a factor scaling the F_{calc} to the F_{obs} 's.

If the atoms were to be placed entirely at random in a non-centrosymmetrical structure like a protein, R would have the value 0.59. For correct structures refined to, for example, 2.0 Å resolution, the R-factor is of the order of 0.20. If it is much higher, the structure is not likely to be correct.

A better estimate for the reliability of a protein structure is the free R-factor (1). It is calculated for a random selection of 5 to 10% of the observed reflections. These reflections are not used in the refinement, so refining and testing are completely independent.

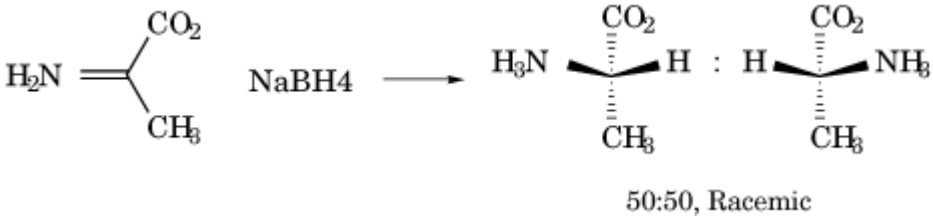
Racemic And Racemization

A mixture containing equal amounts of both **enantiomers** of a compound is a *racemic mixture*, which may also be called a *racemate* . The original compound identified as containing equal parts of two enantiomers was racemic acid as isolated from grapes (1). This compound is now known as (±) tartaric acid. When a **chiral** compound is formed by the reaction of two achiral reactants, the product must be a racemic mixture (2). An example of such a reaction is the reduction of the imine of pyruvate by sodium borohydride as shown in Figure 1. The product alanine is chiral, but both enantiomers must be generated in identical amounts.

Figure 1. Generating the chiral products L- and D-alanine from achiral reactants. The two products are produced in equal amounts, to give a racemic mixture of DL-alanine.



The process of separating a racemic mixture into its two enantiomeric components is called *racemic resolution* . Any process that catalyzes the interconversion of enantiomers, ie, a *racemization* , will necessarily result in a racemic mixture being formed. This must be so because the free energy of formation of the two enantiomers, in the absence of any other chiral compound, must be identical. During the chemical process of peptide synthesis, racemization of the activated amino acid derivatives has been a major problem. Enzymes, such as proline racemase, will racemize a solution of either the L-or D-enantiomer by catalyzing the interconversion of the two enantiomers, generating a racemic mixture of the substrate.

Radiation Hybrid

The fusion of **somatic cells** from different species to create somatic cell hybrids has provided an exceptionally useful tool for mapping of genes to particular chromosomes because the chromosomes of one species are always progressively lost in such interspecific somatic cell hybrids (1). Using hybrid cell lines, it is also possible to use recognizable chromosome breakpoints to localize genetic loci more accurately. This process is greatly facilitated by inducing chromosome breaks with radiation (2). This technique uses a somatic cell hybrid between a rodent and a human cell that contains a single human chromosome, all of the rodent chromosomes, and a selectable marker that confers resistance to the antibiotic neomycin. The chromosomes in this hybrid cell line are fragmented by irradiation such that cell death normally occurs. However, the irradiated hybrid cell line is rescued by fusion with another rodent cell line that is neomycin-sensitive. Growth in neomycin allows selection to operate in favor of the resulting radiation hybrid cell lines, rather than the neomycin-sensitive unfused cell line. Fragments of the human chromosomes are retained and incorporated into the rodent cell chromosomes. The different radiation hybrid cell lines generated in this way can be examined for the presence or absence of molecular markers from the human chromosome.

The production of radiation hybrids has provided a useful methodology for mapping how close genes are in the human chromosome. Two genes that are close together remain together following radiation, whereas those that are far apart are separated. By estimating the frequency of separation, it is possible to build up a physical map of the chromosome providing gene order and distance (3).

Radioactivity

Radioactivity is the property of certain elements to undergo spontaneous transformation of their atomic nuclei, the release of energy, and the formation of new elements (decay products). Radioactive nuclei are unstable and seek a more stable configuration by releasing energetic particles or photons of energy. These particles may include alpha particles, beta particles, and positrons. Photons include gamma rays, X rays, and neutrinos, which are discrete quanta of energy without mass or charge. These emissions impart energy to matter by creating tracks of ionized molecules. The emission of charged particles or gamma rays may be measured with radiation detectors. This property of radioactive materials makes them useful for a great number of practical applications in

the physical and biomedical sciences.

Every chemical element has one or more radioactive isotopes, and the total number of known radioactive and stable isotopes is more than 1500. Radioactive isotopes (radioisotopes or radionuclides) of a given element differ in the number of neutrons in the nucleus and, hence, in total atomic mass. A radioactive label (radiolabel) is a radionuclide or radioisotope in a chemical compound that replaces a stable isotope of the same element. It is used to mark the compound for detection by instruments that measure radioactivity. Radioactive labeling is useful for tracking the uptake, retention, metabolism, or clearance of chemical compounds, or for investigating metabolic pathways, enzyme kinetics, or chemical reactions. Radioactive labels are sometimes called radioactive tracers.

The radioactivity of a particular nuclide is determined by the configuration of its atomic nucleus and is independent of the chemical and physical state of the radioisotope and its environment (temperature and pressure). Radioactivity takes many different forms. The process of radioactive disintegration results in changes to the nucleus in atomic number and in its number of nucleons (protons plus neutrons), as indicated in Table 1.

Table 1. Changes in Atomic Number and the Number of Nucleons by Radioactive Transformation[a]

	Change in	
Radiation Emitted	**Atomic Number**	**Number of Nucleons**
Alpha particle	–2	–4
Beta (minus) particle	+1	0
Beta (plus) particle (or positron)	–1	0
Gamma or X ray	0	0

[a] From F. H. Attix (1986) *Introduction to Radiological Physics and Radiation Dosimetry*, John Wiley & Sons, New York.

An example of radioactive transformation is the decay of phosphorus-32 to sulfur-32 by emission of a beta (minus) particle (or electron), ${}^{0}_{-1}e$:

$$ {}^{32}_{15}\mathrm{P} \rightarrow {}^{32}_{16}\mathrm{S} + {}^{0}_{-1}e + 1.71\ \mathrm{MeV} \qquad (1) $$

Beta decay and positron emission also are accompanied by emission of energy in the form of a nonionizing neutrino. Decay schemes for radionuclides may be complex.

The total energy of the gamma rays and charged particles emitted during radioactive decay is equivalent to the net decrease in the rest mass of the disintegrating atom as it changes from parent to decay product. Its energy, momentum, and electronic charge are conserved. The emitted energy is either kinetic energy of particles in motion or quantum energy of photons, each of which degrades into heat. The ionization of matter through which radiation passes may result in direct or indirect chemical changes and radiation damage.

1. Half-Life

The transformation kinetics of radioactive decay are unique to each radioisotope, and each has its own characteristic, constant decay rate. The time required for any given radioisotope to decay in amount to one-half of its original amount is a measure of the rate at which radioactive transformation takes place. The physical half-life ($t_{1/2}$) of a radioactive atom may range from fractions of a second to billions of years and is unique to each radionuclide. Naturally existing radionuclides have long physical half-lives or are created by the decay of radioisotopes with long half-lives.

If N is the number of identical radioactive atoms and l is the radioactive decay constant (s^{-1}; reciprocal seconds), then 1/l is the activity, and the rate of change in N at any time t is equal to the activity

$$\frac{-dN}{dt} = \lambda N \tag{2}$$

Integrating from $t = 0$ (when $N = N_0$), we obtain

$$\int_{N_o}^{N} \frac{dN}{dt} = -\int_{0}^{t} \lambda dt \tag{3}$$

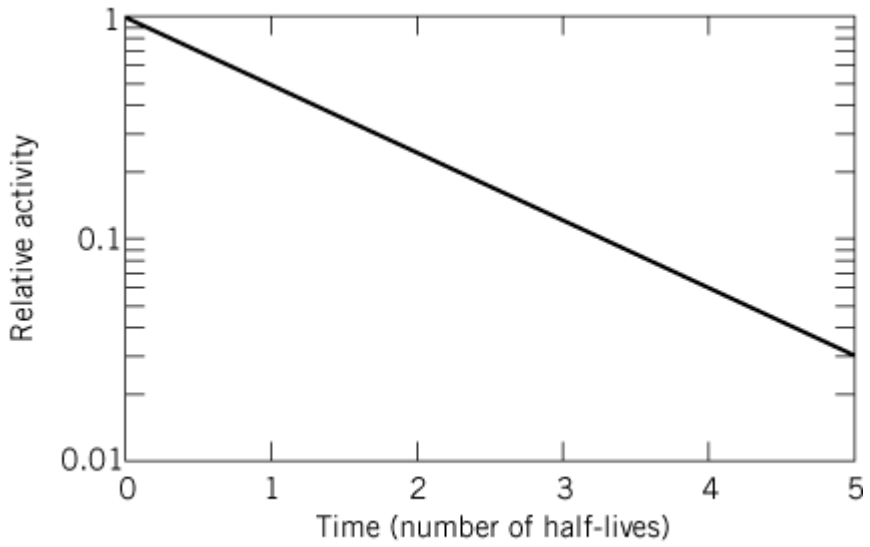
$$\therefore \ln N - \ln N_0 = -(\lambda t - 0) \tag{4}$$

$$\ln \frac{N}{N_0} = -\lambda t \tag{5}$$

$$\frac{N}{N_0} = e^{-\lambda t} \text{ or } N = N_0 e^{-\lambda t} \tag{6}$$

Equation 6 describes the observed law of radioactive decay and is a formula that is useful for determining the amount of a radioactive material remaining after a period of time t (Fig. 1).

Figure 1. Semilog plot of the exponential decay of a radioactive material in terms of the number of half-lives that have transpired.



The unit of activity was originally the curie (Ci), the number of disintegrations per second taking place in 1 g of ^{226}Ra, where

$$1\ \text{Ci} = 3.7 \times 10^{10}\ \text{disintegrations per second} \tag{7}$$

In recent years, the curie has been replaced with the special S.I. unit becquerel (Bq), which is one disintegration per second. However, the units of curie, millicurie, and microcurie are still commonly used.

$$1\ \text{Ci} = 3.7 \times 10^{10}\ \text{Bq} \tag{8}$$

$$1\ \text{mCi} = 3.7 \times 10^{7}\ \text{Bq} \tag{9}$$

$$1\mu\text{Ci} = 3.7 \times 10^{4}\ \text{Bq} \tag{10}$$

2. Mean Life

The mean life of a radioactive material is the time required for an original amount N_0 to decay to $1/e$ of the original amount. Thus

$$\frac{N}{N_0} = \frac{1}{e} = 0.3679 = e^{-\lambda\tau} \tag{11}$$

where t is the mean life (s) of the material:

$$\ln e^{-1} = -1 = -\lambda\tau \tag{12}$$

$$\tau(\text{mean life}) = \frac{1}{\lambda} = 1.443 T_{1/2} \tag{13}$$

3. Specific Activity

The specific activity (Bq/g) is the activity (Bq) of a radioactive material per unit mass (g) or volume. The mass or volume may refer to the element itself or to the medium in which the radioactive material is contained. For example, the specific activity of a carbon-14-labeled compound is the radioactivity (Bq) of the carbon-14 divided by the total mass of all the compound molecules in a given volume.

4. Serial Transformation

If the decay products of a radioactive material are themselves radioactive, a decay chain is said to exist. The ingrowth of the first decay product is dependent on the rate of decay of the parent, and so forth through each daughter-product decay, until a stable isotope finally ends the chain. Three natural radioactive series exhibit long decay chains of successive members: the thorium-232 chain, with 12 members, concludes with stable lead-208; the uranium-238 series, with 19 members, concludes with stable lead-206, and the uranium-235 series, with 14 members, concludes with stable lead-207. A fourth series starting with plutonium-241, with 15 members and concluding with bismuth-209, has been created artificially. Each radioactive isotope of a decay chain emits alpha or beta particles and possibly also gamma rays.

An example of serial transformation is given by the decay of krypton-90, a fission product of uranium-235. Each step involves beta (minus) decay:

$$^{90}_{36}\mathrm{Kr} \xrightarrow[\beta^-]{} {}^{90}_{37}\mathrm{Rb} \xrightarrow[\beta^-]{} {}^{90}_{38}\mathrm{Sr} \xrightarrow[\beta^-]{} {}^{90}_{39}\mathrm{Y} \xrightarrow[\beta^-]{} {}^{90}_{40}\mathrm{Zr} \tag{14}$$

The rate of formation of a daughter radionuclide, or the number of daughter atoms present (N_d) from its parent (N_p), is equal to the rate of formation of the parent; however, each will have different decay rates. If the half-life of the parent (p) is much longer than that of the daughter (d) and only the parent is present at time zero ($t = 0$), the formation of the daughter product is described by secular equilibrium:

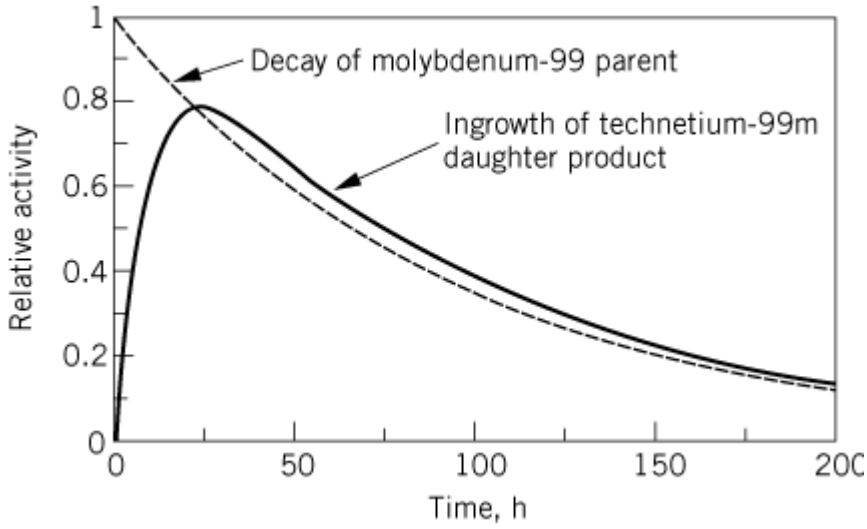
$$(N_d) = \frac{\lambda_p N_p}{\lambda_d}(1 - e^{-\lambda d t}) \tag{15}$$

At equilibrium, $l_p N_p = l_d N_d$, and the activities of each radioactive member are equal ($A_p = A_d$). A state of transient equilibrium exists when the half-life of the parent is somewhat greater than that of the daughter and both half-lives are relatively short. An example is the ingrowth of technetium-99 m (the most widely used radioisotope in diagnostic nuclear medicine) from parent molybdenum-99 (Fig. 2). The number of daughter atoms present at any time t is given by

$$(N_d) = \frac{\lambda_p N_p}{\lambda_d - \lambda_p}(e^{-\lambda p t} - e^{-\lambda d t}) \tag{16}$$

When transient equilibrium occurs, the daughter radioisotope undergoes radioactive transformation at the same rate as it is produced, decreasing in amount with time according to the decay rate of its parent, as shown in Figure 2.

Figure 2. Radioactive decay of molybdenum-99 and ingrowth of technetium-99 m with time (an example of *transient equilibrium*). The amount of radioactivity from each isotope is plotted as a function of time.



5. Alpha Particles

An alpha particle is equivalent to a helium nucleus (two protons plus two neutrons). Alpha decay usually occurs in nuclei of heavy radioactive atoms. An example of alpha decay is the transformation of radium-226 to radon-222 with a half-life of 1600 years:

$$^{226}_{88}\mathrm{Ra} \rightarrow {}^{222}_{86}\mathrm{Rn} + {}^{4}_{2}\mathrm{He} + 4.78\ \mathrm{MeV} \tag{17}$$

Alpha particles are essentially monoenergetic. During formation of radon-222, two electrons are ejected from the outermost electron shell. The +2 charged helium (He^{2+}) nucleus is ejected along a straight path, giving up energy and producing ion pairs along the way. When it comes to rest, it captures two electrons from its environment and becomes a stable, neutral helium atom. Most of the 4.78 MeV is given up to the absorbing medium as kinetic energy. During 95% of the time there is emission of a 4.70 MeV alpha particle and 0.08 MeV as radon-222 recoil energy. In the remaining 5% of the time there is emission of a 4.6-MeV alpha particle, and 0.18 MeV is given off as gamma rays.

The range of the alpha particle in a unit-density medium is only a few micrometers. The thickness of skin or a sheet of paper is sufficient to prevent most alpha-particle penetration. The range, R, of an alpha particle in air at 0°C and 760 mmHg pressure may be estimated from

$$R(\mathrm{cm}) = 0.56E_{\alpha}(\mathrm{MeV}) \text{ for } E < 4\ \mathrm{MeV} \tag{18}$$

$$R(\mathrm{cm}) = 1.24E_{\alpha}(\mathrm{MeV}) - 2.62 \text{ for } 4 < E < 8\ \mathrm{MeV} \tag{19}$$

The range of alpha particles in media other than air may be estimated from

$$R_m(\mathrm{mg/cm^2}) = 0.56A^{0.33}R_{\mathrm{air}} \tag{20}$$

where A is the atomic number of the absorbing medium and R_{air} is the range of the alpha particle in

air (cm).

Alpha-particle tracks may give rise to low energy, secondary electron tracks, called *delta rays*, which radiate outward to distances of tens of nanometers from the primary particle track.

6. Beta Particles

Beta particles are electrons that are ejected from the nucleus of an unstable, beta-emitting atom. Beta particles carry a single negative charge and small mass (only about 1/1800th) that of a proton or neutron). Beta emission appears as the change in a nucleus of one neutron into a proton, and occurs among radionuclides with greater numbers of neutrons than protons in the nucleus. An example was given in equation 1 above.

Beta particles are not monoenergetic, but rather are emitted with a continuous energy distribution, ranging from near zero to the theoretical maximum energy. To comply with the law of conservation of energy, each beta particle is accompanied by emission of a neutrino, whose energy makes up the difference between the theoretical maximum energy of the beta particle and its observed kinetic energy. Gamma rays may accompany beta emission in order to reach the ground energy state of the daughter product. For example, potassium-42 decays 82% of the time by a maximum energy of 3.55 MeV to calcium-42, and 18% of the time by a maximum energy of 2.04 MeV, together with a gamma ray of 1.53 MeV.

When beta particles slow to rest, they transfer a negative charge to the absorber. Their range is a few millimeters in unit-density tissue. The beta energy range may be measured by adding successively thicker absorbers until a count rate cannot be detected. An absorber that stops one-half the beta particles is about one-eighth the range of beta particles. An estimate of the range of beta particles may be obtained from

$$R(\mathrm{mg/cm^2}) = 412E^{1.265-0.0954\ \ln E} \tag{21}$$

for electron energies between 0.01 and 2.5 (MeV).

7. Positrons

Positrons are positively charged electrons that are emitted from atomic nuclei where the neutron:proton ratio is low and sufficient energy is not available for alpha-particle decay. Positron emission represents the transformation within the nucleus of a proton into a neutron. In other ways, the emission of positrons is similar to that of beta (minus) particles, which have similar mass and range in tissue. When a positron comes to rest, it quickly combines with an electron, and the two particles annihilate and give off two gamma-ray photons, whose energies are equal to the mass equivalent of the positron plus the electron (two photons of 0.511 MeV). An example of positron decay is the transformation of sodium-22 to neon-22:

$$^{22}_{11}\mathrm{Na} \rightarrow {}^{22}_{10}\mathrm{Ne} + {}^{0}_{1}e + \mathrm{photon} + \mathrm{neutrino} \tag{22}$$

8. Electron Capture

Some radionuclides decay by the process of electron capture, in which a *K* orbital electron is captured into the nucleus, uniting with a proton or hydrogen nucleus and changing it into a neutron:

$$^{0}_{-1}e + {}^{1}_{1}\mathrm{H} \rightarrow {}^{1}_{0}n + \mathrm{photon} + \mathrm{neutrino} \tag{23}$$

When an atom decays by electron capture, a characteristic X ray (photon) is emitted as an electron from an outer orbit falls into the energy level of the captured electron.

9. Gamma Rays

Gamma rays are monoenergetic photons or quanta of energy with discrete frequency that are emitted from the nucleus during radioactive decay to remove excess energy. Like X rays, gamma rays are highly penetrating electromagnetic photons of energy. Gamma rays usually accompany beta decay and always accompany positron decay. Gamma rays are attenuated by matter, and the efficiency of the shielding increases with atomic number.

10. Internal Conversion

Radioactive decay by internal conversion takes place when an unstable nucleus of a gamma-emitting nucleus gives off excess excitation energy by imparting energy to an orbital *K*- or *L*-shell electron, ejecting it from the atom. Characteristic X rays are emitted as outer-shell orbital electrons collapse inward to fill vacant energy levels produced by ejected electrons. If the characteristic X rays are absorbed by an inner orbital electron, internal conversion may take place, ejecting the electron (called an Auger electron).

11. Radiation Absorbed Dose

Radiation absorbed dose is the energy deposited by radiation per unit mass of the absorbing medium. The radiation absorbed dose in units of gray (Gy) to a unit-density medium containing an alpha-emitter is

$$D(\text{Gy}) = 1.61 \times 10^{-10} E_{\alpha}(\text{MeV}) \frac{N_{\alpha}}{g} \tag{24}$$

where E_a is the average alpha-particle energy, N_a is the number of alpha particles emitted in the medium, and g is the mass of the medium.

The radiation absorbed dose rate ($D°$, in grays per second) from a beta-emitting radioisotope under conditions of charged-particle equilibrium can be estimated from

$$D°(\text{Gy/s}) = 1.61 \times 10^{-10} E_{\beta}(\text{MeV}) \frac{N_{\beta}}{g} \tag{25}$$

where E_b is the average beta-particle energy per disintegration and N_b is the number of beta-particle disintegrations taking place per second, all per gram of medium. If the mass of the medium is small, some of the beta energy may escape, and conditions for charged-particle equilibrium may not be met.

Radioimmunoassay

Radioimmunoassay (RIA) is a technique for determining the content of a particular molecule in a sample, based on displacement of a radioactive antigen from an antibody or **antiserum**. Berson and Yalow and their colleagues developed the RIA method, and first applied it to the assay of human and animal insulins in plasma (1, 2). RIA has subsequently been used most extensively in endocrinology, as the technique is sufficiently sensitive for detection of vanishingly small quantities of hormones, but it is by no means restricted to hormones and has also been applied to all classes of biomolecule. Many modifications of the original technique are in common use. Here we discuss the classical RIA and several of the most common variations.

1. Classic RIA

Materials necessary for a classic RIA are:

- The unknown, that is, a sample of a chemically known antigen whose concentration is unknown and to be determined.
- Standards for calibrating the assay. These must be chemically identical to the unknown and of known concentration.
- A polyclonal or monoclonal antibody preparation that binds the unknown specifically.
- A **radiolabeled** ligand, termed a *tracer*, that binds to the antibody competitively with the unknown. Most often the tracer is chemically identical to the unknown, except for the radioactive tag, which usually is, or contains, an iodine isotope. Identity is not required, however, as long as binding of the tracer and the unknown to the antibody are mutually exclusive.
- A means for rapidly separating bound and free tracer. Separation is often accomplished using an antiglobulin antibody to **immunoprecipitate** the antibody–tracer complex, or an immobilized affinity adsorbent that reacts with the antibody constant region, such as protein A.

The RIA is initiated by adding the antibody to mixtures of a constant amount of tracer and increasing amounts of either the calibration standard or the unknown. Ideally, the tracer will be present in negligible molar quantity, relative to the **ligand-binding** capacity of the antibody, so that saturating half of the antibody sites with standard or unknown will displace half of the tracer. The necessary controls are (*1*) antibody added to tracer with a large excess of the calibration standard, to measure background radioactivity under conditions of complete tracer displacement, and (*2*) antibody added to tracer alone, to measure the radioactivity bound when no displacement occurs. After a suitable time for equilibration of the mixtures, bound and free tracer are separated, and one or both are measured. A dose–response curve, based on the calibration standards, can be plotted directly as the fraction of bound tracer retained or displaced as a function of the amount of standard added. This fraction is relative to the quantity of tracer bound in the absence of added unlabeled standard, not to the total amount of tracer added to the reaction. An example of such a direct plot is shown in Figure 1.

Figure 1. Dose–response curve typical of a classic RIA. Addition of increasing amounts of ligand progressively displaces the radioactive tracer from the antibody in the assay, generating an S-shaped curve. The abscissa in the figure is a concentration scale in units of the amount of unlabeled antigen added. The ordinate is a fractional scale, where 1.0 corresponds to the tracer bound to antibody in the absence of added antigen.

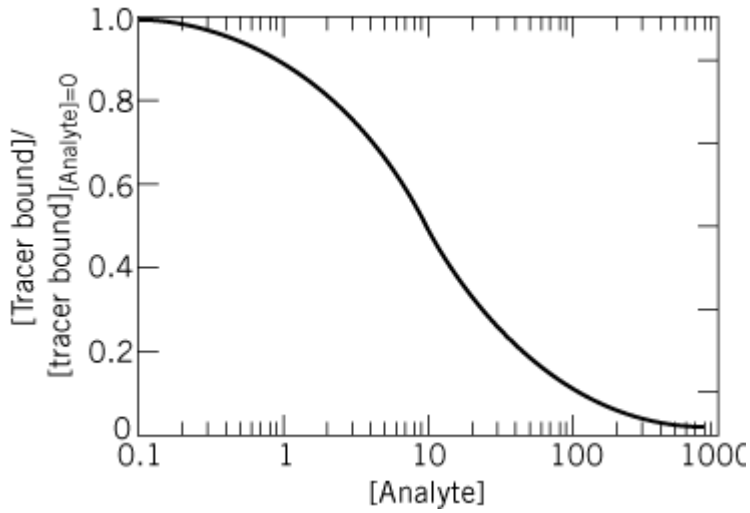

Figure 2. Logit transformation of RIA data from Figure 1. The logit transform converts the S-shaped dose–response curve into a linear form. The advantage of the logit plot is that a straight line is more readily analyzed, and outlying points are more easily identified, than for the direct plot.

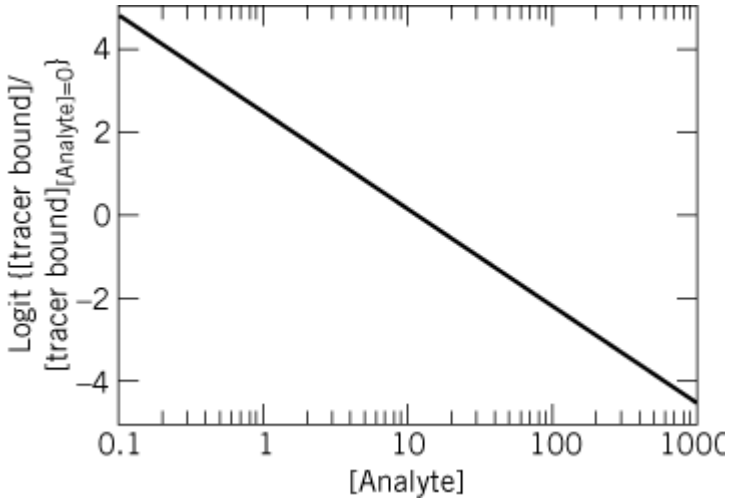

A preferable treatment of data is to construct a logit–log plot (3). The logit transformation for a fraction f is defined as

$$\text{logit} f = \ln \frac{f}{1-f} \tag{1}$$

For RIA data, this corresponds to

$$\text{logit} f = \ln \frac{\text{fraction of tracer retained}}{\text{fraction of tracer displaced}} \tag{2}$$

A plot of logit f versus $\log_{10}$ (standard) is often linear over much of its range; hence it is more easily analyzed than the S-shaped direct plot.

On the basis of the dose–response behavior of the standards, the amount of tracer displaced by the

unknown can be related graphically or algebraically to the quantity of antigen that must have been present in the unknown. Software for statistical analysis of RIA data is also widely available.

2. Solid-Phase RIA

This method is similar to the classical RIA, but with a great practical simplification: as the first step of the assay, the antibody is adsorbed to the surface of plastic assay tubes (4). (Other media such as beads and disks can also be used.) Adsorption is accomplished simply by adding a dilute antibody solution to the tube: a considerable amount of the antibody sticks noncovalently, but essentially irreversibly, to the plastic. The remaining components of the assay mixture—tracer, standards, and antigen—are initially present in solution. On their addition to the tubes, the tracer and antigen bind to the antibody, in ratios determined by their relative concentrations. Unbound assay components are subsequently removed, simply by decanting and washing. The radioactivity retained in the tubes is measured, and the data are analyzed as for the classic RIA.

3. Immunoradiometric Assay

The classic RIA is a competition assay, in which excess sample or antigen competes with tracer in binding to a limiting amount of antibody. An immunoradiometric assay (IRMA) is a noncompetitive design in which the antigen itself is the limiting quantity; hence IRMA is in principle orders of magnitude more sensitive than the classical assay (5). An experimentally important aspect of IRMA is that the antibody is the labeled component of the assay, rather than the tracer. Radiolabeling antibody by **iodination** is technically straightforward and often accomplished more readily than synthesis of labeled tracer (6-9). In the original IRMA method, antigen and labeled antibody are incubated together, and a complex is allowed to form. The mixture is next exposed to an immunosorbent, usually consisting of immobilized antigen, that will complex free antibody through the combining site. The radiolabeled antibody binds, unless it is already binding the antigen. Bivalency of IgG introduces a complication, since one IgG molecule has the ability to bind both antigen and immunosorbent. Nevertheless, measuring the radioactivity in either the solid or solution phase, and comparison of test samples with the standard curve measured using known amounts of antigen, gives an accurate measure of the quantity of antigen in the unknown.

4. Sandwich RIA

The sandwich RIA technique (10, 11), also known as a “two-site IRMA,” is a solid-phase method that uses two different antibodies, one radiolabeled, to detect a limiting amount of antigen. Both antibodies must be specific for the antigen, but they must bind at independent sites. As a first step, an unlabeled “capture” antibody specific for the antigen is immobilized. (An alternative to using immobilized reagents is to immunoprecipitate the antigen or capture antibody.) Antigen that is unlabeled and free in solution is added and allowed to bind to the capture antibody. Unbound components are washed away. The labeled antibody used for detection is added, and it also binds to the now-immobilized antigen. The unbound detection antibody is washed away, and the radioactivity remaining is measured. The antigen allows a “sandwich” structure to form, and the amount of labeled antibody incorporated into the sandwich is a direct measure of the amount of antigen in the sample.

This assay requires that the two antibody molecules bind to the antigen simultaneously, so the sandwich assay is most appropriate for analysis of protein or other large, **macromolecular** antigens. For the sandwich structure to form, the two antibodies must also bind to nonoverlapping **epitopes** on the antigen, so the use of monoclonal antibodies for capture, or for both capture and detection, is advantageous.

Radioisotopes

Isotopes are atomic species of the same atomic number (belonging to the same element) that have different mass numbers. The number of elements in the periodic table is about 110, and each one has more than one isotope; the total number of known isotopes is more than 1500. Each isotope of a given element has the same number of protons in its atomic nucleus, but differs in the number of neutrons in its nucleus. Isotopes of an element cannot be distinguished chemically because they have the same electronic structure and undergo the same chemical reactions.

Although some isotopes are stable, the nuclear configurations of radioisotopes (or radionuclides) are unstable, and they spontaneously undergo a radioactive transformation (or decay) to a more stable energy state (see Radioactivity). The half-life of each radioisotope is the time required for exactly one-half of the atoms to undergo radioactive transformation. Radioisotopes may decay to either stable or other radioactive species. Decay from one radioisotope to another is called a decay series.

Radioisotopes occur in small amounts in nature as the result of the decay of long-lived primordial materials (such as uranium-238). Atmospheric reactions with solar particles also produce radioactive species. Approximately 50 radionuclides occur naturally in the atmosphere, ocean, or the earth's crust; these include carbon-14, potassium-40, radon-222, radium-226, and uranium-238.

Radioisotopes can be produced artificially by nuclear high energy reactions that combine atomic

nuclei. The first human-made or artificial radioisotopes were made by Frederic and Irene Joliot-Curie in 1933, who irradiated a thin aluminum foil with alpha particles and observed tracks in a cloud chamber that diminished in intensity with a half-life of about 3 min, due to phosphorus-30 beta-plus decay. When they replaced aluminum with a boron foil, they found new activity, with a half-life of 14 min, due to nitrogen-13 beta-plus decay (1). In 1934, Lawrence produced small amounts of new radioisotopes at the Berkeley cyclotron using deuteron bombardment reactions on stable-element targets. Fermi produced heavier radioisotopes of the same element by neutron bombardment (or activation), also in 1934 (1). Hevesey conducted the first biological studies with radioisotope tracers. These developments made it possible to discover, produce, and test a large number of scientifically significant radioisotopes during the decade that followed. Radioisotope production continues today. In general, neutron-rich radioisotopes are produced in nuclear reactors, whereas neutron-lean radioisotopes are produced in charged-particle accelerators. A carrier-free radioisotope is one that is not produced or mixed with any other isotope of the same element. The specific activity of a radioisotope preparation is the radioactivity (bequerels or curies) exhibited per unit mass or volume of the radioactive material.

Radioisotopes can be detected easily and identified using radiation detection instruments or photographic film (see Autoradiography and Fluorography). Therefore, they have numerous practical applications in the physical, chemical, and biomedical sciences. Among the most important applications in biomedical research are those that involve the tagging of a radioisotope to a biomolecule to permit tracking of the molecule in reaction processes and metabolism. Animal tissues containing radioisotopes are analyzed by nuclear radiation-detection techniques such as liquid scintillation counting, gamma spectroscopy, alpha spectrometry, and neutron activation analysis—depending on the relevant radiation emission.

In studies of life processes, the most important radioisotopes are those of **hydrogen**, **carbon**, **sulfur**, and **phosphorous**, because these elements are present in practically all cellular components essential to maintaining life. Some of the more common radionuclides used in biomedical research are given in Table 1, together with their mass number, physical half-life, beta-particle yield and energies, and associated gamma-ray energies.

Table 1. Common Radioisotopes Used in Biomedical Research, with Principal Radioactive Emissions, Yields, and Energies (2)

Element	Mass (amu)[a]	Physical Half-Life	Beta Particle Yield	Average Beta Energy (MeV)[b]	Gamma-Ray Yield	Gamma Energy (MeV)
Hydrogen	3	12.35 years	1.0	0.00568	—	—
Carbon	11	20.38 min	0.998	0.386	2.0	0.511
Carbon	14	5730 years	1.0	0.0495	—	—
Phosphorus	32	14.29 days	1.0	0.695	—	—
Sulfur	35	87.44 days	1.0	0.076	—	—
Calcium	45	163 days	1.0	0.0771	—	—
Iodine	125	59.6 days	—	—	0.0667	0.0355
Iodine	131	8.021 days	1.0	0.182	0.0606	0.284
					0.812	0.364

	0.0727	0.637

[a] Atomic mass units.

[b] Million electronvolts.

In molecular biology, the most important application of radioisotopes is the radioactive labeling of nucleic acids and proteins. Radioactively labeled cells, such as **organelles** and chromosomes, can be imaged on high speed X-ray film in a process called autoradiography.

Radius Of Gyration

The radius of gyration, R_g, is a parameter that can be determined for biological molecules in solution using small-angle scattering techniques with X-rays, neutrons, or light. The R_g for a particle is defined as the root-mean-square distance of all elemental scattering volumes from their center of mass weighted by their scattering densities, and it is a simple but useful measure of the overall shape of the particle. R_g values for homogeneous geometrical shapes can be calculated analytically using the relationships in Table 1(1). These relationships can be very useful in interpreting experimentally determined R_g values. Table 2shows how R_g values vary for a single protein of a specific molecular weight and partial specific volume, assuming increasingly asymmetric shapes from a perfect sphere to a cylindrical rod. Also shown in Table 1are the R_g values for a six-subunit assembly assuming various arrangements of the subunits. It is readily seen that R_g gives a simple measure of the asymmetry in a particle. The mathematical formalisms used for determining R_g values from neutron and X-ray scattering data are somewhat different to those used for light scattering. We describe here the conventional equations used in the interpretation of neutron and X-ray scattering data. The formalisms used in light scattering are given in its own topic.

Table 1. Formula for Calculating R_g Values of Simple Geometric Shapes

Sphere radius R	$R_g^2 = \frac{3}{5}R^2$
Hollow-sphere radii R_1 and R_2	$R_g^2 = \frac{3}{5}\frac{R_2^5 - R_1^5}{R_2^3 - R_1^3}$
Ellipsoid, semi-axes a, b, c	$R_g^2 = \frac{a^2+b^2+c^2}{5}$
Prism, edge lengths A, B, C	$R_g^2 = \frac{A^2+B^2+C^2}{12}$
Elliptic cylinder, semi-axes a, b, height h	$R_g^2 = \frac{a^2+b^2}{4} + \frac{h^2}{12}$
Hollow cylinder, height h, radii R_1, R_2	$R_g^2 = \frac{R_1^2+R_2^2}{2} + \frac{h^2}{12}$

Table 2. R_g Values for Various Shaped Objects

	R_g [a] (Å)	Maximum Linear Dimension (Å)
Sphere, radius 10 Å, volume 4189 Å ^{3}	7.75	20
Prolate ellipsoid, semi-axes 6.325, 6.325, 25 Å, volume 4189 Å^3	11.87	50
Cylindrical rod, cross-sectional radius 3.6515 Å, length 100 Å, volume 4189 Å^3	28.98	100.27
Different arrangements of six identical spheres, radii 10 Å, total volume 25,134 Å^3	35	120
	20.66	~70
	21.44	60
		

[a] R_g values calculated using formulae in Table 1 for the single domain structures, each of which has

the same volume. R_g values for the multiple domain structures were calculated using the relationship) $R_f^2 = R_{gm}^2 + \frac{1}{N}\sum_i l_i^2$, where R_{gm} is the radius of gyration of each identical monomer, l_i are the distances of each monomer from the center of mass of the entire assembly, N is the number of monomers, and the sum is over all monomers (6). Note that the lower rosette arrangement has a larger radius of gyration than the rectangular array above it, even though it has a smaller maximum linear dimension. This is because the rosette arrangement has a "hole" in the middle.

1. Determination of R_g from Small-Angle Scattering Data

The small-angle scattering of X-rays or neutrons yields the scattering intensity distribution, $I(Q)$, which is related to the vector length or pair distribution function by a Fourier transformation:

$$I(Q) = 4\pi \int P(r)\frac{\sin Qr}{Qr}dr \qquad (1)$$

$$P(r) = \frac{1}{2\pi^2}\int I(Q)Q \cdot r\ \sin(Q \cdot r)dQ \qquad (2)$$

Q is the amplitude of the scattering vector, which is equal to 4p(sine)/l (l is wavelength of the scattered radiation, and q is half the scattering angle). $P(r)$ is the probable frequency distribution of all possible vector lengths, r, between scattering centers (or small volume elements) within a particle, weighted by the product of the scattering densities at the respective centers. R_g can be calculated as the second moment of the pair distribution function $P(r)$:

$$R_g^2 = \frac{\int P(r)r^2dr}{2\int P(r)dr} \qquad (3)$$

Alternatively, one can determine R_g from scattering data using the Guinier approximation. In 1939 Guinier (2) showed that for sufficiently small Q-values:

$$I(Q) = I(0)e^{\frac{-Q^2R_g^2}{3}} \qquad (4)$$

A plot of log $[I(Q)]$ versus Q^2 thus yields R_g and the zero angle scatter, $I(0)$, from the slope and intercept, respectively. $[I(Q)]_{Q\to 0}$ is directly proportional to the square of the molecular weight, M, of the scattering particle. For spherical particles, the Guinier approximation holds for $Q<1.3/R_g$, and as the scattering particle becomes increasingly asymmetric, the approximation breaks down at even lower Q values.

When one dimension of a particle is much greater than the other two (eg, a rod), Guinier (2) also showed that one can approximate the scattering for certain small- Q values as

$$QI(Q) = I_c(0)e^{\frac{-Q^2R_c^2}{2}} \qquad (5)$$

where R_c is the radius of gyration of cross section $[QI_c(Q)]_{Q\to 0}$ is directly proportional to the mass per unit length, M_L, of the scattering particle. For a rod of radius R, $R_c = R\sqrt{2}$. The range of Q for which equation (5) is valid depends on the shape of the cross section and the aspect ratio of the rod

(3). For infinite cylindrical rods, equation (4) is valid for Q values $<0.8/R_c$. For finite rods there will be a "rollover" near the origin. Explicitly for rods of radius R and aspect ratio $A = L/2R$, the scattering intensity will decrease for values of $Q<5/2AR$ that is, the higher the aspect ratio, the lower the value of Q where the rollover begins. For a rod-shaped object, R_g and R_c are related by

$$R_g^2 - R_c^2 = \frac{L^2}{2} \tag{6}$$

For particles with two dimensions much greater than the third (eg, a disk), the small Q scattering can be approximated as

$$Q^2 I(Q) = I_t(0) e^{-Q^2 R_t^2} \tag{7}$$

where R_t is the radius of gyration of thickness. For a disk of thickness T, $R_t = T/\sqrt{12}$. Equations (5) and (7) break down for particles with low axial ratios, and so they must be used with caution.

1.1. Changes in R_g Values Give Insights into Biological Function

In a series of scattering experiments on the dumbbell-shaped calcium-binding protein calmodulin, it was shown that upon binding a wide variety of amphipathic helices, calmodulin undergoes a dramatic conformational collapse involving its two globular lobes coming into close contact. The collapse is facilitated by a flexible helix linking calmodulin's two globular domains, and it is characterized by an approximately 25% reduction in R_g (reviewed in Ref. 4). This conformational flexibility has proven key to understanding how calmodulin binds and activates a wide variety of target enzymes. Another example of the utility of determining R_g values is the study by Mangel et al. (5) in which they characterized an extremely large ligand induced conformational change in native human Glu-plasminogen which was shown to have an R_g value of 39 Å. Upon occupation of a weak lysine-binding site that regulates the activation of plasminogen, the protein's shape irreversibly changes to give an R_g value of 56 Å. This change in shape is achieved without any accompanying change in secondary structure, and the data have been interpreted in terms of a rearrangement of the five domains of the protein structure from a compact, closed structure that is relatively rigid, to an open flexible structure in which the individual domains no longer interact with each other and hence are more accessible. The increased flexibility in the open form is postulated to account for the observation that this form is more readily activated, because it would facilitate urokinase binding. The open form is also proposed to be key to plasminogen's role in fibrinolysis.

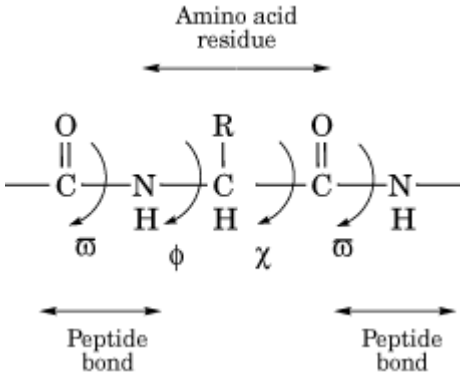
Ramachandran Plot

The Ramachandran plot is a two-dimensional graph of the phi (f) and psi (y) backbone angles for each amino acid residue of a protein; it is a simple method of assessing the quality of a protein structure. It is named after G. N. Ramachandran, who first determined the values of f and y that are theoretically permitted (1). The symbols f and y are used to represent the dihedral angles of the backbone N–C_a; and C_a;–C bonds, respectively (Fig. 1). Omega (w) is the angle of the peptide bond, C–N, but this bond has partial double bond character, so w can only adopt values close to 180° (called *trans*) or 0° (*cis*). Of these two, the *trans* peptide w conformation is observed in most cases, unless the following residue is proline (see Cis/Trans Isomerization).

Figure 1. Section of a polypeptide chain showing two peptide bonds (–CONH–) and one amino acid residue (–NH–C_a; (R)(H)–CO–). The functional group R varies, depending on the type of amino acid. The dihedral angles w, f and y of the peptide backbone are labeled.



The bonds represented by f and y are single bonds, and in principle all bond rotations are feasible. Only certain combinations of the backbone angles f/y are possible in polypeptide chains, however, due to steric restraints imposed by the amino acid side chains. These are defined as the most favorable or "allowed" regions of the Ramachandran plot, and they include the **conformations** of regular **secondary structure** such as **a-helix** or **b-strand**. In general, the f angle only adopts negative values. Of the 20 natural amino acids, 18 have only slightly differing allowed values of f and y. The glycine residue, with only a hydrogen for its side chain, has a high degree of backbone conformational flexibility and can adopt f/y angles that are forbidden for other amino acid residues (positive f angles, for example). In contrast, the cyclic nature of the proline residue restricts its value of f to approximately –60°.

The residues in natural folded proteins generally adopt fully allowed values of f and y; exceptions usually have functional importance. Generally, over 90% of nonglycine amino acid residues in a protein structure have backbone conformations corresponding to the a, b, or turn types of secondary

structure. This can be visualized using plots of the observed f/y combinations for each residue of a protein structure (Fig. 2). The Ramachandran plot is a very useful means of assessing the quality of a protein structure and of identifying residues with unusual backbone conformations.

Figure 2. Ramachandran plot for a typical protein structure. The f/y values of each nonglycine residue are plotted as squares, and those for glycine residues are shown as triangles. The allowed or most favored regions of the Ramachandran plot are shown in red. The top left section corresponds to b-strand secondary structure, the middle left section corresponds to a-helix and the small middle right section corresponds to left-handed helix. Over 90% of the nonglycine residues fall within the most favored (red) regions of the Ramachandran plot. Additional allowed regions are shown in varying shades of yellow. This figure was generated using Procheck (2). See color insert.

Random Coil

Random coil describes the multiconformational state of **peptides** and unfolded proteins and polypeptide chains. In addition, it is sometimes used to refer to the unstructured **conformations** adopted by the N-terminus, C-terminus, and certain loop regions of stable folded proteins. A polypeptide chain in a random coil state adopts multiple interconverting conformations in which the average conformation of each **amino acid residue** is independent of the conformations of all residues other than those immediately adjacent in the primary structure. Proteins usually adopt the random coil state under strongly **denaturing** conditions, such as high concentrations of guanidinium salts or urea.

Random X-Inactivation

It is biologically necessary to make the expression of genes from the two **X-chromosomes** in female cells comparable to that from the single X-chromosome in male cells. To achieve this goal one of the two X-chromosomes in female cells is inactivated (see X-Chromosome Inactivation). The two X-chromosomes from the female cell derive from the male gamete (paternal, X^P) and from the female gamete (maternal, X^M). Both the X^M and X^P chromosomes are functional in the very early female mammalian embryo. Once cytodifferentiation starts in the embryonic and extraembryonic tissues of the embryo, however, X-chromosome inactivation occurs (1). In the mouse embryo, the trophectoderm and primitive endoderm preferentially inactivate the paternally contributed X-chromosome X^P. In all other cell lineages that eventually give rise to the adult animal, there is a random inactivation of X^P and X^M (2). This random X-inactivation occurs in all eutherian (placental) mammals, making females functional mosaics of heterozygous X-linked genes. In marsupials, in contrast, the paternally-derived X-chromosome is always inactivated in the female animal (3).

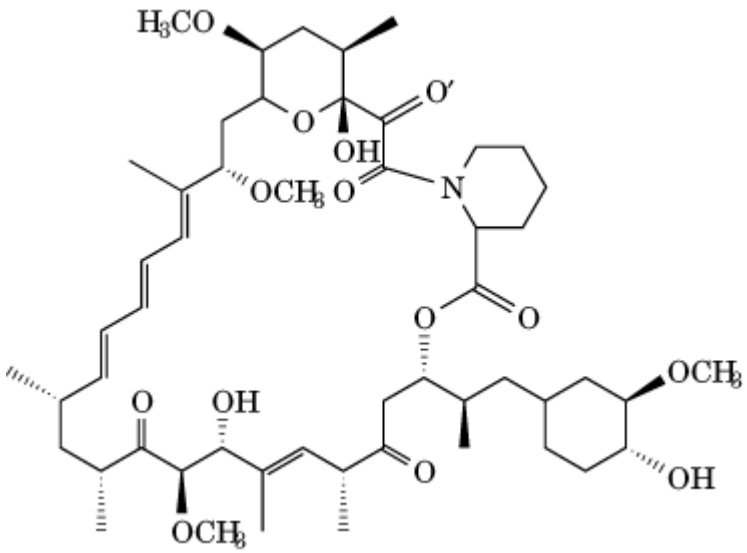
Rapamycin

Rapamycin (also known as Sirolismus, Rapamune) is a 31-membered macrocyclic lactam **antibiotic** of the **FK506**-type (Fig. 1), isolated from the soil actinomycete *Streptomyces hygroscopicus* in 1975 (1). The imidic a-ketoacyl-pipecolinyl bond is subject to cis/trans isomerization, leading to 38 % *cis* isomer in aqueous solution (2). It was initially evaluated as a potent antifungal agent, but later it was

found that it exerts antiproliferative action by disrupting the signaling pathway of lymphokines (IL-2, IL-4, IL-6) which promote T cell, B cell, and mast cells. Some nonimmune cell lines are also blocked in proliferation, although rapamycin does not exhibit the properties of a general inhibitor of cell proliferation. The mode of action in these specific effects on the immune response is different from that of the immunosuppressants cyclosporin A and FK506, in that cells are arrested in the late **G_1 phase**, just prior to the S phase. Moreover, rapamycin suppresses a much wider spectrum of cellular signals. Supporting the belief that it has a pathway distinct from that of other immunosuppressants, only rapamycin inhibits the chronic organ rejection process characterized by graft arteriosclerosis, thus prolonging graft survival. In addition to inhibiting the lymphokine response, the production of antibodies and lymphokines through Ca^{2+}-independent pathway is impaired (3).

Figure 1. The structure of rapamycin.



Typically, these biological effects are obtained at rapamycin levels (picomolar to micromolar) below those at which it is toxic. Rapamycin does not always act synergistically with cyclosporin A and FK506, as in the inhibition of T cell and B cell proliferation, but it often affects identical intracellular signaling events (4). Sometimes, FK506 and rapamycin reciprocally antagonize the parameters tested, suggesting a common cellular receptor for both compounds. Indeed, at doses in the picomolar range of concentration, both drugs bind reversibly to FK506-binding proteins (FKBP). Among mammalian FKBP, the cytosolic FKBP12 is responsible for mediating rapamycin effects (5). Binding always occurs with a concomitant inhibition of the peptidyl prolyl cis/trans isomerase (PPIase) activity of the FKBP, but this inhibition fails to account for the immunosuppressive effects. Instead, several lines of evidence show an indirect positive action of the rapamycin/FKBP12 complex, because rapamycin treatment induces the inhibition of several cellular serine/threonine kinases, including mammalian p70 S6 kinase.

The upstream target, which may represent the protein that physically interacts with the drug/receptor complex, is the 289-kDa RAFT1 protein in mammals (also known as FRAP or RAPT1) (6-8). Similar to its **homologues** TOR1 and TOR2 in yeast, this protein contains a C-terminal **domain** with amino acid homology to several phosphatidylinositol 4- and 3- lipid kinases. It can be postulated that a putative protein/lipid kinase activity of RAFT1/TOR takes part in the **phosphorylation** cascade that governs the function of p70 s6 kinase in controlling **protein biosynthesis**. The effector region of the rapamycin/FKBP12 complex consists of a solvent-exposed part of rapamycin along with residues

from FKBP12 in the loops starting with residues 40 and 80. This region is the unique feature of the complex for targeting the RAFT1/TOR family (9).

Ras Oncogene

The *ras* gene is an important gene that has been transduced by three rodent retroviruses (Harvey sarcoma virus, Balb MSV, and Kirsten sarcoma virus). It has been studied extensively because of its role in **growth-factor**-associated **signal-transduction** pathways (1). The viral *ras* genes code for 21-kDa proteins, also known as p21, that belong to the G-protein superfamily. G-proteins bind to GTP with high affinity and hydrolyze it to GDP (see GTP-Binding Proteins; Gtpases; Heterotrimeric G Proteins). The GTP-bound Ras protein is biochemically active, whereas the GDP-bound form is inactive. More importantly, the proportion of GTP-bound p21 Ras is tightly regulated in normal cells by feedback mechanisms, and it normally represents less than 5% of the total Ras protein. Comparison of v- and c-*ras* revealed that the viral oncogenes contain two point mutations, one in codon 12 and a second in codon 59, both of which impair the intrinsic GTPase activity of the mutant proteins and render them resistant to negative regulation (1, 2). As a result, the v-Ras proteins remain in a constitutively activated (or GTP-bound) state, which contributes to their oncogenic activity.

The human genome contains three closely related *ras* genes, all of which code for 21-kDa proteins, exhibit a high degree of homology, and are known as H- *ras*, K-*ras*, and N-*ras* . (Fig. 1) (1). Of these, the H- *ras* gene is most similar to the v-*ras* genes derived from the Harvey sarcoma virus and BALB-MSV, whereas the K- *ras* gene is most similar to the oncogene encoded by the Kirsten sarcoma virus. The N-*ras* gene was originally isolated from a neuroblastoma following transfection of the tumor DNA into NIH/3T3 cells and analysis of the sequences responsible for inducing transformed foci. Approximately 20% of human tumors contain activated *ras* genes. A detailed analysis of the tumor-derived oncogenic *ras* genes showed that almost all of these genes contain

mutations either in the 12th or the 61st **codon** that result in constitutively activating the protein products. The ras proteins are membrane-bound Gtpases and play a critical role in transmitting growth signals transmitted by growth-factor receptors following their interaction with their ligands. These interactions lead to an increase in the cellular concentration of GTP-Ras, and the activated Ras in turn activates Raf and the Map kinase pathway (Fig. 2).

Figure 1. Comparison of the genomic structures of the *ras* proto-oncogenes. All of these genes encode four exons. K-*ras* encodes a fifth exon which is alternatively spliced during transcription. Although all of the encoded proteins are identical in size, the length of their transcripts and genetic loci differ considerably.

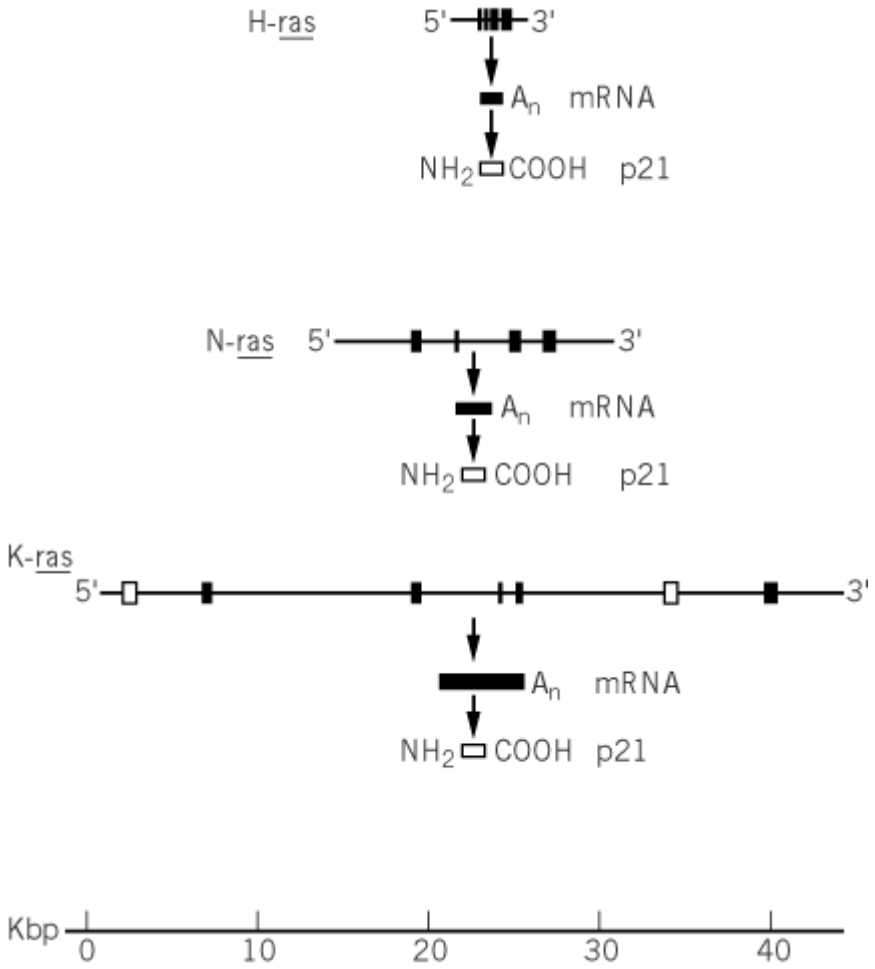

Figure 2. Schematic representation of receptor tyrosine kinase (RTK) signaling. (**a**) In a resting cell, RTKs exist as nondimerized, nonphosphorylated transmembrane proteins. The Grb-2 and Sos adaptor proteins are bound through the two Grb2 SH3 domains and the proline-rich regions of Sos. In addition, ras remains in an inactive, GDP-bound state. (**b**) Once the RTK has bound to its cognate ligand, it dimerizes and undergoes autophosphorylation on multiple tyrosine residues. Now, the phosphorylated receptor can bind to the Grb2:Sos adaptor complex. Because the function of adaptor proteins is to link multiple signal-transducing proteins within a single pathway, the Grb:Sos complex triggers the formation of GTP-bound, activated ras. Subsequently, activated ras initiates the ordered, sequential phosphorylation of RAF, MEK, ERK, and Rsk which is essential for cell growth and differentiation. The phosphorylation of several classes of transcription factors enables them to bind to DNA and induce gene transcription.

Reading Frame

Nucleotide sequences determine amino acid sequences by nucleotide triplet words named **codons**. Codons are arrayed on messenger RNA in a nonoverlapping, side-by-side manner. A nucleotide sequence can be read as codons in three different ways (or reading frames). During initiation of translation, the ribosome selects one of the reading frames by starting from the proper initiation codon and **translates** its reading frame until the stop codon. Maintenance of the reading frame is a highly accurate process, with an estimated error rate of 5×10^{-5} per codon. The reading frame maintenance relies primarily on three mechanisms: (i) unambiguous codon–anticodon triplet pairing between transfer RNA and mRNA; (ii) sufficient stability of codon–anticodon pairing throughout each elongation cycle; (iii) correct entry of aminoacyl-tRNA to a codon adjacent to that paired with peptidyl-tRNA. Theoretically any segment of nucleotide sequence can specify three different amino acid sequences. Some mRNAs, particularly those of viruses, actually contain overlapping protein coding sequences on different reading frames.

A change of reading frame during translation is called translational frameshifting. Some translational frameshifting is genetically programmed and is required for expression of protein products. Similar reading frame changes can occur at transcriptional or post-transcriptional levels. Frameshift mutations are insertions or deletions of one or two nucleotides within the protein coding region, which cause reading frame changes. By frameshift mutations, the amino acid sequence corresponding to the 3′ to the mutation site is completely disturbed, and the polypeptide product is often truncated. Some mutagens, such as acridine dyes, induce frameshift mutations. Earlier genetic analysis of frameshift mutations and their intergenic suppressor mutations had led to the conclusion, even before the assignment of the meaning of the codon, that the genetic code consists of triplets.

A protein-coding region flanked by the initiation codon and the stop codon is, of course, devoid of any termination codons in the same reading frame. In contrast, termination codons tend to appear frequently in the other two reading frames of the protein coding region or regions that do not specify proteins. A reading frame following the initiation codon without interruption by any premature termination codons is called an “open reading frame.” A long open reading frame is likely to be a protein coding region. Hence, searching open reading frames serves as a useful way to predict protein coding regions from nucleotide sequences not yet characterized.

Readthrough

During protein biosynthesis, readthrough in translation is a nonstandard decoding of the stop codon to an amino acid, allowing the ribosome to continue translation beyond the termination codon (1). This phenomenon is also called nonsense suppression. Readthrough is caused by either mutations in the translation machinery or by specific signals on the messenger RNA. Genetically programmed readthrough in response to the mRNA signals is included in the recoding that represents reprogrammed genetic decoding [see Frameshifting (2)]. In a broader sense, translation beyond the stop codon by any mechanism, including frameshifting, is sometimes referred as readthrough. The term readthrough is also used for transcription beyond the transcript terminator.

Nonsense suppressor tRNAs are mutant transfer RNAs that decode one or more termination codons,

usually due to a point mutation in the anticodon. Some of the naturally occurring tRNAs show similar readthrough activity at the stop codon and are referred to as natural suppressor tRNAs. Certain mutations of ribosomes or release factors exhibit various nonsense suppressor activities in the absence of a suppressor tRNA. These mutations enhance the frequency of stop-codon misreading with a natural tRNA by affecting the normal termination process.

The programmed readthrough is further divided into two classes. In one class, canonical amino acids are inserted for the termination codons. At least two cellular genes utilize this type of readthrough. The gene for *E. coli* pili assembly is expressed by readthrough of a UAG codon. *Drosophila kelch* mRNA uses UGA readthrough. A number of virus genes have termination codons to be readthrough. A C-type retrovirus, murine leukemia virus (MuLV), has a UAG codon that is decoded as a glutamine at residue an efficiency of 5% to express the *gag-pol* polyprotein. An animal virus, sindbis, reads a terminating UGA as tryptophan at 10% efficiency. Various RNA plant viruses and bacteriophages also use UGA or UAG readthrough. These phenomena are mRNA- and codon-specific, involving specific signals on the mRNAs. In the case of MuLV, the UAG codon is accompanied by a downstream pseudoknot (see RNA Structure) structure that stimulates the readthrough.

The other category of programmed readthrough is insertion of a selenocysteine residue at certain UGA codons to synthesize selenoproteins (3). Selenoproteins exist in many organisms of all the three superkingdoms—archea, eubacteria, and eukarya—except for some yeast species. In higher eukaryotes, nearly 10 selenoproteins have been identified. The UGA codons in the mRNA are decoded by a specific selenocysteinyl-tRNA encoded by a chromosomal gene. Selenocysteine tRNAs have a unique secondary structure. The tRNA is first aminoacylated with serine, which is subsequently converted to selenocysteine on the tRNA by specific enzymes. Stem loop structures of the mRNA, termed selenocysteine insertion sequence (SECIS), serves as a signal for the insertion. The SECIS is located just 3′ to the UGA codon in bacterial selenoprotein mRNA, while it is on the 3′ untranslated region in animal selenoprotein mRNAs. In bacteria, a special elongation factor, SelB, instead of EF-Tu, delivers selenocysteyl-tRNA to the A site of the ribosome (Fig. 1). The precise mechanism of selenocysteine insertion in animals is not known.

Figure 1. Schematic representation of decoding of the UGA codon to selenocysteine (Sec) on the ribosome using the specific tRNA, elongation factor SELB, and the SECIS signal.

Reassociation, Nucleic Acids

Single-stranded nucleic acid polymers that possess complementary base sequences can combine to form duplexes when mixed under appropriate solution conditions. For complementary short oligonucleotides, the reassociation process is fast and complete. For complementary polymeric nucleic acids, the annealing process is more complex, slower, and not necessarily complete. Monitoring of the rate of reassociation of the duplex is a classical method for evaluating the relative complexity of genomic DNA. The duplex DNA is fragmented by exposure to shear gradients or restriction enzymes. Fragmentation is followed by thermal **denaturation** to produce single-stranded fragments. The reassociation process is monitored as a function of time. From these data, plots are constructed of the fractional extent of reassociation as a function of C_0t, where C_0 is the initial nucleotide concentration and t is time. The value of C_0t at which the fractional extent of reassociation is 0.5, is a measure of the complexity of the genome (see C0t Curve).

Double-stranded DNA exhibits hypochromicity; the absorbance of the duplex is less than the sum of the absorbance of the constituent single strands. Changes in absorbance on reassociation to form duplex DNA can be used to estimate the extent of reassociation at any point in time.

Under conditions of low sodium phosphate concentration, both single-stranded and double-stranded DNA will bind to **hydroxyapatite**. At moderate sodium phosphate concentrations, 0.1–0.2 *M*, double-stranded DNA is retained on the column, but single-stranded DNA is eluted. Double-stranded DNA is eluted at 0.5 *M* sodium phosphate concentration. Because double-stranded and single-stranded DNA can be discriminated by their retention on the hydroxyapatite column, the time course for the reassociation process can be monitored.

Receptors, Hormonal

Hormone receptors act as the essential link between circulating hormones and molecular responses within target cells. Cell growth and function is regulated by a variety of extracellular signals, including not only hormones (in addition to the classical hormones, several so-called vitamins are now recognized to be hormones) but also growth factors and cytokines. Because there are very close similarities between the receptors for all three of these categories of effector, it seems sensible to include all three within this article. For example, the receptor for granulocyte macrophage colony stimulating factor (GM-CSF), a class I cytokine receptor, is very similar in both structure and function to the receptors for growth hormone and prolactin (1). These are all now grouped as members of the class 1 cytokine receptor superfamily.

This classification of GM-CSF receptor along with growth hormone (GH) receptor immediately implies that there are a range of receptor families. Firstly, although the majority of hormones, growth factors, and cytokines have their receptors in the plasma membrane of target cells, molecules such as steroids, thyroid hormones, and vitamins A and D are all membrane-soluble, so they can cross the cell membrane down a concentration gradient. For this reason, their receptors are located within the cell. Thus, the first classification is by site: Receptors are either (a) within the plasma membrane or (b) within the soluble part of the cell.

The receptors found in the soluble part of the cell are all members of the same superfamily and are called the *steroid receptor superfamily*, which will be discussed in more detail later. The remaining receptors, perhaps best called transmembrane receptors, can be subclassified in a variety of ways. All have an extracellular **domain** (usually quite heavily glycosylated), a membrane-spanning domain, and an intracellular domain. The simplest is to classify them according to the nature of the membrane-spanning domain, but adding in some component of their cell signaling mechanism. This method of classification gives rise to four classes of transmembrane receptor. Firstly, there is the class of receptor in which there is *a single membrane-spanning chain* and the internal domain has *no intrinsic tyrosine kinase activity*. Examples of this are the growth hormone receptor, prolactin receptor, GM-CSF receptor, **interleukin-3** receptor, and so on. Secondly, there is the *single membrane-spanning chain that does have intrinsic* ***tyrosine kinase*** *activity*, and this is characterized by the *erb*B family (eg, **EGF receptor**, *erb*B-2, etc.), the insulin receptor, platelet-derived growth factor (PDGF) receptor, and so on. Thirdly, there is the *seven-helix membrane-spanning chain coupled to G-protein*. This represents the majority of hormone receptors and neurotransmitters—for example, receptors for the gonadotrophs (leutinizing hormone, follicle stimulating hormone), glucagon, or adrenaline. For completion, there is the group of several (usually around 12) membrane-spanning subunits that permit the *gated* passage between extracellular and intracellular compartments for ion exchange.

It is not the purpose of this entry to consider *cell signaling*, and readers interested in the details of activation by receptors of **G-proteins**, adenylate cyclase, **ras**, *raf*, mitogen-associated protein (**MAP**) **kinases**, **tyrosine kinases** [including Janus kinases (**Jaks**)], **signal transducers** and activators of transcription (Stats) should consult the appropriate entry. However, hormone receptors would be of little use if the binding of ligand to the receptor did not result in activation of one or more of these pathways. In the case of the growth hormone, prolactin, and GM-CSF family of receptors, there is clear evidence of overlap between the Jak-Stat and Ras/Raf/MAP kinase pathways (2).

Hormone receptors must be biologically selective. This means that any ligand that activates a specific receptor must be associated with the physiological responses associated with that receptor. For example, *estradiol-17b* is an 18-carbon steroid that induces estrogenic responses through the estrogen receptor. *Estrogen-17a* has virtually no estrogenic activity. In studies on the binding of

ligand to receptor, estradiol-17b binds to estrogen receptor with a dissociation constant of about 10^{-10} M, whereas the 17a isomer has a 100-fold lower affinity for the receptor, indicating that the hydroxyl group on carbon-17 plays an important role in the binding of ligand to receptor. However, diethylstilbestrol (DES), which is not a steroid and, on paper, bears little resemblance to the fused ring system of the steroids, has estrogenic activity at an equivalent dose to estradiol. Not surprisingly, in competition assays, estradiol and DES turn out to have very similar binding affinities for the estrogen receptor.

The class 1 cytokine receptor superfamily has already been mentioned, and it gives another interesting example of the importance of the nature of *ligand receptor interaction*. The three cytokines GM-CSF, IL-3, and IL-5 all have similar three-dimensional structures, in that they each contain a region with four a-helices. The receptors for all three ligands are all heterodimers made up of a- and b-subunits, but the b-subunit is common to all three. On examining ligand–receptor interaction (3), it was found that the a-helix nearest the *N*-terminal end of the molecule interacts specifically with the common b-subunit of the receptor, whilst the a-helix nearest the *C*-terminal end gives the biological specificity because it will only interact with the a-subunit of the receptor that is specific for that ligand. The common b-subunit is the one that is involved in the cell signaling processes.

This use of a common subunit for cell signaling is not restricted to the class 1 cytokine receptor superfamily. For example, the receptors for luteinizing hormone (LH), follicle stimulating hormone, b-human chorionic gonadotrophin, and thyroid stimulating hormone are again all heterodimers with the b-subunit again being common—this time to act as the activator of the G-protein signaling system.

One of the interesting features of hormone receptors is that of selectivity in terms of target cell type. For example, a fat cell (adipocyte) will have receptors for LH, glucagon, and so on. If the cell is fully activated by LH, then that activity level of the target enzyme, hormone-sensitive lipase, will be maximal ie, addition of glucagon will give no further activity. However, if the dose of LH used is below saturating, then addition of an appropriate dose of glucagon would push lipase activity up to the maximum. If the fat cells are replaced by Sertoli cells, however, there are no glucagon receptors and so glucagon will have no effect on such cells. Sertoli cells do have LH receptors but do not contain hormone-sensitive lipase. Instead, they are rich in the enzymes required for metabolism of cholesterol, and binding of LH to its receptors on Sertoli cells will result in an increase in synthesis and secretion of testosterone. Thus a common receptor can, nevertheless, give rise to different physiological end-points in different target cells.

The steroid receptor superfamily, which represents the receptors for those molecules which can diffuse across the plasma membrane, has been an important target for studies on regulation of gene expression. It has been recognized for many years that the effects induced by the majority of plasma membrane receptors are short-term (can be seen within seconds of ligand binding to receptor and are complete within a few hours, at most). Responses induced through the steroid receptor superfamily are generally long-term. The reason for this is that the hormones that act through transmembrane receptors are regulating the activity of preexisting enzymes, usually by increasing or decreasing the level of **phosphorylation** of specific serine, threonine or tyrosine residues. The steroid receptor superfamily acts through modulation of transcription of specific genes, so that it is the amount of total protein (enzyme) that is changed, rather than the activity of a preexisting protein.

Historically, long before receptor activation of gene transcription was proven, it was recognized that steroids induce synthesis of fresh enzyme. For example, glucocorticoid induction of tyrosine aminotransferase synthesis in hepatocytes has been known for many years. All members of the steroid hormone receptor superfamily contain similar domains (4). In particular, they all contain a DNA-binding domain that is remarkably well conserved among different members of the superfamily (receptors for estrogen, androgen, progesterone, glucocorticoid, mineralocorticoid,

thyroid hormones, vitamin A derivatives, and vitamin D derivatives). They all contain a ligand-binding domain, and most (not glucocorticoid receptor) contain a nuclear localization sequence (see Nuclear Import, Export). This means that, as each receptor comes off its **polysome**, it is transported into the nucleus, and the empty receptor is located in the soluble part of the nucleus of target cells. Another common feature is that both the *C*- and *N*-termini of the molecule contain transactivation regions that are essential for the final activation of gene expression through interaction with various transcription factors (6).

Empty steroid receptor is found in association with various **heat-shock** proteins. In simplistic terms, these proteins are responsible for transporting the receptor to the nucleus and for preventing its binding to the DNA prior to the arrival of the hormone. For example, sites for binding a dimer of heat shock protein-90 (hsp90) are recognized in both the **DNA-binding** domain and the ligand-binding domain. Once ligand arrives and binds to the ligand-binding site, the receptor molecule undergoes some degree of **allosteric** change such that the hsp-90 molecule disengages and exposes not only the DNA-binding domain, but also a dimerization site. Thus two molecules of receptor, each with hormone attached, come together to form a dimer. This dimer now has high affinity for the specific sequence of nucleotides found in the appropriate hormone response element, which is normally (but not always) upstream of the structural gene(s) known to be activated by that hormone within the particular target cell. In order to get full activation of the gene, the dimer must have both transactivation sites functional, and all appropriate transcription factors must be in place.

Functional hormone receptors are essential to life. Many endocrine diseases are now recognized to occur because of changes in the activity of different hormone (growth factor or cytokine) receptors. For example, cases of diabetes can be due to loss of, or fall in, activity of the insulin receptor. Assays of receptor function are now becoming very important in various areas of medical diagnosis and treatment. A variety of diseases of the digestive tract may be ascribed to over- or underactivity of the epidermal growth factor receptor; and controlled use of selective tyrosine kinase inhibitors that block the function of the EGF receptor, but do not significantly effect other tyrosine kinase-mediated responses, may be very useful in treating such clinical problems.

Treatment for breast cancer is now closely dependent on the detection of estrogen receptor in the primary disease. Patients whose tumors do not contain functional estrogen receptor will not respond to endocrine therapies and thus can be put immediately onto another type of therapy. Previously, it was often the case that all patients received initial additive endocrine therapy and were only switched to alternative therapies once they had failed to show any response to the endocrine therapy. Now, they should be getting a more appropriate therapy at an earlier stage of the disease, at which time it has more chance of success.

Because of the increasing clinical importance of hormone receptor assays, there is much more interest in the reliability of such assays. A number of external quality control assays have been set up. Biochemical assay of the estrogen receptor is very well established, and the results from very large studies are available to give a good guide to expected results (7). As many labs begin to switch from biochemical to immunohistochemical (IHC) assays, it is important to establish the same external QA for these. One such QA scheme has been set up for the IHC of estrogen receptors in breast cancer biopsies and has shown that remarkably good agreement can be reached by quite large numbers of participating labs (8).

1. Summary

Hormone receptors mediate the physiological response of specific target cells to external signals. Depending on the natures of both the ligand and the receptor, the response can be short- or long-term. The chemical nature of the ligand determines whether the receptor will be membrane-bound or present within the internal soluble components of the target cell. A target cell for any specific external effector is defined by the presence of that receptor on or within the cell.

Plasma membrane receptors may be subclassified according to the structure of the transmembrane region and the nature of the subsequent cell signaling mechanism. These receptors act, principally, by altering the activity of preexisting proteins through increasing or decreasing the amount of phosphorylation on specific serine, threonine, or tyrosine residues. Soluble receptors are normally found within the nucleus and, when activated by ligand, become dimerized in such a way that they acquire high affinity for specific nucleotide sequences (hormone response elements) associated with the appropriate structural genes.

Much current medical research is directed toward modulating the activities of these different types of receptor through either directly blocking their action or interfering with the consequences of their activation (selective kinase inhibitors, phosphatases, etc.).

Receptors Linked To Tyrosine Kinases

Many cells are regulated by ligands that bind to cell-surface receptors with a single **transmembrane** domain, but without intrinsic enzyme activities in their cytoplasmic domains. While there are numerous examples of such receptors, these systems are best characterized by the **cytokine** receptor superfamily . Signaling by these receptors depends upon their interaction with cytoplasmic **tyrosine kinases**, which utilize a series of protein–protein interactions similar to those employed by the **receptor tyrosine kinases**.

1. Interactions of Cytokine Receptors

Interferons, many of the **interleukins, growth hormone**, and numerous other molecules bind to the cytokine family of receptors (1). These receptors are characterized by (i) a single **transmembrane** domain with large extracellular regions and (ii) a shorter intracellular domain that does not contain any tyrosine kinase activity. In most cases, these receptors initiate signaling pathways by interacting directly with other signaling proteins, usually tyrosine kinases that are predominately cytoplasmic. In

fact, the receptors characteristically have discrete binding domains for these kinases, as well as a number of tyrosine-phosphorylation sites for interaction with **SH2**-containing proteins.

Although the activation of ***src*** family kinases by cytokines has been extensively studied, these enzymes are not activated by most cytokines. In contrast, cytokine binding to its receptor does lead to the activation of the JAK family of tyrosine kinases. They can couple cytokine receptors to a variety of downstream signaling pathways, but are specific for activation of a unique family of transcription factors, known as STATs (see JAK/STAT Signaling).

Recessive Lethal Mutations

Lethal mutations are mutations that inactivate essential genes. Mutants with dominant lethal mutations exist only if the lethality is conditional (see Conditional Lethal Mutations). In contrast, recessive lethal mutations, even if nonconditional, are propagated in a **heterozygote** because the essential function is supplied by the wild-type **allele** on the other chromosome. The presence of the recessive lethal is confirmed upon mating by the absence of a class of progeny. Recessive lethal mutations are also propagated in **haploids** if they have more than one copy of the relevant gene. For example, an *Escherichia coli* cell carrying an extra copy of a chromosomal gene on a **plasmid**, a **bacteriophage**, or an **episome** is a partial diploid (called a merodiploid). A common use for such a strain is to study the regulation of an essential gene by inserting a reporter gene into one of the copies.

Reciprocal Space

X-ray crystallography uses the concept of reciprocal space, an imaginary space that contains the reciprocal lattice. This lattice is also a nonreal lattice related to the crystal lattice. It is designed as an extremely useful tool to construct the directions of scattering by the crystal in combination with the Ewald sphere (Fig. 1). The reciprocal lattice has a unit cell whose vector axes are **a***, **b*** and **c***, and the collection of these unit cells forms reciprocal space:

1. **a*** is perpendicular to the **b** and **c** axes of the real unit cell and has a length $\frac{1}{d_{(100)}}$, where d(100) is the spacing between the planes in the set of planes (100).
2. **b*** is perpendicular to the **a** and **c** axes of the real unit cell and has a length $\frac{1}{d_{(010)}}$, where d(010) is the spacing between the planes in the set of planes (010).
3. **c*** is perpendicular to the **a** and **b** axes of the real unit cell and has a length $\frac{1}{d_{(001)}}$, where d(001) is the spacing between the planes in the set of planes (001).

Each reciprocal lattice point corresponds to a set of planes ($hk\ell$) in the real lattice. Scattering of the incident X-ray beam by the crystal occurs if a reciprocal lattice point, for example, point P in Fig. 1, passes through the surface of the Ewald sphere.

Figure 1. The Ewald sphere as a tool to construct the direction of the scattered beam. The sphere has radius 1/l. The origin of the reciprocal lattice is at O. s_0 indicates the direction of the incident beam and s of the scattered beam.

Reciprocal Translocation

Reciprocal **translocations** occur when breaks in two nonhomologous chromosomes are followed by the reciprocal exchange of chromosome fragments and repair of the broken ends (Fig. 1). Such reciprocal translocations involve no loss of chromosomal material. During **meiosis**, complete pairing of homologous chromosomal regions is accomplished by association of all four chromosomes, the two involved in the reciprocal translocation and the two in their original form. If **chiasmata** are formed at the end of each chromosome, a quadrivalent is formed (see Multivalents). The formation of fewer chiasmata may generate trivalents and univalents. The resulting problems in meiosis lead to abnormal **gametes** and cause **developmental** abnormalities. Many such defective fetuses spontaneously abort, but the frequency of human births in which balanced translocations have occurred is about 1 in 250.

Recombinant DNA

Recombinant DNA is any **DNA** molecule that has been manipulated by *in vitro* procedures to create a novel sequence. The recombinant molecules produced may have a modified base sequence or contain sequences from two or more different genes or organisms. They are usually introduced into an organism to create a novel **protein** or **RNA** molecule that alters the properties of the organism.

Major recombinant DNA techniques include site-directed mutagenesis (1), cloning, and polymerase chain reaction (**PCR**). Key enzymes required for recombinant DNA work are type-II restriction enzymes, DNA Ligase, **DNA polymerase**, **reverse transcriptase** and DNA **phosphatase**. Some of the uses of recombinant DNA techniques are to clone **genes**, to **knock out** a gene or genes in an

organism (2), to create **antisense** RNAs in an organism so as to interfere with **gene expression** (3), and to add a gene or genes to an organism to engineer a new or modified metabolic pathway (4).

Recombinant Proteins

A recombinant protein is a protein encoded by a gene—on recombinant DNA—that has been **cloned** in a system that supports transcription of the gene into messenger RNA and translation of the resulting mRNA into protein (see Expression Systems). Recombinant DNA technology (also known as *gene cloning* or *molecular cloning*) comprises a number of techniques leading to the transfer of genetic information (deoxyribonucleic acid, or DNA) from one organism to another. The term *recombinant DNA* originates from the idea that insertion of DNA into a cloning vector is a special form of genetic recombination. Genetic recombination is the formation of a new **genotype** by rearrangement of genes, resulting in gene combinations different from those present in the parents.

Several protocols exist for the creation of recombinant DNA. However, a typical cloning experiment could be carried out as outlined below:

1. The DNA from the donor organism is isolated, cleaved with restriction enzymes, and **ligated** to a cloning **vector** that has been digested with the same enzymes as the donor DNA, causing the formation of a new, recombinant DNA molecule (a so-called DNA construct).
2. The DNA construct is transferred (**transformed**) into a host cell, where it can exist independently and be maintained as an extrachromosomal entity.
3. The host cells that take up the recombinant DNA can be identified and isolated from those that do not because of the presence of a selection marker on the cloning vector conferring, for example, antibiotic resistance to the host.
4. The DNA construct can be further manipulated to ensure that the cloned gene is expressed by the host, producing the recombinant protein product.

More recently, the polymerase chain reaction (**PCR**) has proved a valuable tool for the amplification of specific DNA fragments. The technique allows the amplification of tailor-made fragments equipped with restriction sites that facilitate subsequent cloning.

How can a gene encoding a specific protein of interest be identified so that it can be expressed as a recombinant protein? First, a DNA library representing the entire genome (or mRNA) of the donor organism is created by fragmentation of the DNA, followed by the cloning of each of the resulting fragments into a cloning **vector**. The resulting recombinant DNA molecules are transformed into a host. Now a short stretch of DNA with a sequence corresponding to part of the gene of interest, a probe, is created. This probe is used to “fish out” the library clones containing the matching DNA by

hybridization techniques, where the probe is allowed to find a complementary DNA sequence with which it **base-pairs**. The clone encoding the protein of interest can also be identified directly by the presence of that particular protein. For this strategy, an expression library is needed in which the cloned genes can be expressed, giving rise to the corresponding recombinant protein. The protein can now be detected, eg, by immunological techniques or by its activity. If the gene of interest is of **eukaryotic** origin, the expression library needs to contain **cDNA**, which is free of **introns** (the noncoding parts of a gene).

The design of an effective expression system is the key to obtaining a recombinant protein with the properties of interest. Basically, an expression system consists of the expression vector and a host for delivering the enzymatic machinery necessary for transcription and translation of the gene. The choice of host often depends on the intended application of the recombinant protein, as well as the origin of that protein. The expression vector is a complex tool, with a number of elements to adjust for optimal output. It allows the regulation of when, where, and in which form the protein should appear. It is furthermore possible to equip the recombinant protein with different types of "handles" by gene fusion. The protein of interest is then expressed as a **fusion protein**. The ideal fusion partner endows the recombinant protein with helpful features that facilitate its purification, detection, and folding (see Fusion Gene, Fusion Protein).

Recombinant proteins have become of immense scientific and commercial value since the first cloning experiment, giving rise to a hybrid molecule that would express the foreign DNA within it, was successfully performed in 1973 (1). In 1978, the successful expression of human insulin in *Escherichia coli* was reported and, in 1982, the drug became commercially available (2). The immediate advantage of the technology was a more reliable source of the protein than the natural one. Furthermore, the protein could be produced in a more reproducible manner at a lower cost. The recombinant drug had an advantage over the commercially available porcine insulin in that it did not provoke any allergic reaction in the diabetics using it. This is an example of a first-generation therapeutic, a naturally occurring protein produced by recombinant DNA technology. The second generation of drugs are those being designed by use of protein engineering. These proteins are redesigned versions of naturally existing proteins that give them improved properties in terms of stability, activity, and specificity. As an example, a second-generation tissue plasminogen activator (tPA) with a lower clearance rate was engineered by **site-specific mutagenic** replacement of three amino acid residues and introduction of a new N-glycosylation site. The new drug retained its catalytic properties (3). The third generation of therapeutic proteins will be produced not in a fermentor but by the patients themselves, thus starting the era of gene therapy.

Recombinant proteins have found use not only in health care but also for various commercial purposes in industry—not least in the production of foods and beverages. Also, the detergent industry makes profound use of recombinant proteins. Recombinant lipases, proteinases, and cellulases are important ingredients in washing powders. Many of these have been engineered to be able to withstand the harsh environment existing in a washing machine.

Recombinant proteins are obtained by using recombinant DNA technology. Only after the protein has passed the battery of tests needed before its release is approved can it finally be used commercially. The recombinant protein technology provides a protein source that, in almost all cases, exceeds the quantity and quality provided by the natural source.

Recombinase

A major advance was made in the understanding of gene rearrangement of immunoglobulin (Ig) genes with the discovery [by Baltimore and coworkers (1)] of recombinases, encoded by the RAG1 (for recombinase activating genes) and RAG2. These genes are in opposite orientation on a 10-kbp piece of genomic DNA and were identified by screening a cDNA library derived by differential hybridization for its ability to promote an artificial substrate for V–J recombination after transfection into a fibroblast cell line. It was also realized that both RAG1 and RAG2 were necessary to ensure recombination. This was also proven *in vivo* after generating of RAG1$^{/}$ or RAG2$^{/}$ targeted mice, because Ig gene rearrangement was abolished in both mutants, leading to a major severe primary immune deficiency, with B-cell differentiation blocked at the very early proB stage. Incidentally, T-cell development is similarly blocked, indicating that the recombinase is also required for T-cell receptor gene rearrangement.

It was not clear initially whether the RAG genes directly encoded the recombinases or whether they produced an activator of the enzymes; more recently, **gel retardation** experiments with appropriate synthetic substrates revealed that both RAG proteins clearly bind to the heptamer (CACAGTG) and nonamer (ACAAAAACC) recombination signal sequences (RSSs). Binding of recombinase to these sites requires that they be made accessible, as shown by the fact that, prior to gene rearrangement, low levels of germline transcripts of V genes may be identified. Also, in fibroblasts transfected with the synthetic substrate for recombination and the RAG cDNAs, endogenous Ig genes do not recombine, because this cell line does not contain the necessary enzymatic equipment that ensures DNA accessibility at the Ig locus in specialized B cells.

As shown by McBlane et al. (2), RAG proteins are necessary and sufficient to recognize and to cleave an RSS. The cleavage occurs in two steps. First, a nick is made at the 5′ end of the signal heptamer, leaving a 5′ phosphoryl group on the signal part and a 3′ hydroxyl on the coding end. Second, the 3′ OH is joined to the opposite phosphate on the other strand, forming a hairpin structure on the coding end and a blunt signal end. The two steps are strictly RAG-dependent. Evidently, cleavage and hairpin formation must take place on the two gene segments that are going to connect to each other (eg, a D to a J) and come into close contact. Both hairpin-like structures are then cleaved (this occurs at a random position), and partial modification of the coding end takes place, first by removal of some nucleotides and then by adding new nucleotides by terminal deoxynucleotidyl transferase (TdT), thus introducing **N-diversity**. The final step is the joining of the two coding ends, which requires several enzymes and factors, of which a major contributor is a DNA-dependent protein kinase (DNA-PK). Binding to DNA is devoted to the Ku subunits of DNA-PK, whereas the catalytic subunit (DNA-PKcs) is presumably activated after the complex is bound to

DNA. Simultaneously, the signal joints are also formed, making a piece of circular DNA that can be identified in preB cells. Mutations in the Ku DNA-binding subunits and/or DNA-PKcs of the catalytic subunit will result in severe blockage of lymphocyte differentiation, such as the *scid* (severe combined immune deficiency) mutation in the mouse, in which a regulatory subunit is inactivated, leading to the impossibility of making coding joints.

Recombination

Genetic recombination encompasses a variety of processes that produce new linkage arrangements in the two interacting parental chromosomes, or segments of a single chromosome. Several types of recombination can be distinguished according to the parental substrates. In **homologous**, or generalized, recombination, the substrates share extensive **nucleotide sequence** identity, and recombination can occur anywhere within the **homologous** region. In site-specific recombination, the substrates share only limited nucleotide sequence homology (about 10 to 50 base pairs), and recombination occurs at a unique point within these sequences. In transposition, a segment of DNA in one substrate is bounded by special sequences. This segment, or a copy of it, is inserted into random or nearly random sites in the second substrate. Illegitimate recombination includes events that do not fall into these categories. These events often occur between substrates that share only a few homologous base pairs and may reflect aberrant DNA replication.

Recombination can also be classified according to the types of products produced. In homologous recombination, reciprocal recombination (crossing over) produces the two genetically reciprocal recombinant types in the same event. For example, *AB* and ++ parents produce *A*+ and +*B* recombinants. Nonreciprocal recombination (gene conversion) produces one, but not the other, recombinant type. For example, *AB* and ++ parents produce an *A*+ recombinant but not a +*B*. In site-specific recombination, if the two special sequences are in the opposite (indirect) orientation on one chromosome, recombination between the sites inverts the intervening segment. If the sites are in the same (direct) orientation, recombination deletes (or excises) the intervening segment. If the excised segment is circular, reversal of this reaction integrates one substrate into other. In transposition, the transposable element between the special sites may replicate and leave the transposable element in the substrate and introduce a copy of the element into the second substrate. Alternatively, the element may be excised from the first substrate and inserted into the second (cut-and-paste mechanism). In this case, the first substrate may be left broken, or the ends may be joined or otherwise repaired.

Recombination between DNA substrates is most thoroughly characterized, but recombination between RNA substrates, such as in RNA **viruses**, also occurs. RNA recombination may result from a copy-choice mechanism in which a replication complex “jumps” from one template to another at a

homologous point.

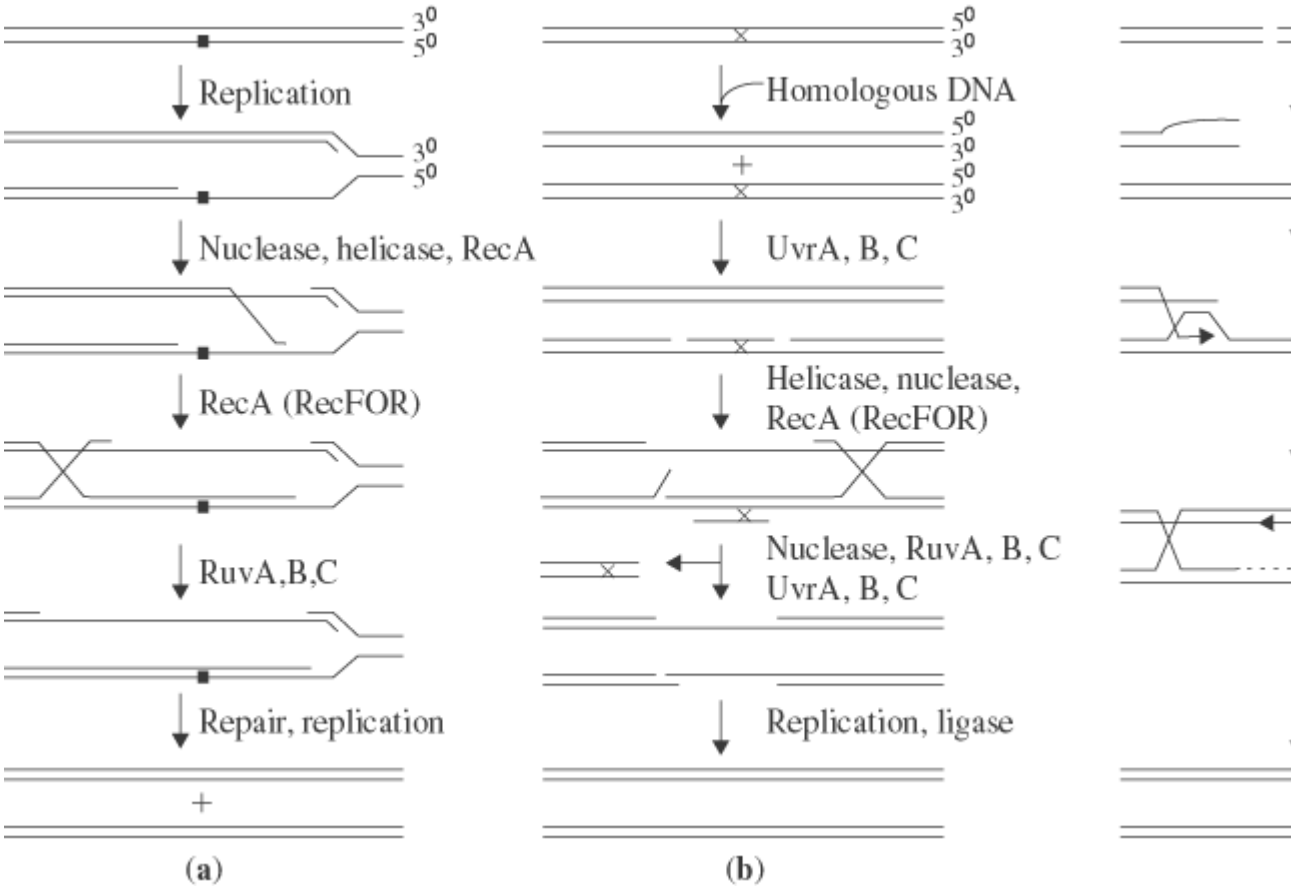
Recombinational Repair

Most DNA repair mechanisms rely on the redundant information inherent to the structure of the DNA double helix to fix the damage: The base that is mismatched, modified, adducted, or fragmented is removed to generate a single-stranded gap, which is then filled in by **DNA polymerase**, using the complementary strand as template, and ligated. Lesions that affect both strands of the duplex cannot be repaired by this general reaction mechanism. Such lesions can be rectified only by retrieving the lost information from a homologous duplex in **diploid** organisms, or from the sister chromatid in haploid organisms such as *Escherichia coli*, which under exponential growth conditions is partially diploid for a major fraction of its chromosome. Three types of lesion affect both strands and are repaired by recombinational repair: post-replication gaps across from a lesion, interstrand cross-links, and double-strand breaks (Fig. 1).

Figure 1. Mechanisms of recombinational repair. (**a**) In post-replication repair a lesion in one strand leads to gap formati gap is invaded by the complementary strand from the sister duplex. Following further processing by nucleases and DNA junction is formed which is resolved by RuvABC resolvase. The remaining lesion in the duplex is then removed by excis link repair, (A)BC excinuclease makes dual incisions in one strand, and the cross-linked oligomer is displaced by the rec generates a Holliday structure and a "dangling" oligomer cross-linked to the duplex. This structure is recognized as a mo excinuclease and is released by dual incisions. The Holliday structure is resolved and the gaps resulting from recombinat in by polymerases and ligated. (**c**) In double-strand break the RecBCD helicase/nuclease unwinds the duplex from both s generates a structure which can be processed by the RecA strand transfer activity. Further action of RecBCD and perhap nucleases generates a double-Holliday structure which is resolved by resolvases.



1. Post-replication Repair

When the *E. coli* replication machinery encounters certain nucleotide adducts, such as pyrimidine dimers, it stops replicating and reinitiates about 1000 base pairs beyond the adduct, generating a single-stranded gap that contains a damaged nucleotide (1). At the same time, a normal duplex is produced from the complementary strand. Thus, replication of a damaged duplex gives rise to one duplex with two normal strands and one partial duplex with a lesion in one strand and a gap in the other. The duplex with the defect is repaired by a process that involves both recombination and excision repair. The **RecA** protein forms a helical filament at the post-replication gap and promotes homologous pairing with the intact sister duplex. This is followed by reciprocal strand exchange, so that the gap is "transferred" from the damaged duplex to the undamaged duplex, concomitant with the formation of a **Holliday intermediate** (2, 3). The latter is resolved by a **resolvase** encoded by the *ruvABC* or *rusA* genes. Filling in the gap by **DNA polymerase**, using the intact strand as template, yields two uninterrupted duplexes, one of which still contains a damaged base which can now be eliminated by a conventional excision repair reaction (4).

At present, there is no evidence that such a single-strand gap across damage is generated by the replication machinery of mammalian cells (5). Hence, post-replication repair has a different meaning in these cells, namely, the elimination of base lesions from DNA following replication of the damaged strand. In mammalian cells, the damaged strand can be converted into a duplex by "translesion synthesis" or by "template switching." In translesion synthesis, the replication machinery simply synthesizes across the damaged base (6, 7), frequently by inserting the wrong base. In template switching, the replication fork stops at the lesion site on the damaged strand, but continues DNA synthesis on the undamaged strand. Then the newly synthesized strand is used as template for the strand of the sister duplex that had been blocked by the lesion (8). Once the synthesis (error-free) past the lesion is accomplished, the nascent strand complementary to the

damaged strand switches back to its parental strand. The end result of translesion replication and template switching is, again, the creation of two duplexes with no discontinuities. The lesion that remains following replication is eventually removed by excision repair. Even if the lesion is not removed by excision repair, however, the post-replication mechanisms outlined above can be repeated through many rounds of replication and consequently aid cell survival by ensuring the inheritance of uninterrupted duplexes to the daughter cells. In contrast to the bacterial system, however, the eukaryotic post-replication repair phenomenon remains ill-defined. For example, because of multiple **origins of replication** in eukaryotes, small post-replication gaps (7) may be generated by utilizing adjacent replication origins, and the resulting gaps may be processed as in prokaryotes.

2. Interstrand Cross-link Repair

Many carcinogenic or chemotherapeutic chemicals, including formaldehyde, nitrous acid, nitrogen and sulfur mustards, mitomycin C, cisplatin, and psoralen plus light, cross-link the two strands of the duplex covalently. Such cross-links prevent separation of the two strands and hence constitute absolute blocks for transcription and replication. Because of this effect on strand separation, cross-links constitute a more challenging lesion to cellular repair machinery than the post-replication gaps. Neither strand of the cross-linked DNA can be replicated to generate an intact duplex and a doubly damaged duplex that could recombine to produce two contiguous duplexes. Instead, the cross-link must be processed by the excision repair machinery. The mechanism of interstrand cross-link repair is relatively well-understood in *E. coli* (9). First, the (A)BC excinuclease incises the ninth phosphodiester bond 5′ of the cross-linked base, as well as the third phosphodiester bond 3′, in one strand only. Second, the resulting “excised” oligomer is displaced by RecA, which may form a filament at the gap and promote strand invasion of the homologous duplex. The recombination reaction generates a gapped duplex from the initially undamaged DNA and a triple-strand intermediate, in which the cross-linked oligomer (12-mer) is flipped out of the duplex. This latter structure is recognized as a form of monoadduct by the (A)BC excinuclease, which cuts out the dangling oligomer and produces a 12-nucleotide gap in one strand. The end-product of dual incision–recombination–dual incision reactions is to generate two duplexes, each with about a 12-nucleotide gap in one strand. These gaps are filled and ligated to complete repair.

The mechanism of interstrand cross-link repair in eukaryotes is not known. In yeast, both excision repair and homologous recombination systems are required to eliminate cross-links *in vivo*, suggesting a mechanism analogous to the prokaryotic excision repair system (10, 11). In mammalian cells, in contrast, mutants defective in the basal subunits of excision nuclease are not extremely sensitive to cross-linking agents, in contrast to mutants defective in homologous recombination, which are 30- to 90-fold more sensitive to mitomycin C than are wild-type cells (12, 13). It is possible that a homologous recombination mechanism, in which strand transfer is initiated from nicks produced by replication origins near the cross-links, leads to eventual elimination of cross-links. It has been found *in vitro*, however, that the excision-repair system acts very efficiently on psoralen cross-links in a very unusual manner. The enzyme system releases a 22- to 28-nucleotide oligomer from one strand on the immediate 5′ side of the cross-linked base, by making dual incisions on the 5′-side of the cross-linked base (14). The resulting gap adjacent to the cross-link may act as a recombinogenic signal, leading to eventual removal of the cross-link by a mechanism rather like that of prokaryotes.

3. Double-Strand Break Repair

The basic mechanism of double-strand break repair in *E. coli* appears to be quite similar to the mechanism of cross-link repair. Again, RecA aided by RecBCD helicase/nuclease promotes strand invasion from the site of the double-strand break, using the homologous duplex as a target. The proposed reaction pathway generates two Holliday junctions, which are resolved by the RuvABC or *rusA* resolvase systems (15, 16). In mammalian cells, the double-strand break repair does not appear

to employ homologous recombination. Instead, the DNA-dependent protein kinase (DNA-PK) complex appears to play a crucial role in restoring the continuity of the broken duplex. The complex consists of a Ku70/Ku80 heterodimer, which has affinity for DNA ends, binds to the site of a double-strand break and recruits the DNA-PK catalytic subunit (DNA-PK_{cs}), a 470-kDa protein with **serine/threonine kinase** activity to the site of the double-strand break.

The details of double-strand break repair in mammalian cells are not known. It is well-established, however, that joining of the coding sequence (CJ formation) during V(D)J recombination of the immune system (see Immunoglobulin Biosynthesis) and joining double-strand breaks caused by ionizing radiation employ the same enzyme system. As a consequence, mutants defective in Ku70, Ku80, or DNA-PK_{cs} are defective in V(D)J recombination and are extremely sensitive to ionizing radiation.

Redox Potential

1. Redox Potential

1.1. Redox reactions and redox couples
The molecule donating an electron is the reductant and becomes oxidized in the reaction, whereas the molecule accepting the electron is the oxidant and becomes reduced. In fact each redox exchange $red_1 + ox_2 \longleftrightarrow ox_1 + red_2$is composed of two reactions:

$$red_1 \longleftrightarrow ox_1 + e^- \quad \text{and} \quad ox_2 + e^- \longleftrightarrow red_2$$

The reductant and its corresponding oxidized form constitute a redox couple, and two redox couples participate in the redox reaction. Each redox couple is characterized by a standard oxido-reduction potential ($\mathbf{E_o}'$), that quantitatively defines its tendency to lose an electron. In a redox reaction, the redox couple having more affinity for the electron will be the oxidant, whereas the couple having more tendency to donate electrons will be the reductant. The same redox couple may thus be reductant or oxidant depending on the redox potential of the other couple in the reaction. This is the way the electron transfer chains like the mitochondrial or the anaerobic bacterial chain and the photosynthesis in chloroplasts work: the reductant of the *(i)* step is the oxidant of the step *(i-1)*.

1.2. Electrode potential
The redox potential can be measured electrochemically as the electromotive force generated by connecting a half-cell of the redox sample with a reference half-cell. The reference half-cell consists of a Platinum electrode (immersed in a 1 M H^+ solution and saturated with H_2 gas at 1 atm); the sample half-cell consists of an electrode immersed in a solution of the redox couple under standard conditions (1 M of the electron donor and acceptor, 25°C and pH 7). The electrodes are connected to a voltmeter. A salt bridge (KCl solution) assures the electrical continuity between the half-cells. The electrons flow in the direction determined by the redox potential of the sample relatively to the reference, which is the Voltage observed when the experiment starts (standard concentration of 1 M) since the redox potential of the Hydrogen electrode is arbitrarily set at 0 Volt. The redox potentials ($\mathbf{E_o}'$) of relevant redox couples are thus expressed relatively to the $H_2/2H^+$ couple.

For a redox reaction $(ox + e^- \longrightarrow red)$, the Nerst equation relays the concentration of the redox species with the redox potential:

$$E = E^\circ + RT/nF \ \ln \ [ox]/[red]$$

where **E** is the redox potential, $\mathbf{E^o}$ is the redox potential for components in their standard state at pH 0, **R** is the gas constant (8.3144 J K^{-1} mol), **F** is the faraday (9.65 × 104 J V^{-1} mol), **n** is the number of electrons transferred, **T** is the absolute temperature. In biology, the equation is generally written as

$$E_h = E_{m,x} + 0.06/n \ \log \ [ox]/[red]$$

where $\mathbf{E_h}$ is the redox potential referred to the standard hydrogen electrode, $\mathbf{E_{m,\,x}}$ is the mid-point redox potential (when [ox] = [red] ≠ standard state) at a defined pH (of x) and 2.303 RT/F = 0.06 for 29.4°C. The value of $\mathbf{E_m}$ for a defined redox couple depends on the relative stability of the oxidized

and reduced state: a more negative the $\mathbf{E_m}$ results from a more stable oxidized form and the couple is a stronger electron donor. Conversely, any factor stabilising the reduced form makes the couple a better electron acceptor having a more positive redox potential.

1.3. Redox potential, free energy and equilibrium constant

The free energy change associated to a redox reaction $(\mathrm{red_1} + \mathrm{ox_2} \longleftrightarrow \mathrm{ox_1} + \mathrm{red_2})$ is related to the difference in redox potential of the reactants by the formula

$$\Delta G^{o\prime} = -nF\Delta E^{o\prime}$$

in which **n** is the number of electrons transferred, **F** is the energy change as one mole of electrons falls through a potential of one volt (23.06 kcal $V^{-1}mol^{-1}$), D$\mathbf{E^{0\prime}}$ is the difference of redox potential of the reactants in volts, D$\mathbf{G^{0\prime}}$ is the free energy change per mole and is expressed in kilocalories. Since we know that at constant temperature and pressure a reversible reaction goes on till an equilibrium position defined by a concentration of reactants related by

$$[\mathrm{ox_1}]/[\mathrm{red_1}] \times [\mathrm{red_2}]/[\mathrm{ox_2}] = \mathrm{Keq}$$

in which **Keq** is the equilibrium constant of the reaction at a certain constant temperature (K), and that **Keq** is related to the D$\mathbf{G^{0\prime}}$ free energy change by

$$\Delta G^{o\prime} = -RT \ln \mathrm{Keq}$$

where **R** is the gas constant (1.987 cal mol^{-1} K^{-1}) and **T** is the absolute temperature (K).

We can also say that

$$-nF\Delta E^{o\prime} = -RT \ln \mathrm{Keq} \quad \text{or} \quad \Delta E^{o\prime} = RT/nF \times \ln \mathrm{Keq}$$

The last relation allows calculating the equilibrum concentrations of redox couples by knowing their redox potentials, or conversely the redox potential of a solution when the relative concentrations of the redox couples are known.

1.4. How to measure the redox potential

The oxidation of a reductant ($\mathbf{red_1}$) by an oxidant ($\mathbf{ox_2}$), at fixed temperature and pH, can be followed potentiometrically by measuring the variation of the electromotive force of a solution of the reductant along its titration with the oxidant. In practice with a Pt electrode connected with a reference one (i.e. calomel electrode), the redox potential of the $\mathbf{red_1}$ solution is recorded after each addition of $\mathbf{ox_2}$. The redox potential increases as the **log** $[\mathbf{ox_1}]/[\mathbf{red_1}]$ increases and is equal to $\mathbf{E_m}$ when the concentration $\mathbf{[ox_1] = [red_1] = 50\%}$. When $\mathbf{[ox_1]}$ is close to 100% the redox potential varies rapidly and the titration comes to the end: the point of equivalence has been reached, i.e. one equivalent of $\mathbf{ox_2}$ has been added to $\mathbf{red_1}$. In biological systems, the redox proteins generally carry coloured groups having a definite absorption in the visible range of wavelengths, which allows a precise determination of the relative concentration of the oxidised and reduced species.

2. Redox Enzymes

Cell life depends on the availability of energy readily usable and storable for the many different specialised functions. This energy is extracted from nutrients by submitting them to a series of

chemical transformations associated to a negative variation of free energy. This transformation can be coupled to another chemical reaction with a positive variation of free energy, but smaller than the previous one. This second reaction is used to store energy. It consists generally of the formation of energy-rich bond between ADP and phosphate (Pi), leading to an ATP molecule. The covalent bond energy is available upon need through dissociation in ADP + Pi. Many of the physiological reactions in a cell, fundamental both in the metabolic pathways of degradation and in the storage of energy *via* production of ATP, involve the electron transfer from one molecule, the donor (or reducing agent), to another, the acceptor (or oxidant), and are thus called redox reactions. Many molecules can act as oxidising and reducing agents in non-biological redox reactions, whereas in the metabolic pathway of living organisms few molecules have been kept by the evolution as redox agents for many different substrates.

2.1. Where and how the electron transfers take place

In prokaryotes, the enzymatic systems metabolising nutrients associated to the complex synthesising ATP are localised in the cytoplasmic membrane. In eukaryotes, the respiratory chain and the oxidative phosphorylation are compartmented in mitochondria. In aerobic organisms, the biological energy comes from oxidation of substrates like glucose to the final state of CO_2 and H_2O and terminal electron acceptor is O_2. In order to allow the liberation of discrete amount of free energy and its optimal conversion to ATP or reducing effectors, like NADH or $FADH_2$, the oxidation of glucose take place by steps. Three main metabolic pathways are involved in the whole process, i.e. glycolysis, tricarboxylic acid cycle and respiratory chain. Under anaerobic conditions, glucose is converted to pyruvate and NADH by glycolysis, and electron acceptors other than $O_2$are used for the oxidation of NADH. Depending on the environmental conditions, some bacteria have developed respiratory chains making use of inorganic substrate like nitrate or sulphate instead of pyruvate; moreover, the final acceptor may be nitrate, Mn^{4+} ions, Fe^{3+} ions, sulphate or CO_2 instead of oxygen.

In the simpler case of Fe in the heme group or in Iron-Sulfur clusters and Cu in copper proteins, one electron is taken in going from the oxidised to reduced state. Conversely, the redox proteins carrying pyridine nucleotides, flavins or quinones as prosthetic groups take two electrons for total reduction. The two electrons can be transferred in a single step or in two successive steps. In the former case, the hydride (H^-) transfer implies the formation of a substrate carbonium ion (C^+), or alternatively the proton (H^+) abstraction mechanism involves a substrate carbanion transition state (C^-) followed by the transfer of 2 electrons. In the case of 2 successive electron transfers, flavins and quinones may also take one electron only and get to a stable semireduced state (semiquinone radical). Moreover, the gain of one or more electrons may be associated with the ionisation of a group in the protein and result in gaining one or more proton. In this last case protons take part in the reaction and the concentration of H^+ in the solution may influence the redox equilibrium.

Looking at the redox potential of the biological cofactors in the Table I and II, it appears evident that the couple NAD^+/NADH is the one having the more negative potential and is thus the one with stronger tendency to transfer electrons and to become oxidised by other cofactors. A thermodynamically favoured sequence would be composed by NADH (–320 mV), flavin (–200 mV), ubiquinone (+100 mV), cyt c (+300 mV), cyt a_3 (+550 mV) and O_2(+820 mV), which is the actual electron transfer pathway found in animal, plant and prokaryotic cells. Copper proteins having a potential in the range 200 to 500 mV, are sometimes present just before oxygen.

Table I. Oxidoreduction potentials of some biologically relevant compounds and free redox groups

Redox Couple	$E_{m,7}$ (mV)
$NAD(P)^+ + H^+ + 2e^- \longrightarrow NAD(P)H$	–320
$S + 2H^+ + 2e^- \longrightarrow H_2S$	–230
$Riboflavin + 2H^+ + 2e^- \longrightarrow Riboflavin\text{-}H_2$	–200
$FMN + 2H^+ + 2e^- \longrightarrow FMNH_2$	–219
$Pyruvate + 2H^+ + 2e^- \longrightarrow lactate$	–190
$Protoheme\ IX\ (Fe^{3+}) + e^- \longrightarrow (Fe^{2+})$	–115
$2H^+ + 2e^- \longrightarrow H_2$ *taken as reference	0.0 *
$Dehydroascorbate\ 2H^+ + 2e^- \longrightarrow Ascorbate$	+60
$Ubiquinone + 2H^+ + 2e^- \longrightarrow Ubiquinone\text{-}H_2$	+100
$MetBleu + 2H^+ + 2e^- \longrightarrow MetBleu$	+110
$Cu^{2+} + 2e^- \longrightarrow Cu^+$	+150
$K_3Fe^{3+}(CN)_6 + e^- \longrightarrow K_3Fe^{2+}(CN)_6$	+360
$NO_3^- + 2H^+ + 2e^- \longrightarrow NO_2^- + H_2O$	+480
$SO_4^{2-} + 2H^+ + 2e^- \longrightarrow SO_3^{2-} + H_2O$	+480
$Fe^{3+} + e^- \longrightarrow Fe^{2+}$	+770
$1/2\ O_2 + 2H^+ \longrightarrow H_2O$	+820

Table II. Oxidation-Reduction Potentials of Some Types of Redox Proteins

Redox Couple	$E_{m,7}$ (mV)	
Fe in [Fe-S] cluster	–570	–300
Flavodoxins	–500	–400
Flavoproteines ox / red	–400	+150
Cytochrome b Fe^{3+}/Fe^{2+}	+80	0
$PQQ + 2H^+ + 2e^- \longrightarrow PQQH_2$	+90	
$TTQ + 2H^+ + 2e^- \longrightarrow TTQH_2$	+100	
Ubiquinone ox / red	+100	
Cyt a $Fe^{3+} + e^- \longrightarrow$ Cyt a Fe^{2+}	+290	
Type I Copper proteins	+350	+240
Cytochromes c Fe^{3+}/Fe^{2+}	+400	+100
Ferredoxines ox / red	+420	
Cyt a_3 $Fe^{3+} + e^- \longrightarrow$ Cyt a_3 Fe^{2+}	+550	
Copper proteins $Cu^{2+} + 2e^- \longrightarrow Cu^+$	+600	+300

2.2. Role of the apoprotein

The apoprotein is involved in at least four important issues: it stabilises the prosthetic group, it modulates the redox potential by binding the redox centre, it insures that the sequence of electron transfer is well followed, and that only specific partners of a given pathway will interact in an

ordered sequence.

The specific role of the apoprotein in the modulation of the redox potential has been the subject of extensive studies and is still matter of debates. In the field of hemoproteins, several properties of the protein have been proposed to influence the redox potential, like the polarity of the environment, the accessibility of the redox group to the solvent, the strength of the axial ligands or the charges on propionates. The role of electrostatic energy in this context has come out strongly in the recent years from the realisation that the determination of the redox properties cannot be done by considering a protein as a non-polar sphere, and that permanent dipoles must be taken into account (1). Another factor playing a role is the presence of charged and ionisable groups. A classical electrostatic analysis can reproduce the midpoints potentials of 4 hemes in *Rhodopseudomonas viridis* photosynthetic reaction centre (2). Moreover, a simple electrostatic hypothesis involving the positive charges on ferric hemes has been proposed recently (3). It allows in particular to explain both the difference in redox potential and the negative cooperativity in heme-heme redox interaction found in the artificially synthesised multi-heme 62 residues di-a-helical peptides.

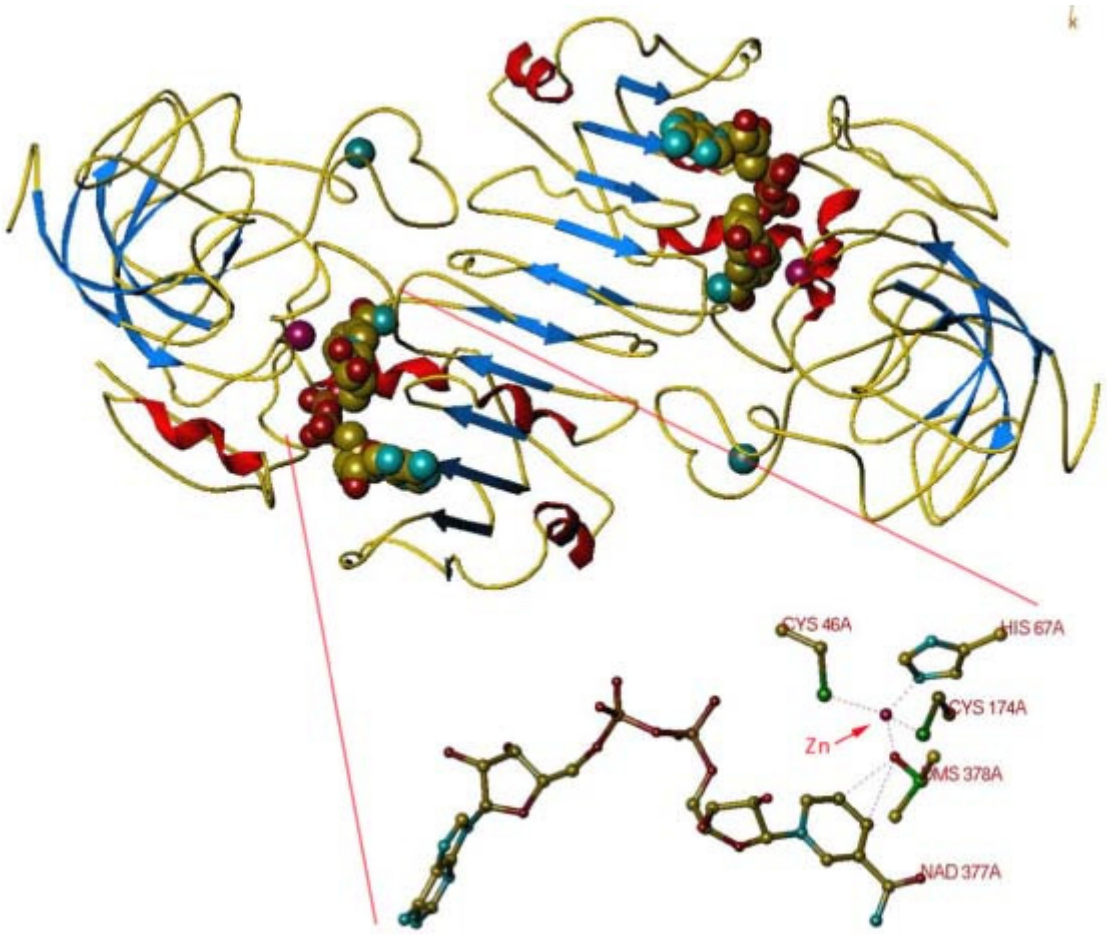
2.3. Groups transferring electrons

2.3.1. Nicotinamide Coenzyme (4, 5)

The redox active centre of NAD (Figure 1) and the functionally equivalent NADP is the nicotinamide ring. These are the coenzymes of most dehydrogenases, which are generally believed to react by hydride transfer. Two electrons reduction and addition of one hydrogen produce a dihydropyridine cycle. Depending on the chemical reaction carried out, different classes of dehydrogenases have been defined (Glyceraldehyde-3-phosphate, Malate, Alcohol (Figure 1) [entry "ADH"], Glutamate, Isocitrate, Lactate [entry ""] Aldehyde dehydrogenase, Steroid reductase, Dihydrofolate reductase). In all of them the coenzyme participate to the reaction as a substrate: the reduced coenzyme dissociate from the apoprotein at the end of each catalytic cycle, thus the apoprotein does not significantly influence the redox potential of the coenzyme. In contrast to the flavin group, a fundamental character of this coenzyme is the stability of the reduced dihydropiridine towards the spontaneous oxidation in air. In spite of their different aminoacid sequence, the coenzyme binding site of all the NAD-dehydrogenases is very similar: a super-secondary structure composed of a parallel six-stranded b sheet flanked by a helices on both side of the sheet (Rossman′ fold). (4, 5)

Figure 1. The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".

Three dimensional structure representation of horse liver alcohol dehydrogenase dimer (PDB entry 6ADH). The NAD captures the reducing hydride from the Zn bound alcoholate, which, after loosing a proton becomes an aldehyde. The catalytic Zn is depicted as a magenta sphere, the structural Zn as a green sphere. Zn ligands are indicated in the close-up view.



2.3.2. Flavin Coenzyme (5)

As in the case of nicotinamide coenzymes, FMN (Figure 2) and FAD are functionally equivalent. The electron-active part of the coenzyme is the highly conjugated isoalloxazine ring. The $2e^-$ reduction results in the formation of 1,5-dihydroflavin, whereas the $1\text{-}e^-$ reduction gives rise to a radical species, flavin semiquinone, which has different charge depending on the enzyme system. Unlike nicotinamide coenzyme, flavin does not freely dissociate from the apoprotein and has to be re-oxidised at the end of each catalytic cycle. The reoxidation of 1,5-dihydroflavin by O_2 in solution is a relatively fast process ($t_{1/2} < 1$ second). The strong binding of flavin prosthetic group make it possible to modulate the redox potential of the flavin by differently binding the 3 redox species of flavin to the apoprotein. The selective stabilisation of the oxidised form makes the redox potential of the coenzyme more negative than that in aqueous solution (–208 mV); by stabilisation of the semiquinone the 1-electron potentials become more separated and the enzyme works essentially as a 1-electron transferring protein. The redox potential of flavoenzymes ranges between – 465 and +149 mV; electron donors and acceptors compatible with these values determine the localisation of the flavoenzyme at specific places in electron transfer chains. Flavoenzymes work as oxidases [entry "Oxidoreductase"] (D-amino acid oxidase, AMP-sulphate reductase, Monoamine oxidase, Glycolate oxidase (Figure 2), Lactate oxidase, Hydroxyacid oxidase) or dehydrogenases (D-lactate dehydrogenase, Succinate dehydrogenase, p-OH-benzoate hydrogenase, Flavocytochrome b_2) depending whether O_2 is a good electron acceptor or other electron transfer proteins like quinone, cytochromes or iron-sulfur cluster are the acceptor; moreover, different types are know among oxidases (Oxidases, Oxidases-decarboxylases, Monooxygenases, Dioxygenases), which differ for the type of product(s) (H_2O, H_2O_2 etc.). Metalloflavoenzymes contain transition-metal ions like Fe or Mo and can work as oxidases or dehydrogenases. Flavodoxins are a class apart having a particularly

negative redox potential (– 400 to – 500 mV), functioning as $1e^-$-transfer proteins and having the dimethyl-benzenoid cycle of the isoalloxazine exposed to solvent. Most of the dehydrogenases transfer to $1e^-$-acceptor, which implies that the $1e^-$-reduced flavinsemiquinone should be a stable radical, at least under specific conditions. Actually, the peculiar role of flavoenzymes in biological oxidation is to be the relay between $2e^-$ and $1e^-$electron transfer. (5)

Figure 2. Three dimensional structure representation of spinach glycolate oxidase (PDB entry 1GOX). The folding motif is a $ß_8a_8$ barrel, analogous to that of triose phosphate isomerase ("TIM barrel"). The FMN co-factor is located at the C-terminus extremity of the internal ß-strands of the barrel. The nitrogen N5 is the electron acceptor.

The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".

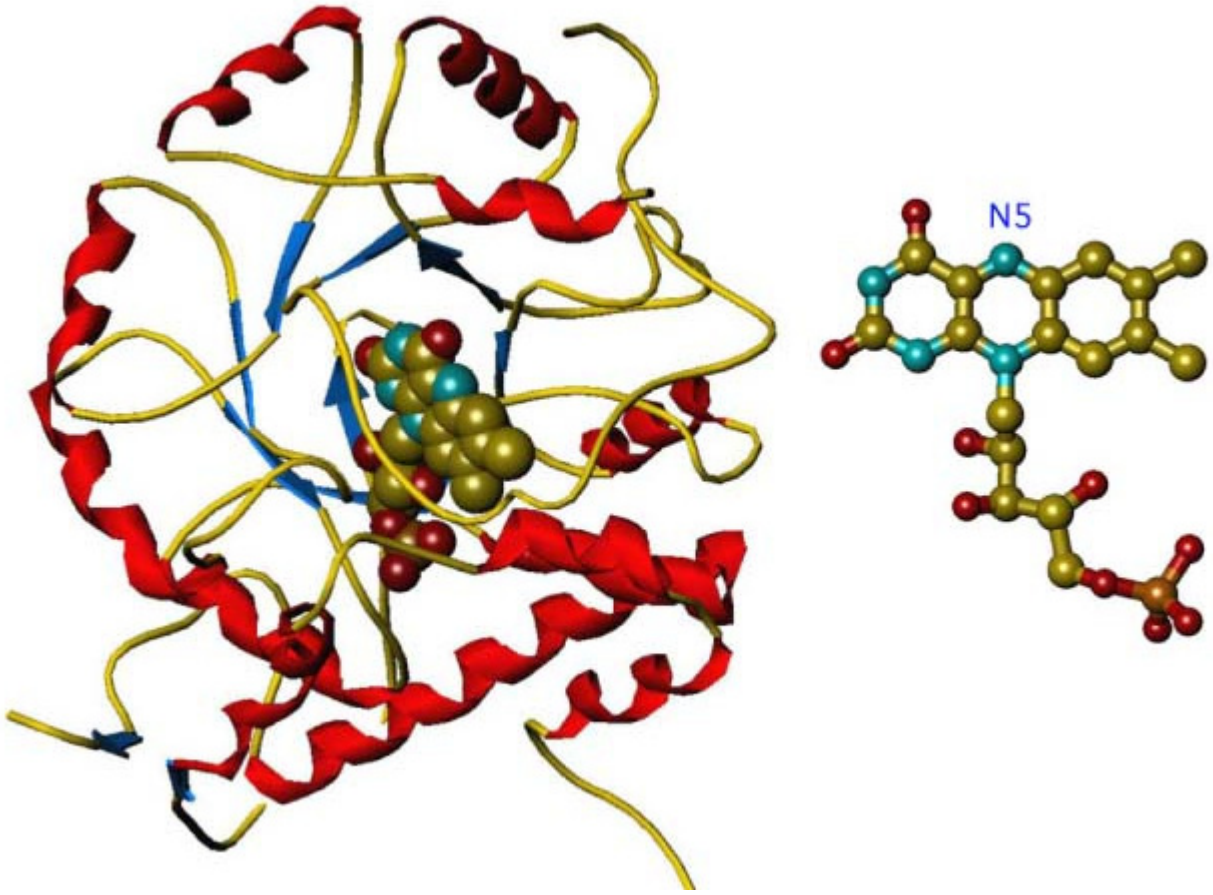


Figure 3. Three dimensional structure representation of the periplasmic DMSO reductase from *Rhodobacter capsulatus* (PDB entry 1DMS). The enzyme catalyzes the reduction of highly oxidized substrates like dimethyl sulfoxide to dimethyl sulfide. At the molybdenum redox center, two single electrons are transferred to the substrate dimethyl sulfoxide, generating dimethyl sulfide and water. The bis(molybdopterin guanine dinucleotide, MGD) has the molybdenum ion bound to the cis-dithiolene group of only one MGD molecule. Three additional ligands are bound to the Mo (see close-up view).

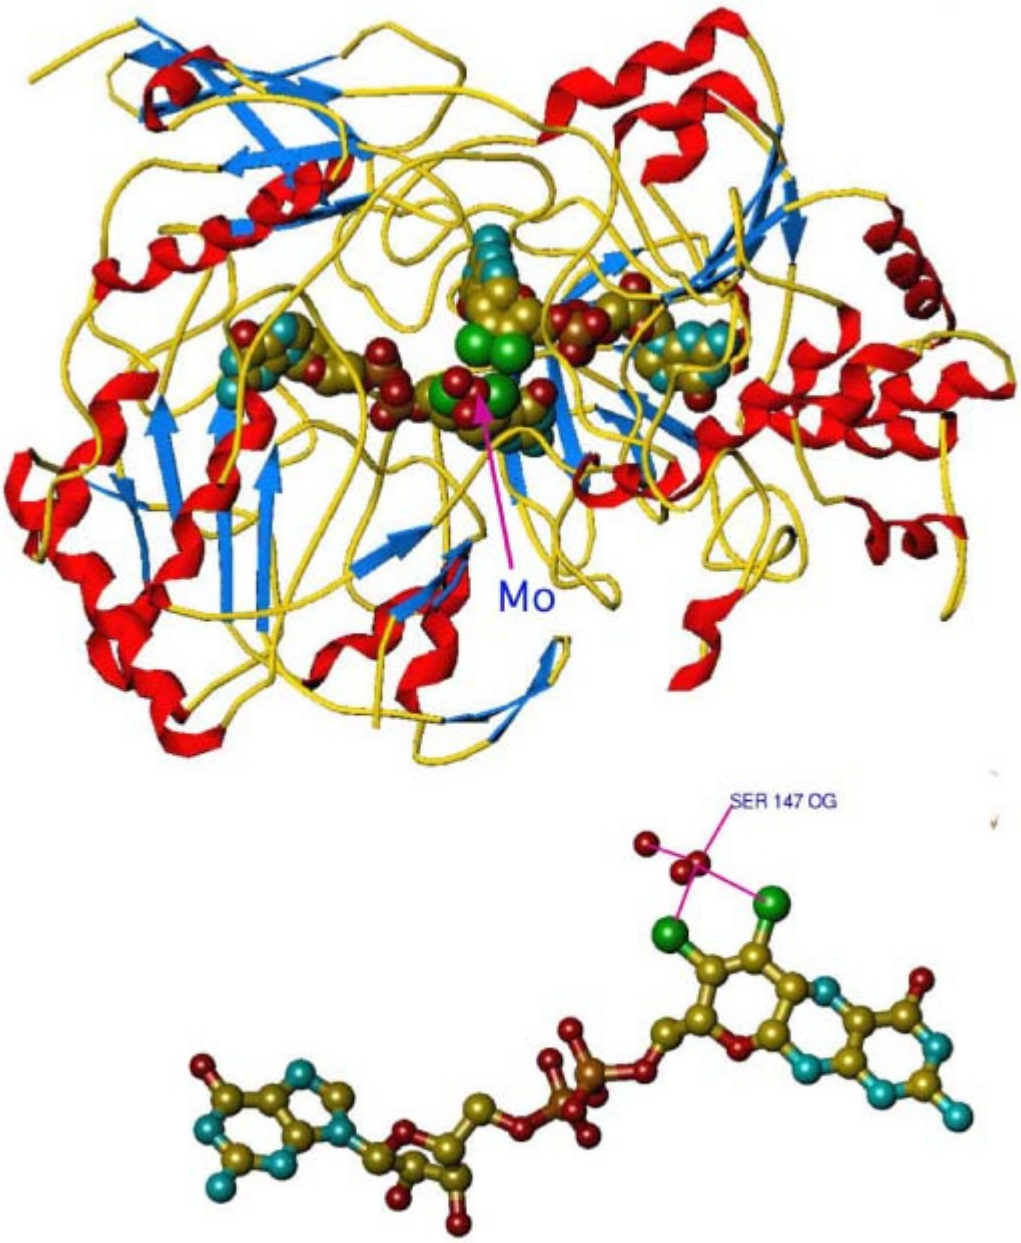
The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".

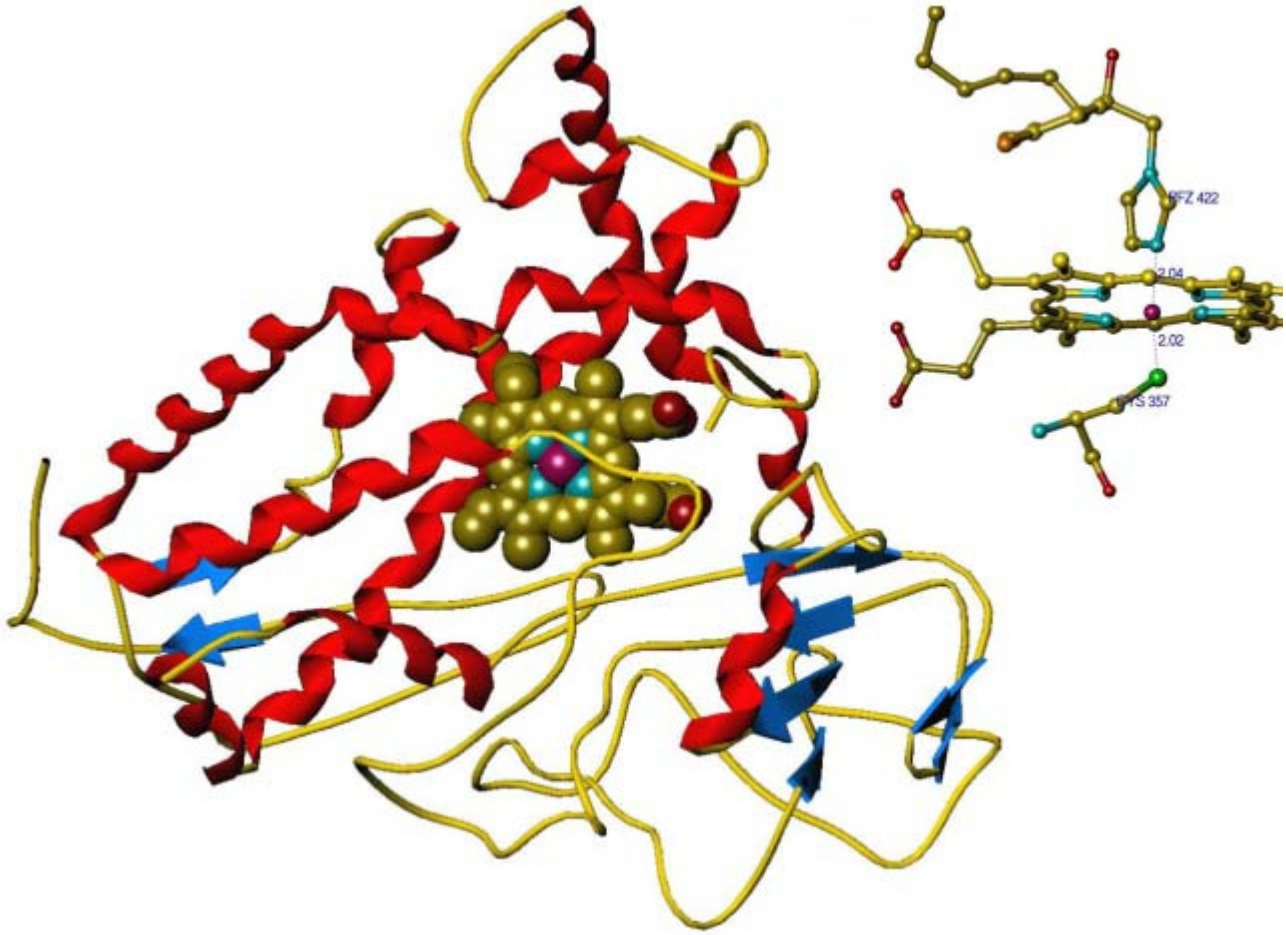


2.3.3. Metalloproteins (6)
[entries “Metalloproteins” “Metal Requiring Enzymes” “Iron Binding Proteins”]. Metals like molibdenum or tungsten are found associated to other redox centre in redox enzymes involved in the metabolism of nitrogen, sulfur and carbon. Generally the metal incorporates into the protein as Mo-cofactor (Mo-co) containing a Mo or W atom coordinated to a pterin cofactor, the structure of which has been determined (Figure 3). Two classes of these enzymes are known catalysing the transfer of an oxygen atom (DMSO reductase from *Rhodobacter* (Figure 3) and *E. coli*, mitochondrial Sulphite oxidase) or the hydroxylation of aldehydes or aromatic compounds (Xanthine oxidase and *Desulfovibrio gigas* Aldehyde oxidoreductases which also contain a flavin coenzyme, and *Pyrococcus furiosus* Aldehyde ferredoxin reductase). These reactions are associated with the Mo atom cycling between the oxidised state Mo(VI) to the reduced state Mo(IV). In DMSO reductase, the substrate takes $2e^-$ from the Mo-co(IV) producing Mo(VI). In sulphite reductase, the $2e^-$ reduction

of Mo-co from (VI) to (IV), is followed by a 1e⁻oxidation by a 1e⁻electron acceptor, which generate an intermediate Mo(V) state. It often occurs that the acceptor redox centre is contained in the same enzyme molecule as the Mo-co. (6)

Figure 4. Three dimensional structure representation of the P_{450} cytochrome from *Pseudomonas putida* (PDB entry 1PHB). The *b* heme iron has a cysteine and the imidazolyl inhibitor as axial ligandsÒ. The C5 of camphor, a substrate, is oxidized in the acoholic product.

The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".



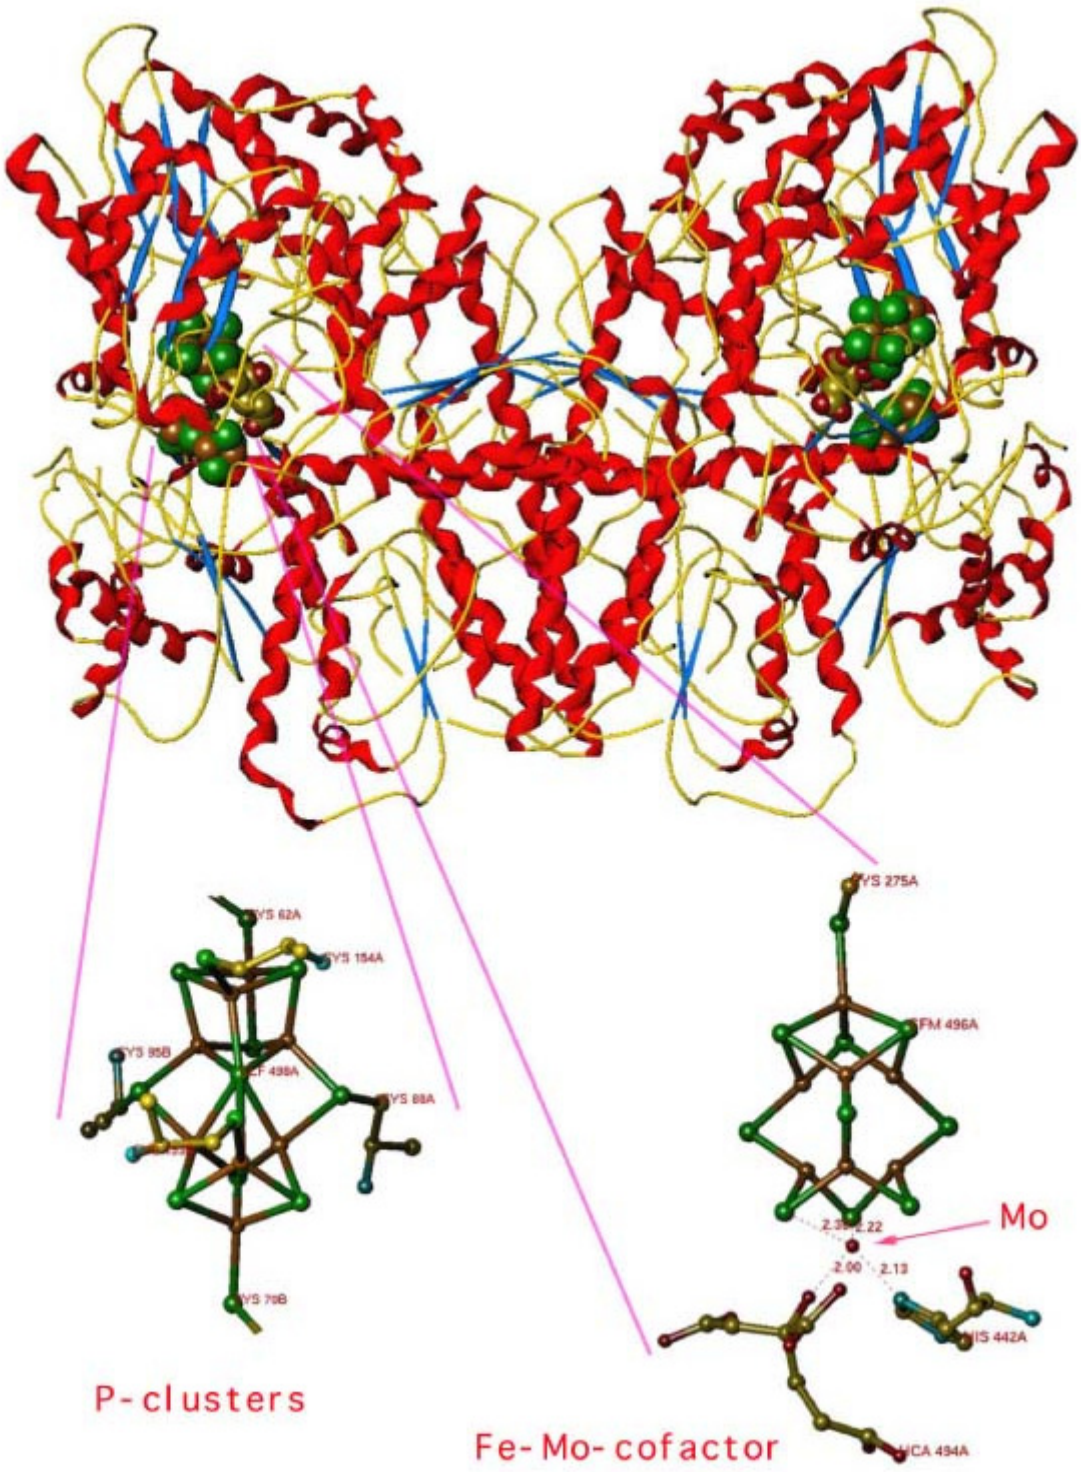
2.3.4. Hemoproteins (5)

[entries "Iron Binding Proteins" "Hemoglobin" "Cytochromes" "O_2 Binding Proteins". The prosthetic group generally bound to hemoproteins is protoporphyrin IX (Figure 4), in which the nitrogen atoms of the 4 pyrroles rings are the 4 equatorial ligands of the iron; other ligands from the apoprotein or not fill the 2 axial positions. The tetrapyrrole macrocycle has different peripheral side chains in cytochrome *b*, *a* and *d*; the *c* heme has the same peripheral side chains as the *b* heme but is covalently bound to the apoprotein by cysteine residues. The different environment in the apoprotein is strongly modulating the reduction potential of the 4 types of hemoproteins. Hemoproteins have different biological roles: binding and transport of O_2(Hemoglobin, Myoglobin), electron transfer (Cytochromes), reduction of peroxides (Peroxidases, Catalases) and terminal component in

hydroxylation or desaturation (P_{450} (Figure 4) [entry "Cytochrome P450"], Cytochrome b_5). (5).

Figure 5. Three dimensional structure representation of the nitrogenase from *Azotobacter vinelandii* (PDB entry 3MIN). Nitrogenases perform the ATP-dependent reduction of N_2 to ammonia. Mo-Fe nitrogenase contains very unusual Fe clusters. The P-cluster contain two 4Fe-4 S clusters bridged by two cysteine thiol ligands and liganded by 6 cysteines SH groups. Among the six, two cysteines bridge the two clusters (bottom,left). The catalytic Fe-Mo cofactor (bottom right) has 4Fe-3 S and 1Mo-3Fe-3 S clusters bridged by 3 non protein ligands (not shown in the figure). The Mo is ligandedby 3 sulfurs, an imidazole from His 442 and 2 oxygens of homocitrate (bottom right). The two clusters may be coupled in the sequence of N_2 to ammonia reduction.

The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".

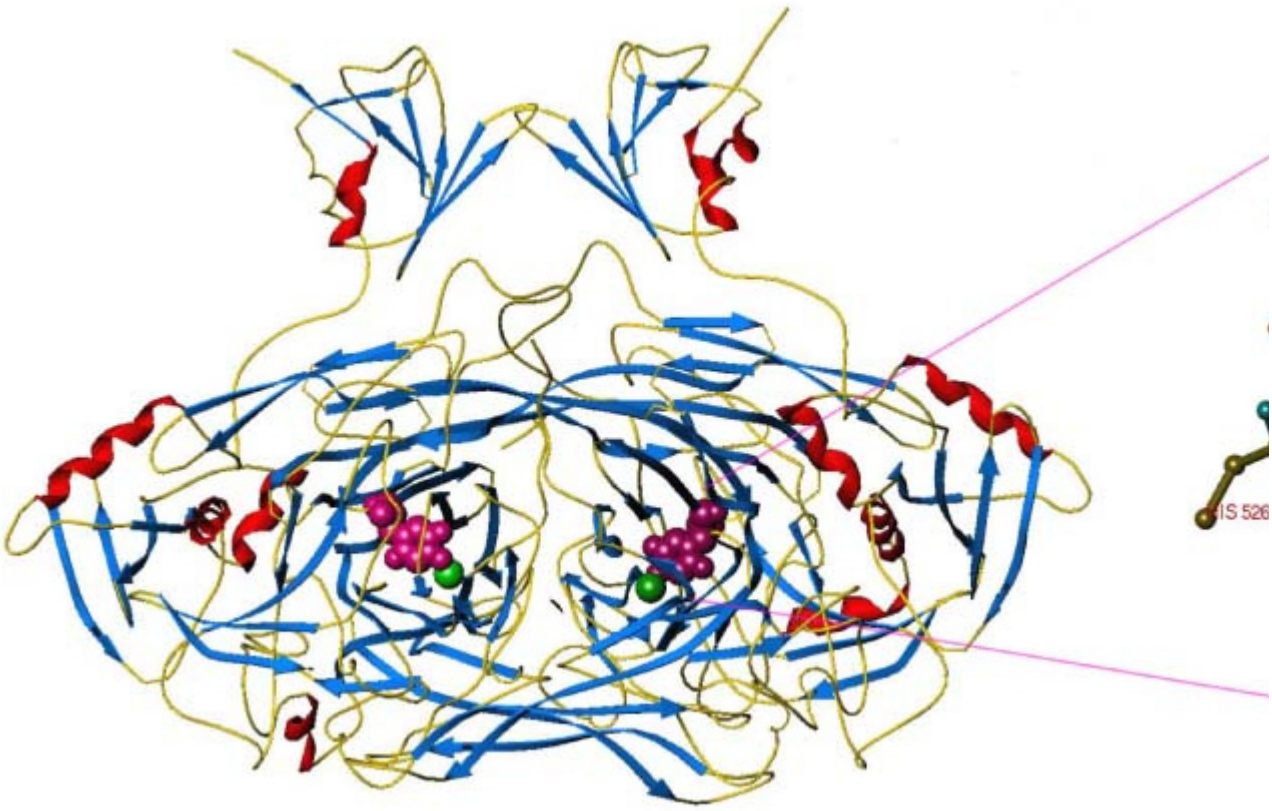


2.3.5. Iron-Sulfur cluster proteins (7)
[entries “Iron Sulfur Proteins” “Ferredoxin”]. Different classes of iron-sulfur containing proteins are defined on the basis of their iron content. The structure around the iron atom is believed to influence the redox potential (+770 mV of free Fe^{3+}/Fe^{2+}). For example, Rubredoxin of anaerobic bacteria have 1 iron liganded by 4 sulfur atoms of cysteines, with a distorted tetrahedron geometry and its redox potential range between + 20 and – 60 mV. Ferredoxins contain 2 iron atoms and 2 inorganic sulfur atoms, 4 cysteine sulfurs are the other ligands of the irons and have a negative redox potential –240 to –460 mV. Bacterial ferredoxins have [4Fe4 S] clusters with a distorted cubic array, 4 cysteine sulfurs are the other ligands of the irons in each cluster. Their redox potential is between 0

and 645 mV. Rubredoxins and ferredoxins act only as electron transfer proteins, however, many redox enzymes contains iron-sulfur clusters in addition to other redox centres: among them we mention monoxygenases and dioxygenases (Methane, 4-methoxybenzoate monoxygenase, Benzene, Toluene, Naphtalene, Phtalate, Benzoate dioxygenase), Molybdopterin enzymes (Xanthine, Aldehyde oxidase, Purine hydroxylase, Carbon monoxide oxidoreductase), Siroheme enzymes (Sulphite, NADH-Nitrite reductase), Fe and Ni-hydrogenase, mixed-metal containing Nitrogenase (Figure 5), Iron-Sulfur non-redox enzymes like Aconitase, Fumarase and Dihydrohydroxyacid dehydratases. (7)

Figure 6. Three dimensional structure representation of the copper amine oxidase from *E.coli* (PDB entry 1OAC). Copper amine oxidases are quinonenzymes that catalyze the oxidative deamination of primary amines to aldehydes, with reduction of O_2 to H_2O_2. The dimer contains two single copper ions and a covalently bound cofactor, TPQ (see text; figure left: TPQ magenta, copper green). The coordination of the copper ion consist of the TPQ cofactor and three histidines (close-up view: copper magenta).

The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".



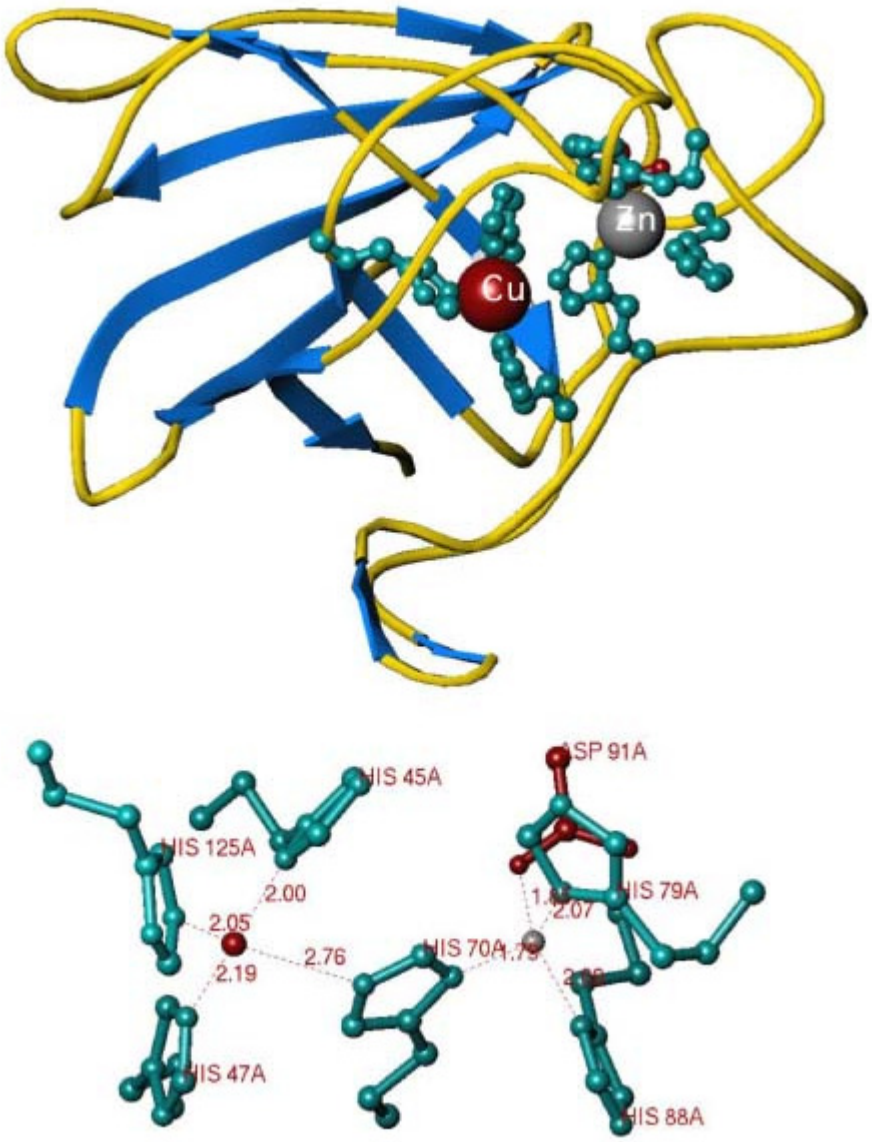
2.3.6. Quinones (8, 9)

It is now established that post-translational modifications of aromatic aminoacid side chains produce redox cofactors of quinoproteins. Tyrosine appears to be more frequently involved in this mechanism (Figure 6). The redox behaviour of quino-dehydrogenases is very similar to that of dehydrogenases using flavins or nicotinamide coenzyme, and based on the 3 redox forms experimentally found, hydride transfer as well as consecutive $1e^-$ transfer steps seem possible. The group most frequently found in the quinoproteins known to date, is PQQ (2,7,9-tricarboxy-1H-pyrrolo[2,3-f]quinoline-4,5-

dione or methoxatin), that contains a pyrrole ring fused to a quinoline ring with an o-quinone in it. Due to the high redox potential of the PQQ/$PQQH_2$ couple (+ 90 mV), this group is able to oxidise most reduced flavin and nicotinamide coenzymes. Methanol DH, Galactose oxidase, Dopamine-b-hydroxylase and lipoxygenase have PQQ as redox cofactor. Another group of quinonproteins contains TPQ (2,4,5-trihydroxy-phenylalanine-quinone) or TTQ (4-(2′-tryptophyl)-tryptophan-6,7-dione). Copper-containing amine oxidase carries a TPQ cofactor (Methylamine oxidase, Phenylethylamine oxidase, Diamine oxidase, and Amine oxidase). In copper amine oxidase (Figure 6), the copper atom was proposed to play a key role in the tyrosine to TPQ conversion reaction (9). Methylamine DH from *Thiobacillus versutus* and *Paracoccus denitrificans* contains TTQ as redox cofactor. The redox potential of the couple TTQ/$TTQH_2$ is high (+100 mV). (8, 9)

Figure 7. Three dimensional structure representation of the super oxide dismutase from *Photobacterium leiognathi* (PDB entry 1YAI). The eukaryotic super oxide dismutases are Cu, Zn enzymes catalyzing the dismutation of O_2^-

The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".



2.3.7. Copper containing enzymes (10-13)

Copper-containing redox proteins are characterised by very different coordination geometry of the copper atom. We can distinguish type I and type II copper proteins by their extinction coefficient at 600 nm, which is very intense for type I (0.7 to 10 mM^{-1} cm^{-1}), and type III by its strong absorbance at 330 nm. Type I proteins are generally involved in electron transfer reactions and the redox change of the copper is associated to the bleaching of the blue absorption (Azurin, Plastocyanin, Pseudoazurin, Cucumber basic blue protein, Amicyanin). Two histidines, one cysteine and one methionine are coordinating the copper atom in a distorted tetrahedral arrangement. Their redox potential ranges between +240 mV and +350 mV. Type II proteins are involved in chemical reactivity and catalysis is not accompanied by redox or absorption change of the copper. The latter proteins reduce O_2 either to H_2O (Super oxide dismutase, dopamine b hydroxylase) or to H_2O_2 (Amine oxidase, Galactose oxidase). Super oxide dismutase (Figure 7) carries out the dismutation of two super oxide anions O_2^- in O_2 and H_2O_2. Hemocyanine and Tyrosinase similarly coordinate copper of type III, with trigonal bipyramidal geometry. Multiple types of copper can also be present on the same protein (Ascorbate oxidase (type I, II, III), Ceruloplasmin (type I, II), Laccase, Cytochrome oxidase, Nitrite reductase (type I and II), Nitrous oxide reductase) (10). Nitrous Oxide Reductase (Figure 8), recently solved, contains in addition to a CuA binuclear centre, similar to that of cytochrome oxidase (11), a catalytic centre CuZ of a totally novel type: four copper atoms, hold in place by seven histidines, are arranged in a distorted tetrahedron; an inorganic Sulfur atom, at the centre of the tetrahedron bridges the four copper atoms (12, 13).

Figure 8. Three dimensional structure representation of the nitrous oxide reductase from *P.nautica* (PDB entry 1QNI). Nitrous oxide reductase catalyses the last step of dissimilatory denitrification in anaerobic bacteria, namely the reduction of N_2O to N_2. The enzyme is a dimer of two identical subunit, each containing a CuA centre with 2 copper atoms, at which electrons enter into the system, and a catalytic CuZ centre, composed of four copper atoms (close-up view: CuZ with the seven coordinating histidines; copper mauve, sulfur green, oxygen red). One monomer is represented in grey. Secondary structure elements of the second monomer are dark and light green in the propeller domain, carrying the CuZ, red and blue in the cupredoxin domain, carrying the CuA centre, and purple in the linker region. In the dimer, the functional unit is formed by the CuA centre of one monomer and the CuZ of the other monomer.

The 3-dimensional structures are depicted using the following convention: ß-strands are arrows, alpha-helices are spirals and turn or coil segments are ribbon. In the 3 dimensional structures, except otherwise mentioned, coenzymes or prosthetic groups are depicted as CPK models, with the color convention for atoms: oxygen red, carbon yellow, nitrogen blue, sulfur green, and phosphate orange. In the close-up figures, except otherwise mentioned, coenzymes or prosthetic groups are depicted in the "balls-and-sticks" representation, with the same color coding as above. The PDB site were the structures are available is "http://www.pdb.bnl.gov/".

Relaxation Spectrometry, Relaxation Time

Kinetic analysis often requires measuring very rapid reactions (see Kinetics), for which relaxation spectrometry is very useful. The temperature or pressure of a reaction mixture can be altered very rapidly, within 1 μs, which perturbs an equilibrium between reactants and products by a small amount. Then the approach to the new equilibrium can be followed on the microsecond timescale, permitting the measurement of kinetic rate constants as great as 10^6 s^{-1}. The equilibrium studied can be a normal chemical reaction or it could be simply the association of two molecules to form a complex.

The two major advantages of relaxation spectrometry are that it operates on very short timescales and that the perturbation of the equilibrium is small in magnitude. For example, in a temperature-jump apparatus, the temperature of the solution is changed by about 5° in 1 μs, which alters the equilibrium of a reaction by a small amount, depending on the enthalpy change of the reaction. The shift to the new equilibrium occurs and can be followed spectrophotometrically. Specific absorbance or fluorescent probes in the macromolecule can be used, or changes in protonation can be followed using pH-sensitive dyes. The advantage gained by perturbing the equilibrium by only a small amount simplifies the kinetic analysis. Each step in a reaction is observed as a single, first-order, kinetic reaction. The reciprocal of such a rate constant is known as the relaxation time.

Because relaxation spectrometry involves approaching equilibrium, both forward and reverse steps of each reaction are involved. As with other kinetic analysis involving approaching equilibrium (see Kinetics), the rate constant measured for each step is the sum of the forward and reverse rate constants for that step.

Another relaxation technique, which does not require perturbation of the system, is **nuclear magnetic resonance** (NMR). It also can be used to measure the rate constants for reactions and for the interaction between protein and ligand.

Release Factor

Termination of translation during protein biosynthesis takes place on ribosomes in response to a stop codon, rather than a sense **codon**, in the "decoding" site (A site). Translation termination requires two classes of polypeptide release factors (RFs): a class I factor, codon-specific RF (RF-1 and RF-2 in prokaryotes; eRF-1 in eukaryotes), and a class II, nonspecific RF (RF-3 in prokaryotes; eRF-3 in eukaryotes) that binds guanine nucleotides and stimulates class-1 RF activity (Table 1). The fact that the two release factors from bacteria exhibit codon specificity suggests that they must interact directly with the codon. However, the underlying mechanism for translation termination represents a long-standing coding problem of considerable interest, because it entails protein-RNA recognition instead of the well-understood codon–anticodon pairing during the **messenger RNA**-transfer RNA interaction (1, 2).

Table 1. Release Factors

	Factor	
Class	**Prokaryotes**	**Eukaryotes**
I	RF-1 (UAG/UAA specific)	eRF-1 (reads all three stop codons—omnipotent)
II	RF-2 (UGA/UAA specific)	
	RF-3 (stimulates RF-1 / 2 activity; recycle factor;GTPase	eRF-3 (stimulate eRF-1 activity; GTPase; prion-likeactivity of yeast eRF-3)

1. Release Factor Genes

The genes encoding bacterial RF-1 (*prfA*) and RF-2 (*prfB*) have been identified. Mutations in these genes often cause misreading of stop signals, increased frameshifting, or temperature-sensitive growth of the cells. The decrease in the cellular level and efficiency of RFs, therefore, leads to increased translational readthrough as the result of an abnormally long pausing of ribosomes at the stop signal. Unlike RF-1 and RF-2, RF-3 has received little attention since its initial characterization in the 1970s; its biological significance in protein synthesis has been a long-standing puzzle. After two decades of silence, the gene for RF-3, *prfC*, was discovered simultaneously by two groups (3, 4). Mutations in *prfC* caused misreading of all three stop codons, and an excess of RF-3 stimulates the formation of ribosomal termination complexes and increases RF-1 or RF-2 activity. The existence of a protein with RF activity in eukaryotes was demonstrated some 20 years ago in rabbit reticulocytes. After two decades of investigation, a eukaryotic protein family with the properties of an RF, designated eRF-1, was discovered (5). It includes a Sup45 protein of *Saccharomyces cerevisiae* that is involved in omnipotent suppression of three **nonsense codons** during translation. Eukaryotic counterparts of bacterial RF-3 were identified recently and are referred to as eRF-3 (6). The eRF-3 family includes a Sup35 protein of *S. cerevisiae* that carries G-domain motifs and is involved in

omnipotent suppression of nonsense codons.

2. Release Factor tRNA Mimicry

Upon accumulation of class I RF sequences from different organisms, conservation of protein motifs has been detected in prokaryotic and eukaryotic RFs, as well as in the C-terminal portion of elongation factor EF-G. EF-G is a translocase protein that forwards peptidyl tRNA from the A site to the P site on the ribosome (see Elongation Factors (EFs)). Because this *C*-terminal part of EF-G, domain IV, mimics the shape of the anticodon helix of tRNA (7), a provocative model has been proposed in which class I RFs mimic a tRNA shape for binding to the ribosomal A site and also mimic an anticodon for pairing to the stop codon ("RF-tRNA mimicry" hypothesis) (8). This view is supported by protein-RNA cross-linking and footprinting data that provide evidence for close contact between the stop codon and the release factor in the decoding site of the ribosome.

3. Class II Release Factors

Analogous to the initiation and elongation steps of translation, the termination step involves hydrolysis of GTP to GDP by RF-3 or eRF-3. The basic function of the G domain, like other Gtpases, is to switch the protein conformation between two alternative states, a GTP-bound ON state and a GDP-bound OFF state. The model of RF-tRNA mimicry predicts that class II GTP/GDP-binding proteins, RF-3 and eRF-3, may be an EF-Tu-like vehicle protein to bring class I proteins to the A site of the ribosome or an EF-G-like translocase protein.

4. Prion-like Activity of Yeast eRF-3

The yeast eRF-3, Sup35, is a non-Mendelian **prion**-like element called [*PSI*$^+$] that was uncovered some 30 years ago as a modifier of tRNA-mediated nonsense suppression in *S. cerevisiae* (9). Sup35 has several *N*-terminal tandem peptide repeats (PQGGYQQYN) similar to those in other prion proteins of mammals. Overexpression of the wild-type *SUP35* gene results in the *de novo* appearance of the corresponding [*PSI*$^+$] phenotype, revealing that the [*PSI*$^+$] factor is a self-modified protein analogous to mammalian prions. Moreover, **molecular chaperone** proteins, such as Hsp104, can cure cells of prions without affecting their viability (10). Therefore, Sup35 is likely to assume two functionally distinct conformations that differentially influence the efficiency of translation termination. In normal yeast strains, most Sup35 protein is soluble and functions in termination in a complex with its partner protein Sup45 (eRF-1). In [*PSI*$^+$] strains, most Sup35 is insoluble, and this insolubility is inherited from generation to generation. It is tempting to speculate that this *N*-terminal "switching" domain of Sup35 is involved in some specific or global control such as cell cycle regulation. The biological significance of the prion-like property of Sup35 remains to be determined.

Renaturation

The term renaturation is used to describe a number of different processes in which the specific native three-dimensional structures of biological macromolecules are refolded *in vitro*. It can pertain to proteins or to **nucleic acids**. Both such types of molecules can be denatured, a process in which they lose their native structures (see Denaturation, Nucleic Acids; Denaturation, Protein). Denaturation is generally accomplished by adding **denaturants** or by exposure to extremes of temperature, pH or pressure. The products are usually very unfolded, random coil-like individual polypeptide or polynucleotide chains, although less disordered chains, such as molten globule polypeptides, can result with only mildly denaturing conditions. Such unfolded chains often contain the information for their folded three-dimensional conformation in their linear sequence of amino acid residues or nucleotides and can regenerate it by a self-assembly process when the conditions are made less denaturing and more physiological. Renaturation involves refolding of the chains, which can involve only changes in conformation of the macromolecule. It can also include the addition of **prosthetic groups**, **coenzymes**, and other ligands, plus the introduction of disulfide bonds between **cysteine** residues in proteins.

With a protein, renaturation is described by protein folding in vitro, starting with the unfolded, denatured state. The structure regenerated is the **secondary structure** and the tertiary structure of a single-**domain** protein that remains monomeric. Quaternary structure is also regenerated if the protein consisted of multiple domains or subunits.

Renaturation of a nucleic acid involves simply regenerating its folded conformation from a single polynucleotide chain, as with a transfer RNA . The term is also used for the regeneration of the specific **double helix** from complementary individual single strands of DNA or RNA (see Hybridization, Nucleic Acids).

If renaturation does not occur, it is usually because the unfolded chains have precipitated or aggregated. Molecular **chaperones** prevent such aggregation with proteins by sequestering the unfolded molecule and permitting it to refold in the absence of aggregation or other nonproductive interactions (see Protein Folding In Vivo). Alternatively, renaturation might not occur spontaneously because the original molecule, which self-assembled spontaneously after its biosynthesis, has subsequently been modified covalently. Chemical modifications of proteins and nucleic acids prevent their self-assembly. Some covalent modifications are used *in vivo* to ensure that macromolecules do not renature spontaneously. For example, a peptide hormone like insulin is synthesized as a precursor, proinsulin, which folds and is then processed proteolytically to mature insulin. The single-chain proinsulin spontaneously folds and forms three disulfide bonds, and it can be renatured readily. Processed, two-chain insulin, on the other hand, does not readily self-assemble if it is unfolded and the three disulfide bonds are reduced. The principle of self-assembly can be expected to apply only to the original covalent forms of proteins and nucleic acids. Subsequent

covalent modifications can prevent renaturation, although not necessarily.

Reovirus

Reoviruses are icosahedrally symmetric, nonenveloped **viruses** that are 85 nm in diameter, whose morphology has been clarified by cryoelectron microscopy and single-particle reconstruction. The name reovirus is an acronym for respiratory and enteric orphan virus, which means that these viruses can be isolated from human respiratory and enteric tracts, but are not associated with serious human diseases. However, reovirus causes a variety of diseases in experimental animals, mice in particular, and this virus has been used extensively as a tool for studying viral pathogenesis in a number of organs, such as the brain, heart, intestines, and liver.

The genomes of reoviruses are characterized by 10 discrete segments of double-stranded RNA (dsRNA) which can be well-separated by polyacrylamide gel electrophoresis: three large (L1–L3), three medium (M1–M3), and four small (S1–S4). The reovirus genome is enclosed by eight structural proteins arranged in two concentric capsids. All of the **genes** from a type 3 strain encompassing 23,548 base pairs in length have been **cloned** and sequenced. All 10 segments contain short noncoding regions; the 5′- and 3′-untranslated regions range between 12 and 32 bases and between 35 and 83 bases, respectively. Sequences at the 5′ and 3′ ends of the 10 plus-strands are highly conserved, and the terminal sequences 5′ GCUC– – – – and – – – –UCAUC 3′ are found in all strains, while segment-specific 5′- and 3′-subterminal sequences are also present. The untranslated regions are likely to include sequences for messenger RNA packaging, recognition by the viral **RNA polymerase** for initiating plus- and minus-strand synthesis, and determining translational efficiency. The 5′ end of each mRNA has a eukaryotic -cap structure, ^{m7}GpppGmpC, but the 3′ end has no poly (A) tract. Each of the segments is monocistronic, except for the S1 gene, which encodes s1 and s1s derived from alternative reading frames.

Replication of reovirus occurs entirely in the cytoplasm. Sialic acid residues on **glycoproteins** of the cell surface are the receptors for the outer capsid protein s1, which forms a trimer with head-and-tail morphology projecting from each of the vertices of the virion. Additional host cell factors also appear to ensure reovirus infection. Concerning the enhancement of infection efficiency conferred by epidermal growth factor receptor and v-erbB, the virus has been suggested to make opportunistic use of an already-activated signal transduction pathway. After virus entry by endocytosis, virions are subject to proteolytic processing of s3 and m1/m1C, and the resultant particle is called the infectious subviral particle (ISVP). ISVP then converts to the core, transcriptionally activated particle. Viral core is a multienzyme complex consisting of l3, l2, l1, m2, and s2 proteins. l3 serves as the RNA-dependent **RNA polymerase**, and l2 provides the guanylyltransferase and methyltransferase activities for the capping process. RNA helicase and nucleotide triphosphatase activities reside on l1 and m2.

Transcription occurs in a conserved and asymmetric fashion in the core, and the mRNA is released from the core through the viral channel surrounded by the l2 pentamer. Each mRNA is transcribed at a rate proportional to the reciprocal of its segment length, providing viral proteins, and also acts as a template to make double-stranded RNA. Translation of the individual reovirus mRNAs is regulated,

and the translation frequency of mRNAs differs as much as 100-fold. Uncomplexed s3 with m1 down-regulates dsRNA-activated protein kinase, an interferon-induced enzyme that inhibits initiation of translation by **phosphorylating** eIF-2a, by sequestering its dsRNA cofactor. Later on in infection, newly made capsid proteins assemble with plus-strand single-stranded RNA into capsid. Nonstructural proteins with ssRNA binding activity, such as mNS and sNS, may play a role in the assortment of the mRNA molecules. However, the mechanism of how one complete set of 10 mRNAs is correctly packaged into each new core remains unknown. The synthesis of dsRNA (the RNA replication process) takes place in the assembled particles, in which the replicase catalyzes a single round of minus-strand synthesis.

When cells are coinfected with two different reovirus strains, a high percentage of the progeny contain novel assortments of gene segments. This process is known as reassortment. New virus strains can arise readily, and evolution occurs by such means. The reassortment is most efficient when the coinfecting viruses are closely related, and sequence divergence in the noncoding regions greatly affects the efficiency of this phenomenon. There is virtually a random distribution of most segments, but some parental **alleles** (such as L1-L2 and L1-M1) exhibit preferential cosegregation in the reassortants. Certain constellations of segments were isolated repeatedly in *in vivo* experiments.

Reassortment has played a major role in identifying (mapping) the viral genes responsible for several biological phenotypes, especially in determining the molecular basis of pathogenesis. For example, the following associations are found: The M2 gene encoding **myristoylated** protein m1 is a major determinant of neurovirulence; the M1 and L2 genes are correlated with myocarditis; and S1 is associated with pneumonia and growth in intestinal tissue. It is noteworthy that the genetic background of the recipient virus, onto which the genes of a donor virus are imposed, can alter the expression of the donor genes. In addition, reovirus reassortants appear commonly to contain mutations in genes that improve their fitness for independent replication.

To date, the genetic engineering of reovirus genes has been restricted to studies in which mutant gene products are analyzed for activity *in vitro* or in transfected cells. Self-assembled core-like particles have also been generated in cells infected with recombinant vaccinia virus expressing several reovirus gene segments, and this system is useful for studies on morphogenesis and protein–protein interactions. Ultimately, an important development would be a system for introducing synthetically modified or foreign nucleic acid into viable virus particles, because this would revolutionize various aspects of reovirus studies; this is hampered, however, by the mysterious assortment mechanism of the segmented genome.

Repeated DNA Sequence Interspersion

A large fraction of the **DNA** in the genomes of **eukaryotes** is made up of families of similar sequences, with members scattered widely throughout the DNA, called interspersed repeated sequences . The members of such a family are related to each other in DNA sequence but are not precise copies, and some may be quite **divergent**. In typical higher eukaryotes, there are many such families, with the number of copies ranging from less than 10 to almost a million. The typical length for short interspersed repeats (Sines) is 300 nucleotides. These sequence families are distinct from

microsatellite and minisatellite DNA, which are principally clusters of repeated copies arrayed in tandem and repeated fairly accurately. There are also families of longer interspersed repeats (Lines), many of which are transposable elements . It is very likely that almost all of the short and long interspersed repeats are the result of insertions of DNA sequences. Much is known about the transposable elements in ***Drosophila*** *melanogaster* (1). No clear function is known for most interspersed sequences, but a few of them have been identified with roles in the regulation of **gene expression** (2, 3).

The most extreme case of interspersion is the set of about half a million copies of the 283-bp Alu sequence repeats of the human genome, which is considered to be a retrotransposon (4, 5). RNA transcripts are derived from a few genes transcribed by **RNA polymerase** III, including the 3′ poly-A tail. Other parts of the genome supply the **reverse transcriptase**, and the RNA transcripts are converted into DNA, which are inserted into the genome by an unknown mechanism. At least half a million copies have been inserted, with an average spacing of only about 4 kbp. They occur in all regions of the chromosomes, except that they (*1*) are correlated with G bands, (*2*) are principally excluded from **exon** sequences coding for protein, and (*3*) are more frequent in the 3′ untranslated regions and **introns**. The pattern is nearly random, except that copies are clustered near some genes. The Alu family can be considered the prototypical interspersed repeat, but other families have entirely distinct mechanisms of replication and insertion (6). The mammalian-wide interspersed repeat (MIR) is an example (7), since it does not include the 3′ poly-A sequence. This sequence is widespread throughout mammalian genomes and has a conserved inner core sequence. Members can be widely divergent within the genome of an individual, but some sequences show little or no divergence between distant mammals. The conservation of the MIR sequence suggests that it has a function that offers an advantage to the host, or perhaps just to the MIR itself.

Repertoire

Because the immune response is specific, a basic question is to understand what are the structural and genetic bases that allow the immune system to make the necessary huge number of different recognition molecules—that is, immunoglobulins (Igs) and T-cell receptors (TCRs) that are required to interact specifically with all the potential antigens of the living world. This is what immunologists call the *repertoire problem*.

Is it possible to give an estimate of the number of potential epitopes that may eventually be encountered by an individual? Several theoretical approaches have been proposed. One is based on the average size of the antibody combining site, which may be taken as 600 $Å^2$, although large

variations do exist from one antibody to another (see Immunoglobulin Structure). Given this size, one may question how many different chemical organic structures could theoretically fill one antibody combining site. Calculations have been made, and the number is astronomic, about 10^{17} different structures. Another possible approach would be to start from an estimate of the number of gene products that can be generated by the living world. To stick to a minimal value, one may limit oneself to animal species (which already excludes viruses, bacteria, and plants!). The evaluation of the number of such species is somewhat greater than 10^6. Taking an average number of 10^5 genes/species leads to 10^{11} different protein molecules. One now has to take into account the **allelic** variants and the number of individual epitopes that can be defined at any protein surface. This easily comes to 10^{14} . This order of magnitude is reasonably consistent with the 10^{17} previously given, because we excluded a large part of the living world in the later estimate. Both values are simply enormous, so the repertoire problem is a major issue. Because T-cell epitopes are linear peptides, with a variable length [9 for those presented by the major histocompatibility complex (MHC) class I molecules and a little more for those bound to class II], a calculation may also be made of the potential number of different peptides that might be generated. Again, the number would be within somewhat similar ranges, perhaps slightly lower.

What is the situation on the immune system side? Both Igs and TCRs are generated from mosaic genes that must rearrange before becoming functional. Because rearrangements are made on a combinatorial basis, one may give an estimate of a minimum number of discrete Igs and TCRs that can be generated from this mechanisms. Taking into account gene rearrangements and random association of chains (H and L for Ig, ab or gd for TCRs), one gets values around 10^7 in both cases. This, however, does not take into account **N diversity**, which brings an additional increment (10^3 or more), nor does it take into account somatic hypermutations, which are, however, strictly restricted to Ig molecules. One must also take into consideration the fact, that despite its specificity, there is some degeneracy in immune recognition. It is therefore very clear that the immune system may potentially face recognition of any epitope. It certainly is quite remarkable that all this diversity is generated by fewer than 500 genes—that is, less than 1% of the entire genome (as expressed from the total number of gene segments, with the actual space actually occupied by the Ig and TCR loci being much lower).

Repertoire diversity is the result of a number of cumulative causes, especially combinatorial mechanisms:

- Degeneracy of recognition
- Combinatorial gene rearrangements of H and L chains of Ig or of a/b and g/d for TCR, including D gene fusion, different reading frame use, and so on
- Random association in polypeptide chain pairing (HL, ab, gd)
- Junctional diversity
- N diversity
- Somatic hypermutations (restricted to Ig chains)

All theoretical combinations are not, however, necessarily used, leading to the distinction between the potential and actual repertoires. For example, some gene segments (V genes, **D genes**, or **J genes**) are used more frequently than others. This may result from pure mechanistic reasons, such as subtle structure in RSS (recombination signal sequences) regions, varying the extent to which they are triggered by recombinases. It seems also clear that not all possible H–L polypeptide chain pairs are encountered and that preferential associations take place. It also has long been observed that the expressed repertoire could vary in life, with some genes preferentially expressed at birth and no longer expressed in the adult. This may of course reflect selective mechanisms that possibly involve idiotype interactions implying a degree of connectivity that may vary with age. Ultimately, the expressed repertoire of any individual evidently reflects its own history and the various and numerous contacts it may have encountered with the outside world.

Repetition Frequency

Repetition frequency is the frequency with which particular DNA sequences are repeated tandemly within a genome (see Repetitive DNA). The basis for the phenomenon is not understood. To account for the observations, a model of sequence-dependent, **unequal crossing-over** and gene amplification (*slippage replication*) has been simulated (1). It was deduced that DNA, whose sequence is not maintained through natural selection, will exhibit repetitive patterns over a wide range of rates of genetic recombination resulting from the interaction of unequal crossing-over and slippage replication, both processes that depend on sequence similarity. At high crossing-over frequencies, the nucleotide patterns generated by the simulations were simple and highly regular, with short, nearly identical sequences repeated in tandem. Decreasing recombination rates increase the tendency to longer and more complex repeat units. Periodicities have been observed down to very low recombination rates (one or more orders of magnitude lower than the mutation rate). At such low rates, most of the sequences contain repeats that have an extensive substructure and a high degree of heterogeneity among themselves. Other high-order structures are superimposed on a tandem array. These structures have been compared to various real structures of tandemly repeated DNA known from eukaryotes (1).

Notwithstanding the interest in this type of simulation and in the many observations on several long fragments of DNA, it is clear that only the total sequence and characterization of **exons** and **introns** in several **eukaryotes** will give us information about the periodicity of interspersed sequences, if any.

Repetitive DNA

Repetitive DNA , in which multiple copies of the same or very similar sequences are in the genomes of **eukaryotes**, was first detected from the kinetics of reassociation of fragmented, **denatured** genomic DNA (1) (see C0t Curve). Two types of repetitive DNA were detected: (1) the fast-

renaturing component consists of rather short sequences tandemly repeated thousands of times, such as those found at the telomeres and the *variable number tandem repeats* (VNTR;). The slower component consists of longer sequences (Sines, including Alu sequences in primates, and Lines, such as Kpn in primates and MIF in rodents), which are repeated several hundred to several hundred thousand times.

Higher eukaryotic genomes often consist of more than 50% repetitive DNA. There are some extreme variations among vertebrates. For example, *Fugu rubripes*, the puffer fish, which has apparently all or almost the same number of structural **genes** as other vertebrates, has a genome much smaller than that of primates because of considerably smaller introns and probably a lesser number of repetitive sequences.

Replication Foci (Factories, Centers)

During **S phase** of the cell cycle, multiple replication origins of eukaryotic chromosomes initiate DNA replication, and numerous replication forks travel along the DNA for long distances. The positions in mammalian cell nuclei where DNA synthesis occurs were analyzed by the pulse-labeling of newly synthesized DNA with bromodeoxyuridine (see 5-Bromouracil) and visualization of the sites by fluorescence microscopy. The results showed that the replication sites do not distribute diffusely throughout nuclei but form discrete foci called *replication foci* (or *replication centers*). In rat fibroblasts, more than a hundred small foci appear in early S phase, and the foci subsequently become fewer and larger through several waves of appearance (1). This profile is thought to result from a transition of replication activation from early to late origins during S phase. Similar foci were observed when sperm with their membranes removed replicated in Xenopus egg extracts (2). These foci are thought to correspond to structures where replicating DNA and replication machineries assemble in an organized manner. Each focus is thought to be composed of several tens of replicating forks from synchronously initiated origins that cluster in a chromosome domain subjected to a common type of **gene expression**. In general, transcriptionally active gene loci are replicated early in S phase, whereas inactive loci or repetitive DNA loci are replicated later.

One replication protein, proliferating cell nuclear antigen (**PCNA**), was originally identified as an autoimmune antigen that specifically localized in S-phase nuclei. The immunostaining showed a characteristic punctuated pattern in nuclei and colocalized with replication foci (3). Thus, replication foci are the sites of replication protein assembly at specific nuclear compartments. Many **replication proteins**, such as **DNA polymerase** a, PCNA (4), RPA (single-stranded DNA binding protein; (5), and DNA Ligase I (6), are associated with replication foci. Assembly of RPA in nuclei also occurs prior to the start of DNA synthesis and is poised for initiation. This means that the formation of replication foci has been initiated at the pre-replication stage at particular sites in nuclei, and S-phase entry signals may change the complexes to replication foci by the addition or activation of a subset of replication proteins. Replication foci include several additional components, such as **cyclin**-dependent protein **kinases** (5), cytosine methyltransferase (7), and chromatin assembly factor 1 (8). Therefore, replication foci are not merely assemblies of the eukaryotic replisome, but functionally organized apparatuses that respond to progression of the cell cycle, modification of the replicated DNA, and formation of chromatin structure, in addition to DNA replication.

One question about replication foci is how the protein assembly is spatially organized in the nucleus. The structure of replication sites in nuclei was visualized by electron microscopy using HeLa cells encapsulated in agarose microbeads, followed by labeling with **biotin**-dUTP of the permeabilized cells (4). Sites of DNA synthesis could be seen in specific dense structures attached to a diffuse nucleoskeleton, appearing at the end of G1 phase, increasing in size and decreasing in number according to the progression of the S phase, similar to the replication foci observed by light microscopy. From their morphology, the dense structures are called *ovoid bodies*, which are distinguishable from other nuclear bodies. The ovoids are strung along the nucleoskeleton and associate with PCNA, in addition to replicating DNA. After short labeling of cells, all replication sites are associated with ovoids, but longer labeling caused the sites to spread into adjacent chromatin. These observations strongly suggest that the ovoid bodies are replication protein assemblies fixed on the nucleoskeleton (Fig. 1) that function as a factory where replication occurs as the template moves through it. In this respect, the protein assemblies at ovoids are called *replication factories*, which are identical structurally to replication foci.

Figure 1. Schematic drawing of a replication factory. One factory unit has a set of replication apparatus, cell-cycle regulation proteins, methylation enzymes, and chromatin assembly factors. An actual factory is composed of more than 10 units and many replicating DNAs. These complexes are fixed on the nucleoskeleton.

Replication Fork (Y-Fork Intermediate)

Elongation of DNA replication proceeds by unwinding the DNA double helix and synthesizing complementary strands on each separated single-stranded template. This generates a fork-like structure at the growing point of replicating chromosomes. The fork structure can be detected as Y-fork intermediates by electron microscopy (**EM**) and by two-dimensional gel electrophoresis of replication intermediates (1). The actual structure *in vivo* is thought not to be a simple fork, but to have a complicated configuration to coordinate the asymmetrical synthesis of leading and lagging strands in opposite directions. In *Escherichia coli*, several models for the replication fork have been proposed, the most accepted being the concurrent synthesis of two strands by an asymmetric complex of DNA polymerase III holoenzyme proposed by Kornberg (2). In this model, DNA helicase (DnaB)-primase complex (the primosome) located at the fork precedes the replication to produce two single-stranded loops, one of which contains RNA primer synthesized by the primosome. **DNA polymerase** III holoenzyme located behind the primosome forms an asymmetric dimer structure containing two different catalytic sites; one polymerizes the leading strand progressively and the other synthesizes the lagging strand discontinuously from RNA primer. Concurrent replication of two single-stranded loops by the single holoenzyme results in a gradual decrease in the size of the leading-strand loop, but causes a dynamic change in the lagging-strand loop, first increasing in size and then suddenly shrinking back to a simple fork structure. This generates a cyclic and dynamic change in structure at the growing fork that is comparable to the movement of a trombone musical instrument (Fig. 1). In **eukaryotes**, the fork structure seems to be more complicated than that of **prokaryotes**. Studies on **SV40 virus** DNA replication *in vitro* have shown that at least two DNA polymerases, polymerase d/e and polymerase a-primase complex, are involved separately in the synthesis of leading strand and lagging strand, respectively (see DNA Replication) (3). In addition, the dissociation of any nucleosome structure precedes the fork movement, and reconstruction of the nucleosome occurs concomitantly with the synthesis of new DNA strands (4). However, essentially the same structure as that of the *E. coli* fork was proposed where a heterogeneous complex between DNA polymerases d and a replaces DNA polymerase III holoenzyme. The principle of the fork structure model is that the primosome, polymerases, and other proteins involved in the synthesis of leading and lagging strands form a supramolecular complex, the replisome, through which the chromosome moves, making a dynamic and cyclic change of the Y-fork structure. Assembly of multiple replisomes on the **nuclear** membrane or matrix is thought to form a large structure like a replication focus that is visible by cytological methods (5).

Figure 1. Dynamic structure of replication fork. A model for the cooperative synthesis of leading and lagging strands by a replication machinery composed of (1) dimeric form of DNA polymerase III, (2) DNA helicase, (3) primase, and (4) DNA polymerase I and DNA Ligase. The structure of the replication fork changes in a cyclic manner, from A to B to C to A. The partially single-stranded loop moves through the machinery back and forth (shown by shaded arrows) as the elongation (A and C) and completion of **Okazaki fragment** synthesis occur (B). Primer RNA is synthesized only at certain intervals.

Replication Origin

A replication origin is a site at which a **chromosome** or minichromosome initiates the DNA replication process. Kornberg and colleagues explored in some considerable detail the molecular mechanisms controlling the highly regulated initiation of chromosomal replication in *Escherichia coli*. This event normally occurs once per cell generation at a single site selected from the entire *E. coli* genome (4×10^6bp). This unique chromosomal origin (oriC, 245 bp long) is recognized by a sequence-specific DNA-binding protein, DnaA, that associates with four noncontiguous 9-bp repeats. Because the DnaA protein functions specifically to determine the site at which replication initiates, it can be called a specificity factor. The protein interacts with individual 9-bp repeats, but only when four are placed in the correct positions relative to each other is a large complex of DnaA protein and the oriC DNA sequence formed. This large nucleoprotein complex is recognized by the other proteins required for replication.

The DnaA protein interacts with DNA and also associates through direct protein-protein contacts with other DnaA molecules. This results in a cooperative association of 20 to 30 DnaA molecules with oriC. DNA is wrapped around the complex of the DnaA protein. The DnaA protein–DNA complex formed at oriC facilitates a specific opening of the **double-helix** in an adjacent AT-rich DNA sequence. The DnaC protein mediates the association of the DnaB helicase with this single-stranded AT-rich sequence, unwinding a substantial segment of the double helix, at which replicative enzymes, such as DNA primase and **DNA polymerase**, begin to act. Interestingly, the protein most analogous to a histone in *E. coli*, the HU protein, facilitates the formation of a functional nucleoprotein complex at oriC, as do topoisomerases. The role of these proteins is probably to facilitate the correct topological arrangement of DNA for the subsequent replicative events.

Several general rules follow from this analysis. The initiation of replication requires exceptional levels of control, as do similar events in **eukaryotic** cells. Although DNA-binding proteins interact with specific sites with high affinity (with **dissociation constants**, K_D, = $10^{-9}$$10^{-13}$M), they also bind DNA nonspecifically ($K_D = 10^{-6}$$10^{-3}$M). Thus the basis of the exceptional precision of replicative events in *E. coli* is unlikely to follow from the binding of a single protein to a single DNA site. Instead, the cooperative interaction of a particular protein (the DnaA protein) with multiple sites over a 200- to 300-bp region of DNA is required for initiation. The precise organization of DNA into these complexes is necessary for other proteins to recognize the origin of replication. This precise organization also requires the mediation of proteins that alter the DNA conformation (HU or IHF) and remove topological constraints to the folding of DNA (topoisomerases).

The precision of regulated events in eukaryotic cells is determined by following the prokaryotic paradigm and by utilizing multiple, high-affinity, sequence-specific DNA-binding proteins that recognize multiple related sequence elements and by masking many of the nonspecific sites by folding them into chromatin (1). The first examples of multiple binding sites within DNA for particular sequence recognition proteins that regulate replication or transcription in eukaryotic cells were observed in viral systems. The **SV40** genome has three binding sites for the T Antigen at the origin of replication (ORI), which is a nucleosome-free region in the minichromosome. Scanning transmission electron microscopy reveals that trimers and tetramers of T antigen bind at each of these sites. Like DnaA, the T antigen also causes significant changes in local DNA structure at the origin. Other viral genomes have a similar requirement that multiple binding sites be occupied by a particular virally encoded protein to initiate replication. The nuclear antigen (EBNA-1) protein of **Epstein–Barr virus** has six specific binding sites in the viral replicative origin region. Thus eukaryotic viruses are likely to regulate replication comparably to *E. coli*.

In *Saccharomyces cerevisiae* chromosomes, a multiprotein complex has been identified that interacts with over 150 bp of DNA at several functionally defined origins of chromosomal replication (or autonomously replicating sequences, [ARS]) (2). This origin recognition complex (ORC) requires that ATP binds specifically to DNA, a property shared with SV40 T antigen and the *E. coli* DnaA protein. Although only a short consensus sequence is necessary for ORC binding, the final DNA sequence organized by the ORC is much more extensive and resembles the in vivo **footprint** at a yeast origin of replication.

The utilization of origins of replication within the chromosomes of metazoans is much more complex than that of *S. cerevisiae* (3). Although it is possible to define limited segments of DNA as small as 500 bp where bidirectional replication is initiated, no consensus sequences that independently direct replicative initiation have been defined. Extended chromosomal regions as large as several kilobase pairs in length can facilitate replicative initiation. A model was proposed to explain these results reflecting the Jesuit maxim that "many are called, but few are chosen." This suggests that, although there are many detectable sites at which replication might begin, the assembly of DNA into nucleosomal arrays, followed by the subsequent assembly of higher order chromatin structures, represses many potential origins and potentiates the activity of others. This might also contribute to the selective utilization of ARS elements as origins of replication in yeast. This model does not offer any explanation as to why and how a replication-competent nucleoprotein complex is assembled at an origin (4).

Arguments that nuclear organization influences the initiation of DNA replication derive from *in vitro* experiments in *Xenopus* egg extracts and *in vivo* experiments with the chromosomes of *Drosophila* and *S. cerevisiae*. Chromatin assembly and nuclear structures are both necessary for replication in *Xenopus* egg extracts. Additional evidence that chromatin structure influences origin utilization comes from the suppression of origin utilization in regions of *S. cerevisiae* and *Drosophila* chromosomes that contain heterochromatin. Nuclear scaffold or matrix attachment regions have also been proposed as facilitating aspects of the replicative process (see Domain, Chromosomal). Chromosomal replication within the nucleus clearly occurs within morphologically defined factories attached to a nuclear scaffold (5). Finally, the nuclear envelope has a regulatory role in determining the activity of the "licensing" process that enables replicative initiation.

Replicative Form

The circular **genomes** of small, single-stranded DNA **bacteriophages**, such as M13 and FX174, are converted to a double-stranded form, called the **replicative form** (**RF**), upon infection of a host

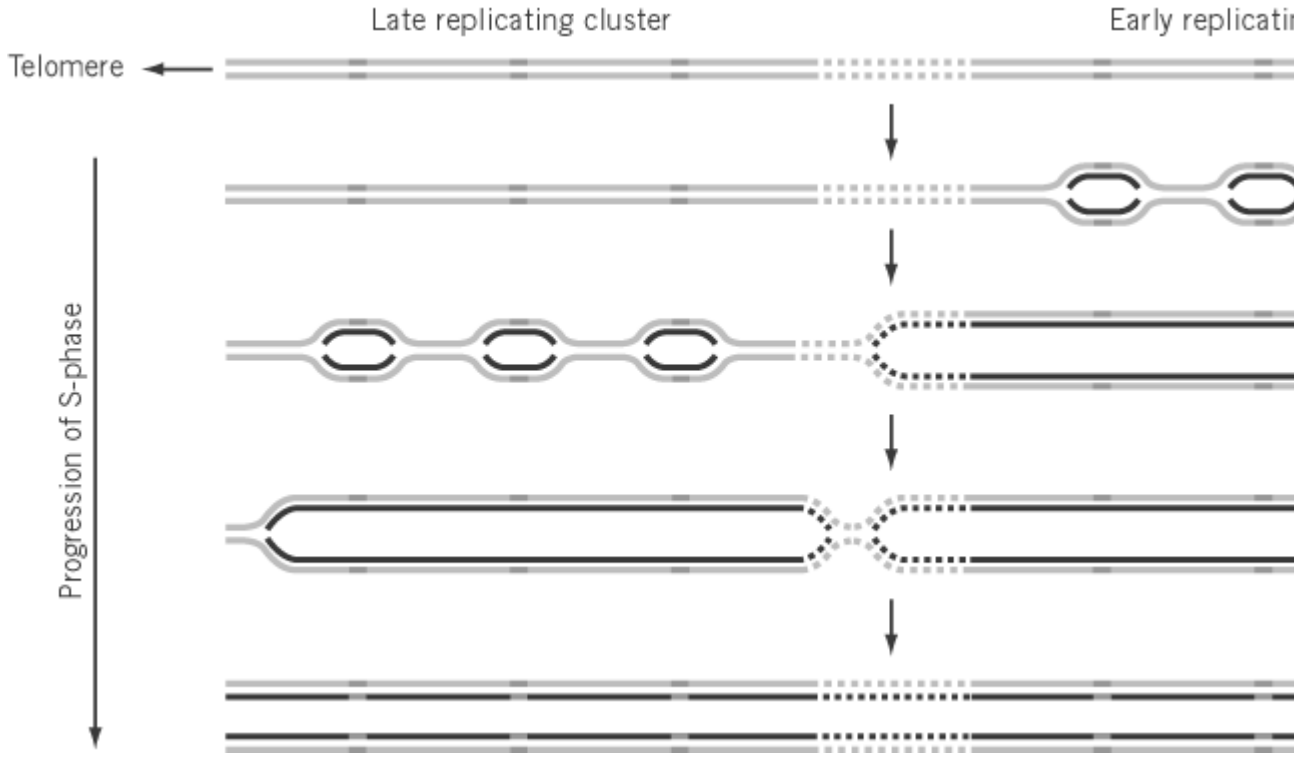
bacterium (see Single-Stranded DNA Replication). Synthesis of the complementary strand of the original single strand is primed using a RNA primer made at a specific site on the viral strand and elongated by the host **DNA polymerase** III holoenzyme from the primer terminus. The initial product of complementary strand synthesis is a duplex circle DNA with a small gap, called RFII. It consists of an intact viral DNA and a nearly full-length linear complementary DNA plus the RNA primer. The RNA primer is then removed, and the resultant gap filled by DNA polymerase I. Subsequently, the nick is sealed by DNA Ligase, and the duplex DNA is converted to the **supercoiled** form (RFI) by DNA gyrase (see DNA Topology). The RFI DNA serves as a template for multiplication of the viral genome and for transcription of messenger RNA for the production of phage proteins.

Replicon

DNA replication of a genome is a self-regulatory process, in which each genome or portion of a genome is replicated independently of each other. Such a unit of replication is called a *replicon*. The concept of a replicon was proposed by Jacob et al. in 1963 (1) as a hypothetical entity that consisted of a replicator, a signal sequence on the **chromosome**, and an initiator, a positive regulator that recognizes its own replicator to initiate replication. The hypothesis was proposed to explain the replication and segregation of chromosome and **plasmid** independently of each other in *Escherichia coli*. In other words, both a *cis*-regulatory element, the replicator, and a *trans*-regulatory element, the initiator, are specific for each replicon. **Prokaryote** and **virus** genomes are found to be composed of a single replicon, each of which contains its own replicator and initiator, as was prophesied by the replicon hypothesis. Both replicators and initiators are variable in structure in plasmid, **bacteriophage**, and viral genomes. In contrast, the initiator, DnaA protein, and its recognition sequence, DnaA-box, are conserved in **eubacteria**. In all cases, the replicator is identical to the replication origin, as replication initiates from within the replicator.

In contrast to prokaryotic genomes, those of **eukaryotes** are composed of multiple replicons of variable size, 10 to 330 kbp (2). A cluster of replicons seems to be replicated simultaneously, but different clusters at varying times during **S phase**, depending on their location along the chromosome. In general, clusters near the **centromere** tend to replicate early, and those near the telomere replicate late in S phase (Fig. 1). No general picture of a replicon as to replicator and initiator in eukaryotes has been devised, since the fine-structure analysis of chromosomal origins is limited to a single species of eukaryotes, *Saccharomyces cerevisiae* (3). About 20 autonomously replicating sequences (**ARS**) have been isolated from *S. cerevisiae* chromosomes, some of which are found to function as origins for the chromosome. Every ARS contains an 11-bp ARS consensus sequence (ACS) that is recognized and bound by a protein complex consisting of six subunits, the origin recognition complex (ORC). The ACS and ORC correspond to the DnaA-box and the DnaA of bacterial replicons. However, the ORC itself is not an active regulator but requires other regulators for the activation of origins. Since the origins of the yeast genome are initiated at different times in S-phase, and vary in the efficiency of their use in the cell cycle, they seem to be regulated specifically by factors that act on regulatory elements of the ORC-ACS complex common to the origins. Replicons of chromosomes containing multiple origins are difficult to define, because termination sites between two adjacent origins are not clear, and in many cases inefficient origins are passively replicated by the **replication fork** coming from neighboring active origins.

Figure 1. A scheme of replication of multiple replicons of eukaryotic chromosomes.



Replicons of higher eukaryotes are ambiguous, because replication initiates randomly from a region ranging from 0.5 to 55 kbp (4). Such a region is called an "initiation zone" and contains no specific signal sequences corresponding to the yeast ACS, although six subunits of ORC were found to be widely conserved from yeast to human cells. The size of a chromosome (more than 10 kb) and the structure of its chromatin seem to be more important than sequence in determining the replicator function of replicons in higher eukaryotes.

Reporter Genes

Reporter genes are used throughout molecular and cell biology, from areas such as gene cloning, gene expression, and functional studies, to use in high throughput drug screens and the development of biosensors. Reporter genes provide visual and quantitative data on gene expression. The primary requirements of reporter genes are that their products be readily detectable, with low background activities from endogenous gene products, and that high levels of ectopic expression of the reporter genes themselves have no adverse effects in the cells in which they are expressed (1). For detection,

reporters fall into three main categories: first, enzymes that convert chromogenic or fluorogenic substrates that can be observed in cells *in situ*, or by spectroscopy in cell or tissue lysates; second, enzymes that catalyze the transfer of radiolabeled groups, which can be detected by liquid scintillation counting or autoradiography; third, bioluminescent proteins, or enzymes that catalyze bioluminescent reactions and that have been cloned and developed as some of the most sensitive reporter genes.

A summary of the reporter genes described here is given in Table 1. See also the following individual entries: Alkaline Phosphatase; Beta-Glucuronidase.

Table 1. Summary of the Common Reporter Gene Systems

Reporter	Origin	Substrate	Major Applications
Chloramphenicol acetyl transferase (CAT)	*E. coli*, transposon 9	[^{3}H]- or [^{14}C] chloramphenicol	*In vitro* gene expression analysis
		+*n*–Butyryl CoA	Identification of *cis*- or *trans*-acting regulatory sequences
b-Galactosidase	*E. coli lac* operon	Xgal	*In situ* analysis of gene expression in transgenic animals
		FDG	Labeling living cells for sorting by flow cytometry
		CMFDG	Normalizing transfection efficiencies *in vitro*
b-Glucuronidase (GUS)	*E. coli gus* operon	X-glu	*In vivo* gene expression in transgenic plants and yeast

1. Chloramphenicol Acetyltransferase

Chloramphenicol acetyltransferase (E.C. 2.3.1.28; CAT) was one of the first reporter genes to be developed and, although less versatile than some of the more recently developed reporter genes, is still widely used (2, 3). The enzyme confers resistance to chloramphenicol on bacteria and is derived from transposon 9 of *Escherichia coli*. It is a trimeric protein with a subunit size of 25 kDa. Significantly, there is no endogenous mammalian counterpart to CAT, so background activities are negligible; furthermore, the protein is relatively stable in mammalian cells, and the messenger RNA transcript has a short half-life.

CAT catalyzes the transfer of acetyl groups from acetyl-coenzyme A to chloramphenicol:

$$\text{Chloramphenicol} + 2\text{Acetyl CoA} \rightarrow 1,3 - \text{Diacetylchloramphenicol} + 2\text{CoA} \quad (1)$$

When radiolabeled substrate (eg, [^{14}C]chloramphenicol) is added to a cell lysate, the amount of the acetylated chloramphenicol produced can be measured and is directly proportional to the amount of enzyme present; significantly, this relationship remains linear over three orders of magnitude. The acetylated and nonacetylated forms of chloramphenicol have different solubilities in organic solvents and may be separated by differential extraction or by using **thin-layer chromatography** (2). Variations on this basic assay include the use of [^{3}H]chloramphenicol and the use of *n*-butyryl CoA

instead of acetyl CoA, because *n*-butyrylated chloramphenicol partitions more efficiently into the organic phase upon extraction than the acetylated form. The amount of radiolabeled *n*-butyrylated chloramphenicol extracted may then be determined by liquid scintillation counting (4).

Although CAT assays are very sensitive, CAT is not as versatile as other reporter gene systems described here. It is used primarily to quantify gene expression in transient expression studies—for example, to assay gene enhancer or **promoter** activities. At present, CAT activity needs to be assayed in cell extracts, which restricts its use to *in vitro* studies. Nevertheless, CAT has been used in a number of transgenic studies in which expression at a cellular resolution was not required. Despite the lack of an *in situ* assay for CAT activity, the presence of CAT protein in a cell can be detected by immunocytochemistry (5). The availability of good **antibodies** against CAT also allows quantitative analysis of the amount of CAT protein produced by using **enzyme-linked immunosorbent assays** (ELISAs), rather than measuring CAT activity (6).

2. b-Galactosidase

Beta-galactosidase (E.C. 3.2.1.23) is encoded by the *lacZ* gene from the ***lac* operon** of *E. coli* and is one of the reporter genes used most widely to study gene expression in transgenic animals. It has been used extensively in all of the major model organisms, including ***Caenorhabditis elegans***, *Drosophila*, ***Xenopus***, and the mouse. Importantly, high levels of ubiquitous *lacZ* expression can be obtained with no apparent adverse effects on development or cell biology (7). An advantage of *lacZ* is its ability to form functional fusion genes. *LacZ* is often used as a fusion gene with the selectable markers for neomycin or hygromycin resistance (neo^r, hyg^r). These fusion genes, bgeo and bhyg, allow direct selection of cells that express the reporter gene and have formed the basis of "gene-trap" vectors that are used to identify, mutate, and clone novel expressed genes simultaneously, principally in mouse embryonic stem cells (8, 9). The construction of fusion genes also enables the subcellular localization of the reporter to be studied. For example, in cell labeling studies, b-galactosidase is often used carrying a nuclear localization signal (10), which provides a more intense stain within cell bodies, and an *N*-terminal fusion with the neurofilament protein Tau effectively labels axonal projections for studies of neural development (11). Exceptionally, fusion genes carrying an *N*-terminal cleavable **signal sequence** do not show b-galactosidase activity (12). b-Galactosidase is not secreted, but it becomes sequestered in the lumen of the endoplasmic reticulum (ER). However, b-galactosidase activity can be restored by adding a transmembrane domain to the fusion gene; in this case, the b-galactosidase becomes anchored within the membrane of the ER, and the b-galactosidase domain of the protein is held in the cytosol. The restoration of b-galactosidase activity of fusion genes carrying secretory and membrane-encoded signal sequences by inclusion of a transmembrane domain at the *N*-terminus of the CD4 gene has formed the basis of an elegant gene-trap strategy to identify novel genes for membrane-bound and secreted proteins (12).

The enzyme comprises a homotetramer, with a subunit size of 116 kDa, and it catalyzes the hydrolysis of various b-galactosides, such as lactose. *LacZ* is most widely used in transgenic experiments, where its expression can be detected *in situ*, in fixed whole tissue preparations, using histochemical substrates such as X-gal (5-bromo-4-chloro-3-indoly-galactopyranoside). Hydrolysis of X-gal in the presence of a ferricyanide/ferrocyanide catalyst releases an indolyl that is oxidized to an indoxyl that forms an indigo blue precipitate (13). This reaction has proved particularly valuable for analyzing gene expression patterns when *lacZ* is expressed from specific promoter sequences, or integrated into endogenous genes by homologous recombination. The stain is clearly visible, does not spread to adjacent nonexpressing cells, and is stable to further histological processing. Although the b-galactosidase reporter gene is derived from *E. coli*, many eukaryotic cells also contain some b-galactosidase activity. For the most part, background staining can be minimized by fixation and by staining at pH 7.5 to 8, because the endogenous b-galactosidases are largely lysosomal and have an optimum pH of about 3.5.

In addition to X-gal histochemistry, a number of other substrates have been developed that have

increased the versatility of b-galactosidase as a reporter gene (13, 14). Hydrolysis of the chromogenic substrate 2-nitrophenyl b-D-galactopyranoside (ONPG) allows quantitative determination of b-galactosidase activity in cell extracts, by measuring the **absorbance** at 420 nm. Quantitative measurement of b-galactosidase is less sensitive than that of other reporter gene activities routinely analyzed in cell extracts, such as luciferase or CAT, but b-galactosidase has a valuable use in normalizing transfection efficiencies when used in combination with the more sensitive reporters.

The most sensitive substrates for b-galactosidase are the **fluorescent** substrates, such as fluorescein di-b-D-galactopyranoside (FDG), which is hydrolyzed to release fluorescein and can be detected using a luminometer or can be observed using standard fluorescein isothiocyanate fluorescence microscopy (13). Although fluorescent substrates increase the sensitivity of detection, higher background levels of activity are also detected due to the endogenous b-galactosidase activity of many cells.

Fluorogenic substrates may also be used to study living cells. For this purpose, derivatives of FDG (C_{12}FDG and CMFDG, from Molecular Probes Inc.) have been developed that improve the loading of cells with the substrate and reduce the leakage of released fluorescein from the cells. A major use of this technology has been to sort expressing from nonexpressing cells in a population, using flow cytometry (15). Sorted cells may then be used for a wide variety of applications. Despite the problem of background fluorescence, living cells may also be observed *in situ* using fluorescent and confocal microscopy. This technology allows cells to be observed in real time and to be identified *in situ* for a subsequent manipulation, such as specific cell injection or performing physiological experiments through patch clamping (16).

3. Luciferase

A number of genes for bioluminescent proteins have been cloned and used in reporter systems (17). Amongst the first such gene, and one of the most widely used, is the **luciferase** gene, *luc*, from the firefly *Photinus pyralis*. Luciferase (E.C. 1.13.12.5) is a monoxygenase, a monomer of 61 kDa, that catalyzes the oxidation of its substrate beetle luciferin, in the presence of Mg^{2+}, oxygen, and ATP, with the emission of green to yellow light (550 to 570 nm), which can be measured using a luminometer. The luminescent reaction is extremely sensitive; a flash of light is observed 0.3 s after the addition of ATP to the enzyme and substrate mixture, and this flash of light then decays over about 15 s. The light output is directly proportional to the luciferase concentration. Importantly, the enzyme activity is very closely coupled to protein synthesis, and its activity remains linear over a remarkable 10^8 concentration range of the enzyme. Because the light emission is so fast, it was necessary initially to use a specialized luminometer in which the ATP is injected into the sample at the time of recording. However, current protocols include the addition of coenzyme A to the substrate mix, and this reduces the decay of light emission, extending it to several minutes (18). This allows multiple reactions to be set up and assayed using less sophisticated equipment.

In addition to firefly luciferase, luciferase genes have been cloned from bacteria (*lux*) and from the sea pansy coelenterate *Renilla reniformis* (*Rluc*). Despite the common feature of light emission, the luciferases are quite distinct; they do not share common evolutionary origins and have different chemistries and substrate specificities. *Renilla* luciferase is a 31-kDa protein and catalyses the oxidation of coelentrazine, with the emission of blue light at 480 nm. Unlike the firefly luciferase, *Renilla* luciferase gives a low level of nonenzymatic autoluminescence, which reduces its sensitivity by about 10-fold. Seldom used alone, *Renilla* luciferase is often used in conjunction with the firefly luciferase in dual labeling studies. The *Renilla* enzyme is particularly useful as an internal control to normalize for variations in transfection efficiencies between samples. In such assays, the firefly and *Renilla* enzymes may be assayed from the same cell extracts by the sequential addition of the luciferin and coelentrazin substrates, determining the ratio of luminescence from the two enzymes (19).

The major use of luciferase is to measure gene activity in transient expression assays. For this purpose, luciferase assays are more rapid, more sensitive (two to three times), and cheaper than CAT assays. For these reasons, this reporter gene system has been developed for the requirements of high-throughput screens of gene expression, in which assays can be performed in 96-well luminometry plates. Despite the high sensitivity of detection of luciferase activity cell extracts, efficient protocols have not been developed to monitor expression in intact cells or in tissue sections.

4. b-Lactamase

The most recent reporter gene to be developed for use in animal cells is TEM b-**lactamase** (penicillin amido-b-lactamhydrolase; E.C. 3.5.2.6), the product of the *E. coli* **ampicillin**-resistance gene Amp^r, which functions to cleave **penicillins** and cephalosporins (20). The gene encodes a 27-kDa monomeric soluble enzyme with a high catalytic efficiency. Initial studies using the chromogenic substrates 3-(2,4-dinitrostyryl)-(6R,7R)-7-(2-thienylacetamido)-ceph-3-em-4-carboxylic acid (PADAC) and nitrocephin showed that b-lactamase is a very sensitive reporter, with as few as 10^7 to 10^9 molecules being detectable, which compares well with the limits of detection of other reporters, such as CAT, luciferase, and human placental alkaline phosphatase (hpAP). Furthermore, as for CAT and hpAP, the steady-state levels of enzyme activity are representative of the steady-state mRNA levels. The enzyme may be secreted, and its activity assayed in the culture medium, or it may be assayed in cell extracts. In either case, the reaction simply requires addition of substrate and measurement of the change in absorbance, measured at 570 nm for PADAC or 470 nm for nitrocephin.

In addition to available chromogenic substrates, Tsien and colleagues have developed fluorogenic substrates for b-lactamase that allow gene activity in single living mammalian cells to be monitored in real time, with very high sensitivity (21). In the system developed, the assay is based on fluorescence resonance **energy transfer** in which the b-lactam ring of a cephalosporin substrate is linked to two fluorophores. Excitation (at 409 nm) of the first, shorter-wavelength, donor fluorophore (coumarin) leads to excitation and green fluorescence emission (520 nm) from the second, longer-wavelength, acceptor fluorophore (fluorescein). Cleavage of the substrate by b-lactamase then separates the two fluorophores, so that excitation of coumarin leads to fluorescence emission of blue light (447 nm) only. Thus the shift in the fluorescence emission wavelength from 520 nm (green) to 447 nm (blue) can be measured, and the ratio of the intensities of the two wavelengths indicates the extent of cleavage, or the level of reporter gene activity.

To study b-lactamase in living mammalian cells, an esterified derivative of the substrate CCF2 (CCF2/AM) was made that could cross cell membranes readily to load cells, without necessitating additional cell permeabilization or shock. The ester groups are then removed in the cell by endogenous nonspecific esterases, to trap the active CCF2 within the cell. One shortcoming of the substrate is that it is free to diffuse throughout the cell; consequently it cannot be used to study subcellular events in the way that **green fluorescent protein** can.

Work to develop the b-lactamase/CCF2 substrate system used cotransfection of b-lactamase under the control of a tandem trimer of nuclear factor of activated T cells (NF-AT) binding sites, together with the M1 muscarinic receptor gene. Stimulation of cells with the muscarinic agonist carbachol then led to a 100-fold increase in b-lactamase expression per cell, with a corresponding switch from green to blue fluorescence. Importantly, b-lactamase activity showed a good dose response to the agonist and revealed kinetic changes in gene transcription at both the population and the single-cell levels. This study also showed b-lactamase to be an excellent reporter of transcriptional readout in drug screens for receptor agonists and antagonists.

Finally, expressing and nonexpressing cells can be sorted easily by flow cytometry. Because the substrate and detection system cause minimal damage to living cells, cells may be selected for

continued culture based on their levels of reporter gene expression. Such cell selection by flow cytometry may circumvent the long and tedious process of picking and analyzing transfected cell clones selected by co-transfection with a drug-resistance gene.

Although b-lactamase is a relatively new addition to the list of genetic reporters, it is likely to become increasingly important in gene expression analysis, because the system combines the sensitivity of enzymatic cleavage of the substrate with the ability to observe, to sort, and, potentially, to manipulate living cells.

5. Reporter Gene Vectors

While significant advances have been made in reporter gene technologies, generating new reporter variants and developing novel substrates, advances have been made similarly in developing gene expression vectors that improve the transcriptional and translational efficacy of the reporter genes. A large number of different reporter gene expression vectors are currently available from a range of companies. In many cases, this has involved customizing the genes for the different contexts in which they are used. Many of the reporters are derived from prokaryotic genes or eukaryotic cDNAs. To improve translational efficiency, most reporter genes are engineered to contain an artificial eukaryotic translation initiation sequence (Kozak sequence) (22) and a polyadenylation signal. In many cases a small **intron** is included in the transcript, because full RNA processing has been found to contribute to message stability and transport. Reporter vectors also include a variety of genetic elements that increase their versatility. To reduce the need for cotransfection, reporter genes may be expressed as part of a bicistronic message, in which translation of the reporter gene may be initiated downstream of a test gene, at a viral internal ribosome entry site (23). Alternatively a gene of interest and the reporter may be expressed in opposite directions from a bidirectional promoter (24).

Traditionally reporter genes have been used to study gene regulation by cloning *cis*-**acting** test enhancer/promoter sequences into a multiple cloning site upstream of the reporter gene. In addition, reporter cassettes are becoming available in which the reporter genes are placed under the control of a variety of specific **transcription factor** binding sites or **response elements**, which then report on the induction of *trans*-**acting** events. Such reporter-gene cassettes can give transcriptional readouts in response to a variety of external stimuli, such as receptor binding, protein–protein interactions, and **virus infections**, which induce specific signal transduction cascades and transcription factor binding. Examples include the NF-TA–b-lactamase reporter described above (21), and reporters under the control of **cyclic AMP** response elements (CRE) (25) or **retinoic acid** response elements (RAREs) (26).

In summary, a range of reporter genes are in common use, some of which are better suited to some applications than others. Many parameters need to be considered in selecting a reporter for a specific experiment, namely message and protein turnover, suitability for *in vitro* or *in vivo* work, assay sensitivity, assay detection, substrate availability, and cost. The field of reporter gene technology is a rapidly advancing field, and novel reporters and substrates will continue to be developed to meet the changing demands of biologists.

Reporter Groups

Biochemical reactions are most easily followed by routine spectroscopic methods, such as **absorbance spectroscopy** and fluorescence spectroscopy. Spectroscopic methods are fast and sensitive, they allow the on-line detection of changes, and they are nondestructive. The chromophore that changes its absorbance or fluorescence during the reaction of interest (which can be an enzyme activity assay, **ligand binding**, protein association, or a conformational change) is called a reporter

group.

In the simplest case, the reporter group is an intrinsic constituent of one of the reactants, such as an aromatic amino acid residue of a protein, or a firmly bound **prosthetic group**, such as a heme group. Absorbing or fluorescing **coenzymes** or substrates such as **NADH**, pyridoxal phosphate, or **FAD** are also very useful reporter groups. If natural substrates do not contain chromophores, substrates that are modified with chromophoric groups can be employed. Widely used are nitrophenyl esters or amides as chromogenic substrates for proteinases, esterases, or **phosphatases**, or chromogenic sugar derivatives as substrates for glycosidases. For **nucleotide-binding** proteins, a variety or fluorescing derivatives of adenosine nucleotides are available.

Proteins can be labeled by the covalent attachment of chromophoric reporter groups. Often fluorescing groups, such as dansyl, pyrene, rhodamine, or fluorescein, are attached. These groups are usually linked to lysine or cysteine residues. Accessible cysteine residues can be introduced at specified positions of a protein by site-directed mutagenesis. It is important to check that labeling is site-specific and that the activity of the protein is not changed by the covalently-linked reporter group. Detailed lists of chromophores and fluorophores that are useful as reporter groups for biochemical reactions are found in (1-3).

Repressors

Encoded within the DNA of every living organism are the **genes** that determine the structures of molecules that constitute the cells. At any given time during its life, the cells that comprise the organism only need the products of a subset of all the genes carried by that cell. The production of unneeded gene products is a waste of precious resources. Moreover, in multicellular organism, these unneeded gene products can disrupt the orderly progression of the organism's growth and development or can cause disease. Hence, the production or expression of the genes within a cell is tightly regulated. Early in the study of gene regulatory mechanisms, Jacob and Monod (1) advanced the idea that gene regulation could occur by preventing or repressing the expression of genes. According to their idea, molecules called *repressors* prevented the cellular machinery from reading and synthesizing the gene products in a process known as transcription. The operon hypothesis of Jacob and Monod was so persuasive that it was initially thought that all gene regulators would be repressors and function by negatively regulating transcription. Subsequent studies revealed that gene expression is also positively regulated by transcriptional activators. In contrast to negatively regulated, genes whose expression is positively regulated are not expressed in the absence of the regulatory molecule. That is, the gene products are not made unless a regulatory molecule stimulates the cellular machinery to transcribe the gene.

Gene expression can be regulated not only at the level of transcription, but also at the subsequent step of translation of gene products into proteins and at the level of regulation of protein and/or

activity. This entry will focus exclusively on the negative regulation of gene transcription. Both transcription and translation are complex multistep processes, however, so there may be parallels in the overall strategy of negative regulation in these two processes. Hence, as the study of the control of translation matures, a variety of mechanisms by which negative regulators function in this process are likely to be found.

An understanding of how repressors of gene transcription function requires an introduction to the process of transcription. Although transcription initiation in eukaryotes is a more complex process than in prokaryotes, the fundamental steps appear to be similar in the two classes of organisms. Thus, for the purposes of simplicity, the description of the steps leading up to the assembly of the cellular machinery capable of juggernaut-like transcription will focus on prokaryotes as a model. Key differences between prokaryotic and eukaryotic transcription initiation will be pointed out in this context.

Initiation of transcription in prokaryotes is comprised of a series of ordered steps. At the outset, the **RNA polymerase** enzyme that is responsible for synthesis of the transcribed product recognizes and binds to a specific sequence in DNA called the **promoter** . Most bacterial promoters contain two conserved regions, namely, the –35 and –10. Specific binding promoter by prokaryotic RNA polymerases is governed by the sigma factor of RNA polymerase (2, 3). Generally, the strength of a promoter is related directly to how tightly the s subunit binds the –35 and –10 sequences. Most promoters with either a near-consensus –10 or –35 sequence are transcribed with moderate efficiency. The s subunit is only needed for promoter-specific transcription initiation; in the absence of s, the RNA polymerase can initiate transcription at the ends of DNA or at nicks or gaps in a nonspecific manner. Moreover, the RNA polymerase-associated s subunit is not needed for the elongation process and is released from the enzyme during elongation of initiated transcripts. In a step subsequent to specific binding of RNA polymerase to the promoter forming a “closed complex,” several lines of evidence suggest that the enzyme undergoes an isomerization step signaling a more intimate interaction between the enzyme and DNA. In this complex, the so-called intermediate complex, the DNA substrate has not yet unwound, but the enzyme–DNA complex is more resistant to dissociation than is the closed complex (4).

The responsibility for RNA synthesis in eukaryotes is divided between three RNA polymerase enzymes. In all three, specific initiation by the RNA polymerase requires the assembly of a “preinitiation complex” (PIC) (5). The process of forming the PIC will be illustrated by considering assembly of the complex needed to direct transcription of messenger RNAs by RNA polymerase II. Unlike prokaryotic RNA polymerase, the promoter-specificity-determining proteins of the PIC assemble at the promoter prior to binding of the RNA polymerase. These proteins bind in an ordered fashion on the promoter DNA, in a complex that is nucleated by the transcription factor TFIID, which contains the DNA recognition subunit TATA binding protein (TBP) (for review, see Ref. 6) (see TATA Box). This subunit binds in a sequence-specific manner to the TATAAAA sequence located between 20 and 45 bp upstream of the transcriptional start site. Association of the RNA polymerase with this part of the PIC nucleates the binding of several other factors, leading to the formation of an RNA polymerase–DNA complex that is tightly engaged with the DNA, but has not yet unwound the DNA. This complex has been likened to the intermediate complex seen in the transcriptional initiation reaction of prokaryotic RNA polymerases. The protein–DNA and protein–protein contacts that govern the formation of the PIC are relatively weak. Hence, in eukaryotes, efficient gene expression often requires the activity of transcription activator proteins. These proteins often function to recruit members of the PIC to the promoter and/or stabilize their interaction with DNA or each other.

Subsequent to the tight engagement between RNA polymerase and promoter DNA in both prokaryotic and eukaryotic RNA polymerase-promoter DNA complexes, a second isomerization occurs that exposes the bases of the template strand of the DNA. This DNA-unwinding step leads to the formation of the open promoter complex. In this configuration, the RNA polymerase is poised to begin synthesizing RNA rapidly from the nucleotide triphosphate precursors. Within prokaryotic

RNA polymerase, formation of the open promoter complex occurs without the input of energy or the assistance of additional proteins. In eukaryotic RNA polymerases, strand separation requires the hydrolysis of ATP and may require the action of the TFIIH subunit. The ATP is used both to catalyze the **helicase** activity of the PIC and to **phosphorylate** the *C*-terminal repeated sequences contained on the largest subunit of the RNA polymerase enzyme. Both of these actions appear to be required to release the RNA polymerase from the PIC.

The final step of transcript initiation is the progression of the RNA polymerase enzyme beyond the first few bases of the transcript. At certain promoters, prokaryotic RNA polymerase enters an idling mode wherein it repetitively synthesizes abortive transcripts between 3 and 12 bases in length. Transition from this abortively initiated complex to the elongating RNA polymerase enzyme is marked by the loss of the s subunit. Although eukaryotic RNA polymerases may initiate abortively, the process does not appear to be a major step along the initiation pathway. Transition to the elongating form of the eukaryotic enzyme may require additional cofactors that promote or inhibit juggernaut synthesis by the enzyme.

In both prokaryotes and eukaryotes, repressors of transcription initiation could, in principle, interfere with any step along the initiation pathway. Moreover, they could act directly on the enzyme itself or function in an indirect manner. The remainder of this entry will focus on specific repressors that act at particular steps along the initiation pathway. The mechanism of each repressor's action will be discussed to the extent that it is known.

1. Repressors of RNA Polymerase Binding at the Promoter

The classical model of repressor function put forth within the operon theory of Jacob and Monod (1) proposes that repressors block access of RNA polymerase to the promoter by occluding the RNA polymerase binding site. Although several prokaryotic repressors use this mechanism, it is not as prevalent as previously thought. The most clear-cut example of repression by promoter occlusion is the **lambda cI repressor** blockage of RNA polymerase binding at the P_R promoter (7). The binding sites for l cI repressor surround the conserved –10 and –35 sequences in the promoter. Examination of the RNA polymerase and l cI repressor binding sites reveals the occupancy of the repressor sites by protein blocks access of RNA polymerase to the conserved sequences of the P_R promoter. This observation does not mean that RNA polymerase cannot bind at in the vicinity of the P_R promoter sequence. In fact, studies with homologous systems show the RNA polymerase and another cI repressor can simultaneously occupy the DNA at the promoter (J. Xu and G. B. Koudelka, unpublished results). This observation suggests that alternative binding sites for RNA polymerase may exist at P_R. Hence l cI repressor-mediated repression at P_R may occur not by inhibiting RNA polymerase binding at P_R, but instead by preventing it from forming a complex at the promoter that would be able to initiate transcription.

In eukaryotes, the transcriptionally competent RNA polymerase assembles at the promoter only after formation of a PIC; there are no repressors that specifically prevent access of RNA polymerase to the promoter DNA. However, several mechanisms exist that prevent the assembly of the PIC or association of RNA polymerase with the complex in either a global or promoter-specific manner.

The assembly of the PIC can be inhibited by the formation of chromatin. Nucleosomes are the primary component of chromatin. DNA associates with nucleosomes in a relatively non-sequence-specific manner by wrapping around this large multisubunit protein. DNA binding by nucleosomes obstructs access of the proteins that form the PIC to the promoter by burying them within the nucleoprotein complex (8). Adding the histone H1 to nucleosome–DNA complexes links them together, stabilizing and compacting the nucleoprotein structure, enhancing the binding inhibitory effect (9). Repression of transcription by chromatin can occur globally, resulting in the inactivation of entire regions of the genome, or locally, inhibiting expression of only one gene. Local inhibition

appears to result from the presence of nucleosomal positioning sequences near the promoter. These sequences bind with high affinity to the nucleosome, resulting in precise placement of the nucleosome over the assembly point for the pre-initiation complex (10). Global transcriptional repression by chromatin (also known as **silencing**) probably results from the folding of large blocks of nucleosomal DNA into an especially compacted form that is refractory to the formation of active transcription complexes (11). The compacted form of the DNA is very stable, presumably as a result of the attachment of these silenced region to the proteins of the nuclear superstructure (nuclear matrix). The most extensive example of silencing occurs in female mammals, where one of the two X chromosomes is not used as a transcription template in each cell. X chromosome inactivation is extraordinarily stable: Once an X chromosome has been inactivated, it is maintained in this state in all subsequent cell divisions, despite repeated replications of the DNA (12).

As alluded to above, most eukaryotic promoters require a constellation of transcription activators in order to be efficiently transcribed. Hence, complete repression of a promoter could be achieved either by interfering with the action of each of a number of activator proteins (see text below) or by acting at a step common to all initiation reactions, the binding of components of the PIC to the promoter DNA. The former mechanism provides a method by which expression levels can be modulated over a wide range. This latter mechanism is analogous to the classical ideas of repressor function and are distinguished from repressors of activated transcription by their ability to repress basal transcription. An example of this type of repressor is the Dr1 protein (13). Proteins that belong to this class of repressors must function early in the PIC assembly pathway, because the more complete complexes are refractory to the repressing effects of these proteins.

2. Repressors That Prevent RNA Polymerase Open Complex Formation

In bacteria, the DNA-bound RNA polymerases progress through at least two isomerization steps prior to strand separation to form the open complex. Although repressors could act at either of these two steps, the transient nature of the intermediate complexes has prohibited detailed studies on the rates of formation and of breakdown of this species. This prohibition prevents a complete understanding of the mechanisms of action of repressors that act on these isomerization steps.

One of the best understood and mechanistically interesting repressors of RNA polymerase isomerization is the MerR protein. This protein influences the transcription rate from mercury-dependent promoters by binding within the promoter. MerR binds as a homodimer to a region of dyad symmetry within the merOP region (14, 15). The mer operon contains two overlapping and divergently opposed promoters, designated P_R and P_T. MerR is responsible for controlling transcription from both of these promoters. Binding of nonliganded MerR to this region represses transcription from both the structural gene promoter, P_T, and the divergently oriented merR promoter, P_R. Upon binding of either liganded or nonliganded MerR protein, the P_R promoter is repressed, apparently through steric interference of the RNA polymerase, for the MerR binding site overlaps the +1 transcription start site (16, 17). At P_T, however, the binding of nonliganded MerR to its site between the –35 and –10, partially overlapping the –35 hexamer, results in the recruitment of S70 RNA polymerase holoenzyme but maintains repression (14). Insight into why the merR-RNA polymerase-promoter is transcriptionally inactive can be ascertained by considering what merR does to activate the P_T promoter. Binding of the allosteric inducer Hg(II) to the MerR–DNA complex results in a structural rearrangement that underwinds the DNA between the –35 and –10 and relaxes the MerR-induced DNA bend (18, 19). This results in dihedral angles between the –35 and –10 elements that would be similar to those found in a promoter with an optimal 17-bp spacer between these two elements. Additionally, the relaxation of the MerR-induced DNA bend would then place both the –35 and –10 elements in contact with the RNA polymerase, facilitating transcription. So it appears that repression by merR occurs by stabilizing a conformation of the DNA in the RNA polymerase-promoter that is incompatible with open complex formation.

Although the assembly of PICs on eukaryotic promoters occurs in the absence of additional components, efficient transcriptional initiation at most promoters requires the presence of transcriptional activator proteins bound to DNA at sites nearby or at a distance. Hence progression from the relatively inactive PIC to actively transcribing RNA polymerase can be repressed by interfering with the action of these activator proteins.

There are three classes of mechanism by which repressors may interfere with the action of a transcriptional activator. In the first two classes, the repressor prevents DNA binding by the activator. In one case, binding of the repressor to a site that either completely or partially overlaps the binding site of the activator protein competitively inhibits DNA binding by the activator. In another case, the repressor may bind to an activator and prevent its DNA binding. Often repressors of this type interact with activator proteins that have multiple subunits. Usually, the repressor shares homology with one subunit of the activator protein, but is unable to contribute a critical component to DNA recognition. In this type of inhibition, the repressor inhibits DNA binding by functioning as a negative dominant mutant subunit of the activator protein. The third type of repressor "quenches" activator function by preventing transmission of the signal from the activation surface of the DNA-bound activator protein to the promoter.

Repressors that function by competing directly with activator DNA binding are not common in either prokaryotes or eukaryotes. An example of this type of repressor is the *Krüppel* (*Kr*) protein. In *Drosophila*, *Kr* binding sites overlap the binding sites of several activator proteins. One of the better-characterized examples is in the *eve* promoter, where the *Kr* sites overlap the binding sites of the bicoid protein. *Krüppel* inhibition of bicoid function alters the pattern formation during embryogenesis in flies (20). By contrast to the paucity of repressors that function by competitive DNA binding, there are many repressors that compete for association with one of the activator subunits. Regulation of the entire class of basic helix–loop–helix proteins occurs ubiquitiously by this mechanism in eukaryotic developmental programs. For example, during development in several organisms, the ability of myoD to bind DNA and activate genes required for muscle development (21) is completely inhibited by the interaction of this protein with the Id (22) or **Notch** (23) proteins. These repressor proteins contain a region that is identical to the oligomerization domain of myoD, but lack the basic region used by myoD to make contacts with DNA. Therefore an Id-myoD heterodimer is inactive in transcriptional activation because it is incapable of binding DNA.

Repression by quenching of an activator surface requires that both the activator and repressor occupy the DNA at the same time. This phenomenon has been observed in a wide variety of systems and often involves an interaction between two proteins that, on their own, function as transcription activators. For example, YY1 activates transcription of a number of different promoters (24). In the *c-fos* promoter, however, binding of YY1 blocks the **cyclic AMP**-dependent induction of this gene. YY1 induces a bend in the promoter DNA that prevents the interaction of the protein bound at the cAMP response element with the PIC (25). Repression by quenching does not always require that the repressor protein be a DNA-binding protein. In this type of repression, a bound protein may recruit a "corepressor" that interferes with the interaction of the activator protein with a coactivator. In one well-studied case, the activation of a set of promoters by DNA-bound Mad-Max heterodimer is repressed by the binding of a member of the mSin3A/B complex. This protein in turn recruits a histone deacetylase that deacetylates the histones at the promoter, which in turn inhibits transcription initiation (26, 27).

3. Repressors that Prevent RNA Polymerase Escape from the Promoter

The observation that some repressors function after synthesis of the first phosphodiester bond appears to be antithetical to the conservatism of cellular metabolic regulation. The wisdom of this mode of transcriptional regulation appears, however, upon considering the need of an organism to respond extraordinarily rapidly to a change in environmental conditions. According to this idea, the RNA polymerase negatively regulated post-initiation is "primed" and ready to go in response to the induction signal. Not surprisingly then, two proteins that control the carbon source utilization of *E.*

coli, the Lac repressor and Gal repressors (see Gal Operon), are thought to exert their repressive effects, at least in part, by this mechanism (28, 29).

One of the best-studied examples repressors of promoter escape is the repression of the early A2c promoter of f29 phage by the p4 repressor. In this system, p4 and RNA polymerase bind cooperatively at the promoter, forming a complex that incorporates nucleoside triphosphates into abortive RNA transcripts. However, the RNA polymerase does not proceed to make full-length transcripts until the level of p4 falls below that needed to occupy its binding site (30).

Until now, repressors that regulate promoter escape have only been identified in prokaryotic organisms. On the one hand, their absence in eukaryotes may represent a fundamental difference in the time scale in which the two types of cell must respond to the environment to survive. On the other hand, these repressors may exist in eukaryotic organisms, and it may just be a matter of time before we discover yet another example of the commonality of transcriptional regulation between prokaryotes and eukaryotes.

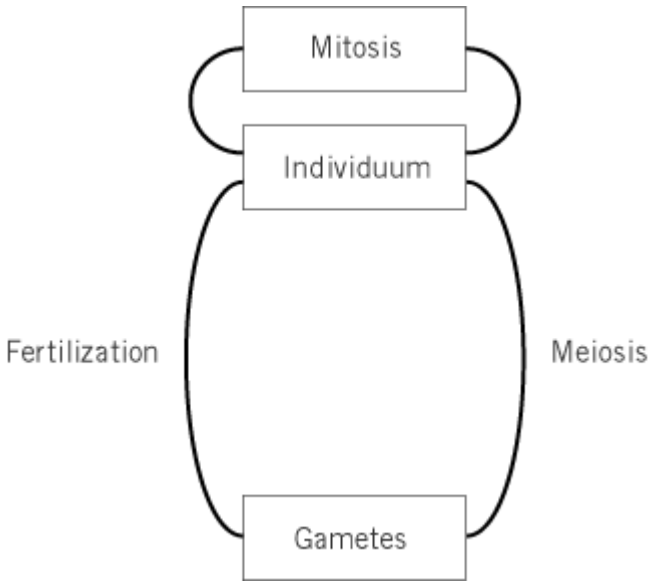
Reproduction, Animal

Reproduction is the process of genetic transfer to the next generation. In animals, reproduction involves two sexes, **meiosis** and multicellularity (1). Thus, reproduction in animals is different from reproduction in **prokaryotes**, such as **bacteria**. A further characteristic of animal reproduction is that animals are mobile and therefore able to spread their own **genes** in a much more efficient way than, for example, **plants** can do. Another characteristic that is related to this subject is the necessity for sexual reproduction. Unlike plants or bacteria, animals have no vegetative reproduction pathways. The rare **parthenogenic** events that occur in some insects like bees and sometimes in frogs are very special exceptions and cannot be considered to be the rule. Also, apart from some fishes (which can be polyploid) or certain stages after reproductive events in some insects, most animals tend to be **diploid** individuals. During gametogenesis, the diploid genotype has to be reduced in order to provide **germ cells** that are haploid; these events, therefore, involve both **mitotic** and meiotic divisions. The joining of the maternal and paternal nuclei during karyogamy results in the creation of a diploid individual (Fig. 1).

Figure 1. Diagrammed relationship between the individual, gametes, meiosis, mitosis, and fertilization. As a rule, mammals are diploid, whereas their gametes are reduced during meiosis to a haploid stage. After a male and a female gamete join during fertilization, a diploid individual is generated. Cells other than the germ cells of the individual divide mitotically.



In animals, there is a strict division between **somatic** and **germ line cells**. Even after just the first stages of cell division following fertilization, germ cells are determined, and they migrate to the primordial urogenital tract, where they develop according to their genetic constitution into either spermatogonia or oogonia. Somatic cells are always diploid, apart from the **G2** and **M phase** of the cell cycle, in which the genome is temporarily **tetraploid**. There are no certain stages in animals and in the animal reproductive cycle as there are in plants during which the whole individual undergoes a haploid or a diploid phase. Although there is a strict separation of somatic and germ cells, neither cell type acts completely independently of the other. The **phenotype**, ie, the morphology and the ethology of animals, is most certainly determined by actions that are regulated by the germ cells. For instance, puberty causes animals to change their phenotype. In frogs, maturation can easily be seen in the metamorphosis of tadpoles to mature frogs. Most of these developmental processes are, in terms of animal reproduction, determined by the action of hormones. For this reason, it is not surprising that a number of hormone **receptors** are present, not only in organs that are directly related to reproductive events but also in organs and somatic tissues in which no direct link with reproductive activity is presupposed. This is, for example, the case with the estrogen receptor, which is expressed in a number of tissues.

Animal reproduction is not restricted to the events of the production of germ cells, reduction to a haploid stage, fertilization, and early development of the embryo. Regarding certain aspects of reproduction, some homology even to reproduction in plants can probably be found. A very important and unique aspect of reproduction in animals, however, is the event of giving birth. Interestingly, there are vast differences among species. The predominant one can be seen when comparing animals in which extracorporal fertilization is the rule (as in spawning frogs) with more sophisticated species, like chordates. In extracorporal fertilization, only the release of the mature gametes into a liquid medium (in most cases, water) has to be regulated. From then on, gamete interaction is directed by protein-protein interactions, as genetic control by the nucleus has not been observed. **Chemotactic** attraction then directs the motile gamete, which is normally that of the male, to the **oocyte**. In species that give birth, not only the gametogenesis, behavioral, and ethological aspects have to be considered to achieve reproductive success, but the hormonal machinery to induce labor, milk secretion, and changes in behavior are also important. This is of sufficient interest to elucidate the molecular basis for the development of these metabolic events.

Animal reproduction also comprises the events that have to take place after birth of the offspring, known as brood care. Although brood care is an important element in most of the primates, in other species the intensity of the brood care varies. In species with extracorporal fertilization, the intensity

of brood care can be extremely low, as can be seen in frogs or in sea urchins. In sticklebacks, the brood care involves at least the construction of a nest, whereas, in birds, brood care also entails feeding the offspring. An interesting exception to this is the cuckoo, which has developed a mechanism that allows it to abuse the brood care of other singing birds. In higher species, brood care also involves the phase of imprinting and teaching social behavior. This is extremely important in terms of animal reproduction because it can be shown that artificially promoted faulty imprinting can lead to animals that have lost the drive to mate. The brood care does not occur in plants or in bacteria and is therefore a characteristic of reproduction in animals, especially in higher mammals with a sophisticated social structure.

Response Element

A response element is a short DNA sequence, usually between 5 and 20 base pairs in length, that is found in all **genes** that show a particular pattern of **gene expression**. Moreover, it can confer that pattern of expression on another gene when artificially linked to it.

Different genes have a wide variety of different expression patterns, with particular genes being expressed in specific tissues of the body (see Development), while others are activated in response to particular hormones or other inducers. Such regulation is primarily produced at the level of transcription by controlling which specific genes are transcribed into RNA in a particular tissue or in response to a particular stimulus; all the other stages of gene expression, such as RNA splicing, transport to the cytoplasm, and translation into protein follow more or less automatically. This conclusion led to a detailed study of the DNA sequences of individual genes in the hope of identifying elements that might confer the response to a particular stimulus or produce a particular tissue-specific pattern of transcription.

Such studies at the DNA sequence level led to the identification of a number of short response elements that were found in the regulatory regions of all genes that responded to a particular stimulus, but not in genes that did not respond. A selection of such response elements is listed in Table 1(1), and several of these are discussed in individual entries (see Glucocorticoid Response Element, Hormone Response Elements, Metal Response Element, Serum Response Element, and Sterol Response Element). The purpose of this article is to provide a more general overview of the nature of response elements and the manner in which they function.

Table 1. Sequences that Confer Response to a Particular Stimulus

Consensus Sequences	Response to	Protein Factor	Gene Containing Sequences
CTNGAATNTT CTAGA	Heat	Heat-shock transcription	hsp70, hsp83, hsp27, etc.

		factor	
T/G T/A CGTCA	Cyclic AMP	CREB/ATF	Somatostatin fibronectin, a-gonadotrophin c-fos, hsp70
TGAGTCAG	Phorbol esters	AP1	Metallothionein IIA a_1-antitrypsin collagenase
$CC(A/T)_6GG$	Growth factor in serum	Serum response factor	c-fos, *Xenopus* g-actin
RGRACNNN TGTYCY	Glucocorticoid	Glucocorticoid receptors	Metallothionein IIA tryptophan oxygenase, uteroglobin, lysozyme
RGGTCANNN TGACCY	Estrogen	Estrogen receptor	Ovalbumin, conalbumin, vitellogenin
RGGTCAT GACCY	Thyroid hormone retinoic acid	Thyroid hormone receptors	Growth hormone myosin heavy chain
TGCGCCCGCC	Heavy metals	Mep-1	Metallothionein genes
AGTTTCNN TTTCNC/T	Interferon-a	Stat-1 Stat-2	Oligo A synthetase guanylate-binding protein
TTNCNNNAA	Interferon-g	Stat-1	Guanylate-binding protein, Fc g receptor[a]

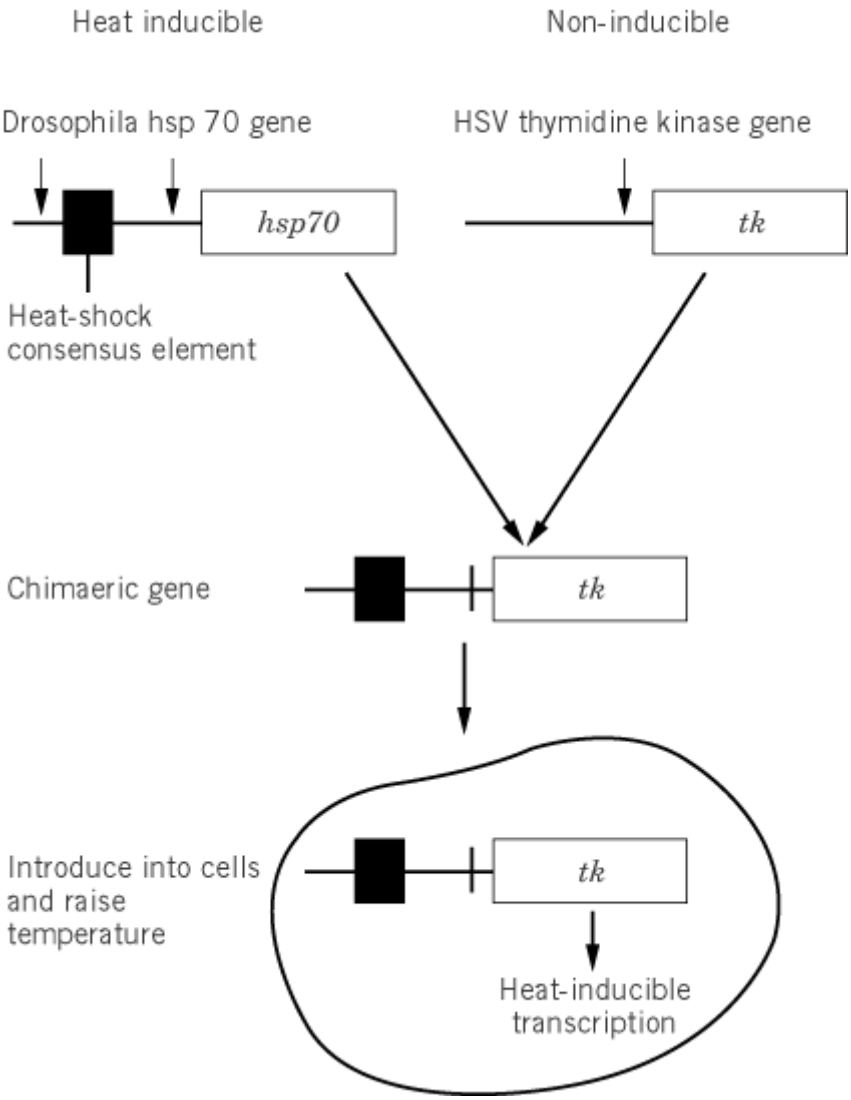
[a] N, any base; R, purine; Y, pyrimidine.

Although the presence of a specific short DNA sequence in all genes that respond to a particular stimulus strongly suggests that this element confers the response to that stimulus, it is necessary to prove that this is the case. In order to do this, the putative response element must be transferred to a gene that is not normally responsive to the stimulus and consequently shown to respond to it.

One of the earliest examples where this was achieved concerns the heat shock element (HSE), which is found in the regulatory regions of genes whose expression is increased in response to elevated temperature. Thus, for example, the gene encoding the 70-kDa heat shock protein (hsp70) contains an HSE within the gene **promoter** that is located approximately 90 bases upstream of the transcriptional start site. Pelham (2) took this HSE and linked it to the non-heat-inducible **thymidine kinase** (tk) gene of the eukaryotic **herpes** simplex virus. He then introduced this hybrid gene into mammalian cells and observed that the hybrid gene could be activated by elevated temperature, leading to increased thymidine kinase production, even though the tk gene was not normally heat inducible (Fig. 1). Hence the HSE constitutes a bona fide response element that can confer the response to heat upon another gene that is not normally heat-inducible. Such a direct demonstration

of the role of a particular element in producing a particular response has now been provided by similar methods for the other sequences that are listed in Table 1. Thus, for example, linking a glucocorticoid response element to another gene renders that gene responsive to glucocorticoid even though that gene normally does not respond in this manner, and so on.

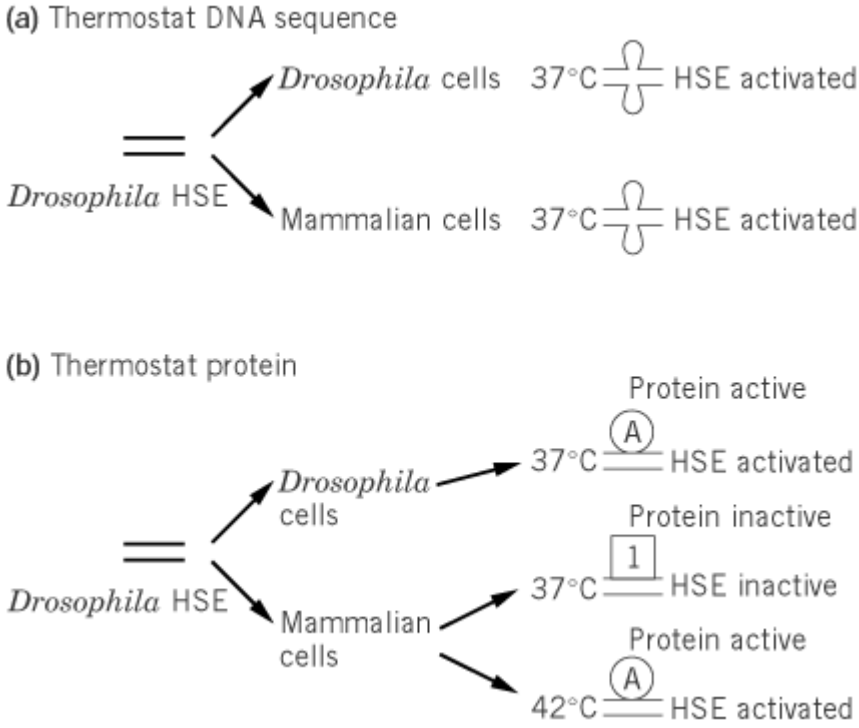
Figure 1. Demonstration that the heat shock element mediates heat inducibility. Transfer of this sequence to the thymidine kinase gene, which is not normally inducible by heat, renders this gene heat-inducible.



The above example concerning the HSE also illustrates another aspect of response elements. Thus, the HSE used by Pelham was taken from the hsp70 gene of the fruit fly ***Drosophila*** *melanogaster*, but the hybrid gene was introduced into mammalian cells. The successful functioning of the fly gene in mammalian cells not only indicates that this process is evolutionarily conserved but permits a further conclusion about the way in which the effect operates. Thus in the cold-blooded *Drosophila*, 37°C would represent a thermally stressful temperature at which the heat shock response would normally be active. Thus if the HSE acts as a temperature sensing thermostat (Fig. 2a), it would be set to go off at 37°C rather than at 42°C, which is the thermally stressful temperature for mammalian cells. In fact, however, the hybrid gene in this experiment was inactive at 37°C in the mammalian cells and was induced only at 42°C. Hence this response element sequence does not act itself as a thermostat but rather must act by being recognized by a cellular protein that is activated only at an

increased temperature characteristic of the mammalian cell heat shock response (Fig. 2b).

Figure 2. Predicted effects of placing the *Drosophila* heat shock element (HSE) in a mammalian cell if the element acts as a thermostat detecting increased temperature directly (**a**) or if it acts by binding a protein that is activated by raised temperature (**b**). Note that only possibility (**b**) can account for the observation that the *Drosophila* HSE activates transcription in mammalian cells only at the mammalian heat shock temperature of 42°C and not at the *Drosophila* heat shock temperature of 37°C.



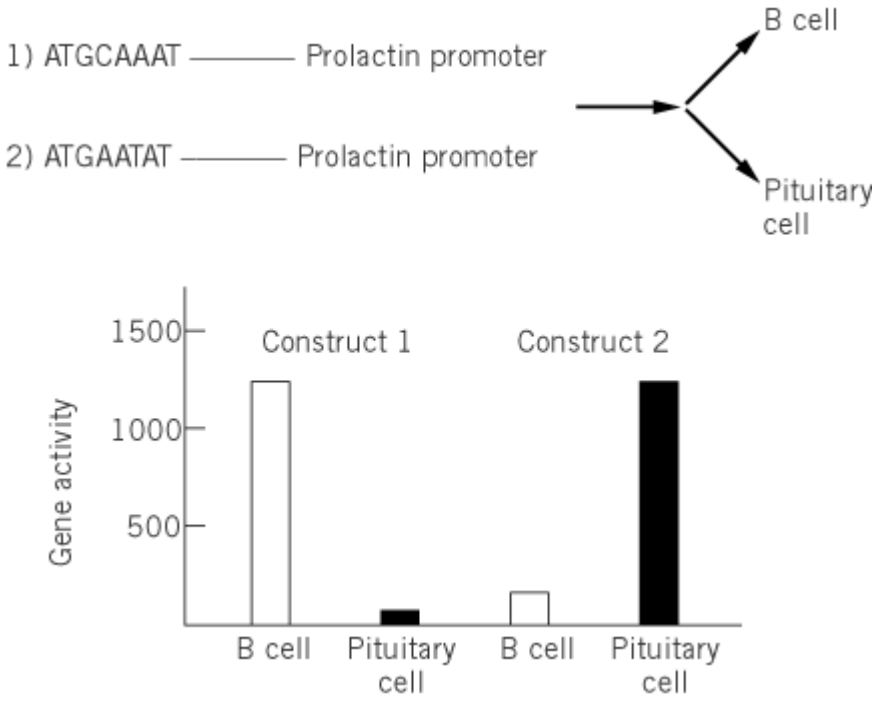
This experiment thus indicates that response elements act by binding specific proteins known as transcription factors. These transcription factors are specifically synthesized or activated post-translationally in response to a specific stimulus and then activate gene transcription via their specific response element. Hence the specificity provided by different response elements producing different patterns of gene activation arises because they bind different transcription factors, which become active in response to these stimuli.

The nature of the transcription factors that bind to each of the response elements listed is shown in Table 1. In the case of the HSE, it achieves its effect by binding a protein known as the heat shock factor (HSF). In response to elevated temperature, HSF undergoes a transition from an inactive monomeric form to a trimeric form that can bind to the HSE and activate transcription of the heat shock genes (3).

Although response elements were first identified in genes that respond to specific stimuli, similar DNA sequence elements in the promoters of tissue-specific genes also play a critical role in producing their tissue-specific pattern of gene expression, by binding factors that are present in an active form only in a specific tissue. Thus, for example, the promoter of the immunoglobulin heavy- and light-chain genes contain a response element known as the octamer motif (ATGCAAAT) (4) that is important in their specific expression in B lymphocytes and not in other cell types. The octamer motif can confer B-cell-specific expression on an unrelated promoter (5), indicating its critical role in this process. Interestingly, the related sequence ATGAATAA/T is found in the genes for prolactin and for growth hormone, which are expressed specifically in the anterior pituitary gland

(6). If this short sequence is inserted upstream of a promoter, the gene is expressed only in pituitary cells, indicating its critical importance in producing pituitary-specific gene expression. In contrast, if this short sequence is replaced with the octamer motif, which differs by only 2 bases, it will direct expression of the same promoter only in B cells (7) (Fig. 3).

Figure 3. Linkage of the octamer motif ATGCAAAT (1) and the related motif ATGAATAT (2) to the prolactin promoter and introduction into B cells and pituitary cells (**a**). Note that the octamer-containing construct 1 directs a high level of activity in B cells but not in pituitary cells, whereas construct 2 directs a high level of gene activity in pituitary cells but not in B cells (**b**).



Thus, specific short DNA sequences can produce either tissue-specific patterns of transcription or result in a gene responding to a particular stimulus. Such sequences play a central role in the regulation of gene transcription acting by binding specific regulatory transcription factors.

Restriction Enzymes

Restriction enzyme refers here to the bacterial type II restriction **endonucleases**—one type of a general class of enzymes that function in restriction–modification systems (see Restriction–Modification Systems for other types of restriction enzymes). Type II restriction enzymes are ubiquitous and simple in composition. They are used extensively in recombinant DNA work and, in fact, made the technology possible. The restriction enzymes are Mg^{2+}-requiring, homodimeric proteins that cleave at defined phosphodiester bonds within or adjacent to specific sequences of 4–8 base pairs (the "restriction site") of double-stranded DNA. The phosphodiester bond cleavage of each DNA strand produces DNA fragments with 5′ phosphate and 3′ hydroxyl termini. The scission of both strands results in either staggered-end or blunt-end double-strand DNA fragments (see Staggered Cut). Depending on the endonuclease used, the termini of the duplex DNA fragments may be completely duplex (blunt) or have protruding 5′ or 3′ single strands (otherwise known as "staggered", "sticky", or cohesive ends). Almost all type II restriction enzymes cut at DNA sequences that are **palindromic**, that is, have a dyad axis of symmetry, so that their complementary strand has the same sequence. Examples are the target sites for *Eco*RI (GAATTC) and *Fin*II (CCGG). Some restriction enzymes classified as type II are monomeric enzymes and cut at defined distances outside specific asymmetric recognition sequences.

Approximately 2600 different restriction enzymes are known, with over 230 cleavage specificities (1). Bacteria synthesize minute amounts of the enzymes to serve their biological function (see Restriction–Modification Systems), but the overexpression of cloned restriction enzyme genes substantially facilitates their preparation and purification. The cognate modification methyltransferase partner of the restriction enzyme prevents endonucleolytic cleavage by methylating specific adenosine or cytosine nucleotides in the recognition sequence (see Methyltransferase, DNA), resulting in a sequence that is refractory to endonuclease hydrolysis.

Under optimized reaction conditions and presumably *in vivo*, restriction enzymes are highly selective for their canonical restriction sites. Changes in restriction enzyme buffer conditions, however, such as pH, ionic strength, divalent metal ion substitutions (Ca^{2+} or Mn^{2+} for Mg^{2+}), or the addition of organic solvents, can induce inaccurate cutting (star activity). Different restriction enzymes that recognize and cut at the same position in identical recognition sites are referred to as isoschizomers. For example, the *Eco*RI and *Rsr*I restriction enzymes both recognize and cut between the G and A of the canonical sequence, GAATTC. Other restriction enzymes, termed *neoschizomers*, recognize identical DNA sequences but cut at different positions within the sequence. For instance, *Asp*718I (GGTACC) and *Kpn*I (GGTACC) cleave between the two Gs and between the two Cs, respectively.

1. Protein Structures

Little amino acid similarity (15–25% identity) exists among the more than 60 known sequences of restriction enzymes (2), indicative of a diversity of target sites and of mechanisms of recognition and catalysis. However, X-ray crystallography structures of type II restriction enzymes that have little or no amino acid sequence homology (*Eco*RI, *Bam*HI, *Eco*RV, *Fok*I (a type IIs enzyme), *Pvu*II and *Cfr*10I), reveal a common structural motif consisting of a five-stranded b-**sheet** with flanking a-**helices** containing the active site (3, 4).

Which bonds in the DNA are cleaved is determined by the spatial positioning of the restriction

enzyme around the DNA double helix. Cleavable phosphodiester bonds generating 5′ or 3′ overhangs are positioned in the major or minor groove, respectively, whereas cleavable bonds generating blunt cuts are on opposite sides of the helix and near the minor groove (5). Accordingly, restriction enzymes that generate 5′ overhangs, such as *Eco*RI and *Bam*HI, dimerize to align critical catalytic residues adjacent spatially to cleavage sites separated by 4 base pairs, with the enzyme facing the major groove. Blunt-end cutters such as *Eco*RV and *Pvu*II dimerize so that their active sites are located on opposite sides of the DNA helix, with the enzymes facing the minor groove. A restriction enzyme generating a 3′ overhang has yet to be crystallized with DNA. The orientation with respect to the grooves of the DNA may also dictate which motifs are used in recognition. *Eco*RI and *Bam*HI use a **four-helix bundle** to make base contacts in the major groove, whereas *Eco*RV and *Pvu*II use loops or strands in the major and minor grooves (6).

Interestingly, the monomeric type IIs enzyme, *Fok*I, which recognizes a pentameric, asymmetric sequence, and cuts a short distance away to leave a 5′ overhang, has a bilobed structure with the catalytic site in one **domain** and the target recognition site in the other. Also, *Fok*I has an active site that is similar to *Bam*HI, uses a-helices for DNA recognition, and has been modeled to cleave in the major groove (4).

Crystal structures of complexes of the enzymes with their target DNA reveal that some restriction enzymes may utilize DNA distortion and bending in their recognition or catalysis. Cocrystals of DNA with *Eco*RI and *Eco*RV have the DNA bent and unwound, whereas cocrystals of *Bam*HI and *Pvu* II contain regular, B-form DNA. Crystal structures will continue to prove valuable for understanding the recognition and catalytic properties of restriction enzymes.

2. DNA Recognition

For the type II restriction enzymes, the dimer first binds DNA nonspecifically and then transverses the DNA by random linear diffusion, apparently pausing at sites resembling the true restriction site, but continuing until the correct recognition sequence is reached. Linear diffusion, rather than three-dimensional diffusion with random collision, speeds the location of a restriction site by reducing the search to one dimension (7). Restriction enzymes such as *Eco*RI and *Bam*HI bind much more tightly to their recognition sites than to nonspecific DNA, whereas others such as *Eco*RV and *Taq*I bind to nonspecific or target DNA with equal affinities. These latter restriction enzymes achieve specific sequence recognition and cleavage on binding Mg^{2+} (8). The differential target recognition properties of restriction enzymes indicate that specificity discrimination may occur at the level of both the initial enzyme–DNA complex and the correct transition state during catalysis. Specific DNA binding by restriction endonucleases is dependent on a network of electrostatic interactions and hydrogen bonds involving both side-chain and main-chain atoms of the enzyme, plus water molecules, with bases and the sugar–phosphate backbone of the DNA. **Hydrophobic** interactions also contribute importantly to DNA binding. All the interactions, along with deformation of the DNA, promote the precise geometry required for successful catalysis. Suboptimal reaction conditions (see Star Activity) or methylation of DNA hinders or alters the structural geometry needed for recognition specificity and catalysis by restriction enzymes.

3. Catalysis

Depending on the restriction enzyme and the reaction conditions, cleavage of both strands of the recognition sequence occurs in either a sequential or concerted manner (9, 10). Scission of the duplex DNA recognition sequence probably occurs by direct nucleophilic attack of water on the phosphorus atom of the phosphodiester bond, rather than through a covalent enzyme intermediate, since there is inversion of configuration at the scissile phosphate bond (9). The mechanism by which the water is activated to form the nucleophilic OH group has yet to be determined. Several possible ligands in the active site could contribute to removing a proton from water, the most obvious candidate is the catalytically essential Mg^{2+} ion. Acidic catalytic site residues also may serve as

general bases (11) to abstract a proton: Asp90 in *Eco*RV, Glu111 in *Eco*RI, or Glu113 in *Bam* HI (6, 11, 12). It has also been suggested that the negatively charged oxygen atom of the neighboring phosphodiester group may serve in proton abstraction (13). Whereas some restriction enzymes, such as *Eco*RI, probably use one Mg^{2+} ion for catalysis, *Eco*RV apparently needs two; one Mg^{2+} is proposed to generate a catalytically competent complex and the other to activate water for hydrolysis (12, 14). Cleavage by restriction enzymes is independent of the **supercoiling** of the DNA but dependent on the length and sequence context of flanking sequences surrounding the restriction site (10). With turnover numbers in the min^{-1} (reciprocal minute) range, restriction enzymes are catalytically slow enzymes, and the product release is the rate-limiting step (9).

4. Applications

Numerous restriction enzymes with a large variety of sequence specificities are commercially available, and they provide an indispensable tool for cloning and recombinant DNA work. The discovery of restriction enzymes allowed the manipulation of large DNA, which has led to a greater understanding of its structure and information content. Restriction enzymes also provide valuable opportunities for studying DNA–protein interactions and enzyme kinetics. Several applications for the manipulation and analysis of DNA using restriction enzymes are discussed in the Restriction Fragment, Staggered Cut, and Restriction Map articles.

Restriction Fragment

Restriction fragments are discrete pieces of double-stranded DNA having unique termini that result from the cleavage of larger DNA by restriction endonucleases, enzymes that recognize specific sequences (usually 4–8 bp in length, in duplex DNA and catalyze the cleavage of both strands within or adjacent to the sequence to generate **cohesive ends** or **blunt ends** (see Restriction Enzymes and Staggered Cut). The discovery of restriction endonucleases allowed the manageable analysis and manipulation of an otherwise huge, experimentally inaccessible macromolecule. The use of restriction endonucleases also led to the development of engineered DNA **vectors** (**plasmids**, **cosmids**, **bacteriophages**, and *yeast artificial chromosomes* (YACs)), which are self-replicating DNAs that are used as carriers to clone and characterize restriction fragments. Important features of these vectors include selectable phenotypic markers (such as antibiotic resistance genes), unique restriction sites grouped in *multiple cloning sites*, where restriction fragments can be introduced, **promoters** for the expression of the inserted DNA, and mechanisms for DNA replication. Vector or chromosomal DNA can be digested into restriction fragments with one or more restriction endonucleases and analyzed for size and fragment distribution using gel electrophoresis (see Restriction Map). Restriction-fragment size is dependent on the type of restriction endonuclease used and the particular sequence. For instance, assuming a random distribution bases in DNA with a 50% (G + C) composition, a given tetranucleotide sequence will occur randomly approximately every 256 base pairs, whereas a hexanucleotide sequence occurs approximately every 4096 base pairs. Large restriction fragments can be generated by (*1*) rare-cutting enzymes, like the octanucleotide (GC^ GGCCGC , where "^" indicates the hydrolysis site in the DNA recognition sequence) cutter R•*Not*I (where "R•" designates restriction endonuclease), (*2*) partial R•endonuclease digestion resulting from short digestion duration or dilute enzyme concentrations, or (*3*) limited methylation of R•endonuclease sites with the cognate methyltransferase enzyme. The properly sized spectrum of generated restriction fragments can be covalently **ligated** into cloning vectors to form a collection of chimeric DNA molecules that can replicate as individual **clones** once introduced individually into a host organism, such as *Escherichia coli*, by transformation, transfection, or transduction. Such a population of clone-containing fragments encompassing all of the original DNA is called a "gene **library**." The genetic information encoded on an individual restriction fragment or library of fragments is easily amplified and manipulated.

1. Methods for Analyzing Restriction Fragments

Several methods are used to analyze restriction fragments separately or in a collection of clones. In Southern blotting, restriction fragments separated on an agarose gel by electrophoresis are processed by transferring the DNA from the gel to a nitrocellulose filter, which provides a stable support for **hybridization** with single-strand labeled probes containing known sequences of interest. If a restriction fragment contains the complementary sequence, the probe will hybridize, and subsequent analysis of the filter for the label will identify the fragment. It can then be isolated and further characterized by sequencing. Another related method, called colony blotting, involves hybridizing DNA probes to colonies containing recombinant DNA that have been fixed to nitrocellulose filters and lysed . Analysis of the filter can then identify clones carrying sequences of interest. **Chromosome walking** uses a genomic library of clones to determine consecutive DNA fragments for mapping or locating a particular region in the genome. In this technique, a cloned DNA fragment is isolated, and the ends of the insert fragment are subcloned and used as probes to find clones containing the same DNA sequences, specifically, DNA adjacent to that generating the probes. Variations in DNA sequences between individual organisms are revealed by digesting DNA with various restriction endonucleases to reveal *restriction fragment length polymorphisms* (RFLP).

RFLPs result from changes in the fragmentation pattern of a restriction digest due to DNA sequence differences, which can be as small as single-base-pair substitutions. RFLP mapping provides a "genetic fingerprint" of the DNA of organisms. DNA fragments containing regulatory sequences, such as, **promoters** or **operators**, can be analyzed by placing them in vectors containing adjacent reporter genes that encode a protein with a measurable activity. Expression of the reporter gene is thereby placed under the control of the regulatory sequence. For instance, an antibiotic resistance gene can be used to report promoter activity. Only clones carrying the expressed antibiotic resistance gene will grow on media containing the antibiotic. Another approach uses enzymatic or functional assays of cell lysates of clones to identify those carrying a DNA fragment containing a gene that encodes the protein of interest.

The generation of restriction fragments by restriction endonucleases has contributed greatly to biotechnology. Fragmentation and sequencing of DNA allows characterization of genes, as well as probing for similar genes in different organisms using hybridization techniques. Sequencing of restriction fragments also reveals the **open reading frames** (ORF) of new genes, and their spatial organization with respect to other genes. RFLP mapping is important in forensic and medical analysis. Restriction fragments provide a starting point for biochemists and molecular biologists to **mutagenize** genes to determine how resultant changes are reflected in protein structure or function. Specially designed cloning vectors containing powerful promoters can overexpress cloned genes of interest to increase protein production. Molecular cloning of restriction fragments is an invaluable tool that has yielded a wealth of information with widespread applications.

Restriction Fragment Length Polymorphism (RFLP)

RFLP is a simple method of detecting variability in the sequences of **DNA** within the genomes of a population of individuals (ie, **polymorphism**) using mutations at the sites of action of restriction enzymes (1, 2). Restriction enzymes are **endonucleases** that cut DNA at specific, very short base sequences, producing restriction fragments whose average size reflects the frequency with which the specific restriction sequence is found along the DNA. Point mutations may cause restriction sites to disappear, may cause the restriction fragment affected to increase in size by addition of the adjacent one, or may cause new restriction sites to appear, splitting one restriction fragment into two smaller fragments. By separating the resulting restriction fragments by gel electrophoresis in agar, on the basis of their lengths, the patterns of DNA bands can be compared in different individuals. This technique is limited by its ability to detect only mutation events occurring within enzyme restriction sites, which are sequences of only 4 to 6 nucleotides separated by hundreds or thousands of bases. This limitation can be overcome to some extent by using several restriction enzymes; however, in a study of vertebrate mitochondrial DNA using 20 restriction enzymes that are specific for sequences of six bases, only about 3% of the genome will be sampled (3).

Consequently, RFPL is not a very powerful method for analyzing polymorphisms. If applied to a random selection of DNA, it will reveal, approximately, a level of polymorphism comparable to that found with protein **isozymes**. An improvement is the use in **Southern blotting** of specific probes revealing fragments belonging to a restricted region whose polymorphism is under study. In the case of a species whose genome is practically unknown, but for which a large number of probes is available, randomly cloned genome fragments may generate RFLP patterns of some interest. It is best, however, to isolate the section of DNA of interest, expand it by the polymerase chain reaction (**PCR**), subject it to the subsequent action of several restriction enzymes, and analyze the pattern of bands obtained by electrophoresis. Given the very large number of restriction enzymes that are available now, it will often be possible to design simple RFLP tests to reveal the alternatives.

Restriction Map

Restriction mapping is a technique for determining the linear order of restriction sites (see Restriction Enzymes) along a DNA molecule. The restriction fragments that are generated by digestion of DNA with different restriction enzymes, alone or in combination, and separated by gel electrophoresis, are used to deduce a restriction map. The resulting map gives the ordered arrangement of the restriction fragments. The choice of restriction enzyme, whether a rare or frequent cutter, depends upon the size of the DNA to be mapped and the frequency of its sites. For instance, rare-cutting restriction enzymes were used for initial mapping of large genomes like those of *Escherichia coli* and *Homo sapiens*, containing 4.2×10^6 base pairs and 3.3×10^9 , base pairs respectively. The resulting large restriction fragments isolated were further mapped by digestion with more frequently cutting enzymes. The fragments are separated by electrophoresis according to the inverse of their molecular weights, specifically, their lengths. Fragment size is determined by comparing the sample with a collection of standards. To illustrate, a linear 13-kb piece of DNA is mapped using two enzymes, *Eco*RI and *Bam*HI. A diagram of the electrophoretic separation of the digests in an agarose gel is given in Figure 1. The DNA was digested with *Eco*RI, *Bam*HI, and both enzymes. The sizes of fragments produced by single-enzyme digests indicate the number of restriction sites for each enzyme and the distances between them, while the fragments from the double digest indicate the relative distances between the *Bam*HI and *Eco*RI sites (Fig. 2). *Eco*RI digestion produced three restriction fragments, 1, 2.5, and 9.5 kb in size. *Bam*HI digestion also produced three fragments, 2, 5, and 6 in size. These findings indicate that each enzyme has two restriction sites on the linear DNA. A linear DNA will give (n+1) fragments, where *n* is the number of restriction sites. The double digest reveals five restriction fragments—0.5, 1, 2, 4, and 5.5 kb in size—indicating four cleavages. The correct, consecutive ordering of fragments must be determined by reconciling each of the single-enzyme digests with the fragments arising from the double digest. All possible fragment orders for both enzymes are listed in Figure 2, as well as the order that gives the restriction map that agrees with the double-digest fragment sizes. In the example given, all fragment sizes from the two single digests and from the double digest sum to 13 kb each, the size of the original DNA. When determining a restriction map, one must remember that some fragments may be larger than the resolution power of the gel or that digestion may generate different fragments of the same size, which will migrate together. In such cases, alternative enzymes must be employed. Another approach uses the timed partial digestion of uniquely end-labeled, linearized DNA, which generates fragments ranging from the full-length DNA to the shortest fragment containing the label. The label identifies one end of the molecule. A restriction map can then be determined by a comparative analysis of the collection of fragments produced.

Figure 1. Idealized pattern of DNA fragments after digestion of a linear 13-kb DNA with *Eco*RI and *Bam*HI, separately or combined, separation by electrophoresis, followed by visualization.

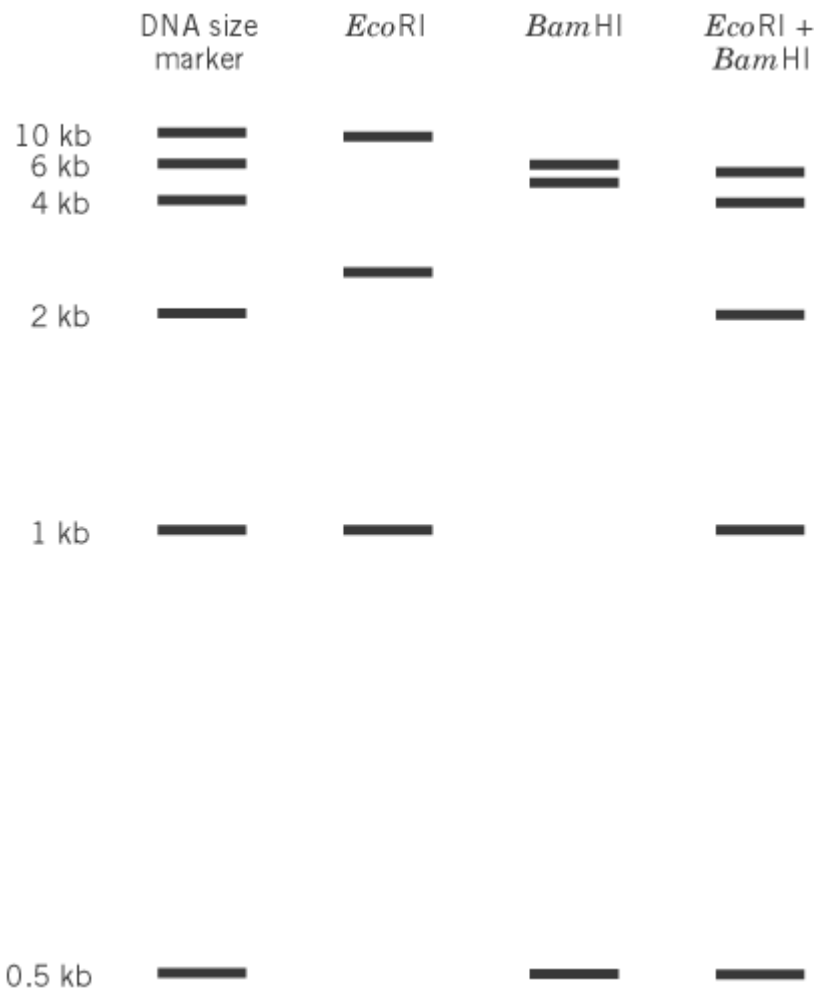

Figure 2. Restriction map derived from the data in Figure 1: (**a**) all possible combinations of linear restriction fragment orders from the individual *Eco*RI or *Bam*HI digests; (**b**) diagram of the final restriction maps showing the correct, unique order of restriction fragments from a double digest with both *Eco*RI and *Bam*HI of the 13 kb linearized DNA. Fragmentation patterns (2) of *Eco*RI and (2) of *Bam*HI combine to give five fragments produced by the double-digest.

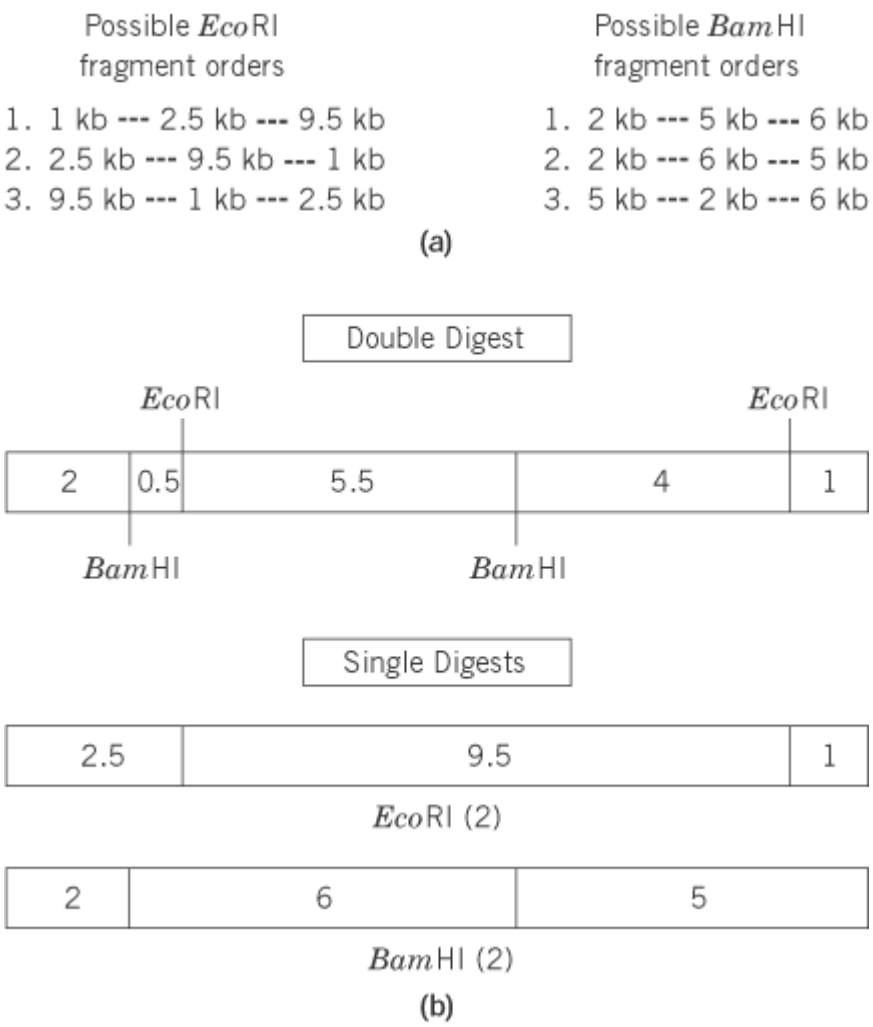

Restriction digestion breaks DNA into fragments of a manageable size for analysis (see Restriction Fragment). Restriction maps are thus helpful in determining gene order or chromosomal organization. Generation of restriction maps from different organisms reveals similarities or differences in their genomic arrangements. One important application of restriction mapping is genetic fingerprinting: the typing of individual DNA molecules based on differences in restriction map patterns. The differences in map patterns are reflected in *restriction fragment length polymorphisms* (RFLPs), which result from changes in restriction sites or distances between restriction sites due to local sequence variations. In some cases, RFLPs can be used as genetic markers for diagnosis of diseases, and can aid in isolating the gene or identifying DNA sequence aberrations causing the disease. Applications for analysis and manipulation of restriction fragments are discussed under the topic restriction fragment.

Restriction–Modification Systems

Restriction–modification (R-M) systems in bacteria consist of pairs of enzymes that presumably provide protection from exogenous foreign DNA, for example, from infecting **bacteriophage**. This phenomenon was observed almost 50 years ago, when some strains of bacteria, those with an R-M

system, were observed to be less susceptible to bacteriophage infection and propagation than others. Their infection by bacteriophage was "restricted"; titers of bacteriophage produced were one to five orders of magnitude lower than in other strains, which lack an R-M system (1). Those bacteriophages that did propagate on the restricted hosts, however, were subsequently "immune" to the restriction and were competent to grow normally on those host strains.

The R-M systems act to prevent or to "restrict" the entrance of foreign DNA into the host bacterial cell by fragmenting it enzymatically with the restriction endonuclease, or restriction enzyme. The foreign DNA is recognized because it is not methylated, or "modified," whereas the DNA of the host is, due to the action of a host methyltransferase (see Methylation, DNA). Over 25% of 10,000 bacterial strains surveyed have been found to contain at least one R-M modification system; some strains contain as many as six (1, 2). R-M systems are dispensable, as bacteria without them are viable and display no deficiencies other than greater sensitivity to bacteriophage infection. The genes for R-M systems can be located on the chromosome, on a **plasmid**, or on a prophage, and those for each pair of endonuclease and methyltransferase are usually found in proximity. More than 160 R-M systems have been cloned, and most of their genes have been sequenced (3).

1. R-M Enzymes

The R-M phenomenon is explained by the action of the two enzymatic activities making up each R-M system. One activity is a restriction endonuclease, or restriction enzyme, which cleaves DNA, whereas the other is a methyltransferase, or methylase, which methylates the host DNA. These two activities can occur on two separate proteins or on an enzyme complex displaying both activities. The restriction enzyme recognizes a specific DNA sequence (usually 4–8 bp long) and catalyzes phosphodiester bond cleavage at sites within or outside of the sequence to produce a double-strand cut in the duplex DNA. The enzyme thus fragments the DNA, which makes it susceptible to further degradation by general exonucleases. The DNA recognition sequence, or "restriction site," can be unique or degenerate (representing more than one unique sequence), continuous or interrupted by unrecognized base pairs, **palindromic** or asymmetric (see Staggered Cut). The partner modification methyltransferase activity recognizes the same sequence as its cognate restriction enzyme and catalyzes the transfer of a methyl group from the cofactor S-adenosyl-L-methionine (AdoMet) to specific recipient bases in the sequence; this methylation prevents cleavage by the partner endonuclease. Sequences methylated on either one or both strands are resistant to endonuclease cleavage. The methyltransferases fall into two major mechanistic classes: one group methylates the 5-carbon of cytosine to form 5-methylcytosine (5mC) and the other the exocyclic amino group of either cytosine to form *N*-4-methylcytosine (N4mC) or of adenine to produce *N*-6-methyladenine (N6mA) (see Methylation, DNA).

2. R-M System Nomenclature

R-M systems are named with an italicized three letter abbreviation that is derived from the name of organism in which that R-M system resides. The first italicized letter (uppercase for protein and lowercase for gene designations) comes from the genus, the lowercase second and third letters from the species. Any strain designation follows the italicized abbreviation, and Roman numerals are used to designate different R-M proteins within the same organism. For example, *Eco*RI, *Eco*RII, and *Eco*RV are different systems from *Escherichia coli* strain R. For the enzymes, the letters R or M, followed by a dot (•) are used before the name: R•*Eco* RI or M•*Eco*RI are the cognate enzyme pair, endonuclease and methylase, respectively, from *E. coli* strain R. For the genes of R-M systems, the name designation is completely italicized and followed with the letter (R) or (M) to designate the activity, eg, *ecoRIM* and *ecoRIR*, for the methylase and endonuclease genes, respectively (2, 4).

3. R-M Gene Expression and Organization

Expression of the genes for R-M systems is assumed to be tightly regulated. The host genome carrying an R-M system must be continuously protected from its restriction endonuclease even

during physiologically difficult times, such as intermittent starvation with concomitant decreases in AdoMet concentration. The genes for R-M systems are spatially linked and tandemly organized. The adjacent genes can be arranged (*1*) in parallel, with the 5′ end of one gene following the 3′ end of the other; (*2*) convergently, with the 3′ ends of the genes in proximity; or (*3*) divergently, with the 5′ ends of the genes near one another. Comparisons of the sequences of R-M enzymes have provided information about their evolutionary relationships (5), as well as the means of their classification. Three different types of R-M systems (I, II, and III) are recognized, and different assemblies of proteins exist for each system (Table 1).

Table 1. Restriction Modification Systems

	Type			
System	I	II	IIs	III
Enzymes	3 subunits: R, M, S (R_2M_2S)	Independent subunits: R and M proteins (R_2 and M)	Independent subunits: R and M proteins (R and M)	2 subunits: R, M (RM)
Cofactors	Restriction: Mg^{2+} and ATP; AdoMet is allosteric effector	Restriction: Mg^{2+}	Restriction: Mg^{2+}	Restriction: Mg^{2+}, ATP is allosteric effector; stimulated by AdoMet
		Modification: AdoMet	Modification: AdoMet	
	Modification: AdoMet, stimulated by ATP			Modification: AdoMet, stimulated by ATP
Recognition site	Asymmetric[a], 3–5 half-sites[c] with spacer region	Palindromic[b] 4–8 bp	Asymmetric, 4–7 bp	Asymmetric, 5–6 bp
Cleavage site	Variable distances from recognition site,	Within recognition sequence	Under 20 bp	25–30 bp
			3′ of recognition site	3′ of recognition site
	ATP-driven translocation			
Modification properties	Opposite strands of each half-site	Within recognition sequence	Methylation of one or both strands	One strand of each recognition site
	(M_2S)			

	Prefer hemimethylated sites over nonmethylated sites			
Sequence	Conferred by S subunit R and M mutually exclusive	Intrinsic to enzyme	Intrinsic to enzyme	Conferred by M subunit
Specificity				
Enzymatic		Separate	Separate	Simultaneous if all cofactors present
Activities				
Example	*Eco*AI:	*Eco*RI:	*Fok*I:	*Hin*fIII:
	GAG(N_7)GTCA	GAATTC	GGATG(N_9)	CGAAT
	CTC(N_7)CACT	CTTAAG	CCTAC(N_{13})	GCTTA

[a] Recognition sites not having the same sequence in both strands of DNA.

[b] Recognition sites having the same sequence in both strands of DNA.

[c] A site containing only half of the necessary DNA sequence for complete enzyme recognition.

3.1. Type I R-M Systems

Fewer than 20 type I R-M systems have been found, but they are present in *E. coli*, *Salmonella typhimurium*, and *C. freundii*. Type I systems contain both the restriction and modification functions in the same multisubunit enzyme. The enzyme is at least a pentameric complex (R_2M_2S) consisting of three nonidentical subunits, referred to as R (for restriction), S (for DNA sequence specificity), and M (for methylation). The enzymes require Mg^{2+}, AdoMet, and ATP for activity, or as **allosteric** effectors (6). If the restriction sequence is fully methylated, ATP hydrolysis drives the dissociation of the enzyme from DNA. If the restriction site is hemimethylated, the enzyme methylates the other strand and dissociates. If unmethylated, the R subunit cleaves at random DNA sites after ATP-driven translocation of the enzyme to variable distances (up to 10^3 bp) from the recognition sequence (6, 7). The asymmetric recognition sequence comprises two half-sites, each 3–5 bp long, separated by a nonspecific sequence of 6–8 bp. In all type I enzymes, the methyltransferase subunit forms specific N6mA residues at each half-site, preferring hemimethylated DNA substrates over unmodified ones (8). The S subunit provides DNA sequence recognition. The type I systems are grouped into three different families: IA, IB, and IC, which are differentiated by their genetic location, immunological cross-reactivity, and gene sequences. The genes of the IA and IB families are located on the chromosome and have the gene order *hsdR*, *hsdM*, and *hsdS* (*hsd* indicates *h*ost *s*pecificity *d*eterminant). The genes of the IC family are encoded on a plasmid in the order *hsdM*, *hsdS*, and *hsdR*. All families of the type I R-M systems have two adjacent **transcriptional** units, with the *hsdM* and *hsdS* genes transcribed from one **promoter** and *hsdR* from the other. Although type I enzymes (such as *Eco*B and *Eco*K) were the first restriction endonucleases to be discovered, type II enzymes have proved more numerous, simpler in composition, and more useful in practical applications.

3.2. Type II R-M Systems

More than 2600 Type II systems, with greater than 230 different specificities exist (3). Type II systems have discrete restriction and modification enzymes. Each enzyme of a pair recognizes the same DNA sequence. Most type II enzymes recognize palindromic, duplex DNA sequences, such as

GAATTC, whose complementary strand has the same 5′–3′ sequence. The restriction endonucleases are homodimeric, require Mg^{2+}, and cleave phosphodiester bonds within or immediately adjacent to (type IIs; see below) the recognition sequence to leave a staggered or blunt double-strand cut (see Staggered Cut and Restriction Enzymes). The methyltransferases are monomeric and require the cofactor AdoMet. Methylation takes place on both strands of the DNA duplex within the recognition sequence, rendering the sequence refractory to cleavage. Interestingly, little amino acid sequence similarity exists between partner endonucleases and the methyltransferases, suggesting that the enzymes evolved independently (5, 9) and reflecting the fundamentally different chemical reactions they catalyze and the mechanisms they use for DNA recognition. Those type II R-M systems in which the two genes are aligned consecutively are believed to operate as single transcriptional units, with the order of the genes being unimportant. Those with the genes arranged divergently or convergently may be subject to independent transcriptional control. The genes for a type II R-M system can be located on the chromosome or on a plasmid. Some type II systems also contain an **open reading frame** encoding a "controller" or "C" protein, with sequence similarity to some DNA-binding proteins. These controller proteins probably regulate the expression of the genes. For example, disruption of the *BamHIC* gene in the BamHI R-M system leads to an increase in modification and a decrease in restriction cleavage (2).

3.3. Type IIs Enzymes

A subset of the type II R-M systems, termed type IIs, share the property of having independent restriction and modification enzymes, but they recognize uninterrupted and asymmetrical sequences (4–7 bp long) and cleave DNA 3′ to the recognition sequence, up to 20 bp away, leaving a staggered double-strand cut (see Staggered Cut). These endonucleases act as monomers and require Mg^{2+} for activation and cleavage. Type IIs target sequences are asymmetric, and the methyltransferases act as monomers to methylate one strand at a time within the recognition sequence. In some type IIs systems, methylation of both strands is performed by a pair of methyltransferases, which may (*eg*, *Hga*I) or may not, (*eg*, *Alw*26I) be of the same class (5mC, N4mC, or N6mA) (see Methyltransferase, DNA). In another system, *Fok*I, methylation is accomplished by a fused, bifunctional enzyme (2). There are over 80 characterized type IIs enzymes, representing over 35 specificities (6). Their sequence specificities are similar to those of type III enzymes.

3.4. Type III R-M Systems

Only a few type III R-M systems are known, with four different specificities identified (6). A single bifunctional enzyme catalyzes both the endonuclease and the methyltransferase restriction activities. The enzymes are composed of two nonidentical subunits: the M subunit (encoded by the *mod* gene) and the R subunit (encoded by the *res* gene). The R subunit must be complexed with the M subunit for restriction activity, because the M subunit provides the sequence specificity for the enzyme. The two enzymatic activities compete for the uninterrupted, asymmetric DNA recognition sequence, which is usually 5–6 bp long. Restriction activity requires that two copies of the recognition site be proximal on the DNA and in opposite orientations to one another. Such an array of sites may also be viewed as one symmetrical sequence separated by a spacer region of undefined length (10). Type III restriction activity is absent when either a single site or two recognition sites in the same orientation are present. Cleavage takes place 25–30 bp away to the 3′ side of the DNA recognition sequence. If one or both of the DNA strands is (are) methylated, no cleavage occurs. The M subunit can act independently as a methyltransferase, requiring AdoMet and methylating only one strand of the duplex recognition sequence at a time, which is sufficient to inhibit the restriction reaction. Methylation is independent of the number and orientation of the restriction sites, suggesting that the enzyme reacts with single sites only (10).

3.5. Other R and M Systems

Other variations of restriction and modification systems exist. For example, endonucleases that recognize and cleave only methylated DNA have been described. Three such methylation-dependent restriction systems have been isolated from the K12 strain of *E. coli*: (*1*) *Mrr* (*m*ethyladenine *r*ecognition and *r*estriction) cleaves DNA with sequences containing N6mA and 5mC bases; (*2*)

*Mcr*A (modified *c*ytosine *r*estriction) cleaves sequences containing 5mC; and (*3*) *Mcr*BC cleaves DNA containing 5mC, N4mC, or 5-hydroxymethylcytosine (11). No corresponding methyltransferases are known for these systems. These systems are thought to restrict foreign methylated DNA, and their presence must be recognized when trying to clone methylated DNA. Among the type II enzymes, R•*Dpn*I cleaves only at methylated GmATC sites, whereas *Dpn*II cleaves only at unmethylated GATC sites. These and other enzymes with similar properties can be used to assess the methylation state of DNA.

Restriction-independent methylases have also been found, such as the adenine-specific Dam and DNA-cytosine (Dcm) methyltransferases. The Dam enzyme methylates the adenine in the sequence GATC and has various functions in methyl-directed mismatch repair, DNA replication, and **gene regulation** (12). Dcm functions in very short patch DNA repair, which serves to repair deaminated cytosine bases using the G-containing template of the complementary strand of the DNA as a guide (2, 5). Finally, **intron**-encoded endonucleases that catalyze methylation-independent restriction have been described. These enzymes recognize large specific DNA sequences (18bp) and cleave within the recognition sequence or up to 20 bp away. They are believed to function in site-specific intron transposition and share some characteristics with type I restriction endonucleases (6).

4. Antirestriction Systems

Bacteriophage have evolved diverse antirestriction mechanisms to defeat the R-M systems of bacteria. Such evasive measures include (*1*) production of phage-encoded proteins that inhibit host R-M enzymes or destroy R-M cofactors, (*2*) stimulation of the host modification function, (*3*) phage self-modification of DNA (using modified bases in their genomes), and (*4*) evolutionary elimination of restriction sites from the phage genome. As examples, phage T3 contains the gene for the enzyme AdoMet hydrolase, which destroys AdoMet; the Ral protein produced by phage l inhibits restriction and stimulates the methylation function of type IA enzymes (11). The T-even phages carry glycosylated hydroxymethylcytosine bases in an effort to evade restriction (5). On the other hand, a restriction enzyme encoded on bacterial plasmid RtsI, *Pvu*RtsI1, specifically cleaves only phage DNA sequences containing hydroxymethylcytosine residues (13). Evolution has clearly promoted the development of both defensive and offensive mechanisms in the competition between bacteria and bacteriophage.

5. Concluding Remarks

R-M systems probably provide an “immune system” for bacteria that shares characteristics with that of eukaryotes (see Immune Response). For example, foreign, “non-self-”DNA is distinguished from “self-”DNA (11). A provocative, alternative hypothesis for the existence of R-M systems suggests that they evolved because of the “selfishness” of their genes. The sociobiologically derived “selfish gene” theory dictates that under certain circumstances natural selection accommodates proliferation of genes that are potentially deleterious to the host carrying them (14). In support of this view, two groups have shown that a daughter bacterial cell not receiving the plasmid encoding the R-M system of the parent is subject to chromosomal DNA cleavage by residual restriction endonuclease remaining after cell division if the residual methylase activity cannot protect all the restriction sites efficiently (15, 16). Thus, selection for progeny carrying the R-M system exists in the absence of their “immunity” role. Other rationalizations for the existence of R-M systems include roles for them in DNA recombination or repair, regulation of gene expression, and acquisition of foreign genes, but these roles are less certain (2).

The discovery of R-M enzymes has revolutionized several areas of research and biotechnology (see Cloning). Isolation and characterization of R-M genes and purification of the proteins have led to greater understanding of protein–DNA and enzyme-cofactor interactions. For example, a novel example was found in the X-ray crystallography structures of two type II 5mC methyltransferases with their target DNA: an extrahelical cytosine base is flipped out of the DNA into pockets in the enzymes (see 5-Methylcytosine). The Type II restriction enzymes provide a vast array of sequence-

specific DNA cleavage tools that allow manipulation and manageable analysis of an otherwise formidable macromolecule. Several applications of restriction endonucleases and methyltransferases are discussed in the entries Restriction Fragment, Restriction Map, and Staggered Cut. R-M systems provide ideal models for studying basic genetic and biochemical mechanisms, as well as serving as practical tools for expanding other areas of biological research.

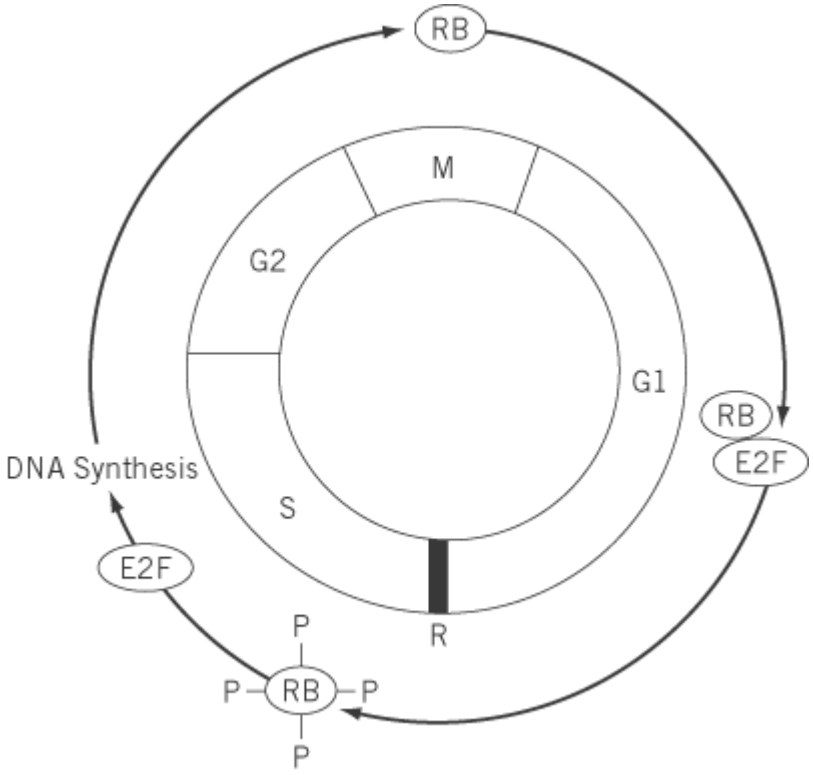
Retinoblastoma Gene

The retinoblastoma (Rb) gene was the first tumor suppressor gene identified by genetic analysis of a **chromosomal** deletion observed in retinoblastoma patients. Familial retinoblastoma is a rare childhood disease that occurs in 1 out of 20,000 patients. In a majority of the cases, it occurs as a

sporadic form of cancer, where the tumor is formed only in one eye, but in others the patients develop tumors in both eyes. The Rb gene is located on chromosome 13q14.2 and is often deleted in tumors of the retinoblastoma. The Rb gene is also deleted or mutated in a number of human cancers, including lung, breast, pancreas, bladder, prostate, and osteocarcinomas. The protein encoded by the retinoblastoma gene is a 105-kDa polypeptide chain, also known as p105RB, which can be **phosphorylated**. The phosphorylation state of p105RB is tightly regulated during the cell cycle, is maximal during S-phase and minimal soon after mitosis. Stimulation of quiescent T cells leads to hyperphosphorylation of p105RB, whereas differentiation of myeloid cells is associated with very low levels of phosphorylated p105RB. Interestingly, only the hypophosphorylated form of RB has tumor suppressor activity. A simple model predicts that p105RB is phosphorylated in the late G1/S-phase and dephosphorylated in the late M-phase, and this has been observed (Fig. 1). In its dephosphorylated state, the Rb gene product binds to a group of transcription factors known as the E2F class of proteins, which are required for DNA synthesis (1, 2). Growth Factors stimulate the phosphorylation of the p105RB protein by activating a group of kinases known as CDC kinases, which carry out the phosphorylation. The p34CDC2 kinase is a candidate kinase (1). Phosphorylation in turn reduces the affinity of p105Rb for E2F, allowing these transcription factors to bind to DNA and to activate transcription of genes required for DNA synthesis. Interestingly, growth inhibitors, such as transforming growth factor b (TGF-b), which inhibits cell proliferation, prevent phosphorylation of p105 RB, even in the G_1/S-phase. These observations suggest that the phosphorylation of p105RB is a critical regulatory event in cell proliferation.

Figure 1. The role of Rb in cell cycle regulation. The Rb protein is in an unphosphorylated state in the G_1-phase of the cell cycle. In this state, it associates with E2F and blocks its ability to transcribe genes required for DNA synthesis. Phosphorylation of Rb makes it unable to bind to E2F, which in turn results in the transcription of genes that are required for DNA synthesis. Then the cell cycle progresses from the G_1- to the S-phase.



p105RB binds to the adenovirus E1A protein, and this association is essential for adenoviral transformation. Hence, the transforming DNA viruses induce transformation by sequestering the

hypophosphorylated form of RB105. The biochemical mechanism of tumor suppression by p105RB is at the level of the expression of the proto-oncogenes c-*myc* and c-*fos* because RB expression suppresses the expression of both genes.

Recent studies have shown that the mammalian gene codes for two other Rb-related genes, known as p107 and p130, which is also known as Rb-2. Like p105RB, these two proteins act as cell-cycle regulators in cells where they are expressed and thus function as tumor suppressor genes.

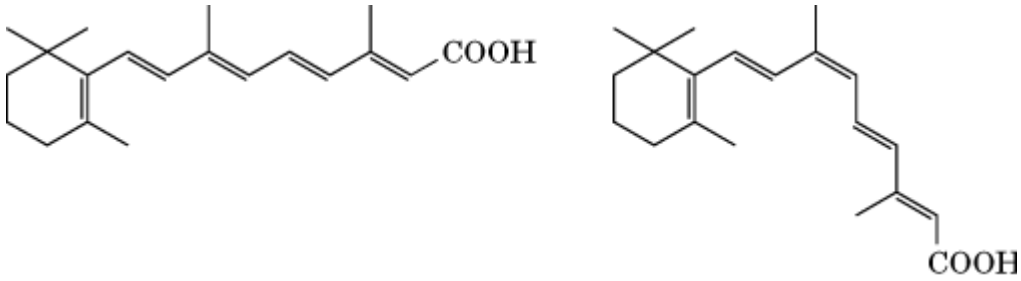
Retinoic Acids

Retinoic acids (RAs) are natural intracellular oxidation products of vitamin A (retinol) that mediate the biological effects of vitamin A (1). The most active compound is the all-*trans*-retinoic acid (t-RA), [2E, 4E, 6E, 8E]-3,7,-dimethyl-9-(2,6,6-trimethylcyclohex-1-en-1yl) nona-2,4,6,8-tetraenoic acid (retinoin, or vitamin A acid) (Fig. 1). A stereoisomer of t-RA, 9-*cis*-retinoic acid (9-*cis*-RA) is also biologically active. The RAs play a major role in vertebrate pre- and postnatal development, are modulators of cellular proliferation and differentiation, and are effectors of morphogenic changes (2-4).

Figure 1. Structure of all-*trans*-retinoic acid and 9-*cis*-retinoic acid.



The biological effects of RAs result from their action on gene transcription and are mediated by specific **receptors** belonging to the superfamily of nuclear receptors. Like steroid hormone receptors, RA receptors represent ligand-inducible transcription factors. Two such families of receptors have been described, the RAR and the RXR (5-7). Three genes that comprise the RAR family (a, b, and g) have been identified. Each of these subtypes can be further divided into different protein **isoforms**, which arise either from different **promoter** usage or from alternative splicing. Although the various receptor isoforms can substitute for one another, they are not truly equivalent functionally. The RXR family also consists of three subtypes a, b, and g and is **homologous**, but with primary structures and ligand specificity that differ substantially from those the RAR family. The highest degree of similarity between RAR and RXR lies in the DNA-binding domain (63% identical), and the rest of the protein molecules show about 30% identity. RARs and the thyroid

hormone receptors belong to the same receptor subclass, due to their high degree of similarity and to an identical P element in the first **zinc finger** of the DNA-binding domain (see Steroid Hormone Receptors). The physiological ligand for RARa, RARb, and RARg is t-RA. Originally, RXR was considered to be an **orphan receptor**, but 9-*cis*-RA was subsequently demonstrated to be its ligand. RAR binds to RA response elements (direct repeats of AGGTCA, separated by five base pairs) as a homodimer, and as a heterodimer it binds to RXR. RXR can act as a homodimer, binding to RXR response elements (direct repeats of AGGTCA, separated by one base pair), but also as a heterodimer with RAR or with the receptors for thyroid hormones, vitamin D, and peroxisome proliferator (8). The heterodimerization with these receptors increases the apparent binding of each receptor to their cognate response elements and increases the regulatory potential of RAs. A physical interaction of RAR with AP1 proteins has been demonstrated, accounting for the repressive action of RAs on several genes. RAR can be **phosphorylated** by protein kinase A *in vitro* and *in vivo*. In transfection experiments, it was shown that phosphorylation of Ser369 of RAR increases its capacity to activate a reporter gene carrying a RAR response element.

Retinoids are important regulators of epidermal cell homeostasis, skin formation, and maintenance and have been used to treat skin disorders (cystic acne, psoriasis, epithelial cancers). *In vitro*, RAs inhibit differentiation of keratinocytes, inhibit the proliferation and squamuous differentiation of head and neck cancers, and inhibit growth of estrogen receptor-positive human breast carcinoma cells in culture. RAs are required for eye and limb morphogenesis and for spermatogenesis. They induce remission in promyelocyte leukemias (PMLs). Translocation of the RARa gene and its fusion in-frame with the PML gene is a key event in the genesis of acute promyelocytic leukemia (APL). The PML gene regulates **hematopoeisis** and controls cell growth and tumorgenesis. Its function is essential for the tumor growth-suppressive activity of RA and for the ability of RA to induce terminal myeloid differentiation of precursor cells by transactivation of specific genes regulating the cell cycle (eg, gene p2/WAF1/CIP1). Disruption of the PML gene by fusion with RARa and translocation induces the pathway to APL (9). Administration of excess RA to mice embryos can lead to teratogenic effects and limb malformations (10).

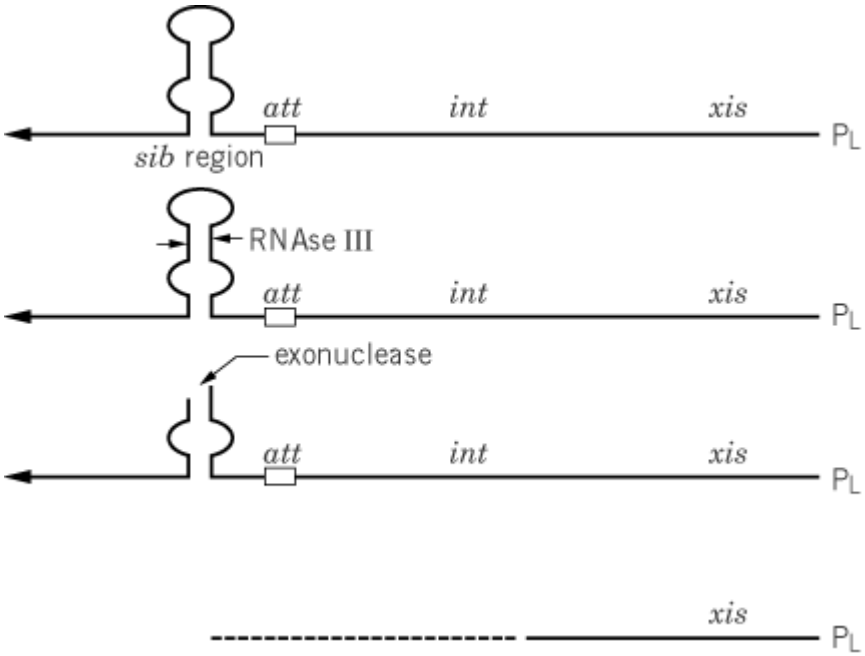
Retroregulation

Retroregulation of gene expression was discovered in the *int* gene expression of lambda phage (1). The *int* gene encodes the integrase that catalyzes integration (and excision) of l DNA to (or from) the *Escherichia coli chromosome*. It is transcribed from the P_L promoter of l in the lytic cycle. The P_L-derived *int* transcript is, however, very labile, and the level of integrase expression is low. Point mutations in the region 260 bp downstream of the *int* gene are known to increase the expression of *int*. Because these mutations are clustered in the *b2* region of l, they are named *sib* for something in *b2*. The *sib* region does not encode a protein, but its RNA transcript can form an extended stem-loop structure that provides a substrate structure for a double-stranded RNA-dependent ribonuclease, RNase III. Therefore, the wild-type *sib* RNA is cleaved by RNase III and rapidly degraded by 3′-to-5′ exonuclease, such as polynucleotide phosphorylase (PNPase). The *sib* mutations destroy the RNase III recognition structure and stabilize the *int* mRNA, resulting in the increased synthesis of integrase; hence, this is referred to as retroregulation. In this case, retroregulation prevents l phage from integrating into the bacterial genome in the lytic cycle. Although little integrase protein is synthesized from the P_L promoter after phage infection, much integrase is expressed after induction of l prophage, where the *sib* sequence is no longer placed downstream of *int* because l phage attachment site, *attP*, truncates these two regions.

Figure 1. Retroregulation of l phage *int* gene. The *int* mRNA transcribed from the P_L promoter is unstable because of dsRNA cleavage with RNase III and subsequent degradation by PNPase. The *int* transcript is stabilized by *sib* mutations which destroy the RNase III recognition structure.



The *int* gene has its own **promoter** upstream of the initiation codon. The *int* promoter is dependent on the l transcription activator protein, *cII*. When cII activates transcription, the *int* transcript terminates at a r-independent terminator located within the *sib* region. Hence, the *int* transcript does

not form a RNase III-recognition site and is stable. On the other hand, the P_L transcript reads through this terminator because of the **antitermination** mechanism.

The 1.1 and 1.2 genes of **T7 phage** provide another example of retroregulation. They are encoded in the T7 early transcript, and the distal site (R5) can regulate these upstream genes by the RNase III-dependent mechanism similar to the *int* gene.

Retrotransposons

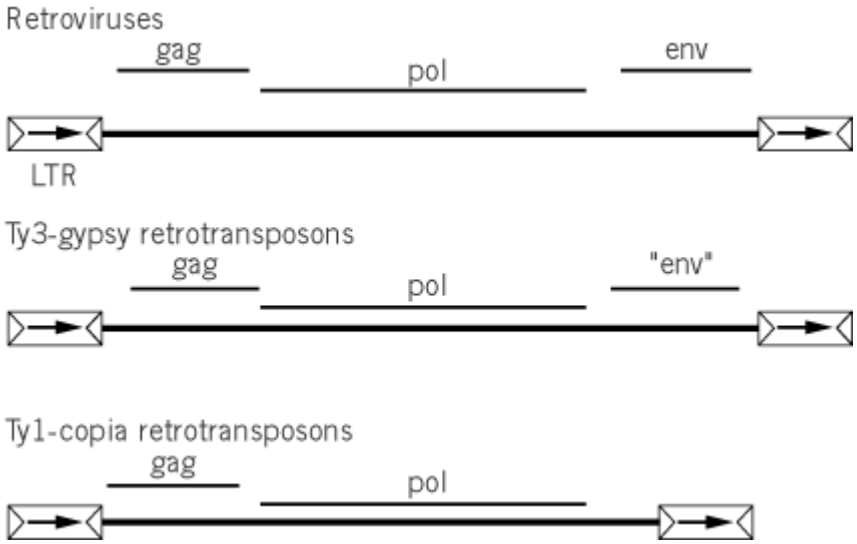
Retrotransposons are a large group of transposable elements that includes retroviruses and other elements that resemble retroviruses, but have no extracellular phase (1). Well-studied retroviruses include human immunodeficiency virus (HIV) and Moloney murine leukemia virus (MoMuV). Well-studied retroviral-like elements include the Ty elements of yeast and the gypsy and copia elements of *Drosophila*.

The transposition substrate for retrotransposons is a DNA copy of the element generated by **reverse transcription** of an RNA copy of the "proviral" form of the element integrated into the genomic DNA. At the ends of this DNA copy are the special sequences, again arranged as inverted terminal repeats, that will be acted upon by the integrase. The chemical steps of transposition—that is, the DNA breakage and joining reactions that process this reverse transcription product and insert it into target DNA—are fundamentally identical to the reactions that mediate the translocation of other DNA-only transposable elements in bacteria, *Drosophila*, and Caenorhabditis *elegans* (2). Moreover, the retrotransposon integrases are related in structure to the transposases of DNA-only elements, including those from bacteria. Indeed, the active site of the bacterial transposase MuA (3), is virtually superimposable with the catalytic region of the HIV integrase (4), although there is little primary structure homology between these proteins.

A retroviral provirus found in genomic DNA has at its ends two directly repeated segments several hundred base pairs long called long terminal repeats (LTRS); at the termini of these segments are short sequences that are recognized by the integrase and mark the sites of recombination (Fig. 1). (Only the sequences at the outside tips of the LTRs are recognized as recombination sequences; recombination does not occur at the two internal sites.) The interior of the element encodes several polyproteins (gag, pol, and env) that are cleaved by element-encoded proteinases to yield their several final products. Gag includes MA, a matrix-associated protein, CA, the major structural component of the viral capsid, and NC, a nucleocapsid component that interacts with the viral genome. Pol includes reverse transcriptase, ribonuclease H, and integrase; the order of these domains does vary among different elements. Env includes several capsid proteins involved in receptor recognition and viral entry. Retrotransposons have a structure similar to retroviruses, but lack an extracellular phase. Indeed, many retrotransposons lack or contain a defective version of env, which is key for the extracellular phase.

Figure 1. Retroviruses and retrotransposons. Retroviruses and retrotransposon generate a mobile DNA copy of the

element by using an element-encoded reverse transcriptase and ribonuclease H to convert an RNA copy of the element into a double-stranded DNA copy. Exposed 3′OH ends on this DNA segment, resulting either from reverse transcription or from processing by the element-encoded integrase, attack the target DNA at staggered positions (see Fig. 2 in Transposable Elements). These elements encode multiple polyproteins, gag, pol, and env: gag includes capsid components, pol includes reverse transcriptase, ribonuclease H, and integrase, and env includes functions for entry into new cells. In some, retrotransposons, the Ty1-copia class (Ty1 being a yeast element and copia a *Drosophila* element), no env gene is recognizable. In the Ty3-gypsy class (Ty3 being a yeast element and gypsy a *Drosophila* element), a defective version of env can sometimes be observed. These elements and other retrotransposons are very widespread.



Transposition begins by the transcription of the provirus by the host **RNA polymerase** to yield a viral RNA copy; some of these molecules serve as messenger RNA for synthesis of the viral proteins. Two copies of the RNA are packaged into the virion, which includes reverse transcriptase and integrase. Viruses bud from the cell and then bind to and enter another cell; retrotransposons move only intracellularly. While in the virion, the RNA is converted to double-stranded DNA. This resulting DNA, with assembled viral proteins, enters into the nucleus, where integration occurs. As with other transposons, insertions of these elements can disrupt genes or bring host genes under the control of viral enhancers.

The substrate for transposition is the DNA copy of the element. Recombination often initiates with the cleavage by integrase of several nucleotides from the 3′ ends of the DNA, to expose the actual element termini, although in some elements this trimming step is not necessary. Thus, as with DNA-only elements, exposing the 3′OH ends of the transposon is a key step. The integrase then promotes the attack of these 3′OH ends on staggered positions in the target DNA; because of this stagger, the newly inserted transposon is flanked by short gaps that will be repaired by the host DNA repair machinery, resulting in target site duplications of a characteristic length for each element.

Retroviruses

Retroviruses comprise a class of single-stranded RNA **viruses** whose genetic information is propagated through a double-stranded DNA intermediate integrated into the host chromosome. First documented in 1904 in the form of a nontumor-forming agent, equine infectious anemia virus and retroviruses of avian, mammalian, reptilian and piscine origin have now been documented (Table 1). They are associated with a variety of neurological disorders, wasting diseases, immunodeficiencies, and malignancies. Clinically significant retroviruses include type 1 and type 2 *human immunodeficiency virus* (**HIV**-1 , HIV-2), the causative agents of *acquired immunodeficiency syndrome* (AIDS), and type 1 and 2 human *T-cell leukemia virus* (HTLV-1 , HTLV-2), which manifest themselves in adult T-cell leukemia (ATL), tropical spastic paraparesis (TSP) and HTLV-associated myelopathy (HAM). Despite the increasing public health problem posed by HIV and HTLV infection, retroviruses have also made a fundamental contribution to biotechnology and molecular medicine. Following the seminal discovery in 1970 that **reverse transcriptase** (RT) catalyzes the flow of genetic information from RNA into DNA (1, 2), this enzyme for **cDNA** synthesis has found widespread use in producing medically important recombinant proteins, such as **cytokines**, growth factors, and hormones. Furthermore, since 1989, molecularly engineered retroviral vectors are increasingly used as delivery vehicles for gene therapy. A recent and ambitious application of retroviral vectors involves the proposal to introduce attenuated strains of HIV as live viral vaccines to control the spread of HIV infection and AIDS.

Table 1. Retroviral Genera

Retrovirus Abbreviation	Full Name	Genus
MMTV	Mouse mammary tumor virus	B-type
ASLV	Avian sarcoma-leukosis virus	Avian C-type
ALV	Avian leukosis virus	Avian C-type
RSV	Rous sarcoma virus	Avian C-type
FeLV	Feline leukemia virus	Mammalian C-type
GALV	Gibbon ape leukemia virus	Mammalian C-type
MLV	Murine leukemia virus	Mammalian C-type
REV	Reticuloendotheliosis virus	Mammalian C-type
SNV	Spleen necrosis virus	Mammalian C-type
MPMV	Mason–Pfizer monkey virus	D-type
SMRV	Squirrel monkey retrovirus	D-type
BLV	Bovine leukemia virus	HTLV-BLV
HTLV	Human T-cell leukemia virus	HTLV-BLV

BIV	Bovine immunodeficiency virus	Lentivirus

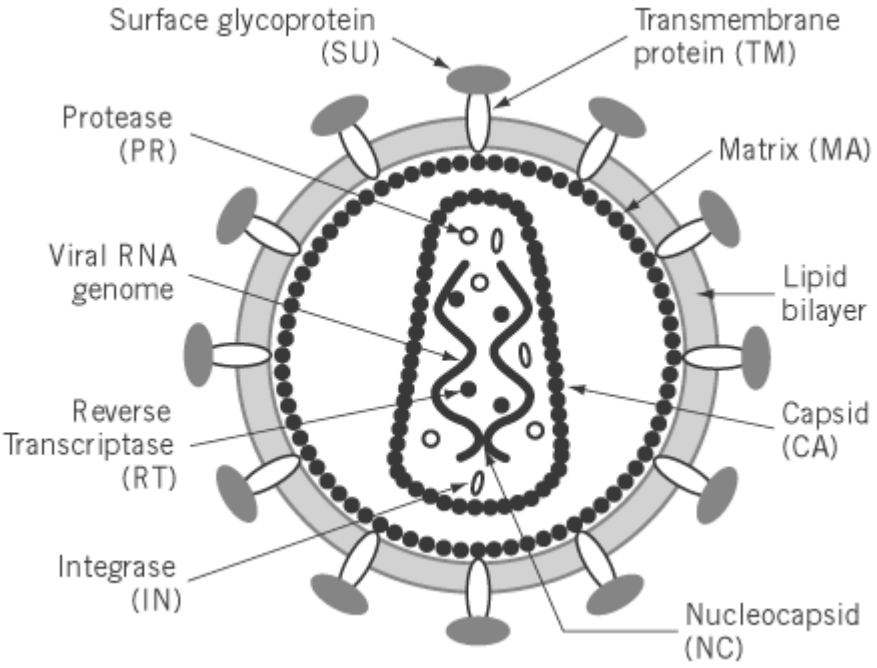
1. General features of retroviruses

1.1. Structure, Classification, and Genomic Organization

Despite significant differences in genetic complexity, host range, and interaction with their host, retroviruses share a common virion structure, a schematic version of which is illustrated in Fig. 1. Virions are typically 80 to 100 nm in diameter, contain an electron-dense core, and derive their lipid bilayer envelope from the host during budding. The virion surface is decorated with the envelope (*env*) gene products, comprised of a large surface **glycoprotein** (SU) (3) connected through disulfide bond linkages to a smaller **transmembrane** protein (TM). Matrix protein (MA), the amino-terminal product of the *gag* precursor polyprotein, is located between the virion envelope and capsid, and it possibly interacts with the TM subunit. Consistent with the notion of membrane association, the amino termini of MA proteins are often modified by the addition of a fatty acid, most commonly a **myristoyl group**. A second *gag* product, *capsid protein* (CA), forms the major internal structure of the virion, the core shell. Although the core shell assumes a highly ordered structure, the manner in which this is accomplished through packing of CA monomers remains to be established. An electron-dense virion core harbors two identical copies of the **positive-stranded** RNA genome, **hybridized** to a host-derived **tRNA** replication primer at the *primer binding site* (PBS) and likely coated over its entire length with the nucleocapsid protein (NC). The ***pol***-coded enzymes protease (PR), RT, and integrase (IN) constitute additional core-associated proteins. Immediately following virion entry, RT and IN are required to synthesize and integrate, respectively, the double-stranded DNA provirus into the host genome, and PR serves to process multi-domain *gag* and *gag-pol* precursor polypeptides during virion assembly at later stages in the retroviral life cycle. In addition to these "generic" core-associated proteins, virion cores of several lentiviruses contain a fourth *pol*-derived enzyme, *deoxyuridine triphosphatase* (dUTPase), whereas those of primate lentiviruses harbor the accessory virus-coded proteins Vpr and Vpx.

Figure 1. Schematic representation of a typical retrovirus virion, illustrating the disposition of structural and enzymatic proteins. Within the virion core, the dimeric RNA genome is most likely completely coated with the NC product of the *gag* gene. The two-letter abbreviation for retroviral proteins is indicated in parentheses.



Before nucleotide sequence data defining genomic organization, electron microscopy was used to distinguish retroviruses according to morphological features, leading to their designation as type *A*, *B*, *C* or *D*.

1. *A* particles are strictly intracellular nucleocapsid structures (containing a dimeric RNA genome, *gag* and *gag-pol* precursors), examples of which are the intracisternal *A* particles (IAP) of several rodent species and the immature form of mouse mammary tumor virus (MMTV). Fully formed immature cores of the *B*-type, *D*-type and spumaretroviruses are included in this group.
2. *B* particles are defined as the extracellularly enveloped form of MMTV. Immediately following budding, *B* particles mature to form condensed acentric nucleocapsid, which contrasts with the hollow appearance of the immature intracellular form. A prominent feature of *B* particles is decoration of their surface with the SU product of the *env* gene.
3. *C* particles comprise the simple avian and mammalian viruses, examples of which include Rous sarcoma virus (RSV) and *Moloney murine leukemia virus* (MOMLV). Such particles can be visualized as crescent-shaped patches on the cell membrane during budding, that is, fully formed intracellular structures are not generally detected. An electron-dense core morphology is also assumed by *C* particles immediately after budding, reflecting **proteolytic** processing of structural precursor polyproteins by the virally coded PR. Unlike their *B*-type counterparts, surface projections are barely visible on *C*-type viruses.
4. *D* particles are exemplified by *Mason–Pfizer monkey virus* (MPMV). These share many features of *B*-type viruses (including an intracellular nucleocapsid) but differ primarily in that their surface projections are less prominent.

More recently, seven genera of retroviruses have been defined, based on combining of nucleotide sequence homology and genomic complexity. Examples of these are provided in Table 1. Although *B*-type and *D*-type viruses remain unchanged, now those of *C*-type have been subdivided into avian and mammalian retroviruses. Both classes of *C*-type viruses contain "simple" genomes, that is, they encode only structural and enzymatic proteins from their *gag*, *pol*, *and env* **open reading frames**. Distinct from these are several groups of "complex" lentiviruses that encode as many as six accessory proteins on their genomes, in addition to *gag*, *pol*, and *env* products:

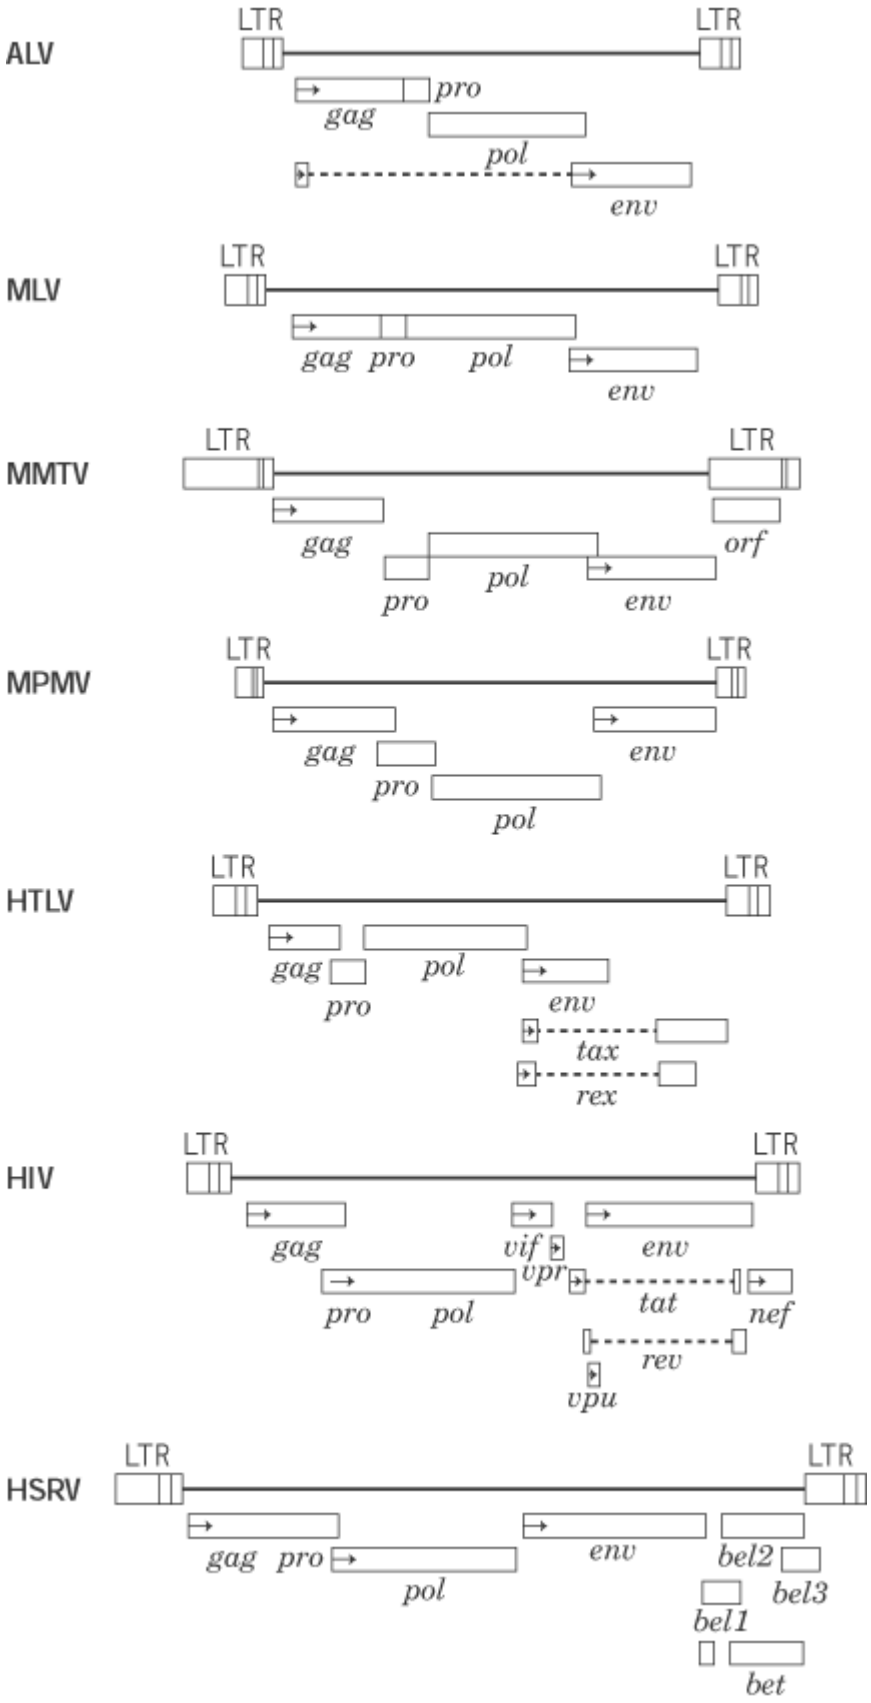
1. *Lentiviruses* are a diverse group of mammalian retroviruses responsible for neurological and

immunological diseases but not directly implicated in malignancies.

2. *HTLV-BLV* genus includes a small number of complex retroviruses associated with B- and T- cell lymphomas, in addition to certain neurological disorders.
3. *Spumaviruses* (alternatively designated foamy viruses because infected cells display highly vacuolated or "foamy" syncitia) comprise a class of complex retroviruses of simian, human, and feline origin with which no disease has currently been associated. A hallmark of spumaviruses is the length of their genomes (>11,000 nucleotides). Additional features of their life cycle that distinguish spumaviruses as a unique class of retroviruses include (i) alternative splicing mechanisms for production of an independent **mRNA** encoding enzymatic proteins of the *pol* gene; (ii), the presence of significant amounts of double-stranded proviral DNA in the virion, and (iii) an unusual site of transport for the preintegrative nucleoprotein complex.

The organizations of several well-characterized retroviral genomes are indicated in Fig. 2. All proviral genomes are characterized by terminal noncoding regions (long-terminal repeats or LTR) that contain ***cis*-acting** functions necessary for replication, between which lie genes for proteins that have structural (*gag* and *env* open reading frames) and enzymatic roles (*pol* open reading frame). The same figure also highlights considerable differences in genomic complexity among different retrovirus genera. The simple -*gag-pol-env*- organization of ALV and MLV can be contrasted with HIV-1, which contains at least six accessory proteins derived via multiple RNA splicing events, the best characterized of which are the **transactivators** Tat and Rev. Through a complex series of interactions with highly ordered structures assumed by the viral RNA genome (the TAR loop with Tat and *rev*-responsive element or RRE with Rev), these proteins play important roles in controlling transcription of the viral genome and cellular localization of the RNA transcripts, respectively. Potential roles for additional HIV-1 proteins have included steps in virion maturation (Vif), nuclear localization of the viral preintegrative complex (Vpr), enhancement of virion release (Vpu) and CD4 receptor downregulation (NEF). Although controversy still surrounds the biological role(s) of these factors, several studies have shown that viruses within which Nef has been deleted or prematurely terminated are attenuated (i.e., less virulent), suggesting an important role for this protein in pathogenicity.

Figure 2. Coding regions of simple and complex retrovirus genomes. The provirus is presented in each case and is bracketed by LTR. Each box under this represents an open reading frame, within which horizontal arrows denote the initiation codon. Dotted lines designate coding regions joined by splicing events. The retroviral protease (*pro*) can exist as a component of the *gag* or *pol* open reading frames or in an independent reading frame.



Counterparts to HIV Tat and Rev proteins have been detected in most, if not all, lentiviruses. In the HTLV-BLV class the Tat counterpart, Tax, fulfills a similar role of transcriptional activation but through an alternative mechanism. Rather than interacting with a control element located in the RNA

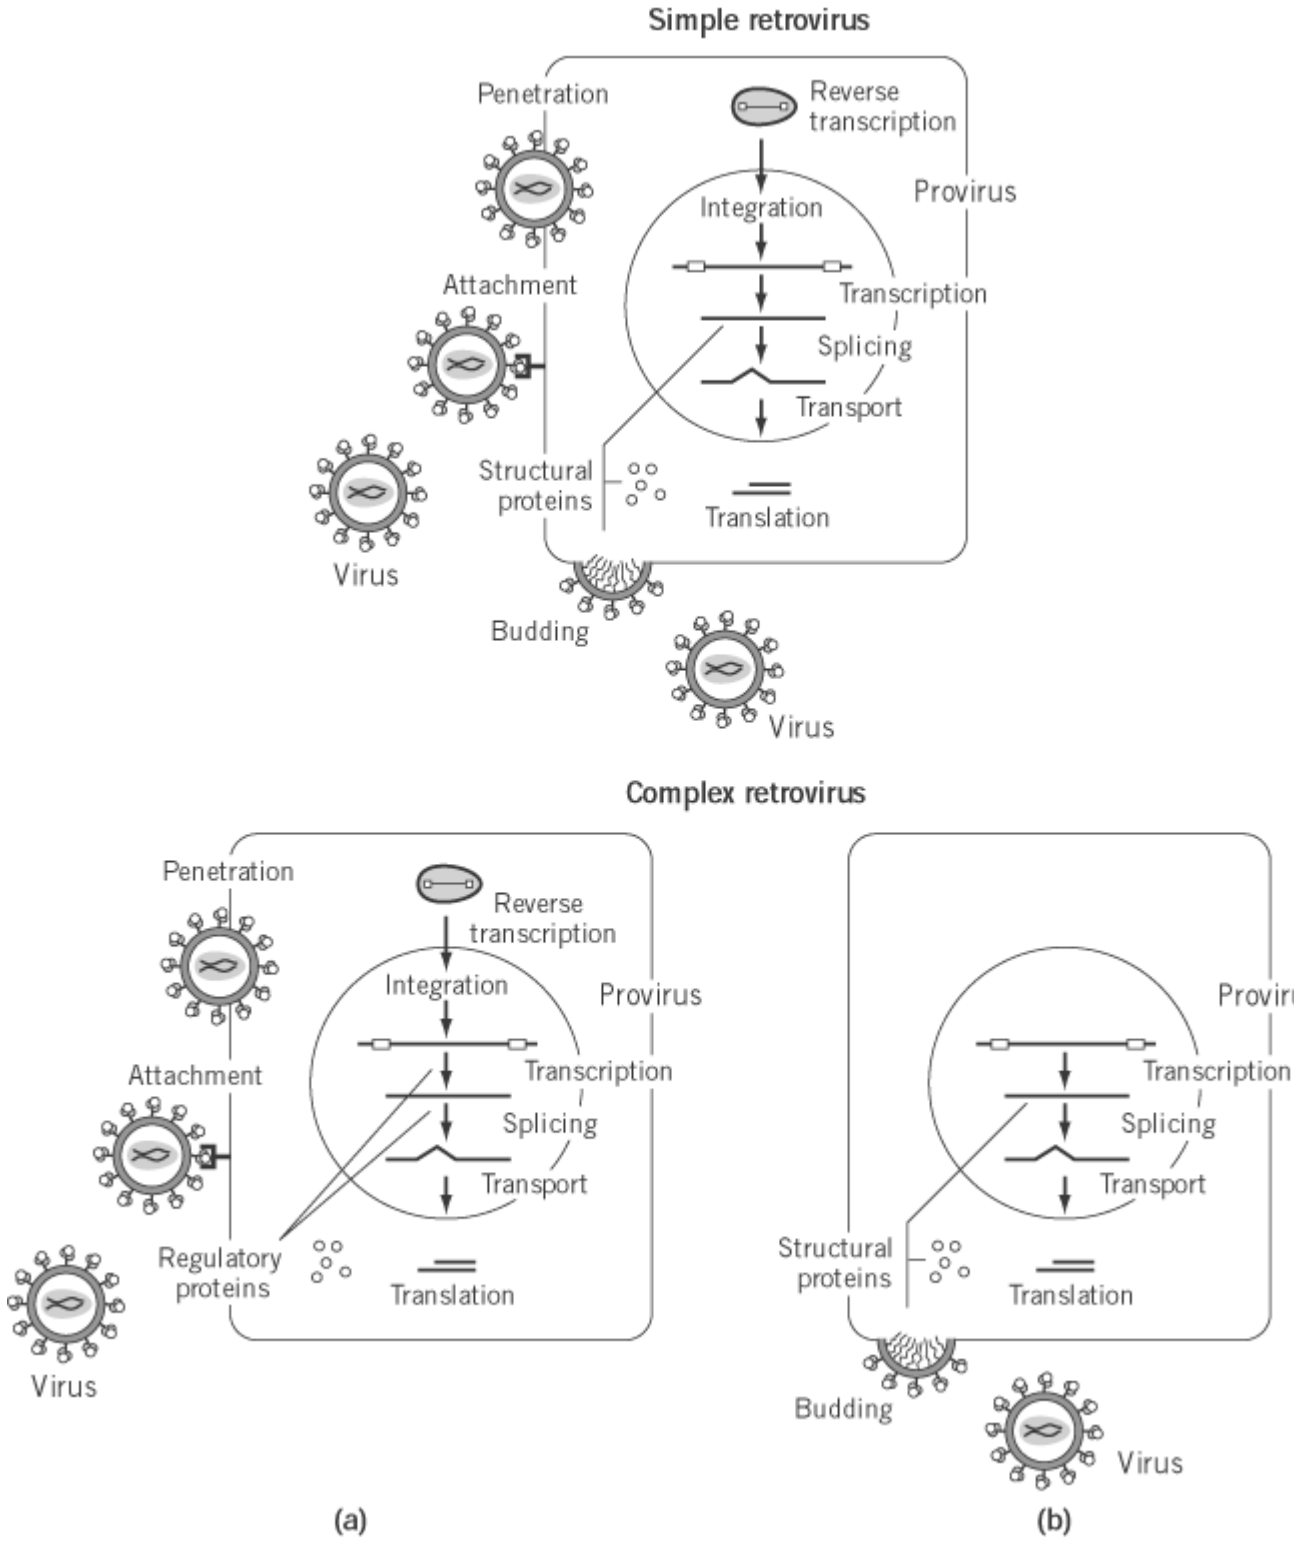
transcript, the target of Tax action is a segment of the retroviral promoter that contains three 21-bp repeat elements. Current evidence suggests that Tax does not interact directly with these motifs but rather with a member of the cyclic AMP response (CREB) family, which shares the same recognition element on the LTR promoter, thereby stimulating host transcriptional machinery. In contrast to Tax, HTLV Rex functions similar to the lentiviral proteins, in this case interacting with its RxRE target sequence on nascent viral RNA to control the levels of singly and multiply spliced transcripts in the cytoplasm. Of the several *bel* genes (between *env* and LTR) described for spumaviruses, the best characterized is the *bel1* product, which functions analogously to HTLV Tax.

2. The retroviral life cycle

The life cycles of simple and complex retroviruses are indicated in Fig. 3. Although both follow a similar pathway leading to establishment of the integrated provirus, they differ in subsequent events leading to maturation, where complex retroviruses have established control mechanisms for maintaining virion RNA within the nucleus. Salient feature of the life cycle include

- attachment to specific **receptor**(s) on the surface of the target cell
- penetrating and uncoating to release virion cores into the cytoplasm
- converting the single-stranded RNA genome into double-stranded proviral DNA
- transporting the "preintegrative" nucleoprotein intermediate into the nucleus
- integrating proviral DNA into the host genome
- synthesizing viral RNA from the integrated provirus
- transporting viral RNA to the **cytoplasm**
- synthesizing polyprotein precursors that encode structural and enzymatic proteins
- assembling nucleic acid and protein components at the cell membrane and budding
- maturing infectious virions

Figure 3. Life cycles of simple and complex retroviruses. For simple retroviruses, the life cycle can be envisioned as two discrete sets of events, (1) establishment of the integrated provirus and (2) expression of the provirus, followed by virion maturation. Although complex retroviruses establish the provirus similarly, then regulatory proteins (Tat, Rev, Rex) are synthesized from multiply spliced RNA (**a**) which aid in transporting unspliced and singly-spliced messages to the cytoplasm. Thereafter, (**b**) events follow the same pattern as simple retroviruses.



2.1. Attachment

The interaction of virions with a cell-surface receptor is mediated by the highly glycosylated SU component of the retroviral *env* gene. One of the most extensively characterized of these is the HIV receptor CD4, which functions in the host cell to aid in signaling the interaction of T-helper cells with **antigen-presenting** cells. Receptors closely resembling transport systems have been identified for both MLV (Rec-1 and Ram-1) and GALV (Glvr-1). Tva, the subgroup A ALSV receptor, is structurally distinct and bears some resemblance to the **low-density lipoprotein** receptor. Candidate receptors for BLV and FIV have been identified but require further characterization. Although the

prevailing dogma envisages a single class of receptor-mediated attachment, the observation that murine model systems bearing the human CD4 receptor support attachment of HIV, but not the subsequent events, means that a second recepetor may be involved. This notion has recently been proven experimentally by the identification of chemokine receptors CXCR-4 (fusin) and CCR5 as important coreceptors in HIV infection (4). Although CXCR-4 mediates infection of CD4+ cells by T-cell line adapted HIV-1 strains, CCR5 allows entry of primary/macrophage tropic strains. Other macrophage-tropic and dual-tropic strains exploit the additional chemokine receptors CCR3 and CCR2b.

2.2. Fusion and Uncoating

Penetration and release of the virion nucleoprotein core occurs by one of two distinct mechanisms: (i) fusion between the viral envelope with the cell membrane or (ii) receptor-mediated endocytosis accompanied by fusion with the **endosomal** membrane. Such events in retroviruses are pH-independent and are mediated by **hydrophobic** amino acids at the amino terminus of the envelope transmembrane (TM) component. Studies with HIV provide compelling evidence that a cellular peptidyl-prolyl isomerase, cyclophilin A (CyPA), participates in events between membrane fusion and initiation of reverse transcription (5). CyPA is incorporated into virions late in the infection cycle through direct interaction with the CA component of *gag* precursor polyprotein, suggesting that it may participate directly in uncoating. The virion structure presented in Fig. 1 predicts that MA provides an outer shell and would not be associated with core particles after uncoating. However, this is not the case with HIV, where a small proportion of MA molecules remain core-associated, possibly to assist in transporting the preintegrative nucleoprotein complex into the nucleus.

2.3. Proviral DNA Synthesis

Proviral DNA synthesis occurs in virion cores whose structure is relaxed to allow access to deoxynucleoside triphosphates. Through the elegant series of events depicted in Fig. 4, positively-stranded viral RNA is converted into double-stranded proviral DNA by a single virus-coded enzyme, RT. However, because signals that determine initiation and termination of transcription by the host **RNA polymerase** reside within the integrated provirus, these by default are absent from the RNA genome of an invading virus. Therefore, a mechanism must be established for regenerating them in the course of the reverse transcription cycle.

First, **minus-strand** DNA synthesis is initiated from a host-derived tRNA that is hybridized via its 3′-terminal 18 nucleotides to the primer binding site (PBS) immediately downstream from U5. Examples of tRNA used to initiate replication include $tRNA^{Trp}$ in RSV, $tRNA^{Pro}$ in MLV, and $tRNA^{Lys,3}$ in HIV. As U5 and R sequences are copied, RT-associated ribonuclease H (RNase H) activity degrades RNA of the RNA–DNA replication intermediate, thereby making R sequences of minus DNA accessible for hybridization to their complement at the 3′ end of the RNA genome. Through a process designated " *strand transfer*" or "switching", nascent minus-strand DNA is relocated to the 3′ end of the same (intramolecular) or a different RNA genome (intermolecular). Continued RNA-dependent DNA synthesis creates a first copy of the LTR-U3-R-U5- hallmark on minus-strand DNA, and RNase H activity continues to degrade RNA of the replicative intermediate. The exception to this is a purine-rich RNA sequence located near the 3′ end of the RNA genome, designated the *polypurine tract* (PPT), which resists hydrolysis to serve as a primer for plus-strand DNA synthesis. Plus-strand, DNA-dependent DNA synthesis ensues, using newly synthesized minus-strand DNA as a template, up to and including the first 18 nucleotides of the tRNA replication

primer (i.e., this is used as both primer and template during replication). At this step, the replication machinery transiently pauses at a methylated base of the tRNA, allowing RNase H-mediated removal of the intact minus-strand primer. As a consequence, plus-strand PBS sequences are made available for hybridization to their minus-strand counterparts to complete a second, intramolecular strand switch (concomitant with which the PPT primer is removed). Subsequent bidirectional DNA-dependent DNA synthesis generates a double-stranded proviral DNA flanked by complete copies of the LTR.

Although this model holds true for many retroviruses, several lentiviruses and yeast retrotransposons harbor a central plus-strand discontinuity, that reflects use of a second primer in the middle of the genome (the central or cPPT) (6). Although the advantage of an additional PPT is unclear, its alteration on the HIV genome has severe consequences for replication. The reverse transcription cycle that accounts for both 3′- and cPPT-initiated plus-strand synthesis is presented in Figure 4 (b). Documentation of a plus-strand discontinuity at the center of proviral DNA imposes an additional constraint on these retroviruses, namely, to provide a mechanism for terminating plus-strand synthesis immediately downstream from the cPPT. Preliminary evidence for this has been provided in HIV, where localized distortion of double-helical DNA geometry (“bending”), causes pausing and dissociation of the replication machinery. The DNA sequence and structure implicated in such events has been designated the *central termination sequence* (CTS). Finally, it should be pointed out that both copies of RNA in the virion core are used to synthesize a single proviral DNA, which indicates that relocation of nascent DNA between genome templates occurs frequently during replication. Because the retroviral polymerase is inherently more error-prone than host **DNA polymerases**, such recombination has the potential to enhance the rate of evolution, in addition to allowing RT to bypass lesions in the RNA genome.

2.4. Transport of Proviral DNA

Following DNA synthesis, the nucleoprotein complex composed of linear DNA, the core protein CA, RT, and possibly NC, is transported through the nuclear membrane (see **Nuclear import, export**). In some cases (eg, MLV), breakdown of the nuclear membrane at cell division is necessary to support these events, evidenced by the observation that inhibiting the onset of **mitosis** delays proviral DNA integration. An alternative strategy is employed by lentiviruses, which do not require the infected cell to enter mitosis. Nonenzymatic HIV-1 proteins, such as MA-derived peptides and Vpr, have been detected as constituents of the nucleoprotein complex, from which it has been postulated that nuclear localization signals of these accessory proteins assume a supportive role in transport (7).

Within the nucleus of infected cells, two variants of circular proviral DNA have been detected that contain either one or two copies of the LTR. Originally proposed as integration intermediates, it has been unequivocally demonstrated that these represent the products of aberrant reverse transcription that have no biological function.

2.5. Integration

Integration is a mechanism whereby proviral DNA is stably inserted into the host genome colinearly with the way it is synthesized by RT. This process is catalyzed by the integrase (IN) component of the *pol* open reading frame and is independent of host factors and external energy sources (8). The immediate LTR termini contain short, imperfect, repeat sequences (***att* sites**) that as shown by mutagenesis studies, constitute essential *cis*-acting sequences recognized by IN. In the absence of an exhaustive analysis, there is insufficient evidence to suggest preferential sites of integration in the host genome. During integration (the catalytic mechanism for which is described later), proviral DNA sequences are characterized by loss of two nucleotides at either end, whereas target sequences immediately adjacent to the integrated proviruses contain a short (4 to 6 bp) duplication, whose size is characteristic of a particular retrovirus. Examples of this are a 5-bp duplication in HIV and a 6-bp duplication in ALSV.

2.6. Viral RNA Synthesis

In essence, integration completes the first half of the retroviral life cycle, after which viral DNA is preserved in the **germ line** and transcribed from the LTR **promoter** by host-coded **RNA polymerase II**. Duplication of terminal sequences in the provirus implies that transcriptional signals of equal strength reside in both the 5′- and 3′-LTR. In fact, only the former is productively used, suggesting that regulatory signals downstream of the 5′-LTR are involved. The full-length genomic transcript initiates at the upstream U3/R junction with a "**5′-capped**" guanosine nucleoside and is **polyadenylated** immediately after the downstream R/U5 junction. In addition to LTR-derived RNA, spumaviruses initiate RNA synthesis from a site upstream of the *bel-1* gene, and additional transcriptional initiation sites have also been identified for MMTV. A later section deals with host-coded factors active on the LTR promoter and the role of the transactivators in augmenting gene expression.

2.7. Splicing and Transport of Viral RNA

In all retroviruses, the intact transcript is both the RNA genome and messenger RNA for synthesizing *gag* and *gag-pol* precursor polyproteins, whereas a singly spliced subgenomic transcript encodes the *env* precursor. Different mechanisms have evolved to maintain a balance between unspliced and spliced mRNA.

Simple retroviruses exploit a *cis*-acting sequence, designated the *negative regulator of splicing* (NRS), which interacts with components of the cellular machinery to reduce splicing efficiency. In contrast, to maintain this balance, complex retroviruses have evolved more elaborate systems, involving the accessory proteins Rex (HTLV) and Rev (HIV, Fig. 2), which are derived via multiple splicing shortly after integration (9). These accessory proteins interact with signals located within either the viral *env* mRNA (Rev) or the R/U3 region of 3′ LTR RNA (RxRE), which otherwise provide a barrier to the export of transcripts harboring such sequences that are characterized by complex secondary structures and designated Rex- or Rev-responsive element (RxRE and RRE, respectively). Additional interactions of this RNA-protein complex with components of the cellular transport machinery facilitate transfer of intact and singly spliced mRNA to the cytoplasm. As outlined in Fig. 3, low-level synthesis of transactivator proteins (Tat, Rev, Rex), shortly after infection or after transcription is activated, has the consequence that unspliced and singly spliced RNA are maintained in the nucleus. However, a threshold level of Rev or Rex is eventually achieved, so that intact and singly spliced RNA are efficiently exported to the cytoplasm and made available to the translational machinery for events leading to virion assembly. Although such elaborate mechanisms are absent in simple retroviruses, RNA containing introns (ie, unspliced) must likewise be transported to the cytoplasm, implying an alternative mechanism. Preliminary data from *D*-type MPMV and RSV suggest that this is facilitated by the interaction of a viral RNA sequence, designated the *constitutive transport element* (CTE), with host-coded factors.

2.8. Protein Synthesis

Spliced mRNA provide the template for synthesizing TM and SU components of the viral envelope (in this case on rough **endoplasmic reticulum**-associated **polyribosomes**), and accessory proteins and **oncogenes**, whereas intact, unspliced RNA fulfills two roles. A portion of these become genomes, and another directs synthesis of virion structural (*gag*) and enzymatic proteins (*pol*). The mechanism by which *gag* and *pol* components are synthesized is a good example of genetic "streamlining" in retroviruses, where different mechanisms have evolved to allow high-level synthesis of structural proteins and low-level synthesis of virion enzymes from the same mRNA (10). MLV achieves this via *transitional suppression*, a mechanism more often associated with **prokaryotic** organisms. A UAG **termination codon** is located between the *gag* and *pol* open reading frames, and to the larger extent terminates synthesis of the *gag* precursor. In about 5% of cases, however, the host translational machinery inserts a glutamine residue at this position, thereby overriding termination to synthesize a *gag-pol* precursor polyprotein. Because the *gag* and *pol* genes in most other retroviruses are not in the same reading frame, an alternative method must be employed. This involves ribosomal frameshifting, where slippage of the translating ribosome allows reading the base before (–1 frameshift) or after (+1 frameshift) together with the *gag* stop codon,

thereby creating the triplet for an amino acid. A single frameshift event is required to cotranslate the *gag* and *pol* genes in viruses, such as ALV and HIV, whereas two frameshift events are necessary when the PR open reading frame is out of frame with both of these (eg, MMTV, HTLV, and MPMV). In a frequently recurring theme, spumaviruses, the exception to these models of *pol gene* synthesis, have evolved an independently spliced mRNA for the *pol* gene that has its own translational initiation codon (11).

2.9. Assembly and Budding

Following their synthesis, *gag*, *pol*, and *env* gene products, together with a dimeric RNA genome, assemble in an ordered fashion at the cytoplasmic face of the cell membrane, gradually becoming enveloped in forming an immature virion. Membrane targeting of *gag* and *gag-pol* precursors is aided by N-terminal fatty acid modifications of MA that locate this protein to its ultimate fate as the inner shell of the virion. Lack of myristylation on *gag* precursors of ALSV and some lentiviruses suggests participation of additional, as yet unidentified, components in membrane targeting. An interaction involving a *cis*-acting element located at the 5′ end of viral RNA (the *encapsidation* or Y sequence) and *gag*-coded NC is critical for packaging the genome. Based the general nucleic acid binding properties of NC and the amount present in virions, it is most likely that this protein interacts with and "coats" the RNA genome. CA, located between MA and NC, is appropriately positioned to provide the virion core shell after proteolytic maturation. *Gag-pol* precursors are most likely oriented at the membrane similarly. They often serve an additional role of sequestering (via the *pol*-coded RT) the appropriate host tRNA isoacceptor required to prime reverse transcription events after subsequent infection. Alternatively, complementarity between viral PBS sequences and the 3′ terminus of the cognate replication primer may achieve the same goal. Only low-level DNA synthesis activity has been reported for RT embedded within the ~170kDa *gag-pol* precursor, which may reflect a control mechanism preventing premature reverse transcription before virion budding. Spumaviruses are the exception to this. Virions contain significant amounts of proviral DNA, which may lie in the observation that the *pol* gene is expressed independently of *gag*.

2.10. Virion Maturation

Immature cores that contain the appropriate protein and nucleic acid components gradually bud from the cell, together with a portion of the plasma membrane concentrated with the Env gene products. Concurrent with or after budding, the virally-coded protease is activated and is responsible for proteolytic maturation of *gag* and *pol* products. Maturation is are accompanied by significant morphological changes. The most notable of these is formation of an electron-dense virion core from "doughnut"-shaped precursor polyproteins that previously concentrated at the inner surface of the budding particle. At this stage, virions are considered capable of initiating a new cycle of infection by interacting with cell-surface receptors.

Reverse Translation

Translation is the biosynthesis of a protein from a messenger RNA template on ribosomes . Reverse translation is not a biological process. Instead, it is inferring DNA sequence from the amino acid sequence of a protein. Reverse translation is often employed to make a **hybridization** probe or a **PCR** primer used to **clone** the **gene** encoding the protein of interest (see Cloning) (1-3).

In most cases, the amino acid sequence of a protein is directly inferred from the DNA or mRNA sequence coding for the protein because each nucleic acid triplet (**codon**) specifies either a single amino acid or a termination signal (see Genetic Code). The converse, determining the DNA or mRNA sequence coding for a specific amino acid, is more complex because the genetic code is "degenerate" (see Degeneracy of the Genetic Code). In the nuclear DNA of **eukaryotes**, 61 codons specify 20 amino acids, so many amino acids are coded by more than one codon. This means that reverse translation of a protein does not produce a single nucleotide sequence. Instead, it results in a population of different sequences that, if translated, would all code for the same amino acid sequence. To identify the actual genomic sequence that codes for the protein *in vivo*, it is necessary to clone and sequence the gene for the protein. The first step in cloning is to synthesize a mixture of oligonucleotides (oligos) that corresponds to all of the potential coding sequences determined by reverse translation. This pool of oligos is used as a "degenerate" (mixed) hybridization probe to isolate the corresponding DNA or cDNA clone from a library. Alternatively, reverse translation is used to design two sets of "degenerate" PCR primers to amplify the gene from genomic DNA.

When using reverse translation to design degenerate oligos for gene cloning, several factors must be taken into account. A 14-base oligo is sufficiently long to identify the gene of interest specifically, but the five-residue stretch of protein that is reverse translated to produce this oligo must be chosen carefully. The more protein sequence that is known, the easier it is to find an appropriate amino acid stretch to reverse translate. Because serine, leucine, and arginine are each coded by six different codons, these residues should be avoided. Protein sequences containing tryptophan and methionine residues are preferred, because they are each coded by only one triplet codon. Fewer different oligo sequences are needed to cover all reverse translation possibilities if less "degenerate" amino acids are chosen, and a less complex set of oligos makes a more efficient probe or PCR primer. Different organisms preferentially use particular codons to specify amino acids, and this **codon usage bias** should also be taken into account when designing oligos by reverse translation. Additionally, computer programs are available to help design synthetic genes and degenerate probes and primers

by using reverse translation (4).

Once many of the large-scale genome sequencing projects are complete (eg, the human, **Caenorhabditis elegans**, and Arabidopsis sequencing projects), and with the ever increasing number of expressed sequence tags (ESTs) available, reverse translation most frequently will be used to isolate genes from organisms where little sequence data is available. For well-studied organisms, database searches (where a computer program compares known protein sequences and translated nucleotide sequences to look for similarities) will replace the need to reverse translate and clone to determine the nucleotide sequence.

Reversed-Phase Chromatography

In general, any **chromatographic** separation, in which the mobile phase is more polar than the stationary phase and polar solutes move with this mobile phase rather than remain with the less polar stationary phase, is called reversed-phase chromatography. More specifically, reversed-phase chromatography (particularly in **HPLC**) refers to those procedures in which the stationary phase consists of silica beads that are completely covered with covalently bound hydrophobic *n*-alkyl chains (eg, octyl, C8, or octadecyl, C18). In reversed-phase chromatography, the adsorption of a solute to the reversed-phase matrix is generally driven by **hydrophobic** interactions, and the solutes migrate in decreasing order of net charge, extent of ionization, and **hydrogen-bonding** capabilities.

Because of its excellent resolution, experimental ease, high recoveries and excellent reproducibility, reversed-phase HPLC now plays a critical role in the biochemical/biomedical studies (see reviews 1, section V of Ref. 2, pp. 273–421, 3 and 4). Detailed practice is beyond the scope of this volume, and interested readers are directed to the reviews cited previously and to a number of excellent monographs (5, 6).

Reversion, Revertant

A reversion is a mutation that restores the wild-type **phenotype** to a mutant. A revertant is an individual who has a reversion mutation. Reversion assays are used to investigate the mechanism by which a mutagen acts. Reversional assays are powerful genetic techniques for studying mutations because revertants are usually easy to detect. Reversion assays rely on restoring a wild-type phenotype, and this gain of function can usually be selected for, as opposed to the loss of function that must usually be screened for (see **Selection**).

The most straightforward revertants are **genotypic** in which the original wild-type **gene** sequence is restored. The most widely used reversion assay was developed by Bruce Ames. Using various strains of *Salmonella typhimurium* with known mutations in the his operon, the frequency of reversion to histidine **prototrophy** is measured after exposure to mutagens. Because the mutations that cause the various examples of histidine **auxotrophy** are known (base-pair substitutions or frameshift mutations), the nature of the mutation that caused the reversion is known.

Phenotypic reversion also occurs by mutation at sites different from those of the original mutation. The second mutation can occur in the same gene, in which case it is a *second-site revertant*. In a protein gene product, the second amino acid change in the protein apparently corrects the first amino acid change. Compensating nucleotide changes are also known in transfer RNA molecules. If the second mutation occurs in a different gene, the phenomenon is known as **suppression**. Such mutations give valuable information about functional protein–protein interactions.

RGS Proteins

RGS proteins, **R**egulators of **G** protein **S**ignaling, are a family of **membrane**-associated multi-**domain** proteins that modulate the activities of the heterotrimeric G proteins. Although the first known RGS protein, Sst2p in yeast, was discovered in 1987 (1), the existence of the family and its mechanism of action was not known until 1996 (2). At least 30 mammalian RGS proteins have been identified at the level of complementary DNA sequences, about a dozen are known in ***Caenorhabditis*** *elegans*, and family members have been identified in several fungi, multiple animal phyla, and higher plants. RGS proteins in animals act on members of the G_i and G_q families of heterotrimeric GTP-binding proteins, with varying degrees of specificity within this large group. Their specificity in fungi and plants is unknown, but it may be limited practically by the small number of Ga subunits in these kingdoms.

The RGS proteins that have been studied biochemically have been found to be **GTPase**-activating proteins (GAPs) for their G-protein targets (3). They bind the activated, GTP-bound form of the Ga subunit and increase the rate at which it hydrolyzes bound GTP. Stimulation of this deactivation rate can be as much as 100-fold. RGS proteins are thus intrinsically inhibitory to G-protein signaling, and overexpression of RGS proteins in animal cells or yeast does indeed inhibit signaling. The

physiological roles of RGS proteins are less well established. In yeast, Sst2p is a feedback inhibitor of the G-protein-mediated **mating** factor signaling pathway. Sst2p transcription is induced by this pathway, and Sst2p rescues yeast from cell-cycle arrest induced by mating factor. Genetic studies of the flb protein in *Aspergillus* and the Egl10 protein in *C. elegans* also suggest that they act by damping a G-protein signal. RGS proteins may not be physiologically inhibitory in all cases, however; they can also lower basal or background signaling in the absence of stimulation by receptors, and they are probably vital for accelerating the return of signals to background levels upon termination of stimulation by agonists. How RGS proteins are themselves regulated, other than by transcription of their messenger RNA, is unknown, although the GAP activities of several RGS proteins were recently shown to be inhibited when their Ga target is linked to a **palmitoyl group**. RGS proteins appear to be expressed at low levels, in some cases well below those of their presumed Ga targets, and limited association with subpopulations of G proteins may add to the specificities of their effects.

RGS proteins can be recognized from their primary structures because of a highly conserved domain of about 115 amino acid residues in length. This "RGS box" forms a **four-helix bundle** that binds end-on to the switch II region of the G-protein a subunit (4). Sequences of RGS proteins diverge markedly on either side of the RGS box, and the functions of these *N*- and *C*-terminal domains are unknown. RGS that have been truncated to leave only the RGS box retain GAP activity, but have diminished affinities for Ga substrates, so the regions outside the box are thought to increase their affinity for G proteins and, perhaps, to enhance selectivity among them. The *N*-terminal regions of several RGS proteins may also contribute to the protein's ability to bind to membranes.

Rhinovirus

Rhinovirus is a major cause of the common cold, and it is a **virus** member of *Picornaviridae* family (see Poliovirus). Members of this family are small, icosahedral, nonenveloped viruses. Their structures have been determined by X-ray crystallography (Fig. 1 and 2). A small shell with a diameter of 30 nm consists of 60 copies each of proteins VP1, VP2, VP3, and VP4, which encapsulate one copy of single-stranded RNA genome of positive polarity. Like other positive-strand RNA viruses, the genome of rhinovirus is infectious and functions as messenger RNA after entry into host cell cytoplasm. Translation of the viral mRNA occurs by entry of a ribosome in an internal nucleotide sequence within the 5′-untranslated region of the RNA. A unique long open reading frame encodes a single large polyprotein that is the precursor for all the virus-specific proteins. The optimal temperature for growth of rhinovirus is 33°C in cultured cells.

Figure 1. Schematic diagram of a human rhinovirus particle. The icosahedral symmetry, subunit organization, and canyon (shaded) are shown. Thick lines encircle the five protomers of VP1-VP3. The fourth viral protein, VP4, is inside the capsid.(From Ref. 1, with permission.).

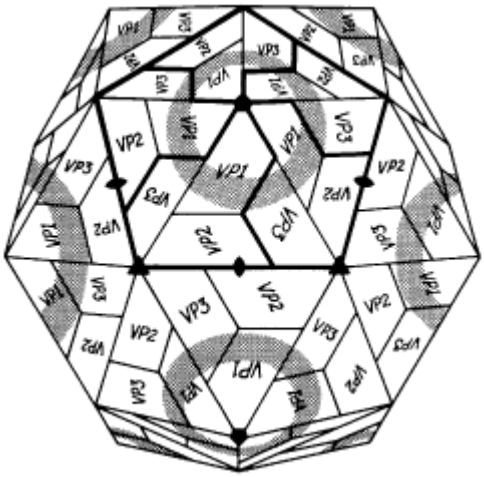

Figure 2. Structures of human rhinovirus. The two pictures on the left give a stereoview of a single-particle reconstruction by cryoelectron microscopy of human rhinovirus 16 in a complex with D1D2, viewed along an icosahedral two-fold axis in approximately the same orientation as in Figure 1. D1D2 is a polypeptide chain consisting of domains 1 and 2 of ICAM-1. The right view is a shaded-surface view of rhinovirus 14, computed from the known atomic structure and truncated to 20-Å resolution. The triangular outline of one icosahedral asymmetric unit corresponding to that in Figure 1 is indicated. Bar = 200 Å.(From Ref. 1, with permission.)

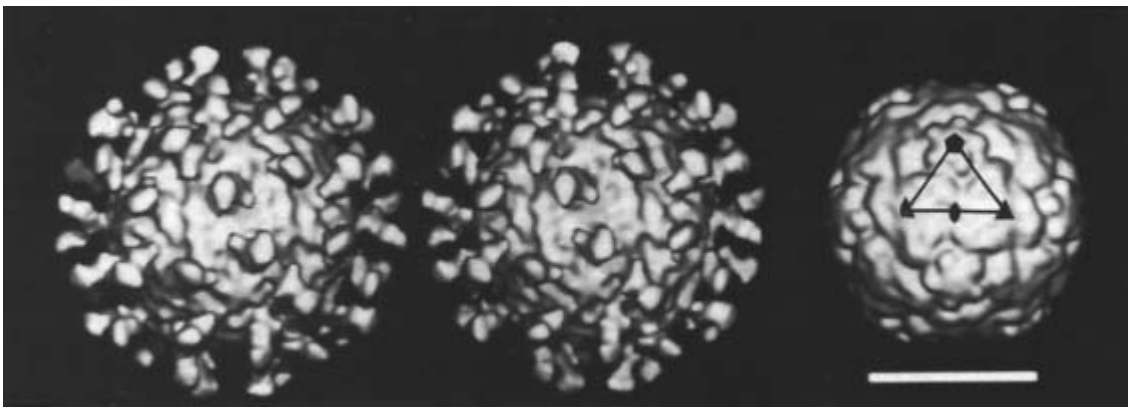

More than 100 different serotypes of human rhinovirus are known. With one exception (rhinovirus type 87), human rhinoviruses use one of two types of receptors to gain entry into the cell. The majority of human rhinovirus, referred to as the major group, bind to the cell-surface molecule known as intercellular adhesion molecule 1 (ICAM-1), a member of the immunoglobulin superfamily. It has been demonstrated that 60 attachment sites for ICAM-1, called the canyon, exist per virion (Fig. 2, see top of next page). Interaction of the receptor with the virion particle results in an alteration of the conformation of the virion structure, which is considered to be important for establishment of the virus infection. The minor group (serotypes 1A, 1B, 2, 29, 30, 31, 44, 47, 49, 62) enter host cells via the low-density lipoprotein receptor (LDLR) and the a_2 macroglobulin receptor/LDLR-related protein, which is also a member of the LDLR family.

Because of the numerous serotypes of human rhinovirus, it has not been possible to develop effective vaccines against the common cold. Thus, most effort has focused on the development of effective antiviral reagents. Elucidation of the three-dimensional structure of rhinoviruses made it possible to study the interaction of drugs with the virus capsid proteins. As a result, many compounds are described to bind to the **hydrophobic** pocket at the floor of canyon on the virion particle, so that the receptor cannot bind the virus. Although topical administration of canyon inhibitors failed to provide a favorable effect, these inhibitors have been used effectively to understand the molecular basis of virus-receptor interaction.

Rho GTPases

Ras homology (RhO) proteins constitute one of the families of cytosolic 20- to 30-kDa **GTPases homologous** to $p21^{Ras}$. They are involved in regulating the actin-**cytoskeleton** organization, gene transcription, membrane trafficking, development, and cell proliferation. The three key members were originally described on the basis of their effects on cultured 3T3 fibroblasts:

- RhoA was implicated in forming stress fibers, bundles of actin filaments that contain myosin and a-actinin.
- Rac1 induces a meshwork of actin filaments associated with lamellipodia and membrane ruffles.
- Cdc42Hs produces actin-rich protrusions called filopodia.

More esoteric members of this continually expanding family include the human proteins RhoB, RhoC, RhoD, RhoE, RhoG, Rac2, Rac3, TC10, Rnd1, Rnd2, and several homologues found in yeast and invertebrates, such as *Drosophila melanogaster* and ***Caenorhabditis*** *elegans*. Because of space limitations, this article focuses on the principal three mammalian Rho GTPases.

1. Overview

Like all GTP-binding proteins, Rho Gtpases cycle between the biologically active, GTP-bound form, and the inactive GDP-bound form. The GDP-bound form is found predominantly in the cytosol, tightly complexed with Rho guanine nucleotide dissociation inhibitor (GDI). The active state of the GTPase has a lifetime limited by the rate at which it hydrolyzes bound GTP to GDP and inorganic phosphate. Because of the very low intrinsic catalytic rates of the GTPases, their biological activity is down-regulated by GTPase activating proteins, or GAP s. Upon GAP-assisted GTP hydrolysis, the GTPase reverts to the GDP-bound ground state and is solubilized in the cytosol by RhoGDI, completing the cycle.

The biological cycle of a Rho GTPase is initiated in response to extracellular signals with the exchange of GDP for GTP, a process that requires dissociation of the RhoGDI–GTPase complex. A

family of guanine nucleotide exchange factors (GEFs) is responsible for stimulating the exchange of GDP for GTP. In the active, GTP-bound state, the Rho GTPases are associated with the cell membrane. This interaction, it is thought, depends primarily on the geranylgeranyl membrane anchor groups on the C-terminal cysteine residues. In their active form, the Rho GTPases bind to and stimulate specific downstream effectors, often protein kinases, thus activating a network of signaling pathways that span the entire cellular space from the focal adhesion complexes to the nucleus.

Signaling pathways that involve the principal Rho GTPases are intertwined. In 3T3 fibroblasts, Cdc42Hs activates Rac, which in turn activates Rho. All Rho proteins function downstream of a Ras-mediated cascade. It is quite possible, however, that the hierarchical patterns differ, depending on the cell type and the physiological phenomena involved.

2. Molecular structure

At present, our knowledge of the molecular structures of Rho proteins is derived from **X-ray crystallographic** studies of Rac1•GppNHp (1), RhoA•GDP (2) and RhoAVal14•GTPgS (3), all in their unprenylated forms. In addition, Cdc42Hs has been studied in both GDP and GTP-analog bound states by multidimensional NMR (4). Like Ras, Rho protein structures consist of a single **domain** with a six-stranded beta-sheet surrounded by **alpha-helices** (Fig. 1). The following description applies specifically to RhoA, which is used as a representative example. The b-sheet contains two antiparallel (B2 and B3) and five parallel beta-strands (B3, B1, B4-B6), five a-helices (A1, A3, A3′, A4, A5), and three 3_{10}-helices (H1–H3). When compared to Ras, Rho proteins contain three insertions and one deletion. The 13-residue insertion (Asp 124 to Gln 136 in RhoA) between strand B5 and helix A4 is the most distinctive feature that clearly differentiates Rho from other Ras-related GTPases. The amino acid sequence in this insert varies considerably among different Rho proteins, suggesting functional implications. Interestingly, the conformation of this helix does not depend on the type of nucleotide bound to the protein.

Conformational differences between RhoA•GDP and RhoA•GTPgS are restricted to the switch I and switch II regions (the nomenclature follows that used for Ras). Dramatic changes in switch I from the GDP- to the GTP-bound state are exemplified by displacements of 5.4 Å and 6.4 Å (1 Å = 10^{-10}m) at Pro36 and Phe39, respectively (Fig. 1**b**). The side chains of Pro36 and Tyr34 become oriented toward the nucleotide, so that the ring of Tyr34 stacks on Pro36. Three **hydrophobic** residues, Val35, Val38, and Phe39, become solvent exposed, suggesting their involvement in target binding following GTP-induced activation. An important difference between the GDP and GTPgS-bound RhoA relates to the mode of Mg^{2+} ion binding. In the former, the Mg^{2+} ion is coordinated by three water molecules, a g-phosphate oxygen atom, and two protein ligands, including the main-chain carbonyl of Thr37, whereas in the GTPgS structure the coordination is similar to $p21^{Ras}$ in its active form and involves the side chain of Thr37.

Switch II contains a segment of the polypeptide chain between strands B3 and B4, including Gln63, which is essential for the catalytic activity of the protein, both intrinsic and GAP-stimulated. In RhoA•GDP, residues 63 to 65 are disordered, whereas in the complex with GTPgS the segment is well defined by two 3_{10} helices, H1(residues 64 to 66) and H2(residues 70 to 72), separated by a short loop. A similar conformation is found in Rac•GppNp, suggesting that it is physiologically relevant. The sequence in this region is relatively well conserved among Rho GTPases and is probably less involved in target selection.

Both GTP and GDP bind to Rho GTPases with nanomolar **dissociation constants**. The nucleotides interact with the phosphate-binding P loop, typical of all small GTPases, and contain a **consensus sequence** Gly-X-Gly-X-X-Gly-Lys-Thr/Ser. Mutation of the second Gly in this motif (Gly14) to Val renders Rho active by inhibiting its catalytic properties, both intrinsic and GAP-induced. As inferred from the RhoA•GTPgS complex, GTP makes 21 direct and nine water-mediated hydrogen bonds to

the protein that involve six residues of the P loop, four residues in switch I, three residues in switch II, and four residues involved in base recognition. This coordination of the nucleotide rationalizes the structural changes in the switch I and switch II regions. Figure 1 shows the representative structural features of the RhoA GTPase.

Figure 1. Structural features of RhoA GTPase. (**a**) The structure of RhoA in an inactive conformation with bound GDP and Mg^{2+}. The secondary structural elements are labeled, and the switch I and switch II regions are highlighted. Also indicated are the locations of the insert helix and residues Gly14, Thr37, and Asn41. (**b**) The conformational changes in switch I upon activation of RhoA. Alignment of the inactive and active structures of RhoA reveals dramatic changes in the switch I region. The GDP-bound conformation is shown as dark line from the same perspective as in A, and the aligned GTPgS-bound conformation is shown as the lighter line. PDB codes 1FTN and 1A2B.

All Rho GTPases undergo complex **posttranslational modifications** . First, Type I geranylgeranyl (20-carbon) transferase attaches the geranylgeranyl group covalently through a thioether linkage to the cysteine residue in the C-terminal Cys-Ala-Ala-X motif, that typically contains Leu in the "X" position. Following prenylation, the three terminal residues are cleaved off by a specific proteinase and the terminal prenylated Cys is carboxymethylated (5). Unmodified Rho GTPases (eg, those expressed in *Escherichia coli*) fail to associate with membranes and do not interact with GDI (see GDI later), but in most cases bind and activate their downstream effectors in complexes with slowly hydrolyzable GTP analogs, such as GTPgS or GppNHp. Although prenylation is a necessary factor for translocating Rho to membranes, it may not be sufficient. Emerging evidence suggests that specific proteins in caveolae—unique microdomains of membranes involved in signal transduction—may be involved in Rho binding (6). The structural aspects of these interactions are not known.

3. Regulatory proteins

Like all GTPases, Rho proteins are subject to tight regulation. This is accomplished in a cell by accessory proteins that act downstream and upstream of the Rho•GTP complex. A brief review follows of what is known about these regulatory proteins.

3.1. Guanine Nucleotide Exchange Factors (GEFs)

GEFs activate Rho GTPases by a >10 fold stimulation of GDP dissociation and concomitant exchange of GDP for GTP. Almost twenty proteins that have Rho GEF function have been identified to date in mammalian genomes. Tight binding is observed for GEFs and nucleotide-depleted GTPases. GEFs cannot act on the GDP-bound cytosolic pool of Rho proteins, which are in complex with GDI, and it is believed that additional accessory molecules are involved. The ezrin, radixin, moesin system (ERM) has been recently implicated in the dissociation of the GTPase-RhoGDI complex (7, 8).

The mechanism of Mg^{2+} coordination in RhoA•GDP and mutagenetic studies are consistent with a model in which GEFs act on Thr37 (RhoA numbering) of Rho to destabilize the bound Mg^{2+} ion before GDP dissociation (9). The catalytic activity of GEFs resides in the Dbl homology (DH) domain, typically linked to a PH (**pleckstrin homology**) domain, responsible for targeting GEF (10). However, several proteins that have DH domains do not show any GEF activity and therefore may recruit Rho to specific locations. Finally, other domains, such as src homology 3 (SH3), and the diacyglycerol-binding "zinc butterfly" motif are also found in GEFs, suggesting additional functions (11).

Some GEFs are quite selective with respect to the GTPase that they activate, and others have broad specificities. For example, Lbc and Lsc are distinctly Rho-specific with respect to both nucleotide exchange and binding, whereas Dbl binds to all three Rho proteins and stimulates GDP for GTP exchange in Cdc42Hs and Rho (12).

Many Rho GEFs, including the prototypical Dbl, are **oncoproteins**, although their oncogenic potential may stem primarily from functions other than their GEF activity.

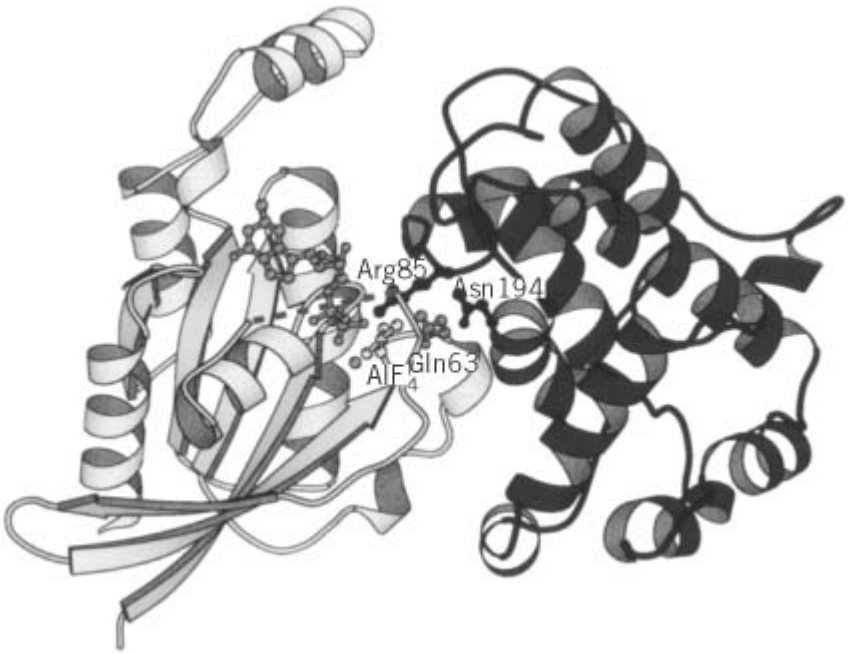
Relatively little is known about the upstream activation events that stimulate the action of GEFs on Rho. **Tyrosine kinase** and G-protein coupled receptors, it is believed, are involved in the activation step (13, 14). The recent discovery of p115RhoGEF, a GTPase activating protein for Ga_{12} and Ga_{13} provides evidence of a direct link between heterotrimeric G-proteins and Rho GTPases (15, 16).

3.2. GTPase-Activating Proteins (GAPs)

RhoGAPs enhance the rate of hydrolysis of GTP by Rho GTPases by a factor of up to 10^5. They are multidomain, often large proteins, but their GTPase activity resides in one particular domain, known as the BH-domain or just the GAP domain (17). The breakpoint cluster region homology (BH)

domains are approximately 200 residues long and constitute a **homologous** family. The BH-domain of the **phosphoinositide 3-kinase** p85a subunit is unique in that it shows no enhancement of hydrolysis although it binds CDc42Hs and Rac (18). BH domains enhance the catalytic activity of Rho GTPases. GAPs bind strongly to Rho GTPases only in the presence of AlF_4, when a transition-state analog is produced by the complex of AlF_4 and RhoGDP [this phenomenon was first observed in RasGAP, which is required to downregulate Ras, also a GTPase (19)]. The structure of the BH domain of p50RhoGAP, a ubiquitous GAP that activates all Rho proteins, has been determined by X-ray crystallography on its own and in complexes with Cdc42Hs•GppNHp and RhoA•GDP, the latter in the presence of AlF_4 (20-22). The tertiary structure of this molecule includes nine helices, four of which form the core bundle (Fig. 2). Though originally not recognized, there is a structural relationship between the RhoGAPs and the RasGAPs, implying possible homology (23). Like RasGAP, the Rho GAPs operate by the "arginine-finger" mechanism. When bound to the transition-state Rho•GTP, GAP donates an Arg residue (Arg85 in the case of p50RhoGAP) directly to the active site. This arginine is functionally equivalent to Arg178 of the heterotrimeric G protein G_{ia1}. In addition to their direct participation in catalysis, GAPs also stabilize the switch regions in the GTPases.

Figure 2. The structure of p50RhoGAP complexed with RhoA GDP in the presence of AlF_4. The transition-state complex is mimicked by the binding of p50RhoGAP (dark area on right side) to RhoA with bound GDP (area near AlF_4) and AlF_4 (light areas on left side). PDB code 1TX4. Arg85 of p50RhoGAP is highlighted, as is Gln63 from RhoA.



The crystal structures also allow rationalizing the observed effects of the Gly14→Val mutation of Rho. Gly14 is within the interface region, and any side chain in this position interferes with GAP binding. Accordingly, the mutant resists the GAP-induced GTP-hydrolysis and continues to activate its its targets.

The structures of the p50RhoGAP complexes show clear interactions with both switch I and switch II residues of Rho. Specifically, Gln63 in RhoA is clearly resolved in the complex that contains AlF_4, suggesting that GAP assists in the stabilizing the catalytically competent conformation that

orients the hydrolytic water molecule during its nucleophilic attack on the g-phosphate. This stabilization can be seen as an **allosteric** contribution to catalysis.

RhoGAPs downregulate the Rho GTPases by accelerating their GTP hydrolysis and concomitant return of the protein to its inert, GDP-bound state, and also by binding to those epitopes on the GTPase that are thought to be involved in the interactions with effectors. It has been postulated that some GAPs may serve as specific Rho effectors, and studies of *n*-chimaerin substantiate this proposal (24). The GAPs are targeted to the appropriate location through their SH2 and SH3 domains, their PH domains, and proline-rich segments that may interact with SH3 domains on other proteins. Some GAPs contain domains harboring catalytic activities, for example, kinases. Others contain GTPase binding domains, GEF domains, or novel domains of unknown function. Rho-specific BH-domains have also been identified in the heavy chains of class IX myosins (25).

The specificity of GAPs toward different Rho family GTPases varies significantly. Most GAPs are active on at least two GTPases. For example, MgcRacGAP acts on Rac and Cdc42Hs (26), whereas Graf activates Cdc42Hs and RhoA, but not Rac (27). Specific activities are typically assayed *in vitro* on either isolated BH-domains or GST-fused BH-domains. It is not clear to what extent the activity of GAPs is modulated *in vivo* by targeting through other domains.

3.3. GDP Dissociation Inhibitor (RhoGDI)

RhoGDI extracts Rho GTPases from membranes and arrests the cycling of these proteins at the GDP-bound point (8, 28-30). Both prenylation and **proteolytic** truncation of the C-terminal three residues from the Cys-Ala-Ala-X motif in Rho are essential for RhoGDI binding, but carboxymethylation is not. Although GDIs have been described for other GTPases, notably Rab, the RhoGDI is a unique protein that has three closely homologous isoforms identified to date: RhoGDIa, GDI/D4 (67% sequence identity)(31) and GDIg (50% sequence identity) (32). Athough RhoGDIa interacts with all three key Rho proteins, the specificities of the other isoforms have not been determined. The ubiquitously expressed RhoGDIa is made up of a single polypeptide chain of 204 residues. There are two domains, the N-terminal domain (residues 1 to 64) which is disordered in solution in the absence of a GTPase, and an ordered domain, which begins approximately at residue 65 and has a b-sandwich fold (33, 34). The N-terminal 22 residues do not to play any functional role, whereas the fragment 23 to 64 is essential for the guanine nucleotide exchange inhibition. Binding to the GTPase, with a dissociation constant in the high nanomolar range, is attributed largely to the b-sandwich domain (a truncated 42 to 204 protein binds to Cdc42Hs only 100-fold less tightly). A narrow hydrophobic cleft in the C-terminal domain is expected to bind isoprenes. The structure of the RhoGTPase-RhoGDI complex is currently not known, but mutagenetic results indicate the insertion helix characteristic of Rho proteins (see above) is involved in the GDP-dissociation inhibition by GDI (35).

4. Downstream effectors

To date, a number of potential targets of Rho proteins have been identified, primarily by the yeast two-hybrid system (36). In many cases, especially those that involve enzymes, the functional significance of these interactions has been substantiated by activation assays. The following are among the targets thought to be physiologically most relevant.

4.1. ROKa/ROKb

These proteins, more than 1300-residues long, coprecipitate with RhoA in its active form and associate with the latter physically and functionally *in vivo* and *in vitro* (37, 38). The two proteins differ only with respect to their N-termini. ROKa is nine residues longer. The catalytic N-terminal domain was identified on the basis of amino acid sequence homology to the Ser/Thr protein kinase A family. The catalytic activity of ROK kinases is enhanced by binding of active RhoA. Downstream of the kinase domain is a putative coiled-coil segment of 600 residues, followed by a PH-domain and a cysteine-rich **zinc-finger** motif. The kinase activity of ROK induces the formation of stress fibers in the absence of the active RhoA, strongly suggesting that the reorganization of the cytoskeleton by

RhoA is mediated through ROK. Among the putative targets of ROK is the myosin-binding subunit (MBS) of myosin light-chain phosphatase (39, 40).

4.2. Protein Kinase N (PKN)
PKN is a 120-kDa **serine/threonine kinase** that interacts with RhoA in a GTP-dependent fashion (41, 42). The kinase domain in this protein is homologous to protein kinase C. PKN is probably involved in the reorganization of cytoskeletal elements, a function mediated through its direct interaction with a-actinin (43).

4.3. p21 Associated Kinases (PAK)s
These Ser/Thr kinases associate with both Rac and Cdc42Hs in a GTP-dependent manner. At least three **isoforms** (PAK1/a, PAK2/g, and PAK3/b) are found in mammalian tissues, albeit they have different tissue distributions (44-46). PAK3 is released from the GTPase upon activation, and the other two remain bound. The protein kinase domains located in the C-terminal part are highly conserved and contain a distinguishing Gly-Thr-Pro-Tyr/Phe-Trp-Met-Ala-Pro-Glu (GTPY/FWMAPE) signature motif, a possible site of regulatory **phosphorylation**. The N-terminal fragment contains a **C**dc42Hs/**R**ac **i**nteractive **b**inding (CRIB) domain, also known as the **p21-b**inding **d**omain (PBD) or **G**TPase-**b**inding **d**omain (GBD) domain, which mediates the interaction of PAK with the GTPase. CRIB-domains have been found in other proteins, and they may effectively help in identifying Rho targets (47, 48). An N-terminal Pro-rich fragment, it is believed, interacts with SH3-containing proteins. Although PH-domains occur in yeast PAK homologues, no such PAKs have been found to date in mammalian genomes. At present, downstream signaling pathways mediated by PAKs are not well understood. Involvement in cytoskeletal rearrangement is very likely.

4.4. Plenty of SH3s (POSH)
This ubiquitously expressed 93-kDa protein interacts with Rac (but not Rho and Cdc42Hs) in a GTP-dependent manner (49). It is implicated specifically in gene transcription regulation, that is, Rac-mediated JNK activation. In Cos-1 cells, POSH induces JNK activation and NF-kB nuclear translocation. The protein contains a potential zinc-finger structure at the N-terminus and four SH3 domains. The two C-terminal SH3 domains are sufficient to induce NF-kB translocation, but not JNK activation. Overexpression of POSH is toxic to cells and results in apoptosis.

4.5. $p67^{phox}$
This protein is a Rac target and a component of the NADPH oxidase complex. It is essential for superoxide formation, along with Rac1, cytochrome b, and $p47^{phox}$ (50). The Rac1 binding site is cryptic and has been mapped to the N-terminal fragment, which can inhibit other Rac-mediated pathways (51).

4.6. Other Targets
Other targets include rhophilin (42) and rhotekin (42), both of which are homologues of PKN devoid of kinase activity and targets of RhoA; citron (52) (target of Rho and Rac); phospholipase D (RhoA, possibly Rac) (53); p140mDia (RhoA) (54); p140Sra-1 (Rac1) (55); phosphoinositide 3-kinase (Rac, Cdc42Hs) (56); IQGAP (Cdc42Hs) (57); and several others.

The Rho-family targets contain a variety of GTPase-binding motifs. Similarly, Rho GTPases utilize several surface epitopes in their interactions with the effectors. Lack of structural information about the complexes precludes a more detailed analysis.

5. The mechanism of *Clostridium* toxins

Several Rho proteins are targets for potent toxins produced by various species of *Clostridium*. Toxins A and B are from *C. difficile* monoglucosylate Thr37 (58, 59). The same residue is modified by the *C. novyi* a-toxin, which transfers an *N*-acetyl-glucosamine moiety onto it (60). These toxins target all three major Rho proteins. The C3 toxin from *C. botulinum* and the staphylococcal

epidermal-cell differentiation inhibitor catalyze specific **ADP-ribosylation** of RhoA on Asn41 (61-63). Because Asn41 is close to the critical region of switch I, ADP-ribosylation may cause steric hindrance to prevent forming productive Rho-effector complexes.

5.1. Physiological and Pathophysiological Phenomena Regulated by Rho

Extensive studies have implicated Rho GTPases in a variety of regulatory mechanisms, specifically those that control cytoskeletal organization and gene transcription. In addition, numerous targets have been identified, typically kinases that become activated when bound to the GTPase. Given the wide ranging effects of Rho on cells, it is often difficult to identify specific physiological effects that the proteins exert on the tissues or systems. Three examples of established physiological functions of Rho are given here.

5.2. Calcium Sensitization of Smooth-Muscle

The regulatory effect of Ca^{2+} on smooth-muscle contraction is amplified by the Ca^{2+} sensitization effect, which involves inhibition of myosin phosphatase (64). RhoA and its target ROKb mediate the process. Abnormal smooth-muscle contractility is a factor in hypertension. The pyridine derivative Y-27632 inhibits ROKb kinase activity, and it consequently inhibits smooth-muscle contraction. Administered to hypertensive rats, the compound drastically reduces their blood pressure, suggesting a new approach to hypertension chemotherapy (65).

5.3. Development

The ability of Rho to reorganize actin filaments is vital for morphogenetic pathways during development. This has been demonstrated primarily in *Drosophila*, where Rac and Cdc42 homologues are expressed ubiquitously in the nervous system and mesoderm and play a key role in neural and muscle differentiation (66). Strong evidence supports the role of Rac and RhoA in neuronal development in humans. Interestingly, X-linked mental retardation has been linked to disruption of RhoA-mediated developmental pathways (67, 68).

5.4. Cell Transformation

Although Rho proteins are not generally regarded as potent oncoproteins, they are essential for $p21^{Ras}$ -induced neoplastic transformation (69). It has been shown that RhoA suppresses $p21^{Waf1/Cip1}$, an inhibitor of the cell cycle that, in RhoA's absence, would interfere with Ras driving the cells into the S-phase of the cell cycle (70).

6. Summary

The studies of Rho-mediated signaling pathways constitute one of the most active contemporary areas of biomedical research. This article provides only a superficial and very selective overview. Interested readers are urged to refer to current literature for the status of the field.

Rhodopsin

Rhodopsin is the key player in the biology of vision; it is a membrane protein with seven a-helices that functions as the photoreceptor in rod cells of the retina in the vertebrate and invertebrate eye (1). Many eukaryotic G-protein-coupled receptors (see Heterotrimeric G Proteins), among them the b-adrenergic receptor, are **homologous** to rhodopsin. In these receptors, the ligands bind to the pocket occupied by the **prosthetic group** retinal in rhodopsin. Bovine rhodopsin consists of 348 residues and resides in the disc membranes of the outer segments of rod cells. The photoactive center of rhodopsin comprises retinal, or vitamin A aldehyde, bound through a protonated Schiff Base to a lysine residue in the *C*-terminal a-helix of the protein. Upon absorption of a photon, the bound chromophore isomerizes from the 11-*cis* form to all-*trans* retinal. The cis/trans isomerization is followed by the sequential appearance of spectroscopic intermediates (known as the rhodopsin

photocycle). Finally, the isomerized chromophore dissociates from the protein, followed by regeneration of the dark form of rhodopsin with 11-*cis* retinal.

An intermediate called metarhodopsin II, in which the retinal is in the all-*trans* configuration and the Schiff base unprotonated, is formed within milliseconds during the photocycle. This is linked to structural changes on the cytoplasmic face of rhodopsin, where it interacts with transducin, a heterotrimeric G protein. This structural change involves a rigid-body movement of a-helix F (2) and leads to the dissociation of the a-subunit from transducin. The a-subunit of transducin activates a **phosphodiesterase**, which hydrolyses cyclic GMP. The decrease in the cyclic GMP concentration closes cation channels in the plasma membrane and causes hyperpolarization of the membrane of the rod cells. Cycles of hyperpolarization in light and depolarization in dark generate the nerve impulses required for vision. The lifetime of metarhodopsin II is of the order of 1 min. Because of the longevity of this state, the activity of metarhodopsin II is also regulated by rhodopsin kinase (see **Phosphorylation**) and by the binding of an inhibitory protein, called *arrestin*, to the phosphorylated site near the *C*-terminus of rhodopsin on the cytosolic side of the membrane.

A structural model of rhodopsin at an intermediate resolution has been constructed using electron microscopy of two-dimensional crystals (3, 4). The model shows that the arrangement of the seven transmembrane helices in rhodopsin is distinct from that of another light-transducing, retinal-containing protein, bacteriorhodopsin. Bacteriorhodopsin from the archeon *Halobacterium salinarium* (formerly *H. halobium*), with its high-resolution structure and wealth of mutagenetic, spectroscopic, and biophysical data, is the most thoroughly characterized membrane protein. It contains 248 residues, has seven transmembrane a-helices, and carries the same prosthetic group as rhodopsin, namely, a retinal bound to a lysine residue via a protonated Schiff base. In both rhodopsin and bacteriorhodopsin, the absorption of a light quantum brings about a photocycle with associated rotational and tilting movements of some transmembrane a-helices. Despite these similarities, there is no sequence homology between bacteriorhodopsin and rhodopsin.

Bacteriorhodopsin is a light-driven **proton pump**. As with rhodopsin, absorption of a photon causes isomerization of the bound retinal in bacteriorhodopsin, but in this case from all- *trans* to 13-*cis*. This primary photochemical event is followed by a characteristic multistep photocycle, in which some steps are linked to slight movements of some a-helices and proton translocation across the cell membrane (5). There are two aqueous channels, one from each side of the membrane to the Schiff base in the middle. Two aspartic acid residues, one on the cytoplasmic side and the other on the extracellular side of the Schiff base, are located in the narrow channels and participate directly in proton transfer across the membrane. During the photocycle, the *cis–trans* isomerization of the retinal (which remains bound to the protein) leads to the movement between inward and outward channels of the Schiff base, which can be reversibly protonated. This movement shuttles the protons across the membrane dielectric and leads to the active transport.

In *Halobacterium*, two homologues of bacteriorhodopsin are involved in **membrane transport** of anions (halorhodopsin) and in phototaxis (sensory rhodopsin) (5). The acidic channel residues of bacteriorhodopsin are substituted with other amino acids, such as threonine in halorhodopsin, which contributes toward the maintenance of osmotic balance in an environment with high salinity by **active transport** of chloride and nitrate. The sensory rhodopsin is involved in the control of light-induced **flagellar** motion. The exact mechanism of its function is not known. It is obvious, however, that the same rhodopsin fold can be employed in different biological functions through a small number of changes in the internal channels.

Ri Plasmid

The root-inducing, or Ri, plasmid is the cause of hairy root formation on dicotyledenous **plants** that are infected by ***Agrobacterium*** *rhizogenes*. Similarly to the Ti plasmid, a defined region of **DNA** of the Ri plasmid, the transferred or T-DNA (see **T-complex**), is transferred from the **bacteria** to the infected plant cell and integrated into the plant genome.

Ri plasmids have been less studied than the Ti plasmids. Like the Ti plasmid, Ri plasmids can be characterized by their **opine** specificity, agropine or mannopine. There are similarities in sequence between Ti and Ri plasmids, most notably in the T-DNA and the virulence (*vir*) regions (1). Transfer of the T-DNA from Ri plasmids to the plant cell most probably uses the same mechanism as T-DNA transfer from Ti plasmids (2). **Vectors** for transferring foreign DNA to plant cells based on Ri plasmids have been developed for use in plant genetic engineering (3).

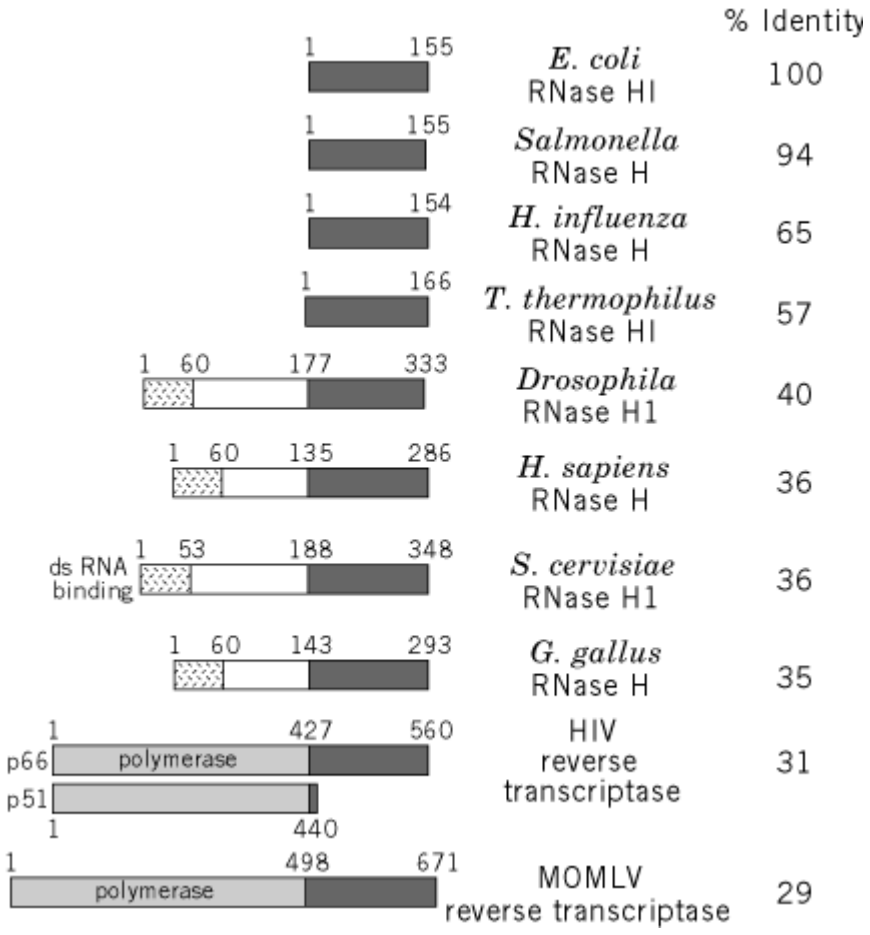
Ribonuclease H

Ribonuclease H (RNase H) is an enzyme that cleaves RNA from RNA•DNA hybrids in a divalent cation (Mg^{2+} or Mn^{2+})-dependent manner. RNase H (H for "hybrid") can act in both an endonucleolytic and an exonucleolytic manner, yielding 3′ hydroxyl and 5′ phosphate groups as products (unlike the prototypical ribonuclease, **ribonuclease A**, which leaves 3′ phosphates and 5′ hydroxyls). The 3′ hydroxyl groups left by RNase H are then competent substrates for both **DNA polymerase** and DNA Ligase. RNase H activity is important for retroviral reverse transcription by retroviruses, removal of RNA primers in DNA replication, and the action of antisense oligonucleotides. RNase H is commonly used in molecular biology applications where cleavage of RNA in a heteroduplex with DNA is required, such as second-strand synthesis of complementary

DNA (cDNA) or in the selective targeting of RNA by the hybridization of a sequence-specific oligonucleotide.

There are several classes of RNase H proteins, but the best-characterized is a large family of structurally-similar enzymes that exist in prokaryotes (including proteins whose genes have been cloned (see Cloning) from *Escherichia coli*, *Salmonella*, and *Thermus thermophilus*) and in eukaryotes (including yeast, trypanosomes, *Drosophila*, chickens, mice, and humans). This class also includes an essential domain of retroviral reverse transcriptases (RT) (Fig. 1). These RNases H are small (~150residues) and have a mixed a/b protein structure . The prokaryotic members of this family contain only the RNase H domain, whereas eukaryotic RNases H contain an additional N-terminal domain that is known to bind double-stranded RNA. In retroviral reverse transcriptases, the RNase H domain is covalently linked to the N-terminal polymerase domain.

Figure 1. Primary structures of various ribonucleases H. The RNase H domain is shaded dark; other domains are indicated. The percent identity of each RNase H domain to the sequence of *E. coli* RNase HI is indicated.



1. Roles of RNase H

RNase H plays diverse roles in biology, some of which are not yet fully understood. The requirements for RNase H as part of RT in the replication of retroviruses, such as human immunodeficiency virus (HIV) and Moloney murine leukemia virus (MoMLV), are well-understood. Whereas MoMLV RT is a monomeric, multi-domain protein, HIV RT is a heterodimer composed of two polypeptide chains: p66 and p51 (Fig. 1). The 66-kDa subunit contains both the polymerase and RNase H domains, but the 51-kDa subunit carries only the polymerase domain and lacks the RNase

H domain, which was removed by HIV protease. In all reverse transcriptases, RNase H functions to degrade the genomic RNA following its use as a template for DNA synthesis by the polymerase domain. This occurs in a roughly sequence-independent, exonucleolytic manner, although more specific patterns of endonucleolytic cleavage are required for removal of the initial transfer RNA primer and the creation of a second-strand primer (see Reverse Translation). A number of mutations dramatically alter the exonucleolytic function, but not the endonucleolytic function (1-4) suggesting some independence in the two modes of RNase H cleavage.

The biological importance of RNase H in bacteria and yeast is less clear. These proteins are not essential for viability, so it has been difficult to pinpoint their specific roles. Two RNases H exist in *E. coli*: RNase HI and HII. RNase HI prevents initiation of replication at origins other than *oriC* (5-7). Any false origins generated by RNA polymerase are eliminated by RNase H, so therefore RNase HI serves as a specificity factor for replication initiation. Furthermore, mutations in *dnaA*, the gene for a protein needed for initiation of DNA replication at the normal origin, *oriC*, are suppressed by the loss of RNase HI activity. RNase HI is also required for viability in cells that lack functional RecBCD proteins (8). Interestingly, RecBCD is a **nuclease** involved in DNA repair, but whether RNase H is needed in some capacity for DNA recombination and repair is not yet certain. *E. coli* RNase HI also contributes to the required removal of RNA primers used in the leading and lagging strands of DNA replication. The vast majority of this activity, however, is contributed by the 5′ to 3′ exonuclease domain of DNA polymerase I. Finally, RNase HI is necessary for the replication of ColE1-based **plasmids**. Following production of an RNA primer by RNA polymerase on ColE1, RNase HI processes the RNA, making it competent for elongation by DNA polymerase. As mentioned earlier, a second enzyme, *E. coli* RNase HII, has also been identified (9). This protein has very weak activity and no sequence homology with RNase HI, and its cellular significance is yet unknown.

The budding yeast *Saccharomyces cerevisiae* contains an RNase H1 enzyme with a C-terminal domain similar to that of *E. coli* RNase HI and an N-terminal region that contains a 50-residue RNA-binding motif that is also seen in Cauliflower Mosaic Virus P6 protein. This region binds double-stranded RNA in the absence of the RNase H domain (10) (Fig. 1). Interestingly, increasing Mg^{2+} levels decrease the enzyme's affinity for double-stranded RNA while increasing its activity on RNA•DNA hybrids. It is unknown, however, if or how this relates to the control of the RNase H portion, which cleaves RNA only within heteroduplexes with DNA.

In mammalian cells, two different classes of RNases H have been identified. Type I RNases H are larger (68 to 90 kDa) and can utilize either Mg^{2+} or Mn^{2+} as cofactors. Type II RNases H are only ~40kDa and are inhibited by the presence of Mn^{2+}. Type-I RNase H from calf thymus acts *in vitro* as an endonuclease to cleave RNA replication primers one nucleotide from the RNA/DNA junction (11). Gene sequences encoding type-II RNases H in mice and humans have been deposited into the GenBank database (see Sequence Databases). They are very similar to other RNases H, including those from bacteria, lower eukaryotes, and retroviruses, and they also contain an N-terminal domain similar to the yeast duplex RNA-binding region. Given their similarity to prokaryotic RNases HI, these mammalian RNases H are probably better termed RNase HI despite the original “Type II” designation applied to these activities prior to the cloning of their genes.

RNase H activity is also required for the action of antisense oligonucleotides. Antisense technology works to eliminate specific populations of mRNA *in vivo*. Complementary DNA oligonucleotides are introduced into the cells of interest and hybridize to the target mRNA; this creates a RNA•DNA hybrid suitable for RNase H hydrolysis. RNase H cleavage of the hybrid then specifically destroys the mRNA target.

2. Structure/function of RNase H

The three-dimensional structure of RNases H from *E. coli*, *Thermus thermophilus*, and HIV have

been determined by X-ray crystallography (12-15). Each has a similar fold containing alpha-helices flanking a five-stranded beta-sheet (see Beta-Pleated Sheet). RNase H belongs to a superfamily of structurally similar nucleic acid-modifying proteins termed the "polynucleotidyl transferases" (16, 17). In addition to RNase H, members of this superfamily include retroviral integrases, Mu transposase, and *E. coli* RuvC. These proteins all require metal ion cofactors, leave 3′ hydroxyl and 5′ phosphate groups, and probably share a similar catalytic mechanism.

A combination of biochemical and structural experiments has elucidated the importance of several specific regions to the catalytic function and structural stability of RNase H. Five highly conserved residues (three aspartate, a glutamate, and a histidine residue) map to similar metal-binding active sites in each protein. The "basic helix/loop" region seen in both *E. coli* and *T. thermophilus* RNases H contains a large number of positively-charged residues that contribute to the enzyme's affinity for its nucleic acid substrate (18). In a manner that is not yet understood, RNase H is able to discriminate RNA in a heteroduplex with DNA from duplex RNA and from single-stranded RNA. Regions of the protein that interact with the substrate have been mapped using NMR analysis (19). Nonetheless, a high-resolution description of RNase H binding nucleic acid would help resolve questions regarding its specificity in catalysis.

Despite the importance of the basic helix/loop to substrate recognition in *E. coli* RNase HI, this region is absent from the HIV RNase H domain. The HIV RNase H domain is inactive when expressed independently of the polymerase domain. Grafting the *E. coli* RNase H basic helix/loop onto the HIV domain partially reactivates it (20, 21), suggesting that the inactivity of the isolated RNase H domain is due, at least in part, to lack of substrate affinity. Furthermore, the C-terminal helix and loop of the HIV protein is known to be dynamically disordered in solution (22). Site-directed mutagenesis of this region in *E. coli* has demonstrated its importance for the activity of the protein (23-25), suggesting that the destabilized C-terminal region also contributes to the inactivity of the isolated HIV RNase H domain.

A single Mg^{2+} ion binds the active site of *E. coli* RNase HI (12, 26), whereas two Mn^{2+} ions were identified in the HIV RNase H crystal structure (15). Based upon these results, several different catalytic mechanisms have been proposed (15, 19, 23). It is still uncertain whether one or two metal ions are required for catalysis, but recent experiments support the idea that one is needed to activate the enzyme and that a second metal ion can inhibit this activity (27). A large number of mutations that inactivate the enzyme with Mg^{2+} do not eliminate its Mn^{2+}-dependent activity (20, 21, 25, 28), suggesting potential differences in the way metal ions activate RNase H. Interestingly, while Mg^{2+} has traditionally been considered to be the more physiologically relevant cation, due to its higher cellular concentrations (~1-5mM), *E. coli* RNase HI requires a much lower concentration of Mn^{2+} (~2 μM) to achieve maximum activity (27, 28).

RNase H also serves as an excellent model for studies on **protein folding** and protein stability (29).

Ribonuclease P

Transfer RNA (tRNA) molecules are synthesized as long RNA transcripts that must be trimmed down to the appropriate size and then processed further (see tRNA Biosynthesis). Removal of the 5′-leader sequence is catalyzed by the enzyme ribonuclease P (RNaseP). Hydrolysis of the

phosphodiester bond yields a mature tRNA carrying a 5′-phosphate and a leader sequence carrying a 3′-hydroxyl. Early genetic (1, 2) and biochemical experiments (3) established the *Escherichia coli* enzyme as a ribonucleoprotein, consisting of both RNA and protein. In 1983, Guerrier-Takada et al. (4) made the remarkable discovery that RNA from the *E. coli* and *Bacillus subtilis* RNaseP, in the absence of their protein subunits, could catalyze the removal of 5′ leaders from tRNA precursors *in vitro*. The elements necessary for binding and catalysis were RNA-specific, because the RNA alone had the same affinity for pre-tRNA as the holoenzyme (5). Such catalytically active RNA molecules are now known as ribozymes. The RNA from bacterial RNaseP is generally able to process tRNA precursors in an *in vitro*, protein-free reaction, but that from **eukaryotes** and **archaebacteria** have not yet been found to be catalytically active in the absence of their protein partners. RNA subunits have been identified in the RNaseP from mitochondria (6), but not from chloroplasts (7), leaving open the possibility that 5′-tRNA processing in chloroplasts is fundamentally different.

Insight into the structure of the bacterial RNaseP RNA has been possible because a large database supports convincing alignments of primary sequence and covariation analyses necessary to identify homologous nucleotides on the basis of location in the secondary structure (8). The continuously growing database of bacterial RNA sequences (8) strengthens the validity of the inferred secondary structure and identifies possible elements of tertiary structure. In spite of the differences in primary sequence and the occurrence of discrete helical elements at distinct sites, a core containing similar sequences and secondary structure has been identified. Indeed, a 211-nucleotide RNA missing all the evolutionarily variable structures found in the smallest, naturally occurring, catalytically active 276-nucleotide RNA from *Mycoplasma fermentans* (9) retains catalytic activity and defines a phylogenetic minimal RNaseP RNA. This and other such “minimal RNA” require increased ionic strength and display lower thermal stability, indicating that the variant helix elements contribute to the stability of essential structural domains that contain the active site of the ribozyme.

No single nucleotide is essential to catalysis (10), suggesting that, although specific nucleotides are important to promote interactions between structural domains, the elements responsible for binding and catalysis are distributed through the sequence. Recent additions to the archaebacteria database reveal that the these RNA are similar in primary and secondary structure to those from **eubacteria**, in spite their great evolutionary distance (11). Although secondary structure models of eukaryotic RNA (12) produced to date do not have the rigor of the bacterial and archaebacteria models, it is clear that all RNaseP RNA share short elements of primary sequence similarity and are predicted to share some common structural features (13). This supports the conclusion that they are all related and, despite some lacking *in vitro* RNA activity, serve as the catalytic subunit of RNaseP. Two three-dimensional structures of the *E. coli* RNaseP RNA, on the basis of chemical probing and crosslinking, in conjunction with secondary structure models, have been proposed (14, 15) but the challenges of arriving at a definitive structure and identifying the active site remain.

The Cs in the CCA 3′ end of tRNA interact with the well-conserved G292 and G293 through canonical base pairing in the RNA from *E. coli* and other bacteria (16). Many crosslinking, footprinting, and binding experiments (17) have identified nucleotides that interact with either the tRNA substrate and/or the protein subunit. While they are found in separate regions of the secondary structure model, the tertiary models bring them together in the conserved core. Whether the bases identified in these studies function directly in catalysis or are required for structure, protein binding, or metal binding is currently under investigation. Despite ease of assay, a refined secondary structure and the rapidity that *in vitro* reactions using RNA alone bring to mutagenic and chemical probing experiments, a mechanism has yet to be established.

All RNaseP RNAs are made as precursors. In *E. coli*, ribonuclease E is responsible for processing the 3′ end and, although it is not known what processes the 5′ end, ribonucleases E, P, and III have been eliminated (18). In the yeast nucleus, Rpr1r is made as a precursor with an 84-nucleotide 5′ leader and a 3′ trailer of about 33 nucleotides (19). In yeast mitochondria, Rpm1r is cotranscribed

with two flanking tRNA molecules. Although separation of the tRNA from the transcript does not depend on Rpm2p, the protein subunit of the mitochondrial enzyme, Rpm2p, has a critical function in further RNA processing steps necessary to make mature Rpm1r (20).

Given that the RNA is the catalytic subunit of RNaseP, what is the function of the RNaseP protein (s)? The *in vivo* role of the protein is not yet known, but it is essential. *In vitro* it stimulates the rate of cleavage and of product release, and it affects substrate specificity (21, 22). One way that the protein might affect the reaction in these ways is by counteracting electrostatic repulsions between RNA phosphates in the substrate and the RNA subunit of the enzyme (4, 23). Or, it may stabilize the structure of the RNaseP RNA. The fact that the presence of the protein can overcome many of the mutations that affect the activity of the RNA by itself supports the idea that it serves as a stabilizer for the RNaseP RNA structure (24).

The RNaseP proteins identified to date are structurally diverse. The 14-kDa (kilodalton) eubacterial proteins have a core of highly conserved basic and **hydrophobic** residues and semiconserved and conserved aromatic residues (25). Stoichiometry of the RNA and protein subunits is 1:1 (25). Only two eukaryotic RNaseP proteins, both yeast proteins, Pop1p (26) and Rpm2p (27), had been identified by the end of 1996. Rpm2p appears to be the major protein subunit of the **mitochondrial** RNaseP, whereas Pop1p appears to be one of several proteins important to RNaseP activity in the nucleus. Mutations in *POP1* cause defects in the RNA processing enzymes MRP and nuclear RNaseP (28). While *S. cerevisiae* MRP and nuclear RNaseP compositions appear complex, it is interesting that purification of nuclear RNaseP from *S. pombe* reveals a single protein the size of Pop1p (29). Rpm2p copurifies with mitochondrial RNaseP activity (30), and biochemical, immunological, and genetic evidence demonstrates that Rpm2p is a subunit of mitochondrial RNaseP (30). Rpm2p and Pop1p are about the same size, but approximately 100 kDa larger than the bacterial proteins. They do not show any obvious sequence similarity with each other or with the bacterial proteins.

Ribonucleoprotein (RNP)

Ribonucleoprotein (RNP) is widely defined as a biologically important molecular assembly composed of both **RNA** and protein. Such RNP complexes are key elements in many steps throughout the expression of DNAs genetic information into functional proteins. For example, protection of the ends of chromosomes against DNA degradation is mediated by the enzyme telomerase, a protein-RNA complex that requires RNA for its activity. The replication of RNA viruses involves interactions between RNA-dependent **RNA polymerase** or **reverse transcriptase** and viral RNAs. The machinery for gene transcription contains RNA polymerase (I, II, or III) in action on a DNA template, with associated nascent RNA. Further processing of the nascent RNAs (eg, transfer RNA modification; **ribosomal RNA** modification, processing, and storage; processing of RNA polymerase II transcripts including RNA splicing) also occur while the RNAs are associated with their respective specific proteins in the form of RNP complexes. **Protein biosynthesis** takes place within a distinct class of RNP complexes—the ribosomes. Finally, specific proteins associate with messenger RNA to control and perform its degradation. The term "RNP" was originally coined for the complex that assembles on the precursor messenger RNA (pre-mRNA) in the nucleus of eukaryotic cells. Later it was realized that these complexes carry out the processing of nuclear pre-mRNA. This chapter focuses on this class of RNP complexes.

Most eukaryotic transcripts that code for proteins are transcribed in the nucleus by RNA polymerase II to yield pre-mRNA molecules. These primary transcripts undergo several obligatory processing events within the nucleus to produce mature messenger RNAs (mRNA) that can then exit from the nucleus into the cytoplasm to be translated into proteins. These nuclear processing activities include 5′-end capping, pre-mRNA splicing, 3′-end processing, RNA Editing, and, finally, RNA transport

from the nucleus to the cytoplasm. During transcription, the nascent pre-mRNA is packaged with proteins and additional components to form RNP particles, in which the transcript is processed and remains packaged in the nucleus until it is exported to the cytoplasm. The packaging of the pre-mRNA in nuclear RNP particles is proposed to play a dual role. On one hand, it protects the pre-mRNA from untimely degradation. On the other hand, it provides the machinery that enables accurate processing at defined and precise locations within the pre-mRNA sequence, and it facilitates the processing of the pre-mRNA in a temporally and spatially regulated fashion. It is therefore expected that the native nuclear RNP particle will indeed harbor all the components that are required for the above-mentioned processing activities.

The term RNP was originally given, in the early 1960s, to the complexes in which nuclear transcripts of RNA polymerase II were found packaged with proteins (1). In early studies, these transcripts were collectively termed heterogeneous nuclear RNA (hnRNA) due to their diverse length. Accordingly, the RNP particles that package hnRNA were termed heterogeneous nuclear RNP (hnRNP) particles (2). At the time this terminology was coined, some of the pre-mRNA processing events had not yet been discovered. Today, a more accurate definition of RNA polymerase II transcripts is pre-mRNA, and the respective RNP particles are thus defined as pre-mRNP particles.

RNP particles that package mRNA in the cytoplasm are termed mRNP particles. The protein compositions of nuclear pre-mRNP and cytoplasmic mRNP particles are thought to be different, although recent studies indicate that some of the nuclear proteins accompany the mRNA into the cytoplasm (3). Although the mRNP particles have not yet been fully characterized, they likely play a role in the translation and stability of the mRNA, and they may also have an effect on the localization of the mRNA in the cytoplasm.

The extensive research on pre-mRNA splicing *in vitro* led to the characterization of a group of uridine-rich, small, nuclear RNAs (U snRNAs) as essential pre-mRNA splicing factors (4, 5). For this function, the U snRNAs are packaged with specific sets of proteins to form complexes that are called U small nuclear RNP (U snRNP) complexes (6). Purified snRNP particles have sedimentation coefficients of 12–25 S in density gradients. The studies of splicing *in vitro* led to the definition of yet another RNP complex—the 60 S spliceosome, which is the RNP complex that assembles on one **intron** flanked by two exons and is capable of removing that intron. The spliceosome is composed of spliceosomal U snRNPs and non-snRNP proteins (7-9).

Early biochemical and electron microscopy studies dealt mainly with the general population of pre-mRNP complexes. With the development in the early 1980s of **genetic engineering** techniques, the study of specific RNP particles was made possible through the use of probes for specific pre-mRNAs. This led to the identification of RNP particles in which specific pre-mRNAs, as well as most **polyadenylated** nuclear RNAs, are packaged. These particles sediment in sucrose density gradients as 200 S complexes and are thus termed large nuclear RNP (lnRNP) particles (10). In the following sections, early studies of RNP particles will be discussed, with emphasis on mammalian nuclear RNP particles. lnRNP particles will be described in detail, and their relationship to other RNP complexes implicated in pre-mRNA splicing will be discussed.

1. Early RNP models

In situ electron microscopy studies of chromatin, using sections of fixed and stained nuclei or cells, revealed already in the 1950s that nascent RNA transcripts are packaged in RNP particles (11-13). Early attempts in the 1960s and 1970s to isolate the nuclear RNP complexes of ^{3}H-uridine-labeled nascent RNA polymerase II transcripts used mild digestion by exogenous or endogenous ribonucleases (RNases). Fractionation of the resultant nuclear supernatants in sucrose gradients gave RNP complexes that sedimented in the 30 S–40 S region of the gradients. These RNP complexes were composed of RNA of variable length (500–1000 bases), and their major protein component was a set of six proteins of 35–45 kDa, designated A1, A2, B1, B2, C1, and C2 (1, 14-16). The short

length of the RNA suggested that the 40 S RNP particles were the products of degradation of the native pre-mRNP particles by endogenous **nucleases**. These observations raised the intriguing question of whether the 40 S particles represented a structural element of the native complexes or they were the outcome of an uncontrolled degradation. Attempts to inhibit the endogenous ribonucleases with specific inhibitors gave a heterogeneous population of RNP complexes, sedimenting at 40 S–250 S in sucrose gradients, which were later termed hnRNP particles. The protein composition of hnRNP particles was similar to that of the 40 S particles, but the hnRNP RNA was longer (2, 17). Electron micrographs of such preparations were interpreted as displaying a repeating unit (18). This led to a "beads-on-a-string" model for the hnRNP particle, in which, by analogy to chromatin, the 40 S particle was analogous to the nucleosome, and the six hnRNP core proteins were analogous to the histone core proteins. Although this conclusion seemed logical at the time, it was not corroborated by subsequent systematic visualization of spread preparations of chromatin (19). Furthermore, because these studies dealt with the general, uridine-labeled population of nuclear RNA, whether or not the sizes of specific pre-mRNAs were preserved during the RNP isolation was not known. It was therefore impossible to determine unambiguously whether the 40 S–250 S hnRNP particles represented the native pre-mRNP particles or degradation intermediates thereof.

2. Protein Composition of hnRNP Particles

Determining the protein composition of RNP particles has been hampered by difficulties in isolating intact particles and by the uncertainty in the degree of preservation of the pre-mRNA during isolation. A methodology that circumvents these problems involves identifying nuclear RNP proteins that are directly associated with pre-mRNAs by UV-induced crosslinking in situ and isolation of polyadenylated RNA under denaturing conditions. The proteins that are crosslinked to the RNA can thus be identified. Using this method, several proteins were identified as associated with pre-mRNA, including the 30–45-kDa proteins previously identified as A1, A2, B1, B2, C1, and C2, as well as proteins of 120, 68, and 53 kDa (3, 20). Monoclonal antibodies were raised against these proteins and were used for indirect **immunoprecipitation** of proteins complexed in RNP particles. About 20 RNP proteins were identified and were designated alphabetically from hnRNP protein A to hnRNP protein U (21). The hnRNP proteins are very abundant. They include not only the previously identified A, B, and C proteins but also additional abundant proteins. Most hnRNP proteins bind RNA, as was shown by their UV-induced crosslinking and their association with single-stranded DNA. Their association with RNA is attributed to the presence of an RNA-binding domain (RBD) in most of the hnRNP proteins, or to the presence of additional RNA binding motifs such as the KH motif and an RGG box (Arg-Gly-Gly repeats interspersed with several aromatic residues) (22) (see RNA-Binding Proteins). The hnRNP proteins are very diverse owing to the presence of **isoforms** generated by alternative splicing and also owing to post-translational modifications, such as **phosphorylation** of serine and threonine residues (eg, the A/B, C, and U proteins) and **methylation** of arginine residues (eg, A1 and A2 and potential sites in U and K proteins). The composition of human hnRNP proteins (21) is described in the text below.

2.1. A/B Proteins

These proteins have apparent molecular weights of 34–40 kDa and isoelectric points (pI) of 8.4 to 9.0. A1, A2, and B1 each have two RBD motifs and a glycine-rich domain at the C-terminus. A2 and B1 are identical, except for an additional 12 residues at the N-terminus of B1, and are probably derived from the same gene by alternative splicing. The RBD of A1 is rather **homologous** to that of A2 and B1, whereas the glycine-rich domain is more diverse. Several variants of A1 have been identified, some resulting from alternative splicing and some owing to post-translational modifications. The A/B proteins are phosphorylated *in vivo*, and the A proteins are methylated on arginine residues at the C-terminal glycine-rich domain.

2.2. C1/C2 Proteins

These proteins of apparent molecular weight of 41 and 43 kDa (pI = 5.9) are identical, except for 13 additional residues present in C2 in the middle of the protein; they are probably derived from the

same gene by alternative splicing. The amino terminus contains an RBD domain, whereas the C-terminal domain contains a negatively charged region. The C proteins undergo phosphorylation *in vivo*.

2.3. D, E, G, F/H Proteins

These proteins are less well characterized. Their respective molecular weights are: 44–48, 36–43, 43, 53, and 56 kDa, and their respective pIs are 7 to 7.8, 7.3, 9.5, and 6.1 to 7.1. RBD domains were found in the E, G, and F/H proteins.

2.4. I Protein

The hnRNP I protein has an apparent molecular weight of 59 kDa and a pI of 8.5. This protein is identical to PTB, a protein that binds to the polypyrimidine tract at the 3′-end of introns and is proposed to play a role in RNA splicing. The I protein has four noncanonical RBD domains. Analysis of **cDNA** clones revealed several isoforms that are probably derived from alternative splicing. On nuclease digestion, the I protein is more readily released from RNP complexes than other RNP proteins.

2.5. K/J Proteins

These proteins have apparent molecular weights of 66 and 64 kDa, and pIs of 6.1 and 6.4, respectively. The two proteins are immunologically related and lack the RBD motif but have a KH motif thought to play a role in RNA binding.

2.6. L Protein

This protein has an apparent molecular weight of 64–68 kDa and a pI of 7.4–7.7. It has four noncanonical RBD domains and is similar in structure to protein I.

2.7. M, N, P, Q, R, S, and T Proteins

These proteins are less well characterized. Their respective molecular weights are 68, 70, 72, 76–77, 82, 105, and 113 kDa, and their respective pIs are 7.8–8.2, 8.7–8.9, 9.0, 8.3, 8.0, 8.8, and 8.4.

2.8. U Protein

This protein has an apparent molecular weight of 120 kDa and a pI of 6.6–7.2. It is an abundant protein that undergoes phosphorylation. It does not contain an RBD motif; instead, it has an RGG motif that binds RNA.

Studies of the protein composition of pre-mRNP particles from cells of other organisms, including vertebrates, avians, and amphibians, revealed proteins of similar composition to the 20-hnRNP A–U proteins identified in humans. In addition, invertebrate RNP proteins, especially those of the fruit fly *Drosophila melanogaster*, revealed domain structures similar to those of the human RBD motif (21).

3. Alternative RNP Models

An important issue that should be considered in formulating a model for the native nuclear pre-mRNP particle is the discovery in the late 1970s that pre-mRNA is composed of exon and intron sequences and undergoes a series of splicing reactions. In these reactions, the introns are removed and the exons are ligated to produce the mature mRNA; this is an obligatory step to allow the export of the mRNA to the cytoplasm to code for proteins. The discovery of RNA splicing required a conceptual change in the early RNP model for two main reasons. First, the model should account for the new functional role of the pre-mRNPs; second, it should accommodate the components that are essential for splicing—ie, the U snRNPs and the other protein splicing factors (7-9). Taking this new information into account, revised models were put forward. One approach implies that the overall assembly of a pre-mRNP particle occurs by the assembly of individual 60 S spliceosomes on each intron of the pre-mRNA. According to another approach, the overall structure is built in a modular fashion from 40 S RNP particles assembled on exons and 60 S spliceosomes assembled on introns (23). Yet another model describes an RNP fibril composed of hnRNP proteins and pre-mRNA, in

which spliceosomal components are associated with intron junctions (21).

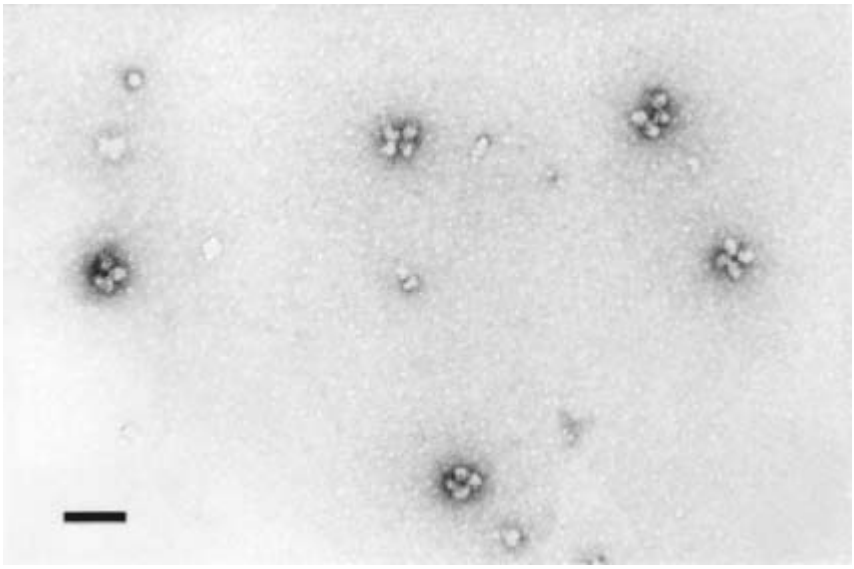
The beads-on-a-string concept that underlies some of the models of the pre-mRNP particle predicts that mild ribonuclease digestion of the RNP should yield a set of RNA fragments whose sizes approximate an integer multiple of a basic unit length (ie, an RNA ladder). This is analogous to the beads-on-a-string model of chromatin, in which a ladder of DNA fragments that are multiples of about 200 bp is generated on mild deoxyribonuclease digestion. This ladder represents the repeating unit of chromatin—the nucleosome—which is composed of a repeating unit of DNA complexed with a repeating unit of the histone core proteins (24). In contrast to this prediction, attempts to generate a ladder of RNA fragments by nuclease digestion of RNP particles did not succeed, and the 40 S RNP particles thus generated did not have a fixed length of RNA (25). Thus, a new pre-mRNP model was required—one that conforms to the present knowledge on pre-mRNA splicing and to the proposed intron and exon compositional differences.

A different, unprejudiced approach to the identification of the native pre-mRNP complex was taken with the development of a methodology for isolating native nuclear RNP particles from mammalian cell nuclei, using preservation of the entire length of specific pre-mRNAs as a criterion for nativeness (26). The protocol utilizes several potent RNase inhibitors during all steps of the preparation. It involves preparation of clean nuclei and their lysis by mild microsonication. This is followed by precipitation of the chromatin in the presence of tRNA (to avoid nonspecific adhesion of RNP proteins) and fractionation of the nuclear supernatant in a sucrose gradient. The advantage of following the fate of a specific transcript in developing the protocol for isolation of native RNP is that two criteria that had not been applied before—namely, whether the specific transcript was released into the nuclear supernatant as RNP particles in a nearly quantitative yield and in an intact, undegraded form—were now used to judge the quality of the protocol. The resulting RNP particles, and the model that was proposed based on their biochemical and structural characterization are discussed below.

4. RNP Particles of Mammalian Cells—lnRNP Particles

The protocol described above was first tested by following the release of RNA encoding the multifunctional protein carbamoyl phosphate synthetase, aspartate transcarbamoylase, dihydroorotase (abbreviated CAD) from the nuclei of Syrian hamster cells into RNP particles. More than 85% of the nuclear CAD mRNA was packaged in RNP particles that sedimented at the 200 S region in a sucrose gradient (26). These 200 S particles contained not only 25-kb CAD pre-mRNA molecules but also their splicing intermediates and mature 7.9-kb CAD RNA (28). Subsequent experiments showed that other mammalian specific RNA transcripts that differ greatly in size (eg, the 36 kb pre-mRNA and the 1.6 kb mRNA of the dihydrofolate reductase (DHFR) gene, and the 3.5 kb pre-mRNA and the 1.8-kb mRNA of the b-actin gene), as well as practically all polyadenylated nuclear RNAs, were each found assembled in 200 S RNP particles (10, 27, 28). These results were corroborated by visualization by electron microscopy, which revealed large compact particles, 50 nm in diameter, composed of substructures (Fig. 1) (27). The large RNP particles were therefore termed large nuclear RNP (lnRNP) particles. The unique feature of the lnRNP particles is that different transcripts, independent of their length and the number of introns they contain (eg, 37 introns for CAD pre-mRNA (29) and 5 for b-actin (30)) are all found packaged in particles of the same size and hydrodynamic properties. These surprising results could not be explained by the beads-on-a-string RNP model or by related models, because these models predicted that the size of an RNP particle should be proportional to the length and/or number of introns of the RNA it packages.

Figure 1. Visualization of lnRNP particles. Electron micrographs of negatively stained particles from the 200 S peak of a HeLa cell nuclear supernatant fractionated in a sucrose density gradient. Bar = 100 nm.



To determine the composition of lnRNP particles, monoclonal antibodies directed against lnRNP components (31) as well as antibodies against U snRNP components were utilized in **Western blot** and **immunoprecipitation** analyses. These experiments revealed that the lnRNP particles contain as integral components all spliceosomal U snRNPs (U1, U2, and U4/U6.U5 snRNPs) (32, 33), hnRNP proteins, and all known essential protein splicing factors, including the SR proteins, U2AF, and PTB (33-36) (see Table 1).

Table 1. Components of Large Nuclear RNP (lnRNP) Particles[a]

snRNAs	Probes	Reference
U1	cDNA, anti-sense RNA	(32)
U2	cDNA, anti-sense RNA	(32)
U4	cDNA, anti-sense RNA	(33)
U5	cDNA, anti-sense RNA	(33)
U6	cDNA, anti-sense RNA	(32)
Proteins	**Antibodies**	**Reference**
hnRNP core proteins A1, A2, B1, B2, C1, C2	SLE autoantibodies, MAb iD2	(10)
snRNP proteins	SLE autoantibodies, anti-200 S MAbs	(32, 31)
56 kD antigen	Myositis autoantibodies	(64)
SR proteins	MAb104	(36)
U2AF	Anti-U2AF^{65}	(36)
PTB	Anti-PTB	(36)
783	Anti-200 S MAb 783	

88 kD	Anti-200 S MAb 53 / 4	(34)
35 kD	Anti-200 S MAb 15 / 7	(31)
32 kD	Anti-200 S MAb 84 / 3	(31)

4.1. Stability of lnRNP Particles

Mild RNase digestion of lnRNP particles resulted in their conversion to 30 S particles, apparently without going through intermediate stages that give rise to an RNA ladder (10, 26). A similar observation had been made in 1979 by Wahrman and Augenlicht, who reported that limited nuclease digestion of hnRNP in nuclei revealed some discrete bands of RNA that appeared transiently, early in the course of digestion. But no multiples of a monomeric size RNP were evident (25).

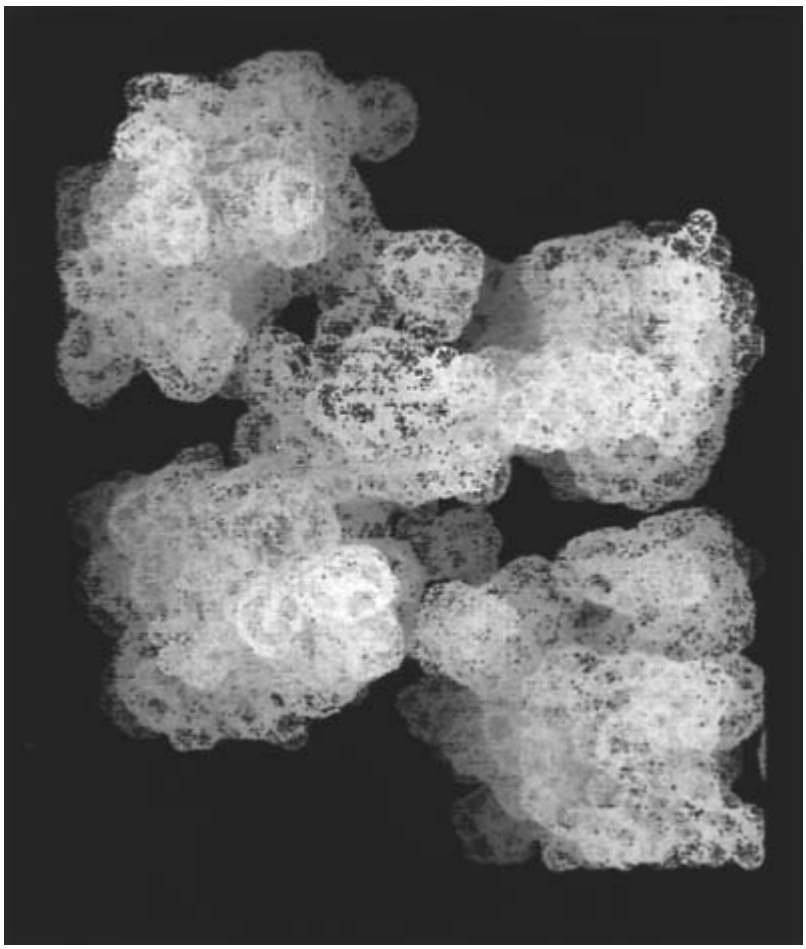
The 200 S lnRNP particles require Mg^{2+} cations for their integrity, as they are more resistant to RNase digestion when incubated in the presence of magnesium cations than when incubated in the presence of EDTA. The addition of EDTA results in conversion of the 200 S lnRNP particles into RNP particles that sediment at the 70 S region of the sucrose gradient. This shift is not due to pre-mRNA degradation but is caused by dissociation of some lnRNP components (eg, U1 snRNP), leaving the pre-mRNA packaged with only a subset of the components of the 200 S lnRNP. Importantly, the dissociation into 70 S particles is reversible, as indistinguishable 200 S lnRNP particles are obtained after back addition of Mg^{2+} cations to the EDTA-dissociated particles (33). The importance of Mg^{2+} ions to the preservation of the lnRNP particles is in accord with the known effect of Mg^{2+} ions on RNA folding (37) and with the proposed role of magnesium cations in RNA splicing (38). The sensitivity of lnRNP particles to environmental conditions is consistent with the known labile nature of RNP particles, and it may explain some of the difficulties in earlier attempts to isolate intact RNP particles.

4.2. Structure of lnRNP Particles

Three-dimensional image reconstruction of isolated lnRNP particles by automated electron tomography was performed at an optimal resolution of 2 nm (see Single Particle Reconstruction). The reconstructions revealed a quadrangular compact structure whose dimensions are 50×50×35nm (Fig. 2). The model is composed of four major subunits of similar dimensions that are connected to each other. An additional domain is sometimes observed toward the center of the particle. The four major subunits of the reconstructed models have an elongated globular shape pointing toward the center of the particle, where each subunit is connected to its two neighboring subunits at an internal radius close to the center of the particle (39, 40). Although an assessment of the interactions involved in these contacts cannot yet be made, it is plausible that the RNA transcript (mRNA) is participating in these inter-subunit interactions, although protein–protein interactions also can contribute. The automatic electron tomography studies were reinforced by mass measurements of the lnRNP particles using scanning transmission electron microscopy (STEM). These studies confirmed the similarity of the individual lnRNP particles and by measuring the mass of hundreds of particles revealed that the mass of the tetrameric lnRNP particle is 21±1.6mDa. Furthermore, the apparent similarity in dimensions of the four major subunits was also confirmed by the STEM mass measurements, showing that the lnRNP particles are composed primarily of four similar subunits, each having a mass of 4.8±0.5mDa (41). Interestingly, a rough estimate of the mass of the 60 S spliceosome, whose composition is similar to that of the lnRNP particle, gives an almost identical value of 4.9 mDa. These observations have raised the possibility that the monomeric subunit of the native lnRNP particle is equivalent to the in vitro spliceosome. The model that emerges from these studies is of an lnRNP particle that is composed mainly of four similar subunits, presumably 60 S

spliceosomes. Thus, the lnRNP particle can be viewed as a supra-spliceosomal complex.

Figure 2. A three-dimensional model of an lnRNP particle. The model was reconstructed by automated electron tomography from a tilt-series of 71 images (39).



5. RNP Particles in Other Systems

The lampbrush chromosome loops, seen especially in amphibian oocytes, are a very suitable system to study the assembly of pre-mRNP particles. Studies on lampbrush chromosome loops of frogs and salamanders using Miller spreads (42) revealed the extended DNA template that forms the axis of the lateral loops that are transcribed simultaneously by several RNA polymerase II molecules. The nascent transcripts that are being packaged during transcription in RNP particles make the strands vary from thin to thick, depending on the length of the transcript (18, 43). Most lampbrush chromosome loops were shown to contain several hnRNP proteins, U snRNAs, snRNP proteins, and non-snRNP protein splicing factors, including the SR proteins family. Further, for all factors the signal extended throughout the length of the transcription unit. The conclusion of this study was that the nascent transcripts on lampbrush chromosome loops are assembled into a unitary hnRNP/snRNP particle that is maintained throughout the transcription process (44). These observations were also supported by in situ studies of perichromatin fibrils, which are proposed to represent extranucleolar RNP (45). These findings are consistent with studies on the composition of the lnRNP particles from mammalian cells, in which U snRNPs, non-snRNP and hnRNP proteins were found to be associated with the pre-mRNA in the lnRNP particles.

Another system that attracted attention is the **puffs** of polytene chromosomes. These interphase

chromosomes replicate many times without separation of the replication products and exhibit a clearly distinguishable structure with a series of bands and interbands. The puffs in these chromosomes depict the extreme loosening of a band that accompanies DNA transcription activation in the band. One example of such studies are the puffs of the giant polytene chromosomes in the dipteran *Chironomus tentans* salivary glands (11, 18). Three large puffs, designated the Balbiani ring (BR), are sites of active transcription. The 35- to 40-kbp BR genes encode secretory polypeptides that are major components of salivary gland cells. In early electron microscopy studies of in situ sections, the very large, nascent BR pre-mRNA was observed to be assembled into 50-nm RNP particles. Furthermore, BR particles were seen as RNP globules of about 50 nm diameter in the nuclear sap and as elongated particles in the **nuclear pores** during translocation from the nucleus to the cytoplasm (46). The translocation of the BR RNP through the nuclear pore was further studied by electron microscopy methods, including electron tomography (47).

Interesting information concerning the assembly of BR RNP can be obtained from in situ studies, as the BR gene is transcribed simultaneously by several RNA polymerases. Thus, the proximal part of the gene represents initial stages of RNP assembly on short transcripts, whereas the distal part represents RNP particles close to maturation. In the proximal part of the active gene, the RNP fiber increases gradually in length and later coils into a thicker fiber. In the distal region, no further increase in the length of the RNP fiber is observed. Instead, the growing RNP fibers are packed into globular particles that increase only slightly in size along the gene and reach a constant diameter of 50 nm (48). The BR RNP particles were reported to contain hnRNP-like proteins and the Sm and snRNP proteins (47). Electron microscopy tomographic studies of individual BR RNP particles at 8-nm resolution revealed compact particles of 50 nm in diameter in which a thick RNP ribbon is bent into a horseshoe-shaped structure (49, 50). The use of osmium amine-B, a nucleic acid-specific stain, revealed particulate substructures (51, 52), which may be related to the subunit structure observed for the lnRNP particles.

6. Coupling of Transcription to the Assembly of pre-mRNP

Numerous studies have established that nascent pre-mRNA transcripts are assembled during transcription with hnRNP proteins, U snRNP particles, and non-snRNP proteins, to form pre-mRNP complexes. The cotranscriptional assembly model is further supported by recent studies that demonstrate that several splicing factors are associated with the C-terminal domain repeat of RNA polymerase II large subunit (53, 54). Furthermore, the 5′-end capping enzymes, which are responsible for the capping activity of the 5′-end of pre-mRNAs, associate with the C-terminal domain, but only with its phosphorylated form (55, 56). This observation fits nicely with findings that 5′-capping occurs at early stages of transcription, ie, transcripts about 20 nucleotides long are already capped (57). Also, association of the 5′-capping enzymes only with the phosphorylated C-terminal domain, which is the stage when the polymerase becomes processive, ensures that only transcription units destined to be fully transcribed will be capped at their 5′-end. A yet unresolved question is why transcripts of RNA polymerase II assemble into pre-mRNP particles, whereas transcripts of RNA polymerase I and III do not, even though RNA-binding domains are highly abundant in most pre-mRNP proteins. Because this distinction must occur early in transcription, when pre-mRNP assembly initiates, it may be attributable to the association of the 5′-capping enzymes with the C-terminal domain. This association is unique to RNA polymerase II transcripts, as the other RNA polymerases do not have a C-terminal domain. Thus, capping the transcripts of RNA polymerase II not only protects them from degradation but also “marks” them as pre-mRNAs to be assembled as pre-mRNP complexes. Recent observations that splicing factors and factors involved in 3′-end processing also associate with the C-terminal domain (58-60) support this view.

7. Naturally Assembled pre-mRNPs are Large

The lnRNP particle is a very large molecular assembly that sediments at the 200 S region in sucrose gradients and has a diameter of 50 nm (10, 27, 29). An interesting note is that similarly large RNP

particles have been observed in other systems using different methodologies. For example, 150–300 S complexes were observed by Wassarman and Steitz (61) on centrifugation of HeLa Cells nuclear extracts active in splicing. These complexes contained all the spliceosomal U snRNAs. Remarkably, the U2-U6 snRNA base-pairing interaction, which is typical of active spliceosomes, was found only within the large particles. These complexes probably represent particles assembled on endogenous HeLa transcripts. Another example are the BR RNP particles that were studied both in situ and in isolation and were shown to have a compact structure of about 50 nm in diameter (46, 49, 51). Finally, electron microscopy of spread preparations of chromatin, prepared under conditions that more closely resemble the physiologic ones than the standard conditions used for Miller spreads, revealed compact structures of about 60 nm in diameter (19). It therefore seems likely that the very large particle of 50 nm in diameter represents the native pre-mRNP particles in a broad range of living organisms.

8. A Model for the Native pre-mRNA Processing Machinery

Among the nuclear RNP complexes isolated thus far, the lnRNP particle is unique in the sense that it contains intact pre-mRNA and all known components of the splicing machinery, and it can be viewed as a supraspliceosome complex. A speculative model can thus be formulated, assuming that the supraspliceosome is composed of four spliceosomes, each being capable of processing a single intron. In that case, it is quite simple to imagine how a pre-mRNA consisting of four introns is packaged in such a structure. The RNA would be displayed on the surface of the supraspliceosome in such a way that each intron would be looped around one subunit, thereby bringing the 5′ and the 3′ splice sites into juxtaposition. Pre-mRNAs with three or less introns would be assembled on the supraspliceosome occupying the respective number of subunits and leaving the remaining ones unoccupied. Notably, even RNA molecules that do not contain introns, such as the intronless nuclear histone H4 mRNA, are packaged in 200 S lnRNP particles (10). The packaging of intronless pre-mRNAs in a supraspliceosome should not be surprising, because the assembly of RNP complexes in living cells initiates on an exon sequence as soon as the nascent pre-mRNA is synthesized (18). This is also suggested by studies of histone transcription units of lampbrush chromosomes of frog oocytes, in which spliceosomal U snRNPs, hnRNP proteins, and non-snRNP splicing factors were observed to be assembled on histone transcripts (44). The packaging of pre-mRNAs having more than four introns requires that the pre-mRNA be processed in steps. The prediction here would be that each step constitutes splicing of four introns at a time. Once a splicing event occurred, the ligated exons would translocate to make room for the association of another pair of exons that are part of the next set of four exon pairs to be spliced.

The concept of a supraspliceosome complies with the necessity to splice simultaneously more than one intron in a multi-intron message and fits well with current notions that the multiple spliceosomes that form on multi-intron pre-mRNAs must communicate to identify splice sites correctly and ensure the ligation of exons in the correct order (62). This issue becomes even more important in the case of regulated splicing that requires communication between alternative 5′ and 3′ splice sites that do not belong to the same intron. In this case, the supraspliceosome might act as a single mold on which alternative splice sites can be checked and approved for splicing. Finally, the organization of the splicing machinery in a multifunctional structure can also account for the fact that the introns of a multi-intron pre-mRNA are not removed by a linear progression of the splicing machinery from one end of the transcript to the other (eg, the APRT pre-mRNA, in which the third intron is removed first (63)), as would have been required for a processive mono-functional particle. The supraspliceosome, in contrast, allows the removal of introns in a nonlinear fashion while maintaining processivity throughout the entire splicing event. At the present stage, the lnRNP model may help us understand the structure–function relationship of the naturally assembled spliceosomes, and it should especially help us design experiments to establish the structure and function of these RNP particles.

Ribonucleotide Reductases

In all living cells, a ribonucleotide reductase (RNR) provides the deoxyribonucleoside triphosphates (dNTPs) for DNA replication and **repair** (1). A single enzyme replaces the OH group at C2′ of the ribose moiety of the four common ribonucleotides with hydrogen. The reaction occurs with either ribonucleoside di- or triphosphates as substrates. Different organisms employ widely different forms of three different classes of the enzyme and, in some cases, contain more than one enzyme. *Escherichia coli* has three RNRs, two aerobic class I enzymes, and one anaerobic class III. All classes of RNR share two exceptional features:

1. The polypeptide chain of the active enzyme harbors a free radical amino acid residue that participates in the catalytic process; the mechanism for radical generation sets the classes apart

2. The specificity toward the four ribonucleotides is tightly controlled by **allosteric** effects that are remarkably similar for the three classes.

1. Reaction Mechanism

All ribonucleotide reduction proceeds via controlled free-radical-based chemistry, in which a free radical amino acid residue of an RNR generates a substrate radical by abstracting a hydrogen atom from C3′ of the substrate, to facilitate the leaving of the OH group on the vicinal C2′ (2) (Fig. 1a). A thiyl group of a cysteine residue performs this function (3) (Fig. 1). Two additional redox-active cysteine residues then provide the reducing equivalents for the subsequent reduction at C2′. This general mechanism has strong experimental support for class I and II enzymes. The three-dimensional structure of the catalytic site of the *E. coli* class I enzyme beautifully fits this mechanism (4) (Fig. 1b). For class III RNR, the evidence for a similar mechanism is indirect.

Figure 1. (**a**) Free radical mechanism for the reduction of a ribonucleotide. A protein radical (thiyl for class I and II) abstracts the hydrogen from C3′ of the ribotide, thereby transferring the radical function to the substrate. Subsequently, C2′ of the activated substrate is reduced by redox-active cysteine residues, and the abstracted hydrogen is restored to C3′, with regeneration of the protein radical. (After Ref. 2, simplified.) (**b**) Three-dimensional structure of the large protein of *E. coli* with a substrate modeled into the catalytic site. The suggested thiyl of Cys439 is located on the b-face of the ribose ring in close vicinity to C3′, whereas the redox-active Cys462 and Cys225 are strategically located on the opposite a face, ready for reduction of C2′. 2. Three Classes of RNR

2.1. Structural Aspects

RNR can be grouped into three separate classes on the basis of structural and functional differences (5) (Table 1). Each class has a distinct quaternary structure: Class I and III are a_2b_2 heterotetramers (for class I, a_2 is called R1 and b_2 is called R2), while class II has an a (or a_2) homomeric structure. Within each class, the amino acid sequences are related, whereas **homologies** were originally not

found between the classes. However, the sequences of some class II RNR from primitive bacteria were recently found to contain stretches of homology also with class I and III enzymes.

Table 1. Properties of RNRs Belonging to Different Classes

	Class Ia	Class Ib	Class II	Class III
Respiration	Aerobic	Aerobic	Aerob/anaerobic	Anaerobic
Structure	a_2b_2	a_2b_2	$a(a_2)$	a_2b_2
Metal center	Fe–O–Fe	Fe–O–Fe	–Co–	4Fe–4 S
Radical	Tyr. .cys	Tyr. .cys	AdB_{12}. .cys	AdoMet. .gly AdoMet. .cys**?**
Reductant	Redoxins	Redoxins	Redoxins	Formate

The large a-polypeptide of all three classes has a molecular mass of between 80 and 100 kDa, with binding sites for substrates and for all allosteric effectors (see text below). It is the business end of RNR, where the reaction outlined in Figure 1 takes place. The small b-polypeptide, close to 40 kDa for class I and 20 kDa for class III, functions in radical generation.

The tertiary structures of both the large a_2 (4) and the small b_2 proteins (6) of the *E. coli* class I RNR and of the b_2 protein of the mouse class I RNR (7) have been determined to high resolution. A plausible structure was suggested for the a_2b_2 holoenzymes. The b-polypeptide contains a m-oxygen-linked diferric cluster with a stable tyrosyl radical in close vicinity. The exceptional stability of this radical (weeks in solution at cold room temperature) is explained by its extreme **hydrophobic** environment. The tyrosyl harnesses the free radical reactivity of the enzyme between turnover. During catalysis, when substrate is bound to the a-subunit, a coupled electron and proton transfer process between the tyrosyl radical of b and Cys439 of a (*E. coli* numbering) generates the thiyl radical required for abstraction of hydrogen from C3′ of the substrate. This transfer occurs over a long distance (in *E. coli* estimated to be 25 to 30 Å), probably via a specific pathway involving bonded amino acid residues from both a and b, several of which have been identified from site-directed mutagenesis and considerations of the three-dimensional structure (8, 9).

Class II RNRs contain no stable free radical. Adenosylcobalamin replaces the function of b and forms a transient free radical during catalysis by homolytic cleavage of the carbon–cobalt bond. This radical, in turn, generates the thiyl radical on the cysteine residue involved in substrate activation (3).

Class III enzymes are constructed in a still different manner. Their b_2-protein harbors a 4Fe–4 S cluster bridging the two polypeptide chains (10) (see Ferredoxins), but no free radical amino acid residue. Instead, a glycyl radical is located at the carboxy-terminal end of the a protein. Under anaerobic conditions the radical is very stable, but it is lost on admission of oxygen. The b_2-protein generates this radical (see text below).

Class I can be divided further into two subgroups (Ia and Ib) for which the two aerobic RNR of *E. coli* are the prototypes (Table 1). Class Ib RNR lack the first 50 amino-terminal residues, which in Ia RNR form the first two a-helices (11). One of the two allosteric sites of class I RNR is located in this

region, and it is lacking in class Ib enzymes.

2.2. Occurrence in Nature

Class I RNRs occur only in aerobic organisms, because the generation of their tyrosyl radical requires oxygen. **Eukaryotes** contain subclass Ia, whereas **microorganisms** usually contain subclass Ib (1). *Enterobacteriaceae* and some related bacteria are an exception and use Ia as the physiologically active enzyme. Several *Enterobacteriaceae* in addition contain a potentially active Ib form whose physiological function is unclear, because Ib does not complement conditional mutants of Ia unless several copies of Ib DNA are introduced into the cell. The *E. coli* Ia enzyme was the first discovered RNR, and extensive studies of its function have spearheaded our understanding of ribonucleotide reduction.

Members of class II occur among almost all groups of bacteria (1) (Table 2). They function both with and without oxygen and are common in both aerobic and anaerobic bacteria. The latter include several types of **archaebacteriae**. Nature's choice between class II and I is not obvious. Closely related bacteria may have either class. Class II has not been found in eukaryotes, with *Euglena gracilis* being an exception.

Table 2. Distribution of Various Classes of RNRs in Nature

	Class			
	Ia	Ib	II	III
Eukaryotes	+		(+)	
Eubacteria				
Thermotoga			+	
Green nonsulfur bacteria			+	
Deinoccus and relatives			+	
Gram-positive (high GC)			+	+
Gram-positive (low GC)		+	+	+
Purple bacteria				
a			+	
b			+	
g	+	+	+	+
Cyanobacteria			+	
Green sulfur bacteria			+	
Archebacteria				
Methanogens				+
Halophils			+	
Extreme thermopiles			+	

Class III enzymes (12) were discovered only recently, and their full potential is probably not yet appreciated. So far, all our knowledge rests on studies of the *E. coli* and **bacteriophage** T4 enzymes,

and caution should be exercised in extrapolation to other members of this class. The existence of other active class III RNR has been deduced from DNA sequences found in various facultative aerobes and strict anaerobes (Table 2). Interestingly, *Methanobacteria* use class III and not class II enzymes, in spite of the abundance of cobalamines in these microorganisms. The protein sequences deduced from genes are all homologous to that of the anaerobic *E. coli* RNR, including a sequence motif around the radical-carrying glycyl residue at the carboxy-terminus.

3. Generation of the Stable Free Radical

For class I enzymes, the tyrosyl radical can be generated *in vitro* in the iron-free form of the b_2 protein (the apoprotein) by treatment with ferrous iron and oxygen (13). Ferrous iron is bound in the appropriate site and oxidized to ferric iron, with generation of the tyrosyl radical. Intermediate steps probably involve the initial formation of a diferric peroxide, followed by several unstable intermediates, whose detailed structure is under discussion (13).

In cells, iron exists mainly as ferric iron and must be reduced before it can generate the radical. Reduction is catalyzed by a ubiquitous flavin reductase, ferric reductase (14). This enzyme also reduces a diferric center inside a form of b_2 (met-protein) that has lost the tyrosyl radical (eg, by treatment with the radical scavenger hydroxyurea) but maintains its diferric center. In the presence of oxygen, flavin reductase then regenerates the radical and restores activity to the enzyme.

The generation of the glycyl radical of class III enzymes requires ***S*-adenosylmethionine** (AdoMet). An a_2b_2 holoenzyme that lacks the glycyl radical binds AdoMet to its b_2 moiety, but only after its 4Fe–4 S center has been reduced (15). Reduction can be made either chemically or by an enzyme system consisting of NADPH, flavodoxin, and flavodoxin reductase. Bound AdoMet is cleaved reductively to methionine + 5′-deoxyadenosine, driven by the oxidation of the iron–sulfur cluster. Simultaneously, the glycyl radical is formed on a_2. The 5′-deoxyadenosyl radical is a probable intermediate in the reaction, as in the adenosylcobalamin-driven radical generation of class II enzymes. Two other enzymes, pyruvate formate lyase (16) and lysine 2,3-amino mutase (17), use AdoMet in a similar fashion for radical generation.

Similar to the stable tyrosyl radical of class I enzymes, the glycyl radical of class III may not activate the substrate directly but generate a second, transient protein-derived radical for abstraction of the hydrogen on C3′.

4. Electron Donors

Figure 1a shows that after one catalytic turnover the two redox-active cysteine residues of the enzyme have formed a disulfide bond that requires reduction before the next cycle. For class I and II enzymes, NADPH ultimately provides the required electrons. Several different small redoxins (**thioredoxins** and **glutaredoxins**) act as intermediates between NADPH and the disulfide on the enzyme. The reduced forms of these small proteins first interact with and reduce two cysteine residues at the carboxy-terminus (cysteine 754 and 759 of the *E. coli* class Ia RNR), which, in turn, by intramolecular transthiolation, reduce the disulfide at the active site (18).

Formate (19), rather than NADPH, is the reductant with class III RNR. Tritium from [^{3}H] COOH is not incorporated into the product deoxyribotide but is instead incorporated into water, demonstrating formation of an intermediate carrying exchangeable protons. This tentatively suggests that redox-active protein-bound cysteine residues also function with class III RNR.

5. Inhibitors of RNR

The requirement of RNR for DNA synthesis gives inhibitors of the enzyme a potential medical

interest. Hydroxyurea (20), a scavenger of the tyrosyl radical, has been used clinically for some time. The compound has also been employed to distinguish between class I and II RNR and to study the function of the tyrosyl radical of class I enzymes. Experiments with substrate analogs that carry substitutions at C2′ and that act as mechanism-based inhibitors were of paramount importance for the understanding of the radical chemistry catalyzed by RNR (2). Some such inhibitors have found their way into the clinic. Other potentially very interesting drugs are peptidomimetics that prevent binding of a_2 to b_2. Such compounds can specifically inhibit the **herpes simplex virus** RNR without affecting the mammalian enzyme (21).

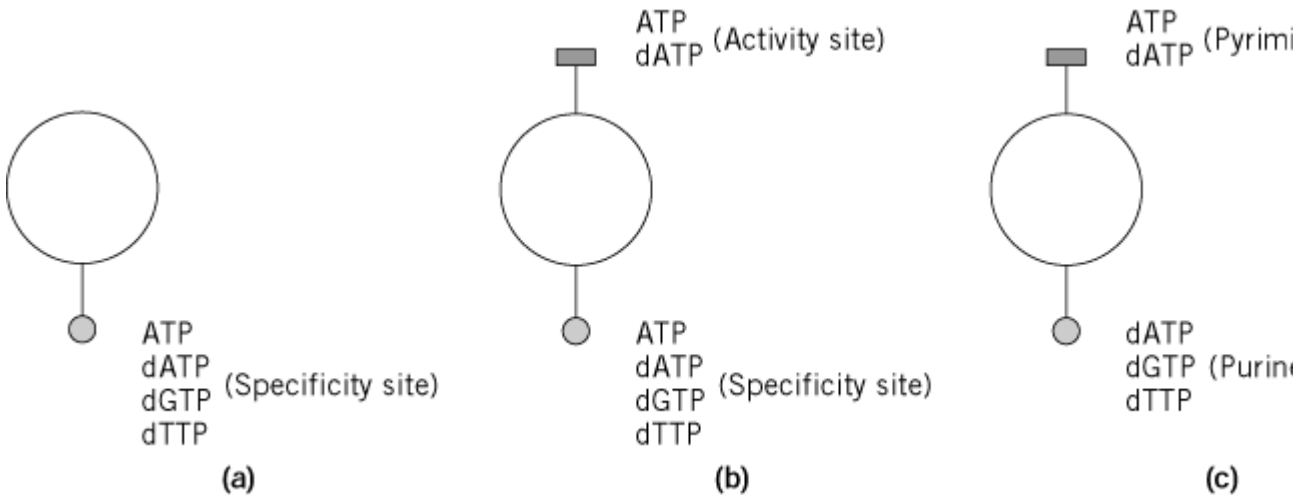
6. Allosteric Regulation

All three classes regulate their substrate specificity toward the four common ribonucleotides by binding nucleoside triphosphates to a specific allosteric site of the protein (the specificity site) (5). Class I and some class II RNRs distinguish between nucleoside *di*phosphates as substrates and nucleoside *tri*phosphates as effectors. This distinction provides them with a more sophisticated regulation.

A specificity site binds either ATP, dATP, dTTP, or dGTP. Each binding event transforms the RNR into a form that reduces a specific substrate: with class I and II enzymes, ATP and dATP favor reduction of pyrimidine substrates, dTTP favors guanine nucleotides, and dGTP favors adenine nucleotides. The degree of specificity varies between different enzymes; it is very high for the mammalian enzyme. The effects are remarkably similar for the three classes in spite of the large differences in primary structure. The molecular mechanism is not known, but a direct interaction between effector and substrate nucleotides can be excluded, since the two binding sites are too far apart. Instead, it appears likely that subtle conformational changes induced by effector binding transform the substrate binding site and adapt it to a given substrate.

Class Ia RNRs contain a second allosteric site that binds only ATP and dATP (5). This site is named the activity site, because binding of ATP activates the enzyme, whereas dATP turns it off. The anaerobic *E. coli* class III enzyme is physiologically regulated in the same way as the Ia enzyme, but by a slightly different mechanism. It also has two separate allosteric sites, but both determine its substrate specificity. Because dATP binding to either site inhibits the enzyme, the final result is the same as for class Ia. Figure 2 shows models for the allosteric regulation of the various RNR.

Figure 2. Models for allosteric effector binding. (**a**) Large protein of a class Ib or class II RNR. A single site binds all ef the regulation of substrate specificity; (**b**) Large protein of a class Ia RNR. A specificity site binds the effectors that regu substrate specificity of the RNR, and a separate activity site regulates enzyme activity by binding either ATP (activating) (inhibiting). (**c**) Large protein of a class III RNR. One site (the pyrimidine site) binds either ATP (activation of CTP and reduction) or dATP (inhibitory). The second site (the purine site) binds either dGTP (activating ATP reduction), dTTP ((reduction), or dATP (inhibitory).



7. Evolution(1)

The diversity of RNR may at first sight suggest that each of the three classes has evolved independently and that existing similarities are caused by **convergent** evolution. **Divergent** evolution is, however, favored by the similarity in allosteric effects and also by the ubiquitous and similar involvement of cysteine residues in the catalytic mechanism (1, 5). The properties of class III RNRs make them a favorite candidate for being the closest relative of a hypothetical "ur" reductase. The use of formate and of an iron–sulfur cluster fits a primitive enzyme. AdoMet can be considered a forerunner of adenosylcobalamin, the corresponding radical generator of class II RNR. Also, the fact that class III RNRs are strictly anaerobic enzymes speaks in their favor. Ribonucleotide reduction should have preceded photosynthesis during evolution and therefore was originally an anaerobic process. With the appearance of oxygen, other mechanisms had to come into play, leading to the emergence of class II and eventually class I RNR.

Ribophorins

Ribophorins I and II are transmembrane **glycoproteins** characteristic of the endoplasmic reticulum (ER) membrane of all cells. They are restricted to the "rough" subcompartment of the ER, and they derive their name from their association with the translation machinery of **protein biosynthesis**. This association has been demonstrated in several experimental ways: (i) ribophorins are co-enriched with membrane-bound **polysomes** through multiple purification steps (1), with a molar ratio of approximately one of each ribophorin per ribosome; (ii) ribophorins can be chemically **cross-linked** to ribosomes; (iii) their distribution in the plane of the ER membrane coincides with the ribosomes; and (iv) **antibodies** to the cytosolically exposed **epitopes** of ribophorins inhibit the co-translational translocation of a secretory protein into microsomes (2).

The tight association of the ribophorins with ribosomes initially led to the suggestion that they serve as ribosome receptors in the rough ER. It is now known, however, that the ribophorins are not involved in the translocation *per se*, but rather in the process of Asn-linked ***N*-glycosylation**. Ribophorin I and II were identified as two subunits of the mammalian oligosaccharyltransferase (OST) complex, which also contained a 48-kDa subunit. The transmembrane segment of ribophorin I is homologous to a recently proposed dolichol recognition **consensus sequence** (3), suggesting that ribophorin I could be involved in glycolipid binding and delivery.

The *Saccharomyces cerevisiae* OST complex consists of six nonidentical subunits. The a subunit is encoded by the Ost1 gene, which has significant sequence identity to mammalian ribophorin I. The d subunit is encoded by the Swp1 gene, which shares homology with the C-terminal half of mammalian ribophorin II. Expression of the Ost1 protein is essential for vegetative growth of yeast, and conditional Ost1 mutants have a pleiotropic effect of underglycosylation of soluble and membrane-bound glycoproteins (4). Microsomal membranes from Ost1 mutant yeast are markedly deficient in the *in vitro* transfer of high-mannose oligosaccharide from an exogenous lipid-linked donor to a glycosylation-site acceptor tripeptide, Asn–X–Thr/Ser (4).

Given these data, the previous experiments showing association of ribophorins with the translational machinery may indicate the existence of a supramolecular complex in the ER membrane, which performs docking of ribosomes, translocation of nascent chains across the membrane, Asn-linked glycosylation, and retrograde translocation of misfolded proteins out of the ER.

The human and rodent genes encoding ribophorins are single-copy genes. The human ribophorin I gene is located on chromosome 3q21, and the mouse gene is located on chromosome 6 (5). The human ribophorin II gene is on chromosome 20q12-q13.1 (6), while the murine gene is on chromosome 2, close to the *Src* proto-**oncogene** (7). Human ribophorin I and II are polypeptide chains of 68.5 and 69.3 kDa, respectively. Primary structure analysis, coupled with proteinase protection studies of intact microsomes, indicate that both ribophorins are synthesized as precursors having cleavable amino-terminal **signal sequences** of 22 to 23 amino acid residues (8). Ribophorin I and II are largely luminally disposed: Their *N*-terminus is in the lumen, they span the membrane once with a 23-residue putative **transmembrane** domain, and they have 150- and 70-amino-acid-residue cytoplasmic domains, respectively.

Rat ribophorin I is glycosylated on one out of three potential Asn sites, and the carbohydrate remains in the high-mannose form (5), as expected from a resident ER protein. Detailed analysis of the glycosylation changes indicates that, unlike other ER proteins, the ribophorins always reside in the ER and do not cycle significantly to the Golgi apparatus (9, 10).

Ribosomes

Over thirty years ago, the central dogma of molecular biology stated the way genetic information flows: **DNA** is transcribed into messenger RNA (mRNA) that, in turn, is translated into proteins (1). The *ribosome*, discovered in the mid 1950s, is the universal cellular organelle facilitating the translation step, by catalyzing the sequential polymerization of amino acids according to the blueprint encoded in the mRNA. Although the ribosome catalyzes a rather simple chemical reaction, the formation of peptide bonds, the process of **protein biosynthesis** is highly complicated and

sophisticated, and it depends on a large range of recognitions and interactions. The ribosome guarantees its fidelity and high efficiency by providing highly specific sites with various affinities for a large variety of incoming and outgoing molecules involved in protein synthesis. In **prokaryotes**, during exponential cell growth, the ribosomes may account for up to 50% of the dry cell mass and are distributed in the **cytoplasm**. **Eukaryotic** ribosomes are found also in mitochondria and **chloroplasts**. Ribosomes in all organisms are giant ribonucleoprotein (RNP) particles consisting of two subunits of unequal size, known as the large and small subunits. Two-thirds of the ribosomal mass is ribosomal RNA (rRNA), the rest is composed of 50 to 82 different ribosomal proteins (r-proteins), depending on the ribosomal source (Table 1). The names of the r-proteins are composed of L or S (depending on whether the protein is from the large or small subunit), and a running number, according to the position of this protein on **two-dimensional electrophoresis** gels.

Table 1. Ribosomal Components

Ribosome Source	Avg. Sedimentation Coefficient(range)	rRNA Chains (Large Sub/SmallSub)	Approx. No. r-Proteins
Bacterial	70 S	5 S, 23 S/16 S	50–60
Mitochondria (mammals)	55 S	16 S/12 S	80–90
Chloroplasts	70 S	23 S, 5 S, 4.5 S/16 S	50–60
Mitochondria (fungi, protozoans, mammals)	70 S (55 S–80 S)	21–24 S/15–17 S	65–90
Archaebacteria	70 S	5 S, 23 S/16 S	65–75
Plant mitochondria	75 S	5 S, 26 S/16 S	70
Eukaryotes (cytoplasm)	80 S	5 S, 5.8 S, 26–28 S/17–18 S	70–90

Owing to the fundamental significance of ribosomes, they have been the target of numerous biochemical, biophysical, and genetic studies (see Appendix 1). These resulted in the elucidation of the gross structure of the ribosome, as well as the approximate locations of several functional sites. Due to recent significant technical advances, current ribosome research is characterized by major conceptual revisions resolving previous ambiguities and introducing substantial spatial rearrangements (2-5).

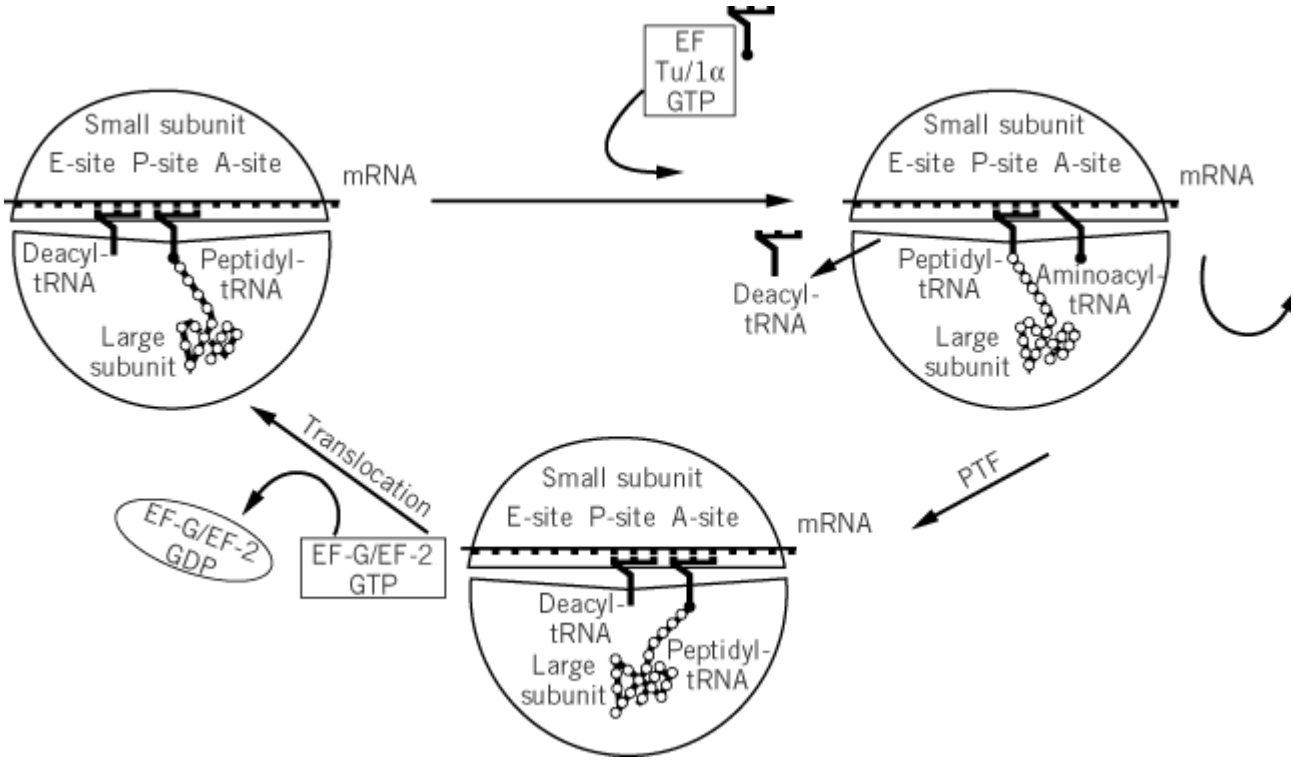
1. The Biosynthetic Process: An Overview

Protein biosynthesis can be divided into three functional steps: initiation, elongation, and termination. The initiation step requires the formation of the initiation complex, which is made of the small ribosomal subunit, initiation factors (IF), energy-rich compounds (GTP), initiator formylmethionine-**transfer RNA** (fMet-tRNA), and the mRNA molecule, with the initiation codon (usually AUG) in a favorable context. When the large subunit binds to the initiation complex, the elongation cycle can start.

The core of translation is the elongation cycle (reviewed in Ref. 6). In this step, one amino acid at a time is integrated into the growing nascent chain. The amino acids are brought to the ribosome in an activated state, bound to their corresponding tRNA through a high-energy phosphodiester bond. To ensure incorporation of the correct amino acid, the anticodon of the aminoacyl-tRNA must match the codon in the translated mRNA (see Aminoacyl tRNA Synthetases). In the early 1960s, Watson (7) and Lipmann (8) suggested a model for the elongation cycle with two tRNA binding sites on the ribosome: the A-site (acceptor site for aminoacyl-tRNA) and P-site (peptidyl-tRNA site). In the beginning of the 1980s, the existence of a third site, E (exit)-site, that binds only deacylated tRNA was proposed (9).

In the first round of the elongation cycle, only one tRNA is bound to the ribosome (the initiator tRNA, which is Met-tRNA in eukaryotes and fMet-tRNA in prokaryotes). During all other elongation rounds, two tRNA molecules are bound to the ribosome. Elongation starts with the f/Met-tRNA at the P-site. Subsequently, the decoding stage takes place, and an aminoacyl-tRNA carrying the amino acid coded by the next mRNA triplet is selected from the tRNA pool and delivered to the A-site by the elongation factor (EF) Tu in prokaryotes and EF-l-a in eukaryotes, which is a GTP-binding protein, in the form of a ternary complex, aminoacyl-tRNA/EF/GTP. Once the right aminoacyl-tRNA is bound to the A-site, the EF leaves the ribosome as EF-GDP, and the ribosome carries out its intrinsic enzymatic task, the formation of the peptide bond. After peptide bond formation (the pre-translocational stage), the growing peptide is bound to the tRNA (as peptidyl-tRNA) at the A-site. At this point, a second elongation factor (EF-G in bacteria, EF-2 in eukaryotes, both **G proteins**) binds to the pre-translocational ribosome and catalyzes the translocation of the peptidyl-tRNA from the A-site to the P-site. At the same time, the deacylated tRNA from the P-site moves to the E-site (as illustrated in Fig. 1). In this way, the ribosome moves by one codon and reaches the post-translocational state (peptidyl-tRNA at the P-site, deacylated tRNA at the E-site). Now it is ready for the next round of elongation. Once the aminoacyl-tRNA corresponding to the next codon binds to the ribosome at the A-site, the deacylated tRNA bound at the E-site leaves the ribosome and the elongation cycle repeats itself, incorporating a new amino acid to the nascent peptide with each round of elongation. It has recently been suggested that during translocation the ribosome moves like a rigid frame along the mRNA between the three binding sites (A, P, and E), carrying two tRNA molecules so that the microtopography of the sites adjacent to the decoding region does not change (10).

Figure 1. Schematic diagram of the process of the elongation cycle.



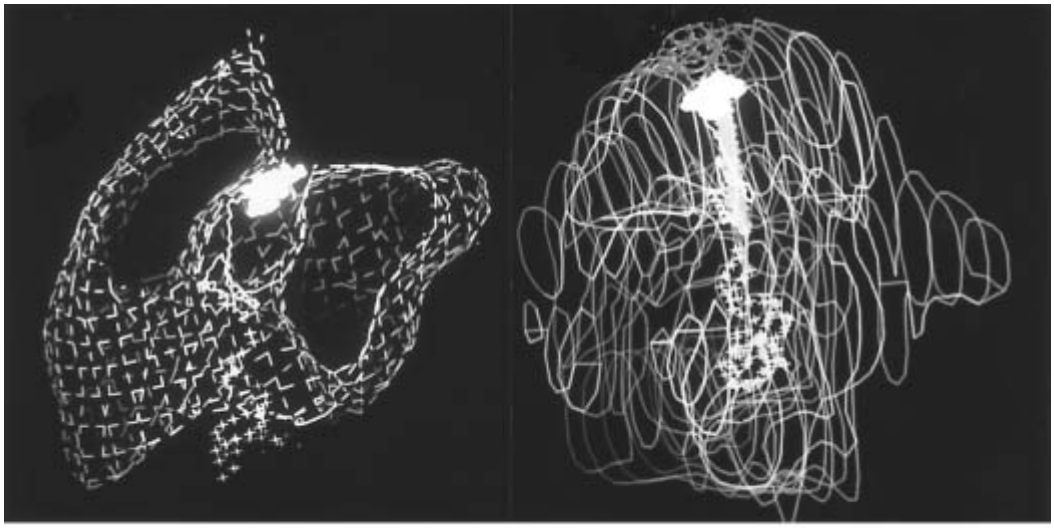
The elongation process ends when a stop codon is present at the A-site. The mechanism of the stop codon recognition by the termination factors and the subsequent release of the nascent protein from the ribosome is still not completely understood. In prokaryotes, it requires two release factors and one that stimulates them; in eukaryotes, a **homologous** family has been identified. It is known that the interaction of the release factors with the peptidyl transferase center catalyzes the addition of a water molecule instead of an amino acid to the peptidyl tRNA. This reaction frees the carboxyl end of the growing polypeptide chain from its attachment to the tRNA and promotes the release of the mature protein from the ribosome.

Additional compounds involved in this process are the signal recognition particle (SRP) in eukaryotes [or the corresponding complex in prokaryotes (11)], which facilitates the targeted translocation of the nascent peptides; **chaperonins**, responsible for the correct folding of the nascent peptide; hydroxylase, acetylase, and aminopeptidase, a series of enzymes catalyzing amino acid modifications that can act cotranslationally; and regulators of ribosomal function under normal or stressful conditions, heat or starvation shock (eg, the relA gene product).

The various enzymatic activities associated with the process of protein biosynthesis take place in an internal ribosomal gap at the interface between the two subunits (12, 13). This assignment is based on extensive biochemical investigations that showed that the ribosome masks most of the components participating in the biosynthetic process: a stretch of about 30 nucleotides of the mRNA, the aminoacylated tRNA molecules (14), and a significant part of the nascent polypeptide chain (15-17). Spatial considerations allow the placement of three molecules of tRNA in this void, as well as the factors participating in the elongation cycle (17-22). Two of the tRNA molecules can be positioned so that their anticodons are close to the presumed rRNA-rich path of the bound mRNA, on the surface of the small subunit, and their CCA-termini pointing so that the growing peptide chain may extend into a tunnel spanning the large subunit. This tunnel originates at the subunit interface and terminates on the opposite side, at a location compatible with the exit site of the nascent polypeptide chain identified by immunoelectron microscopy, and is thus suggested to be the path for the nascent proteins. Indeed, *in vitro* cotranslational folding was shown for the synthesis of full-length proteins (eg, rhodanese and ricin) while being bound to the ribosome (23). A feasible

description of these assignments is given in Figure 2.

Figure 2. Structural models of bacterial ribosomes. (**a**) A computer graphics display of the outer contour of the 70 S ribosome (13) (in blue). The image was reconstructed from negatively stained crystalline arrays of 70 S ribosomes from *B. stearothermophilus* at 47 Å resolution (17, 18). A model-built tRNA molecule was placed in the gap at the subunit interface so that its CCA 3′ end points into the tunnel within the 50 S subunit. Following an *in vitro* cotranslational experiment (23), the main chain of the MS2 coat protein was placed along the tunnel in a partially unfolded conformation, maintaining the native **beta-strands** and the native (crystallographically determined) conformation of the segment of residues 1 to 47. The C-terminus was placed in the vicinity of the proposed peptidyl transferase center and the N-terminus at the exit domain of the tunnel. The region 1 to 47 includes all atoms and is shown as a space-filling structure. (**b**) A slice of 50 Å thickness of the 50 S subunit (within the 70 S shown on the left), as reconstructed from electron diffraction (11, 12) with the same components.



The synthesis of a complete protein of average size takes 20 to 60 seconds. Nevertheless, multiple initiations of translation would ensure a faster and efficient translation of mRNA molecules. Accordingly, *polysomes* (or **polyribosomes**) can be formed along a single molecule of mRNA from several ribosomes spaced as close as 25 codons apart.

2. Proposed Functional Relevance of Ribosomal Components

2.1. The Ribosomal Components

The natural tendency of the ribosomes to disintegrate led originally to the assumption that they are nonspecific aggregates. Later on, the contrary was established, and the composition of ribosomal particles from various sources was determined (24). By far the best biochemically characterized bacterial ribosome is that of *Escherichia coli*. It contains about quarter of a million atoms, and has a molecular weight of about 2.3 million daltons and **sediments** with a coefficient of 70 S. About two-thirds of the mass of the ribosome is composed of three chains of rRNA (with a total of about 4500 nucleotides). One copy of each of its 58 different proteins is present in the ribosome, with the exception of the tetrameric L12. The ribosomes of **archaebacteria** and eukaryotes are somewhat larger (eg, eukaryotic ribosomes migrate with a sedimentation coefficient of 80 S), reflecting the higher complexity of the eukaryotic cellular environment.

2.2. Ribosomal RNA Chains

Although it has been suggested that the original, primitive ribosome may have been composed solely of rRNA (see RNA World), until recently it was assumed that the catalytic activities of the ribosome

are carried out mainly by the r-proteins and that the rRNA molecules have a more passive role in providing the scaffold for the ribosome and in binding the mRNA. Recently, it became clear that the ribosomal functions are no longer due solely to r-proteins, and the ribosomal RNA has been proven to play an active part in the ribosomal functions (25). The prominent catalytic activities of the rRNA are:

1. The peptidyl transferase activity (PTF) resides in the large subunit. In some organisms, it was found that a model assay of this activity is relatively resistant to proteolysis (26). The minimal set of components indispensable for peptidyl transferase activity was identified as a stretch of approximately 100 nucleotides, at the central loop of domain V of the 23 S RNA, plus a small fraction of the r-proteins (about 5 to 10% of the total mass). The aminoacyl end of the bound tRNA has been shown to make contacts with this rRNA loop, and mutations in this region abolish the PTF reaction completely or make the ribosomes resistant to antibiotics that target the PTF activity.
2. The GTPase center is associated with a highly conserved stretch of 23 S rRNA that binds the moderately conserved protein L11. Whereas the rRNA is essential for this activity, cells lacking protein L11 are viable.
3. The first step in protein biosynthesis, the formation of the preinitiation complex, depends in prokaryotes on the base-pairing interaction of the small ribosomal subunit with a region of the mRNA, called the Shine–Dalgarno sequence, located 3 to 10 bases 5′ of the initiation codon (usually AUG). Moreover, the rRNA from the small subunit provides the decoding site, where the mRNA and anticodon loop of the tRNA interact.

Crystallographic studies led to the determination of the structure of two rRNA domains, both part of the 5 S rRNA: a synthetic ribonucleic oligomer of 12 base pairs, imitating Helix A; and stretches of 29 nucleotides containing the sarcin/ricin loop as well as 62 nuclease-resistance nucleotides (helices I and IV, loop E) and a part of it, a dodecamer containing the minimum 11 base pairs required for binding the protein L25. The last, composed of loop E, exhibits an irregular geometry of cross-strand purine stacks.

2.3. The r-Proteins

Because of the complexity of the ribosome and its functions, it is still not possible to assign a function to each ribosomal protein. It is assumed that the r-proteins play an important role in the proper folding of the rRNA and enabling it to function efficiently. As mentioned above, some of the r-proteins are essential for the enzymatic properties, such as the PTF (eg, L2), whereas others are involved in the binding of tRNA (S7 and S8). In addition, there is evidence for the bifunctionality of a number of r-proteins (in prokaryotes), which function as regulators of translation by their ability to bind to the polycistronic mRNA coding for them. In some cases, they bind to similar structural motifs in the rRNA and mRNA, suggesting that these proteins interact in a similar fashion with mRNA and rRNA (eg, the interactions of Ll and S8, which possess a stable structure even in isolation); in others, the structural motifs of the rRNA and mRNA target sites do not resemble each other (eg, S15, which exhibits significant flexibility in isolation).

Complete sequences of the r-proteins from *E. coli* and many other bacteria and eukaryotes have been determined (24, 26). Some ribosomal proteins undergo post-translational modifications. Among others are acylation (eg, Ll7/L12 in *E. coli*) and phosphorylation (eg, the eukaryotic P1, P2, and P0). Several structural motifs have been suggested for the r-proteins. Among them are clusters of basic/acidic residues; amino acid sequence repeats in shared elements; **zinc finger** domains; basic regions; leucine zipper motifs; and carboxyl extensions of **ubiquitin**-like proteins.

For over two decades, the production of crystals of r-proteins useful for X-ray crystallography was extremely poor. This, together with the observation that some ribosomal proteins lose their *in situ* conformation upon isolation, led to the assumption that the conformations of almost all r-proteins are dictated by their *in situ* supporting environment. Furthermore, no correlation has been found between

the crystallizability of individual r-proteins and the degree of their evolutionary conservation, their localization within the ribosomes, or their involvement in primary contacts with rRNA. An appropriate example of a highly conserved r-protein that is intimately bound to r-RNA in a major functional center (GTPase activity), and undergoes significant conformational changes upon isolation from the ribosome, is protein L11. Interestingly, L11 regains its natural fold and can be reconstituted into core particles lacking it, even when a large chemical moiety with a molecular weight approaching a third of its own is bound to it (17).

The recent increasing sophistication in instrumentation, the implementation of powerful genetic techniques, and the use of ribosomes from **thermophilic** bacteria resulted in major progress in the structure determination of isolated r-proteins. Though it remains to be seen whether the structures of the isolated ribosomal components bear resemblance to their *in situ* conformation, it has been suggested that components possessing an intrinsic characteristic fold may crystallize, provided they are not damaged during their preparation. The structures that have been determined (fully or partly) by either X-ray crystallography or solution heteronuclear NMR are: S4, S5, S6, S7, S8, S17, L1, L6, L9, L7/I12 (the C terminal fragment), L14, L21, L22, L25, L30 (27, 28). Most share the split b-a-b fold, called the "common" motif and abbreviated as RRM (RNA recognition motif) (see RNA-Binding Proteins). A few proteins show different folds, called "unique" and "multiple" in which the interacting regions are built mainly of loops. One protein (S8) exhibits versatility in its RNA contact sites, since one interacts with rRNA and the other is involved in binding tRNA. Two novel RNA-binding domains have been recently detected. One can be aligned with **homeodomains** (DNA-binding proteins) consisting predominantly of **alpha-helices** connected by a turn and exhibiting structural flexibility, acquiring stability upon RNA binding (S15 and in the C-terminal of L11). The other is a b-ribbon arm, similar to that found in DNA-bending proteins, observed in S7. This protein acts as the main regulatory element for one of the r-protein operons and is crucial for tRNA binding and assembly of the small subunit.

2.4. Assembly and Reconstitution

In prokaryotes, the assembly of ribosomes occurs in the cytoplasm and is coupled to the transcription of rRNA molecules. Thus, r-proteins bind to rRNA while being synthesized. In prokaryotes, the *in vivo* ribosome assembly requires between 2 and 3 min. In eukaryotes, the situations is different and more complicated. The r-proteins are synthesized in the cytoplasm and then imported into the nucleolus (a substructure of the nucleus), where ribosomal assembly takes place. Once the ribosomes are assembled, they are exported back into the cytoplasm. Thus, ribosome assembly and transport take between 30 min (for the small subunit) and 1 hour (for the larger one).

In prokaryotic ribosomes, both subunits can be separated into their components and then reconstituted *in vitro* to fully active articles, even after partial or total unfolding has occurred. Interestingly, the reconstitution process is performed under nonphysiological conditions and takes considerably longer than the *in vivo* assembly (90 min vs 3 min). The ability of the ribosomes to reconstitute *in vitro* shows that the information required to obtain the active quaternary structure of the ribosome resides within the ribosomal components. Originally, it was assumed that the r-proteins governed the assembly process and the rRNA chains undergo significant conformational changes throughout the assembly process. However, it has been suggested recently that rRNA may influence the conformations of some r-proteins (eg, S15, L11), as conformational changes in these r-proteins were induced by their interactions with rRNA (29).

Reconstitution experiments led to the construction of ribosome assembly maps, showing the sequential binding of the different r-proteins to the rRNA molecules during assembly. It was found that two ribosomal proteins initiate the assembly of each ribosomal subunit. These proteins are defined as structural inducers, since they bind directly to the respective RNA without cooperativity during the onset of assembly and are assumed to induce the creation of *in situ* microenvironments that serve as assembly nuclei within the ribosome. It has been shown that, in general, the *in vitro* assembly patterns imitate the *in vivo* formation of ribosomes, but recent studies indicate the involvement of nonribosomal cell products in the *in vivo* ribosome assembly. These include the

chaperonin DnaK (30) and RNA Helicases belonging to the **DEAD box** protein family.

2.5. Evolution vs Universality

Ribosomes from the three kingdoms (eubacteria, eukaryotes, and archaebacteria) vary considerably in their size and the number of their components. However, they also exhibit a high degree of conservation with respect to their architecture and some r-proteins and rRNA regions (31, 32). As the ribosome is basically an RNA enzyme (a **ribozyme**), it can be regarded as ancient on the evolution scale. The existence of r-proteins conserved throughout all three **phylogenetic** kingdoms implies that they appeared in the first stages of evolution. With the progression from primitive to higher organisms, the number of the r-proteins increases, indicating their participation in the more complex functions of the eukaryotic ribosomes.

The ribosomes from archaeabacteria are thought to be vestiges of transition stages in the evolution from prokaryotes to eukaryotes. Thus, it has been frequently remarked that the amino acid sequences of archaebacterial r-proteins are closer to their eukaryotic homologues than their bacterial counterparts, whereas the organization of their genes mimics that of eubacteria. Furthermore, in several *in situ* substructures, the level of conservation is so high that ribosomal proteins from one source can be fully exchanged by their homologues from other ribosomes, even when they belong to two different kingdoms or function under totally different conditions. It is not surprising that protein L11 from *E. coli* binds well to cores of *Bacillus stearothermophilus* lacking it because of the high homology of these ribosomes, but the universality of the internal substructure of L1 and of a segment of the 23 S rRNA is rather unpredictable. Despite the evolutionary distance between the eubacteria and archaebacteria, chimeric complexes of L1 were reconstituted between halophilic components and their corresponding mates from *E. coli* .

2.6. Inhibitors of Ribosomal Function

Many antibiotics act directly on ribosomes, and most of them interact in one way or another with rRNA. Their binding sites were determined in different ways, including by rRNA mutations leading to drug resistance. The antibiotic functions of the PTF drugs involve interference with the reaction itself (puromycin and chloramphenicol) or with the movements required to perform the elongation cycle. **Tetracycline** is the classical antibiotic that inhibits the binding of the aminoacyl-tRNA. The aminoglycosides, streptomycins and the family of the gentamycins, kanamycins, and neomycins block A-site occupation and stimulate misreading, resulting in the incorporation of the wrong amino acids and leading to the production of nonfunctional proteins. **Erythromycin** and lincosamide probably stimulate the dissociation of peptidyl-tRNA by blocking the entrance to the tunnel that conveys the exiting nascent peptide. Thiostrepton and spectinomycin prevent translocation, ie, they inhibit the conformational change between the pre- and post-translocational states.

Among the most potent inhibitors of protein synthesis are naturally occurring peptide toxins acting mainly as **nucleases** and known as ribosomal-inactivating proteins (RIP). This group includes a-sarcin, **ricin**, arbin, mitogillin, restrictocin, shiga toxin, and vero toxin. Most hydrolyze a single phosphodiester bond in the large subunit rRNA, whereas colicin E3 acts on the 16 S RNA (Table 1) and pokeweed antiviral protein (PAP) interacts with the EF binding site. a-Sarcin and ricin bind to a loop in the large subunit rRNA that includes a universally conserved dodecamer sequence, which appears even in ribosomes that are not sensitive to these toxins (eg, those from *Haloarcula marismortui*). This domain is involved in aminoacyl-tRNA and elongation factor binding, as well as GTPase activity.

3. Structural Information

3.1. Approximate Shapes and Positions

A large number of traditional, as well as specifically designed structural methods (see Appendix 1), have been employed for shedding light on the structural organization of the ribosome and elucidating its quaternary structure. The relative positions of the centers of mass of the *E. coli* r-proteins have been determined, and the spatial *in situ* proximities between several ribosomal components could be

approximated (2-5). In parallel, attempts to determine accurately the secondary structure of rRNA, pinpoint tertiary structure elements, and assign to them functional relevance, resulted in proposals for fairy detailed topological models for the organization of the rRNA (32). Computational and **phylogenetic** analyses of possible tertiary interactions in the rRNA, combining results of chemical, physical, and functional experiments with energy minimization, were also carried out.

For over three decades, a wide variety of electron microscopy techniques have been the methods of choice for viewing ribosomes at various levels of detail. Since the late 1980s, along with the refinement of sophisticated and powerful microscopical and image reconstruction techniques, these studies enabled feasible assignments of functional relevance to a few structural features. The first reconstructed three-dimensional models were obtained from periodically ordered monolayers (ordered arrays) of eukaryotic and prokaryotic ribosomes and their large subunits that occurred naturally (12) or were grown *in vitro* (13). Despite their low resolution, these models revealed several key features, associated mainly with internal vacant spaces, cavities, gaps, tunnels, and partially filled hollows, that had not been detected earlier. Consequently, the ribosome, which was traditionally conceptualized as a compact network, was shown to be rather spongy.

3.2. Higher Resolution Studies

The accumulated knowledge about ribosomes has not yet revealed the molecular mechanism of protein biosynthesis. To extend the limits of our understanding of this process, an accurate and reliable model of the ribosome is required. Such a model should be obtained by X-ray crystallography. Two approaches have been taken. One focuses on isolated ribosomal components (r-proteins and rRNA described above); the second aims at the elucidation of the structure of entire ribosomal particles. Being ribonucleoprotein complexes that are notoriously flexible, unstable, and prepared routinely as conformationally mixed populations, ribosomes provide an extremely complicated system for crystallographic studies. On the other hand, the natural periodic organization of ordered helical or two-dimensional arrays of ribosomes has been observed in eukaryotic cells (eg, lizard, chicken, amoebae, and human) exposed to stressful conditions, such as suboptimal temperatures, wrong diet, or lack of oxygen, and it has been hypothesized that these periodically ordered forms are the physiological mechanism for temporary storage of ribosomes, aimed at preserving their integrity and activity for the expected better future. Thus, we have had the crystallization attempts aimed at extending the natural tendency to form periodic arrays into the growth of well-ordered three-dimensional crystals. Perhaps the most striking and unexpected achievement of the last decade is the growth of usable crystals of ribosomal particles from **halophilic** or thermophilic bacteria (17). As a strong correlation was found between the activity of the ribosomes and the quality of their crystals, it has been suggested that these ribosomes are more stable than those from eubacteria and retain their integrity and activity during the isolation and crystallization processes. Furthermore, far beyond the initial expectations, one of these crystal forms (of the 50 S subunit from *H. marismortui*) diffracts to almost atomic resolution, 2.7 Å (34, 35), the other (of the small subunit from *T. thermophilus*) to 3.0 Å (36). As initial phases could be derived at medium resolution (31), the way to structural analysis of the ribosome has been paved.

APPENDIX 1: Summary of methods used to study ribosomal structure and/or function

- Tests for ribosomal activity: RNA-binding; Poly-U-dependent Poly-Phe synthesis; natural mRNA *in vitro* translation; the use of synthetic tRNA and analogs
- Total ribosomal reconstitution (from isolated r-proteins and r-RNA) for ribosome assembly studies
- Selective removal of r-proteins under mild chemical conditions (salt or organic solvents) followed by partial *in vitro* reconstitution (ribosomal cores+split proteins)
- Heterologous ribosomal reconstitution (using rRNA with r-proteins from a different species and vice versa)
- Reconstitution in the absence of single components, to determine the effect of single r-protein omission in either assembly or ribosomal function
- Chemical footprinting, hydroxyl radical cleavage, and protection studies of ribosome–ligand

interactions (eg, tRNA, mRNA, and antibiotics)

- Chemical modification probing of selected ribosomal moieties
- Specific cleavages by **nucleases**: a-sarcin, ricin, ribonuclease H, etc.
- rRNA-r-protein, rRNA-rRNA, mRNA-rRNA, and subunit crosslinking by mild UV irradiation or chemical agents to map contact topography or functional sites
- Photo-activated reagents in affinity labeling of ribosomal ligands or components
- Fluorescence **energy transfer** to follow the binding of ribosomal ligands (eg, tRNA) or the dynamics of the growth of the nascent polypeptide and its folding
- Single-site mutations (in rRNA) leading to antibiotic resistance or ribosome inactivation
- Probing exposed single-stranded rRNA regions with complementary DNA oligonucleotides
- Modeling of rRNA, based on distance geometry, energy minimization, or phylogenetic conservation
- Sequence determination and secondary-structure predictions of r-proteins and rRNA
- Comparisons between species and determination of homologous conserved regions
- Light scattering and **hydrodynamic** measurements for size/shape estimation
- Triangulation: Reconstitution or binding of one or a few protonated components (r-proteins, tRNAs) into deuterated ribosomes. The locations of the centers of mass are approximated by **neutron scattering**, including proton-spin contrast variation.
- Electron microscopy (EM), dark field and tunneling, negative and positive staining
- Electron microscopy coupled with three-dimensional image reconstruction using (1) optical diffraction of tilt series of ordered two-dimensional arrays (monolayers) or (2) single particles embedded in vitrified ice and viewed with normal- or low-dose electrons, followed by image processing and angular reconstitution of isolated particles
- Immunoelectron microscopy: gross r-protein mapping through electron microscope localization of **antibodies** bound to the r-proteins that were the immunogen
- **Neutron diffraction** coupled with contrast variation, investigating the gross localization of the ribosomal components, benefiting from the different scattering properties of protein and RNA
- Heteronuclear three-dimensional NMR spectroscopy of isolated small r-proteins or fragments of the larger ones
- X-ray crystallography of ribosomal particles, as well as crystallizable ribosomal components

Ribozyme/Catalytic RNA

A ribozyme is defined as an **RNA** molecule capable of **catalyzing** a chemical reaction in the absence

of proteins. Ribozymes can promote their reactions with rate enhancements as large as 10^{11} and specificities of better than 1 site in 1000. Catalytic RNA can fold into a compact three-dimensional structure that defines and efficiently activates a single phosphate linkage for a chemical reaction. All of the known biological ribozymes catalyze transesterification reactions of phosphate diesters and participate in RNA maturation or processing. Although the majority of catalytic RNAs in biology perform autocatalytic functions, all of them can be converted into true enzymes capable of multiple turnover catalysis by altering the covalent connectivity of the RNA, so that the "substrate" can be added in *trans* to the active site. The discovery of catalytic RNA has led to the speculation that ribozymes might have contributed to self-replication and **protein biosynthesis** in early evolution, an idea termed the RNA World hypothesis (1).

Catalytic RNAs are found in a broad variety of biological situations. Four small catalytic RNAs were identified in **satellite RNA** from plants and animals . These include the hammerhead, the hairpin, the hepatitis delta virus (HDV), and the Varkud satellite (VS) ribozymes. All of these RNAs perform the same cleavage reaction, but they differ substantially in their **secondary** and tertiary structures. In each case, the satellite RNA is proposed to replicate via a complementary RNA intermediate by a **rolling circle** mechanism. The ribozymes participate in the replication by self-cleaving the tandem satellite repeats into monomer units.

A second and more common category of catalytic RNA comprises the self-splicing **introns** (2). These RNAs provide the active site necessary to complete their own RNA **splicing** from an RNA transcript, with concomitant ligation of the flanking exons. Self-splicing introns are divided into two classes (group I and group II) based on differences in their conserved structures and reaction mechanisms. In addition to splicing, both classes of introns can catalyze reverse splicing reactions, which allows them to act as mobile elements for the horizontal transfer of genetic information.

A third example of a ribozyme is ribonuclease P (RNase P), which participates in transfer RNA (tRNA) processing (3). It acts in *trans* to catalyze the removal of nucleotides from the 5′-end of the pre-tRNA. The cellular form of this enzyme consists of both an RNA and a protein component (M1 RNA and C5 protein in *Escherichia coli*). Both are biologically essential; however, the RNA subunit alone is sufficient to carry out the tRNA processing reaction, albeit at a slower rate then the holoenzyme.

1. Reaction Mechanisms

Each reaction mechanism of these ribozymes involves in-line attack by an activated nucleophile at a phosphodiester linkage. This results in inversion of the stereochemical configuration at the phosphate group. The primary difference among the various catalytic RNA reaction mechanisms is the identity of the nucleophile and the leaving group (4). All four of the small catalytic RNAs utilize an internal nucleophile, the 2′-OH located immediately adjacent to the scissile phosphate, to displace the 5′-O of the phosphodiester. This one-step reaction mechanism produces RNAs with 2′-3′ cyclic phosphate and 5′-OH termini. Identical products result from alkaline hydrolysis of RNA, although the ribozyme reaction is specific to a single phosphodiester linkage.

The group I introns perform two consecutive transesterification reactions that employ external nucleophiles (5). In the first step of splicing, the 3′-OH of an exogenous guanosine **cofactor** attacks the phosphate linkage at the 5′-exon-intron boundary. This reaction covalently adds the guanosine onto the 5′-end of the intron and releases the 5′-exon. The second step of splicing is essentially the reverse of the first step but utilizes the 3′-OH of the guanosine at the intron-3′-exon boundary as the leaving group.

The group II introns employ a reaction mechanism that is a hybrid between these two classes (2). It utilizes an internal nucleophile, the 2′-OH of a bulged A nucleotide but the hydroxyl group is not

adjacent to the scissile phosphate. The phosphate is some distance away, at the 5′-exon-intron boundary. As with the group I intron, the 3′-OH of the 5′-exon is the leaving group for the first step of group II splicing and the nucleophile for the second step. The intron is released as a **lariat structure**, with the 5′-end of the intron covalently attached to the 2′-OH of the bulged A nucleotide. This is the same reaction mechanism employed in the more complex process of messenger RNA precursor splicing that is catalyzed by the spliceosome.

Unlike the reaction mechanisms of the other naturally occurring catalytic RNAs that primarily use either the 2′ or 3′-OH for chemical reactions, RNaseP utilizes water as its nucleophile (3). The hydrolysis reaction displaces the 5′-leader sequence to produce a tRNA with a terminal 5′-phosphate group. Because it both employs an external nucleophile and acts on an external substrate, RNaseP is the only natural RNA known to act as a true multiple turnover enzyme *in vivo*.

2. Metals in Catalysis

All of the naturally occurring catalytic RNAs (with the possible exception of the hairpin ribozyme) require divalent metal cations for activity (6, 7). Although the metal specificity varies substantially between ribozymes, it can usually be met by Mg^{2+} or Mn^{2+}. These metals play both a structural and a catalytic role. A dramatic example of divalent metals in RNA folding is the P5abc subdomain of the *Tetrahymena* group I intron. Three Mg^{2+} ions coordinate to disparate phosphates within the subdomain (8). This allows the RNA to fold inside out, ie, the phosphates point into the structure and the nucleotide bases point out to solvent. Some structural metals in RNA can often be substituted with polycations such as **spermidine** or cobalt hexamine, which emphasizes the importance of charge neutralization for RNA folding.

Other metals included in the ribozyme fold are required for catalysis. These metals activate the nucleophile or stabilize the leaving group within the transesterification reaction. A well-characterized example is the group I intron, where a different metal is required for each of these functions (9, 10). The metal-binding sites are highly selective and cannot be substituted with a generic polycation. A ribozyme active site with two metal ions is analogous to what occurs within the **DNA polymerase** enzyme and might be a general feature of catalytic RNAs (11).

3. Catalytic RNA Structure

To understand RNA catalysis it is necessary to understand the three-dimensional (3D) arrangement of the nucleotides, metal ions, water molecules, and co-factors that comprise the RNA structure. The very concept of a catalytic RNA with a substrate binding site requires that the structure be much more complex than the single-stranded description given in early textbooks. Several methods, including chemical modification, **phylogenetic** comparison, X-ray crystallography, and NMR spectroscopy, have shown that RNA can adopt a complex globular structure with many deviations from the canonical **Watson-Crick base pairs** and the traditional **double helix**. Although a surprisingly small amount of high-resolution structural information is available on catalytic RNAs, a set of structural motifs is gradually being identified that includes several surprises. For example, RNA can form a pseudo base pair between two consecutive A nucleotides in a single-stranded region (termed an *A-platform*) that serves as a platform for tertiary helix-stacking interactions (12). There are also examples of **pseudoknots**, G · U wobble pairing receptors, GAAA **tetraloops**, and U-turns (13-16). The **consensus sequences** of these structural motifs are seen repeatedly in the phylogenetic databases, which suggests that they have been used as building blocks to create a variety of RNA structures.

Although a large domain of the *Tetrahymena* group I intron has also been reported, the 3D structure of only one complete catalytic RNA is currently available. The structure of the hammerhead ribozyme was determined with an all-deoxy substrate and with a substrate containing a single 2′-O-methyl substitution in place of the 2′-OH nucleophile (14, 17). Both structures are very similar. A

third structure was determined with an all-ribose substrate in the absence of divalent metal ions (18). Metal soaking and freeze-trapping experiments have suggested that only small conformational changes are necessary for the ribozyme to move from the ground state to the chemical transition state.

4. Other potential ribozymes

In addition to the ribozymes described above, other essential cellular processes might also be catalyzed by RNA. The ribosome and the spliceosome have essential and highly conserved RNA components. It is a matter of intense interest and investigation whether the active sites of these molecular machines are composed of RNA or protein. For example, a ribosome treated extensively with detergent and proteinase K, conditions that **denature** and degrade the protein components of the ribosome but leave the RNA intact, could still catalyze rudimentary peptide bond formation (19). Although this was highly suggestive of an RNA active site in the ribosome, at least three proteins remained intact after the proteinase treatment, and all activity was lost if these proteins were removed. It remains uncertain whether the RNA or the few remaining proteins comprise the active site, but the intriguing possibility remains that the ribosome might also be a ribozyme.

5. New unnatural ribozymes

Several new RNA catalysts have been identified from large sequence pools by SELEX, a combinatorial amplification technique that exerts evolutionary pressure on an RNA population to select and optimize for a particular catalytic function. The range of reactions catalyzed by selected ribozymes in vitro is now well beyond that known for natural RNAs (20). Some of the notable activities identified by this approach include an RNA-based **RNA polymerase** that utilizes nucleotide triphosphates and releases pyrophosphate as the leaving group, a **polynucleotide kinase** that can transfer the g-phosphate from ATP onto the 5′ or internal 2′-OH of an RNA substrate, and RNAs that utilize Ca^{2+} or Pb^{2+} instead of Mg^{2+} for catalysis. RNAs have also been identified that catalyze chemical reactions other than transesterification at phosphate. An aminoacyl-RNA synthetase was identified that can transfer an aminoacyl group from Phe-AMP onto the 3′-end of an RNA substrate (see Aminoacyl tRNA synthetases). In vitro selection was also used to identify ribozymes that catalyze formation of carbon-nitrogen and carbon-sulfur bonds. In one example, in which a transition state analogue was used as the bait for selection, an RNA was isolated that could catalyze the isomerization of a bridged biphenyl linkage. A variety of catalysts such as these would be necessary in a prebiotic RNA world where RNA would act as both the information storage molecule and the catalyst for reactions. This Darwinian approach to in vitro evolution has also demonstrated that nucleic acid-based catalysts are not restricted to RNA. **DNA** catalysts have been identified that promote reactions with rate enhancements comparable to the small, naturally occurring ribozymes (21). Although the diversity of reactions remains rather limited, there is ample reason to believe that the chemical reactions catalyzed by RNA will continue to expand.

Ribulose Bisphosphate Carboxylase/Oxygenase (Rubisco)

Ribulose bisphosphate carboxylase/oxygenase (Rubisco) is probably the best-studied plant enzyme, partly because of its great abundance (constituting 30–50% total protein in leaves) but also because of its importance in the metabolism of all cells. By catalyzing carbon dioxide fixation during photosynthesis, this enzyme is responsible for virtually all of the reduced carbon found in living organisms. Rubisco couples the inorganic and organic carbon pools on earth and is the most significant route for linking these pools together by the synthesis of carbohydrate. It is, however, a poor **catalyst**, having both a low affinity for carbon dioxide and a small turnover number ($3s^{-1}$). **Autotrophic** organisms must devote a major part of their synthetic capacity to produce sufficient enzyme to sustain life. The high concentrations of Rubisco and its messenger RNA have provided many opportunities to study the molecular biology of plants. This includes gene organization and **gene expression** in both **nuclei** and chloroplasts, **protein targeting** to chloroplasts, **molecular chaperones**, enzyme assembly, and many other aspects of plant cell biology.

1. Reactions Catalyzed by Rubisco

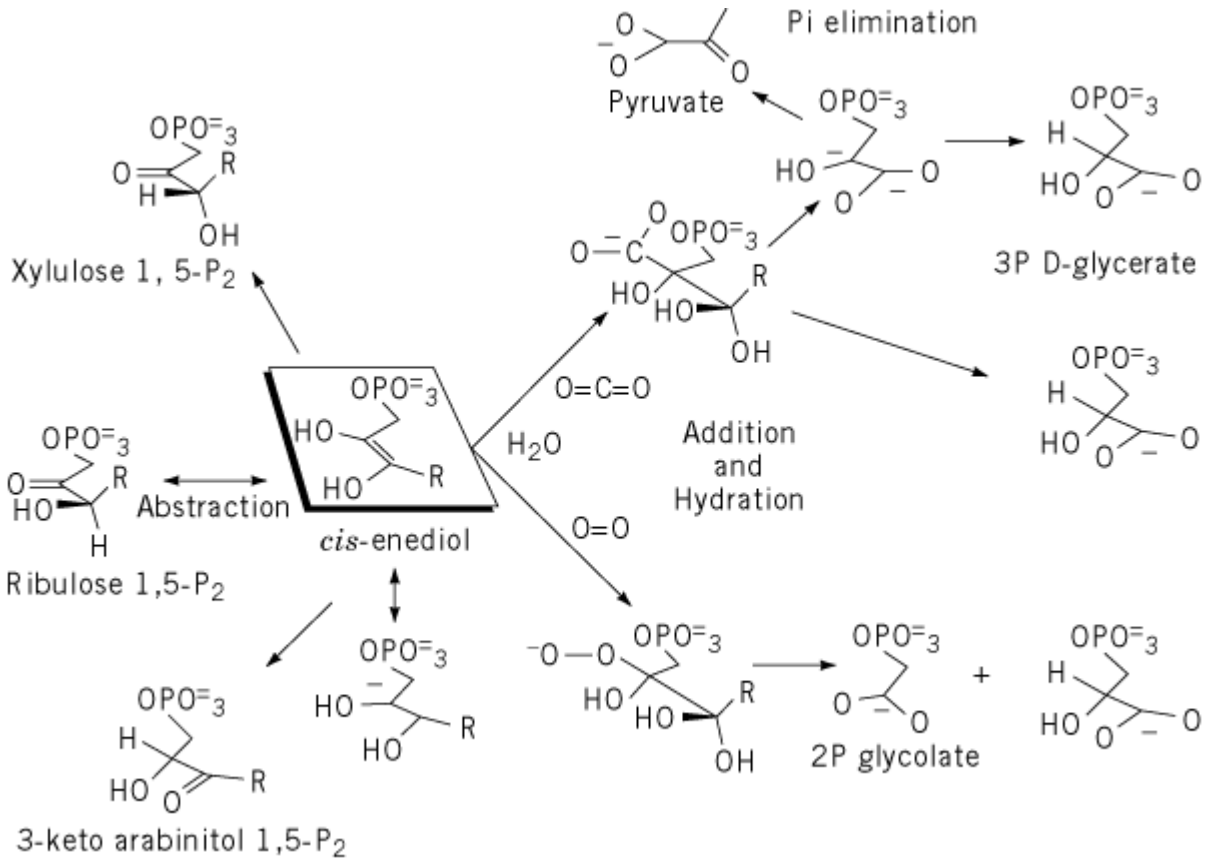
Rubisco catalyzes the first reaction in the pathways of both photosynthesis and photorespiration (1), which are respectively its carboxylase and oxygenase activities:

$$\text{Photosynthesis}: CO_2 + H_2O + \text{ribulose } 1,5 - P_2 \rightarrow 2(3 - \text{phospho} - D - \text{glycerate}) \quad (1)$$

$$\text{Photorespiration}: O_2 + \text{ribulose } 1,5 - P_2 - > 3 - \text{phospho} - D - \text{glycerate} + 2 - \text{phosphoglycolate} \quad (2)$$

Photosynthesis and photorespiration are interlocking metabolic cycles, with Rubisco determining the relative rates of carbon flow through the two pathways (Fig. 1). Rubisco requires both CO_2 and Mg^{2+} as obligatory **cofactors**, resulting in carbamylation of an **active-site** lysine residue by CO_2 and coordination of Mg^{2+} (1, 2).

Figure 1. The reactions catalyzed by Rubisco. The first intermediate of catalysis is the C2,C3 *cis*-enediol form of ribulose-bisphosphate (ribulose 1,5-P_2) after abstraction of the C3 proton. The enediol can partition a number of ways, the majority into the products of carboxylation (upper reactions) or oxygenation (lower reactions). However, a number of misprotonated isomers of ribulose 1,5-P_2, for example, xylulose–bisphosphate, have been detected with the wild-type enzyme that are produced in quantity by mutations of specific amino acid residues involved in proton transfer. Phosphate elimination of the carbanion forms of intermediates are also produced by some mutants. R, —CHOH —$CH_2OPO^{2-}_3$; 3P D-glycerate, 3-phospho glycerate; 2P glycolate, 2-phosphoglycolate. (Gutteridge and Gatenby, 1995; the material is copyrighted by the American Society of Plant Physiologists and is reprinted with permission.)



Five discrete partial reactions have been described for the carboxylation reaction (Eq. 1) of ribulose bisphosphate (3). The initial formation of a C2,C3-enediol intermediate of the ribulose bisphosphate substrate is followed by its carboxylation, where the enediol reacts with CO_2 at the C2 position. The

resulting six-carbon intermediate is hydrolytically cleaved to two molecules of 3-phosphoglycerate, resulting in an overall gain of carbon during photosynthesis.

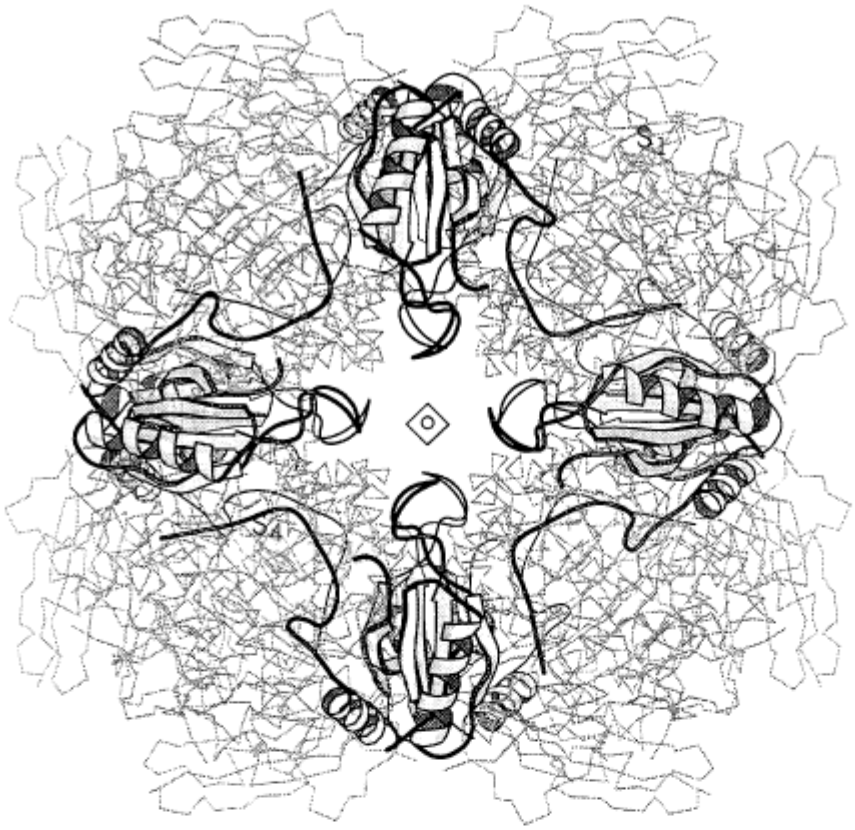
In the oxygenase reaction (Eq. 2) of photorespiration, however, the enediol intermediate reacts with molecular oxygen to form a hydroperoxy derivative that breaks down to 2-phosphoglycolate and 3-phosphoglycerate. Photorespiration consumes ribulose bisphosphate, which results in no net gain of carbon, and also requires the consumption of energy to recycle the lost carbon. Partitioning of ribulose bisphosphate between the two reactions of photosynthesis and photorespiration can vary significantly between different photosynthetic organisms (4), which has stimulated interest in improving the carboxylation efficiency of crop plants.

Rubisco activity is modulated in plants by an inhibitor and an activator. The inhibitor 2′-carboxy arabinitol 1-phosphate (2CAIP) accumulates in some plants during darkness and binds to the active site of Rubisco (5, 6). 2CAIP is degraded by a specific phosphatase, which presumably allows Rubisco to function during photosynthesis in the light. Rubisco can be severely inhibited by a range of sugar bisphosphates, including substrate analogues. The enzyme *Rubisco activase* has the ability to relieve the inhibition caused by sugar bisphosphates (7), possibly by interacting with Rubisco and altering the affinity of the enzyme for bisphosphates.

2. Structure of Rubisco

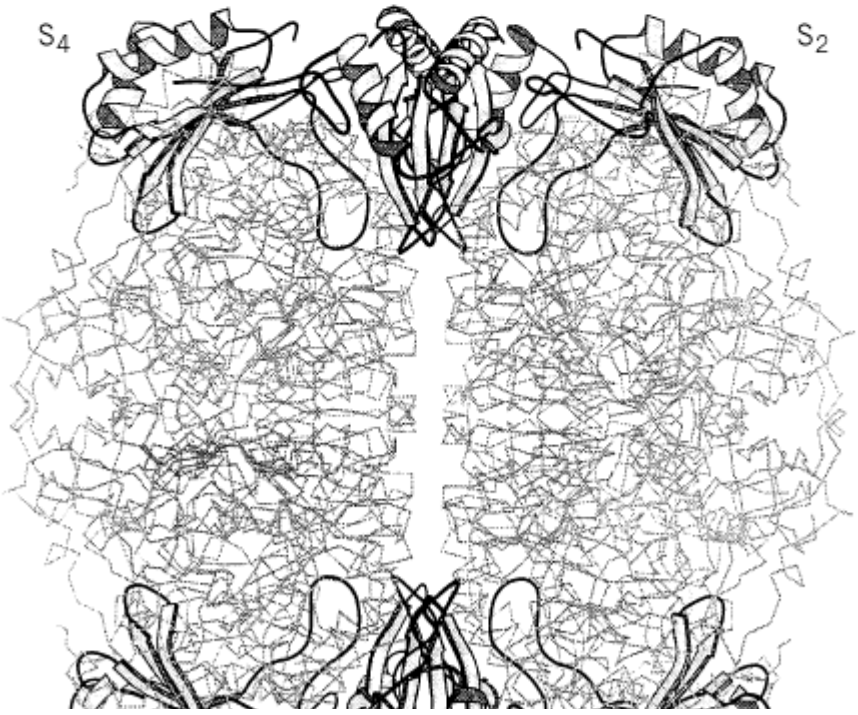
Two distinct forms of Rubisco found in different species can be differentiated by their quaternary structures . Form I Rubisco is the most common structure found in photosynthetic bacteria and plants (Fig. 2a). It has a hexadecameric structure (L_8S_8) with an equivalent number of both large (L) (50–55-kDa) and small (S) (12–18-kDa) subunits. Form II Rubisco has a much simpler structure, containing L subunits alone. It is less efficient than the form I enzyme and is present in some photosynthetic bacteria that are sensitive to oxygen.

Figure 2. The organization of the subunits of L_8 S_8 Rubisco. In (A) the display is from above the fourfold axis of symmetry of the enzyme. The four L-subunit dimers are shown only schematically by a light trace of the positions of the Ca atoms of the backbone, whereas the structural elements of the S subunits have been displayed with Molscript. The four S subunits shown reside at the top of the molecule situation between each L-subunit dimer, with a loop extending into, but not obscuring, the prominent central channel of the L_8 core. In (B), the other four S subunits are found to occupy the same position at the bottom of the core. (This figure was kindly provided by Steven Gutteridge and is reprinted with permission from JAI Press Inc.).



Spinach rubisco

(***a***)



Structural analysis of the L_2 Rubisco dimer from *Rhodospirillum rubrum* reveals that amino acid residues essential for the function of each of the two active sites are located on both L subunits (8). Although the quaternary structure of L_8S_8 Rubisco from plants is clearly more complex than the *R. rubrum* homodimer, X-ray crystallographic studies reveal that the L_8 core of L_8S_8 molecules can be built up from four *R. rubrum*–like dimers arranged around a fourfold axis (9). The eight S-subunits occupy large crevices between the ends of the L_2-like dimers at the top and bottom of the L_8 core, making extensive interactions with L subunits to stabilize the L_8 core. The S subunits do not contribute directly to the active site, but they do influence substrate affinities and turnover through contacts to elements that form the site (10).

3. Gene Organization and Expression

In most **prokaryotes**, the organization of the Rubisco S-subunit (*rbcS*) and L-subunit (*rbcL*) genes is relatively simple, with both genes usually closely linked and **transcribed** together. To the 5′ side of the initiator methionine residue of many *rbc* genes is a sequence similar to a **Shine–Dalgarno** site for ribosome binding, and sufficiently conserved to allow correct translation when **cloned** into *Escherichia coli* (11, 12).

Plant cells compartmentalize Rubisco in chloroplasts, but the genetic information is shared between chloroplast and nucleus. The *rbcL* genes are present in chloroplast DNA (13), and their transcription and translation in plastids uses sequences that are similar to those found in prokaryotes (14, 15), to the extent of allowing direct expression when transferred to *E. coli* (16). The S-subunit genes are located on nuclear chromosomes and have a more complex structural arrangement. The *rbcS* genes contain **introns** and are present as small multigene families that are often closely linked (17). Light-induced expression is mediated by both phytochrome and blue light photoreceptors (18), and positive and negative regulatory sequences are located in ***cis****-acting* transcriptional control regions. The *rbcS* **promoters** also appear to contain nuclear matrix attachment regions (MARs) (19), which may be important for their expression. The highest level of *rbcS* mRNA is found in leaves, but it is also found in the photosynthetic tissues in stems, petals and pods. S subunits are synthesized on free cytoplasmic **polyribosomes** as precursor molecules with an *N*-terminal transit peptide (20). The S-subunit precursors are imported post-translationally into chloroplasts in a process requiring ATP, and the transit peptide is removed (21, 22).

4. Rubisco Assembly

Following import into chloroplasts and removal of the transit peptide, mature S subunits are assembled with chloroplast-synthesized L subunits to give the active L_8S_8 Rubisco holoenzyme (21, 22). This assembly process requires the assistance of another chloroplast protein (23) now known as chaperonin 60 (cpn60) (24, 25). In fact, studies on the assembly of Rubisco in chloroplasts and bacteria (23, 26, 27) led to the discovery of the molecular chaperone cpn60 and its role in the correct folding of Rubisco and many other proteins (24, 25, 28). Productive folding of Rubisco requires Mg^{2+}, ATP hydrolysis, and a smaller cochaperonin molecule (29). Cpn60-mediated folding of Rubisco in bacteria uses a cochaperonin oligomer with 10-kDa subunits (24), but the folding of Rubisco in chloroplasts seems to involve a co-chaperonin oligomer with 21-kDa subunits (30). The reason for this larger cochaperonin in chloroplasts and the mechanistic details of the Rubisco assembly process in plants are currently under investigation.

Ricin And Ribosome-Inactivating Plant Toxins

Ricin is the prototype of a large family of toxic **glycoproteins** expressed by several **plant** tissues, particularly by seed endosperm cells (1). These plant toxins are synthesized as pre-pro-toxins, with a **leader sequence** of about 35 residues, which are then processed proteolytically to A-B type toxins. The mature form of isotype D of ricin (from *Ricinus communis* seeds) has an A chain of 267 residues **disulfide bond**-linked to a B chain of 262 residues (2).

The ricin B chain binds to a large number of different glycolipid and glycoprotein cell surface **receptors** containing a terminal galactose residue. Ricin is then internalized by endocytosis inside **clathrin**-coated and uncoated **vesicles** that merge in **endosomal** compartments, from where it can follow different intracellular trafficking pathways (3). Some molecules are recycled back to the cell surface, whereas others are degraded inside **lysosomes**, and still other ricin molecules are transported retrogradely through the **Golgi** stacks to the endoplasmic reticulum (3). There is evidence that ricin has to reach the Golgi apparatus before the A chain can translocate into the cytosol. Other A-B plant toxins, such as modeccin, abrin, and viscumin, may follow different intracellular routes, depending on their cell surface receptors (1).

These toxins arrest cell protein biosynthesis by inactivating the 60 S subunit of ribosomes (hence, they are called RIPs, ribosome-inactivating proteins) (1). Once in the cytosol, their A chains display a hydrolytic activity specific for the N-glycosidic bond of Adenine4324 of 28S ribosomal RNA (4), which is at the center of a ribosome area involved in binding of aminoacyl-transfer RNA, involving **elongation factor** 1, and in GTP hydrolysis and translocation, catalyzed by elongation factor 2 (5). The same enzymatic activity is associated with the A chain of Shiga and Shigalike toxins produced by *Shiga spp.* and *E. coli spp.*

Many plants also produce single-chain RIPs consisting of solely the A chain (1). These RIPs are a thousand times less toxic than the A-B type toxins, because of their very inefficient entry into cells. They are increasingly used to assemble immunotoxins, whose cell binding and intracellular routing is determined by the antibody part (see Antibody-Conjugated Toxins). Also, **fungi** of the genus *Aspergillus* produce a family of protein toxins of potential usefulness in the preparation of immunotoxins. They are single polypeptide chains of about 150 amino acid residues with two intramolecular disulfide bonds endowed with a **ribonuclease** activity specific for the phosphodiester bond on the 3′ side of Guanine4325 of 28 S ribosomal RNA (6). They and ricin recognize the same essential GAGA sequence, which is present in a conserved loop of the 28 S ribosomal RNA molecule (5).

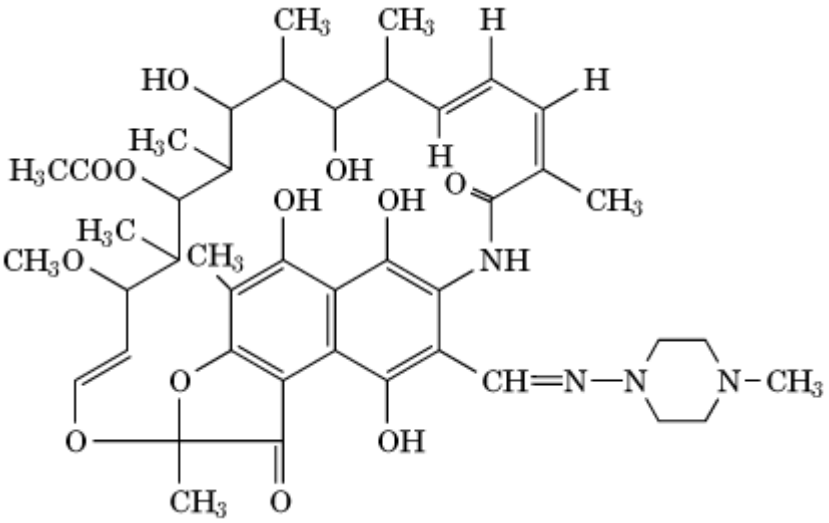
Rifampicin

Rifampicin (RIF), also known as rifampin (1971), is a semisynthetic antibacterial agent derived from rifamycin B, which was isolated from *Nocardia mediterranei* in 1957 (1960). RIF has wide bactericidal activity against **Gram-positive** and Gram-Negative Bacteria, both intracellular and extracellular organisms. Since it was introduced in 1968, it has had wide clinical use, especially as an effective antituberculosis drug; even now, it is a very important agent for the treatment of many infections. Recently, it was reported that RIF activates the human glucocorticoid receptor and acts as a immunodepressant (1998).

RIF is a semisynthetic derivative of rifamycin B, a fermentation product of the mold *Nocardia mediterranei*, which was reclassified in 1969 as *Streptomyces mediterranei* (1969). RIF is 3-(4-methyl-piperazinyl-iminomethyl)-rifamycin SV ($C_{43}H_{58}N_4O_{12}$, molecular weight 822.95) (1996) (Fig. 1), which belongs to a group of macrocyclic compounds (ansamycin) (1972). RIF is used as a first-line drug in antitubercular therapy, along with isoniazid (INH), pyrazimanid, and streptomycin (or ethambutol), as recommended by the World Health Organization (WHO) (1991).

Figure 1. The structure of rifampicin.



RIF exhibits bactericidal activity by inhibiting RNA synthesis (transcription) and, consequently, the initiation of a new round of **DNA replication** (198319841977). It inhibits transcription by binding to prokaryotic DNA-dependent **RNA polymerase**, which consists of four subunits (a, b, b′, d, encoded by the *rpoA, rpoB, rpoC*, and *rpoD* genes, respectively). RIF binds only to the holoenzyme of RNA polymerase ($a_2$bb′ and d) and not to the individual b subunit of RNA polymerase, even though mutation in the *rpoB* gene encoding the b subunit causes RIF resistance. RIF inhibits the initiation of transcription by interfering with the first translocation of RNA polymerase on template DNA and/or with the dissociation of the b subunit from template DNA (19761979), but it does not affect chain elongation. It also binds to viral DNA-dependent RNA polymerase and **reverse transcriptase**. In contrast, eukaryotic nuclear RNA polymerase is less sensitive to RIF. Therefore, the toxicity of RIF

is highly selective.

Resistance to RIF is conferred by drug inactivation, the alteration of either its target sites, or the changes in membrane permeability (199519941994). Drug inactivation occurs by phosphorylation, glucosylation, and ribosylation in Nocardia and rapidly growing mycobacteria (1995). The alterations of target sites occurr by missense, deletion, and insertion mutations in a restricted central portion of the *rpoB* gene that encodes the b subunit of RNA polymerase (1988), which in *Escherichia coli* consists of 1342 amino acid residues (1981). Jin and Gross (1988) classified the mutated region into three clusters (I, II, and III). Clusters I and II comprise amino acid residues 507–533 and 563–572, respectively, whereas cluster III possesses one affected site at amino acid 687. In addition, Lisitsyn et al (1984) found one mutation site at residue 146. Resistance mutations occur most frequently in cluster I. Mutations in clusters I and II confer especially high-level RIF resistance, whereas mutations in cluster III or at position 146 confer only low-level RIF resistance. Alterations in membrane permeability were reported in *Neisseria meningitidis* (1996), *Pseudomonas aeruginosa* (1982), and mycobacteria (1977). Recently, increased efflux of the drug from the cell was found in resistant *Pseudomonas fluorescens*, which was mediated by a **plasmid** (1998). It was reported that RIF-resistant strains of *Francisella tularensis* have reduced virulence (1994).

Because of the emergence of multiple **drug resistant** *M. tuberculosis* strains, the mechanism of RIF resistance has been studied on the basis of data from *E. coli* (19931995). The b subunit of RNA polymerase from *M. tuberculosis* consists of 1178 amino acids (1994). The region corresponding to that mutated in the *rpoB* gene of *E. coli* was sequenced. Nearly 95% of RIF-resistant *M. tuberculosis* strains have mutations in this region of the *rpoB* gene. Of these, more than 90% have missense mutations in the region corresponding to cluster I of the *E. coli rpoB* gene; mutations at residues 526 and 531 were found most often. Even in cluster I, hot spots occur frequently in resistant mutations, and the level of RIF resistance depends on which and where the mutation occurred, as had been found in *E. coli* (19961996).

RIF has been used also for the treatment of infection by *M. avium-intracellulare* complex and *M. leprae*. The in vitro RIF susceptibility varies significantly among *M. avium-intracellulare* complex serovars. Most *M. avium-intracellulare* complex organisms are resistant in vitro, even though only one of 31 resistant strains possessed a missense mutation in the region equivalent to cluster I of the *rpoB* gene of *E. coli* (1994). RIF resistance of *M. avium-intracellulare* complex organisms is assumed to be conferred by other mechanisms, presumably by decreased uptake or increased efflux of the drug. RIF-resistant strains of *M. leprae* have mutations in cluster I of the *rpo* B gene, although mutations occur most frequently at residue 531, instead of at residue 526 (1993).

Rifabutin, a spiro-piperidyl derivative of rifamycin S (1987), has been used for some RIF-resistant *M. tuberculosis* and *M. avium-intracellulare* complex infections in AIDS patients. Mutations at positions 513, 526, or 531 in the *rpo* B gene had high-level cross resistance to RIF and rifabutin, whereas mutations at residue 511, 516, or 522 do not confer rifabutin resistance.

RIF shows wide bactericidal activity against Gram-positive and Gram-negative bacteria and both intracellular and extracellular microorganisms (1996). It is able to enter phagocytes and kill living intracellular organisms (1983). RIF is bactericidal for wild-type *M. tuberculosis* and affects intracellular, slowly replicating bacilli in caseous lesions, as well as actively replicating tubercle bacilli in open pulmonary cavities. However, it shows bacteriostatic activity against enterococci. It has a broad antibacterial spectrum and is also effective against *P. aeruginosa, M. tuberculosis, M. leprae, M. kansasii*. It shows variable activity against *M. avium-intracellulare* complex and *Legionella* species. It is also highly active against *Staphylococcus aureus*, *N. meningitidis*, and *Haemophilus influenzae*. Its antibacterial activity is high; for example, *S. aureus*, *M. tuberculosis*, and *E. coli* are inhibited at concentrations of 0.002, 0.2, and 20 mg/ml, respectively.

RIF is well absorbed from the gastrointestinal tract and is well distributed to almost all body tissues and fluids. RIF is activated in the liver and excreted in the bile; therefore, the dosage should be

adjusted for patients with severe hepatic dysfunction. About 30% to 40% of the administered drug is excreted in the urine.

Adverse effects include hepatotoxicity, gastrointestinal and hypersensitivity reactions (drug fever, skin rashes, and eosinophilia), and a red-orange discoloration of urine, tears, saliva, sweat, and other body fluids (1996). RIF also induces increased hepatic metabolism of a wide variety of other drugs. RIF-induced hepatitis occurs more frequently during concurrent isoniazid therapy for tuberculosis. The drug antagonizes the effect of oral contraceptives and diminishes the anticoagulant activity of warfarin. Recently, it was reported that RIF activates the human glucocorticoid receptor, a nuclear steroid hormone receptor, and acts as a immunodepressant (1998).

RNA Blots (Northern Blots)

Northern blots are similar to Southern blots, but the polynucleotide being **blotted** and immobilized is **RNA**, rather than DNA (see Blotting and Southern Blots (DNA Blots)). In this technique, for example, samples of total cellular RNA are resolved by electrophoresis in denaturing agarose gels containing **formaldehyde**, they are subsequently transferred to a **blotting matrix**, ultimately to be probed with **radioactive** DNA to identify RNA molecules complementary to the DNA probe (1-3). The major obstacle in developing this procedure was that RNA did not bind efficiently to nitrocellulose matrices under conditions suitable for DNA blots. In 1977, however, chemically reactive blotting matrices [such as diazobenzyloxymethyl (DBM) filters] were used to bind the blotted RNA covalently (4), thus illustrating the feasibility of "Northern blotting," the term coined as a play on words in contrast to Southern's DNA transfers (5).

Since the original protocols for RNA blotting were introduced, conditions for using of nitrocellulose have been developed (6). Moreover, a common alternative matrix is a nylon membrane (3). In principle, the analyses and applications of RNA blots do not differ from the methods used for Southern blots, except for the additional requirement that caution should be applied in handling RNA samples because this nucleic acid is markedly more sensitive to degradation than DNA.

RNA Cap

The RNA cap refers to the cap modification that is characteristic to **eukaryotic** RNAs **transcribed** by **RNA polymerase** II. It consists of an inverted 7-methyl-guanosine nucleotide linked via a 5′-5′-triphosphate bridge to the first base of the messenger RNA precursor. The cap plays an important role in the metabolism of RNA polymerase II transcripts. It provides stability against 5′-3′ **exonucleases** (1), is required for efficient pre-mRNA **splicing** (2, 3), polyadenylation (4, 5), and contributes to the export of U **small nuclear RNA** (snRNA) from the nucleus to the **cytoplasm** (6, 7). It also increases the rate of mRNA export to a lesser extent, approximately twofold (6). In the cytoplasm, the cap increases the efficiency of mRNA translation (8).

RNA Degradation *In Vitro*

The ultimate fate of all cellular **RNA** molecules is their destruction. The final products are mononucleotides, which can be used in new **RNA biosynthesis**. RNA degradation *in vivo* involves site-specific cleavages performed by a diverse ensemble of cellular **ribonucleases** (RNase). These enzymes include both **endonucleases** and **exonucleases** that recognize specific RNA sequences and structural features and can act in a coordinated manner to establish a specific decay pathway. RNA degradation can also regulate **gene expression** by controlling the levels of messenger RNA (mRNA). For example, an increased rate of mRNA degradation lowers the steady-state level of that mRNA and, consequently, the amount of protein expressed from it. Cells can also control gene expression quickly by coupling rapid mRNA degradation with cessation of its biosynthesis by transcription. The physical (or chemical) **half-life** of an RNA is distinct from its functional half-life. The physical half-life is a measure of the rate of chemical degradation of an RNA species, whereas the functional half-life is a measure of the rate at which it becomes inactive and perhaps remains chemically stable. Functional inactivation (eg, repression of an mRNA to prevent its translation) can be caused by a change in RNA structure or by binding of a protein factor. Often, mRNA functional inactivation

precedes physical inactivation. There are significant differences in the mechanisms and pathways of RNA decay in **prokaryotic** and **eukaryotic** cells because of their different mRNA structural features; the coupling of bacterial transcription and translation; and the subcellular compartmentalization of RNA synthesis and utilization in the eukaryotic cell. However, there is growing evidence for the functional conservation of a number of enzymes involved in RNA decay.

1. Bacterial mRNA Decay

Bacterial mRNA are generally short-lived species that have physical half-lives typically ranging from 1 to 3 minutes (1, 2). Degradation of an mRNA can occur even before its synthesis is complete, when full-length transcripts are rarely observed. However, some mRNA have half-lives greater than the cell division time (which for *Escherichia coli* is 20 minutes at 37°C). The lifetime of an mRNA depends on the accessibility of its potential cleavage sites and on the amount and location of the **nucleases**. The substrate for degradation is not naked mRNA, but one that is covered with translating ribosomes. Translocating ribosomes can occlude cleavage sites, so the frequency of translation can control the rate of decay. A major mRNA decay pathway begins with a site-specific cleavage, often near the 5′ end. This cleavage can be **rate-limiting** and is usually carried out by RNase E or in several cases by RNase III (2, 3). Cleavage blocks further translation initiation, which allows internal cleavage sites to appear after passage of the last translocating ribosome. This pathway fragments mRNA with an overall 5′ to 3′ directionality (1, 2). Further degradation of the mRNA fragments is accomplished by the combined action of **poly(A)** polymerase and one or more exoribonucleases. Poly(A) polymerase adds a poly(A) tail of variable length to the 3′ ends of the RNA fragments, creating substrates for the 3′ → 5′ exoribonucleases RNase II or polynucleotide phosphorylase. The former enzyme is a **phosphodiesterase** that yields ribonucleoside 5′-monophosphates, whereas the latter uses phosphate as a cosubstrate to produce ribonucleoside 5′-diphosphates (3). It is not known if these exonucleases completely digest the RNA fragments, but a third 3′ → 5′ exonuclease, oligoribonuclease, degrades short RNA to mononucleotides (3).

The major mRNA decay pathway is mediated by a multisubunit complex called the RNA degradosome (4, 5). RNase E and polynucleotide phosphorylase are integral components of this complex. Other components include enolase, the heat-shock **chaperonin, DnaK**, and an RNA helicase. The RNA helicase may melt RNA secondary structure, providing more efficient degradation. Other enzymatic activities occur within this complex but are only partially characterized. RNA degradosome activity may be regulated by the physiological state of the cell. There are mRNA decay pathways, however, that are independent of the RNA degradosome (6). Stable RNA in cells includes **ribosomal** RNA and transfer RNA, which are normally not degraded. However, stable RNA degradation can be triggered under certain conditions, such as carbon starvation (3), and provide precursors for new RNA synthesis in the absence of *de novo* nucleotide synthesis. The nucleases involved in this process are not known.

2. Eukaryotic RNA Decay

The physical half-lives of eukaryotic mRNA range from minutes to hours. Two key structural features of eukaryotic mRNA—the 7-methylguanosine cap and the poly(A) tail at the 3′ end—are key participants in translation and also in degradation. The compartmentalized structure of the eukaryotic cell also plays a key role in RNA degradation. Thus, the nuclear membrane separates the synthesis and maturation of mRNA in the nucleus from its translation and degradation in the **cytoplasm**. RNA decay in mitochondria and chloroplasts also represent distinct pathways. A diverse, yet interrelated set of decay pathways has been revealed by genetic and biochemical studies in **yeast** (7, 8). A major pathway for mRNA decay is initiated by the shortening of the poly(A) tail, which is accomplished by a poly(A)-specific, 3′ → 5′ exoribonuclease. The rate of poly(A) tail shortening depends on specific sequences in the mRNA 3′ **untranslated region** (3′-UTR), which are recognized by specific proteins. A decrease in poly(A) tail length below a certain size triggers the hydrolytic

removal of the Cap structure. The yeast decapping activity, Dcp1, releases m^7GDP and creates an RNA chain with a 5′ terminal monophosphate (5′-pRNA) (9). A second, nuclear-localized decapping activity may also exist. The 5′-pRNA is a substrate for 5′ → 3′ exoribonuclease action. In yeast this is accomplished by XRN1 that creates 5′-mononucleotides (7, 8) [in contrast, a 5′ → 3′ exoribonuclease activity has not been detected in any bacterial cell (1-3)]. It is assumed that this step is rapid (and therefore not rate-limiting) because intermediates of this step have not been detected. A second deadenylation-dependent pathway involves shortening of the poly(A) tail, followed by 3′ → 5′ exonucleolytic digestion of the remainder of the mRNA (7, 8). In this pathway, the 5′ cap is not obligatorily removed.

Several deadenylation-independent mRNA decay pathways have been characterized. In one pathway, decay is initiated by decapping, followed by 5′ → 3′ exonucleolytic digestion. This pathway may participate in a "surveillance" mechanism, in which the presence of a premature **termination codon**—produced by mutation or by a failure to **splice** or **edit**—in conjunction with downstream sequences provides a signal for mRNA decapping and 5′ → 3′ decay (7, 8). The process of mRNA surveillance is conserved evolutionarily, reflecting its importance in ensuring fidelity of gene expression. A third deadenylation-independent decay pathway involves one or more endonucleolytic cleavages upstream of the poly(A) tail. These events functionally inactivate the mRNA and permit further degradation by a pathway that is not yet well defined. This latter pathway may be specific to mRNA that encodes functionally related proteins, and it may depend on protein recognition of an AU-rich sequence element in the 3′-UTR (7, 8). A fourth pathway that occurs in animal cells involves the activation of a latent ribonuclease. **Interferon** or **viral** infection of animal cells stimulates the production of 2′-5′ oligo(A) that activates RNase L, which endonucleolytically cleaves cellular and viral RNA. This inactivates protein biosynthesis, thereby limiting viral replication (7). Whether RNase L participates in normal cell RNA metabolism is unclear. Finally, histone mRNA, which are non-polyadenylated species, are degraded by a 3′ → 5′ exonuclease (10).

Most studies on eukaryotic RNA decay have used yeast as the model organism. Attempts to relate fungal RNA decay pathways to those in animal and plant cells have been hampered by the difficulty in performing comparable biochemical genetic analyses with these cells. Nonetheless, the basic steps in RNA decay may be conserved because activities have been characterized in animal and plant cells that shorten the poly(A) tail, remove the 5′ cap, or exonucleolytically digest RNA with 5′′3′ directionality (10). There is also growing evidence that the Cap and Poly(A) tails interact functionally during translation. A model relating eukaryotic mRNA translation and mRNA decay proposes that when translation initiation is disrupted by a disengagement of the mRNA 5′↔3′-end interaction, the mRNA is shunted into one of the decay pathways (7, 8).

RNA Editing

RNA editing can best be defined as changing the **nucleotide sequence** of an **RNA** so that of a mature RNA differs from that encoded by the **genomic** sequence. In **eukaryotes**, RNA editing is widespread, occurring in organisms as diverse as **yeast** and humans. Many different classes of RNA, transfer RNA, ribosome RNA, and messenger RNA, are edited to varying extents, and in many cases the changes introduced by the editing process have been shown to be functionally important. In recent years, much has been learned about both the types of modifications that occur and the factors involved in the modification reaction (for extensive reviews, see refs. 1-3).

There are two broad classes of RNA editing. The first is restricted to site-specific base modifications that give rise to either nucleotide **transitions** or **transversions**. The second is the less well understood insertion/deletion editing that occurs primarily in kinetoplastid protozoan parasites.

1. Site-Specific Base Modification Editing

This type of editing includes nucleotide transitions or transversions in all classes of RNA. Many different RNAs are edited in a site-specific manner, and the number of RNAs found to be edited is growing. Several independent mechanisms direct the editing machinery to the site to be edited, depending on the example. The first is a "mooring" sequence in the RNA that is specifically recognized by the editing complex, and editing is directed to this site; this occurs in apolipoprotein B mRNA. The mRNA for ApoB is deaminated at a specific cytosine to a uracil, by a deamination reaction that converts a CAA codon (coding for glutamine) to a UAA stop codon. In this case, editing produces two **isoforms** of the ApoB protein.

The second type of modifications are restricted to double-stranded regions of RNA (see text below). In general most of the edited sites are not edited to completion. One of the best understood examples of this class of RNA editing is in the case of the ionotropic glutamate gated **ion channel** receptors (gluR) in mammals, which involves deamination of adenosine to inosine at specific sites in the pre-mRNA. The functional receptor is encoded by a **gene family** of five receptor subunits—gluR-B, gluR-C, gluR-D, gluR-5, and gluR-6—which can form either homo- or heteropentameric transmembrane channels. Editing has been detected in all five of the glutamate receptor subunits. However, it is the editing events in exons 11 of gluR-B, gluR-5, and gluR-6 that is best double-stranded RNA, which results from base pairing between sequences from exons and introns. This means that editing has to take place before the introns have been removed by **splicing** of the RNA; by implication, it must occur during transcription. The Q/R editing site in exon 11 of gluR-B is found to be edited at frequencies approaching 100%. A CAG codon coding for glutamine is converted to a CIG codon for arginine by deamination of the adenosine residue. The functional consequence of editing at this site is a glutamate receptor that has altered permeability to calcium ions (see Calcium Signaling). In **transgenic** mice in which the Q/R site of one copy of gluR-B made editing incompetent, the mice developed seizures and died (5). This demonstrates that the editing event is essential for normal brain function. An enzyme that preferentially catalyzes this reaction has been characterized and cloned: ADAR2 (adenosine deaminase that acts on RNA) belongs to a family of such enzymes that show differing specificities for other editing sites. *In vitro*, ADAR2 efficiently edits the Q/R site, in the absence of cofactors, by deamination of adenosine to inosine ((6). It remains to be determined whether ADAR2 also catalyzes this reaction *in vivo*.

2. Insertion/Deletion Editing

This type of editing is found in the mitochondria of kinetoplastid protozoan parasites. It involves the

precise insertion or deletion of uridylates in the pre-mRNA to generate a functional mRNA. Unlike site-specific base modification editing, which occurs at only a few specific sites, the edited kinetoplastid RNAs are very highly modified. The first case of editing was described by Benne and co-workers (7), who found a precise insertion of four uracil nucleotides in the Cox II mRNA from trypanosome mitochondria that was not encoded by the genomic DNA. Since then may examples of such editing have been described in kinetoplastids. At the present time, the factors involved in this editing are not well characterized, although a mechanistic description of the editing process is becoming apparent.

The sites in the pre-mRNA to be edited are defined by small RNAs that are complementary to edited RNA sequences. These are commonly referred to as guide RNA. The guide RNAs have three domains: (*1*) the 5′ region, which is complementary to the substrate pre-mRNA and acts as an "anchor"; (*2*) the central domain, which contains the information necessary to insert and/or delete uridylates in the pre-mRNA to make the edited sequence, and is normally around 30–40 nucleotides in length; and (*3*) the 3′ end of the guide RNA, which is characterized by a poly U tail. The editing reaction takes place in a large ribonucleoprotein complex that has been termed the *editosome*. The site to be edited is cleaved immediately 5′ to the base-paired guide RNA; Us are either inserted or deleted, and then the RNA halves are religated. This reaction is repeated until the region covered by the guide RNA is completely edited.
